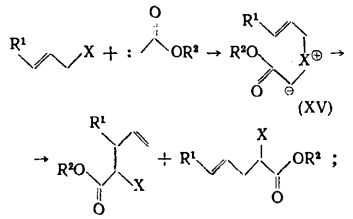
Detailed study of the dependence of the regioselectivity of this reaction on the electronic and steric effects of the substituents[28,29] led to the conclusion that the reactivity decreases in the following sequence in relation to the carbene centre: tertiary > secondary > primary C–H bonds. The allyl and benzyl C–H bonds are less reactive. The reactions are also characterised by a high degree of diastereoselectivity.[30,33] For example, the cyclopentanone derivative (XI) with the *trans*-disposition of the phenyl and methyl substituents is formed on cyclisation of the δ-phenyl-substituted α-diazo-β-ketoester:[30]

An important advantage of this method is also the retention of the absolute configuration of the carbon atom subjected to carbene attack.[7,9,32] The effective synthesis of (+)-α-cuparenone (XII) from the chiral β-ketoester (XIII) serves as a good illustration of this:[32]

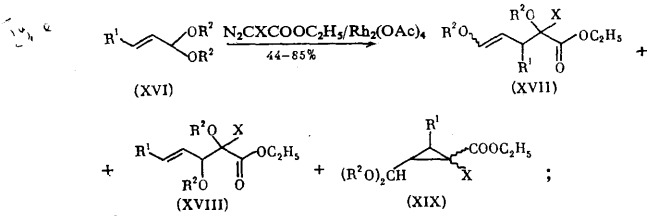


It has been found recently that the cyclisation of α-diazo-β-dicarbonyl compounds containing carbocyclic[36] and heterocyclic substituents[37] can also be used effectively for the synthesis of four-membered rings, which has been demonstrated, in particular, in relation to the synthesis of compound (XIV)—a key intermediate in the synthesis of thienamycin analogues:[37]

3. Insertion of keto- and alkoxycarbonyl-carbenes in carbon–heteroatom bonds

A specific method for the introduction of acyl and acylmethyl groups into organic substrates is also based on reactions involving the insertion of the corresponding carbenes in carbon–heteroatom bonds (see the relevant reviews[7,9,11]). Compounds containing

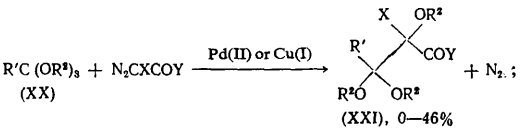
heterosubstituents in the allyl position relative to the multiple bond exhibit an increased tendency to undergo reactions of this kind. The generally accepted mechanism of these reactions includes the initial attack by the carbene on the heteroatom with formation of the corresponding ylide (XV), which then undergoes a [2,3]- or [1,2]-sigmatropic rearrangement:[7,8,11,38,45]



(XV)

X=Cl, Br, I, OR^3, SR^3, NR^3_2.

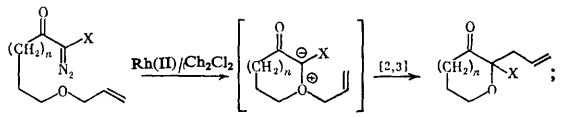
As in the reactions involving insertion in C–H bonds (see above), the yields of the products of the intermolecular reactions in which carbonyl-containing carbenes are inserted in carbon–heteroatom bonds are as a rule low and the conversion of the substrate into a cyclopropane derivative is frequently a competing process. It was of interest that the ratio of the insertion of cycloaddition products depends to a large extent on the conditions in the generation of the alkoxycarbonylcarbene. The decomposition of diazo-compounds by direct photolysis or under the influence of metallic catalysts leads to the preferential formation of insertion products, while photosensitised decomposition of diazo-compounds, affording a triplet carbene, gives rise to cycloaddition products. The difference in the behaviour of the carbene species is apparently caused by the inability of triplet carbene to form the corresponding ylides (XV).[7,9,11] It has also been established that the use of rhodium(II) acetate or the hexarhodium carbonyl cluster $Rh_6(CO)_{16}$ as catalysts of the decomposition of diazoacetic ester leads to the exclusive formation of the products of the [2,3]sigmatropic rearrangement in reactions with allyl iodides, aryl sulphides, and dialkylallylamines (yield 49–96%). In order to obtain similar products in the reactions with allyl bromides and chlorides, it is preferable to use copper catalysts.[38,39]



In contrast to alkyl allyl ethers, which afford products of conversion into cyclopropane derivatives in reactions with ethyl diazoacetate and dimethyl diazomalonate, the acetals (XVI) are converted into the corresponding 2,5-dialkoxy-4-alkenoates (XVII); the products of the "direct" insertion in the C–O bond [compounds (XVIII)][40,43] and of conversion into cyclopropane derivatives [compounds (XIX)] are formed only as minor components:

(XVI) (XVII) (XVIII) (XIX)

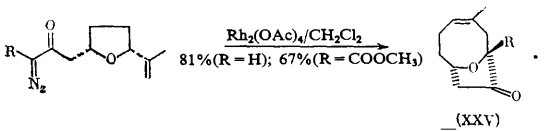
R^1 = H, C_6H_5; R^2 = CH_3, C_2H_5, $(CH_2)_2$; X = H, $COOC_2H_5$.



The decomposition of diazocarbonyl compounds in the presence of the orthoesters (XX) and copper (II) triflate or rhodium(II) acetate also leads to the insertion of the corresponding carbenes in the C–O bond, but the yields of the products (XXI) are in most cases low:[46]

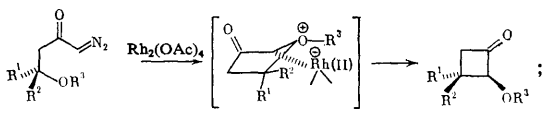
(XX) (XXI), 0—46%

R′=H, CH_3, C_2H_5; R^2=CH_3, C_2H_5, X=H, $COOCH_3$; Y=OCH_3, OC_2H_5, C_6H_5.



The intramolecular generation of the allyloxonium ylides (XXII) from α-diazocarbonyl compounds (XXIII) and their subsequent [2,3]sigmatropic rearrangement constitute a convenient method of synthesis of five-membered oxygen-containing heterocycles:[44,45]

(XXIII) (XXII) (XXIV)



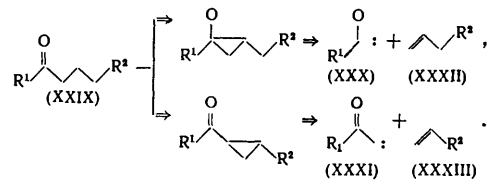
X = H, $COOCH_3$, $COOC_2H_5$; n = 0,1.

The yields of 2-substituted 3-furanones (XXIV, n = 0) are 67–95%, while an increase in the chain length by one carbon atom (n = 1) greatly increases the fraction of the products of insertion in the C–H bond.[44,45] A similar reaction has been used effectively in the synthesis of the bicyclanones (XXV) with an eight-membered oxygen-containing ring:[45]

(XXV)

The insertion of ketocarbenes in C–O bonds has also been used to synthesise the cyclobutanones (XXVI):[44]

(XXVIII) (XXVII), 45–68% (XXVI)



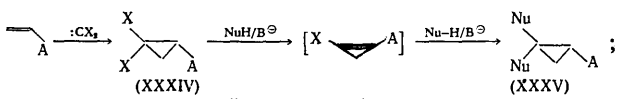
R^1 = H, CH_3; R^2 = CH=CH_2, C_6H_5; R^3 = CH_3; R^2R^3 = $(CH_2)_2$.

It is suggested[44] that the reaction proceeds via the formation of the oxonium ions (XXVII) and their subsequent decomposition with regeneration of the rhodium catalyst. It is remarkable that the cyclisation of the ketone (XXVIII, R^1=R^3=CH_3, R^2=C_6H_5) proceeds under these conditions with retention of the absolute configuration of the quaternary carbon atom.[44]

III. Conversion into cyclopropane derivatives and subsequent ring opening

Apart from the methods for the insertion of carbonyl groups via carbene reactions, examined in the previous Section, the use of the two-stage sequence of reactions involving the cycloaddition of the carbene to the alkene and the opening of the ring in the product formed also frequently proved effective. As in the insertion reactions, methods based on the conversion of alkenes into cyclopropane derivatives by dihalogeno-, keto-, and alkoxycarbonylcarbenes have the greatest synthetic importance. The retrosynthetic analysis of the formation of the carbonyl compounds (XXIX) with

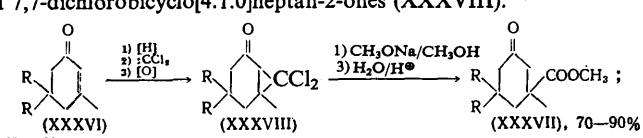
the aid of this reaction leads to the carbenes (XXX) and (XXXI) and the corresponding alkenes (XXXII) and (XXXIII):



(XXIX) (XXX) (XXXII) (XXXI) (XXXIII)

Evidently, the efficiency of the formation of compound (XXIX) with the aid of the synthetic equivalents of the carbene synthons (XXX) and (XXXI) is determined not only by the efficiency of the cyclopropane formation stage but also by the possibility of the regiospecific ring opening in the cyclopropane intermediate. By virtue of the high internal strain in the three-carbon ring and the pronounced influence of substituents on the strength of its carbon–carbon bonds,[47,50] ring opening in many cyclopropane derivatives with functional group substituents can be achieved under mild conditions with high degrees of conversion and a high regioselectivity. The so called "donor–acceptor cyclopropanes", containing *p*-electron-donating and π-electron-accepting substituents in the vicinal positions, are especially promising in this respect. Their concerted activating effect weakens the C–C ring bond nearest to the two substituents and the bond undergoes ready heterolytic cleavage.[2,4,6,11,12,50]

1. Reactions of dihalogenocarbenes

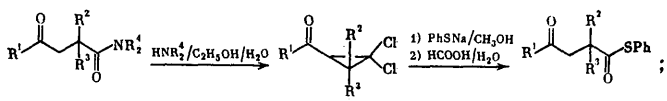


The dihalogenocarbene precursors are at the present time the most convenient synthetic equivalents of the carbene synthons (XXX) for preparative purposes. The cycloaddition of dihalogenocarbenes to alkenes has been investigated in a large number of instances and can be readily achieved experimentally in many cases.[3,51] However, reactions of the type of cyclopropyl–allyl isomerisation with the opening of the C–C ring bond located opposite to the halogen atom are characteristic of the *gem*-dihalogenocyclopropanes formed.[3,12,52] Favourable conditions for the dissociation of one of the nearest C–C ring bonds can be created by substituting the halogen atoms by *p*-electron-donating groups. Such reactions can be achieved fairly easily only between nucleophiles and *gem*-dihalogenocyclopropanes (XXXIV) containing a mobile hydrogen atom in the α-position relative to the π-electron-accepting substituent:[2,3,8,12,53–63]

(XXXIV) (XXXV)

A=CHO, COAlk, COAr, COOAlk, CON(Alk)$_2$, CN, Ar; X=F, Cl, Br; Nu=AlkO, ArO, ArS, Alk$_2$N.

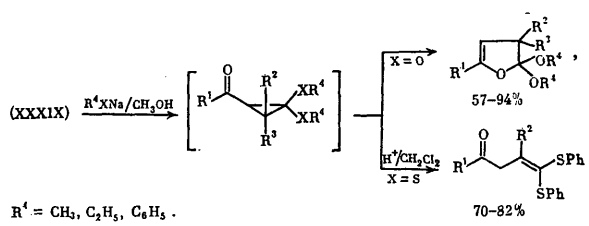
The substitution of halogen atoms in compounds (XXXIV) takes place via the elimination–addition mechanism and leads to the corresponding "donor–acceptor" cyclopropanes (XXXV) or the products of their subsequent reactions with ring opening. Thus 3-substituted 2-cyclohexenones (XXXVI) can be readily converted into the corresponding 3-methoxycarbonylcyclohexanones (XXXVII) via 7,7-dichlorobicyclo[4.1.0]heptan-2-ones (XXXVIII):[56,62]



(XXXVI) (XXXVIII) (XXXVII), 70–90%

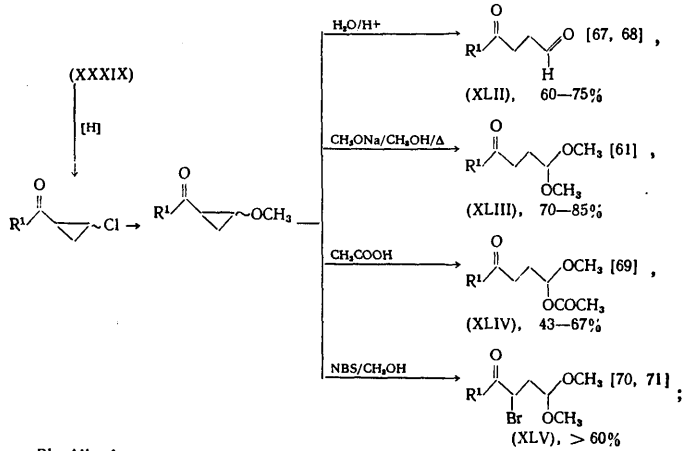
R=H, CH$_3$.

The electrophilic dichloroacarbene plays in this sequence of reactions the role of a synthetic equivalent of the nucleophilic alkoxycarbonylanion and ensures the formation of compounds (XXXVII), in which the alkoxycarbonyl group is linked to a quaternary carbon atom. Similar reactions have been observed between sodium alkoxides and monocyclic 1-acyl-2,3-dichlorocyclopropanes (XXXIX) and derivatives of 2,2-dichlorocyclopropanecarboxylic acids.[2,3,8,12,53–55,59,61]



When secondary amines or sodium thiophenoxide are used as nucleophiles in reactions with acylcyclopropanes (XXXIX), it is possible to obtain high yields of the corresponding dialkylcarbamoyl derivatives (XL)[57] and phenylthiocarbonyl derivatives (XLI):[64]

(XL) (XXXIX), 60–90% (LI)

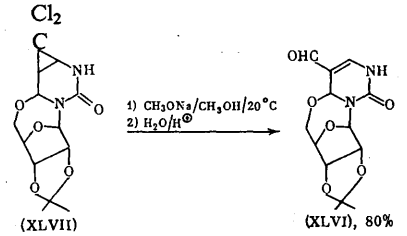


R^1, R^2, R^3 = H, Alk, Ar; R^4 = C$_2$H$_5$; R$^4_2$ = (CH$_2$)$_5$, (CH$_2$)$_2$O.

One of the advantages of this method for the introduction of acyl substituents into organic substrates is the possibility of their generation in a protected form at the stage involving the opening of the cyclopropane ring:[64,65]

R^4 = CH$_3$, C$_2$H$_5$, C$_6$H$_5$. 57–94% 70–82%

This gives rise to the possibility of modifying one of the carbonyl groups of the latent 1,4-dicarbonyl compounds and also of achieving the regiospecific introduction of additional substituents.[64,66] The latent ester group can also be modified at the stage involving the dihalogenocyclopropane intermediate, because the corresponding monohalogenocyclopropanes exhibit similar properties in relation to nucleophiles:[61,68–71]‡



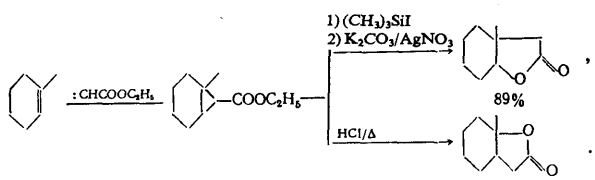
(XXXIX) (XLII), 60–75% (XLIII), 70–85% (XLIV), 43–67% (XLV), > 60%

R^1=Alk, Ar.

‡ In the formulae below and henceforth, the numerals in square brackets denote references (Ed. of Translation).

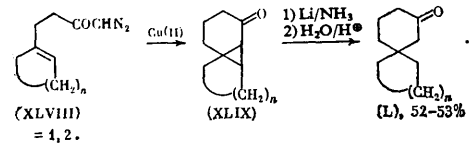
Thus the addition to a double bond of the formyl group, in the free or protected form, with formation of compounds (XLII) and (XLIII)–(XLV) respectively can be achieved with the aid of dichlorocarbene.

An interesting example of the introduction of the formyl group via the formation of *gem*-dichlorocyclopropane is also provided by the formation of the aldehyde (XLVI) on treatment of the cyclopropa[4,5]pyrimidine system (XLVII) with sodium methoxide:[72]



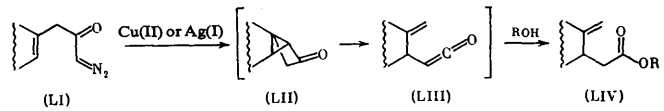
(XLVII) (XLVI), 80%

The key stages in this reaction are probably the elimination of a proton from the nitrogen atom of the pyrimidine ring under the influence of the base, the opening of the cyclopropane ring induced by the anion formed under these conditions, and the subsequent nucleophilic substitution of the chlorine atoms.[72]



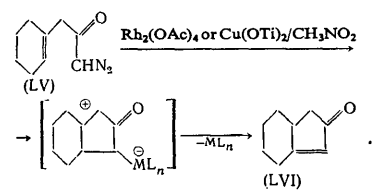
2. Reactions of keto- and alkoxycarbonyl-carbenes

The main difficulties in the introduction of functional groups into alkenes not containing *p*-electron-donating substituents at the double bond via conversion into cyclopropane derivatives by means of keto- and alkoxycarbonyl-carbenes are associated with the carrying out of the stage involving the opening of the cyclopropane ring. Although the opening of the ring in cyclopropanes having two π-electron-accepting substituents usually proceeds comparatively readily (see the relevant reviews[2,5,6]), the analogous reactions of the corresponding monosubstituted compounds require much more severe conditions and the use of acid reagents or catalysts.[2,6] It has recently been possible to overcome these difficulties in many respects by using trialkylhalogenosilanes as the electrophiles.[73,76] When the latter are allowed to react with acylcyclopropanes having different structures, the ring is as a rule opened under mild conditions and with a high regioselectivity. Examples of the successful use of these reagents are provided by the general methods for the conversion of alkenes into γ-butyrolactones[75] and α-methylene-γ-butyrolactones.[73] The formation of the lactone can then exhibit the opposite regiospecificity compared with the proton-catalysed reactions:[75]



Pyridine hydrochloride[77] and acylmethanesulphonates[78,79] are also effective reagents for the opening of the ring in acylcyclopropanes.

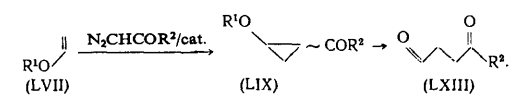
The reactions involving the reductive cleavage of the ring in cyclopropyl ketones are likewise of considerable preparative value.[80] For example, the intramolecular conversion of monocyclic unsaturated diazoketones (XLVIII) into cyclopropane derivatives and the subsequent regioselective reduction of the tricyclic ketones (XLIX) with lithium in liquid ammonia constitutes a general method of synthesis of spiran bicyclic systems (L), which has been used successfully in the synthesis of certain natural sesquiterpenes:[80]



(XLVIII) (XLIX) (L), 52–53%
= 1, 2.

Acyclic and monocyclic βγ-unsaturated α′-diazoketones (LI) undergo the vinylogue Wolff rearrangement in the presence of copper(II) or silver(I) in alcohols, affording satisfactory yields of the esters of the corresponding γδ-unsaturated acids.[82,83] Evidence has been obtained showing that the skeletal rearrangement involves the initial conversion of the double bond into a cyclopropane derivative with formation of substituted bicyclo[2.1.0]pentan-2-ones (LII). The subsequent cleavage of the three-carbon ring leads to the substituted ketens (LIII) and, after the addition of an alcohol, to the final products (LIV):[83]

(LI) (LII) (LIII) (LIV)

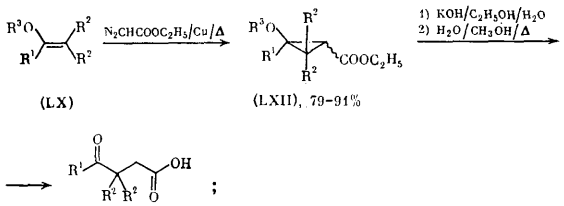


On the other hand, in the absence of protic solvents, the decomposition of the diazoketone (LV) by copper(II) and rhodium(II) leads to the corresponding bicyclic ketone (LVI), which the authors believe to proceed via the stage involving the intramolecular addition of the electrophilic metallocarbene complex to the double bond:[46]

(LVI)

$Cu(OTf)_2$ = copper(II) trifluoromethanesulphonate.

The introduction of functional group substituents into the enol ethers (LVII) by diazocarbonyl compounds, leading to 1,4-dicarbonyl compounds (LVIII) and their derivatives (important intermediates in the synthesis of five-membered carbocycles and heterocycles), is of great preparative value:

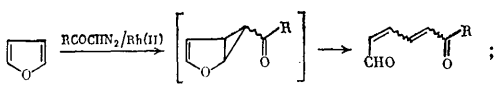


(LVII) (LIX) (LXIII)

The key stage of the process is the formation of the corresponding hydroxycyclopropane intermediates (LIX), usually achieved by the copper-catalysed decomposition of diazo-compounds in the presence of an excess of the enol ether (see the relevant reviews[4,7,9,10]). The use of copper catalysts sometimes induces the formation of considerable amounts of products of rearrangements or of insertion in C–H bonds. The employment of rhodium catalysts has advantages as regards the selectivity of the process for a nearly equimolar reactant ratio characteristics of each reactant also have the course of the reaction. Among diazoc esters of diazoacetic,[7,9–11] diazopyruvic,[85] a

diazoacetoacetic acids[86–88] as well as diazoketones[4,89–93] and derivatives of diazodiacetyl[95,96] have been investigated in reactions with alkyl vinyl ethers. Under these conditions, the corresponding acylcyclopropanes are formed as a rule in satisfactory yields when diazocarbonyl reagents containing only one π-electron-accepting group conjugated with the diazo-group are used. Otherwise the formation of derivatives of the dihydrofuran series, formally corresponding to the 1,3-dipolar cycloaddition of the ketocarbene to the double bond of the enol ether, is normally observed.[9,85,86] The reactions of the dialkyl acetals of ketens with diazoketones leads to similar compounds,[92] while the reactions with ethyl diazoacetate make it possible to obtain, together with products of rearrangements, also cyclopropane adducts.[92,94–96] The latter are likewise formed readily in the reactions of alkyl diazoacetates with silyl ethers of enols.[9,97–104]

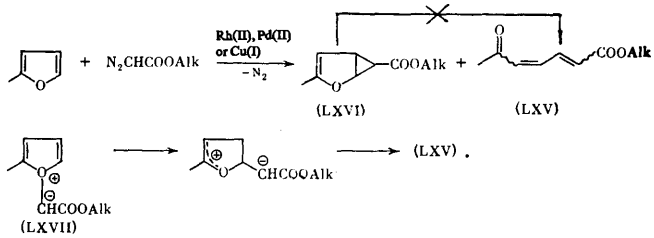
Depending on the nature of the substituent at the ether oxygen atom in compounds (LIX), reactions involving the cleavage of the C(1)–C(2) bond in three-membered ring take place under the conditions of acid or base catalysis. Thus the conversion of the double bond into a cyclopropane derivative by ethyl diazoacetate, the hydrolysis of the resulting stereoisomeric esters of 2-alkoxycyclopropanecarboxylic acids (LXII), and the hydrolytic cleavage of the three-membered ring in the latter by brief refluxing in aqueous methanol constitutes a convenient method for the conversion of the enol ethers (LX) into 4-ketocarboxylic acids (LXI):[100]



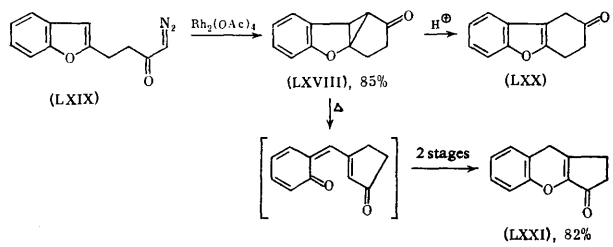
(LX) (LXII), 79–91%

(LXI), 84–95%

R^1 = C_6H_5, 3,4-$(CH_3O)_2C_6H_4$, $(CH_3)_2CH$, $(CH_3)_3C$; R^2 = H, CH_3; R^3 = CH_3, C_2H_5.



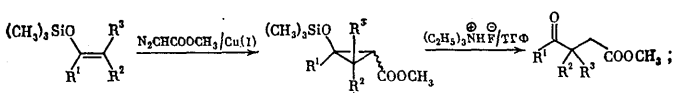
The acid-catalysed solvolysis of 2-alkoxycyclopropanecarboxylic acid esters and 2-alkoxycyclopropyl ketones, leading to the formation of the corresponding 1,4-dicarbonyl compounds or their derivatives, also takes place under mild conditions.[61,67–70, 93–97] On the other hand, the adducts (LXIII) of ketocarbenes with furan, which are bicyclic analogues of 2-alkoxycyclopropyl ketones, are spontaneously converted into *cis,trans*-6-oxoalka-2,4-dienals (LXIV) with a high stereoselectivity:[105]



(LXIII), 50–72% (LXIV)

R = CH_2—C≡C—$(CH_2)_3$ $COOCH_3$, CH_2—C≡C—CH_2—C≡C—C_5H_{11}.

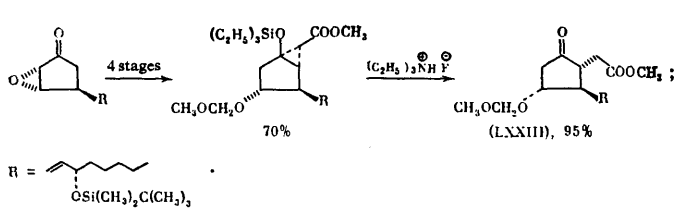
In this case, the process proceeds via the dissociation of the C(1)–C(3) bond in the 2-alkoxycyclopropyl ketone fragment of compound (LXIII), which may be induced by factors similar to those which are responsible for the preferential attack by the electrophile on the α-carbon atom of the furan ring. The reaction is probably general,[20,106] but it has been found that, in the interaction of alkoxycarbonylcarbenes with sylvan, the stereoisomeric esters of 6-oxoheptadionoic acids (LXV) are not formed from the cyclopropane precursors (LXVI) but are probably generated by the rearrangement of the ylides (LXVII):[106]



The ring opening reactions in the products of the intramolecular conversion of furyl-substituted ketocarbenes into cyclopropane derivatives proceed similarly and lead to the corresponding cycloalkenones.[107] On the other hand, in the reaction with the benzofuran derivative (LXVIII), obtained by the intramolecular cyclisation of the diazoketone (LXIX), the regiospecificity of the ring opening changes rapidly as a function of the conditions selected. Treatment of the ketone (LXVIII) with trace amounts of protic acids leads to high yield of the benzofuran (LXX), while heating of the ketone (LXVIII) at 180 °C affords the benzopyran (LXXI):[107]

(LXIX) (LXVIII), 85% (LXX)

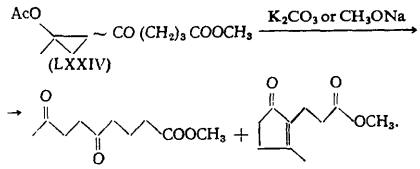
(LXXI), 82%



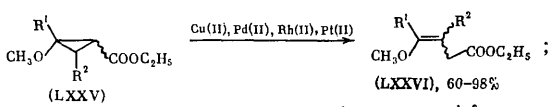
The opening of the three-membered ring in 2-trimethylsiloxycyclopropanecarboxylic acid esters (LXXII) takes place both in the presence of strong acids[102,108] and under virtually neutral conditions on treatment with triethylammonium fluoride:[98,101,109]

(LXII), 55–97% 67–93%

R^1, R^2, R^3 = H, alkyl, alkenyl, $OSi(CH_3)_3$.



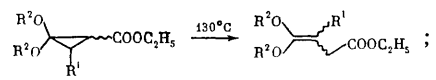
Trialkylsilyl ethers of enols can be usually obtained under much milder conditions and with a higher regioselectivity than the corresponding alkyl ethers, which made it possible, in particular, to use successfully suitable cyclopropane intermediates in the key stage of a new synthesis of the familiar prostaglandin precursor (LXXIII):[101]



70%

When functional groups are substituted into enol acetates by diazocarbonyl compounds, the opening of the three-membered ring

in the cyclopropane intermediates (LXXIV) takes place readily in an alkaline medium:[90]

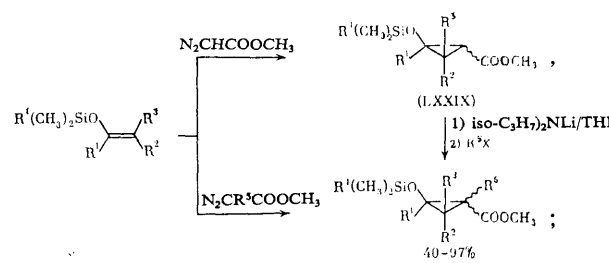


2-Alkoxycyclopropanecarboxylic acid esters (LXXV) are capable of isomerising to the corresponding vinyl esters (LXXVI) in the presence of catalytic amounts of transition metal salts:[110–112]

(LXXV) (LXXVI), 60–98%

$R^1 = CH_3$, $CH_2{=}CH$, C_6H_5, $CH_2{=}C(OCH_3)$; $R^2 = H$, C_6H_5; $R^1R^2 = (CH_2)_4$.

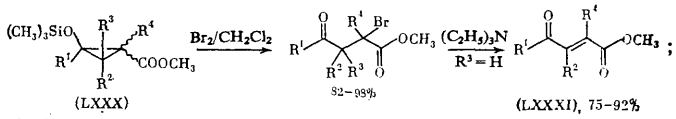
Ethyl 2,2-dialkoxycyclopropanecarboxylates (LXXVII) rearrange to keten dialkyl acetals (LXXVIII) in the absence of catalysts[92] at 130 °C:



(LXXVII) (LXXVIII), ~100%

$R^1 = H$, CH_3; $R^2 = CH_3$, C_2H_5.

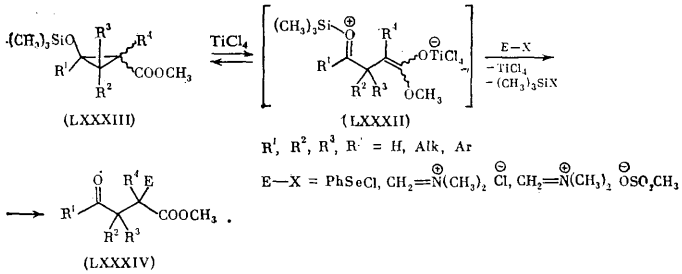
The similar isomerisation of 2-trimethylsiloxycyclopropanecarboxylic acid esters in the presence of iodotrimethylsilane or nonafluorotrimethylsilylbutanesulphonate has also been reported.[113]



An important advantage of the methods for the introduction of functional groups into alkenes via the intermediate formation of activated cyclopropanes is the possibility of modifying the cyclopropane intermediate by carrying out reactions with retention of the three-membered ring and also the possibility of using ring opening reactions for the introduction of additional functional groups into the molecule or the formation of new carbon–carbon bonds. Since diazocarbonyl compounds containing substituents in the geminal position relative to the diazo-group are as a rule much less readily available than the corresponding unsubstituted reagents, a more convenient pathway to the target molecule may proceed via the intermediate stage involving the alkylation of alkoxycarbonylcyclopropanes (LXXIX):[109,114,115]

(LXXIX) 40–97%

R^1, R^2, R^3, R^4, R^5 = H, alkyl, alkenyl, aryl; X = Br, I, OSO_3CH_3.

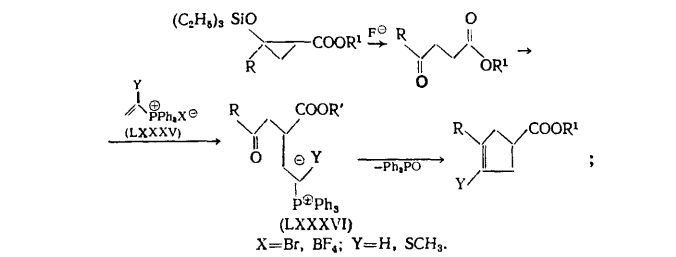


The oxidative cleavage of the three-membered ring in the donor–acceptor cyclopropanes (LXXX) by successive bromination–dehydrobromination reactions proceeds under mild conditions and constitutes a convenient method of synthesis of 4-oxo-2-alkenoates (LXXXI):[116]

(LXXX) 82–99% (LXXXI), 75–92%

R^1, R^2, R^3, R^4 = H, D, CH_3, $C(CH_3)_3$, SCH_3.

The enolate (LXXXII), formed as an intermediate from substituted 2-trimethylsiloxycyclopropanecarboxylates (LXXXIII) in the presence of Lewis acids, reacts readily with electrophiles, affording the corresponding esters of 2-substituted 4-oxoalkanoic acids (LXXXIV):[117–120]



(LXXXIII) (LXXXII)

R^1, R^2, R^3, R^4 = H, Alk, Ar

E—X = PhSeCl, $CH_2{=}\overset{\oplus}{N}(CH_3)_2\ \overset{\ominus}{Cl}$, $CH_2{=}\overset{\oplus}{N}(CH_3)_2\ \overset{\ominus}{OSO_2CH_3}$

(LXXXIV)

The use of triphenyl(vinyl)phosphonium salts (LXXXV) as the electrophiles in a similar reaction leads to the intermediate phosphonium ylides (LXXXVI), which subsequently undergo the Wittig reaction:[121]

(LXXXV) (LXXXVI)

X=Br, BF_4; Y=H, SCH_3.

The entire sequence of reactions constitutes a new type of [3 + 2]annelation, which has been used effectively in the synthesis of tricyclo[6.3.0.$0^{2,6}$]undecanes with functional group substituents.[121]

- - - o0o - - -

It follows from the data presented in this review that the introduction of acyl and acylmethyl fragments into organic substrates by means of carbene reactions makes it possible in many instances to achieve unique reactions ensuring the formation of new carbon–carbon bonds under mild conditions with a high regioselectivity and stereoselectivity. The carbene species then frequently behave as reagents with "inverted" polarity of the reaction centre, and the significant dependence of the chemical properties of the carbene intermediates on their spin state and on the presence of a complex forming agent imparts additional flexibility to the synthetic methods. The possibility of achieving alternative pathways leading to the opening of the ring in cyclopropane intermediates and their great synthetic possibilities also give rise to excellent prospects for the introduction of functional groups into alkenes by means of carbene reactions.

Carbonylcarbenes in the specific synthesis of natural products

T V Mandel'shtam
Leningrad State University

ABSTRACT. Studies on the specific synthesis of natural products and their analogues, using alkoxycarbonyl- and keto-carbenes as well as their synthetic equivalents, are surveyed. Properties of carbonylcarbenes such as cycloaddition to alkenes and reactions involving intermolecular and (especially) intramolecular insertion in C–H, N–H, and C–X (X = heteroatom) bonds have found wide scale application. These reactions permit the stereoselective and regioselective synthesis of a wide variety of carbon atom and heteroatom molecular skeletons which are difficult to obtain by other procedures.†

The bibliography includes 134 references.

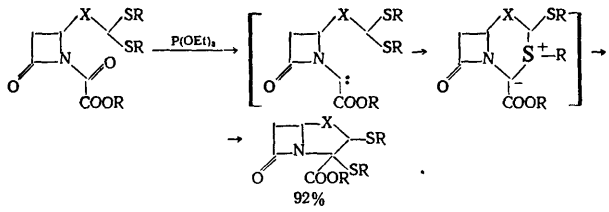
I. Introduction

The varied chemical properties of keto- and alkoxycarbonylcarbenes have been described in a series of reviews and monographs[1–6] and many of their reactions have been recommended as convenient preparative methods for the construction of various structural fragments. This review deals with the way in which these recommendations are used in practice in the specific synthesis of biologically active natural products and their analogues. The author did not attempt to provide an exhaustive bibliography on this question; the studies quoted serve merely as an illustration of the possibility of the synthetic use of carbenes.

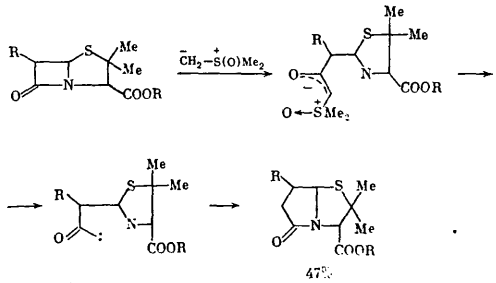
† This review was intended for publication in issue No. 7 (1989) of this journal, which was devoted to the chemistry of carbenes.

II. Synthetic equivalents of carbonylcarbenes



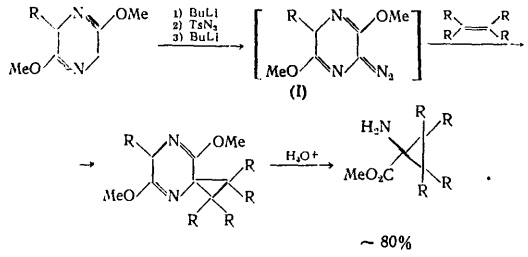
In the selection of a reagent for the creation of a structural element of the target compound, the detailed mechanism of its interaction with the substrate is of secondary importance; the question of the limits of the applicability of the method and the procedures for increasing the regio- and stereo-selectivity of the reagent comes to the fore. For this reason, the differences between free carbenes and carbenes bound in complexes and even between their precursors are unimportant for synthetic chemists provided that these species behave in the same way. All these compounds with the aid of which it is possible to introduce the $R-\overset{|}{\underset{|}{C}}-COOR$ or $R-\overset{|}{\underset{|}{C}}-COR$ synthons into the molecule, are combined in the concept of "synthetic equivalents of carbonylcarbene".

Diazocarbonyl compounds are a traditional source of carbonylcarbenes. Virtually only the catalytic decomposition of the latter is used in specific synthesis, because the carbenes generated by the thermolysis or photolysis of diazo-compounds are too active and their reactions are insufficiently selective. The experiments where it is necessary to carry out the Wolff rearrangement, which is known to occur best under photolytic conditions, are an exception.



Various compounds are used as catalysts of the decomposition of diazoketones and diazoesters:[7,8] copper, rhodium, ruthenium, platinum, and tungsten complexes. In selecting a particular catalyst, the aim is to reduce the decomposition temperature of the diazocompound, to alter its regioselectivity, and to increase the stereoselectivity of the reaction.

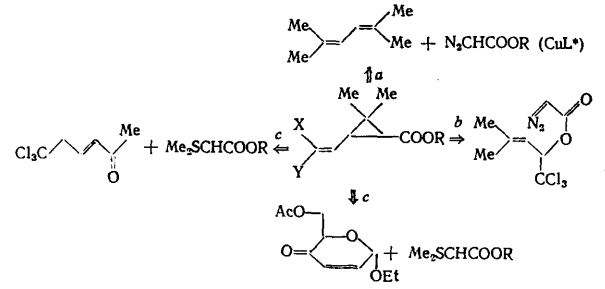
Bivalent rhodium salts (the acetate, trifluoroacetate, etc.) have been used particularly frequently in the specific synthesis in recent years. Indeed, in the presence of these compounds it is frequently possible (but not always) to carry out the decomposition of diazocompounds at room or an even lower temperature and the regioselectivity of the reaction proves to be higher than that of the reaction using copper salts. Rhodium acetate is superior to copper compounds as the catalyst of the reactions involving the insertion of the carbene in a C–H bond[9] and its addition to arenes.[10] On the other hand, copper compounds have not lost their importance in the catalysis of reactions involving cycloaddition to alkenes. Copper acetylacetonate [$Cu(acac)_2$] or its hexafluoro-derivative [$Cu(F_6\text{-}acac)_2$] are frequently used for this purpose. The employment of copper complexes with chiral ligands (L*) as catalysts of the decomposition of diazoacetic acid ester enabled a number of investigators[11–15] to achieve a high degree of stereocontrol in the synthesis of chrysanthemic and related acids.



Communications have been recently published about new sources of carbonylcarbenes. Thus, according to Kametani et al.,[16] carbonylcarbene arises when a substituted oxalic acid amidoester is acted upon by triethyl phosphite:

A carbonylcarbene, which underwent the Wolff rearrangement, has been obtained by the reaction of a β-lactam with dimethylsulphoxonium methylide:[17]

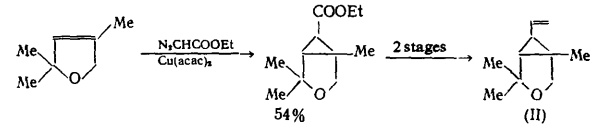
A derivative of diazodihydropyrazine (I), which reacts with alkenes with evolution of nitrogen at the instant of its formation, may be called a synthetic equivalent of aminomethoxycarbonylcarbene:



Acid hydrolysis of the spiroadduct led to the formation of aminocyclopropanecarboxylic acid.[18]

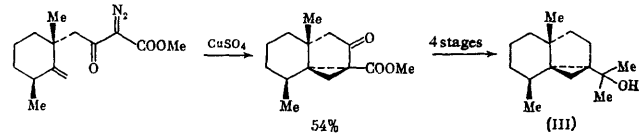
The carbene generated in the presence of copper is known[1-6] to possess electrophilic properties. Nevertheless, in certain cases it has been possible to add this species to the "activated" double bond of acrylic esters. This result has been achieved[19] by adding to the reaction mixture copper sulphate and a carbene acceptor—dimethyl sulphide. The addition of the diazoester yielded a sulphonium ylide,[20] which served as a reagent transferring the nucleophilic alkoxycarbonylcarbene.[21] A similar result was obtained in the reaction of "activated" double bonds with dimethylsulphonium methylides, synthesised beforehand by other methods,[22-24] which makes it possible to regard these compounds as the synthetic equivalents of alkoxycarbonylcarbene.

III. The use of the [1 + 2]cycloaddition reaction for the synthesis of the cyclopropane fragment of the molecular skeleton



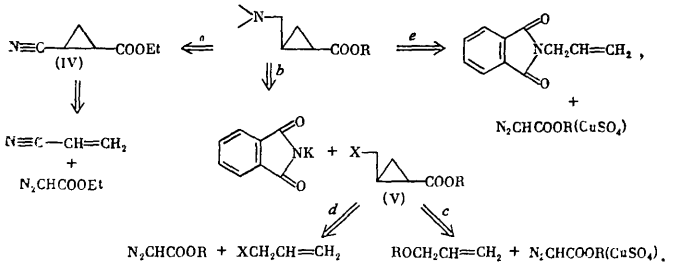
Fairly numerous natural products whose skeleton contains a three-carbon ring are known. The [1 + 2]cycloaddition reactions of carbonylcarbenes are widely used to construct this structural fragment.

The carbene synthesis is most important for the preparation of a wide variety of pyrethroids, which are based on chrysanthemic acid and its derivatives.[25] Various ways of synthesising acids of this group with the aid of equivalents of alkoxycarbonylcarbene are known:

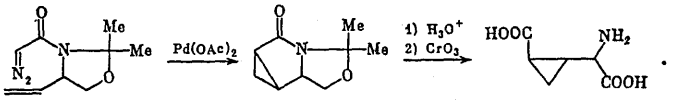


(*a*) Stereoselective[26,27] and asymmetric[11-14] synthesis involving the use of a bulky group in the diazoacetic ester and (or) the application of copper complexes with chiral ligands as catalysts; (*b*) the stereocontrolled intramolecular cycloaddition of the carbene C atom to a weakly nucleophilic double bond;[15,18] (*c*) the use of sulphonium ylides to convert an "activated" double bond into a cyclopropane derivative.[22-24]

The intermolecular conversion of an alkene into a cyclopropane derivative by diazoacetic ester has been used in the unambiguous synthesis of artemiseole (II), a natural monoterpene having a skeleton which conflicts with the isoprene biosynthesis rule:[29]



The intramolecular cyclopropane formation reaction has been the key stage in the synthesis of a sesquiterpene antibiotic—cycloeudesmol (III). With the aid of this method, it has been possible to introduce the quaternary C atom common to the three condensed rings and having the necessary configuration:[30]



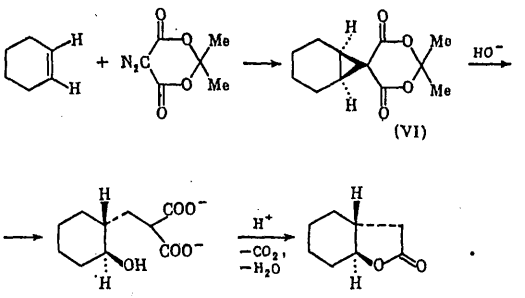
The rigidity of the system in this instance led to the formation of only one stereoisomer of the compound. The intermolecular conversion of the double bond into a cyclopropane derivative with the aid of diazoacetic ester [CuI.P(OMe)$_3$ catalyst, yield 74%] has been used in the synthesis of 23,24-dihydrocalysterol.[31]

Aminoacids of the cyclopropane series occupy an outstanding place among biologically active natural products.[32] Various approaches to the synthesis of the cyclic analogue of γ-aminobutyric acid (GABG) have been demonstrated on the basis of the scheme presented below:

(*a*) The addition of diazoacetic ester to acrylonitrile, the pyrolysis of the resulting pyrazoline, and the hydrogenation of the nitrile (IV);[33] (*b*) the alkylation of potassium phthalimide by the halogenomethylcyclopropanecarboxylic acid ester (V).[34] The ester (V) can be obtained (*c*) by treating allyl acetate[35] or allyl alcohol[36] with diazoacetic ester and subsequent substitution of the hydroxy-group in compound (V) (X = OH) by a halogen.[37] The same ester can be obtained by another procedure (*d*) involving the interaction of diazoacetic ester with allyl chloride in the presence of copper sulphate.[38] The ester of 2-chlorobut-3-enoic acid is then formed as the side product as a result of the rearrangement of the intermediate chloronium ylide.[39] The formation of the ylide and hence of the unsaturated ester can be avoided if the reaction of the diazoester with allyl chloride is performed under the conditions of photosensitised deazotisation, i. e. with participation of triplet ethoxycarbonylcarbene,[40] or if rhodium acetate is used as the catalyst of the decomposition of the diazoester.[41] Finally, the cyclic analogue of GABA can be obtained by converting *N*-allylphthalimide into a cyclopropane derivative. By virtue of the influence of the phthalimide group, the nucleophilicity of the nitrogen atom in *N*-allylphthalimide is reduced and the formation of the ylide in the insertion reaction does not therefore take place[42] (pathway *e*).

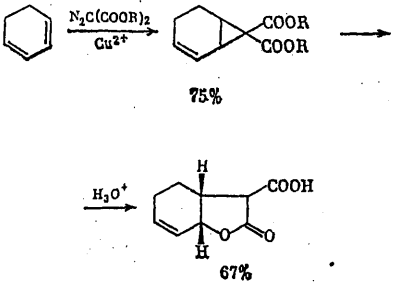
An analogue of glutamic acid, containing a three-carbon ring, has been obtained[43] by the intramolecular cycloaddition of a diazoamide to the double bond and the subsequent hydrolysis and oxidation of the alcohol group:

IV. The use of the [1 + 2]cycloaddition reaction for the synthesis of active intermediates



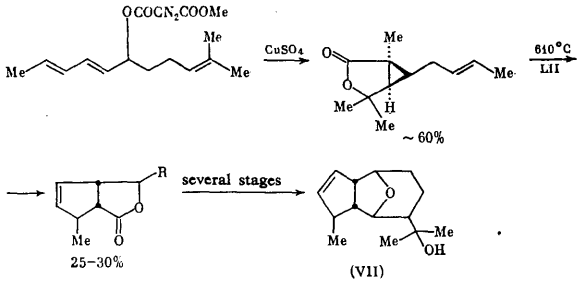
Compounds with a three-carbon ring, obtained as a result of the [1 + 2]cycloaddition of carbonylcarbenes to carbon–carbon double bonds, are frequently convenient synthons for the construction of a wide variety of structural elements. This is associated, on the one hand, with the ease of the formation of carbonyl cyclopropanes by carbene synthesis and, on the other hand, by the large store of energy in these compounds and hence the frequently high tendency towards ring opening, which takes place regio- and stereo-selectively.

A monograph (Ref. 44, Chapter 4) and a review[45] have been devoted to the use of cyclopropanecarboxylic acids, their derivatives, and cyclopropyl ketones in organic synthesis. Here we shall quote only individual examples.

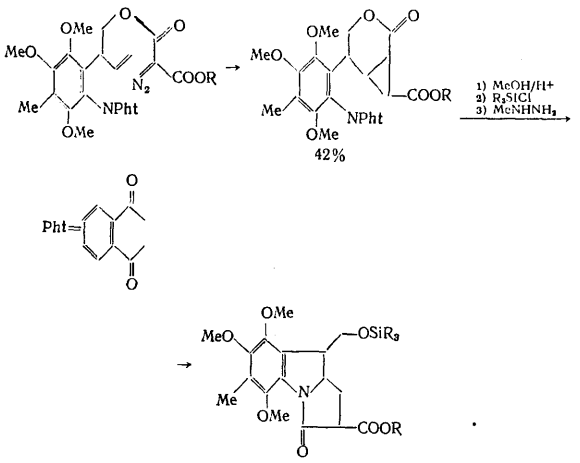


1. The ring opening in cyclopropanes and the problem of the reversal of the polarity of the synthons

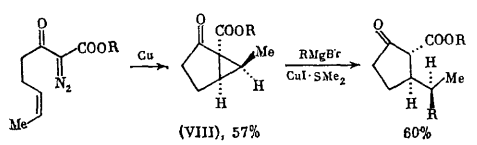
The electron density in cyclopropanes containing the electron-accepting carbonyl group is known[46] to be distributed non-uniformly in such a way that the C–C bond of the ring lying opposite the substituent is stronger than the bond adjoining the substituent. The C(1)–C(2) bond is in fact dissociated when carbonylcyclopropanes are acted upon by electrophiles and nucleophiles or, catalytically, by excited hydrogen. The nucleophilic species always add to the second carbon atom of the three-membered ring with inversion of the configuration of the atom; the electrophilic species is found at the first carbon atom. This atom usually undergoes racemisation.[47]



The nucleophilic opening of the ring or the homocoupled addition to carbonylcyclopropanes proceeds under mildest conditions if the compound contains two electron-accepting groups at one carbon atom, the bisecting [staggered] conformation of the two groups being optimal. This is achieved in spiran derivatives of type (VI):[47]

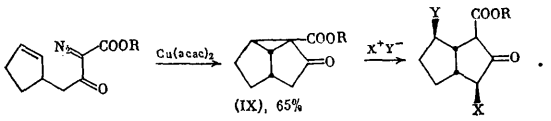


The γ-butyrolactone fragment, condensed with a larger ring, enters into the composition of many natural products.[48] Compounds with both *cis*- and *trans*-fused rings are known. Danishefsky's strategy,[47] consisting in the formation of a spiro-activated cyclopropane and the opening of the three-membered ring of the latter with the aid of a base, makes it possible to obtain *trans*-fused lactones (see above). Conversely, the opening of the ring in cyclopropanecarboxylic acids in an acid medium leads to the formation of *cis*-fused lactones:[49,50]

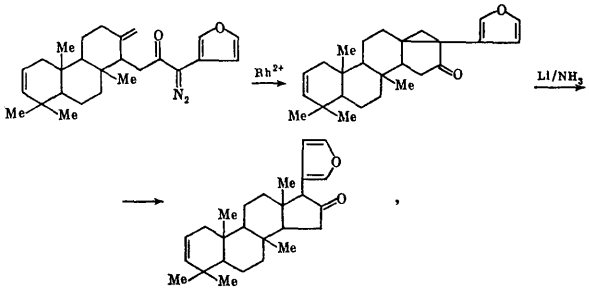


cis-Fused lactones can also be obtained by the intramolecular conversion of the esters of unsaturated alcohols into cyclopropane derivatives. The combination of this method and the vinylcyclopropane–cyclopentene rearrangement (see below) made it possible[51] to devise an approach to the creation of the guaiane system (VII):

If the nucleophilic centre is in the side chain of the cyclopropane carboxylic acid or cyclopropyl ketone, then its homocoupled addition to the activated three-carbon ring proceeds under mild conditions under rigorous stereocontrol and, depending on the character of the nucleophilic centre, leads to the formation of carbocycles or heterocycles.[47] The use of this reaction for the synthesis of a precursor of the alkaloid mitomycin is illustrated below:



The intramolecular conversion of the double bond into a cyclopropane derivative and subsequent homocoupled addition of alkyl cuprate to the bicyclo[3.1.0]hexan-2-one (VIII) constitutes a convenient method of synthesis of cyclopentanones with control of the stereochemistry of the side chain:[53]

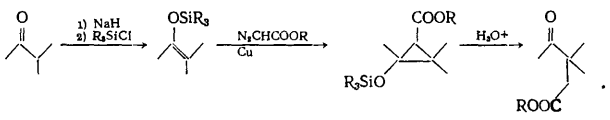


This strategy has found applications in the synthesis of prostaglandins, terpenoids, and other natural products (see, for example, Adams and Belley[54]).

The intramolecular cycloaddition of carbonylcarbene to the double bond of the cyclopentene fragment and subsequent electrophilic or nucleophilic opening of the three-membered ring of the tricyclic compound (IX) afford a condensed system made up of two five-membered rings having a defined stereochemistry:[55]

This reaction is of interest in connection with the synthesis of polyquinanes and iridoid monoterpenes.[56]

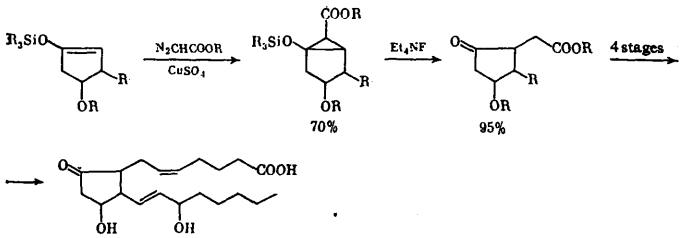
Finally the opening of the ring in cyclopropyl ketones, also obtained by the intramolecular cyclopropane formation reaction, with the aid of lithium in liquid ammonia has been used in the synthesis of the cyclic system of limonoids:[57]



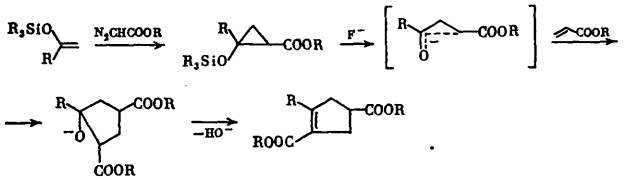
and also in the synthesis of pentalenene.[58]

The acid-catalysed ring opening in cyclopropane derivatives obtained by the carbene synthesis[59–64] is used widely in the synthesis of sesquiterpenes, diterpenes, gibberellins, and steroids. The reaction proceeds especially readily, frequently spontaneously, at room temperature or on slight heating in those cases where there is an electron-donating group at the second carbon atom of the carbonylcyclopropane.

Bifunctional fragments in which the functional groups are separated by an odd number of carbon atoms are known[65] to constitute a definite problem in organic synthesis, because the usual isohypsic reactions lead to the formation of compounds with an odd number of carbon atoms between the functional groups. Carbonylcyclopropanes are synthetic equivalents of the $^{+}C-C-C-C=O$ synthon with inverted polarity at the γ-carbonyl atom. Derivatives of 2-hydroxycyclopropanecarboxylic acids are very useful in synthesis from this point of view.[66]



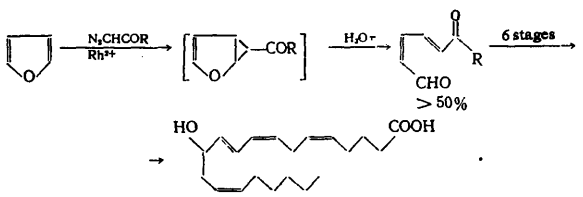
The acid-catalysed ring opening in siloxycyclopropane produces a result equivalent to the α-alkylation of a carbonyl compound:



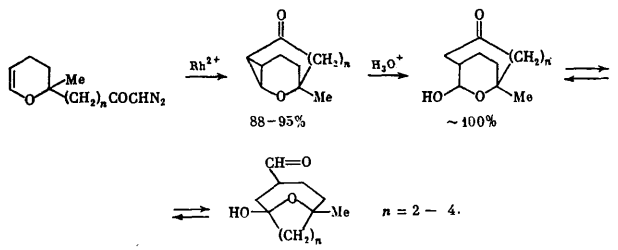
Quaternary centres in the α-position in the ketone can be obtained in this way.

The copper sulphate-catalysed addition of alkoxycarbonylcarbene to the silyl ethers of enols and subsequent ring opening with the aid of the fluoride ion constitutes a new strategy for the synthesis of

1,4-dicarbonyl compounds. In particular, it has been used to synthesise dihydrocompactin,[67] prostaglandins,[68] and related compounds,[69] for example:



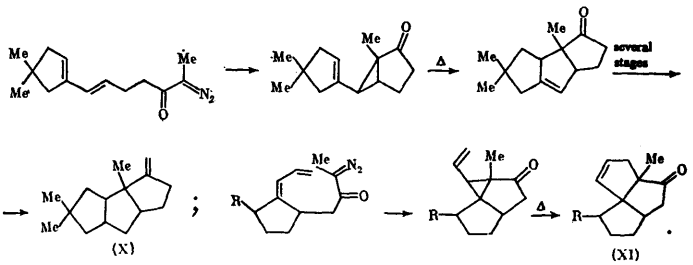
A new strategy for [2 + 3]annelation is based on the interaction of the fluoride ion with siloxycyclopropanecarboxylic acids.[70] The essential feature of this strategy consists in carrying out three consecutive reactions: the conversion of the silyl ether of an enol into a cyclopropane derivative, the opening of the ring in the latter with the aid of the fluoride ion, and the trapping of the carbanion formed in this process by electrophilic alkene.



The reaction results in the formation of a cyclopentene derivative.

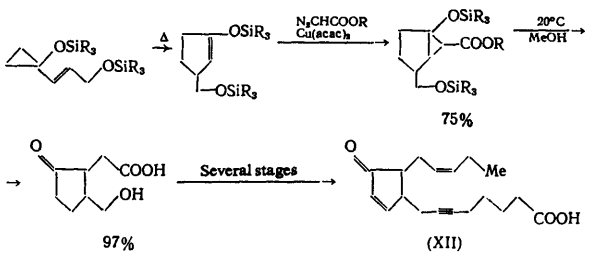
The reaction of ketocarbenes with furan and its homologues provides a unique possibility for the stereoselective synthesis of (*Z*, *E*)-isomers of dienealdehydes. This method has been used successfully to synthesise isomeric hydroxyeicosanetetraenoic acids:[71-73]

The analogous reaction with sylvan made it possible to obtain (7*E*, 9*Z*)-dodeca-7,9-dien-1-yl acetate[74]—the pheromone of one of the pests on grapevine.



The opening of the ring in 2-alkoxycyclopropyl ketones constitutes a pathway leading to rings of moderate size (7-membered—10-membered),[75] in particular to widdrol:

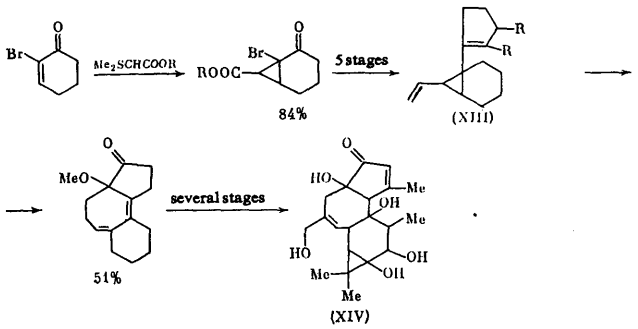
The thermal isomerisation of the adducts of ethoxycarbonylcarbene with pyrimidines and isoquinolines led to the synthesis of modified and alkaloids.[76]



2. The vinylcyclopropane—cyclopentene rearrangement

The conversion of conjugated dienes into cyclopropane derivatives affords vinylcyclopropanes, which are capable of isomerising to cyclopentene on heating.[77] This rearrangement constitutes yet another way of obtaining polycyclic systems. Examples of the synthesis with its aid of the sesquiterpenes hirsutene (X) and isocomene (XI) are presented below:

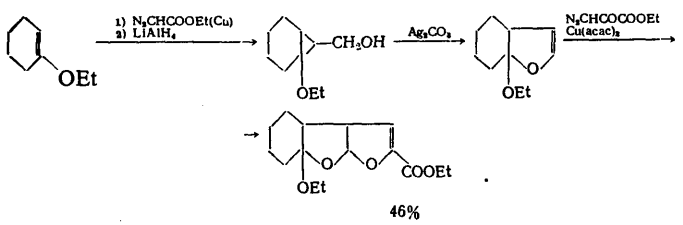
The two-stage process involving the cycloaddition of the carbene fragment and rearrangement, which can be achieved without isolating the intermediate vinylcyclopropane, is equivalent to [4 + 1]cycloaddition, permitting at the same time the closure of several rings. The vinylcyclopropane—cyclopentene rearrangement ensures an effective stereocontrol of the reaction: *cis*-fused rings are formed. The reaction can be catalysed by lithium iodide.[78]



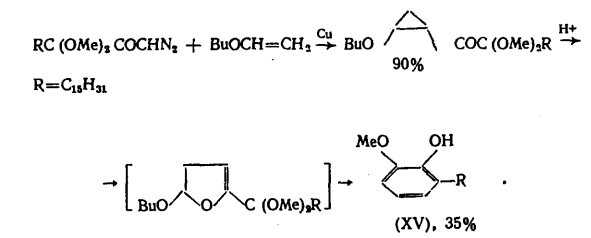
In the synthesis of dicranenone A—an aliphatic acid related to prostaglandins (XII)—the fragment containing the cyclopentane ring and two carbonyl groups in the 1,4-positions and involving the *trans*-dispositions of the ring substituents was constructed using the methodologies described above: the vinylcyclopropane—cyclopentene rearrangement, the formation of the cyclopropane derivative, and the opening of the ring in siloxycyclopropanecarboxylic acid:[69]

3. The Cope rearrangement of divinylcyclopropanes

The Cope rearrangement of *cis*-divinylcyclopropane takes place spontaneously and leads to the formation of cycloheptadiene. The similar reaction of compound (XIII), obtained by the conversion of the corresponding bromovinyl ketone into a cyclopropane derivative by means of dimethylsulphonium methylide, has been used in the

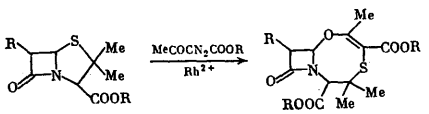


synthesis of tricyclic and tetracyclic diterpenes, in particular phorbol (XIV), which has interesting pharmacological properties:[79]



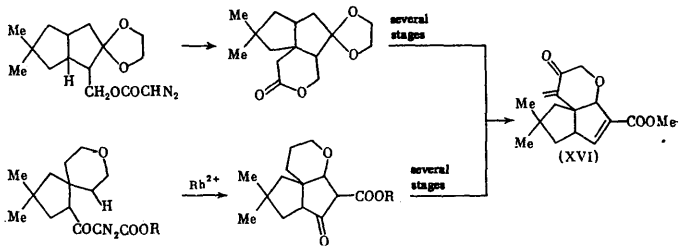
The above rearrangement allows the conversion of bicyclo[4.1.0]-heptadienes into cycloheptatrienes and hence makes it possible to obtain seven-membered rings via the reactions of carbenes with mononuclear aromatic compounds. The carbene method of synthesis of azulenes has been known for a long time. This method has undergone a new development in studies of recent years. It was found that the reaction can be carried out intramolecularly, providing a new and simple method of synthesis of compounds of this class.[80,81] Ring-substituted aryldiazoketones cyclise regio-selectively in the presence of rhodium trifluoroacetate; the bicyclic ketones obtained can be converted into substituted azulenes or into tetralones. McKervey et al.[82] suggest that the method which they describe be used for the synthesis of sesquiterpenes of the perhydroazulene series.

V. The use of other cycloaddition reactions of carbonylcarbenes

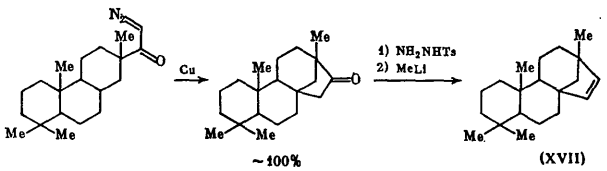


Carbonylcyclopropanes are capable of rearranging to dihydrofuran derivatives. In certain cases, dihydrofurans are formed directly in the reaction of a carbonylcarbene with an alkene.[8,45] This formal [2 + 3]cycloaddition of the 1,3-dipolar form of carbonylcarbene has found an application in organic synthesis. Dihydrofurancarboxylic acid esters, having a structure similar to that of aflatoxin, have been obtained in this way:[83]

A series of natural products containing the furan ring,[84] intermediates in the synthesis of eburnamonine and certain other alkaloids,[85] as well as the monomethyl ether of hydrourushiol (XV), a natural derivative of catechol,[86] have been obtained by the same method:

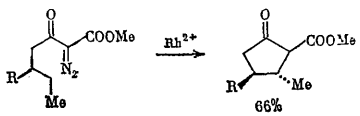


The insertion of the 1,3-dipolar form of a carbonylcarbene in the carbon–sulphur bond of a penicillannic acid, which results in the formation of a new antibiotic of the β-lactam group, has been described:[87]



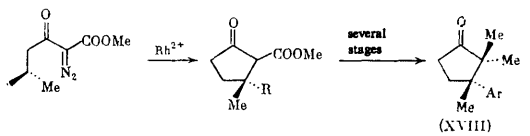
VI. The use of reactions involving the insertion of carbonylcarbenes in a C–H bond

The reactions involving the intramolecular insertion of carbonylcarbenes and their equivalents in C–H bonds have come to be widely used synthetically in recent times. The reaction leads to the formation of cyclopentane derivatives. The rigidity of the transition state in the insertion reaction ensures high regio- and stereo-control. The insertion of the carbene C atom in a tertiary C–H bond has been used[88] in the synthesis of the pentalenolactone (XVI); subsequently, the same compound was obtained[9] by the reaction involving insertion in a secondary C–H bond:



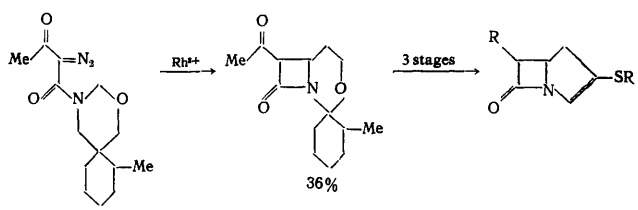
The advantage of this method of synthesis of cyclopentanes is evident: in contrast to other methods of ring closure, which require the presence of two functional groups in the compound, here one is sufficient and it is possible to achieve in one stage an appreciable increase in the complexity of the molecule.

Bridged structures, for example hibaene (XVII), are obtained with the aid of the reaction involving insertion in a C–H bond:[89,90]



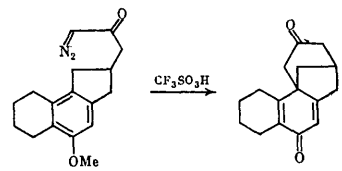
The intramolecular insertion of a carbonylcarbene proceeds with a high degree of regioselectivity via a pathway leading to the formation of five-membered rings.[92,92] The insertion in diastereotopic C—H bonds is characterised in addition by stereoselectivity:[93]

A *trans*-3,4-disubstituted cyclopentanone is formed preferentially.



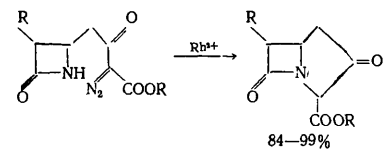
In the deazotisation of a 2-diazo-3-ketoester in the presence of the rhodium catalyst, the insertion in a C—H bond can proceed with retention of configuration, as happened in the synthesis of α-cuparenone (XVIII):[96]

Thus the reaction represents a general strategy for the enantioselective synthesis of carbocycles having a chiral centre.



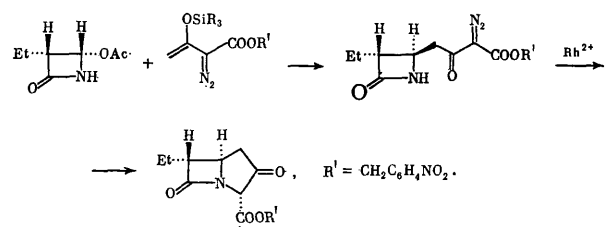
The use of a divalent palladium complex of benzonitrile as the catalyst of the decomposition of a diazoester makes it possible to obtain products of insertion in C—H bonds even when the reacting molecule contains a C=C double bond.[95] The insertion proceeds regioselectively at a decreasing rate in the sequence CH > CH_2 > CH_3. Allyl and benzyl C—H bonds proved to be less reactive than the C—H bonds of saturated compounds. The insertion in aromatic C—H bonds has been achieved successfully.[96,97] In the presence of the rhodium catalyst, the insertion in tertiary C—H bonds predominates over cycloaddition, but secondary and primary C—H bonds are less reactive than the C=C bonds. The replacement of the catalyst by a copper catalyst leads to the predominance of cycloaddition in all cases.[98]

The reaction involving insertion in a C—H bond has not been used solely for the synthesis of carbocycles; heterocycles[99] and intermediates in the synthesis of analogues of thienamycin,[100] penicillin,[101] and cephalosporin[102,103] have been obtained by this method:



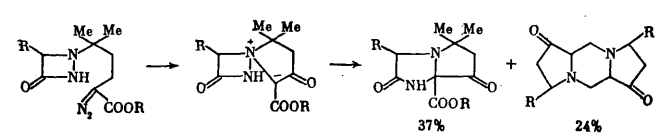
When an attempt was made to carry out the same reaction photolytically,[103] it was found that it is insufficiently selective.

An unusual reaction has been observed for ketocarbenes containing in the δ- or ε-position an aromatic ring with an alkoxy-group in the *para*-position, capable of being converted into a quinone. Treatment of these ketones with a strong acid yielded bridged systems, which were subsequently used in the syntheses of gibberellins and diterpenoids:[104]

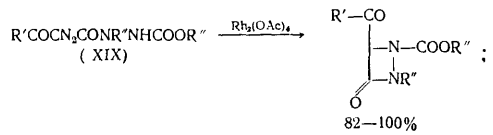


VII. The use of reactions involving insertion of carbonylcarbenes in a N—H bond

The insertion of carbonylcarbenes in N—H bonds is used in the synthesis of β-lactam antibiotics:[105,106]



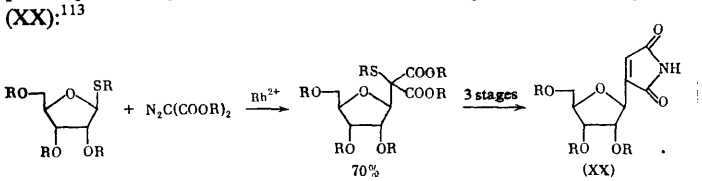
Phosphorus analogues of thienamycin[107] and nuclear analogues of β-lactam antibiotics[108] have been obtained by the same procedure. It is possible to synthesise pure enantiomers of β-lactams and carbapenems by starting with a pure enantiomer of a β-lactam and a diazoester having a bulky alcoholic group:[109]



The reaction involving insertion in a N—H bond has been used also in other asymmetric syntheses, in particular for the preparation of a pure alanine enantiomer.[110]

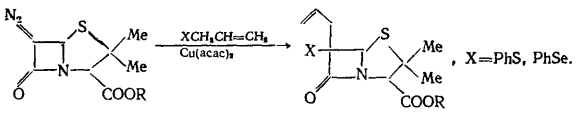
The programme undertaken to synthesise aza-analogues of β-lactam antibiotics by the insertion of a carbene in a N—H bond led to an unexpected result:[111] tricyclic compounds were obtained as a result of the carbene attack not on the lactam but on the amine nitrogen atom in diazetidines and the subsequent rearrangement of the ylide. This afforded a new group of pharmacologically interesting compounds:

At the same time, the decomposition of the diazodihydrazide (XIX) in the presence of the rhodium catalyst was accompanied by the almost quantitative insertion of the carbene in the amide N–H bond:[112]



82—100%

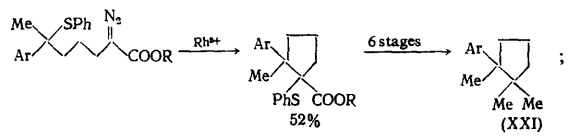
R‴ = Bu^t, CH_2Ph; R″ = CH_2Ph, COOEt; R′ = Me, OEt.



VIII. The use of reactions involving the insertion of carbonylcarbenes in C–X bonds

The interaction of carbenes with compounds containing heteroatoms is known to entail the formation of ylides. Sulphur ylides are formed particularly readily.[21] The rearrangement of the ylides can produce a synthetically interesting result.[39] The insertion in a C–S bond at the anomeric carbon atom in pentoses opens a pathway to the synthesis of the antitumour compound showdomycin (XX):[113]

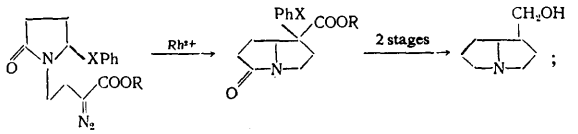
70% (XX)



The rearrangement of the ylides formed as a result of the intramolecular attack by a copper carbenoid on the sulphur atom in penicillins constitutes a general method for the formation of a new C–C bond in compounds of this class.[114] The rearrangement of the ylides constitutes the basis of the synthesis of penems and carbopenems from diazopenicillin:[115,116]

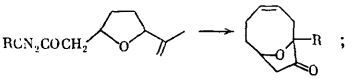
33—66%

Another source of a carbonylcarbene for the synthesis of penems and carbopenems with the aid of the reaction involving insertion in a C–S bond was described above.



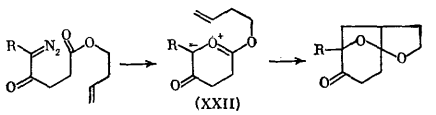
The reaction of diazoacetic ester with benzyl sulphides is used to generate a quaternary centre in the benzyl position in the synthesis of the aromatic sesquiterpene cuparene (XXI):[117,118]

52% (XXI)



Art = *p*-$C_6H_4CH_3$.

The same procedure has been used in the synthesis of pyrrolizidine alkaloids trachelanthamidine, isoretronecanol, etc.:[119–121]

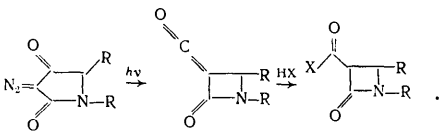


X=S (55%), X=Se (36%).

The formation of oxonium ylides proceeds with greater difficulty than that of the sulphur ylides. Nevertheless, the rearrangement of a tetrahydrofuran ketocarbene, which led to the bicyclic heterocycle oxocane, apparently occurred with their participation:[122]

R = H(81%), R = COOEt (67%).

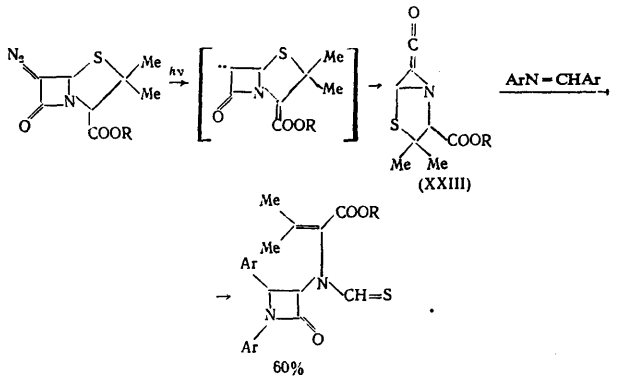
Oxonium ylides of type (XXII) are intermediates in the recently proposed[123] method of synthesis of complex heterocyclic systems encountered in various groups of natural products:



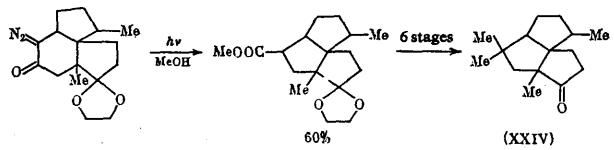
(XXII)

IX. The use of other reactions of carbonylcarbenes

One of the most interesting properties of ketocarbenes—the Wolff rearrangement—has also found an application in the specific synthesis of natural products. This rearrangement is very widely used in the synthesis of homologous acids by the Arndt–Eistert method and in the ring contraction reactions for cycloalkanes and their heterocyclic analogues. A detailed description of this problem is outside the scope of the review and we shall confine ourselves to several examples.

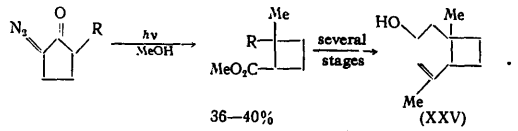


Certain β-lactam antibiotics[124] and their aza-analogues[125] have been synthesised with the aid of the Wolff rearrangement: this method has proved very suitable for the synthesis of a strained β-lactam ring:

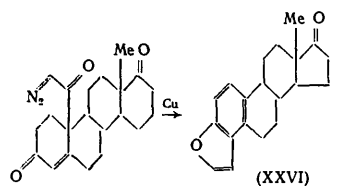


~ 90%

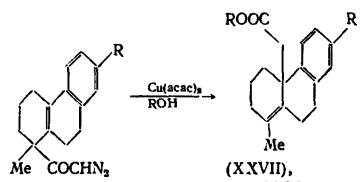
The Wolff rearrangement of a ketocarbene obtained by a non-traditional method[17] has been used, as shown above, for the synthesis of penicillin homologues. The addition of a ketone—the product of the Wolf rearrangement of the amidocarbene (XXIII)—to a Schiff base affords (after the opening of the aziridine ring) new



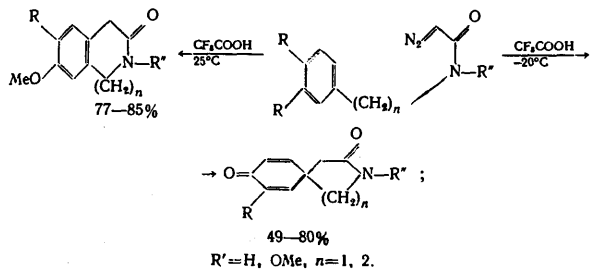
compounds with a β-lactam fragment which are potential antibiotics:[126]



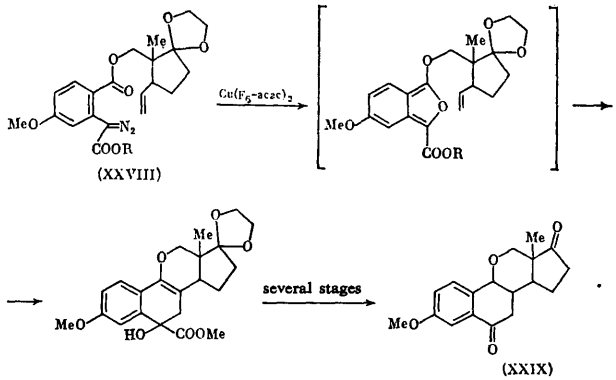
The rearrangement has also been used in the synthesis of 3-oxosilphinine (XXIV):[127]



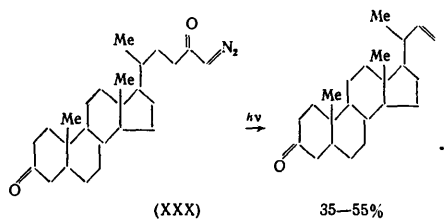
The method of ring contraction with the aid of this rearrangement has proved convenient for the synthesis of precursors of grandisol and fragranol (XXV):[128]



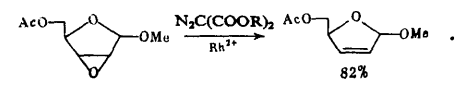
Finally, the vinylogue Wolff rearrangement[129] helped to obtain the modified oestrone (XXVI):



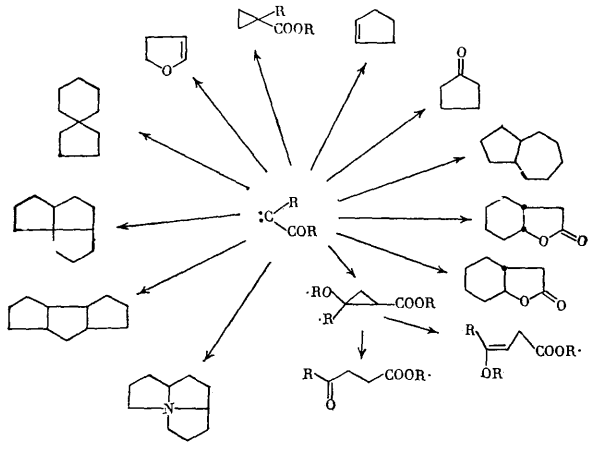
The same reaction can serve as a method of synthesis of angularly substituted polycyclic compounds of type (XXVII):[130]



One may note certain other reactions of α-diazocarbonyl compounds, which have been used in the specific synthesis of the structural fragments of natural products and in which either carbonylcarbenes or their synthetic equivalents were involved. Thus the acid-catalysed cyclisation of aromatic diazoacetamides has been used[131] for the synthesis of isoquinolinones and benzazepinones having the structural elements of natural alkaloids:



The copper-catalysed decomposition of the diazoester (XXVIII) led[132] to the 6-oxo-11-oxasteroid (XXIX) via the intermediate formation of an isobenzofuran derivative:



Carbene reactions sometimes play an auxiliary role in the synthesis of natural products. Thus the photolysis of the α-diazoketone (XXX) in the presence of imidazole, leads to the formation of nor-olefins. This method has been used in the degradation of the side chains of bile acids:[133]

Diazomalonic ester has been used to remove the oxiran group protecting a double bond, which has been used in the synthesis of biologically important $\Delta^{2,3}$-nucleosides:[134]

Various structural fragments of natural products, which can be synthesised with the aid of carbonylcarbenes and their synthetic equivalents, are presented in the scheme below:

The wide variety of these structures shows that the chemistry of carbonylcarbenes makes an important contribution to the range of available methods in synthetic organic chemistry.

ABSTRACT. The principal aspects of the chemistry of amino- and oxy-nitrenes—the nitrogen analogues of carbenes in which the sextet of the nitrogen atom is linked to another nitrogen atom or two oxygen—are examined. The available information about the methods of detection, structure, methods of generation, and properties of these usually unstable intermediate species are analysed critically. Attention is concentrated on the comparison of amino- and oxy-nitrenes, their rearrangements, and their interactions with unsaturated compounds.†

I. Introduction

Vigorous studies on the nitrogen analogues of carbenes—the nitrenes X—N̈: (I)—have led to the creation of a large and rapidly developing field of chemistry.[1,2] The so called heteronitrenes, where the sextet of the nitrogen atom adjoins a heteroatom (see Scriven,[2] Chapter 5) and in the first place aminonitrenes (*N*-nitrenes or 1,1-diazenes) (I, X = R_2N), occupy a special place in this field. It is determined by the important role which aminonitrenes play in numerous reactions of organic hydrazine derivatives[3] and the wide variety of their synthetic applications, in particular for the preparation of *N*-aminoaziridine and other nitrogen heterocycles, which are otherwise difficult to obtain, and new classes of acyclic polynitrogen compounds. This is perhaps the most thoroughly investigated type of nitrenes and therefore special attention will be devoted to it in the present review. Information about the oxygen analogues of aminonitrenes—oxynitrenes (or *O*-nitrenes) (I, X = RO), which are of interest as possible intermediates in reactions of hydroxylamine derivatives, is much more scanty, but data obtained in recent years permit a comparative characterisation of these two types of nitrenes, which was lacking in the previous reviews.

The hypothesis of the existence of aminonitrenes, which arose in the middle of the 1950's (see Ioffe et al.,[3] Chapter 3) received rapid recognition and the last two decades have becomes a period of vigorous development of the chemistry of aminonitrenes. A number of methods for their generation and the variety of their reactions have rapidly increased and the first synthetic applications of the reactions of these unstable species became outlined. At the end of the 1960s, search was begun for evidence indicating the existence of the analogous oxynitrenes, which rapidly led to the successful synthesis of alkoxyaziridines, which stimulated the systematic investigation also of heteronitrenes of this kind. The principal results of this kind have been summarised in monographs[1–3] and a number of reviews.[4–7]

At the end of the 1970s there was a return to a more critical analysis of the accumulated data. A rigorous revision of the results began and more attention began to be paid to the demonstration of the involvement of *N*- or *O*-nitrenes in particular reactions and to the relation between their structure and behaviour. Studies on the reactivity of these nitrenes were concentrated on aspects promising from the synthetic point of view such as reactions with unsaturated groups, including heteroatomic groups, and a wider variety of intermolecular cyclisations. At the same time the search for milder methods for the generation of these species and their new reactions did not cease.

A series of fundamentally important results, which have significantly altered the features of this branch of the chemistry of nitrenes, have been obtained during the past decade. Most of them have not been included in the latest reviews[2,7] and we have therefore endeavoured to survey these data, covering the literature up to the middle of 1987.

II. Structure and properties

1. The results of quantum-chemical calculations

Quantum-chemical calculations have until recently been the only source of information about the structure of amino- and oxy-nitrenes. As a result of the adjoining positions of the heteroatoms with the unshared (lone) electron pairs (LEP), here preference was usually given to non-empirical methods. Furthermore, the incomplete electron cloud to the "nitrene" nitrogen atom requires allowance for configuration interaction in order to obtain reliable results. All these features have sharply complicated the calculations and have virtually restricted them to the simplest molecules, such as aminonitrene itself H_2NN (II) or hydroxynitrene HON. Admittedly, these compounds are incorporated in a kind of "set of tests" for the testing of new bases and new computational schemes and even new results appear annually for these species (see, for example, Decleva and Lisini[8] and the annual bibliography of non-empirical calculations in the "Journal of Molecular Structure"). However, there have been nevertheless few studies of real value to experimental chemists and among them one would wish to mention in the first place calculations of the structure of the simplest aminonitrene (II)

† This article was planned for publication in issue No. 7, 1989, which was devoted to the chemistry of carbenes.

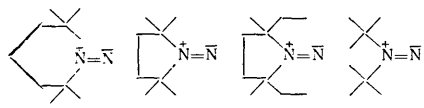
by the general valence bond method taking into account the configuration interaction.[9]

These calculations made it possible for the first time to demonstrate reliably that nitrene (II) has a singlet ground state (S_0). The first triplet state (T_1) has an energy higher by 63 kJ mol^{-1} and the energy of the first excited singlet state (S_1) is higher by 212 kJ mol^{-1},[9] which corresponds to absorption in the visible region of the electronic spectrum at above 560 nm (the $S_0 \rightarrow S_1$ transition). The calculated first ionisation potential is 9.4 eV.[9] The calculated enthalpy of formation of aminonitrene is $\Delta H^{298} = 361$ kJ mol^{-1}, i.e. is higher by 123 kJ mol^{-1} than ΔH^{298} for the isomeric *trans*-HN=NH and is higher by 103 kJ mol^{-1} than ΔH^{298} for *cis*-N_2H_2.[9,10]

In the ground state (S_0), the $H_2N\ddot{N}$: molecule is planar and the nitrogen–nitrogen bond length is 125 pm—a value typical for the N=N bond in azo-compounds. This indicates a decisive contribution of the polar structure (IIb) to the resonance stabilisation of aminonitrene via the transfer of the electron density of the LEP of the amino-nitrogen atom to the unoccupied *p* orbital of the nitrene atom:

(IIa) (IIb)

The large calculated dipole moment of aminonitrene (4D) is entirely consistent with this find, the nitrogen atom constituting the negative end of the dipole.[9]



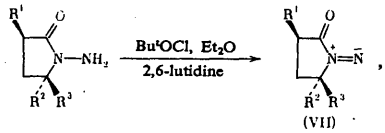
On exciting of the molecular of compound (II), the electron of one of the LEP of the nitrone nitrogen atom is transferred to the unoccupied *p* orbital. As a result, the molecule resembles a hydrazyl radical and the role of resonance stabilisation diminishes sharply. In agreement with this finding, the H_2NN molecule in the T_1 state is no longer planar (although the barrier to the inversion of the amino-nitrogen atom is only 0.8 kJ mol^{-1}), while the equilibrium N–N bond length increases to 137 pm.[9] At the same time it is nevertheless shorter than the N–N single bond in hydrazines (145 pm [3]); together with the appreciable dipole moment (2.35 D), this shows that in the triplet state of the nitrene (II), the LEP of the amino-nitrogen atom is appreciably delocalised. Similar changes in geometry occur also in $S_0 \rightarrow S_1$ transition.[9]

The calculated N–H bond energy is 180 kJ mol^{-1},[10] which makes it possible to estimate the C–N bond strength in substituted aminonitrenes as ~100 kJ mol^{-1}. Aminonitrenes should therefore be comparatively resistant to decomposition with rupture of the N–H or C–N bond which gives rise to the hope that they may be detected and identified.

2. The synthesis and properties of stable aminonitrenes

One of the ways of stabilising unstable intermediate species such as carbenes or nitrenes is their binding in complexes. At the beginning of the 1970s, the first complexes of *N*-nitrenes, including also the simplest aminonitrene (II),[11] with tungsten and molybdenum ions, were already discovered. Later complexes of aminonitrenes were obtained with rhenium, niobium, and tantalum,[12,16] as well as a series of iron-porphyrin complexes.[17,18] As a rule, these are very stable compounds and the properties of the aminonitrenes bound in them should naturally differ appreciably from those of the free species.

However, it was found that aminonitrenes can be detected in a state other than the complexes. As early as 1978, immediately after the calculations of Davis and Goddard,[9] a series of studies began to be published[19–26] on this synthesis (specifically the synthesis) and properties of stable aminonitrenes. It was shown that, when there are tertiary substituents at the amino-nitrogen atom, the dialkyl-aminonitrenes (III)–(VI), relatively stable at low temperatures, can be obtained by the classical method—the oxidation of the corresponding 1,1-disubstituted hydrazines by t-butyl hypochlorite in the presence of triethylamine[19–21,23–26] or active nickel peroxide:[226]



(III) (IV) (V) (VI)

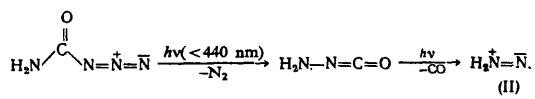
cis (a), *trans* (b)

Bright crimson or purple solutions of the nitrenes (III)–(V) in ether are stable at –78 °C for several days and at –85 °C they can be actually purified by chromatography on Al_2O_3. However, they decompose rapidly on raising the temperature to 0 °C. The nitrene (VI) can be stored only at –127 °C, decomposing rapidly even at –90 °C.[25] The comparative stability of these compounds can be accounted for by the presence of the bulky tertiary substituents which prevent both intermolecular reactions (dimerisation to tetrazenes) and intramolecular reactions (for example rearrangement to hydrazones).

The structure of the *N*-nitrenes (III)–(VI) has been unambiguously demonstrated by a set of spectroscopic characteristics (Table 1), which demonstrate agreement with calculated data,[9] as well as by their reactions on raising the temperature (decomposition, dimerisation to tetrazenes), which are entirely similar to the familiar reactions of unstable dialkylaminonitrenes (see also Section IV). Indeed, in agreement with predictions,[9] the nitrenes (III)–(VI) have a broad absorption band with a fine structure in the visible region. The low intensity of this band and its hypsochromic shift following an increase in the polarity of the solvent agree with its assignment to the $n-\pi^*$ transition in the $\rangle\overset{+}{N}=\overline{N}$ chromophore, isoelectronic with the carbonyl group, while the position of the transition between the zero-point vibrational levels (λ_{0-0}) agrees well with the calculated estimate (~560 nm [9]). The marked difference between the electronic absorption and fluorescence spectra indicates a marked change in the equilibrium geometry, also predicted by calculations,[9] on transition from the ground (S_0) to the first excited singlet state (S_1). The high frequency of the ν(N–N) vibrations in the IR spectra (the assignment of the band has been confirmed by isotope substitution), which actually exceeds somewhat the usual frequency of the N=N double bond vibrations (1574 cm^{-1} in azomethane) agrees with the conclusion[9] that the nitrogen–nitrogen bond in the simplest aminonitrene has a significant double bond character. The frequency ν(N–N) in the IR spectra then virtually agrees with the fine structure interval in the fluorescence spectra of compounds (IV) and (V), which constitutes additional confirmation of the assignment. It is remarkable that, on passing from the six-membered amino-nitrene (III) to the five-membered aminonitrenes (IV) and (V), the characteristics of the IR and the electronic spectra change in the same way as for the isoelectronic cyclohexanone and cyclopentanone derivatives.[24] The structure of the hydrocarbon substituents in compounds (III)–(VI) follows from their ^{1}H NMR spectra, while the unusual character of the nitrene nitrogen atoms is reflected in the enormous value of its chemical shift (δ = 917 p.p.m.) in the ^{15}N NMR spectrum of the nitrene (III).

The even more stable cyclic acylaminonitrenes (VII) were synthesised by the same method in 1984:[27,28]

R^1=H, R^2=R^3=Ph (a);
R^1=H, R^2=Me, R^3=Ph (b);
R^1=Me, R^2=Ph, R^3=Me (c);
R^1=Me, R^2=Me, R^3=Ph (d);
R^1=R^2=H, R^3=Ph (e).



Compounds (VIIa–d) are stable in solutions at room temperature for several days and even weeks, but the nitrene (VIIe), having a hydrogen atom in the α-position, isomerises rapidly under these conditions to the corresponding tetrahydropyridazinone (see Section IV).

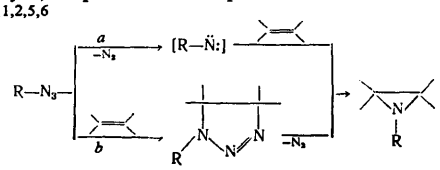
Table 1. The properties of the nitrenes (II)–(VII).

Compound	Electronic absorption spectrum: λ_{max} ($\lambda_{0\text{-}0}$), nm	Fluorescence spectrum (−196 °C): $\lambda_{0\text{-}0}$, nm	ν(N–N), cm^{-1}	$E^{\ddagger}_{decomp}$, kJ mol^{-1}
(II)	636	—	1574	—
(III)	543* (620)	684	1595	80—84
(IV)	497* (572)	607	1638	80—84
(V)	507* (568)	620	1630	80—84
(VI)	506	715	—	54
(VIIb)	520**	—	—	122

* $\varepsilon_{max} \simeq 18-20$.
** $\varepsilon_{max} \simeq 90$.

Finally, in 1984 it was possible to detect in a matrix and to characterise by IR and UV spectroscopy (see Table 1) also the simplest aminonitrene (II),[29] generated by the photolysis of the azide of carbamic acid (the Curtius rearrangement):

The isotopomers of the nitrenes (II) with two deuterium atoms and a nitrene ^{15}N were obtained in the same study, which made it possible to confirm the assignment of the IR bands, in particular the ν(N=N) band, whose frequency (1574 cm^{-1}) is much higher than for the isomeric *trans*-diazene HN=NH [ν(N=N) = 1529 cm^{-1} in the Raman spectrum[29]]. The spectroscopic properties of compound (II) fit one series with the properties of the substituted aminonitrenes (III)–(VI) (see Table 1) and agree well with the calculated estimates.[9] However, they differ sharply from Wiberg's "isodiazene",[30,31] to which the structure (II) was also attributed. According to the set of available data, Wiberg's report of the detection of the nitrene (II) on decomposition of the caesium salt of toluene-*p*-sulphonic acid hydrazide should probably be regarded as erroneous.



III. Methods of generation

The reactions in which the formation of amino- and oxy-nitrenes has been postulated are very numerous,[3–7] but the oxidation of 1,1-disubstituted hydrazines and alkoxyamines is most often employed for the generation of these species. The alkaline cleavage or thermolysis of the corresponding sulphonamides, the decomposition of sulphimines and sulphoximines, a series of cheletropic reactions, in particular the decomposition of *N*-aminoaziridines, and incomplete reduction of nitrosamines are of considerable interest. The neutralisation of the corresponding diazenium salts is a convenient method for the generation of dialkylaminonitrenes.[3]

The hypothesis of the existence of aminonitrenes was put forward initially to account for the so-called "anomalous" (with evolution of nitrogen and the formation of hydrocarbons) oxidation of 1,1-disubstituted hydrazines. The "anomalous" reduction of nitrosamines and the decomposition of sulphonic acid hydrazides was almost immediately included in this group of reactions. The similarity of the products of these reactions suggested a common intermediate—aminonitrene. Admittedly, the involvement of aminonitrenes in the normal course of these processes remained debatable. The next landmark was the stereospecific synthesis of *N*-aminoaziridine derivatives by the oxidation of a whole series of hydrazines in the presence of alkenes (see Section IV)—by analogy with the chemistry of carbenes, this was explained by the intermediate generation of aminonitrenes and their addition to the C=C bond. Naturally, the synthesis of *N*-alkoxyaziridines via the oxidation of *N*-alkoxyamines in the presence of alkenes, which soon followed, was immediately regarded as proof of the oxidative generation of alkoxynitrenes. Finally, the formation of a whole series of aminonitrenes in oxidation reactions was recently convincingly demonstrated by spectroscopic methods.

Hitherto, the main piece of evidence for the involvement of amino- or oxy-nitrenes in the reaction has usually been the similarity of the products of the given reaction to those of others for which the nitrene mechanism has already been established. Even more remote analogies are sometimes employed, for example, the analogy with the rules governing the occurrence of carbene reactions (Skell's postulate is usually invoked). Having demonstrated the nitrene mechanism of the reaction in relation to 1–2 examples, it is then usually subsequently extended to other similar reactions.

Such reasoning is entirely natural and acceptable in practice. However, it is at the same time extremely vulnerable. Indeed, it is actually clear that for the same process mechanism the composition of the products depends markedly on the specific reaction conditions: the method of generation of the nitrene, temperature, solvent, the presence of oxidants and reductants, the pH of the medium, etc. In order to compare the results, it is therefore necessary to resort in this instance to fairly bold extrapolations. On the other hand, typical "nitrene" products can sometimes be obtained without any involvement of nitrenes. A classical example is provided by the interaction of azides with alkenes, where, depending on the reaction conditions, aziridines can be formed both via nitrenes (pathway *a*) and wholly via the "azide" mechanism, as a result of the decomposition of the primary 1,3-dipolar addition products—2-triazolines (pathway *b*):[1,2,5,6]

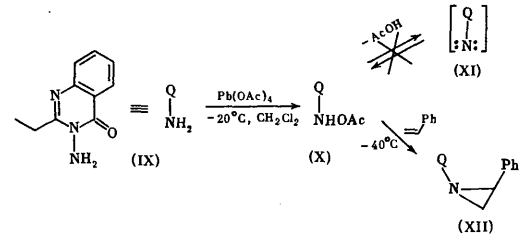
Thus unambiguous demonstration of the nitrene mechanism of the reaction requires the consideration of very many of its aspects, in the first place a set of kinetic data. There have so far been few such studies in the chemistry of amino- and oxy-nitrenes and we usually deal merely with the hypothesis of the involvement of nitrenes in the reaction, which is not always sufficiently well founded. The data described below should be considered from precisely this point of view.

1. Oxidation of amino-compounds

Historically the first[3-6] and hitherto the most convenient and most widely used method for the generation of amino- and oxy-nitrenes (I) is the oxidation of corresponding hydrazines or hydroxylamines:

$$X{-}NH_2 \xrightarrow[-HY]{YZ} \left[X{-}N\begin{matrix}Z\\H\end{matrix}\right] \xrightarrow{-HZ} X{-}\ddot{N}: \quad ; \qquad (1)$$

(VIII) (I)



X=R_2N, RO.

The assortment of oxidants employed is extremely wide,[3-7] but the lion's share of the results have been obtained using 2–3 most popular reagents. Yellow mercury oxide was usually employed in the early studies. Nowadays lead tetraacetate (LTA), t-butylhypochlorite, and nickel peroxide are most often used.

The formation of the nitrenes (I) in a whole series of oxidation reactions has been demonstrated extremely reliably—it is sufficient to recall that stable aminonitrenes have been obtained by precisely this procedure (see above). However, we may note that, according to Eqn. (1), the oxidative generation of nitrenes should include at least two stages: the formation of the intermediate compound (VIII) and the subsequent α-elimination of HZ. The nature of the group Z is determined by the oxidant and it is evident that, depending on its leaving capacity, the tendency of the molecule of compound (VIII) to undergo α-decomposition varies significantly. In principle, the intermediate (VIII) may prove to be fairly stable and can participate in subsequent reactions without decomposing to the nitrene.[3] It is sometimes fairly difficult to distinguish reactions proceeding via the nitrenes (I) from reactions involving their precursors (VIII).

This problem has already been discussed in the literature.[3,32] In particular, it has been noted that, for certain oxidants the reactions with 1,1-disubstituted hydrazines afford only a small amount of the usual aminonitrene conversion products (hydrocarbons, hydrazones, etc.) and sometimes they are altogether absent. Such a discrepancy (the dependence of the results on the nature of the oxidant) clearly indicates a decisive role of the first oxidation stage. The oxidation of 1,1-disubstituted hydrazines by derivatives of tetravalent selenium may serve as an example.[33,34] According to the authors, intermediate compounds of type (VIII) with a N–Se bond are formed during this reaction but the process does not go as far as the formation of aminonitrenes.

The case where the reactions of the nitrene precursor (VIII) resemble those expected for the nitrene itself is much more insidious and unexpected. Thus a communication has been published recently stating that the low-temperature oxidation of *N*-aminoquinazolinone (IX) by LTA, i.e. under the "standard" conditions for the generation of amino- and alkoxy-nitrenes, affords almost quantitatively the *N*-acetoxy-derivative (X), which is stable in solution up to ~0 °C.[35] However, even at –40 °C the addition of styrene (1.5 equiv.) to this solution leads to the rapid disappearance of compound (X) and the formation of the *syn*-invertometer of the aziridine (XII) in 76% yield, which has always been regarded as typical for the corresponding aminonitrene (XI):

Furthermore, the involvement of the nitrene (XI) or the nitrenium ion, which are intermediates in equilibrium with compound (X), in the reaction is ruled out because neither the NH proton nor the acetoxy-group are exchanged in CF_3COOD, while the hypothesis of the non-equilibrium generation of the nitrene (XI) with its subsequent addition to the double bond conflicts with the observed dependence of the rate of disappearance of the acetoxy-derivative (X) on the alkene concentration.[35]

Hitherto the oxidation of amino-compounds by LTA was regarded as one of the most reliable methods for the generation of most varied nitrenes and the principal piece of evidence was in fact the stereospecific formation of the corresponding aziridine derivatives in the presence of alkenes. An alternative interpretation has now appeared: since the acetoxy-derivative of type (X) is in essence the nitrogen analogue of peracetic acid, the formation of aziridines can be treated similarly to the epoxidation of alkenes by peracids, which is incidentally also stereospecific. Evidently the non-trivial results of Atkinson and Kelly[35] require a critical analysis of the mechanism of not only the formation of aziridines but also of a whole series of seemingly typical "nitrenes" reactions.

It is remarkable that intermediates of the non-nitrene type in the oxidation of hydrazine by LTA had already been sought earlier[36] but it had been assumed that they must be compounds of the type X–NH–$Pb(OAc)_3$. For the oxidation of *N*-aminopyrrole derivatives by LTA and lead tetrabenzoate, on the one hand, or by $PhI(OAc)_2$ and $PhI(OCOCHCl_2)_2$, on the other, it was then shown that the results are almost independent of the type of oxidant and hence the involvement of a lead-containing compound in the rate-determining state of the reaction is unlikely.[36] An *N*-acetoxy-compound of type (X) also occurred more than 10 years ago in the mechanism of the oxidation of *N*-aminophthalimide by LTA [37] but it was assumed that it is obtained as a transient formation as a result of a side process—the interaction of phthalimidonitrene with acetic acid, and that it does not play a significant role in this reaction.

In conclusion of the discussion of the study of Atkinson and Kelly,[35] one must state that its results by no means rule out the possibility of the formation of nitrenes of type (XI) in the oxidation of the corresponding amino-compounds—in fact acylaminonitrenes (VII) are obtained by precisely this procedure. However, they indicate that the acetoxy-group leaves the molecule of the nitrene precursor (VIII) extremely unwillingly and, in order to direct the reaction precisely along the aminonitrene pathway, it is best to use not LTA but another oxidant, for example t-butyl hypochlorite.

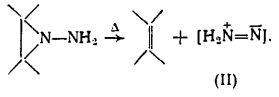
Apart from studies using the traditional range of oxidants, a number of communications have appeared in recent years concerning the oxidative generation of aminonitrenes under new conditions, in particular, in the electrochemical oxidation of certain hydrazines.[38,39] The formation of aminonitrenes has been postulated in the oxidation

of 1,1-disubstituted hydrazines by oxygen,[40] nitrogen dioxide,[41] and nitrobenzene[42] and also in the pyrolysis of 2,2-dimethyltriazanium chloride,[43] the result of which can be regarded as an intramolecular oxidation-reduction reaction. However, in all these cases one is dealing merely with hypotheses while reliable evidence for the intermediate formation of *N*-nitrenes in the above investigations[40–43] is lacking.

2. Decomposition of sulphonic acid derivatives and other methods

A second general method for the generation of amino- and oxy-nitrenes is the alkaline decomposition of the corresponding sulphonamides:[3–7]

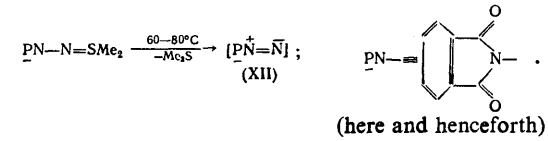
$$XNHSO_2R' \xrightarrow[\Delta]{B^-} \underset{(I)}{X{-}\ddot{N}:} + BH + R'SO_2^-;$$



$$X = R_2N,\ RO;\quad R' = Me,\ Ph,\ p\text{-}MeC_6H_4.$$

This procedure is especially suitable for the generation of the nitrenes (I) at a high temperature.[3–7,32,44] The high-temperature decomposition of the sulphonic acid hydrazides themselves[45] as well as the thermolysis of dry salts of the type R_2NNMSO_2R', where M is an alkali metal,[46,47] are variants of this method. It has been claimed that the last reaction is one of the "cleanest" methods of generating aminonitrenes.[47]

The reactions discussed above exhaust the known methods for the preparation of *O*-nitrenes. The approaches used to obtain *N*-nitrenes are significantly more varied[3,7] but the applicability of many of them is extremely limited. Thus the formation of aminonitrenes in the reduction of nitrosamines[3] is evidently an exception rather than the rule: typical "aminonitrene" reactions are observed in this instance mainly when sodium hydrogen sulphite is used as the reductant but even then not always:[3,32]

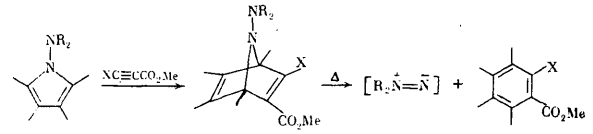


$$R_2N{-}NO \xrightarrow[OH^-]{Na_2S_2O_4} R_2N{-}\ddot{N}:$$

In the remaining cases the participation of aminonitrenes in the reaction must be postulated with much caution[48] and their presence in complex mechanisms of the reactions of a wide variety of nitrosamines[49–51] bears in our view a formal character in many respects. The possibility of the formation of the simplest amino-nitrene (II) in the thermolysis of a number of *N*-aminoaziridines is purely tentative,[52] although here one may note that the generation of acylaminonitrenes by the thermolysis and photolysis of the corresponding substituted derivatives has already been described in the literature:[3]

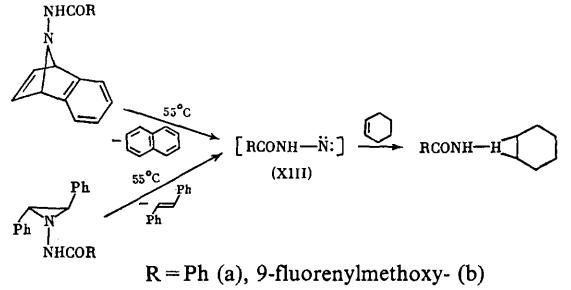
(II)

Few new methods for the generation of aminonitrenes have appeared during the last decade. In 1979 it was suggested that phthalimidonitrene (XII), perhaps the most thoroughly investigated aminonitrene, be generated by decomposing its adduct with Me_2S at a comparatively low temperature:[53]



(XII)

(here and henceforth)



This method of generation makes it possible to obtain adducts of the nitrene (XII), which are sensitive to strong heating, oxidants, or acids. In particular, it has been possible to obtain aziridine in the reaction with *p*-methoxystyrene by this procedure.[54]

The intermediate formation of *N*-nitrenes in the reactions of various *N*-aminopyrroles with electron-deficient acetylenes has been postulated:[55–57]

R = H, Me, $PhCH_2$; R_2N = $NHCO_2Me$, $N(CH_2CH_2)_2O$; X = CO_2Me, SO_2Ph.

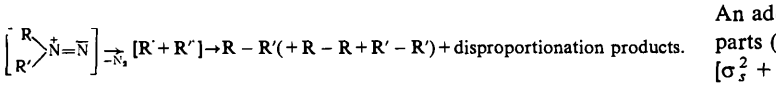
Subsequently a similar reaction was used to obtain acylamino-nitrenes (XIII) [58] and here it proved possible to observe for the first time an intermolecular reaction of monosubstituted nitrenes:

(XIII)

R = Ph (a), 9-fluorenylmethoxy- (b)

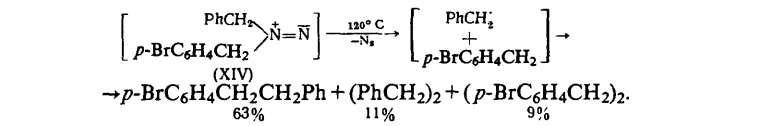
In addition, the nitrene (XIIIb) has been obtained also by a more traditional method—the decomposition of the corresponding 2,3-diphenylaziridine.[58]

IV. Reactions of amino- and oxy-nitrenes



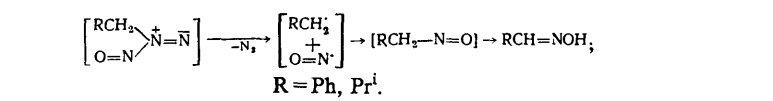
The known reactions of amino- and oxy-nitrenes can be divided into three large groups: decomposition, isomerisation, and addition to double bonds or unshared electron pairs. The occurrence of the reaction via a particular pathway is determined in the first place by the structure of the nitrene. Decomposition has been observed so far only for aminonitrenes and its driving force is evidently the formation of the stable nitrogen molecule. The presence of substituents of the benzyl or allyl type at the amino-nitrogen atom makes decomposition the principal reaction pathway. The tendency of amino- and oxy-nitrenes to undergo rearrangements with migration of groups to an atom with an incomplete electron shell is determined in many respects by the migrating capacity of the substituents. Finally, if the nitrene is relatively stable in relation to intermolecular reactions, then, in the presence of a suitable reagent in the reaction mixture, it can add to multiple bonds or can attack an unshared electron pair with formation of the corresponding adducts.

All these processes usually occur simultaneously and the contribution of each is determined additionally by the reaction conditions and the comparative reactivities of the components of the reaction mixture. An increase in temperature usually increases the contribution by fragmentation and rearrangement processes. On the other hand, the addition of a large excess of active nitrene "trapping" agents, such as dimethyl sulphoxide (DMSO), makes it

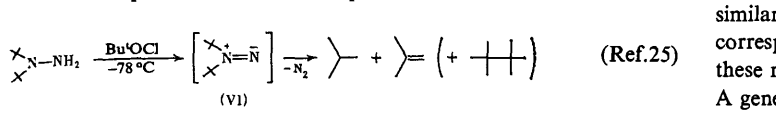


possible to obtain adducts even for nitrenes which usually tend to undergo rearrangements or decomposition.

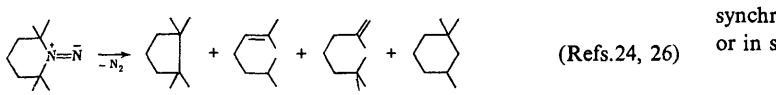
1. Decomposition of aminonitrenes



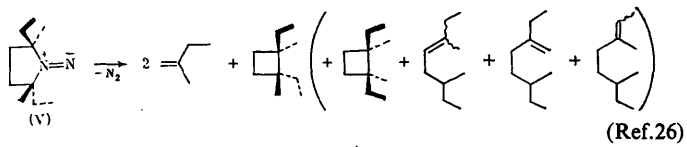
Decomposition with evolution of nitrogen is one of the most general reactions of aminonitrenes for the most varied methods of their generation. The ease of their decomposition and its mechanism depend significantly on the structure of the nitrene, but in most cases the available data fit satisfactorily within the framework of the biradical mechanism with a strong cage effect, which increases the stereospecificity of the reaction:[3,46,47]



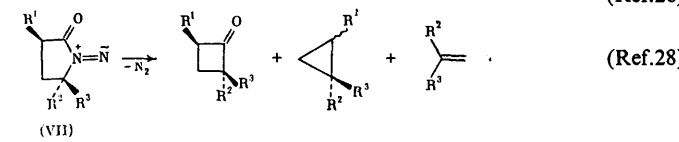
The decomposition with the recombination of the radicals formed is most typical for dibenzylaminonitrene derivatives. It is, on the one hand, a convenient method of synthesis of bibenzyl derivatives[3] and, on the other hand, it is a kind of diagnostic test for the aminonitrene reaction mechanism.[32,39,42,46,47,55] The radical decomposition of dibenzylaminonitrene has been demonstrated reliably by EPR methods using "spin trapping agents"[46] and CINP [47] and it has been established that dibenzylaminonitrene produces a singlet radical pair and therefore decomposes in the singlet state, which is apparently the ground state[47] (cf. the calculations of Davis and Goddard[9]). The decomposition of the asymmetrically substituted nitrene (XIV) confirmed the major role of the cage effect, but, in contrast to the earlier study,[3] the cross-products,[47] obtained when the radicals emerge from the cage into the solution, were isolated in an appreciable yield:



Ready decomposition with recombination of the species formed is characteristic of many other aminonitrenes having substituents at the amino-nitrogen atom which give rise to fairly stable radicals.[3] For example, the decomposition of nitrosaminonitrenes proceeds via this mechanism:[59]



On passing to alkyl-substituted aminonitrenes, the main pathway becomes the disproportionation of their radicals,[25] while the decomposition of cyclic *N*-nitrenes[19–21,23,24,26–28,45] usually leads to a mixture of products of these two processes:

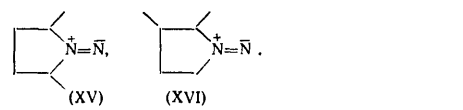


(Ref.25)

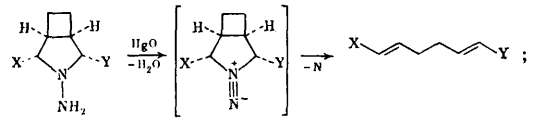
(Refs.24, 26)

(Ref.26)

(Ref.28)

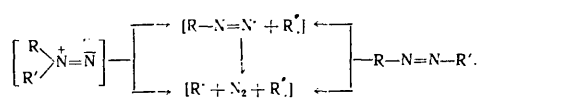


An additional possibility of concerted fragmentation into three parts (β-decomposition) via Scheme 2, symmetry-allowed as a $[\sigma_s^2 + \sigma_s^2 + \sigma_s^2]$ process, appears for five-membered aminonitrenes under these conditions:



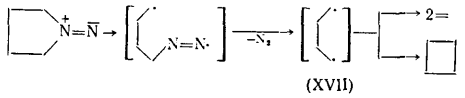
(2)

On the other hand, such decomposition can be treated also as a result of the cleavage of the central bond in the intermediate 1,4-biradical.



The study of the thermal and photochemical decomposition of a large series of five-membered *N*-nitrenes,[21,24,27,28] including the "stereochemically labelled" nitrenes (V) and (VIIc, d) and the *cis*- and *trans*-isomers of the nitrenes (XV) and (XVI),[45] showed that the main reaction pathways usually involve the formation of cyclobutane derivatives and β-elimination, both processes occurring highly stereospecifically with preferential retention of the relative disposition of the substituents:

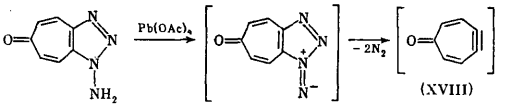
The stereospecificity of the β-decomposition is especially high (> 96%),[45] which has been used in the synthesis of a series of long-chain (*E*, *E*)-1,5-dienes:[60]



The composition and stereochemistry of the products of the thermolysis and direct photolysis of aminonitrenes are extremely similar and also resemble the outcome of the decomposition of the corresponding azo-compounds, which suggests the involvement in these reactions of common intermediate species of a radical type. A general question also arises: how are these radicals formed—synchronously, with the simultaneous cleavage of both C–N bonds, or in stages?

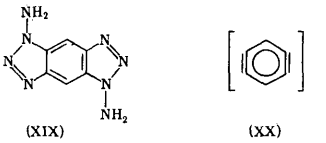
Computational assessment of both possibilities for the aminonitrene (II) itself,[10] diethylaminonitrene,[61] and the corresponding azo-compounds[10,61,62] has indicated in all cases that the multistage process with the intermediate formation of diazenyl radicals is preferred. This pathway agrees with experimental data for the fragmentation of azo-compounds[61,62] and in principle does not conflict with the results of studies of the decomposition of many aminonitrenes.[19-21,23-28,45] However, according to Savin,[47] the benzyldiazenyl radical is not formed as a kinetically independent species in the decomposition of dibenzylaminonitrene and both C–N bonds are therefore cleaved synchronously. This is apparently associated with the high stability of the benzyl radicals obtained, which is responsible for the sharp decrease in the strength of the C–N bonds in the aminonitrene which are weak in any case.

In any case, the decomposition of the five-membered aminonitrenes (and the corresponding azo-compounds) via the radical-mechanism should proceed via a derivative of the biradical (XVII) (tetramethylene):



(XVII) (3)

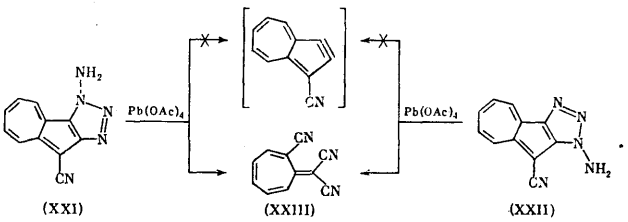
However, a non-empirical calculation for tetramethylene yielded remarkable results: it was found that, instead of a minimum a kind of "plateau" on the energy surface corresponds to this 1,4-biradical.[63] Consequently, if one disregards entropy factors, this is not an intermediate compound but a transition state and processes with its participation can be regarded as "quasi-concerted". According to calculated data, the fate of tetramethylene depends on its geometry: the *gauche*-conformer cyclises while the *anti*-conformer undergoes non-activated decomposition into two ethylene molecules.[63]



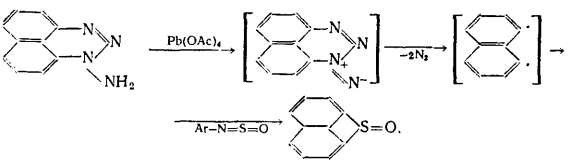
Taking into account the foregoing as well as kinetic and stereochemical data,[20,21,23,24,26-28,45] the decomposition of five-membered cyclic aminonitrenes presumably proceeds via two parallel channels:[45] as concerted β-decomposition via Scheme 2, with complete retention of the configuration of the substituents in the reaction products, and as a multistage process of type (3), which begins with the formation of the diazenyl biradical. In the absence of substituents capable of stabilising the biradical of the tetramethylene type, the subsequent cyclisation or decomposition of the latter should take place almost simultaneously with the elimination of the nitrogen molecule. The contribution of each pathway is determined by the nature of the substituents. Thus unsubstituted pyrrolidinonitrene apparently decomposes wholly via the concerted pathway into nitrogen and ethylene (although, contrary to old data, approximately 2% of cyclobutane was detected in the products[45]), while the introduction of alkyl and even more so aryl substituents in the 2- and 5-positions favours the radical process.

The usual consequence of the radical mechanism is a low stereospecificity of the reaction, but the fragmentation of aminonitrenes and of the corresponding azo-compounds represents a clear exception. The cyclisation and β-decomposition of the biradical intermediates (whatever their structure) is apparently appreciably faster in this instance than the rotation around the C–C single bonds. As was to be expected, with increase in temperature there is an increase in the fraction of the β-elimination products and the stereospecificity of the decomposition is reduced.[45] Similar changes occur on passing from the direct photolysis of stable aminonitrenes and azo-compounds to the sensitised photolysis,[26] which can be naturally accounted for by the involvement of triplet biradical species in the process.

The fragmentation of unsaturated 1-(1,2,3-triazolyl)nitrenes via Scheme 2 has found wide scale application for the generation of aromatic dehydrohydrocarbons and other unstable acetylene derivatives.[3] It has been used in recent years to obtain 4,5-dehydrotropone (XVIII) and its adducts with dienes[64,69] or enamines.[70]

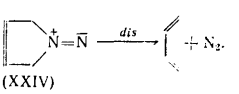


(XVIII)



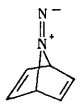
(XIX) (XX)

Similarly, 1,5-diaminobenzobistriazole (XIX) (and its 1,7-isomer) is an excellent synthetic equivalent of "1,4-dibenzyne" (XX) in 1,3- and 1,4-cycloaddition reactions (the yields of the diadducts are 40–93%);[71-73] however, when an attempt is made to obtain the corresponding dehydroazulene from the aminoazulenotriazoles (XXI) or (XXII) via the same scheme, only the rearrangement product (see below—the heptafulvene (XXIII)—is isolated:[74]



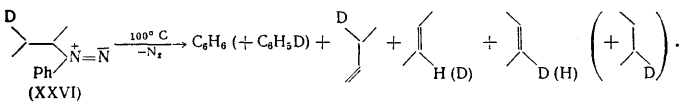
(XXI) (XXIII) (XXII)

A similar reaction has been used to generate 1,8-dehydronaphthalene:[75]



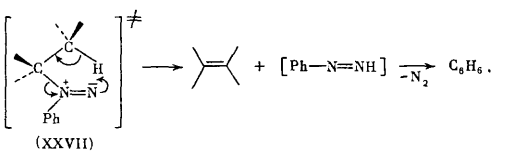
A concerted cheletropic decomposition is allowed for 3-pyrroline derivatives of type (XXIV) and it has been shown for a whole series of examples that, in conformity with the Woodward–Hoffmann rules, this process is indeed disrotatory and is fully stereospecific:[3]

(XXIV)



The results of recent calculations[76] have confirmed the possibility of the concerted decomposition of the nitrene (XXIV), but they predict a highly asymmetric transition state for this reaction (the process is concerted but not synchronous). The calculations permit a synchronous or almost synchronous fragmentation only for the

nitrene (XXV),[77] but, in Dewar's view, this exception merely confirmed the general conclusion that the transition state in cheletropic reactions is asymmetric:[76,77]

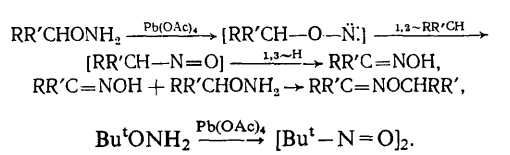


(XXV)

The study of the decomposition of the diastereoisomeric (*threo-* and *erythro-*) deuterio-substituted aminonitrenes (XXVI)[44] showed that this process proceeds highly stereospecifically as *cis*-1,2-elimination:

(XXVI)

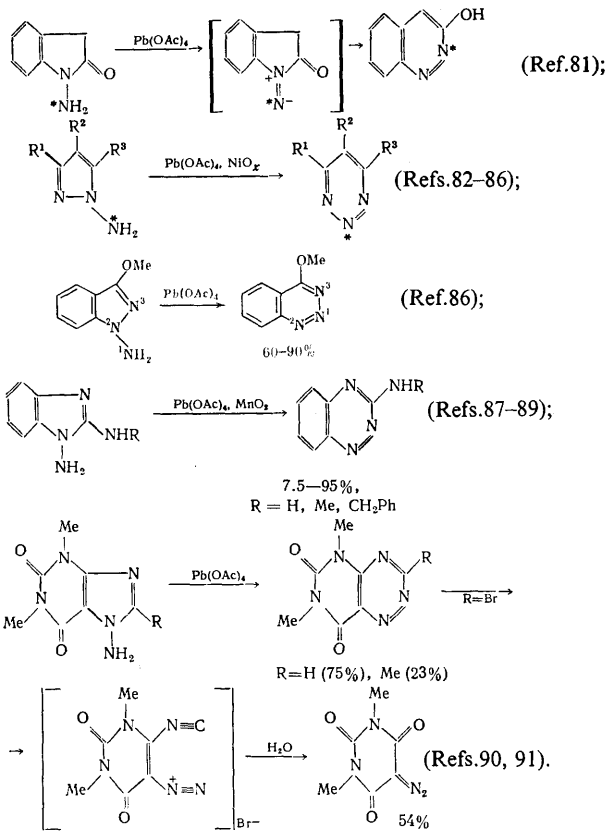
In each case deuterium remains in only one of the two-isomeric but-2-enes, which can be explained by proton transfer to the nitrene nitrogen atom in the transition state (XXVII). This resembles the mechanism of the fragmentation of amine oxides:[44]



(XXVII)

Thus the concerted (but not biradical) decomposition of amino-nitrenes is possible also in the acyclic series.

2. Rearrangements

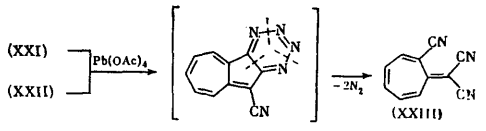


Rearrangements, including the 1,2-migration of substituents to the atom with an incomplete electron shell, are characteristic of all the sextet species, including amino- and oxy-nitrenes. For alkoxy-nitrenes, this is the cause of the permanent presence in the reaction mixtures of oximes, their ethers, and nitroso-compounds:[78,79]

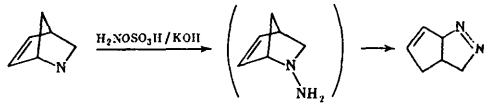
The yields of the oxime ethers are 16–32% and that of the dimer of the tertiary nitroso-compound is up to 57%.

The corresponding conversion of the simplest aminonitrene (II) to the significantly more stable (by 123 kJ mol^{-1} [9]) *trans*-diazene HN=NH is symmetry-prohibited[80] but nevertheless the *trans*-diazene is one of the nitrene(II) reaction products already at 90 K.[29] On the other hand, the 1,2-migration of the alkyl group with inversion at the migrating centre is already an allowed process for dialkylaminonitrenes, but unambiguous examples of the rearrangement of dialkylaminonitrenes to aliphatic azo-compounds are not as yet available in the literature. On the other hand, a whole series of conversion of *N*-heteroarylnitrenes to the corresponding azo-compounds with ring expansion are known; many of them are of preparative value.[3] Here an additional driving force is the formation of a stable aromatic system.

Thus, cinnolinol has been obtained by oxidising *N*-amino-oxindole,[3,81] compounds of the 1,2,3-triazine series have been synthesised from *N*-aminopyrazoles[82–86] and indazoles,[86] while substituted 1,2-diaminobenzimidazoles[87–89] and theophylline derivatives[90,91] can be converted into the corresponding 1,2,4-tri-azines:



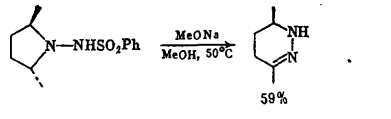
(Ref.81); (Refs.82–86); (Ref.86); (Refs.87–89); (Refs.90, 91).



Best results are achieved as a rule by oxidising amino-compounds with LTA—the yields of 1,2,3-triazines are then usually 40–80%. However, 1-aminopyrazole itself affords only about 2% of 1,2,3-triazine when LTA is used,[85] although the yield increases to 20% on oxidation with nickel peroxide.[83–85] Such dependence of the yield on the nature of the oxidant, particularly when account is taken of the possible role of *N*-acetoxy-compounds in the oxidation of amino-compounds by LTA,[35] clearly requires a revision of the degree of involvement of aminonitrenes in the reactions described above.

Substituents have a significant and not always understood influence on the course of rearrangements. The unsubstituted 1,2,3-triazine is obtained in a low yield, while the 4,5,6-triphenyl-substituted derivative is not obtained at all.[86] Among different 2-substituted 1-aminobenzimidazoles, ring expansion is observed only for the 1,2-diamino-derivatives.[87,88] The results of studies of the mechanisms of the first three reactions with the aid of isotope substitution have also contributed little to the foregoing[81,86] (they are illustrated in the corresponding schemes).

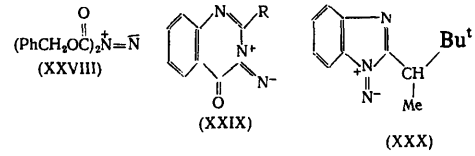
A related rearrangement but one involving the formation of the 1,2,3,4-tetrazine ring may occur on oxidation of the aminotriazoloazulenes (XXI) and (XXIII) with LTA (see above),[174] whose final product is the heptafulvene (XXIII):



Finally, one cannot rule out the possibility that aminonitrenes participate in rearrangements of the allyl type on oxidation or reduction of certain derivatives of 2-azabicyclo[2.2.1]hept-5-ene,[48] for example:

Another variant of the isomerisation of aminonitrenes is their conversion into monosubstituted hydrazones, the so called "diazene–hydrazone" rearrangement:

Mono- and also di-substituted hydrazones (see below concerning the possible pathway leading to their formation) are the usual products of the oxidation of hydrazines,[3,39,42,43,92] the cleavage of sulphonic acid hydrazides, and other reactions in which the intermediate involvement of aminonitrene is postulated. In the heterocyclic series, the rearrangement results in ring expansion,[27,45,93] for example:[45]

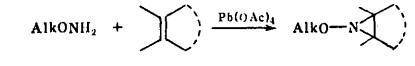


The reaction appears to be entirely similar to the rearrangement of alkoxynitrenes to oximes already considered, especially bearing in mind that aliphatic azo-compounds also isomerise comparatively readily to the more stable hydrazones.[33] However, here the similarity is mainly formal. This is demonstrated most convincingly by the results of the alkaline decomposition of 1,1-diethyl- and 1-benzyl-1-phenyl-2-arenesulphonyl[2-^{15}N]hydrazines,[3] as well as the present authors' experiments on the neutralisation of solutions of 1,1-diethyldiazenium bromide, similarly labelled with ^{15}N. In all cases hydrazones are obtained with the label present preferentially and (frequently exclusively) in the imine nitrogen atom. Furthermore, it is evident that, if the reaction occurred in accordance with the "nitrene → azo-compound → hydrazone" mechanism, both nitrogen atoms would have been labelled to equal extents. In order to explain the rearrangement, other mechanisms have also been proposed (with the intermediate formation of diaziridines, azomethine imines, etc.[3]).

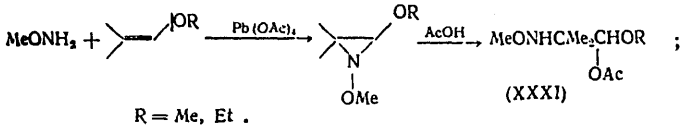
3. Addition to carbon–carbon multiple bonds

The addition of amino- and alkoxy-nitrenes to the C=C bond constitutes a general method of synthesis of a wide variety of *N*-amino- and *N*-alkoxyaziridines.[1–7,94] It has been shown in numerous instances that the reaction proceeds entirely stereospecifically with retention of configuration and that the yields of products depends strongly on the nature of the substituents at the double bond and on the type of nitrene.

Calculation for the simplest model reaction of the aminonitrene $H_2N\dot{N}$: (II) with ethylene[80,95,96] has shown that it can proceed via two pathways—as the reduction of ethylene to ethane with formation of a N_2 molecule[80] (without the rearrangement of $H_2N\dot{N}$: to the *cis*-diimide HN=NH—cf. Lahti[52]) and as a linear cheletropic formation reaction of *N*-aminoaziridine[95,96] with retention of the symmetry plane as the reactants approach one another.[96] The results of *ab initio* calculations[96] and calculations by the MNDO method[95] agree that the addition is electrophilic in character. The degree of charge transfer from ethylene to the nitrene in the transition state is ~0.1–0.16 e, the excess negative charge being concentrated mainly on the central nitrogen atom. The heat of the reaction is extremely low and the activation barrier is estimated as 90–100 kJ mol^{-1}.



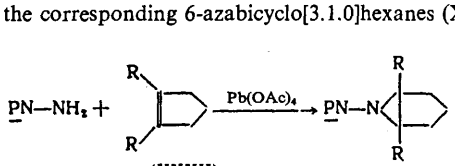
It follows from the data presented that the addition of aminonitrenes to the C=C bond is not unduly favourable from the energetic standpoint but it should be facilitated when the aminonitrene molecule contains substituents capable of stabilising the additional negative charge in the transition state. Accordingly, only aminonitrenes which have at least one or better two electron-accepting substituents enter into reactions via multiple bonds: phthalimidonitrene (PIN) (XII), the acylnitrenes (XIII) and (XXVIII), the heteroaromatic nitrenes (XXIX) and (XXX), and similar compounds:



It may be that the presence of the electronegative oxygen atom in fact accounts for the ability of the alkoxynitrenes to enter into addition reactions.

N- and *O*-nitrenes are usually generated in reactions with multiple bonds by oxidising the corresponding amino-compounds with LTA. However, as already stated, at least in the oxidation of aminoquinazolinone (IX) the corresponding *N*-acetoxy-derivative (X) assumes the role of the nitrene (XI)[35] (see above). It is extremely likely (although not in fact obligatory) that in many other instances similar nitrenoids are in fact the real intermediates and instead of alkoxynitrenes we may be dealing with derivatives of *N*-acetoxyhydroxylamine. This alternative must be always borne in mind, although for the sale of brevity we shall henceforth no longer make this stipulation.

The oxidation of alkoxyamines by LTA in the presence of various alkenes affords the corresonding *N*-alkoxyaziridines:[2,5,6,94,97–99]

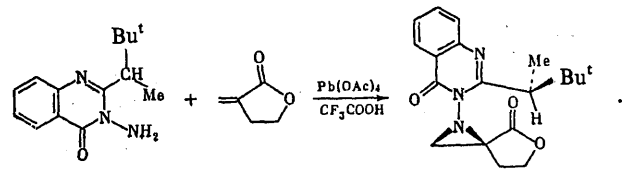


The yields of the adducts vary within wide limits (7–45%) and are apparently determined not only by the reactivity of the double bond in the alkenes but also by the ease of the corresponding rearrangements (see above). It has been shown for the stereoisomeric but-2-enes that the addition is entirely stereospecific[97] (the earlier opposite conclusion apparently arose because of errors in the determination of the structures of the products). In the reactions with vinyl ethers, the acetates (XXXI), which can be regarded as the products of the opening of the ring in the intermediate 1,2-dialkoxaziridines by acetic acid, were isolated:[101]

R = Me, Et .

The set of aminonitrenes involved in the reactions with C=C bonds in studies carried out during the last decade is fairly traditional. These are in the first place PIN (XII)[35,53,54,102–114] and nitrenes of the quinazolinone (XXIX)[35,105,115–117] and benzimidazole (XXX)[118] series. The yields of the aminoaziridines are in this instance usually 50–70% but can also approach 95% in the presence of a very slight excess of the alkene. It has recently been suggested that the diacylaminonitrene (XXVIII) be used in the synthesis of aminoaziridines,[119] but, in order to obtain even fairly moderate yields of the aziridines (30–70%), an almost hundredfold excess of the substrate is required in this case. At the same time, aziridines are formed in fair yields on addition of monosubstituted acylaminonitrenes (XIII) to cyclohexene and (*Z*)-4-methylpent-2-ene,[58] this being in general the first example of intermolecular reactions of monosubstituted nitrenes. Hitherto it has been assumed that they are too unstable and decompose instantaneously with liberation of nitrogen. At the same time the stable acylaminonitrene (VIIb) does not interact with cyclohexene, or dihydropyran, or methyl acrylate.[27]

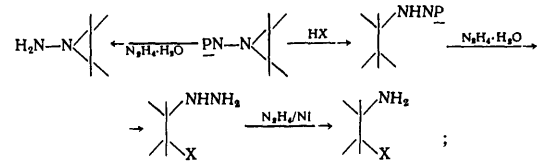
Phthalimidonitrene (XII) and other heteroarylnitrenes react smoothly with most varied multiple bonds. The corresponding aminoaziridines have been obtained in satisfactory yields from indenes[105,108,113] and indoles[110] (cf. Meyer et al.[105]), derivatives of cyclopentadiene[108,109] and vinyl phosphonate esters,[103,117] norbornadiene and its analogues,[104,107,114] propelladiene,[102] etc. The reactions of PIN (XII) with cyclopentene derivatives (XXII) afford the corresponding 6-azabicyclo[3.1.0]hexanes (XXXIII):[105,120]



(XXXII) (XXXIII)

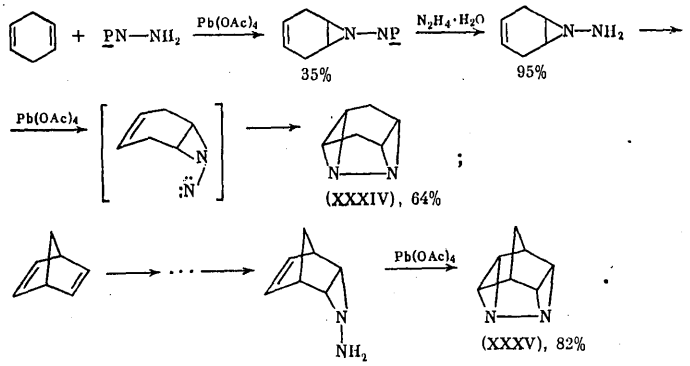
R = H (a), Co_2Me (b).

The nitrene (XXIX, R = Me) reacts with cyclopentene (XXXIIa) itself but not with the diester (XXXIIb).[105] Nor has it been possible to obtain its adduct with 1,2-di(methoxycarbonyl)cyclobutene,[105] whereas PIN affords the aziridine (XXXIIIb)[105] and adds even to 1,2-dichlorocyclobutene, forming the strained 1,4-dichloro-5-azabicyclo[2.1.0]pentane.[120]



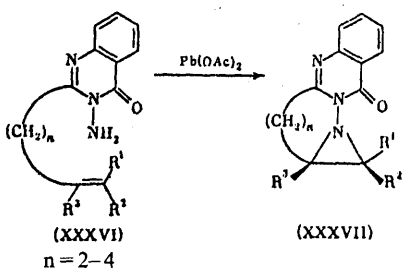
The addition of the chiral nitrenes [XXIX, R = Bu^t(Me)CH][115,116] and (XXX)[118] to prochiral alkenes leads to mixtures of diastereoisomeric aziridines in various proportions. After the addition to the reaction mixture of several equivalents of trifluoroacetic acid (TFAA), the reaction can be carried out at –60 °C, which sharply increases its stereoselectivity.[115,116] For example, in the presence of TFAA only one aziridine is formed from methylenebutyrolactone instead of approximately equal amounts of diastereoisomers:[115,116]

The addition of up to 10 equiv. of TFAA greatly facilitates the conversion of relatively unreactive substrates into aziridines by quinazolinone derivatives.[117] Thus the yield of the adduct of allyl chloride (1.5 equiv.) with the nitrene (XXIX, R = Et) increases from 10 to 90% in the presence of 6 equiv. of TFAA. Furthermore, according to data obtained by means of competing reactions, the selectivity of the reacting species increases. The protonation of the intermediate aminonitrene (XXIX) at the N(1) atom of the quinazolinone ring is believed to be a possible explanation of all these changes.[115–117]



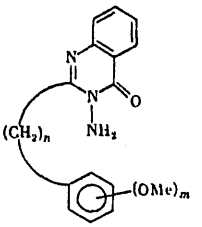
Although, as already mentioned, *N*-heteroarylnitrenes react with the most varied substrates, the view has been established that they are nucleophilic in nature (see, for example, Meyer et al.[105]). However, we have shown recently for a typical and perhaps most thoroughly investigated nitrene of this kind, namely PIN (XII), by the method of competing reactions that its addition to a series of ring-substituted styrenes is electrophilic in character.[111,113] Secondary orbital interactions of the heterocyclic ring of the *N*-nitrene with unsaturated substituents at the bond attacked (aromatic ring, double bond, carbonyl group, etc.) play a major role in the reaction.[3,112–118] For their occurrence, it is necessary that the aminonitrene and the substrate are arranged in parallel planes in the transition state, the *syn*-orientation of the unsaturated substituent and the heterocyclic residue being essential. The suitability of this structure of the transition state is clearly manifested in the preferential formation of the thermodynamically less stable *syn*-invertomers of aziridines[3,112–118] and it may be one of the causes of the asymmetric induction in the reactions of chiral nitrenes.[115,116,118]

The adducts of *N*-nitrenes with C=C bonds, which consist of a wide variety of aminoaziridines, are not only of intrinsic interest but are also of interest as possible intermediates in the synthesis of numerous derivatives of hydrazines, amines, etc. with functional group substituents.[121] *N*-Phthalimidoaziridines are especially convenient in this respect, because the phthaloyl group can be easily removed:[102,104,121]



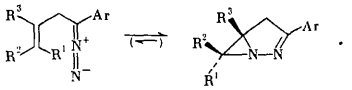
X = PhO, PhS, PhNH, TsO, OH, OAc, etc.

This possibility has been used in the synthesis of polycyclic hydrazines (XXXIV) and (XXXV):[104]



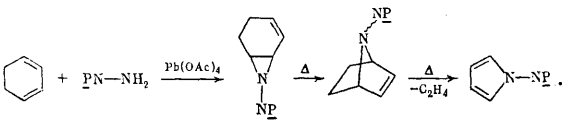
Admittedly, it is essential to note that the addition of PIN to norbornene and norbornadiene derivatives affords mainly the *exo*-adducts[104,107,114] and that the *endo*-aziridine required for the synthesis of compound (XXXV) constitutes only about 10% of the mixture of isomers.[104]

Apart from the intramolecular reactions quoted, other instances of the addition of dialkylaminonitrenes to the C=C bond are unknown. Evidently the success in this instance can be explained by the steric proximity of the interacting groups[104] (cf. Rüttimann and Ginsburg[102]). The influence of electronic and steric factors on the intramolecular addition of typical acylaminonitrenes has been investigated in detail in relation to aminoquinazolinone derivatives.[122–133] It has been shown for a large series of alkenylaminoquinazolinones (XXXVI), frequently containing two different double bonds in the branched side chain, that the reaction proceeds in all cases via a concerted mechanism and leads to the corresponding polycyclic aminoaziridines (XXXVII):[122–126]

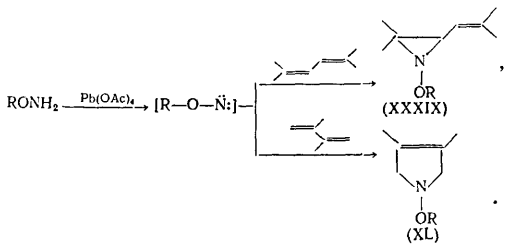


However, for a short side chain (n = 2), the symmetrical transition state must be greatly strained. The two C–N bonds are therefore formed non-synchronously and a polar seven-membered transition state is formed with the localisation of an appreciable positive charge on the β-carbon atom of the double bond.[126]

Similar conclusions follow the results of the oxidation by LTA of aminoquinazolinones (XXXVIII) containing an activated aromatic ring in the side chain.[127–133] Similarly to intermolecular reactions,[134] when n = 2–4, the products of the insertion of the nitrene in aromatic C–H bonds and also of the expansion of the aromatic ring to the azepine ring are formally produced,[127–133] but the short connecting bridge (n = 1) rules out the involvement of the aryl substituent in the reaction:[127]

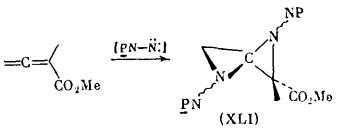


An increase in chain length by one unit (n = 2) leads to a highly polar seven-membered transition state and the process proceeds in essence via an S_E mechanism. The reaction of the long-chain compounds (n = 3, 4) includes, as usual,[1,4] stages involving the formation and cleavage of 7-azanorcaradienes.[127–133] It is important to note that in all the reactions considered[122–133] the quinazolinonylnitrene exhibits electrophilic properties.

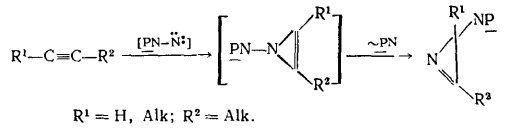


The remarkable analogy between aminonitrenes and diazocompounds can be seen from the intramolecular cyclisation of allyl-substituted aryldiazomethanes:[135]

The interaction of aminonitrenes with 1,3-dienes and cyclooctatetraene produced the corresponding aziridines in 30–70% yields. Asymmetric dienes (isoprene, penta-1,3-diene) afford a mixture of comparable amounts of two isomeric vinylaziridines. Neither diadducts nor 1,4-addition products are then formed.[3] Vinylaziridines are extremely unstable and undergo ready ring opening on treatment with nucleophiles, isomerising on heating to 3-pyrroline derivatives,[136,137] for example:[137]

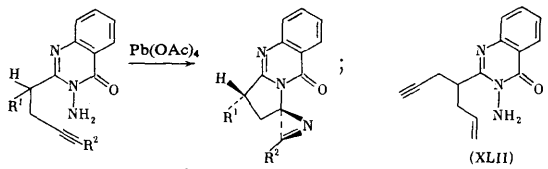


Alkoxynitrenes react with conjugated dienes in different ways:[99] their addition to 2,5-dimethylhexa-2,4-diene affords the alkoxyaziridines (XXXIX), apart from the analogous unsaturated aziridine, the isomeric 3-pyrrolines are formed from 2,4-dimethylpenta-1,3-diene, while in the reactions with 2,3-dimethylbuta-1,3-diene the main products are 1-alkoxypyrrolines (XL):[99,100]



Formally 3-pyrrolines can be regarded as the products of the 1,4-addition of alkoxynitrenes but it may be that they are formed simply as a result of the ready isomerisation of the intermediate unsaturated alkoxyaziridines.[94]

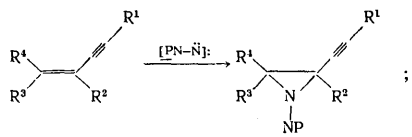
The addition of PIN (XII) to the methyl ester of 2-methylbutadienoic acid leads, in contrast to 1,3-dienes, to a diadduct, to which the spiro-structure (XLI) has been attributed:[138]



(XLI)

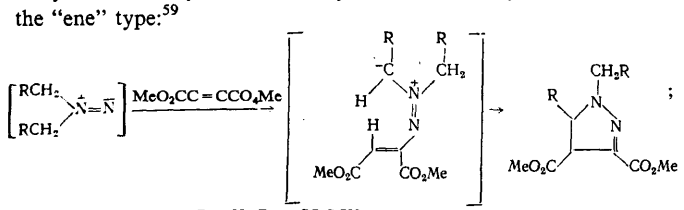
The interaction of the same nitrene with alkylacetylenes leads to 2*H*-azirines in low yields (2–15%).[139] The antiaromatic 1*H*-azirines are probably formed in the first stage:

$R^1 = H$, Alk; $R^2 =$ Alk.



Acetylenes with electron-accepting substituents, tolane, and phenyl-t-butylacetylene do not enter into this reaction at all.[139] The intramolecular addition to the C≡C bond proceeds readily, affording azirines in 80–100% yields:[140–142]

(XLII)

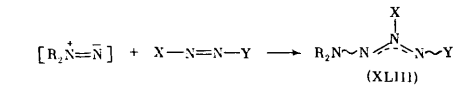


$R^1 = H$, $CH_2C{\equiv}CR^2$; $R^2 = H$, Me.

At the same time, oxidation of aminoquinazolinone (XLII) by LTA results in the formation of only the adduct involving the C=C bond in 84% yield.[142] The reaction of PIN (XII) with conjugated enynes also proceeds fully regio-selectively[139,143] § and may serve as a convenient method of synthesis of 2-alkynyl-1-aminoaziridines having different structures:

R^1–R^4=H, Alk, Ph.

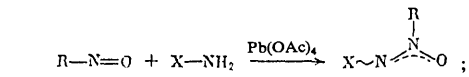
Addition to multiple bonds is characteristic almost exclusively of acylaminonitrenes. However, a reaction has been described recently which is treated as the interaction of the triple bond in dimethylacetylenedicarboxylate with dialkylaminonitrenes by a mechanism of the "ene" type:[59]



R = H; $R_2 = CO_2OCH_2$.

§ See also M A Kuznetsov, V V Semenovskii, V N Belov, V A Gindin *Khim. Geterotsikl. Soedin.*, 1989, 235.

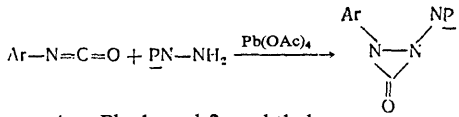
4. The reactions with N=X (X = N, O, C) bonds



The interaction of aminonitrenes with azo-compounds leads to the formation of 1,3-dipolar compounds of a new class—aminoazimines (XLIII):

(XLIII)

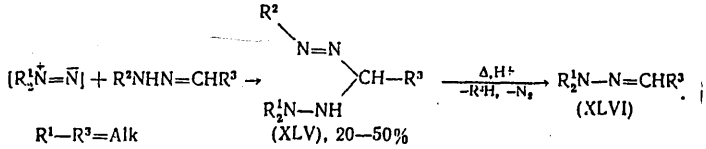
Since this reaction has been described in detail in a recent review,[144] here we should like merely to note the general rule of the "mutual complementarity" of substituents in the nitrene and the azo-compounds. It has been found that PIN (XII) adds smoothly to azoalkanes, 1-pyrazolines, and azoarenes, while, conversely, diphenyl- and dialkyl-aminonitrenes react satisfactorily with derivatives of azodicarboxylic acid, but all attempts to carry out "cross reactions" have so far been unsuccessful.



PIN (XII)[145–147] as well as a series of alkoxynitrenes[148,149] add similarly (at the LEP of the nitrogen atom) to various *C*-nitroso-compounds[145,148] and nitrosamines:[146,149]

X = PN, OAlk; R = Bu^t, t-C_5H_{11}, cyclo-C_6H_{11}, Ar, $R_2'N$. (4)

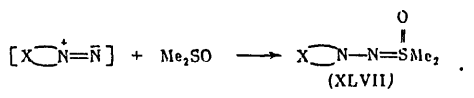
Phthalimidodiazene oxides (XLIV, X = PN) can be obtained from *C*-nitroso-compounds in 80–94% yield (with the exception of nitrosocyclohexane for which the yield is 18%[145]). The yield of the adducts of PIN with nitrosamines are 70–80%.[146] The yields of the alkoxydiazene oxides (XLIV, X = OAlk) are usually lower but they too can reach up to 60–70%.[148,149] It is important to note that, in the generation of PIN by the thermolysis of its adduct with acetylbenzofuran in the presence of nitrosocyclohexane, the corresponding diazene oxide (XLIV, X = PN, R = cyclo-C_6H_{11}) was obtained in 23% yield[145] (which is even higher than in the case where LTA is used). The attempt to extend reaction (4) to *O*-nitroso-compounds was unsuccessful: when aminophthalimide was oxidised by LTA in the presence of isopentyl nitrite, the formation of adducts was not detected.[146]



There are no reliable examples in the literature of the addition of acylaminonitrenes and alkoxynitrenes to the C=N bond. In fact it has been reported that possible adducts were not detected in the reaction mixtures after the oxidation of alkoxyamines by LTA in the presence of a large series of compounds: azomethines, azines, hydrazones, and oximes and their ethers.[98] However, it has been claimed that PIN is capable of adding to the C=N bond of aryl isocyanates, affording phthalimidodiazirinones:[150]

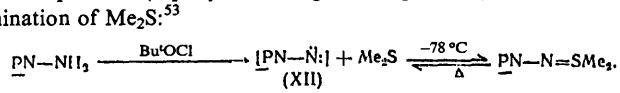
Ar = Ph, 1- and 2-naphthyl.

However, here one should note that aryl isocyanates react readily with primary amines, affording urea derivatives. Therefore, when they are mixed with aminophthalimide, the corresponding semicarbazide should be formed rapidly and the latter apparently is in fact oxidised further by LTA.



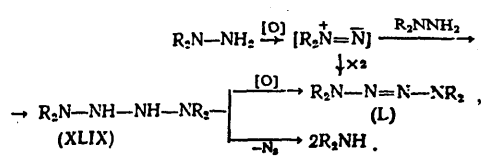
At the same time, dialkylaminonitrenes react with aldehyde monoalkylhydrazones, affording the so called geminal azohydrazines (XLV):[151]

On heating, on treatment with acids, and simply on standing, azohydrazines (XLV) decompose to the disubstituted hydrazones (XLVI).[151] Since monosubstituted hydrazones are readily obtained in the diazene–hydrazone rearrangement, it may be that the invariable presence of disubstituted hydrazones among the products of the reactions of dialkylaminonitrenes can be accounted for by this sequence of reactions.



5. Reactions with dimethyl sulphide and sulphoxides. The formation of tetrazenes

The reactions listed in the heading have a common feature, namely they all reduce to the attack by the nitrene on the LEP of some kind of heteroatom. We have already seen examples of such interaction in the previous subsection—the addition of nitrenes to azo- and nitroso-compounds does actually occur at the LEP of the nitrogen atom. *N*-Heteroarylnitrenes, capable of adding to multiple bonds, react similarly with the classical "trapping agent" for sextet species—dimethyl sulphoxide, and other sulphoxides:[3,27,28,85,119]



The extremely stable sulpoximines (XLVII) are then formed in a nearly quantitative yield. The attack on the LEP of the sulphur atom is so fast that vinyl-substituted sulphoxides are converted into unsaturated sulphoximines without any traces of addition to the double bond.[152] The stable nitrene (VIIb) does not react with DMSO,[27] although the sulphoximines (XLVII) corresponding to the nitrenes (VIIa, b) can be obtained by oxidising the initial acylhydrazines by LTA in DMSO.[28] Here they are clearly formed from "precursors" of the free nitrenes. Contrary to expectations, after the oxidation of alkoxyamines by LTA in DMSO, the adduct of alkoxynitrenes with the solvent could not be detected.[98]

The addition of PIN (XII) to dimethyl sulphide gives rise to a fairly labile sulphimide (XLVIII), which dissociates slowly even at room temperature (rapidly on raising the temperature) with elimination of Me_2S:[53]

The interaction of aminonitrenes with the starting materials used in their synthesis, usually hydrazine derivatives, is of a general character.[3] Here the intermediates are the extremely unstable tetrazans (XLVI), which can decompose, affording deamination products, or can be converted into 2-tetrazenes (L), which are the usual products of the oxidation of 1,1-disubstituted hydrazines:[3,85,119]

The tetrazenes (L) give rise to stable aminonitrenes simply as a result of dimerisation.[20–26]

By analogy with tetrazenes, one would expect the formation of 1,2-dialkoxydiazene RON=NOR in the oxidation of alkoxyamines but these compounds are extremely unstable and so far they have never been detected in any reactions of alkoxynitrenes.

- - - o 0 o - - -

The last decade has provided extensive data illustrating the wide variety of the reactions of amino- and oxy-nitrenes. Although the range of reactions and methods for the generation of oxynitrenes investigated is appreciably narrower, the data obtained demonstrate their similarity to aminonitrenes. The general problem of the separation of the reactions of nitrenes proper and "nitroenoids" is associated directly with further progress in this field of the chemistry of sextet nitrogen intermediates. The properties and reactions of stable nitrenes can serve as a kind of standard. From the standpoint of theoretical organic chemistry as a whole, the study of the mechanism of the decomposition and rearrangements of amino- and oxy-nitrenes is of interest. There are good prospects that their reactions with a wide variety of unsaturated compounds will prove useful in syntheses. Evidently in the immediate future the search for new types of amino- and oxy-nitrenes, new methods for their generation, and new reactions of these species will becomes of current interest.

Vicarious nucleophilic substitution of hydrogen

M Makosza
Institute of Organic Chemistry, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT. The reaction involving the vicarious nucleophilic substitution of hydrogen in aromatic nitro-compounds and certain electrophilic heterocycles is discussed. The applications of the reaction, its limitations, the problems concerning its mechanism and mode, as well as the possibilities of the practical application of this new method in organic synthesis are examined.

The bibliography includes 101 references.

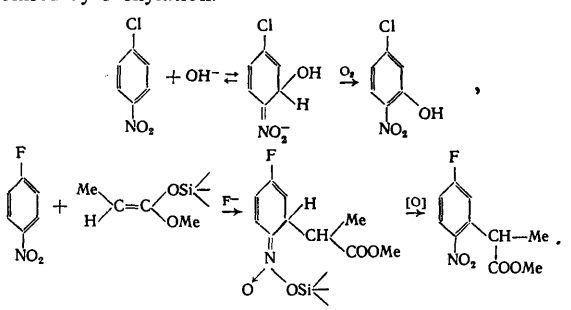
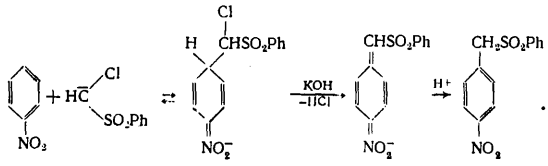
I. Introduction



Reactions involving nucleophilic substitution in an aromatic ring[1–5] differ from aliphatic nucleophilic substitution reactions not only by a greater variety of mechanisms but also by the wide variety of groups which can be substituted by nucleophiles. Such a group can be even the hydride ion, but, despite numerous examples,[6,7] the general method for the nucleophilic substitution of hydrogen in aromatic systems has been lacking hitherto, if one disregards the Chichibabin reaction, whose applications are limited to the amination of individual heterocycles.[8] The known instances of the nucleophilic substitution of hydrogen described in the literature are fairly specific and their mechanisms differ very greatly.[7,9–12]

At the end of the 1970s, the present author began to develop a new method for the direct substitution of hydrogen in aromatic nitro-compounds and other electrophilic arenes on the basis of reactions with carbanions. The starting point in our research was the most general reaction involving the nucleophilic substitution of the halogens and other leaving groups in nitroarenes, which proceeds via an addition–elimination mechanism.[1,2] For example, the interaction of a nucleophile with *p*-chloronitrobenzene begins with the addition of the reactant to the carbon atom linked to chlorine whereupon an anionic σ^{Cl}-adduct (frequently called the Meisenheimer complex) is formed and then decomposes rapidly into chloride ion and the nucleophilic substitution product:

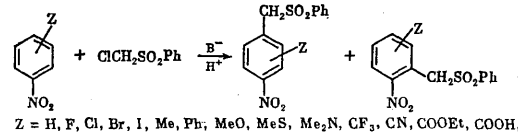


Evidently the formation of the σ^{Cl}-adduct is due to the presence of the nitro-group, which is capable of delocalising effectively the negative charge. For this reason, the nucleophile can also add to the carbon atom in the *ortho*-position relative to the nitro-group. Although the examples of the formation of such σ^{H}-adducts are known,[11,13] the latter are usually incapable of further reactions because of the impossibility of the elimination of the hydride ion.

It follows from the numerous investigations into the chemistry of stable σ-adducts of polynitro-compounds that the addition of nucleophiles to an unsubstituted carbon atom is faster than the addition to one linked to substituents, even substituents such as halogens. On the other hand, the σ-adducts formed in the latter reaction are usually thermodynamically more stable.[14,15] When these observations are extended to the short-lived σ-adducts of mononitro-compounds, one arrives at the conclusion that in most instances of the nucleophilic substitution of a halogen in nitroarenes, the nucleophile adds initially to the carbon atoms linked to hydrogen and σ^{H}-adducts are formed. Since the latter are in general unable to react further because of the impossibility of the elimination of the hydride ion, the formation of such adducts has been unremarked even in the numerous kinetic investigations[1] and the observed reaction is the substitution of the halogen via the slower formation of the σ^{X}-adduct. Hence it follows that the development of a general method for the nucleophilic substitution of hydrogen in nitroarenes is entirely feasible and useful and should be based on the rapid subsequent conversion of the σ^{H}-adducts, including the hydrogen abstraction process. The seemingly most evident approach to this problem, namely the oxidation of the σ^{H}-adducts, cannot have a general importance in view of the reversibility of the addition, the unfavourable equilibrium position, and, usually, the sensitivity of nucleophiles to oxidation. Nevertheless, such a process can be carried out by using non-oxidisable nucleophiles[9] or by ensuring a high concentration of the σ^{H}-adducts. This occurs for polynitro-compounds,[16] in the reactions of organomagnesium compounds with nitroarenes,[17] and also when the resulting σ-adducts of carbanions are stabilised by *O*-silylation:[18]

Our approach to the solution of this problem was based on the hypothesis that the σ^{H}-adducts, formed by carbanions containing a leaving group X (for example, chlorine) at the carbanionic centre,

can undergo further reaction via the elimination of the X^- anion as a result of the 1,2-migration of the hydride ion from the ring to the carbon atom of the entering substituent. This should result in the formation of the product of the substitution of hydrogen by the dehalogenated carbanion residue. The formation of σ-halogenocarbanions is frequently accompanied by autocondensation and in the first attempt to carry out this process we therefore chose as the reagent chloromethyl phenyl sulphone, which is fairly stable in this respect.[19] The reaction of nitrobenzene with this sulphone in the presence of powdered potassium hydroxide in dimethyl sulphoxide occurred with an intense exothermic effect and was accompanied by the development of a very deep blue-violet colour of the reaction mixture. This resulted in the formation of a mixture of *o*- and *p*-nitrobenzyl phenyl sulphones in a satisfactory yield:[20]

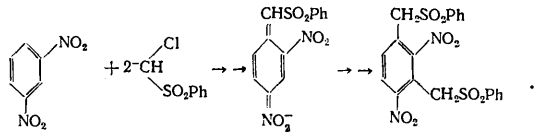


The hydrogen atom in the *o*- and *p*-positions relative to the nitro-group was substituted in this reaction by the carbanion residue, but, from the point of view of the stoichiometry, the halide ion and not the hydride ion was eliminated from the intermediate σ^H-adduct. Thus the halogen plays the role of the leaving group instead of the ring hydrogen, which is incapable of being eliminated in the form of the anion. We therefore designated this process in English as "vicarious nucleophilic substitution of hydrogen (VNS)"†. The study of the reaction mechanism showed that the σ-adducts are converted into the final products not via the hydride complex, as postulated initially, but as a consequence of the β-elimination of hydrogen chloride (or HX in the general case).[21] The earlier important hypothesis of the faster addition of the nucleophile to the unsubstituted rather than the halogen-substituted ring carbon atom has been fully confirmed. In the reactions of *p*- and *o*-chloronitrobenzenes with chloromethyl sulphone in the presence of an excess of a base, hydrogen is substituted exclusively; chlorine substitution products were not detected.[20] The higher rate of the VNS of hydrogen, usually exceeding the rate of the usual substitution of a halogen, is one of the most significant features of this reaction. Here one should note that several examples of VNS had also been known previously. These include the methylation of nitroarenes and certain heterocycles by carbanions derived from DMSO[22–24] and from methyl sulphone[25] and dimethylsulphonium[26] and sulphoxonium[27,28] ylides as well as the dichloromethylation of *p*-halogenonitrobenzenes by trichloromethyllithium.[29] The amination of certain nitroarenes by hydroxylamine in the presence of bases[30,31] also belongs to reactions of this type. However, these few observations were not developed further, since the general character of these reactions was not discovered and the proposed speculative mechanisms were not usually correct.[25,27,31] In our subsequent studies, the general character of this new reaction was demonstrated and its specific features, the principal elements of its mechanism, direction rules, as well as the conditions necessary for its successful performance were found.[32–34]

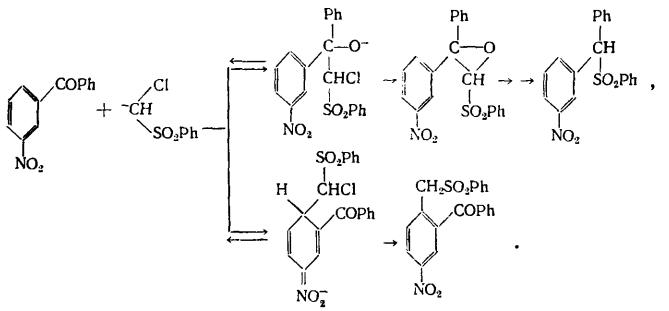
†Vicarious = substituting another, acting for another.

The carbanion is usually generated directly in the reaction mixture in the presence of an aromatic nitro-compound by treatment of the corresponding CH acid with a base. Since the elimination requires a second equivalent of the base, the base is required in at least a twofold excess relative to the other reactants. The reaction products are formed as intensely coloured nitrobenzyl carbanions derived from strong CH acids. They are protonated only on treating the reaction mixture with an acid. The success of the reaction depends on the nature of the base, the character of the solvent, temperature, and other conditions. The base must ensure the deprotonation of the CH acid and rapid elimination, while the solvent must ensure a high reactivity of the carbanion and the base. Satisfactory results were obtained when the carbanions are present as solvate-separated ion pairs, so that sodium hydroxide, potassium hydroxide, potassium t-butoxide, and sodium methoxide in dimethyl sulphoxide, dimethylformamide, liquid ammonia, and sometimes in tetrahydrofuran are most often used. The carbanions derived from the initial CH acids and the products are frequently unstable, which makes it necessary to carry out the reaction at low temperatures and to neutralise the reaction mixture immediately when the reaction has reached completion.

II. Applications of the reaction



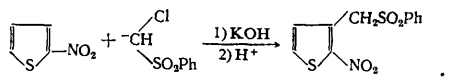
Both reactants participate in the VNS reaction, so that its applications must be determined by their character, namely the electrophilicity of the arenes (usually nitroarenes) and the stability of their carbanions, i.e. ultimately their structure. In order to determine the structural requirements as regards nitroarenes, chloromethyl sulphone has been used. As stated above, it does not undergo autocondensation in the presence of bases[19] and its conjugate carbanion is fairly stable. This sulphone reacts very effectively with nitrobenzene and its substituted derivatives, forming the products of the substitution of hydrogen in the *ortho*- and *para*-positions relative to the nitro-group:[20,35]



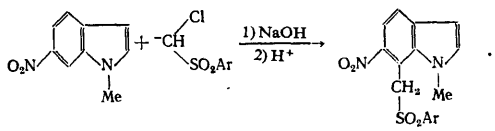
Z = H, F, Cl, Br, I, Me, Ph, MeO, MeS, Me_2N, CF_3, CN, COOEt, COOH, SO_3H, SO_2Me, NO_2, $CH(OR)_2$, COPh, etc.

In the case of *p*-halogenonitrobenzenes (Z = *p*-halogen), only the *ortho*-substitution product is formed. Only when Z = F is the VNS reaction accompanied by the nucleophilic substitution of fluorine. As shown below, this process can be suppressed by carrying out the reaction under special conditions.[21,36] Naturally, when the substituent Z is in the *ortho*- and *meta*-positions relative to the nitro-group, there is a possibility of the formation of two or even three isomeric substitution products. The character of the substituents in the aromatic nitro-substituted ring which do not prevent the reaction is virtually unlimited but there is no doubt about their influence on the rate of the reaction and the site of substitution. The few substituents inhibiting the VNS include also those which are deprotonated under strongly basic reaction conditions with formation of anions containing a free electron pair in the position conjugated with the aromatic ring and the nitro-group, such as, for example, the hydroxy-group in nitrophenols, the mercapto-group in nitrothiophenols, etc. In the case of the substituents COO^- [37] and SO_3^-,[38] where there is no conjugation of this kind, their presence

does not prevent the VNS. Since the VNS products exist in the reaction mixture as nitrobenzyl carbanions, this reaction is very selective in relation to monosubstitution. The inhibiting effect of conjugated negatively charged substituents can be compensated by the presence of a second nitro-group. Whereas nitrophenols do not enter into the VNS reaction, the substitution in dinitrophenols proceeds fairly smoothly.[39] The activating effect of the second nitro-group has also been demonstrated by the reaction of *m*-dinitrobenzene with an excess of a sulphone, which leads to disubstitution products, while in 1,3,5-trinitrobenzene there is even a possibility of trisubstitution:[39]

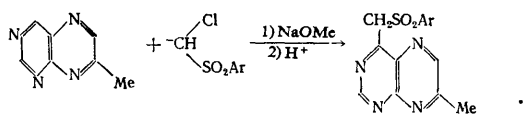


It must be emphasised that the rates of substitution of the first, second, and third hydrogen atoms in polynitroarenes differ greatly, which ensures the process selectivity. Certain limitations in VNS may arise as a consequence of the presence of substituents capable of reacting with carbanions. For example, in the reaction with nitrobenzophenones the mode of reaction is determined principally by the structure of the substrate: the *para*-isomer enters exclusively into the Darzens condensation, the *ortho*-isomer is involved in the VNS reaction, while in the case of the *meta*-isomer the two reactions compete and the conditions ensuring a high concentration of the base promote the substitution of hydrogen:[40]

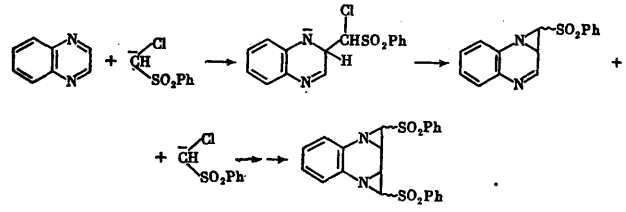


Presumably there is a possibility of the VNS of hydrogen not only in a monosubstituted but also in any nitroarene having at least one hydrogen atom in the *ortho*- or *para*-position relative to the nitro-group. Here it must be emphasised that in all these cases the VNS of hydrogen is faster than the usual nucleophilic substitution of a halogen, as has been observed, for example, in the reactions of chloronitrobenzoic[37] and chloronitrosulphonic acids.[38]

Nitronaphthalenes are distinguished by an especially high reactivity in the VNS reaction, which is undoubtedly associated with the increased stabilisation of the σ-adducts by the second aromatic ring. 1-Nitronaphthalene forms a mixture of 2- and 4-substituted products in which the 2-isomer greatly predominates. The substitution of hydrogen in 2-nitronaphthalene takes place exclusively in the 1-position.[41] VNS reactions are characteristic also of heterocyclic compounds. The nitro-derivatives of aromatic heterocycles are usually very reactive in the reaction with the chloromethyl phenyl sulphone carbanion. Thus the VNS reaction proceeds readily and affords substitution products in satisfactory yields for **2-, 3-, and 4-nitropyridines and also their chloro-, ethyl-, and** methoxy-derivatives.[42] In the case of chloronitropyridines, in which the nucleophilic substitution of chlorine is known to proceed at a high rate, the VNS of hydrogen is observed exclusively.[42] The VNS reaction takes place very smoothly in nitro-derivatives of five-membered heterocycles: 2-nitrothiophen,[43] 2-nitrofuran and its derivatives,[43] *N*-substituted 2- and 3-nitropyrroles,[43] and nitroimidazoles,[44] for example:

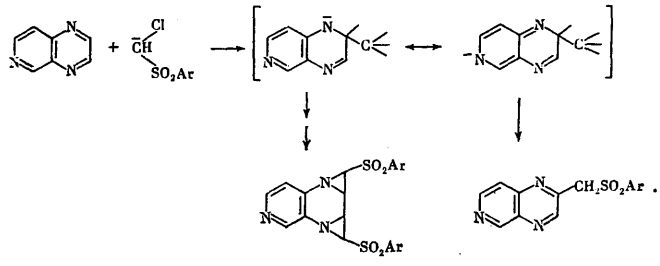


Nitroquinolines are very reactive in the VNS reaction and, as in nitronaphthalenes, mainly or exclusively the hydrogen atom in the *ortho*-position relative to the nitro-group is substituted; for example, in the 6-, 5-, and 7-positions respectively in 5-, 6-, and 8-nitroquinolines.[45] The substitution of hydrogen via the VNS mechanism can also be carried out in *N*-derivatives of nitroindoles:[46]



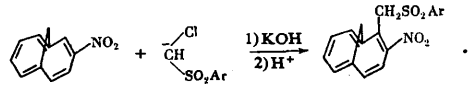
Certain heterocycles are sufficiently electrophilic for the occurrence of the VNS reaction even in the absence of the nitro-group. Thus the methylation of acridine, quinoline, and certain other heterocycles by DMSO and methyl phenyl sulphone anions was noted previously.[23,25]

The chloromethyl phenyl sulphone carbanion is less nucleophilic than the two carbanions used previously, but it is also capable of substituting the hydrogen in acridine, benzothiazole, and benzoxazole.[147] 1,2,4-Triazine and its derivatives are especially interesting, since in this instance nucleophilic attack may be directed to the 5-, 3-, or even 6-positions in the ring, the reactivity of the hydrogen atoms relative to nucleophiles decreasing in the sequence 5-H > 3-H > 6-H.[48] Using the corresponding substituted triazines, it is possible to carry out the VNS reaction in all these positions.[48,49] Pteridine derivatives exhibit a comparatively high reactivity in the VNS reaction. The reaction with unsubstituted pteridine could not be carried out apparently as a consequence of the instability of the ring under the highly basic reaction conditions, but the reaction with 5-methyl- and 5-phenyl-pteridines proceeds fairly readily:[50]



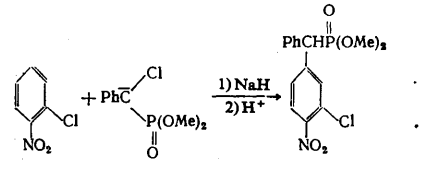
The attempts to extend the VNS reaction to certain other electrophilic heterocycles without the nitro-group, such as quinoxaline and naphthyridines, were unsuccessful: the reaction occurred in a different direction, namely via the bisannelation pathway.[51] The first stage of this process—the formation of a σ-adduct—is undoubtedly common to the VNS, but its subsequent reaction pathway is different. Instead of β-elimination, intramolecular nucleophilic substitution of chlorine takes place and the monoannelation product

formed, containing a reactive aliphatic C=N double bond, reacts rapidly with a second carbanion:

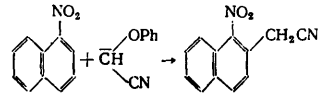


As a consequence of the partial delocalisation of the negative charge in the σ-adduct of quinoxaline, the neighbouring nitrogen atom has fairly pronounced nucleophilic properties promoting substitution and at the same time hindering β-elimination. This situation is absent in quinoxaline *N*-oxide, which forms a σ-adduct with a low negative charge on the nitrogen atom, as a result of which VNS takes place exclusively.[52] The negative charge density on the N(1) atom in the corresponding σ-adduct is reduced as a consequence of the conjugation with the N(6) atom, as a result of which competition is observed between the VNS and bisannelation reactions; the mode of the reaction of the σ-adduct can be controlled by varying the reaction conditions. A high concentration and an excess of the base as well as a low temperature promote bimolecular elimination, leading to VNS, while reduction of the base concentration and an increase in temperature promote bisannelation:[53]

Similar phenomena have been observed when the substituents in the substrate were varied. Thus the interaction of 1-cyanonaphthalene with the chloromethyl phenyl sulphone carbanion leads to the exclusive formation of the bisannelation product. The introduction of a second CN group increases the delocalisation of the negative charge in the σ-adduct, which promotes β-elimination and VNS; thus the mode of reaction is susceptible to control.[52]



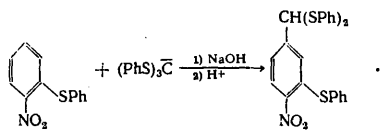
Finally, one should note that sufficiently electrophilic nonbenzenoid aromatic systems are also capable of VNS. The most interesting example is provided by derivatives of 1,6-methano-[10]annulene, which is an analogue of naphthalene as regards properties.[54] Thus in the reactions of 2- or 3-nitro-1,6-methano-[10]annulenes with chloromethyl phenyl sulphone, the hydrogen atom in the 3- and 2-positions respectively is substituted. Cyanomethanoannulenes are less reactive in this reaction. However, cyano-1,6-difluoromethano[10]annulenes undergo VNS, although the yields of the product are low.[55]



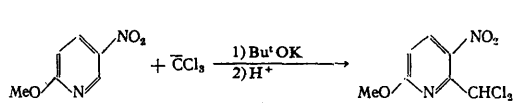
The possibility of VNS in the tropylium cation has been demonstrated in a few instances.[56]

The VNS concept can also be extended to electrophilic alkenes (the so called Michael acceptors). These compounds react with α-halogenocarbanions usually via an addition–intramolecular substitution mechanism with formation of cyclopropane derivatives.[57] By selecting the alkene and the reaction conditions, it is nevertheless possible to induce β-elimination in the adducts and to carry out the VNS of the hydrogen also in aliphatic systems.[58]

The results presented make it clear that the VNS of hydrogen in electrophilic aromatic compounds is of an extremely general character. Similarly, the carbanions of t-butyl chloromethyl, t-butyl *p*-tolyl, and t-butyl chloromethyl sulphones react with various electrophiles like the chloromethyl phenyl sulphone carbanion,[35] but it has to be stated that other alkyl chloromethyl sulphones are not usually employed in this reaction as well as other reactions proceeding via carbanions because they undergo rapid Ramberg–Baecklund rearrangements.[59] Other chloromethanesulphonyl compounds, namely *NN*-dialkylamides[35] and the phenyl or neopentyl ester of chloromethanesulphonic acid,[65] are also satisfactory precursors of carbanions in the VNS reaction. The tertiary carbanions formed from α-chloroalkyl or α-chlorobenzyl sulphone react with nitroarenes in accordance with the VNS mechanism but differ from the chloromethyl derivatives of sulphones by their reactivity and especially by the preferential substitution in the *para*-position.[35] In carbanions stabilised by sulphonyl groups, chlorine is the most convenient leaving group; other halogenomethanesulphonyl compounds are less easily available and undergo side reactions more readily.[35] Not only halogens but also certain other substituents, such as PhS, Me_2NCS_2, or PhO are capable of β-elimination, but the applicability of the corresponding substituted sulphones in VNS reactions is limited as a consequence of the low rate of elimination, which frequently leads to the preferential elimination of benzenesulphonic acid.[53] Chlorine is the most convenient and effective leaving group also in other carbanions stabilised by benzenesulphinyl,[61] diphenylphosphine oxide, and diethoxyphosphonyl[62] groups. For example, dimethyl α-chlorobenzylphosphonate reacts effectively with many nitroarenes, affording esters of *p*-nitrophenyl(phenyl)methylphosphonic acids:[62]

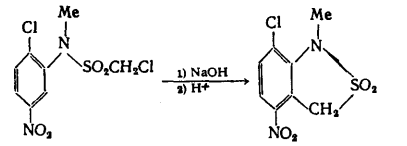


Despite the fact that α-chloronitriles, especially chloroacetonitrile, are fairly unstable in the presence of bases, they are capable of undergoing the VNS reaction but satisfactory results are obtained only in reactions with reactive nitroarenes.[63,64] Thus the cyanomethylation of chloronitrobenzenes or nitronaphthalene by chloroacetonitrile proceeds with a satisfactory yield. In the reaction with nitrobenzene, moderate yields have been achieved, while less reactive alkoxynitrobenzenes do not react with chloroacetonitrile via the VNS mechanism.[63,64] The cyanomethylation of the less reactive nitroarenes can be achieved with the aid of substituted nitriles such as $PhSCH_2CN$ or $PhOCH_2CN$, which are more stable in the presence of bases:[63–65]



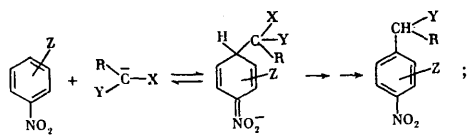
The reaction of α-chloropropionitrile with many nitroarenes usually leads to VNS products in satisfactory yields.[63,64]

The carbanions derived from chloroacetic,[66] dichloroacetic,[67] and α-chloroalkanoic acids[68] are fairly reactive in the alkoxycarbonylalkylation of nitroarenes via the VNS mechanism, but the process is very sensitive to the reaction conditions and the electrophilicity of arenes. Here too the more stable esters containing PhS or Me_2NCS_2 leaving groups have found more general application.[64] An example of the alkoxycarbonylmethylation reaction, in which the leaving group is the ammonium substituent, is known.[69]



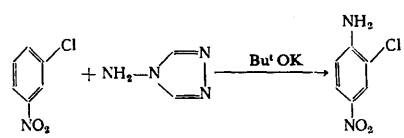
The majority of leaving groups stabilise the corresponding carbanions, so that many of these compounds are fairly strong CH acids capable of being deprotonated on treatment with bases and then reacting further with nitroarenes via the VNS mechanism. For example, PhS is a group of this kind. In fact tri(phenylthio)-methane substitutes the hydrogen atom in the *para*-position relative to the nitro-group in many nitroarenes, forming diphenyl dithioacetals of *p*-nitrobenzaldehydes:[70]

The similar reactions of the diphenyl dithioacetals of aldehydes or of benzyl phenyl sulphides with nitroarenes lead to the formation of nitrobenzyl phenyl sulphides[71] and diarylmethane derivatives.[72] There is no doubt that the VNS reaction with trihalogenomethyl-carbanions is of greatest interest in view of the ready availability of the initial haloforms as well as the possibility of further reactions of the dihalogenomethyl groups introduced. In analysing the possibilities of these reactions, account must be taken of the instability of the trihalogenomethyl anions, which dissociate rapidly with formation of dihalogenocarbenes,[73] and also of the instability of nitrobenzylidene dichloride carbanions.[74] As already mentioned above, McBee et al.[29] carried out the dichloromethylation of *p*-halogenonitrobenzenes by trichloromethyllithium at temperatures in the range −100 to −65 °C and proposed a carbene reaction mechanism.[29] We have found that, when potassium t-butoxide is used in a tetrahydrofuran–dimethylformamide mixture at temperatures in the range −65 to −70 °C, it is possible to achieve the dichloromethylation and even the dibromomethylation of many nitroarenes by the corresponding haloforms frequently in high yields.[75,76] The dihalogenomethylation reaction is very sensitive to the conditions and the reactivity of the nitroarenes. There is no doubt that it proceeds via a mechanism typical for the VNS reaction–the addition of the CX_3^- anions and the elimination of HX from the σ-adduct formed:[76]



Instances of VNS occurring with ring opening or closure are known. Thus the carbanions of phenylcyanooxirans react with nitronaphthalene to form σ-adducts, the subsequent reaction involving β-elimination from them and being accompanied by the opening of the oxiran ring.[77] Examples of intramolecular processes leading to ring formation are more numerous. They include the intermolecular VNS in chloromethanesulphonamides formed from *m*-nitrobenzylamine and *m*-nitroaniline derivatives:[78]

The synthesis of tetracyclic derivatives of anthraquinone via intramolecular VNS which follows Michael addition is extremely interesting.[79]

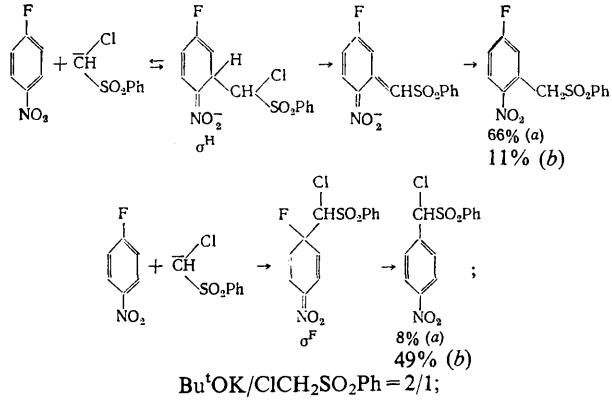


It is evident from the examples quoted above that the range of carbanions suitable for VNS reactions is wide. A necessary requirement which must be met by the structure of the carbanions is the presence at the carbanionic centre of a group X capable of undergoing β-elimination in the form of HX from the intermediate σ-adduct under the influence of bases. Thus carbanions capable of undergoing the VNS reaction can be represented by the general formula X–$\bar{C}$YR, where X is the leaving group, Y the group stabilising the carbanion, and R its substituent. A mechanism of VNS is presented below in a general form (examples of the group Z were presented above):

X = Cl, Br, PhO, PhS, Me_2NCS_2, etc;
Y = SO_2Ar, SO_2OPh, SOPh, CN, COOEt, $P(O)Ph_2$, Cl, PhS, etc;
R = H, Alk, Ar, Cl, PhS, etc.

Virtually any combination of X, Y, and R presented in the scheme gives rise to a carbanion capable of reacting in accordance with the VNS mechanism. Certain limitations in the use of such carbanions are associated with the tendency of some of them to undergo autocondensation ($ClCH_2CP$) or to decompose (CCl_3^-). Such carbanions react smoothly only with reactive nitroarenes. In addition, appreciable stabilisation induces a reduced nucleophilicity of the carbanions, which can also prevent the reaction. Finally, bulky tertiary carbanions (R ≠ H) are frequently incapable of undergoing the hydrogen substitution reaction in the *ortho*-position relative to the nitro-group or to other bulky substituents, principally as a result of the steric hindrance in the elimination stage.

The VNS of hydrogen is not limited to the reactions of carbon-based nucleophilic carbanions. The amination of nitroarenes by hydroxylamine and, especially effectively, by 1-amino- and 1-alkylamino-1,3,4-triazoles takes place via the same addition–β-elimination mechanism:[80,81]



III. The reaction mechanisms

The VNS reaction is undoubtedly a multistage process including, in the first place, the formation of the σ-adduct of the carbanion and the nitroarene and its further reactions. Thus the reaction

mechanism must provide answers to the following questions: how is the σ-adduct formed and in what way is it converted into the product. Furthermore, it is necessary to determine the ratios of the rates of these stages.

σ-Adducts can be formed via two alternative pathways: as a result of the direct nucleophilic attack or in two stages via electron transfer from the carbanion to the nitroarene with subsequent recombination of the radical-anion and the radical formed.[82] The question via which pathway the σ-adducts are formed in the VNS reaction has not been studied in detail but certain observations and preliminary experiments suggest that here we are dealing with direct nucleophilic attack. For example, the *ortho*-directing effect in the VNS reactions, determined by the existence of the carbanions as close ion pairs,[36] while the formation of the σ-adducts of organomagnesium compounds with nitroarenes via one-electron transfer[17,83] usually affords a statistical mixture of the *ortho*- and *para*-isomers, leads to the same conclusion. The hypothesis that the VNS proceeds via the direct addition of the nucleophile and not as a one-electron transfer has been confirmed by the results of studies of reactions using the so called free-radical clocks, because these reactions occur without appreciable competition with free-radical processes.

In our view, the question of the way in which the σ-adducts are converted into the VNS products is more important. Among the various possibilities, the 1,2-hydride shift with the concerted elimination of the X^- anion and the base-induced β-elimination of HX appeared most likely. The study of the influence of the concentration of the base on the rate of reaction led to the conclusion that the VNS proceeds via the elimination pathway.[21] The influence of the base on the rate of reaction was studied by the method of competing reactions—the competition between the fluorine and hydrogen substitution reactions in *p*-fluoronitrobenzene was studied:

$Bu^tOK/ClCH_2SO_2Ph = 2/1$;
(*a*) high concentration of Bu^tOK,
(*b*) low concentration of Bu^tOK.

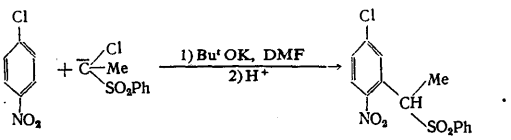
The rates of formation of the σ^F- and σ^H-adducts as well as the rate of conversion of the σ^F-adduct into the fluorine-substitution product are independent of the base concentration, like the rate of conversion of the σ^H-adduct into the product via hydride transfer, while the rate of conversion of the σ^H-adduct into the product via the β-elimination of HCl should be directly proportional to the base concentration. Thus an increase in the concentration of the base should appreciably increase the fraction of the hydrogen-substitution products, which has in fact been observed. Similarly, when there is intermolecular competition between the substitution of *p*-H in nitrobenzene and *p*-F in *p*-fluoronitrobenzene by the phenylphenoxyacetonitrile carbanion (this tertiary carbanion substitutes only the hydrogen in the *para*-position relative to the nitro-group), the mode of reaction is determined by the base concentration. In the absence of an excess of the base, the usual fluorine substitution has been observed, while in the presence of an excess of the base the exclusive formation of the products of the VNS of hydrogen in nitrobenzene has been observed, while *p*-fluoronitrobenzene remained unaltered[21]!

These results show not only that the conversion of the σ^H-adducts into the VNS products is accelerated by the base and hence that it proceeds via the pathway involving the β-elimination of HX but also that the formation of σ-adducts is a reversible and rapid process compared with β-elimination and that the rate of formation of σ^H-adducts is higher than that of σ^F-adducts. Numerous kinetic studies of nucleophilic aromatic substitution have shown that the rate of substitution of fluorine is much higher than the rate of substitution of chlorine and other leaving groups, which increases still further the ratio of the rates of formationof σ^H-adducts and other corresponding adducts.[1]

On the basis of this ratio, one can control the mode of reaction of chloromethyl phenyl sulphone with *m*-nitrobenzophenone[40] and azaquinoxaline:[53] a high concentration of the base promotes the VNS, while the use of more dilute solutions and the absence of an excess of bases lead to other processes.

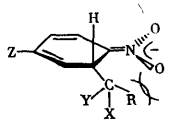
Important data concerning the mechanisms of the reactions involving the dissociation of a C–H bond have been obtained in the study of the kinetic isotope effect.[84] For the two-stage VNS process, in which a C–H bond is cleaved (as shown above) in the second stage, which limits the overall rate of reaction, we expected the appearance of a distinct primary effect where the ratio $k_H/k_D > 1$. Unexpectedly, the ratio k_H/k_D for *p*-nitro[D]benzene {determined by comparing the ratios of the *o*- and *p*-isomers in reactions of chloromethyl phenyl sulphone with *p*-nitro[D]benzene and nitrobenzene} proved to be less than unity, amounting to 0.9. Thus a secondary isotope effect is observed. This is possible in the addition stage but not in the elimination stage. These at first sight contradictory results can be accounted for by analysing the energy profile of the process, which in the case of mononitro-derivatives, when the latter are stable, involves the formation of an unstable intermediate (σ-adduct). The subsequent β-elimination of HCl converts this adduct into the highly stabilised nitrobenzyl carbanion and the structure of the early transition state in this stage should therefore be asymmetric.

The difference between the rates of cleavage of C–H and C–D bonds in such processes is known to be insignificant. In other words, in this case $k_H/K_D \simeq 1$ for β-elimination, as a result of which a secondary isotope effect can be manifested in the addition stage. In fact, the addition of the carbanion to the nitrobenzene ring is accompanied by a change in the hybridisation of the ring carbon atom from sp^2 (in the initial nitrobenzene) to sp^3 (in the σ-adduct), which is known to be promoted by the replacement of hydrogen by deuterium. Since the addition is reversible while deuterium retards the dissociation, the equilibrium constant, which determines the concentration of the σ-adducts, is higher for the σ^D-adduct, i.e. $k_D > k_H$.



In the absence of the isotope kinetic effect in the elimination stage, the observed rate of substitution of deuterium exceeds the rate of substitution of hydrogen, i.e. $k_H/k_D \simeq 0.9$. These considerations, which are partly speculative, have been confirmed by the results of

the study of the kinetic isotope effect for the VNS reactions in which the elimination proceeds via a symmetrical transition state. The kinetic effects, i.e. the ratios k_H/k_D, reach appreciable values (3–7) in specific examples.[85,86]

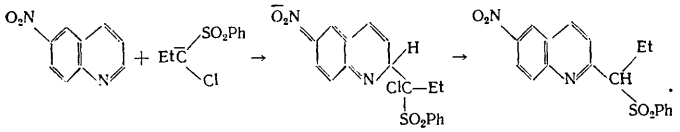


The above conclusions concerning the characteristic features of the VNS mechanism are a result of so far fairly simple studies at a qualitative level. They require further revisions and corrections, especially those based on quantitative measurements. In particular, many observations indicate that the ratios of the rates of addition and elimination found above can vary.

IV. The problem of the reaction site

Although the proposed VNS mechanism is of a preliminary character, nevertheless it indicates effectively the complexity of the problem of the reaction site. As a rule, the reaction proceeds via the rapid and reversible formation of σ-adducts, which then undergo the slower β-elimination. The relative rates of substitution of hydrogen in different positions in the nitroarene therefore depend on the ratios of the rates of formation of the isomeric σ-adducts, the corresponding equilibrium constants, and the elimination rate constants. The overall picture is complicated by the fact that carbanions can also act as bases in the elimination step, while their concentration varies during the reaction. Furthermore, the problem of the reaction site can be approached phenomenologically by analysing the influence of the principal variable parameters on the reaction site: the structure of the carbanions, the structure of the nitroarenes, and the reaction conditions. The ratio of the products of *ortho*- and *para*-substitution, formed in the VNS of the hydrogen atoms in nitrobenzene by the carbanions of α-halogenoalkyl phenyl sulphones depends greatly on the steric effects. Secondary carbanions of the type $X\overline{C}HSO_2Ph$ (X = halogen) substitute the hydrogen atom in the *ortho*- and *para*-positions relative to the nitro-group, the fraction of the *ortho*-isomer diminishing with increase in the size of the halogen, i.e. in the sequence F > Cl > Br > I, whereas tertiary carbanions $Cl\overline{C}RSO_2Ph$ (R = Me, Ph, etc.) give rise exclusively or mainly to *para*-substituted products.[35,87] This does not mean that tertiary carbanions are incapable of substituting hydrogen in the *ortho*-position relative to the nitro-group. In the case of *para*-substituted nitrobenzenes, for example, *p*-chloronitrobenzene, the α-chloroethyl phenyl sulphone carbanion,[87] and certain other tertiary carbanions substitute smoothly the hydrogen atom in the *ortho*-position:[64,66]

The substitution by tertiary carbanions in the *ortho*-position relative to the nitro-group has also been observed in nitrobenzene derivatives having a bulky group in the *meta*-position.[87] Many observations have shown that the VNS is more sensitive to steric hindrance than the classical nucleophilic substitution of a halogen. One can therefore postulate that steric hindrance in the VNS reaction has a greater effect in the elimination stage and not in the addition stage. Since the transition state in the elimination step requires an antiperiplanar disposition of the hydrogen atom and the leaving group, the sensitivity of this process to the size of the groups R and Y is evident.



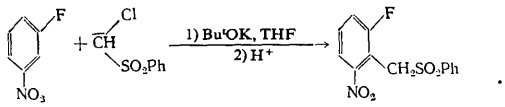
The steric effects in elimination from *ortho*-σ-adducts formed by tertiary carbanions can usually be compensated by the increased nucleophilicity of such carbanions (which increases the equilibrium constants of the addition reactions) and also by the presence of several leaving groups, etc. A good example is provided by the substitution reaction with participation of the tertiary trichloromethyl carbanion, which occurs preferentially in the *ortho*-position relative to the nitro-group even in the interaction with nitrobenzene.[76]

The conditions where the carbanions are present as solvate-separated ion pairs are most favourable for VNS. This happens for the sodium and potassium salts of deprotonated nucleophiles in DMSO, dimethylformamide (DMF), liquid ammonia, etc. in the presence of an excess of a soluble base. Under these conditions, the ratio of the *ortho*- and *para*-substitution products depend little on the nature of the cation and the solvent and is determined mainly by the structure of the carbanion and the nitroarene. The nature of the base can also have a significant influence on the reaction site under these conditions. For example, the NaOH and KOH frequently employed are almost insoluble in these solvents, so that they are used in the powdered state in a large excess. One must postulate that in such cases the elimination occurs mainly on the surface of the solid phase and partly under the influence of the carbanion as a base. It has been demonstrated experimentally that, depending on the character of the base, the ratio of the *ortho*- and *para*-isomers (the products of the VNS of the hydrogen in nitrobenzene by the potassium salt of chloromethyl phenyl sulphone) varies from 1.80 (when the elimination takes place under the influence of the excess Bu^tOK) to 0.86 (when it is induced by the excess carbanion).[88]

The degree of association of the ion pairs has a very powerful influence on the ratio of the *ortho*- and *para*-substitution products in VNS. Thus virtually only *ortho*-substitution is observed in the reaction of chloromethyl phenyl sulphone with nitrobenzene in the Bu^tOK–THF system. The product of the substitution of the second ortho-hydrogen atom is formed exclusively even in the case of *o*-chloronitrobenzene.[36] Similar effects have also been observed in reactions with other carbanions.[89] These phenomena are induced by the intense association of the cation–carbanion ion pairs in a moderately solvating solvent of the type of THF. The K^+ cation in this close ion pair is attracted to the negatively charged oxygen atoms of the nitro-group, which leads to the formation of the *ortho*-σ-adduct and *ortho*-substitution. The solvation character of this effect has been demonstrated by adding to the system an equimolar amount of crown-ether, which strongly binds the K^+ cation in a complex and this entails the formation of a mixture of *ortho*- and *para*-substitution products characteristic of dipolar solvents.[36]

In considering the influence of the structure of nitroarenes on the reaction site, it is necessary to consider the electronic structure of the ring and the influence of substituents. The ratios of the *ortho*- and *para*-substitution products in the VNS reactions with nitrobenzene and nitropyridines differ insignificantly as a consequence of the

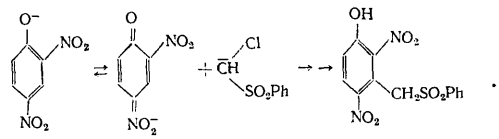
similar electronic structures of these aromatic systems. In less symmetrical aromatic systems, the ratio usually changes in favour of the *ortho*-isomer, which happens, for example, in the bicyclic naphthalene and quinoline systems. In the case of 1-nitronaphthalene[41] and 5- and 8-nitroquinolines,[45] the reaction takes place preferentially in the *ortho*-position relative to the nitro-group, i.e. at the C(2), C(6), and C(7) atoms respectively. The *para*-isomers are formed only in small amounts. On the other hand, 2-nitronaphthalene and 6-nitroquinoline react exclusively in the 1- and 5-positions respectively and only with secondary carbanions. The reaction does not take place with tertiary carbanions apparently because of the significant steric hindrance induced by the nitro-group and the hydrogen atom in the *peri*-position. For the same reason, the product of the VNS of the hydrogen atom at the C(2) atom was obtained in a low yield in the reaction of 6-nitroquinoline with α-chloropropyl *p*-tolyl sulphone:[45]



The preferential or exclusive *ortho*-directing effect in the VNS reaction with nitro-derivatives of bicyclic arenes is caused by the significant double bond character of the C(1)–C(2) bonds in naphthalene and also the C(5)–C(6) and C(7)–C(8) bonds in quinoline, which induces the preferential addition of nucleophiles to the positions indicated above in the corresponding *nitro*-derivatives. The addition to the C(3) and C(7) atoms in 2-nitronaphthalene and 6-nitroquinoline is also very much less favourable, because the stabilisation of the σ-adduct by conjugation with the nitro-group would lead to the breakdown of the aromaticity of the second ring. A similar situation arises in five-membered heterocycles such as thiophen, pyrrole, furan, etc. in which the C(2)–C(3) and C(4)–C(5) bonds have an appreciable double bond character. Therefore in 2-nitro-derivatives the VNS takes place preferentially at C(3), while in 3-nitro-derivatives it takes place exclusively at C(2).[43] It must be emphasised that this "*ortho*"-direction occurs also in reactions with tertiary carbanions, which is promoted by the geometry of the five-membered ring in which the steric effects of the neighbouring substituents are weaker than in the six-membered ring.

The question of the influence of the substituent Z in the nitrobenzene ring on the site of the VNS is fairly complex. This problem is naturally absent in the 4-Z-nitrobenzenes and can be solved fairly simply in 2-Z-nitrobenzenes. The ratio of the *ortho*- and *para*-substitution products in the latter case changes mainly as a result of the statistical factor. Sterically bulky substituents can prevent the reaction, hindering the coplanarity of the ring and the group, which is essential for the effective stabilisation of the σ-adduct (the so called secondary steric effect). Nevertheless, the reaction proceeds with a satisfactory yield even with *o*-nitrobenzoic and *o*-nitrobenzenesulphonic acids.[37,38]

The site of the reaction in 3-Z-nitrobenzenes, where one may expect, in principle, the formation of three isomeric products of the substitution of hydrogen in the 2-, 4-, and 6-positions, constitutes the most complex problem. The relative amounts of these isomers depend on the nature of the substituent Z and the carbanion and on the reaction conditions, which leads to a fairly complex picture. In the reaction series with participation of chloromethyl sulphone as the source of the carbanion, the substituents Z promote, regardless of conditions, substitution at either the neighbouring C(2) or C(4) atom (first group) or at the more remote C(6) atom (second group).[35,36,42,90] The halogens, Me, MeO, Me_2, etc. belong to the first group and CF_3, COOEt, NO_2, etc. belong to the second group.



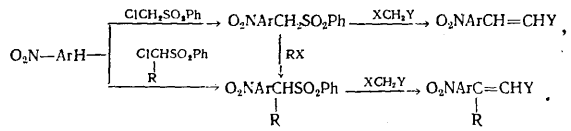
Such influence of the substituents on the reaction site is observed also in reactions with certain other secondary carbanions.[64,89] Bearing in mind that the use of Bu^tOK in THF leads to *ortho*-substitution, it is possible in many cases to synthesise 2,3-disubstituted nitrobenzene derivatives:[36]

The influence of the substituent Z on the reaction site can be determined by its influence on the rate of addition, the equilibrium constant, the rate of elimination, and the electronic and steric factors. The influence of the substituent Z on the electronic effects can be illustrated by a quantum-chemical calculation, which reveals a correlation between the parameters of the lowest unoccupied MO of the substrate and the character of the reaction site; however, better results were obtained when classical electronic effects were resorted to in order to explain this influence.[90] Overall, the effects indicated can account for the influence of the substituent Z on the rate of addition of the nucleophile and, to a lesser extent, on the equilibrium constant, but its influence on the rate of addition of the nucleophile, which can be explained on the basis of steric effects, is less understandable from the standpoint of electronic effects.

The attempts to explain the strong directing effect of the substituents of the first group (Me, MeO) indicated above in terms of the polarisabilities (the so called Bunnett–Reinheimer effect[91]) were unsuccessful, since many non-polarisable substituents (for example, F) have a similar effect.

The influence of substituents with a strong electron-donating activity on the reaction site is very interesting. As already mentioned previously, in contrast to mononitrophenols, dinitrophenols enter into the VNS reaction.[39] Unusual reaction sites are observed in such cases. Thus, substitution in 2,4-dinitrophenol takes place at the C(3) atom, whereas in 2,4-dinitroanisole it occurs at the C(5) atom. In the latter case, the hydrogen atom substituted is in the *para*-position relative to one nitro-group and in the *ortho*-position relative to the other, as for substitution at the C(4) atom in 1,3-dinitrobenzene.[35] The unusual VNS reaction site in 2,4-dinitrophenol is induced by the fact that in a fairly basic medium the phenol reacts as the dinitrophenoxide anion whose negative charge is delocalised, mainly between the oxygen atoms of the nitro-groups:

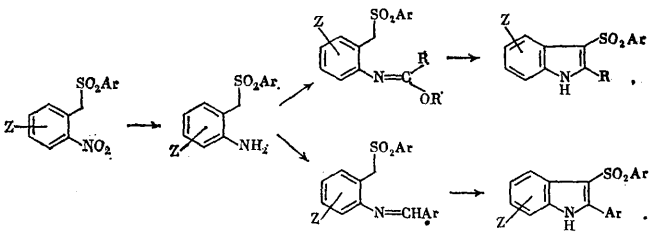
Hence it is evident that the nucleophilic attack must be directed to the C(3) atom.[35] For the same reason, 1,3-di(benzenesulphonyl)-methyl-2,4-dinitrobenzene is formed in the reaction of *m*-dinitrobenzene with an excess of chloromethyl phenyl sulphone; in this case, the substitution of the second hydrogen atom takes place in the dinitrobenzyl anion whose electronic structure is similar to that of the 2,4-dinitrophenoxide anion.[35] The characteristic features of the VNS reaction sites in the amino-derivatives of dinitrobenzene,



alkoxynitropyridines, *N*-alkyl-2-nitropyrroles, and other structurally related compounds can be explained similarly.

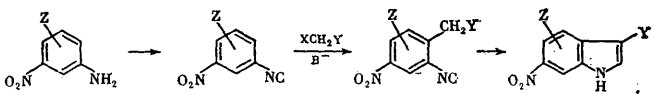
V. Practical applications

The VNS of hydrogen is a new hitherto little investigated reaction in organic chemistry. Our studies were directed mainly towards the elucidation of its applications and the solution of the problems of the mechanism, reaction site, and other general questions. However, certain possibilities for the practical application of the VNS can also be inferred from these results. Readily available starting materials are necessary for the VNS reaction, the reaction does not require any complex conditions, and its result is the direct substitution of the hydrogen atom in the aromatic nitro-substituted ring by alkyl substituents containing functional groups. The prospects for the practical application of the VNS reaction therefore appear very favourable.



In the first place, the VNS products are fairly strong CH acids; on treatment with bases, they are readily converted into the corresponding carbanions. Despite their moderate nucleophilicity due to the very effective stabilisation, the latter are capable of entering into many reactions characteristic of carbanions. For example, the carbanions derived from nitrobenzyl sulphones and nitriles by the VNS reaction are readily alkylated and add to Michael acceptors.[92] These reactions occur particularly readily under the conditions of phase transfer catalysis.[93]

The possibility of synthesising derivatives of nitrocinnamic acid and other substituted nitrostyrenes by VNS is very interesting. The alkylation of nitrobenzyl sulphones by the esters of carboxylic α-halogenoacids and other alkylating agents containing an electron-accepting group is accompanied by the elimination of benzenesulphonic acid, which leads to the formation of nitrostyrene derivatives.[94] Thus two-stage substitution of a hydrogen atom by the vinyl residue is achieved:

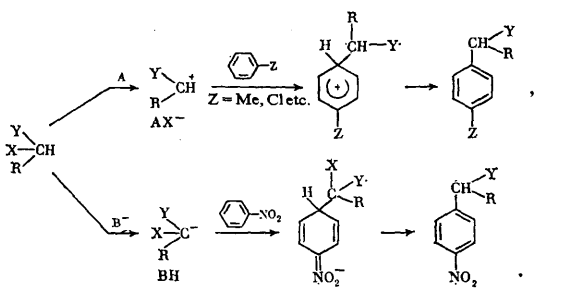


The possibility of introducing carbon-based functional groups into aromatic nitro-substituted rings by means of VNS and the subsequent reactions of the products are of significant interest. Thus the reaction with tri(phenylthio)methane leads to the formation of the dithioacetals of *p*-nitrobenzaldehydes, which afford aldehydes on hydrolysis, whilst their alkylation followed by hydrolysis leads to alkyl nitroaryl ketones.[70] An even more convenient synthesis of nitroarylaldehydes is based on the dihalogenomethylation of nitroarenes by haloforms followed by hydrolysis.[75,76] The VNS products can be readily converted into aromatic nitroacids after oxidation or hydrolytic halogenation and hence one can achieve a two-stage carboxylation of nitroarenes.[95]

By virtue of the possibility of introducing various functional group-containing substituents in the *ortho*-position relative to the nitro-group, the application of the VNS reaction in the synthesis of heterocyclic systems, especially indoles, is very promising. For example, the reduction of substituted *o*-nitrobenzyl phenyl sulphones leads, as a result of the VNS, to the corresponding amino-derivatives, which are converted into substituted indoles as a consequence of the initial conversion into isonitriles, imidates,[96] or Schiff bases[97] and the subsequent condensation in the presence of a base:

The existing method of synthesis of indoles by the catalytic hydrogenation of derivatives of *o*-nitroarylacetonitriles[98] is of limited importance because of the low availability of the initial compounds. The possibility of synthesising various *o*-nitroarylacetonitriles by direct cyanomethylation via the VNS reaction[64,65,89] makes this method of great value. All the isomeric hydroxy- and alkoxy-indoles have been synthesised in this way.[65]

Nitroindoles can be obtained directly by the VNS reaction from *m*-nitroaniline:



The *m*-nitrobenzoisonitrile obtained is introduced into the VNS reaction with various carbanions; the VNS products formed, in which the functional group-containing methyl substituents are in neighbouring positions relative to the isonitrile group, undergo cyclisation, which leads to nitroindole derivatives.[99]

VI. Conclusion

The data presented in this review permit the conclusion that VNS is an extremely general process for the substitution of hydrogen in electrophilic arenes (predominantly in nitroarenes) by alkyl groups containing functional groups in the α-positions. In this respect, it is possible to deduce a significant similarity between the VNS reaction and the Friedel–Crafts reaction, which takes place via an electrophilic substitution mechanism.

In fact the stoichiometries of the VNS and Friedel–Crafts reactions are similar. Also similar are the types of products obtained, but these processes differ radically in their mechanisms and in the influence of the polarity of the reactants:

Thus, as regards stoichiometry and the results, VNS can be regarded as a process analogous to the Friedel–Crafts reaction but with the reverse polarity of the reactants. It is therefore entirely appropriate to apply the term "umpolung" (reversal of polarity) introduced by Seebach[100] to define the principle of the reversal of the polarity of reactants in organic synthesis. By extending this term to reactions taking place with reversal of polarity, one may say that VNS represents the "umpolung" of the Friedel–Crafts reaction. Apart from these terminological considerations, it must be emphasised that VNS is a process complementary to the Friedel–Crafts reaction, since it makes it possible to substitute a hydrogen atom by carbon-centred substituents in those arenes which are incapable of undergoing electrophilic substitution. Thus a possibility is created for substituting hydrogen by carbon-based residues in virtually any aromatic systems. The general character of the VNS, which is much faster than the usual nucleophilic substitution of the halogens, finally demonstrates the lack of validity of the generally adopted view[1] that the nucleophilic substitution of hydrogen in aromatic systems is a possible phenomenon but is not usual. On the contrary, bearing in mind that the addition of nucleophiles to the carbon atoms of a halogen-substituted aromatic ring takes place at a high rate at the positions containing hydrogen and not halogen atoms and also taking into account the many possibilities for further reactions of the σ^H-adducts obtained in this way, the traditional nucleophilic substitution of the halogen in halogenonitroarenes can be frequently regarded as a side process, developing against the background of the reactions indicated above.[101]

Complexes of oligo(poly)nucleotides with structural anomalies

N G Dolinnaya, O I Gryaznova
Faculty of Chemistry, Lomonosov Moscow State University

ABSTRACT. The results of studies on the structure and properties of DNA-RNA hybrids and complexes of oligo(poly)nucleotides containing non-canonical base pairs or unpaired bases both within and at the ends of the double helix are surveyed. The methods used in the study of such systems are briefly characterised: X-ray diffraction analysis, NMR and UV spectroscopy, circular dichroism, scanning microcalorimetry, etc. A comparative analysis of the influence of the non-canonical pairs on the structure and the energetic and kinetic parameters of the formation and dissociation of the oligonucleotide complexes has been carried out. The question of the stability of the non-canonical pairs as a function of their nature and position in the double helix is considered. The mechanisms of the formation of the hydrogen bonds between the bases of non-complementary pairs are discussed.

The bibliography includes 171 references.

I. Introduction

The interest in the double helix complexes of nucleic acids with various structural anomalies arose in connection with the study of the mechanism of the transmission of genetic information. Thus it has been established that hybrid DNA–RNA duplexes are formed as intermediates in key biological processes—replication, transcription, and reverse transcription.[1,2] The correct "reading" of genetic information is known to be ensured by the complementation interactions of the nucleic acid (NA) bases and is controlled by the corresponding enzyme systems. However, the inclusion of "erroneous" nucleotides, forming non-complementary pairs, nevertheless occurs, although extremely rarely, leading to substitutional mutations.[3,4] On the other hand, non-canonical pairs are formed fairly frequently in codon-anticodon interactions (in the third position of the codon triplet)[5] and also on formation of the secondary or tertiary structures of different RNAs.[6–8] The development of the site-specific mutagenesis served as a powerful stimulus to the study of the spatial disposition and energetic parameters of the non-canonical pairs incorporated in the regular double helix structure. The use of the site-mutagenesis technique makes it possible to achieve point substitutions of nucleotides, deletions, and insertions in specified positions in DNA. The appearance of interest in the study of structures of this type coincided with the development of synthetic nucleotide chemistry and the improvement of modern methods for structural studies. This made it possible in recent years to obtain and to study in detail sets of DNA duplexes with non-canonical pairs and "superfluous" nucleotide units in specified positions. Such compounds are convenient models for the investigation of various cell processes—replication, transcription, translation, and mutagenetic processes. In addition, they are of interest as instruments for the study of enzymes of NA metabolism and the structure and conformational possibilities of NA. The available information about the thermodynamics and kinetics of the formation and dissociation of DNA-duplexes with non-canonical pairs is used widely for the diagnosis of genetic diseases.[9]

The data for the geometry of the pairing of certain types of non-complementary bases and their influence on the parameters of the double helix have been analysed in review articles published in 1987.[10,11] This review considers the structure of the DNA–RNA hybrid structures and NA complexes containing all the investigated combinations of the non-complementary pairs and "superfluous" nucleotide units; the influence of structural anomalies on the thermodynamic and kinetic parameters of complex formation and on the secondary structure of the double helices is considered. The structural anomalies induced by minor or modified bases are not included in the review.

II. Methods used to investigate double helix nucleic acids with structural anomalies

X-Ray diffraction analysis of single crystals (XRDA) and X-ray diffraction in oriented fibres (XRDF). The most complete information about the structure of oligonucleotide duplexes independent of conceptual models can be obtained with the aid of XRDA; high-resolution XRDA (~1.5–2 Å) makes it possible to determine the coordinates of all the non-hydrogen atoms, to observe experimentally the influence of modifications of the local and overall structures of the double helix, and to investigate its hydration shell.[10,12–14] XRDF is used to characterise the double and triple helices formed by polynucleotides[15] and yields much less information than XRDA.

High resolution NMR spectroscopy. Such spectroscopy has been widely used recently to investigate oligomeric duplexes.[16] From the ^{1}H NMR spectra, one can infer the local environment of each

proton, which makes it possible to follow the variation of the conformations of the individual nucleotide pairs as the temperature, pH, etc. are varied. Two groups of resonance proton signals are analysed.

(a) The signals of non-exchanging protons—H(5) and H(6) of the pyrimidine bases, H(2) and H(8) of the purine bases, and the protons of the CH_3 group of thymine and the carbohydrate rings. The thermal dissociation of the duplexes leads to a downfield shift of the signals. The thermodynamic parameters of the helix–coil transition can be calculated from the curves for the temperature dependence of the chemical shifts δ of these proton signals and it is possible to follow the dissociation of each nucleotide pair of the duplex.

(b) The signals of the slowly exchanging protons of the imino-groups N(1)–H of guanine and N(3)–H of thymine (uracil), participating in the formation of hydrogen bonds, are recorded in aqueous solutions. The presence of signals in the region of low fields indicates unambiguously the formation of hydrogen-bonded nucleotide pairs. With increase in temperature, an upfield shift, broadening, and disappearance of the signals take place owing to the increase in the relative content of the open-chain forms and the rapid exchange of the imino-group protons in the open-chain forms with water. The temperature of the disappearance of the signals is not related to the thermodynamic stability of the duplexes and merely yields a comparative characteristic of the stability of the individual nucleotide pairs. The study of the kinetics of the exchange of the imino-protons with water makes it possible to estimate the lifetimes τ of the individual base pairs in the helical complex. The activation energies and the rate constants for the dissociation and formation of individual nucleotide pairs are calculated from the temperature variation of τ.[17]

Measurement of the vicinal spin–spin coupling constants of the protons of the C(1′) and C(2′) atoms makes it possible to estimate the conformation of the carbon rings. Information about the distances between the atomic nuclei can be obtained with the aid of the nuclear Overhauser effect (nOe);[18] the nOe is observed for pairs of nuclei separated by distances not greater than 4 Å.

^{31}P NMR spectra contain data about the conformation of the sugar phosphate skeleton of the oligonucleotide constituting the double helix.

Scanning microcalorimetry (SMC). This is used to determine the thermodynamic parameters of the conformational transition.[19] The enthalpy of the helix–coil transitions ΔH^0 can be obtained directly from the curve for the temperature variation for the heat capacity of the system by calculating the area bounded by this curve. The van't Hoff enthalpy $\Delta H^0_{v\text{-}H}$ can be calculated simultaneously from the same experimental data.[20] It has been suggested that $\Delta H^0_{v\text{-}H}$ corresponds to the enthalpy of the helix–coil transition when the two states model is valid. The difference between the experimental ΔH^0 and $\Delta H^0_{v\text{-}H}$ is evidence that on fusion the system passes through a series of partially bound structures and makes it possible to estimate the length of the cooperatively melting section of the duplex.

UV spectroscopy. The curves for the temperature variation of the UV absorption by the system permit the determination of the melting point (T_m) of the double helix and the calculation of the thermodynamic parameters of the complex formation process. The temperature jump method,[21] based on the analysis of the change in the UV absorption after an abrupt increase in temperature, is widely used to obtain the kinetic characteristics of the helix–coil transition.

Circular dichroism (CD) and optical rotary dispersion (ORD). The interpretation of CD (ORD) data, based mainly on the empirical assignment of the spectra to the known conformations of the polymers, permits conclusions concerning the similarity of the geometrical parameters of the double helix structures and their inclusion in a particular study of Na forms ($\overline{A}$, $\overline{B}$, $\overline{Z}$).

Raman spectroscopy (RS). This spectroscopy makes it possible to estimate the secondary structure of double helix oligo(poly)nucleotides both in solution and in the crystalline states.[22]

Theoretical estimation of the conformation of the oligonucleotide duplexes. This is done by calculating the energies of the non-valence interactions by the method of atom–atom potential functions (AAPF).[23] The minimisation of the energy of the non-valence interactions in terms of different variables (parameters determining the geometry of the pairing of bases and the positions of the pairs relative to the axis of the helix, parameters of the helix, torsional angles, etc.) makes it possible to establish the most probable conformation of the non-canonical pairs and of the duplexes containing such pairs. It is noteworthy that the accuracy of calculations of this kind depends on the number of independent variables considered.

III. Hybrid DNA–RNA complexes

1. The secondary structure of the DNA–RNA hybrids

Natural DNA and synthetic polydeoxyribonucleotides are known to exist in aqueous solution and in fibres with a high relative moisture content in the form of the $\overline{B}$ family; forms belong to the $\overline{A}$ family are characteristic of the double helix RNA. Although both conformational families refer to right-hand helices, they differ sharply in their helix parameters. A significant factor determining the type of secondary structure is the conformation of the sugar: C(3′)-endo(*N*) in the $\overline{A}$ family and C(2′)-endo(*S*) in the $\overline{B}$ family. The only form in which the double helix RNA exists is the *A*-form. The conformational possibilities for DNA are much wider: depending on the conditions in the medium and the nucleotide sequence, the DNA duplexes can exist in the form of the $\overline{B}$ and $\overline{A}$ families, the alternating *B*-form, and the left-hand *Z*-form. It has also been shown that the local parameters of the nucleotide pairs vary within wide limits.[24]

By analysing the available literature data, it is possible to conclude that the DNA–RNA hybrids belong most typically to the $\overline{A}$-family of conformations. However, depending on the nucleotide composition and sequence and also on the complex formation conditions, the hybrid complexes can form structures of a new type—*B*- and *Z*-complexes as well as dimorphous complexes containing elements of both forms (Table 1).

We shall consider in greater detail some of the data presented in Table 1. The conformations of the hybrid heptameric complexes†

*Relative humidity below 80%.
** Relative humidity above 80%.
***I = inosine.

On the basis of the spin–spin coupling constants for the protons of the carbohydrate residues, it has been established that the furanose rings in the "rA.rU" and "rA.dT" complexes are in the *N*-conformation (*A*-form), while the deoxyribose residues in "dA.dT" are in the *S*-conformation (*B*-form). The complex formation reaction between d(C A_5G) and r(C U_5G) leads to the preferential formation of the triple helix d(C A_5G).2r(C U_5G), which belongs to the *A*-family according to CD data.

Under the conditions of a high relative humidity, the polymeric complexes poly(dA).poly(rU) and poly(dI).poly(rC) (in the form of fibres) have unusual diffraction patterns representing a superposition of the reflections corresponding to the *A*- and *B*-forms of the helix.[15] It has been suggested that the carbohydrate residues of the polymeric strands in these complexes have different conformations—of the *N*-type for ribose and of the *S*-type for deoxyribose. A similar dimorphous structure of the DNA–RNA hybrid complex can play an important role in the functioning of the DNA- and RNA-polymerases.

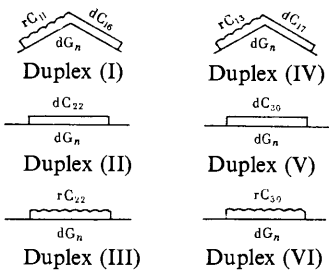
Interesting data have been obtained in studies of poly(rA).poly(dT). This ribo-deoxyribonucleotide hybrid is an analogue of the DNA-duplex poly(dA).poly(dT). The latter retains the *B*-form of the helix even under conditions where the natural non-regular DNA exists in the *A*-form. Apparently the "B affinity" is retained also in the hybrid complex despite the presence in the latter of the conformationally rigid polyribonucleotide chain. The poly(rA).poly(dT) fibres form a helix belonging to the $\overline{A}$ family only for a relative moisture content below 90%.[32] With increase in moisture content, there is a conformational transition to a structure similar to the *B*-form of DNA in terms of geometrical parameters but the structure is dimorphous according to the conformation of the carbohydrate residues.[32,33] It has been shown by ^{1}H NMR, using nOe studies, that in an aqueous buffer solution poly(rA).poly(dT) exists in the *B*-form and the carbohydrate residues in both strands have the same *S*-type conformation.[34] However, owing to the steric hindrance generated by the 2′-hydroxy-group of ribose, the geometry of the hybrid helix differs little from that of the classical *B*-form of the DNA. In particular, the inclination and twist of the bases as well as the distances between the bases and the axis of the helix have increased. It has been found that the *B*-form of the helix in solution is characteristic also of the duplex with the heterogeneous composition d(TCACAT).r(AUGUGA).[36]

The study of the structure of the double helix complexes whose composition includes covalently bound DNA and RNA fragments is of special interest. The mixed composition hybrid with the alternating ribodeoxyribonucleotide sequence poly(rG-dC).poly(rG-dC) is an analogue of the DNA-duplex poly(dG-dC).poly(dG-dC); the latter undergoes a transition into the left-hand *Z*-form at a high ionic strength.[40] At a moderate NaCl concentration, the structure of poly(rG-dC).poly(rG-dC) is analogous to *A*-RNA in terms of geometrical parameters and the conformation of the carbohydrate residues.[37] The transition of the hybrid helix to the *Z*-form occurs, in contrast to its DNA-analogue, both with increase and with decrease in the ionic strength with average *A–Z* transition points at 25 mM NaCl in the low salt region and at 1500 mM NaCl in the high salt region.[37,38] In the presence of tetrabutylammonium ions (> 30 mM) an additional conformational transition of the hybrid complex to the *B*-form is observed.[39]

The hexanucleotide mixed composition duplex

r(G C G)d(C G C)
(C G C)d(G C G)r

forms a helix in the *A*-form in the crystalline state according to RS data[22] and all the carbohydrate residues (both ribose and deoxyribose) have the same *N*-conformation. In aqueous solution, the geometry of the complex is in the main retained, but the deoxyribose rings of the terminal cytidine residues assume an *S*-type conformation, which is associated, according to the authors, with the lower stability of the end pairs and hence their greater conformational mobility.



The secondary structure of the decameric duplex

1 2 3 4 5 6 7 8 9 10
r(G C G)d(T A T A—C G C) ,
(C G C—A T A T)d(G C G)r

in which the double helix tetranucleotide DNA fragment (d.d) is flanked by hybrid sections on both sides, has been investigated.[41,42] According to XRDA data, in the presence of a low water content, this duplex forms a helix which is similar, in terms of geometrical parameters, to the *A*-form of DNA with the same *N*-conformation of the carbohydrate ring.[41] According to the authors, the presence of hybrid sections at the end of the duplex stimulates the transition of the central d.d fragment to the *A*-form. In aqueous solution, the situation is somewhat different.[42] According to ^{1}H NMR data, which made it possible to estimate the ratio of the conformers for each nucleotide unit, all the ribose rings of the above duplex have the *N*-conformation. The existence of the *S*- and *N*-conformers is characteristic of all the deoxyribose residues located in both the hybrid and d.d sections of the duplex, the equilibrium constant

depending on the local environment of the individual nucleotide unit (Fig. 1). The carbohydrate residues dC (in the 8-position), dG (in the 9-position), and dC (in the 10-position), belonging to the hybrid fragment, contain respectively 52, 37, and 33% of the *N*-type conformers. This sequence in the variation of the percentage contents of the *N*-conformers is caused by the greater conformational freedom of the terminal deoxynucleotides. The data obtained permit the conclusion that a conformational transmission effect (the influence of the RNA fragment on the conformation of the carbohydrate rings of the DNA sequence linked to it) is observed with covalently bound DNA–RNA hybrid molecules. In the duplex considered, the effect is extended mainly to the two nucleotide residues dT (in the 4-position) and dA (in the 5-position) and to a lesser extent DT (in the 6-position) and dA (in the 7-position). Consequently there is a smooth transition from the *N*-conformation to the predominatly *S*-conformation. The occurrence of the stacking interaction between the bases along the entire molecule, with the predominance of the "stacking" characteristic of the *A*-form in r(GCG) and the "mixed" type in the d(TATACGC) section, has been demonstrated by ^{1}H NMR spectroscopy.

The structures of the hybrid polymeric-oligomeric duplexes $dG_n.rC_{11}dC_{16}$ and $dG_n.rC_{13}dC_{17}$ ($n > 70$) have been investigated.[43,44] The systems investigated are indicated below in a conventional schematic form.

It follows from the analysis of the ^{1}H NMR spectra of the duplexes (I)–(III) that the two fragments of the duplex (I) form helices with different conformations—the hybrid section of the molecule is in the *A*-form characteristic of the duplex (III) and the (d.d) section is in the *B*-form, like the duplex (II).[43] The CD spectra of the duplexes (IV)–(VI) have led to the analogous conclusion that the *A*- and *B*-forms coexist in the hybrid duplex (IV).[44] Analysis of the fusion curves (UV spectroscopy) shows that, despite the presence of two forms, the helix–coil transition in the duplex (IV) is cooperative and single-phase. According to the authors,[44] the existence of two adjoining conformations in the covalently bound hybrid duplexes (I) and (IV) leads to geometrical distortions—the bending of the axis of the helix at the boundary between the two forms; the transitional region between the *A* and *B* forms then includes only one nucleotide pair, belonging to the DNA fragment, and the phosphodiester linkages adjoining it. Analysis of the geometrical structure of the hybrid duplex (Fig. 2), obtained by computer modelling,[44,45] showed that in the region of the bend in the helix the complementation and interplanar interactions between the bases are retained.

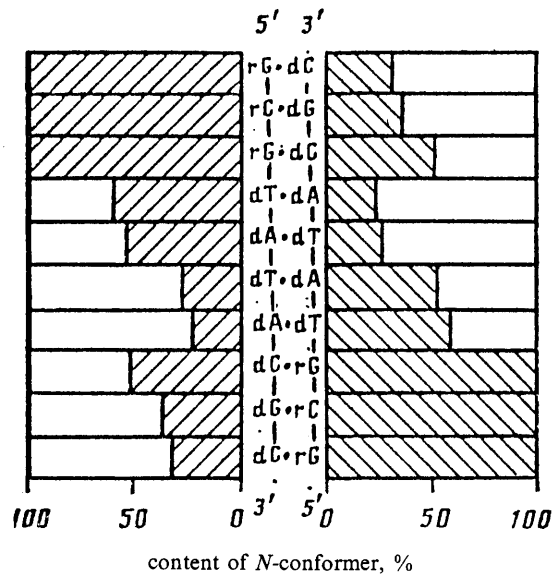


Figure 1. Conformation of the carbohydrate rings of the duplex formed by r(GCG)d(TATACGC) in aqueous solution (according to ^{1}H NMR spectroscopic data).[42]

The conclusions concerning the structure of the covalently bound DNA–RNA hybrid duplexes reached in this series of studies differ from the conclusions arrived at by Mellema et al.[42] for the

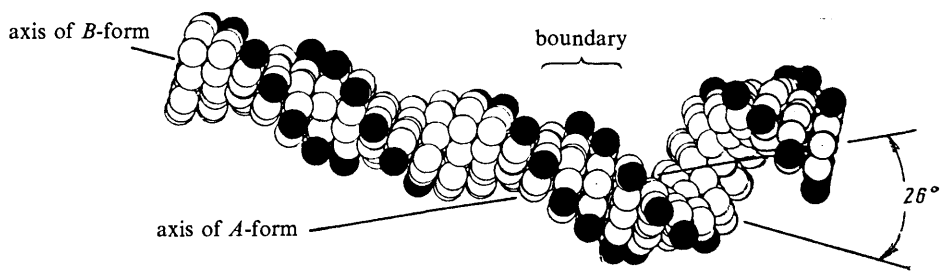

Figure 2. A molecular model of the complex $dG_n.rC_{11}dC_{16}$.[44]

decameric duplex, which can be accounted for by the differences between the lengths of the r.d and d.d sections, the nature of the nucleotide pairs (A.T or G.C) at the "junction" between these sections, and certain assumptions in the interpretation of the data.

2. Thermodynamic and kinetic aspects of the formation of DNA–RNA hybrid complexes

A comparative analysis of the thermodynamics and kinetics of the formation of hybrid double helices and of their DNA and RNA analogues has been performed on the model heptameric complexes "rA.dT", "dA.rU", "dA.dT", and "rA.rU" (see above).[17,30,46] The following duplex stability sequence has been established with the aid of UV and ^{1}H NMR spectroscopy: "dA.dT" > "rA.dT" > "rA.rU" » "dA.rU", which agrees with the stability series for polymeric complexes formed by poly(rA), poly(dA), poly(rU), and poly(dT) in analogous combinations.[47] Comparison of the equilibrium constants ($K_{25°}$) for the formation of the heptameric double helices (Table 2) shows that the duplex "dA.dT" is 10 and 4 times more stable than "rA.rU" and "rA.dT" respectively, while the hybrid duplex "dA.rU" is almost 200 times less stable than "rA.dT". It has been suggested[30] that the *S*-conformation is preferred for the dA clusters and the latter cannot therefore form stable DNA–RNA hybrids. According to the authors, the presence of such clusters facilitates the termination of transcription.

Table 2. Thermodynamic and kinetic parameters of the formation of hybrid oligomeric duplexes and the corresponding ribo- and deoxyribo-nucleotide analogues.

Parameter	«rA·dT»	«dA·rU»	«dA·dT»	«rA·rU»	Refs.

Note. Complex formation conditions: 0.01 M phosphate buffer, pH 7, 0.1 mM EDTA, 0.2 M NaCl, $c_0 = 2 \times 10^{-4}$ M; the structures of the duplexes are shown in the text.

Kinetic parameters[17,46] have confirmed the thermodynamic data concerning the stability sequence of the duplexes "dA.dT", "rA.rU", and "rA.dT". The rate constant (K_r) for the formation of the duplex "dA.dT" is a little greater than the approximately equal corresponding constants for the duplexes "rA.rU" and "rA.dT" (Table 2). It has been suggested that this can be accounted for by the slower formation of the stacking-conformation in the ribonucleotide chain.[46,48] On the other hand, the approximate quality of the activation energies ($E_{a,r}$) for the formation of the above duplexes (Table 2) suggests identical mechanisms of the association of the ribo- and deoxyribo-nucleotide strands. The kinetic parameters characterising the dissociation of the double helices differ appreciably (Table 2). The rate constant (K_d) for the dissociation of the duplex "dA.dT" is appreciably lower than the corresponding values determined for the duplexes "rA.rU" and "rA.dT". This feature has been confirmed by the results of studies of the kinetics of the exchange of the imino-protons with water:[17] it has been established that the values of τ for the non-terminal pairs of the duplexes "rA.rU" and "rA.dT" are approximately the same and significantly lower than τ for "dA.dT".

According to ^{1}H NMR data, the end "fraying" effect, i.e. the rapid formation and breakdown of hydrogen bonds between the bases at the end of the duplex under the conditions of the thermodynamic stability of the double helix, is observed for these duplexes. It is essential to emphasise that the "fraying" of the end pairs is characteristic of RNA, DNA, and hybrid duplexes to approximately equal extents.

Overall, the data concerning the comparative stabilities of the hybrid, ribonucleotide, and deoxyribonucleotide complexes are ambiguous. For the majority of systems investigated, it has been shown that the hybrid duplexes are less stable than DNA and RNA of the same composition. For polymeric complexes, the difference is very small and amounts to 2–4 °C.[25,26,28,47,49] In oligomeric systems, the difference is more clear cut. Thus T_m for the complexes $rA_n.pdT_9$ (n = 6–9) is on average lower by 7 °C than T_m for $dA_n.pdT$ with the same n.[50]

On the other hand, other relative stabilities of the hybrid duplexes have been established in a number of studies. For example, the stability of the polymeric complexes, formed by different combinations of poly[d(r)I] and poly[d(r)C], varies in the sequence poly(rI).poly(rC) > poly(rI).poly(dC) > poly(dI).poly(dC) > poly(dI).poly(rC),[51] while for covalently bound DNA–RNA hybrids of the type $dG_n.rC_idC_k$, the following stability series has been determined: $dG_n.dC_{30} < dG_n.rC_{13}dC_{17} < dG_n.rC_{30}$.[44]

Analysis of the rates of exchange of the imino-proton duplexes poly(rA).poly(dT), poly(dA).poly(rU), poly(rA).poly(rU), and poly(dA).poly(dT) for deuterium[52] makes it possible to determine the ratios of the rates of dissociation of these complexes and hence their relative stabilities—poly(dA).poly(dT) > poly(dA).poly(rU) ⩾ poly(rA).poly(rU) > poly(rA).poly(dT). The relative stabilities of the hybrid complexes and their DNA and RNA analogues apparently depend on the nucleotide composition.

Generalising the literature data on the DNA–RNA hybrid complexes, the following conclusions can be reached:

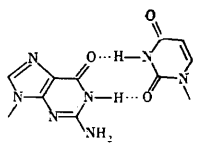
1. The conformationally more rigid ribonucleotide chain has a dominant influence in the majority of systems investigated on the geometrical structure of the duplex as a whole and also on the conformation of the carbohydrate rings of the deoxyribonucleotide residues (complementary with respect to the ribo-fragment or covalently bound to it).

2. A dimorphous structure, i.e. different conformations of the ribo- and deoxyribo-nucleotide strands of the helix, is characteristic of a series of hybrid duplexes and triplexes formed by homopolymers.

3. According to thermodynamic and kinetic properties, the hybrid complexes are closer to the double helix RNA than to the DNA.

IV. Complexes of nucleic acids with non-canonical base pairs

In the analysis of the literature data on complexes of NA containing non-canonical base pairs, attention has been concentrated on the following questions:



1. The mechanism of the pairing of the bases in the non-canonical pairs.

2. The influence of modification on the interplanar interactions of the bases and on the conformation of the sugar phosphate skeleton; the influence of the non-complementary pair on the secondary structure of the double helix.

3. The thermodynamic and kinetic parameters of the formation and dissociation of the modified oligomeric duplexes.

1. The dG.dT(G.U) pair

The possibility of the existence of the non-canonical G.U pair, stabilised by hydrogen bonds, was first postulated by Crick to account for the degeneracy of the genetic code.[53] He also put forward a mechanism of the formation of hydrogen bonds between the guanine and uracil residues:

G (*anti*) U (*anti*) .

Subsequently the study of various model systems, containing G.U(T) pairs, by modern experimental and theoretical methods confirmed the validity of the proposed mechanism.

Calculation of the conformations with the aid of AAPF and the construction of molecular models[23,54,55] showed that the bases of the dG.dT pair are in the usual tautomeric forms and have the *anti*-orientation relative to the carbohydrate rings. The inclusion of the dG.dT pair in the double helix does not reduce the interatomic contacts and induces only a small increase in the energy of the non-valence interactions and a slight deviation of the angles of the sugar phosphate skeleton from the standard values characteristic of the Watson–Crick helix.

An experimental study of the molecular structure of the dG.dT pair and of its influence on the conformation and the thermodynamic and kinetic parameters of the DNA double helix has been carried out by Patel and co-workers[56–60] in relation to the dodecameric duplex "GT":

```
  1 2  3  4 5 6 6' 5' 4' 3'  2' 1'
d(C G |T| G A A T T C |G| C G)
  G C |G| C T T A A G |T| G C)d
```

duplex "GT" .

The unmodified duplex "GC",[61] formed both in solution and in a crystalline state, having the helix in the *B*-form,[62,63] was used as a control:

```
  1 2 3 4 5 6 6' 5' 4' 3' 2' 1'
d(C G C G A A T T C G C G)
 (G C G C T T A A G C G C)d
```

duplex "GC" .

The presence in the ^{1}H NMR spectrum of the duplex "GT" of two signals due to imino-protons corresponding to the dG.dT pair, which are located in a stronger field than the signals due to the dG.dC pair in the same position in the duplex "GC", indicates unambiguously the existence of two hydrogen bonds with carbonyl acceptor groups between the guanine and thymine residues. This confirms the structure of the dG.dT(G.U) pair presented above and rules out interactions with participation of rare tautomeric forms of the bases. The inclusion of the dG.dT pair leads to the breakdown of the interplanar interactions of the bases of this pair, in particular the thymine residue, with the neighbouring bases. According to ^{31}P and ^{1}H NMR data, the conformational perturbations introduced by the dG.dT pair are localised in the modifcation section and involve only the nearest nucleotide pair from the 3′-end.

The replacement of two dG.dC pairs in the duplex "GC" by the dG.dT pairs induces a decrease in the T_m of the duplex by 20 °C, but the enthalpy of the transition from the double helix state to the single helix state does not then change (see Table 4 below). Accoring to the authors, this is associated with a slight breakdown of the stacking interactions in the duplex "GT". The closeness of the ΔH^0 and the difference between the T_m for the duplexes "GC" suggest that the destabilising influence of the dG.dT pair is entropic in nature. It has been established on the basis of the difference between the values of $\Delta H^0_{v\text{-}H}$ and ΔH^0, determined from the heat absorption curves (SMC), that the cooperatively melting section, both in the duplex "GC" and in the duplex "GT", comprises 9 nucleotide pairs, i.e. it embraces the modification sections. According to ^{1}H NMR data, the end "fraying" effect, involving the nucleotide pairs in the 1- and 2-positions, is observed in the duplexes "GC" and "GT". The presence of the dG.dT pair increases this effect, as a result of which a broadening and disappearance of the signals due to the imino-protons of the dG.dC pairs (in the 1- and 2-positions) in the duplex "GT" takes place at lower temperatures than in the duplex "GC". Comparative analysis of the kinetic data for the exchange of the imino-protons of the duplexes "GT" and "GC" confirms this conclusion that the region corresponding to the spreading of the structural perturbations introduced by the dG.dT pair is limited only by the pair adjoining the non-canonical pair [at 35 °C, τ for the dG.dT pair and the neighbouring dG.dC pair (position 4) of the duplex "GT" are smaller by factors of 10 and 2 respectively than τ for the pairs in the same positions in the duplex "GC"]. The activation energy for the formation of the duplex "GT" has been determined by the temperature jump method[64] and proved to be much higher (22 kcal mol^{-1}) than the same parameter of the unmodified double helix.[65] On this basis, the authors suggested that the formation of the dG.dT and dG.dC pairs (in the 4-position) in the duplex "GT" can be accompanied by conformational adjustments requiring additional energy.

The influence of non-canonical pairs on the thermodynamic and kinetic parameters of the formation of the hexadecameric duplex has been investigated.[66] The hexadecanucleotide d(CAACTTGATATTAATA), which corresponds to the fragment of the bacteriophage ΦX174, was adopted as a basis. Together with the complementary sequence, it forms the protein binding section of the gene *A*. The structure of the initial complementary complex and the studied replacements of the canonical pairs by the dG.dT pair are presented below:

```
   1 2 3 4 5  6 7 8 9 10 11 12 13 14 15 16
d (C A A C T T G A T A T T A A T A)
  (G T T G A A C T A T A A T T A T) d
```

duplex "6TG" duplex "7GT" duplex "12TG" .

All the duplexes containing the dG.dT pair have T_m lower than that of the duplex "O" (see the duplexes 6–8 and 12, Table 4), the destabilising effect being greater for the substitution of the dG.dC pair by a non-complementary pair compared with the analogous substitution of the dA.dT pair and also when the substituted pair is located closer to the centre of the duplex. The dG.dT pair, substituting the dA.dT pair in the 12-position (the duplex "12TG"), indicates the smallest destabilisation. The smaller difference between the free energies of formation (ΔG) of the duplex "O" and the duplexes "6TG", "7GT", and "12TG" ($\Delta\Delta G \simeq 3$ kcal mol^{-1}, Table 4) indicates an insignificant disturbance of the stacking interactions of the bases by the dG.dT pair. The study of the kinetics of the formation and association of the duplexes "O" and "7GT" shows that the perturbations introduced by the G.T pair increase the rate constant for the dissociation of the duplex, while the formation rate constants remain almost the same. The destabilisation of the "7GT" duplex is apparently associated with the increase in the rate of dissociation.

Using the nOe technique, the A.T-rich duplex, containing the inner dG.dT pair, has also been investigated:[67]

d(AAATT|T|TCAAA)
(TTTAA|G|AGTTT)d .

Apart from determining the geometry of the dG.dT pairing, information was obtained in the above study about the degree of hydration of the small groove in the vicinity of the non-complementary pair.

A recent X-ray diffraction study of a synthetic dodecamer in the *B* form with two dG.dT pairs,

d(CGC|G|AATT|T|GCG)
(GCG|T|TTAA|G|CGC)d ,

confirmed that the structural changes induced by these non-complementary pairs are local in character and hardly disturb the overall conformation of the duplex.[68] Nevertheless, precisely this combination of bases (the dG.dT, dA.dC, and dA.dG pairs were compared) forms the most asymmetric pair (a characteristic feature of the Watson–Crick pairs is the presence of a twofold pseudoaxis located in the plane of the bases). This can be the cause of the effective repair of the dG.dT pair by the corresponding enzyme systems "recognising the deviations from the pseudosymmetry.[10,68] It is noteworthy that the dG.dT pair is also effectively discriminated by a restriction enzyme. Thus the replacement of the dG.dC pair by dG.dT or dG.dU in the recognition section of a series of restriction endonucleases leads to a sharp decrease and in some cases to a complete inhibition of the cleavage of the modified DNA duplexes.[69,70]

Two octameric duplexes having identical compositions but differing in the positions of two dG.dT pairs served as the object of study of the influence of the local environment of the dG.dT pairs on the conformation and stability of DNA in the *A* form:[12,71–73]

d(GG|G|GC|T|CC)
(CC|T|CG|G|GG)d
I

d(GGG|G||T|CCC)
(CCC|T||G|GGG)d .
II

A characteristic property of the DNA duplexes containing GG and CC clusters is that in the crystalline state they form a helix in the *A* form.[74] It has been demonstrated by XRDA that the inclusion of the dG.dT pairs leads merely to a slight distortion of the sugar phosphate skeleton of the molecule and that the deformation generated is localised in the modification section and is limited to the nearest phosphodiester linkages. The stacking interactions in the region of the non-canonical pair are disturbed mainly by the decrease in the overlap of the bases of the dG.dT pair with those of the neighbouring pair from the 3′-end, while the "stacking" with the nearest "neighbour" in the 5′-position is retained in almost the same form as in the unmodified duplex. The thermodynamic stabilities of the crystal structures of the duplexes (I) and (II) differ appreciably—the crystals of the duplex (II) are stable at room temperature while those of the duplex (I) melt at 6 °C. According to the authors, one of the causes of the difference between the stabilities of the duplexes is the reduced contribution of the stacking interactions to the stabilisation of the structure of the duplex (I). In the duplex (I), the dG.dT pairs are separated by two dT.dC pairs and the stacking interactions are then disturbed in four out of the seven sites of the interplanar contacts between the base pairs, while in the duplex (II), where the dG.dT pairs are located next to each other, such perturbations occur at only three sites. The different destabilisations of the duplexes (I) and (II) can also be associated with the different states of the hydration shells. In particular, it has been shown that in the duplex (I) there are no bridging hydrogen bonds stabilising the dG.dT pairs. On the basis of these data, it is concluded that the consecutively arranged dG.dT pairs destabilise the double helix less than the isolated pairs.[12,71–73] The influence of the dG.dT pairs on the structure of DNA in the *Z* form has been investigated by the XRDA method in relation to the hexameric duplex[75]

d(C|G|CG|T|G)
(G|T|GC|G|C)d .

Despite the smaller flexibility of the sugar phosphate skeleton of *Z*-DNA compared with *B*-DNA, the non-complementary pair is incorporated in the *Z*-helix virtually without distorting it. It has been shown that the alternation of the conformations of the glycosidic linkage (*syn*-, *anti*-) and of the furanose ring (*N*- and *S*-) is virtually preserved in the nucleotide residues of the duplex, although in the dG.dT pair the deoxyribose of guanosine has the non-characteristic C(4′)-*endo*-conformation. The dG.dT pair, incorporated in the *Z*-helix, not only does not impair the interplanar interactions, but actually stabilises them to some extent, because a more complete overlap of the guanine and thymine residues with the bases of the neighbouring pairs is observed compared with the dG.dC pair located in the same position in the unmodified duplex. It has been established that the hydration shell of the duplex plays an important role in stabilising the dG.dC pair. Bridging hydrogen bonds are formed with participation of water molecules between N(2) and O(6) of guanine and between O(2) and O(4) of thymine respectively, compensating partly for the absence of such a bond in the dG.dT pair compared with the dG.dC pair.

It is noteworthy that the structure of the hydration shell in the vincinity of the non-complementary pair hardly depends on the form of DNA (*A*, *B*, or *Z*).[10,68]

We shall also note briefly certain studies in which the influence of the dG.dT pairs on oligomeric duplexes has been analysed. According to ^{1}H NMR data, the dinucleotides pd(GT) and pd(TG) do not form complexes in solution under conditions where the self-complementary dinucleotides are associated with formation of mini-duplexes.[76,77] On the other hand, the polymer poly[d(GT)] can exist in solution in the form of a double helix.[78–80] This has been demonstrated by UV, CD, and ^{1}H NMR spectroscopy, and also on the basis of the binding of ethidium bromide.

Data characterising the destabilising influence of the dG.dT pairs on oligomeric duplexes have been published.[50,81,82]

A series of studies have been devoted to the ribonucleotide complexes containing the G.U pair. According to XRDA data, the terminal G.U pairs in the tetrameric duplex

r(G GC U)
(U CG G)r

hardly disturb the stacking interactions of the bases.[83]

Table 3. Thermodynamic parameters of the varied nucleotide pair in the octadecameric DNA duplex.[127]

* T_m was measured in 1 mM cacodylate buffer (pH 7.1) containing 0.5 M NaCl, 0.1 M EDTA, and nucleotide at a concentration of 0.3 A_{260}/ml.

The influence of the G.U pair and of its local environment on the stability of pentanucleotide double helices has been investigated.[84,85] The series of duplexes investigated are presented below:

r(C A G U G) (G U U A C)r	r(A G G C U) (U C U G A)r
duplex "5GU"	duplex "5*GU"
r(C A A U G) (G U U A C)r	r(A G A C U) (U C U G A)r
duplex "5AU"	duplex "5*AU"
r(C A G U G) (G U C A C)r	r(A G G C U) (U C C G A)r
duplex "5GC"	duplex "5*GC"
series I	series II .

In the series I duplexes, the central pair is flanked by the A.U pairs, while in the series II duplexes it is flanked by G.C pairs. It has been shown that all the series II complexes are more stable than the corresponding series I complexes. According to ^{1}H NMR data, the T_m of the G.U pair in the duplex "5GU" is lower by 4 °C than the T_m of the remaining pairs, i.e. the G.U pair is a region of local instability of the duplex, while in the duplex "5*GU" the G.U pair has the same T_m as the remaining pairs. The substitution of the central complementary pair by G.U in the series I duplexes reduces their stability the destabilisation being greater on replacing the G.C pair (the T_m of the duplexes "5GU", "5GC", and "5AU" are respectively 23, 38, and 28 °C). In the series II duplexes, the destabilising influence of the G.U pair is much smaller and is manifested solely on substitution of the G.C pair; the replacement of A.U by G.U hardly affects the stability of the double helix (the T_m of the duplexes "5*GU", "5*GC", and "5*AU" are respectively 44, 54, and 45 °C). According to the authors,[85] the different effects accompanying the inclusion of the G.U pair between the A.U or G.C pairs are associated with the fact that the interplanar interactions between the bases of the G.U pair and the pairs flanking it are disturbed to a greater extent in the duplex "5GU" than in the duplex "5*GU".

A comparative analysis of the thermodynamic parameters of the formation of oligomeric duplexes containing G.U pairs and of the unmodified duplexes containing A.U pairs in the same positions (see the duplexes 34–49 in Table 4) has been carried out[86] and it has been established that the substitution of the A.U pair by G.U reduces the stability of the complex, such decrease depending on its composition, nucleotide sequence, and the position of the G.U pair in the oligomer chain and its local environment. The destabilisation of the complexes induced by such substitution is mainly enthalpic in nature, although a decrease in the stability of duplexes containing adjoining G.U pairs is associated with the unfavourable alteration of the entropy of complex formation (Table 4).

The destabilisation effect of the replacement of the canonical pairs by the G.U pair has also been pointed out in a number of others studies.[5,87–89] However, the formation of the G.U pair is thermodynamically more favourable than the appearance of other non-canonical pairs under the same conditions. Thus the pentaribonucleotide AGGCU forms on self-association the duplex "GU" with two G.U pairs and not the duplex "GG" with a single G.G pair:[85]

r(A G GC U) (U CG G A)r	r(A G G C U) (U C G G A)r
duplex "GU"	duplex "GG"

A similar conclusion concerning the preferential formation of the G.U pairs before the G.G pairs was reached by Uhlenbeck et al.[90]

The study of the influence of the terminal G.U pairs on the thermal stability of RNA duplexes showed that the contribution of the free energy of the G.U pair, flanking the tetrameric GC-containing core, is approximately equal to the contribution of the terminal A.U pair and is smaller by ~1 kcal mol^{-1} than the contribution of the G.C pair.[91] Other terminal non-complementary pairs (A.A, A.C, A.G, and U.U) are less stable than the corresponding Watson–Crick pairs. Furthermore, it has been shown that the terminal G.U pair is more stable if it contains 5′-G and 3′-U but not conversely.[91]

The thermal stabilities and conformational characteristics of the polymeric complexes of the ribo- and deoxyribo-series, consisting of the G.U or dG.dT pairs, i.e. poly[r(GU)] and poly[d(GT)], have been compared on the basis of CD data.[79] It was established that the DNA duplex is formed at a higher ionic strength (0 °C, 0.1 M NaCl) than its ribo-analogue (0 °C, 0.02 M NaCl). In the NaCl concentration range from 0.1 to 1 M, the poly[d(GT)]$_2$ helix undergoes conformational rearrangements (within the limits of the *B*-form), which entails a smooth variation of the CD spectrum. The relative stabilities of the duplexes depend on the ionic strength of the buffer: the ribonucleotide duplex is more stable in 0.1 M NaCl, the T_m for poly[r(GU)] and poly[d(GT)] being 14 and 3 °C respectively, while the deoxy-analogue is more stable in 1 M NaCl (the T_m are 23 and 30 °C). However, these duplexes are much less stable than the duplexes formed by the self-complementary polymers—poly[r(AU)] and poly[d(AT)] (the T_m for the latter in 0.1 M NaCl are 65 and 57 °C respectively).

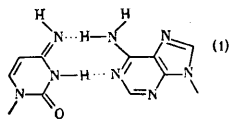
2. The A.C pair

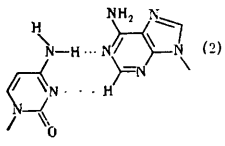


The structure of the dA.dC pair and its influence on the conformation and stability of the DNA duplex "AC"

1 2 3 4 5 6 6′ 5′ 4′ 3′ 2′ 1′
d(C G C | G A A T T C | A C G)
(G C A | C T T A A G | C G C)d

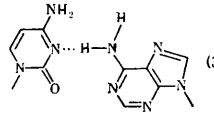
duplex "AC"

have been investigated.[92]



The theoretically possible ways in which the bases can be paired are illustrated below:

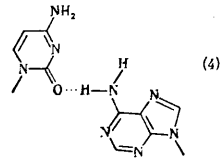
(1)



C (*anti*).A (*anti*)

;

(2)

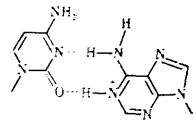


C (*anti*).A (*anti*)

(3)

C (*anti*).A(*anti*)

;



(4)

C (*anti*).A(*anti*)

.

The ^{1}H NMR spectrum of the duplex "AC" contains no signals due to the exchanging protons of the dA.dC pair and Scheme (1), postulating the involvement of the cytosine enolic form in the formation of the hydrogen bond, does not therefore reflect the real structure. The absence of an nOe between the H(2) atom of the adenine in the dA.dC pair and the imino-protons flanking the defect in the dG.dC pairs rules out the orientation of the bases illustrated in Scheme (2). The authors suggest that the dA.dC pair is stabilised by one hydrogen bond between the N(6)-imino proton of adenine and the N(3) atom [Scheme (3)] or the O(2) atom [Scheme (4)] of

cytosine. However, one cannot rule out the possibility of the protonation of the N(1) atom of adenine, which leads to the formation of a second hydrogen bond between the $N^+(1)$–H group of adenine and the O(2) atom of cytosine [Scheme (5)]:

C(*anti*).A^+(*anti*)

The location of the H(6) and H(5) signals of the cytosine in the dG.dC pair adjoining the non-canonical pair (4-position) of the duplex "AC" in a stronger field compared with the signal of the corresponding protons in the duplex "GC" (see above) is evidence of the disturbance of the stacking interactions in the region of the non-canonical pair. It has been suggested that one or both bases of the dA.dC pair are outside the helix. Significant distortions of the sugar phosphate skeleton of the duplex "AC" around the dA.dC pair have been observed by ^{31}P NMR.

The replacement of two dG.dC pairs in the duplex "GC" by the dA.dC pairs reduces the T_m of the duplex by 30 °C (Table 4). According to ^{1}H NMR data, the presence of the dA.dC pair in the third position in the duplex "AC" results in the "fraying" of the dG.dC pairs in the first and second positions of this duplex at lower temperatures than in the duplex "GC". The study of the kinetics of the exchange of the imino-protons of the duplex "AC" with water established τ for the dG.dC pair in the fourth position and for the dA.dT pairs in the fifth and sixth positions are smaller by factors of 3 and 2 respectively than τ for the analogous pairs of the duplex "GC". Consequently, the destabilising influence of the dA.dC pairs is not restricted to the neighbouring pair but involves the entire molecules of the duplex "AC".

However, different conclusions were reached concerning the character of the influence of the non-complementary dA.dC pair on the local and overall DNA structure after a deeper study of the structure of the duplex "AC" and its isomer

d(CG|A|GAATTC|C|CG)
(GC|C|CTTAAG|A|GC)d

by ^{1}H and ^{31}P NMR spectroscopy and after the estimation of the interatomic distances from nOe data.[93] Thus it is clear that the A and C residues are incorporated in the double helix, participating in stacking interactions with the neighbouring bases and inducing only local conformational rearrangements which do not extend to the central AATT segment. The results obtained do not permit a choice between the two A.C pairing schemes (3) and (5).[93]

This interpretation agrees well with the conclusions reached in a study[94] where the defective duplex

d(CGC|C|GC|A|GC)
(CG|A|CG|C|CGC)d

containing two dA.dC pairs was investigated by NMR spectroscopy and studies[95,96] devoted to the XRDA of the duplex "CA" whose nucleotide sequence is similar to that of the duplex "AC":

d(CGC|A|AATT|C|GCG)
(GCG|C|TTAA|A|CGC)d
duplex "CA".

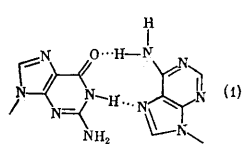
It has been established that, when the dA.dC pair is integrated in the DNA, the stacking interaction with the bases of the neighbouring pairs and the conformation of the sugar phosphate skeleton are only insignificantly disturbed. According to XRDA data, Scheme (5), involving the protonation of adenine, is preferred for the A.C pairing; the important role of bridging hydrogen bonds, with participation of the water molecules incorporated in the hydration shell of the duplex, in the stabilisation of the dA.dC pair has been emphasised.

A comparative analysis of the formation of complexes by 11-, 14-, and 17-unit oligonucleotides with the DNA ΦX174 and a mutant DNA in which a G–A point substitution had been carried out, has been performed.[97] The modified complexes investigated are indicated below:

d(AACA|C|CCTATG)
(...CTTTGT|A|GGATACCC...)d
complex "11AC"

d(AACA|C|CCTATGGGA)
(...CTTTGT|A|GGATACCCTCG...)d
complex "14AC"

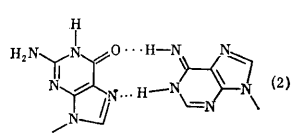
d(AACA|C|CCTATGGGAGCG)
(...CTTTGT|A|GGATACCCTCGCTTT...)d
complex "17AC".



(The complexes with the non-mutant DNA containing the complementary dG.dC pair are designated respectively by "11GC", "14GC", and "17GC".) It was demonstrated that the degree of binding of all three oligonucleotides to the mutant DNA is much weaker than to the natural DNA. Furthermore, the duplexes containing the dA.dC pair are much less stable than their complementary analogues. The replacement of one dG.dC pair by dA.dC is equivalent as regards destabilisation to the removal of three nucleotide pairs (the temperatures of the half-dissociation of the complexes "17AC" and "14GC" and also "14AC" and "11GC" are 43 and 41 °C and 32 and 33 °C respectively).

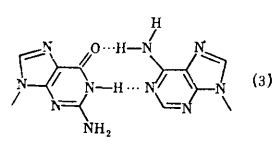
The destabilising influence of the dA.dC pairs on the DNA duplexes has also been noted in other studies.[66,81,98]

The replacement of dG.dC pair by dA.dC in the recognition section of restriction endonucleases SmaI, KpnI leads to the complete inhibition of these enzymes.[70]



3. The purine–purine pairs

The following schemes for the formation of hydrogen bonds in the dG.dA pairs have been analysed in the literature:



(1)

G (*anti*).A (*syn*)

(2)

G (*syn*).A (*anti*)

(3)

G (*anti*).A (*anti*) .

Theoretical analysis of the conformations of the DNA duplexes showed that the structures (1) and (3) correspond to minimum energies of non-valence interactions.[54,55]

The relative disposition of the bases in the dG.dA pair has been studied experimentally in three model systems. The structure of the dodecameric duplex "GA" has been investigated by NMR spectros-

copy in solution:[99]

1 2 3 4 5 6 6′ 5′ 4′ 3′ 2′ 1′
d(C G | Ā | G A A T T C | Ḡ | C G)
(G C | G | C T T A A G | A | G C)d
duplex "GA".

The nOe between the H(2) atom of the adenine in the dG.dA pair and the imino-protons of the neighbouring dG.dC pairs indicates the *anti*-conformation of adenosine [Scheme (2) and (3)]. The absence of an nOe between the H(2) and H(8) atoms of adenine and guanine respectively rules out the relative disposition of the bases illustrated in Scheme (2). On the basis of these data, the authors conclude that Scheme (3) actually obtains. A similar conclusion concerning the relative orientations of the bases in the dG.dA pair was reached in a study[100] where a decameric duplex containing two adjoining dG.dA pairs was investigated by ^{1}H NMR:

d(C C A A | Ḡ | | Ā | T T G G)
(G G T T | A | | G | A A C C)d .

The same duplex has been investigated by XRDA.[101] It was found that in the crystalline stage too both nucleotide residues of the non-canonical pair are in the *anti*-conformation, the bases being retained by two hydrogen bonds [Scheme (3)]. A distinct propeller disposition of the bases (the bases are rotated relative to one another by 24.8°) is characteristic of the dG.dA pair in this conformation, which facilitates pairing. Despite the fact that the distance between the C(1′) atoms of adenine and guanine is greater by 2 Å than in the Watson–Crick pair, the block consisting of two dG.dA pairs is fairly effectively incorporated in the double helix. The small changes in the individual torsional angles of the sugar phosphate skeleton observed under these conditions are within the limits characteristic of canonical pairs.

A different geometry of the dG.dA pairing with the *syn*-conformation of adenine [Scheme (1)] arises in the dodecameric duplex "AG", whose primary structure is similar to that of the duplex "GA":[13,102]

d(C G C | Ḡ | A A T T | Ā | G C G)
(G C G | A | T T A A | G | C G C)d
duplex "AG".

This investigation was also carried out by XRDA. It is significant that the incorporation in *B*-DNA of the pair dG.dA in which the nucleotide residues have respectively the *anti*- and *syn*-conformations is accompanied by a minimal adjustment of the parameters of the sugar phosphate skeleton. It has been postulated that the realisation of a particular pairing scheme [(1) or (3)] may depend on local conditions, because, according to theoretical calculations, the energy difference between these two states of the dG.dA pair is small.[101]

It has been established that the dG.dA pair, both in the state (1) and in the state (3), is incorporated in the double helix virtually without disturbing the interplanar interactions.[13,99–102]

The destabilising influence of the dG.dA pair is shown by the decrease in the T_m of the duplex "GA" by 17 °C compared with the duplex "GC" (Table 4). Data for the exchange of the imino-protons of the duplex "GA" with water have shown that the perturbations introduced by the dG.dA pair are local in character and involve only the neighbouring dG.dC pair in the fourth position.[99]

Experimental data for the molecular structure of the dA.dA pair have been obtained recently in a NMR study of the DNA duplex:[103]

d(C C C | Ā | G G G)
(G G G | A | C C C)d .

It has been shown that stable hydrogen bonds are not formed between the bases of the non-complementary pair. The incorporation of the dA.dA pair in the double helix is achieved via the stacking interaction of the adenine bases with the neighbouring bases and is accompanied by the displacement of the adenine residues from the plane in order to reduce the overlap of the opposite imino-groups and also by an appreciable distortion of the sugar phosphate skeleton.

The structure of the G.G pair in the NA duplexes has not been investigated by experimental methods.

Purine–purine pairs induce a marked destabilisation of the double helices (Table 4). Comparison of the thermal stabilities of the oligomer-polymeric complexes $dG_n.dC_{12}A_mC_x$ and $dG_n.dC_{10}G_mC_x$ (n = 100, m = 0–6, x = 5–41) having different numbers of consecutively arranged dG.dA or dG.dG pairs shows[104] that the destabilisation of the duplexes is proportional to the number of non-canonical pairs. The inclusion of one dG.dA or dG.dG pair induces a decrease in the T_m complex corresponding to the removal of on average three dG.dC pairs. However, the presence of the dG.dA or dG.dG pairs in the central section of the complex does not disturb the cooperative nature of fusion. Such non-canonical pairs are apparently incorporated in the regular double helix and participate in stacking interactions both with one another and with neighbouring dG.dC pairs.

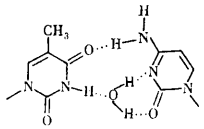
The influence of the local environment on the destabilising effect of the A.A and G.G pairs has been demonstrated.[84,85] According to ^{1}H NMR spectroscopic data, pentaribonucleotide complexes of the type

r(C A | X̄ | U G)
(G U | X | A C)r

with central A.A and G.G pairs flanked by A.U pairs are not formed. On the other hand, the relatively stable duplex "5*AA" (T_m = 26 °C), in which the A.C pair is surrounded by G.C pairs, is formed:

r(A G | Ā | C U)
(U C | A | G A)r
duplex "5*AA".

4. Pyrimidine–pyrimidine pairs



Conformational analysis of the DNA duplexes using AAPF showed that the formation of a dimer stabilised by a hydrogen bond is possible for each pyrimidine–pyrimidine pair.[23,54,55]

The molecular structure of the pyrimidine–pyrimidine pair has been little investigated by experimental methods. The results of a NMR spectroscopic study of the dodecameric duplex "CT"[105]

1 2 3 4 5 6 6′ 5′ 4′ 3′ 2′ 1′
d(C G | C̄ | G A A T T C | T̄ | C G)
(G C | T | C T T A A G | C | G C)d
duplex "CT"

established that the dC.dT pair is retained by two hydrogen bonds: a full hydrogen bond between the NH_2 group of cytosine and the O(4) atom of thymine and a weak hydrogen bond between the

N(3)–H group of thymine and the electron-accepting groups of cytosine with participation of a water molecule:

T (*anti*).C (*anti*).

The replacement of two dG.dC pairs in the duplex "GC" (see above) by the dC.dT pairs reduces T_m by 30 °C (Table 4), the destabilising influence of the dC.dT pair involving all the inner base pairs of the duplex "CT". According to data for the rate of exchange of the imino-protons of the duplex "CT" with water, the lifetimes of the dG.dC (in the 4-position) and dA.dT (in the 5- and 6-positions) pairs are respectively smaller by a factor of 10 and 6 than the values of τ for the analogous pairs in the duplex "GC".

The destabilisation of the oligomeric complexes induced by the replacement of dA.dT by the dC.dT pair is also indicated by the results of other studies[50,66] (see the duplexes 6 and 11 in Table 4).

The existence of U.U pairs stabilised by a hydrogen bond has not been demonstrated experimentally. UV-photohydration and photodimerisation data for the polymeric complexes poly(U).poly(A,U) have led to the conclusion[106] that the uridine residues in poly(A.U) are outside the helix and do not participate in the stabilisation of the secondary structure. It has been demonstrated on molecular models that the formation of such inner loops does not induce appreciable structural changes in the double helix.[107] The increase in the content of uridine residues in the copolymer poly(A.U) diminishes the stability of the complex poly(U).poly(A,U),[88,108,109] while the polynucleotide poly(A,U), containing 49 mol% of uridine does not enter at all into complementation interactions with polyuridylic acid.[107]

The smallest, compared with other nucleotides, capacity of uridine for stacking interactions, which play an important role in the stabilisation of double-stranded structures, is the reason why the pentanucleotide r(AGUCU) does not form a duplex in solution, in contrast to the pentamers containing A, G, or C in the third position.[85]

The geometry of the dT.dT pair has been discussed.[110] According to ^{1}H NMR spectroscopic data, this pair is not stabilised by hydrogen bonds,[103,111] although it is effectively incorporated in the double helix with minimum distortions of the conformations of the bases and of the sugar phosphate skeleton.[103,111,112] The study of the characteristic features of the molecular structure of the dT.dT pair in the duplex

d(CCC|T|GGG)
(GGG|T|CCC)d

showed that equilibrium between two or more conformations is characteristic of thyine residues in the temperature range 10 to 20 °C.[110]

The presence of the dT.dT pair in the duplex "TT"

d(ATCCTA|T|TAGGAT)
(TAGGAT|T|ATCCTA)d

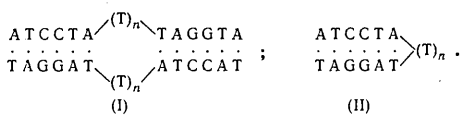
duplex "TT".

reduces its T_m by 11 °C compared with the dodecameric duplex

d(ATCCTATAGGAT)
(TAGGATATCCTA)d

Furthermore the dT.dT pair forms a local unstable section in which the double helix dissociation process is initiated on raising the temperature simultaneously with fusion, which begins at the ends. A similar conclusion was reached[113] in a study of the duplex

d(CGCGA|T|TCGCG)
(GCGCT|T|AGCGC)d .



The dependence of the stability of the non-complementary dT.dT pair on the nature of the neighbouring pairs is illustrated by the following data.[103,110] The dT.dT pair has the greatest destabilising effect when it replaces the central dA.dT pair in the

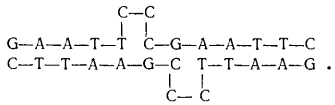
—ATA—
—TAT—

sequence and has the smallest effect on replacement of the dA.dT pair in the sequence

—CAG—.
—GTC—

It has been shown in a series of studies[114,115] by NMR and temperature jump methods that the oligonucleotides d[ATCCTA(T)$_n$.TAGGAT] (n = 0–7), the primary structure of which contains palindrome elements, can form in solution both defective double helices (I) and monomolecular "pins" (II):

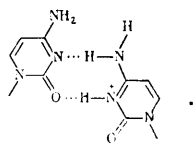
(I) (II)



Oligomers containing more than three non-complementary thymine units form "pins" exclusively, while the coexistence of both forms is characteristic of oligonucleotides with $n \leqslant 3$. A decrease in the nucleotide concentration and in the ionic strength of the solution promotes the preferred formation of "pins". According to ^{1}H NMR spectroscopic data, the stabilisation of loops in the "pin" structures containing less than three paired thymine residues is achieved as a result of the decomposition of the nucleotide pairs adjoining the oligo(dT) sequence. The most stable structures are those with loops containing 4–5 nucleotide units. The enthalpies of dissociation of the base pairs in the double-stranded section of the molecule show that the pairs closest to the loop are more stable than the terminal pairs, i.e. the loop stabilises to some extent the double helix fragments. By measuring the nOe, it has been established that the stabilisation is achieved as a result of the "stacking" of the first (from the 5′-end) unpaired thymine residue and the base of the neighbouring nucleotide pair.

The formation of "pin" structures analogous to (II) has also been detected for the oligonucleotides d[CGCGCG(T)$_n$CGCGCG] (n = 4, 5)[116,117] and d(CGCGATTCGCG).[113]

Experimental evidence for the formation of hydrogen bonds between the bases of the C.C pair has not so far been obtained. According to many workers, the absence of hydrogen bonds from the C.C pair and also the incomplete "stacking" of the unpaired cytosine and the bases of the neighbouring nucleotide pairs lead to both cytidine residues "sticking out" from the helix, i.e. to the formation of an inner loop. The destabilising effect of the C.C pair is due to the same factors.[84,85,90,118]



It has been established in the study of the formation of complexes by the oligonucleotides ($A_6C_mU_6$) (m = 1–8)[20,119] that the oligomers with m = 1–3 form a bimolecular helix with an inner loop and that, when m = 4–8, the "pin" structure becomes thermodynamically

more favourable. Among the "pins" formed by oligoribonucleotides, the one whose loop consists of six nucleotide units has the maximum stability. It has been established from ^{1}H NMR and nOe data[120] that the oligonucleotide d(GAATTCCCGAATTC) forms an unusual bimolecular structure containing non-coinciding loops:

The protonation of one of the cytosine residues of the C.C pair promotes the formation of hydrogen bonds between the bases. Thus, according to CD data, the oligomer d($C_4A_4T_4C_4$) forms a duplex with terminal dC.dC$^+$ pairs.[121] The presence of the central d(A_4T_4) section promotes the formation of dC.dC$^+$ pairs between antiparallel chains (in earlier studies[122,123] it was postulated that the C.C$^+$ pairs can arise only between parallel strands) and that this process occurs at higher pH than, for example, the association of dC_8 with $d(C^+)_8$.

The following structure has been proposed for the dC.dC$^+$ pair, which can be incorporated, according to the authors,[81] in the double helix of DA without causing significant changes in the geometrical parameters:

C (*anti*).C$^+$ (*anti*)

It has been suggested that the dC.dC$^+$ pairs are also formed on self-association of poly[d(CT)] and poly[d(AC)].[124]

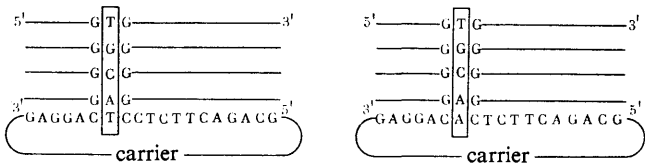
V. Comparative analysis of the influence of the non-canonical pairs on the structure and energetic parameters of the formation of the oligomeric complexes

(1) The pyrimidine–purine non-complementary pairs as well as the dG.dA pair, incorporated in nucleotide double helices, are retained by two hydrogen bonds. The dA.dA pair is not stabilised by hydrogen bonds. There is no rigorous experimental evidence concerning the molecular structure of the dG.dG pair and the pyrimidine–pyrimidine pairs. The bases in the non-complementary pairs are in the usual tautomeric forms and as a rule in the *anti*-conformation [the dG(*anti*).dA(*syn*) pair is an exception].

(2) The replacement of the A.T and G.C pairs by non-canonical pairs alters the conformation of the sugar phosphate skeleton.

(3) Depending on the nature of the heterocyclic bases in the non-canonical pairs and on their immediate environment, the bases of such pairs can be incorporated in the double helix, participating in the stacking interaction, or can be displaced from the helix, forming a loop.

(4) The smallest perturbations of a local character are induced by the G.U, dG.dT, and dG.dA pairs, which coexist with the complementary pairs within the double helix.



(5) The dA.dA and dC.dT pairs exert the most extensive perturbing influence. The bases of these pairs are arranged, at least partially, outside the double helix.

(6) The replacement of the Watson–Crick pairs by non-canonical pairs reduces the stability of the duplex. The degree of destabilisation depends on the length of the modified duplex, the nature of the non-canonical and replaced (G.C or A.T) pairs, the relative number of "erroneous" pairs and their positions in the duplex, and the local environment, as happens, for example, in the series of DNA duplexes[110]

d(C A A A $\boxed{\text{X}}$ A A A G)
(G T T T $\boxed{\text{X}'}$ T T T C)d

X, X′ = A, C, G,T .

The study of their melting profiles yielded the following stability series (the X.X′ pairs are indicated): dG.dT > dG.dG > dG.dA > dC.dT > dA.dA = dT.dT > dA.dC = dC.dC. Computer analysis of 100 t-RNA made it possible to estimate the relative stabilities of the non-complementary pairs in DNA: G.U ≃ G.G > C.C, U.U, C.A, A.A > G.A, U.C.[125] Measurement of the rates of dissociation of a series of oligomer–polymer DNA duplexes fixed on a dry agarose gel, i.e.

led to the derivation of the following series based on decreasing thermal stabilities as a function of the nature of the varied nucleotide pair: dT.dA ≃ dA.dT > dG.dT ⩾ dG.dA > dA.dA ≃ dT.dT ≃ dC.dA > dC.dT.[126] The thermodynamic parameters of the formation of oligomeric complexes with non-canonical base pairs are summarised in Table 4.

(7) In the general case, the destabilisation of the modified duplex compared with the "regular" duplex is associated with a decrease in the enthalpy of complex formation (as a result of the disturbance of the stacking interactions in the region of the non-canonical pair) overlapping the favourable change in entropy (as a result of the greater conformational mobility of the "erroneous" pairs).

The comparative characteristics of the influence of all the possible combinations of non-canonical pairs on the thermodynamic parameters of the complex formation process have been obtained[127] in relation to the DNA duplex

d(C G T C G T T T $\boxed{\text{X}}$ A C A A C G T C G)
(G C A G C A A A $\boxed{\text{Y}}$ T G T T G C A G C)d

X, Y = A, C, G, T .

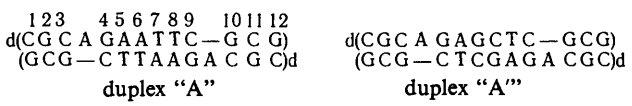
Only the components of ΔH^0 (X.Y) and ΔS^0 (X.Y) (calculated per nucleotide pair) characterising the stacking interactions of the non-canonical pair with neighbouring pairs (the "virtual stacking" approximation) were analysed (Table 3).

The data obtained led to a hypothesis concerning the structural features of the non-complementary pairs. Three main types of conformations of such pairs have been considered.

(a) Bound pairs (the so called "wobble" pairs). They are characterised by the same value of ΔS and somewhat reduced values of ΔH compared with the Watson–Crick pairs, they have paired bases, and are incorporated in a double helix.

(b) Open chain pairs. They are characterised by low values of ΔH and ΔS; such pairs form loops.

(c) Weak nucleotide pairs. They have intermediate (between extremum values) thermodynamic parameters and form intermediate



structures of different types. A direct correspondence has not been found between the structural features of the pairs and their destabilising influence. It is of interest that the T_m of duplexes with the non-canonical pairs X.Y and Y.X, differing only in the relative disposition of the bases in the complementary chains, are not the same although the environment of these pairs and hence the interplanar contacts are not altered. This is apparently associated with the effect of the long-range interactions of the non-canonical pairs.

Consideration of the formation and reparation of the non-complementary pairs has led to the conclusion that the reparation systems eliminate with the greatest efficiency the most frequently encountered pairs. Thus the repair system of *E. coli* effectively "mends" the dT.dG, dG.dG, and then dC.dA pairs and to a much lesser extent the dG.dA, dA.dG, dT.dT, dC.dC, dT.dC, and dC.dT pairs.[128] It has been suggested that the recognition of the "erroneous" pairs by reparation enzymes is not associated with the degree of destabilisation but is determined by the orientation of the bases relative to the sugar phosphate residue and the profile of the functional groups in the grooves within the double helix.[10,127]

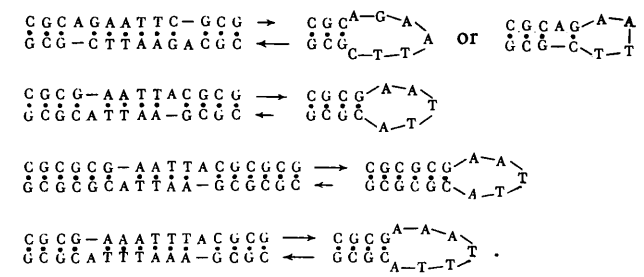
VI. Complexes of nucleic acids containing unpaired nucleotide residues

1. Inner unpaired units

Analysis of the structure of the DNA duplexes "A" and "A'",[14,57–59,64,129,130] whose composition includes adenosine residues without a partner on the complementary chain, i.e.

showed that the unpaired purine base is incorporated in the helix and particpates in the stacking interaction with the neighbouring dG.dG pairs. However, the inclusion of a "superfluous" unit is acompanied by an increase in the distance between the G.C pairs and hence leads to the disturbance of the "stacking" of the bases of the unmodified strand of the duplex. Furthermore, a distortion of the sugar phosphate skeleton as well as a change in the length and torsional angles of the P–O bonds of the phosphate section opposite the "superfluous" adenosine have been observed in the modification section (^{1}H NMR spectroscopic data).

The presence of an unpaired residue greatly destabilises the duplex (Table 4). The similarity of the values of ΔH^0 for the duplexes "GC" (see above) and "A" [the disturbance of the stacking interactions between the G(3) and C(4) bases on the unmodified strand is compensated by the additional interplanar interactions of the "superfluous" adenosine] indicates the entropic nature of the destabilising effect. On the basis of the difference between $\Delta H_{v\text{-}H}$ and ΔH^0, determined by the SMC method for the duplex "A", it has been established that the cooperatively melting section comprises 9 ± 1 nucleotide pairs, i.e. includes the "superfluous" unit. According to data for the rate of exchange of the imino-protons of the duplex "A" with water, the destabilising influence of the unpaired adenosine involves all the inner pairs of the duplex.



An NMR spectroscopic study of a longer sequence containing the unpaired adenosine residue, i.e.

also showed that the "superfluous" base is integrated in the double helix.[131] However, this entails not an increase in the distance between the bases on the opposite strand, as in the case of the duplex "A", but some bending of the helix. Since the defects are arranged symmetrically on different strands of the duplex, the helix acquires an S shape. The bases of the unmodified strand opposite the unpaired residue are then in fairly effective contacts.

It is of interest that in the crystalline state the conformation with the disposition of the unpaired adenosine outside the helix is characteristic of both duplexes—"A"[132] and "A'".[133,134] Despite the palindrome sequence, both "superfluous" bases are oriented in different ways (probably owing to the influence of the crystal packing). Furthermore, the local structure in the region of the defect is different for the "A" and "A'" duplexes. Thus in solution the unpaired adenosine residue is incorporated in the double helix, while in the crystalline state it "sticks out". The data obtained indicate the conformation flexibility of DNA duplexes modified in this way and their ability to pass from one conformational state to another when the external conditions are altered.

The study of the conformational transitions in a series of imperfect palindromes with inserts comprising superfluous adenosine residues has shown[135,136] that the distance between the insert and the "central symmetry" determines the equilibrium between the duplex and the single-stranded "pin". The theoretically possible conformations of the oligodeoxyribonucleotides investigated are illustrated in the scheme below:

It has been established on the basis of UV and NMR spectroscopic and SMC data that the introduction of additional adenosine units does not induce a change in the enthalpy of complex formation regardless of their positions in the sequence.

The DNA duplex[137]

served as a model of a double helix with a "superfluous" guanosine residue.[137] A three-dimensional model of the duplex "G" has been constructed from ^{1}H NMR spectroscopic data and by means of computer modelling (incremental approach). The series of structures differing in the length of the double helix sequence flanking the defect proved to be very similar. The duplex "G" is a double helix belonging to the $\overline{B}$-family; the axis of the helix is bent by 18–23°. As was to be expected, the unpaired residue is incorporated in the double helix.

The structure and stability of the DNA duplex "C", containing a superfluous cytidine residue, have been investigated:[138]

1 2 3 4 5 6 7 8
d(C A A A C A A A G)
(G T T T — T T T C)d
duplex "C".

The occurrence of an nOe duplex "C" between the imino-protons of the dA.dT pairs (in the 4- and 5-positions) and also the absence of an upfield shift of the signls of the non-exchanging protons of the unpaired cytosine as the temperature reduced indicate that the "superfluous" cytosine residue "sticks out" from the helix and does not participate in the stacking interaction with the bases of neighbouring pairs. Cytosine is apparently "expelled" by the neighbouring purine bases, which are known to possess an enhanced capacity for stacking interactions. The position of cytosine outside the helix destabilises the duplex (the duplexes 13 and 14 in Table 4 and in the paper of Aboul-Ela et al.[110]), the destabilising effect being enthalpic in nature in this instance.

The question arises whether the unpaired cytosine always occupies a position outside the helix. It has been found that its conformation depends on temperature. Thus a study by two-dimensional NMR spectroscopy and the analysis of nOe parameters of the DNA duplex

d(C C G C G A A T T C — C G G)
(G G C — C T T A A G C G C C)d

showed[139] that at low temperatures (0 °C) the "superfluous" cytosine is outside the helix, while the adjoining bases participate in the stacking interaction. With increase in temperature, the conformational equilibrium shifts towards the formation of structures in which the cytosine residue is built into the duplex (> 40 °C). It is noteworthy that the disturbances in the sugar phosphate skeleton extend to a region remote from the site of the defect.

Even more interesting results have been obtained in a study of the conformational characteristics of other unpaired pyrimidine bases—thymine and uracil—in the duplexes "T"[140] and "U":[141]

d(C T G G T G C G C)	r(C U G G U G C G C)
(G A C C — C G C G)d	(G A C C — C G C G)r
duplex "T"	duplex "U" .

These duplexes, which have a similar sequence, differ only in the nucleotide residues belonging to the deoxyribo- or ribo-series. The set of NMR spectroscopic data, the nOe parameters, the temperature dependence of the chemical shifts of the proton signals, etc. show that the unpaired thymine residues are built into the duplex "T". According to the results of computer modelling, the insertion of the "superfluous" thymine does not induce appreciable changes in the structure of *B*-DNA under these conditions: the base pairing is not disturbed and there are no appreciable distortions in the torsional angles. We may note that, when the more bulky adenine residue is intercalated, the structural perturbations are much more pronounced.

In contrast to thymine residues, the uracil in the duplex "U" is preferentially located outside the helix. The regular structure of *A*-RNA is then hardly disturbed. The authors suggest that the difference in the behaviour of these bases in the DNA and RNA duplexes can be accounted for by the different tendencies of thymine and uracil to participate in stacking interactions.

If the unpaired thymine residues are not unique but are encountered regularly and frequently in the duplex, then a position outside the helix is more characteristic of them. Such a conformation has been postulated for the polymeric duplex poly[d(GGAA)].poly[d(TC)][142] from data for the formation of cytosine photodimers:

—G—G—A—G—G—A—
—C C—T—C C—T— .
T T

It has been established that the "superfluous" thymine residues do not disturb the cooperative nature of the fusion but diminish greatly the stability of the defective helix compared with the regular poly[d(GGA)].poly[d(TCC)].

A similar conclusion that the unpaired thymine residues are located outside the helix has been reached on the basis of a study of the duplex poly[d(GA)].poly[d(TTC)].[143]

Interesting data for the stability and dynamics of a series of duplexes with a nucleotide sequence corresponding to the mutation "hot spot" with a shift of the frame have been obtained by NMR spectroscopy:[144]

d(G A T G G G C A G)	d(G A T G G G — C A G)	d(G A T G G G — C A G)
(C T A C C C G T C)d	(C T A C C C C G T C)d	(C T A C C C A G T C)d .
duplex "N"	duplex "C_N"	duplex "A_N"

It was found that the unpaired adenine exerts a mainly local influence on the stability of the nucleotide pairs (the duplex "A_N"), while the delocalisation of the destabilising effect along the G.C track of the duplex "C_N" as a result of the migration of the defect is characteristic of the unpaired cytosine:

d(G A T G G G — C A G) → d(G A T G G — G C A G) →
(C T A C C C C G T C)d ← (C T A C C C C G T C)d ←
→ d(G A T G — G G C A G) → d(G A T — G G G C A G)
← (C T A C C C G T C)d ← (C T A C C C C G T C)d
duplex "C_N" .

The greater thermal stability of the duplex "C_N" compared with the duplex "A_N" (ΔT_m = 5.7 °C) has been explained by the authors in terms of the positional degeneracy of the defect (unpaired cytosine) and the associated increase in entropy. It is noteworthy that the results of the above study[144] conflict with the results and conclusions of a number of other studies[57,64,129] as regards a series of aspects associated with the character of the influence of the "superfluous" adenosine on the stability of the duplex pairs and the enthalpy of complex formation.

In the next study of the above series, the conformational dynamics of the "superfluous" guanine residue, located in the G.C track of the analogous duplex, was investigated.[145] The presence of free imino-protons of the unpaired guanine made it possible to follow the migration of the defect. It was discovered that the "superfluous" unit occupies all possible positions, although it occurs more frequently at the ends of the track. One cannot say with certainty that the rate of migration of the defect is the same for oligopurine and oligopyrimidine sequences. As regards the location of the "superfluous" base relative to the duplex, experimental data show that the unpaired purine bases are incorporated in the double helix, while the pyrimidine bases are involved in equilibrium between the *endo*-helical and *exo*-helical conformations.

Overall, one can say that the ways in which DNA neutralises perturbations induced by unpaired bases are fairly varied and depend on the local "stacking" of the bases, the nature of the superfluous unit, the flexibility of the sugar phosphate skeleton, and the nucleotide sequence.

2. Oligonucleotide duplexes flanked by unpaired units

The influence of the terminal unpaired nucleotides on the stability of the NA double helices has been investigated mainly on short ribonucleotide duplexes.[146–159] Analysis of the available literature (Table 5) permits the following conclusions.

Table 5. Thermodynamic parameters of the formation of oligonucleotide complexes flanked by unpaired nucleotide residues.*

* Data for the fully complementary complexes are quoted for comparison.

** The values of ΔH^0_{v-H} are given in brackets.

*** c_0 is the oligonucleotide concentration.

The flanking of the double helix by an unpaired terminal residue increases the stability of the duplex.

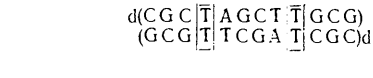
Stabilisation is achieved as a result of additional interplanar interactions of the unpaired residue with the terminal paired base of the opposite strand; this entails a decrease in the end pair "fraying" effect.

The increase in stability is due to the favourable change in the enthalpy of complex formation (the contribution by additional "stacking") which exceeds the unfavourable entropic effect (the decrease in the degree of "freedom" of the pendant residue) compared with the fully complementary duplex.

The following sequence in the stabilisation by unpaired residues has been established: G ≃ A > U ≃ C, i.e. purine bases are more effective than pyrimidine bases. A similar dependence of the stability of the duplexes also on the nature of the base involved in overlapping with the unpaired residue has also been observed.

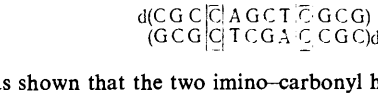
In helices of the ribo-series, the 3'-terminal base increases stability to a greater extent than the base located at the 5'-end. On the other hand, in deoxyribonucleotide duplexes, the 5'-terminal unit makes a greater contribution to stabilisation,[112] which is apparently associated with the differences between the structures of the *A*- and *B*-forms.

Conversely, the presence of more than one unpaired residue at the ends of the duplex reduces the stability of the double helix.[155]



- - - o0o - - -

During the preparation of the manuscript for the press, a number of communications on the subject of the review were published.



It was shown that[160] by the RS method that the non-complementary G.T pair induces a greater disturbance of *B*-DNA (solution) than of *Z*-DNA (crystalline state). Arguments are put forward in support of the hypothesis that this method in fact yields most information required to determine the geometry of the phosphodiester linkages near the non-complementary pairs.

A comparative study of the fine structure of the DNA duplexes in the *A*-form, one of which contains two adjacent G.T pairs while the others are unmodified analogues, has been carried out by XRDA (1.7 Å).[161] The thermal stability of imperfect and fully complementary double helices has also been studied (UV spectroscopy).

The structural features of the pyrimidine–pyrimidine non-complementary pairs C.C and T.T forming part of the composition of the 12-unit DNA duplexes have been studied by NMR spectroscopy:[162]

and

It was shown that the two imino–carbonyl hydrogen bonds, stabilising the T.T pair, are weaker than the corresponding bonds in the G.T pair. As regards the C.C pair, the experimental data did not permit a correct choice between several pairing schemes. It was only evident that one of the bases of the pair must be protonated.

A study has been made[163] of the stability of the formation of the $C.C^+$ pairs in 2-, 3-, or 6-unit cytosine tracts localised within an antiparallel DNA duplex. It had been shown earlier that such pairs are formed at the ends of an antiparallel duplex.[121] According to CD data, the pairing of cytosine residues does not occur in any of the duplexes studied.

The interrelation between the thermodynamic parameters of the fusion of defective duplexes, formed by the matrix DNA and decanucleotide primers containing non-complementary bases at the 3'-end (variants of the non-complementary pairs—G.T, C.T, and T.T), on the one hand, and the accuracy of the DNA replication, on the other, has been analysed.[164] The causes of the ambiguous relation are discussed.

The influence of the nucleotide sequence of the matrix DNA on the type of the non-complementary pair has been observed in the DNA-polymerase reaction.[165] The frequency of errors counted was artificially increased by using only three out of the four deoxyribonucleotide triphosphates.

The additional possibility of the formation of non-canonical pairs has been discussed in a theoretical study.[166] According to calculations of the energies of the intermolecular interactions (AAPF), in alternative pairing schemes one of the bases is in the *syn*-orientation and a water molecule participates in the formation of hydrogen bonds. According to the authors, such pairs are closer to the Watson–Crick pairs in terms of geometrical parameters.

The influence of the terminal non-complementary pairs (A.C, A.A, and A.G) on the thermal stability of oligoribonucleotide duplexes has been discussed.[167]

The dimorphous structure of poly(rA).poly(dT) has been confirmed by Raman spectroscopy.[168]

Comparative studies have been made of the thermal stabilities and of the secondary structures (by UV and CD spectroscopy) for a series of oligomeric DNA, RNA, and hybrid RNA.DNA duplexes.[169] It has been shown that the ribonucleotide duplex is the most stable, the hybrid duplexes occupying an intermediate position. The *A*-form of the double helix is characteristic of the latter but it is not fully identical with *A*-RNA.

The influence of two unpaired thymine residues, flanking the hexanucleotide duplexes $[d(GC)_3]_2$ or $[d(CG)_3]_2$ at the 3'- or 5'-end, on the thermodynamic and structural characteristics of the double helices has been studied.[170] It has been observed with the aid of UV, NMR, and CD spectroscopy and by computer modelling that the presence of thymidine residues stabilises the double helix as a result of the stacking interaction of the unpaired bases, the effect being greater in the case of 5'-terminal substituents.

The individual thermodynamic contriution of the four-unit loop and of the unpaired base in the double helix section has been determined for 14-pin ribonucleotide structures.[171] It has been shown that the destabilising effect of the unpaired purine is greater than that of pyrimidine and depends on the nucleotide sequence of the section adjoining the defect.

Photoionisation detection in gas chromatography

V L Budovich, A F Shlyakhov
All-Union Research and Design Institute of Chromatography, Moscow

ABSTRACT. Problems of the design and application in gas chromatography or photoionisation detectors with separated and non-separated ionisation and detection compartments are examined. The characteristics of the detectors of both types are described and specific problems of their construction are discussed. The mechanism of the signal generation and the factors determining the magnitude of the response are examined.

Extensive experimental data concerning the use of photoionisation detectors with separated detection and ionisation compartments in gas-chromatographic analysis are presented. The application of such detectors in multi-detector schemes in combination with flame-ionisation, electron-capture, and other detectors is discussed. The employment of such combinations of detectors for the purposes of identification is analysed.

The bibliography includes 151 references.

I. Introduction

Among the numerous detection methods used in gas chromatography, ionisation methods based on the use of a non-independent discharge have come to be widely used. Depending on the type of the external source of ionisation in the measuring compartment, it is possible to distinguish radioionisation and photoionisation detection. Both methods have been used successfully for the solution of various analytical problems. They possess advantages such as high sensitivity and a virtually non-disruptive character of their effect on the compounds analysed.

Photoionisation detection is technically more complex than radioionisation detection because it requires the use of a stable source of emission of vacuum UV radiation. The development of the technique of photoionisation detection is determined to a large extent by the improvement of the emission sources. Therefore, despite the fact that the first photoionisation detector (PID) was described as early as 1960,[1] the industrial production of chromatographs with PID did not begin until the end of the 1970s when it became possible to incorporate adequate sources of UV radiation.

The use as ionisation sources of resonance UV lamps working stably over long periods of time made it possible to simplify significantly the design of the apparatus. In particular, there is no need for an auxiliary gas, the open flame is eliminated, and there is no need for the use of radioisotopes. It becomes possible to employ air as the carrier gas. These properties combined with high sensitivity, selectivity, and the large linear range promoted the use of PID in laboratory and portable chromatographs.[2–5]

The use of PID in the gas-chromatographic analysis has led to the appearance of a whole series of studies devoted to the design, operating conditions, and practical use of this detector (see, for example, Refs. 6–8). The available literature data (for the last 15 years) concerning the design, characteristics, and analytical applications of the photoionisation detector are analysed in the present review.

II. Signal generation in the photoionisation detector

The essential feature of the operation of the PID is that a flux of photons emitted by the source in the far ultraviolet ionises the substance to be analysed. The motion of the charges produced in the ionisation chamber generates a current signal characterising the concentration of the substance analysed.

The ionisation of the molecules AB can occur as a result of direct ionisation with formation of an ion and an electron:

$$AB + h\nu \rightarrow AB^+ + e + \text{energy},$$

direct ionisation with formation of an ion pair:

$$AB + h\nu \rightarrow A^+ + B^- ,$$

or with preionisation:

$$AB + h\nu \rightarrow AB^* \rightarrow AB^+ + e .$$

The contribution of each of these processes to the formation of charged species is determined both by the characteristics of the radiation (its spectrum and its monochromatic nature) and by the characteristics of the substance irradiated (the distribution of molecules with respect to energies in the ground state, the distribution of the energy level density in the excited state, and the distribution of the probability of ionisation transitions).

In the range of energies close to the ionisation threshold, the direct ionisation processes predominate. With increase in the energy of photons, the contribution of the preionisation processes rises. Preionisation can occur with appearance of fragment ions, formed

from excited molecular ions. The fraction of fragment ions increases for energies exceeding the second ionisation potentials of the molecules.[9]

Apart from the processes mentioned, molecular excitation and dissociation processes are also important when molecular gases are acted upon by UV light.[10]

The overall cross-section of the processes enumerated determines the overall absorption cross-section. The photoionisation cross-section is only a fraction of the absorption cross-section, which depends on the radiation energy.

The absorption of photons in the ionisation chamber of the detector obeys the Beer–Lambert–Bouguer law:

$$I = I_0 \exp\left(-\sigma N_A c l \frac{P}{760}\frac{273}{T}\right), \quad (1)$$

where I_0 and I are the intensities of the entering and emerging light fluxes respectively, σ is the overall absorption cross-section, N_A the Loschmidt number, c the concentration of the test substance, l the length of the absorption path, and P and T are respectively the pressure and temperature in the ionisation chamber.

The absolute photoionisation quantum yield is

$$\eta = i/(I_0 - I), \quad (2)$$

where i is the ion current.

The dependence of the current on the concentration of the ionised component is determined from Eqns. (1) and (2). If the exponent in Eqn. (1) is less than unity, then we have, for P = 760 mmHg and T = 273 °C,

$$\eta = i/(I_0 \sigma N_A c l). \quad (3)$$

Multiplication of the right- and left-hand sides of Eqn. (3) by σ yields the expression

$$i = I_0 N_A c l \sigma_i, \quad (4)$$

where $\sigma_i = \eta\sigma$ is the effective photoionisation cross-section. It has been noted[11] that equations of type (4) are valid for low pressures of the test substance and for a short length of the ionisation chamber. When applied to the PID under gas-chromatographic conditions, this expression holds at normal pressure P owing to the low value of c.

For a cross-sectional area of the ionisation chamber S and a light flux density $j_0 = I_0/S$, the current is given by

$$i = j_0 N_A c V \sigma_i, \quad (5)$$

where V is the volume of the chamber.

Thus the current in the ionisation chamber is proportional to the concentration of the substance analysed and the sensitivity of the PID is proportional to the volume of the ionisation chamber.†

The ion current is also linearly related to σ_i but the latter quantity itself depends as a rule on the wavelength of the radiation in a complex manner. Since mainly non-monochromatic sources are used currently for photoionisation detection several emitted lines of different intensity are involved in signal generation. In many cases fragment ions with different masses are produced in the ionisation chamber together with molecular ions under these conditions. The fraction of particular ions in the overall ion current depends on the characteristics of the source of the UV radiation.

† The mechanisms of the current limitation, inducing deviations from linearity, are not discussed here.

Fig. 1 presents curves for the efficiency of the photoionisation (the ratio of the current of ions with the selected mass to the photon flux) of a methanethiol with formation of the molecular ions CH_3SH^+ and the fragment ions CH_3S^+.[12] The most intense lines in the argon, krypton, and xenon line spectra are also indicated. Fig. 1 shows that, when the argon emission is used for ionisation, the photoionisation efficiency can increase as a result of the appearance of fragments ions, while part of the xenon line spectrum makes no contribution at all to the current flowing in the ionisation chamber.

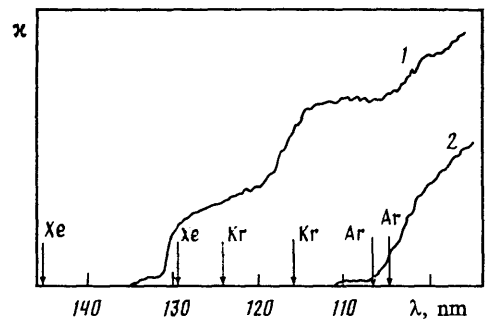

Figure 1. Photoionisation efficiency curves for methanethiol: *1*, the CH_3SH^+ molecules ion; *2*, the CH_3S^+ fragment ion.

III. Detectors with non-separated emission and detection compartments

Vigorous investigations of detectors with non-separated emission and detection compartments began in the middle 1960s. In these detectors, the radiation emitted by the electric discharge in an inert gas or hydrogen is introduced via a light conducting channel into the ionisation chamber. The chamber is not then separated from the emitter by any partition preventing the movement of the gas from one compartment to the other. The gas pressures in the source of radiation and in the ionisation chamber are the same. Eqn. (4) quoted above is not suitable for this detector, because some of the charged and metastable species from the radiation source also enter the ionisation chamber.

Such detectors make it possible to detect both organic and inorganic substances depending on the working medium in the radiation sources—the gas involved in the discharge. The use of helium, for example, makes the detector universal because of the presence in the spectrum of this gas of an intense continuum up to 50 nm (photon energy 24.3 eV). A d.c. discharge[1,13–20] and HF and UHF discharges[21–24] are used to excite the emission. There is a possibility of devices of two types: detectors in which the gas is present at low[1,15–17,21] and high (not more than atmospheric) pressures.[13,14,18–20] Table 1 shows that the characteristics of the different detectors in general agree with one another.

Despite the high sensitivity and universality of detectors of this type, they have not found applications in commercial instruments, since, firstly, detectors operating at reduced pressures require a vacuum system and, secondly, the spectroscopic characteristics of the radiation, influencing the sensitivity, vary as a function of the

Table 1. The working characteristics of PID with non-separated emission and detection compartments.

pressure in the detector. Although the detectors operating at atmospheric pressure are in fact incorporated at the outlet from the chromatographic column without auxiliary devices, nevertheless they too suffer currently from a series of disadvantages retarding their application. In the first place one must include among such disadvantages the increased noise level caused by the instability of the discharge and the transfer of charged species from the emitting to the detecting compartment.

In order to ensure the stability of a d.c. discharge with $i < 1$ A, it is desirable to use a gas with a high thermal conductivity—hydrogen or helium.[25] In practice, helium is used, since the short-wavelength part of its spectrum makes it possible to determine inorganic gases. Since the presence of impurities in helium affects the emission spectrum, it is essential to use pure gas and to take special precautions to reduce the erosion of the electrodes and to prevent the diffusion of the substances analysed into the emitting compartment.

In order to increase the stability of the discharge in detectors with a d.c. discharge, measures are taken to optimise the electrode system. As a result, it has been possible to reduce the noise from 10^{-12} A [26] to 10^{-13} A and below.[15] It has been noted [15] that an increase in the discharge current increases the noise and does not always reduce the detection threshold. The detector described by Roesler[15] has been used[27] to analyse organic and inorganic compounds.

The employment of an electrodeless discharge makes it possible to solve the problem of erosion and to increase the power injected and the sensitivity of the detector. Thus the sensitivity of a PID in a UHF discharge amounting to 1.57 K g^{-1} has been reported,[22] which is probably the maximum value at the present time (the power injected into the discharge was 20 W).

For the wide-scale practical use of the PID considered, the maximum working temperature must be increased. The question of the stability of the temperature (owing to its influence on the discharge current) is also important in this respect.[15] The maximum working temperature of PID with non-separated emission and detection compartments is at present 200 °C.[21]

IV. Detectors with separated emission and detection compartments

The difficulties in the practical use of PID with a reduced pressure in the detection compartment stimulated not only the development of sources operating stably at atmospheric pressure but also the appearance of photoionisation detectors of a new type, with separated emission and detection compartments. The first suggestion to separate these compartments was made in Ref. 28 and was then additionally justified by Locke and Meloan.[16] The first descriptions of the design of PID with an optical window between the source of vacuum UV radiation (VUV) and the ionisation chamber soon appeared.[29–31] The window is normally part of the design of the hermetically sealed UV source in which the pressure does not exceed tens of millimetres of mercury. This technical solution proved extremely promising and the manufacture of chromatographs with built in PID was initiated.[32] This was promoted by the development and manufacture of stable sources emitting vacuum UV radiation.

Metal halides and certain oxides can be used as materials for the transmission of the radiation. The dependence of the transmittances of some of these compounds on wavelength in the VUV is illustrated in Fig. 2.[33] Thin SiO films fixed on a metallic grid also have a satisfactory transmittance in the range 60–90 nm (20–70%). However, their mechanical strength is inadequate. A SiO window 100 nm thick and 10 mm in diameter can withstand a pressure difference not greater than 1000 N m^{-2}.[33]

In terms of the combination of optical and mechanical properties, lithium and magnesium fluorides are the most acceptable materials. However, lithium fluoride, which has the lowest transmittance limit (106 nm) among all the halides, has not come to be used as widely as magnesium fluoride because of its high hygroscopicity which alters the emission spectrum. The transmittance of lithium fluoride is also impaired on VUV irradiation owing to the formation of colour centres.[34] Magnesium fluoride has a fairly low short-wavelength limit (113 nm), which makes it able to transmit photons with the energy required for the ionisation of the majority of organic

substances. Some decrease in the transparency of magnesium fluoride is observed when it is heated to 200–400 °C with simultaneous exposure to the VUV radiation.[35] The decrease in the transmittance of magnesium fluoride windows can be associated with the absorption by the film (including the substance to be analysed) present on the surface of the crystal.[36,37] Organic films can be removed from the surface by employing VUV radiation in the presence of oxygen.[38] In chromatographic practice, the transparency of windows is restored mechanically (by wiping).[4]

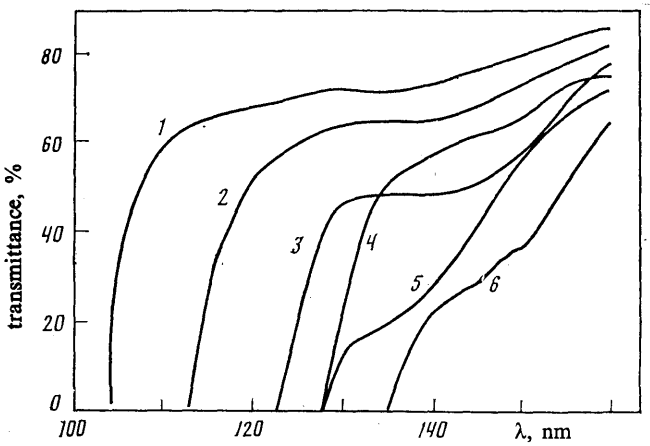

Figure 2. The transmittances of certain metal halides as a function of wavelength in the VUV region: *1*, LiF; *2*, MgF_2; *3*, CaF_2; *4*, NaF; *5*, SrF_2; *6*, BaF_2.

The characteristics of the materials which can be used to transmit VUV radiation have been specified in detail.[39]

Sources, with a line spectrum, capable of operating for a long time under continuous conditions,‡ have come to be most widely used for the generation of the VUV radiation in photoionisation detectors. For a discharge in a rarefied gas, there are lines at 104.82 (11.8 eV) and 106.67 nm (11.6 eV) in the argon spectrum, at 116.49 nm (10.64 eV) and 123.58 nm (10.03 eV) in the krypton spectrum, and at 129.55 nm (9.57 eV) and 146.96 nm (8.44 eV) in the xenon spectrum (the energy is indicated in brackets).[41]

Fairly reliable resonance lamps, filled with different substances and working in glow or arc discharge regimes, are currently widely used in PID designs. Inert gas (krypton and xenon) resonance lamps each emit virtually two resonance lines, the intensity of the long-wavelength lines being higher by 1–2 orders of magnitude than that of the short-wavelength lines.[42] The emission quantum yield for such sources is $10^{14}-10^{16}$ quanta s^{-1} behind the window of the lamp. He–Kr on He–Xe gas mixtures at a Kr or Xe pressure of 0.12–0.06 mmHg are used in such lamps, which makes it possible to obtain non-self-reversed Kr and Xe resonance lines, in the presence of which He is not excited.[43] Modern modifications of the krypton and xenon resonance lamps, developed in the USSR, have been described.[44] The power required by such lamps does not exceed 1–2 W.

Resonance lamps manufactured by the HNU Systems Company filled with krypton, xenon, and argon are used in chromatographs produced by a series of foreign manufacturers and fitted with photo-ionisation detectors. These lamps differ in the values of so called nominal energy. The nominal energies do not determine the energy of the photons emitted by the lamp but represent a conventional designation defining the type of the lamp. Lamps with nominal energies of 8.3, 9.5, 10.0, 10.2, 10.9, and 11.7 eV are known. Detectors with the corresponding lamps are designated by PID-8.3, PID-10.0, etc. The distribution of the emission energy in the line spectra of lamps with nominal energies of 8.3, 9.5, 10.2, and 11.7 eV, obtained using a vacuum UV spectrometer, has been published.[45] Only the lamp with a nominal energy of 8.3 eV produces monochromatic radiation. The remaining lamps emit not less than two lines. The intensity of the emitted lines in the range of the working currents is independent of the current in the lamp. The lamp with a nominal energy of 11.7 eV has a lithium fluoride optical window. Its operating life is several hundreds of hours.[46]

It has been suggested[47] that electrodeless UHF discharge lamps be used as radiation sources in PID. A portable chromatograph, fitted with a PID incorporating a UHF discharge lamp was later constructed.[48,49]

In the development of PID ionisation chambers, serious specific problems frequently arise. They are associated with the hermetic seal in the chamber, the reduction of the influence of the photoeffect, the elimination of the contamination of the window, etc. The question of the volume of the detector in a capillary chromatograph is of fundamental importance. The first, commercially produced PID had an ionisation chamber with a volume of 50 μl [32] (Fig. 3). The volume of the modified detector of the same series was 175 μl.[50] Such a volume is not optimal when used in conjunction with capillary columns, although it does make it possible to ensure a high sensitivity of detection.

Studies designed to reduce the detector volume are being prosecuted both to reduce the physical (total) volume and to reduce the effective volume responsible for the signal generation.

The decrease in the physical volumes of the ionisation chamber involves difficulties arising from the need to ensure a hermetic seal and a high sensitivity, but such reduction makes it possible to operate at lower potentials on the polarising electrode and with low flow rates of the make-up gas. The latter is important because the PID is a concentration detector.

A detector with a physical volume of 50 μl operating with a make-up gas flow rate of 2–3 ml min^{-1} has been reported.[51] There are data concerning the operation of PID altogether without a make-up gas flow. Thus the experimental results of a study of the influence of the volume of the photoionisation detector on the spreading of the chromatographic peaks of acetone have been published.[52] Fig. 4 reproduces these data,[52] obtained for detectors with volumes of 225, 150, and 50 μl and also for a flame-ionisation detector (FID). The figure shows that spreading could not be eliminated completely even in the detector with a volume of 50 μl.

The efficiency of the chromatographic system in which a PID with a volume§ of 50 μl and a FID were connected in series has been estimated. The loss of efficiency compared with the direct inclusion

‡ It is essential to note that the use of laser multistep ionisation, ensuring a high selectivity, is undoubtedly promising.[40]

§ The 50 μl volume was referred to as effective in the relevant study although a make-up gas was not supplied to the detector.

of the FID at the outlet from the chromatographic system after recalculation in terms of the number of theoretical plates is less than 10%.[53] A detector with a volume of 37 μl not requiring a make-up gas has also been reported.[45] In one of the variants of fluid chromatography, the designs of PID with volumes of 70 and 7 μl were investigated.[54]

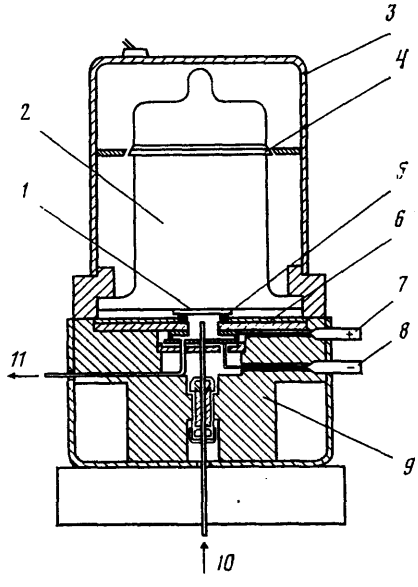

Figure 3. The design of the photoionisation detector based on the system of the HNU Systems Company: *1*, window for the transmission of radiation; *2*, vacuum UV lamp; *3*, lamp shell; *4*, electrode; *5*, Kalrez seal; *6*, graphite seal; *7*, measuring electrode; *8*, polarising electrode; *9*, heating block; *10*, gas inlet; *11*, gas outlet.

A decrease in the effective detector volume is achieved by reducing the irradiated region and by organising a "shielding" gas flow. The effective detector volumes were 1 and 10 μl respectively in the studies of Nutmagul et al.[55] and in Ref. 56. In the study of Gmür et al.,[54] the make-up gas flow rate was maintained at the level of 8–10 ml min^{-1}, which is close to the make-up flow rates of 10–15 ml min^{-1} used in a commercial detector with a volume of 150 μl.[57,58]

The shell of the ionisation chamber is made of a material with the highest possible specific resistance and the lowest porosity: PTFE,[47,59] boron nitride,[53] and a special glass.[55] In order to ensure a background current at the level of 10^{-11} A at a detector supply potential of ~100 V, the specific resistance of the insulators must be of the order of 10^{13} Ω cm. At temperatures up to 200 °C, PTFE is suitable. Ceramics are more heat resistant, but their electrical resistances fall significantly on raising the temperature to 300–400 °C, which increases the background current and the noise level and hence impairs the characteristics of the detector. The specific resistances ρ_V of several types of ceramics at 20° and 500 °C have been published in a monograph.[60] The ceramic based on Al_2O_3, which also has a low porosity, is the most suitable (Table 2).

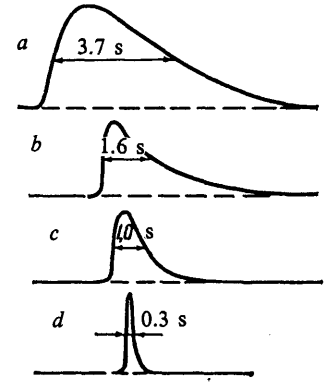

Figure 4. Chromatographic peaks of acetone obtained with PID having a chamber with different volumes (μl): *a*, 225; *b*, 150; *c*, 50; *d*, obtained with a FID.

Table 2. Specific resistances of various types of ceramics.[60]

Type of ceramic	ρ_V, Ω cm	
	20° C	500° C
Al_2O_3	10^{14}	10^{12}
$2MgO \cdot SiO_2$	10^{14}	10^{10}
$MgO \cdot Al_2O_3$	10^{14}	10^{11}
MgO	10^{14}	10^{12}
BeO	10^{14}	10^{12}

When the PID is series-connected to other detectors, the problem of its hermetic seal becomes important. It is solved mainly in the traditional manner using the seal between the ionisation chamber and the lamp. The limiting temperature for this design using perfluorinated rubber is 300 °C.[45] It has been suggested[61] that an additional window, glued to the shell of the ionisation chamber, be introduced into the PID design to ensure a hermetic seal. A disadvantage of this design is the weakening of the radiation flux in the chamber and also the impossibility of cleaning the additional window. It has likewise been suggested that the MgF_2 window be sealed to the chamber with the aid of a conical sealing arrangement.[62] A hermetically sealed junction between the shell and the window and also between the ceramic shell and the electrode can be achieved with the aid of diffusionally hardening solders.[63] In order to increase the maximum working temperature of the detector, it has been suggested[64] that the hermetic seal in the ionisation chamber be abandoned so that the release of gas through the gap between the detector shell and the optical window can be ensured.

A coaxial electrode system is most often employed in the ionisation chamber of the PID. In this system, the central electrode is generally subjected to VUV radiation, which increases the background current. The shielding of the electrode from the direct effect of the radiation made it possible to reduce the background current by three orders of magnitude.[53]

The optimum configuration of the electrodes for which the highest signal is attained has been sought.[55] The possibility of achieving such a configuration may be associated with the fact that the chamber operates under conditions far from saturation. Optimisation implies the attainment of maximum sensitivity for low detector supply potentials when the gas-induced intensification processes are absent and the leakage through the insulator is small.

It is shown below how the nature of the carrier gas affects the sensitivity of the PID with a 10.2 eV lamp in the detection of benzene:[65]

Carrier gas	Air	Ar	CO_2	N_2	CF_4	He	CO
Response, rel. units	0.542	1.401	0.285	1.00	1.01	0.987	1.07

It has been suggested that the following processes are responsible for the decrease in the response of the PID; the capture by the carrier gas of the electrons formed as a result of photoionisation; the absorption of the UV radiation by the carrier gas; the de-excitation of the components analysed on their collision with the molecules of the carrier gas having vibrational and rotational levels. The fact that the response of the PID is greatest when argon is used has been explained[65] by the high rate of drift of the electrons (v_e) in this gas, which lowers the losses in recombination compared with He or N_2. However, in argon v_e is greater than in He or N_2 only for $E/P < 10^{-2}$ V cm^{-1} (mmHg)$^{-1}$ (E is the strength of the electric field between the electrodes of the ionisation chamber).[66] Under real conditions, where $E/P > 10^{-1}$ V cm^{-1} (mmHg)$^{-1}$, the quantity v_e in argon is smaller than in He or N_2. The increased values of v_e in argon may be caused by its greater sensitivity to molecular impurities.[66] The presence of the latter (including ionisable impurities) diminishes the electron temperature and increases v_e.

Table 3. Characteristics of PID with separated emission and detection compartments.

Gas filling the lamp	Background current $10^{11}I_b$, A	Noise $10^{14}I_n$, A	Detection limit w.r.t. benzene	Maximum working temperature, °C	Detector volume, μl	Linear dynamic range	Refs.
H_2, Ar, Kr, Xe	1.4	4	2×10^{-12} g	300	175 50	10^7	[50]
H_2	2	—	0.6×10^{-12} g	200	1	—	[55]
H_2	—	2	0.5×10^{-12} g	220	10	10^5	[56]
H_2	2	5	0.67×10^{-14} g s^{-1}	300	—	10^6	[68]

The fluctuation noise in PID constitutes a serious problem. The nature of the noise is determined mainly by the variation of the photocurrent with the composition of the gas in the detector and by the contamination of the insulating elements, causing leakage.[45,67] The increased level of PID noise (compared with FID) precludes the full utilisation of its greatest advantage—its high sensitivity.[67]

Certain characteristics of PID with separated emission and detection compartments are presented in Table 3. It follows from Table 3 that, in terms of their characteristics, the detectors are similar. The PID produced by the HNU Systems Company is outstanding as regards its long linear range. The detection threshold and the linear range of the PID are illustrated in Fig. 5, which includes for comparison the analogous data for FID and the electron capture (ECD), flame-photometric (FPD), and ultraviolet (UVD) detectors.

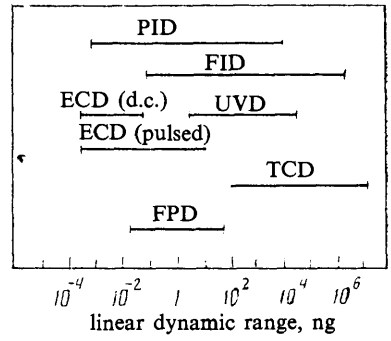

Figure 5. The linear dynamic range for certain detection methods[7] [TCD = thermal conductivity detection (Ed. of Translation)].

V. The response of the photoionisation detector

The magnitude of the response of the PID depends on the effective photoionisation cross-section σ_i, which is determined by the energy of the photoionising photons and by the characteristics of the substance analysed. The dependence of σ_i on the energy of the ionising photons E_{ph} is complex. It can be estimated using the photoionisation efficiency curves (PEC) $\eta(E_{ph})$, obtained, for example, with the aid of photoionisation mass spectrometry.[9] These relations have been resorted to in order to explain qualitatively the influence of the energy of the photons on the response.[69] However, the PID responses cannot be estimated quantitatively with the aid of the PEC because of the different intensities of the lamps and the non-monochromatic nature of the radiation.

The PID response can be estimated to a first approximation with the aid of the quantity $E_{ph} - E_i$, where E_i is the ionisation energy of the test substance. For non-monochromatic lamps, one must take into account not only the most intense line but also other lines. If the quantity $E_{ph} - E_i$ is fairly large (1–2 eV and more), ionisation occurs along the PEC section remote from the threshold value, where the $\eta(E_{ph})$ relation has a plateau for many substances. The response is then independent of E_i.[69] On the other hand, if the difference $E_{ph} - E_i$ is small (a fraction of an electron-volt), then ionisation occurs in the pre-threshold region on the PEC, and the response therefore also depends on the closeness of the E_i to the photoionisation threshold or, for a given E_{ph}, on E_i. A greater difference $E_{ph} - E_i$ obtains when a lamp with a nominal energy of 11.7 eV is used, 71.1% of its radiation corresponding to photons

with an energy of 11.62 eV. The PID responses to alkanes, alkenes, and aromatic hydrocarbons are in this case approximately the same. A small difference $E_{ph} - E_i$ is characteristic of a large number of compounds of different classes when a lamp with a nominal energy of 10.2 eV is used (the spectrum contains photons with energies of 10.03 and 10.64 eV). It is essential to note that, when $(E_{ph} - E_i) < 0$, a signal due to the removal of electrons from vibrationally excited molecules may be observed and may increase with increasing temperature in proportion to $\exp[-(E_{ph} - E_i)/kT]$, where k is the Boltzmann constant. An attempt has been made[70] to relate the PID response to the number of electrons participating in the formation of multiple carbon–carbon bonds, but the conclusions reached[70] were subjected to serious criticism.[37]

It has been established experimentally that PID is highly sensitive to aromatic hydrocarbons with low ionisation potentials. In practice, it is convenient to determine the absolute sensitivity and the PID detection limit with respect to benzene (Tables 4 and 5). The molecular sensitivity coefficients $K_{i,M}$ have been measured[71] for a large number of organic compounds relative to benzene (Table 4):

$$K_{i,M} = (S_i/S_{st})(c_{st}/c_i),$$

where S_i and S_{st} are the peak area of the ith substance and benzene and c_i and c_{st} are the concentrations (in nmol ml^{-1}) of the ith substance and benzene in the model mixture respectively. A model P1-51-02 PID from the HNU Systems Company, fitted with a UV lamp having a nominal energy of 10.2 eV, was used for the measurements.

Table 4 shows that the molar sensitivity of the PID increases with increasing number of carbon atoms in the molecule within the limits of the homologous series. The linear equation

$$K_{i,M}=0.715n-0.475.$$

is valid for n-alkanes. The following sequence in the variation of the $K_{i,M}$ is characteristic of normal aliphatic compounds with different functional groups and having the same numbers of carbon atoms: alkanes < alcohols < methyl ethers < ethyl ethers < aldehydes < 2-ketones < 3-ketones. Branches in the carbon chain of the molecule and the presence in the latter of saturated rings or double bonds tend to increase the PID response, whilst the presence of nitro-groups tends to decrease it.

* The following abbreviations have been adopted: P = packed column; C = capillary column; MP = micropacked column.
** The dash denotes the author's own design.

The high sensitivity of the PID with respect to the characteristic features of the carbon skeleton of organic compounds is very important for the practical purposes of group identification. It is noteworthy that, since the PID selectivity varies with the quantity $E_{ph} - E_i$, it can be regulated by using UV lamps with different nominal energies.

For example, when a lamp with a nominal energy of the 11.7 eV was used, the molar sensitivity coefficients for benzene, cyclohexane, and cyclohexene were approximately the same[72] and, when a 10.2 eV lamp was employed, the PID responses to cyclohexane and cyclohexene were respectively 15 and 30% of the response to benzene.[57] According to the results of Locke and Meloan,[16] the signal of the PID with an 11.7 eV lamp in response to arenes exceeded on average by 30% the signal in response to alkanes. When a 10.2 eV lamp was used, the sensitivity of the PID to arenes was found to be higher by a factor of 5.[73]

The non-monochromatic radiation from certain lamps, the probable change in the distribution of the emission energy as the temperature of the PID is varied, and the marked difference between the emission intensities of lamps having different nominal energies have an interfering effect on detailed studied of the relation between $E_{ph} - E_i$ and the relative sensitivity coefficients and on the development of methods for the determination of the required compound against the background of large amounts of other substances. An idea may be obtained about the last interfering factor by comparing the sensitivities of PID with 8.3, 9.5, 10.2, and 11.7 eV lamps of polyalkylated arenes and benzenes, which are in the proportions 1 : (10–20) : (100–400) : 20 respectively.[51,57] The high intensity of the emission proved to be decisive in reducing the benzene, butadiene, carbon disulphide, and trichloroethylene detection limits in a PID with a 10.2 eV lamp compared with one fitted with an 11.7 eV lamp. The sensitivity of the PID to n-butane depends mainly on the quantity $E_{ph} - E_i$ and it is therefore seven times greater for the PID with an 11.7 eV lamp.[74] One should also bear in mind the influence of the change in the emission intensity of the same lamp on the relative sensitivity coefficients of the PID. It has been found[75] that an increase in the emission intensity of 10.2 eV lamp by a factor of 1.6 led to an increase in the ratios of the responses to C_4-C_5 alkenes to the response to toluene by 30–40%. For alkanes and alkylbenzenes, these changes are significantly smaller.

The threshold sensitivity of the detector or the detection limit (DL) is important for the determination of microimpurities. In practice, the threshold sensitivity of the detector is usually expressed in terms of the amount of the substance (in grams or moles) generating a detector signal (the height of the chromatographic peak) greater by a factor of 2–5 than the noise of the zero line. Although this quantity is determined by the characteristics of the entire chromatographic system and the analytical conditions (namely the volume of the chromatographic peak at the outlet from the column, the rate of its passage through the detector, the make-up gas flow rate, etc.), nevertheless the data in Table 5 contain useful information about the real results obtained with PID in the analysis of trace amounts of substances. To facilitate the comparison of the data in Tables 5 and 4, the detection limits in Table 5 are expressed in grams and moles. Table 5 shows that the DL has been reached at the level of picograms for light aromatic hydrocarbons, alkenes, and amines and at the level of tens of picograms for mercaptans, sulphides, chloroalkanes and chloroalkenes, nitrosoamines, steroids, certain polyarenes, and inorganic gases. For barbiturates and aniline derivatives, with the exception of nitroanilines, the DL can apparently be reduced by improving the efficiency of the gas-chromatographic separation.

The choice of the lamp with a specific nominal energy depends on the sample composition and the purposes and conditions of the analysis. For example, in the determination of substances with comparatively short retention times in mixtures with a large amount of a polar solvent (methanol, Freon 11, methylene chloride, acetonitrile), it is useful to employ a PID with a 10.2 eV lamp, which is only slightly sensitive to solvents of this type. As a result the solvent tail is diminished and the accuracy of the determination of the substances eluted in the vicinity of the solvent peak is increased.

The photoionisation detector can be used under conditions where the useful signal is generated as a result of electron capture[92,93] or the absorption of radiation.[94] A specific feature of experiment under these conditions is that a large background current ($10^{-8}-10^{-9}$ A) is generated by virtue of the ionisation of the make-up gas introduced into the ionisation chamber and ionised by the radiation from the lamp. The useful signal is generated at the expense of the decrease in the background current.

Air (5 ml)	Ethane-, t-butane-, propane-, and s-butanethiols: DL 4 μg m^{-2} (12 μg m^{-3} for butanethiol)	"	Packed column 2.7 m long 15% SF-96 + 6% OV-225 on Chromosorb WAW DMCS	60 °C	N_2, 30 ml min^{-1}	"HNU Systems", 10.2 eV lamp, 200 °C	[78]
Air (10 litres)	Carbon disulphide: DL 1×10^{-5}%	Enrichment on a tube with activated charcoal, desorption with acetonitrile	0.75 m × 2.1 mm packed column, Chromosorb 108; 80/100 mesh	105 °C	N_2, 30 ml min^{-1}	"HNU Systems", 210 °C	[103]
Water	Benzene, toluene, xylene, and vinyl chloride: DL 1 μg $litre^{-1}$	Gas extraction from 100 ml of H_2O at 45 °C, enrichment on a tube with Porapak N, desorption with methanol	For arenes: 2 m × 2 mm packed column, 20% SE-30 on Gas Chrom Q; for vinyl chloride: 2 m × 2 mm packed column, Porapak T; 80/100 mesh	Heating from 40° to 60 °C at a rate of 3 K min^{-1}; 90 °C for vinyl chloride	He, 30 ml min^{-1}	"HNU Systems", 200 °C	[104]
Water	Vinyl chloride: DL 0.01 μg $litre^{-1}$	Analysis of 5 ml from 60 ml of equilibrium vapour over 100 ml of water at 56 °C	0.9 m × 2 mm packed column, Chromosorb 104	90 °C	He, 20 ml min^{-1}	"HNU Systems", model PI-52-02, 10.2 eV lamp, 250 °C	[77]
Water (18 litres)	Bicyclic and tricyclic arenes and their chloroderivatives: DL at the level of ng $litre^{-1}$ and mg $litre^{-1}$	Concentration by the HPLC method on a column with C_{18}-Corasil II with elution of fractions by a mixture of H_2O and acetonitrile	2.4 m × 2 mm packed column, 1.5% SP 2250 + 1.95% SP 2401 on Supelcort; 100/120 mesh	182 °C	N_2, 23 ml min^{-1}	"HNU Systems", model PI 51, 250 °C; N_2 make-up gas flow at a rate of 10–75 ml min^{-1}	[36]
Sewage water (1 litre)	Aniline and halogeno-, halogenonitro-, nitro-, and dinitro-anilines [the quantitative analysis is difficult owing to the complexity of the chromatogram. The (N/P)-detector is recommended]	Extraction with CH_2Cl_2, purification by the LC method on a column with Florisil	30 m × 0.25 mm glass capillary column, SE-52	Heating from 80° to 230 °C at a rate of 4 K min^{-1}	He, 30 cm s^{-1}	"HNU Systems", model PI 50, 10.2 and 9.5 eV lamps, He make-up gas flow	[89]
Blood serum (10 ml)	Barbiturates and other medicinal drugs (the sensitivity of the determination with a FID is 8–16 times higher than with a PID	Extraction with CCl_4, distillation of solvent, dissolution of residue in acetonitrile	1.8 m × 2 mm packed column, 3% OV-17 on Gas Chrom Q deactivated with H_3PO_4	Heating from 200° to 285 °C at a rate of 12 K min^{-1}	N_2, 19 ml min^{-1}	"HNU Systems", model PI 52-02, 10.2 eV lamp	[105]
Blood (5 g) and urine (20 g)	Mono-, di-, tri-, tetra-, penta-, and hexa-chlorobenzenes: DL 3–19 ng g^{-1} in blood and 0.7–4.9 ng g^{-1} in urine	Extraction with CCl_4, purification by the LC method on a column with silica gel	1.8 m × 3 mm packed column, 0.2% PEG 40 M + 0.5% synerg C on Chromosorb WAW	Heating from 60° (2 min) to 180 °C at a rate of 12 K min^{-1}	N_2, 18 ml min^{-1}	"HNU Systems", 10.2 eV lamp, 250 °C	[99]
Deposit (15 g)	Benzene, alkylbenzenes, chloroalkenes, and halogenobenzenes: DL 7 ng g^{-1}	Gas extraction at 120 °C with concentration on a tube with Porapak N, desorption with methanol	60 m × 0.25 mm quartz capillary column, DV-5	Heating from 50° to 170 °C (156 min) at a rate of 4 K min^{-1}	He, 60 cm s^{-1}	"HNU Systems", 10.2 eV lamp, 220 °C, He make-up gas flow at a rate of 8 ml min^{-1}	[106]
Atmospheric dust (9.8 mg)	Tri-, tetra-, and pentacyclic arenes (the more selective FID with an 8.3 eV lamp is recommended)	Vacuum sublimation at 260 °C with cryogenic concentration in a trap	30 m × 0.32 mm quartz capillary column, DV-5	Heating from 55° (10 min) to 225 °C (30 min) at a rate of 10 K min^{-1}	He, 6 ml min^{-1}	"HNU Systems", model PI 52-02, 9.5 eV lamp, 230 °C, He make-up gas flow	[107]
Meat products	Nitrosoamines (owing to the complexity of the chromatogram, the determination of low concentrations is difficult)	Extraction, purification by the LC method on a column with silica gel	50 m × 0.32 mm glass capillary column, Triton X-305	Rapid heating from room temperature (4 min) to 60 °C followed by heating to 160 °C at a rate of 5 K min^{-1}	He	"HNU Systems", 9.5 and 10.2 eV lamps, 250 °C, He make-up gas flow	[79]

In the operation of the PID under electron conditions, a threshold level of detection of heptachlorodicyclopentadiene (heptachlor) of 10^{-12} g was attained.[93]

Light hydrocarbons, having large absorption coefficients *in vacuo* in the UV region of the spectrum, have been determined with the aid of PID.[94] The detection limit with respect to methane was 8×10^{-7}%.

The operation of the detector under conditions corresponding to the generation of a negative signal by the diminution of the background current improves the selectivity and extends the scope of the photoionisation detection method, since it makes it possible, for example, to detect certain substances whose ionisation energies exceed significantly the energy of the emitted photons.

VI. The application of the photoionisation detector in the gas-chromatographic analysis of mixtures of organic and inorganic compounds

The high sensitivity and selectivity of the PID promoted its application primarily for the determination of impurities in complex multicomponent systems. The PID is particularly promising in the

analysis of substances in the environment: air, natural and waste water, soils, marine and lake deposits, etc.

Table 6 presents the characteristics of certain practical methods employing PID. It shows that the main components of air and water determined with the aid of PID are benzene, C_7-C_9 alkylbenzenes, halogeno-derivatives of these compounds, halogenoalkenes, and polycyclic aromatic hydrocarbons. The lowest detection limit of benzene in air using cryogenic concentration is 2×10^{-11}% (HNU Systems Detector with a 10.2 eV lamp),[74] while without concentration it amounts to 2.5×10^{-8}% (Photovac detector with a 10.9 eV lamp).[83] These figures are satisfactorily correlated, since the volume of the sample in the former case was 1 litre, while in the latter case it was 1 ml. The employment of high performance capillary columns and PID in which the volume of the working chamber was 30–40 μl for a minimal make-up gas flow rate or even in its absence made it possible to reduce still further the DL. The use of PID for the determination in air and aqueous media of alkylbenzenes, chloroalkenes, chlorobenzenes, mercaptans, carbon disulphide, and formaldehyde as microimpurities is effective. A DL of 10^{-8}% has been attained for formaldehyde on a HNU Systems microprocessor gas chromatograph 301D fitted with a PID having an 11.7 eV lamp.[95]

At the same time, the increased sensitivity of the PID to compounds of certain classes sometimes does not compensate for the non-clear-cut gas-chromatographic separation. Thus the use of PID with a 9.5 eV lamp for the determination of polyarenes in atmospheric dust without preliminary fractionation of the sample components gives rise to difficulties. The background due to alkanes, cycloalkanes, ethers, etc. is too large to analyse reliably trace elements of polyarenes.[107] The authors recommend a more selective PID with an 8.3 eV lamp. An analogous result has been obtained in a study of synthetic fuel using a 10.2 eV lamp.[108] The employment of 9.5 and 8.3 eV lamps made it possible to ensure a higher selectivity in relation to polyalkylated arenes, napthalene, and *N*-heterocyclic compounds, but the absolute sensitivity was significantly lower than that obtained with a 10.2 eV lamp. The insufficient selectivity of the PID-10.2 to aromatic amines and their halogeno- and nitro-derivatives and the insufficient sensitivity of the PID-9.5 to nitro- and dinitro-amines precluded the determination of the admixture of these compounds in a complex mixture of subtances.[89] For this purpose, it was necessary to employ columns with a greater separating capacity or to fractionate more fully the sample before the gas-chromatographic analysis.

In order to increase the sensitivity of PID to steroids and alcohols, it has been suggested that they be converted with the aid of flophemesyl chloride (pentafluorophenyldimethylsilyl chloride) into the corresponding derivatives.[90,109] The DL of the initial substances and their derivatives, obtained on a capillary column (15 m × 0.33 mm) with SP 2100 at 275 °C and a PID at 300 °C, are compared in Table 7.

The possibilities for the quantitative determination of more than 40 chlorine-, sulphur-, phosphorus-, and nitrogen-containing pesticides and for the recognition of their structures using PID with two lamps (9.5 and 10.2 eV) have been investigated.[110,111] A highly sensitive method has been developed for the determination of methadone in blood plasma. When a PID and a capillary column (25 m × 0.2 mm) with VR-5 was used, the DL was 10 fg.[112] Significant advantages of PID with a 10.2 eV lamp compared with FID have been discovered in the analysis of the methyl esters of saturated and unsaturated $C_{16}-C_{18}$ essential acids. In terms of sensitivity, the PID was superior to the FID by a factor of five and in addition to experiments with the PID the molar response was found to vary linearly with the number of double bonds in the acid molecule.[91] It has been suggested that the PID be used for the continuous monitoring of the content of epoxyethane in air[113] and for the determination of PH_3,[114] amines,[115] light hydrocarbons, arsine, phosphine, hydrogen sulphide, carbon disulphide, dimethyl sulphoxide, and chlorofluorohydrocarbons.[116] A portable Photovac 10A10 chromatograph, fitted with (0.25–4) m × 2.5 mm Teflon columns with SE-30 or CSP-20M, deposited on Chromosorb GAWDMCS, was used in the last case. The separation was carried out at room temperature. The detection limit for chlorofluorohydrocarbons was 10^{-8}%. In PID, new chemically bound stationary phases were tested for DB-624 capillary columns[117] and for HNU-permabond packed columns.[118] The phases proved to be extremely effective for the determination of polyarenes and chlorophenols[118]—the principal contaminants of the environment.[117] The piezoelectric detector was tested with the aid of the PID.[119]

Table 7. Detection limits of steroids and their derivatives.

Compound	Detection limit, pg	
	initial compounds	derivatives
Androsterons	33.3	6.2
Testosterone	55.4	13.9
Cholesterol	ND*	21.2
Ergosterol	ND*	39.5
Oesterone	61.6	8.1
Oestradiol	69.0	10.1
Etisterone	ND*	29.9

*ND – not detected.

The PID has come to be widely used in specialised gas chromatographs and systems. A method has been described[120] for the identification of 40 solvents ranging from n-pentane to 1,1,2,2-tetrachloroethane, including aliphatic hydrocarbons, arenes, alcohols, ketones, etc., on a Nordion/HNU Micromat two-channel chromatograph. The sample was separated on two parallel quartz capillary columns 25 m long, with SE-54 and Yukon 50. A PID with a 10.2 eV lamp was used. The identification was based on a retention index data bank.

Two PID with a non-separated emission and detection compartments[19] were built into a 4-channel multidimensional chromatograph.[27] The PID detected permanent gases and C_1-C_2 hydrocarbons after their separation on a micropacked column (2 m × 0.53 mm) with Porapak N or on a capillary column of the PLOT type (10 m × 0.32 mm) with 5 Å molecular sieves. Heavier hydrocarbons were determined on capillary columns with chemically bound stationary phases connected to two FID. The combination of FID and PID in a multidimensional chromatograph has been used to determine volatile impurities (including oxygen-containing compounds) in air.[121,122] Through a three-way connector, 6% of the gas stream emerging from the first packed column with 1,2,3-tri(2-cyanoethoxy)propane was directed into the PID and benzene and toluene were determined quantitatively, the formation of the required fraction being monitored at the same time, i.e. the

instant of its being directed to the cryogenic trap was determined. The trapped fraction was analysed in detail on a quartz capillary column (50 m × 0.3 mm) with OV-101 connected to the FID.

Attempts were made to use the PID-10.2 in hypercritical fluid chromatography.[54] A design for a PID with a hermetic seal, withstanding high pressures of the carrier gas, has been described. Tests of the PID showed that the sensitivity of the detector, determined with respect to benzene, falls sharply with increase in the CO_2 pressure: it is 4×10^{-4} C g^{-1} at a 1 atm pressure and 5×10^{-8} C g^{-1} at 100 atm. There is a corresponding increase in the DL—from 2×10^{-9} to 1.8×10^{-5} g s^{-1}. The authors explained the reduced sensitivity of the PID by the quenching effect:

$$M + h\nu \rightarrow M^+ + \bar{e}, \quad CO_2 + \bar{e} \rightarrow CO_2^-,$$
$$CO_2^- + M^+ \rightarrow CO_2 + M.$$

It has been concluded that the PID cannot compete with the FID in liquid chromatography.

Investigators,[87] who tested the PID (model 52-02 from the HNU Systems Company) with a 10.2 eV lamp at atmospheric CO_2 pressure, arrived at the opposite view. A pneumoresistance, heated to 400 °C, was mounted at the outlet from a micropacked column, while the outlet from the PID freely communicated with the atmosphere. Comparison of the PID with the FID in the determination of polyarenes, up to coronene, showed that the DL with the PID (0.2—1 ng) is significantly lower than with the FID. Furthermore, owing to the instability of the flame, particularly at a high CO_2 flow rate (20—70 ml min^{-1}), sharp deviations and a shift of the zero line were observed when the FID was used. An experiment involving the use of a PID in high performance liquid chromatography (HPLC) for the analysis of traces of organic compounds has also been described.[123,124]

VII. Multidetector systems

Different variants of multidimensional chromatography with several selective detectors have undergone a new development recently.[125] The substances emerging from the column pass simultaneously to several detectors connected in series or in parallel. The simplified chromatograms thus recorded reflect mainly the presence of substances to which a particular selective detector is sensitive. The case where virtually all the substances are detected by the detectors but the signal from each detector for the same substance is different is also important. Since in the series connection of the detectors the amount of the substance entering into each detector is the same while in the parallel connection it is possible to measure and take into account the ratio of the separated fluxes, the ratio of the signals due to the same substance from two detectors A and B is the ratio of the sensitivity coefficients. For stable characteristics of the detectors and for linearity of their response, this ratio is independent of the concentration of the substances being determined and is a constant suitable for identification. In order to increase the stability of the constants, the responses are normalised with respect to a selected standard:

$$K_i^{A/B} = (R_i^A/R_{st}^A)/(R_i^B/R_{st}^B),$$

where $K_i^{A/B}$ is the ratio of the normalised responses of the detectors A and B with respect to the ith substance, R_i^A and R_{st}^A are the responses (the peak area or height) of the detector A with respect to the ith substance and the standard respectvely, and R_i^B and R_{st}^B are the responses of the detector B.

As will be shown below, the values of $K_i^{A/B}$ differ appreciably for substances of different classes of chemical compounds and significantly less so for substances within a single class. The quantities $K_i^{A/B}$ are therefore used mainly for group identification. A universal analytical system has been developed in which the sensitivity ratios for the two detectors are used together with universal retention indices.[126]

Table 8. The values of $K_i^{PID/FID}$ for organic compounds.[75]

Compound	$100\ K_i^{PID/FID}$	Compound	$100\ K_i^{PID/FID}$
n-Pentene	2	Hept-3-ene	51
n-Hexane	4	Hept-2-ene	57
n-Heptane	7	2-Ethylhex-1-ene	57
n-Octane	8	α-Pinene	75
n-Nonane	14	β-Pinene	65
n-Decane	16	Vinyl chloride	53
n-Undecane	15	1,1-Dichloroethylene	190
2,3-Dimethylbutane	7	Trichloroethylene	300
2,3-Dimethylpentane	10	Tetrachloroethylene	290
2,2,4-Trimethylpentane	18	*cis*-1,3-Dichloropropene	124
3-Methylheptane	7	Acetone	160
2,2,5-Trimethylhexane	21	Butanone	153
Cyclohexane	25	2-Pentanone	105
Methylcyclohexane	36	3-Pentanone	141
But-1-ene	65	Propionaldehyde	84
Pent-1-ene	64	Butyraldehyde	60
Hex-1-ene	59	Isobutyraldehyde	67
Hept-1-ene	49	Isovaleraldehyde	66
Oct-1-ene	44	Valeraldehyde	56
Non-1-ene	52	Methanethiol	650
Dec-1-ene	36	Ethanethiol	350
Undec-1-ene	35	Butanethiol	133
Tetrahydrothiophen	185	n-Butylbenzene	66
Benzene	112	p-Diethylkbenzene	75
Toluene	100	Indan	80
m-Xylene	95	Naphthalene	123
o-Xylene	77	Chlorobenzene	150
p-Xylene	105	*m*-Chlorotoluene	135
Ethylbenzene	87	*o*-Chlorotoluene	124
n-Propylbenzene	79	*p*-Chlorotoluene	130
p-Ethyltoluene	79	*m*-Dichlorobenzene	154
1,3,5-Trimethylbenzene	117	*o*-Dichlorobenzene	137
1,2,4-Trimethylbenzene	81	*p*-Dichlorobenzene	155

Note. A 10.0 eV lamp was used; the standard was toluene

1. The photoionisation detector/flame inisation detector combination

The flame-ionisation detector (FID) is a universal detector with a high sensitivity and a wide linear dynamic range. One of the first two-detector combinations developed abroad[127] and in our country[128] and designed for identification incorporated a FID. The properties of PID and FID have been compared.[129] Table 8 presents the values of $K_i^{PID/FID}$ for oganic compounds. The PID/FID combination was first tested for the group identification of hydrocarbons and pesticides.[69] The values of $K_i^{PID/FID}$, normalised for C_5—C_8 alkanes, alkenes, and arenes, differ appreciably: <2, 2—4, and 5—10 respectively. For the sulphur- and chlorine-containing pesticides having aromatic and aliphatic carbon skeletons, the values of $K_i^{PID/FID}$ differ by a factor of 12—16, while pesticides with alkene structures have intermediate values of $K_i^{PID/FID}$. The possibility of the group identification of hydrocarbons has been investigated in numerous studies. Polotnyuk et al.[130,131] successfully used the PID-10.2/FID combination to assign the components of petrol [gasoline] to alkenes and cycloalkanes (K_i = 0.02—0.45), alkenes and cycloalkenes (0.4—0.65), and dienes and arenes

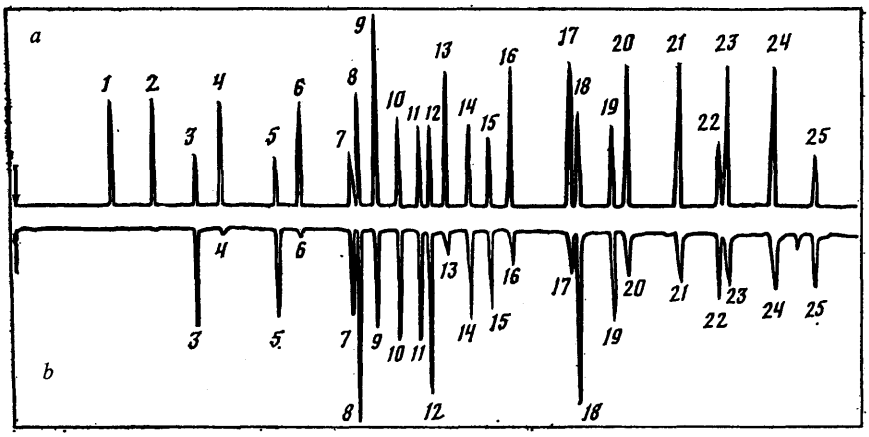

Figure 6. Chromatograms of a model mixture of hydrocarbons obtained with a FID (*a*) (8×10^{-9} A scale) and a PID-10.2 (*b*) (32×10^{-9} A scale).[57] 24 m × 0.5 mm × 1.1 μm glass capillary column with SE-54; carrier gas N_2; flow rate 1.6 ml min^{-1}; the stream of nitrogen from the column is divided between the detectors in proportions of 1 : 1; flow rate of the N_2 make-up gas for FID and PID 30 and 14 ml min^{-1} respectively; column temperature rise programmed between 40° and 270 °C at a rate of 6 K min^{-1}; temperature of detectors 270 °C; 0.12 μl sample injected directly into the column; *1*, n-C_5; *2*, n-C_6; *3*, benzene; *4*, n-C_7; *5*, toluene; *6*, n-C_8; *7*, ethylbenzene; *8*, *m*-xylene + *p*-xylene; *9*, n-C_9 + *o*-xylene; *10*, cumene; *11*, n-propylbenzene; *12*, mesitylene; *13*, n-C_{12}; *14*, *p*-cymene; *15*, n-butylbenzene; *16*, n-C_{11}; *17*, n-C_{12}; *18*, naphthalene; *19*, n-hexylbenzene; *20*, n-C_{13}; *21*, n-C_{14}; *22*, n-octylbenzene; *23* n-C_{15}; *24*, n-C_{16}; *25*, n-decylbenene.

(0.65 – 1.00) and demonstrated the effectiveness of this procedure for the refinement of the gas-chromatographic identification. According to the authors,[132,133,138] the ratios of the sensitivities of the PID and the FID combined with the retention indices ensure a reliable identification of the peaks. An experiment involving the group identification of alkanes (0 – 43), alkenes (44 – 48), and arenes (75 – 158) in $C_6 - C_9$ hydrocarbons present in air has been described.[55] Measurements have been made[57] of the quantities $K_i^{PID/FID}$ using PID-10.2 for methyl ethers and aldehydes (< 1) and alkanes, isoalkanes, naphthenes, and alcohols (1 – 6), alkenes (12 – 17), alkylbenzenes (6 – 17), and *N*-heterocyclic compounds (5 – 40). It was shown that, with increase in the molecular weight of the substances, the overlap of the $K_i^{PID/FID}$ ranges for different groups increases (Fig. 6). The photoionisation detector with a 9.5 eV lamp is more selective but its sensitivity is appreciably lower. The reliability of the group identification could be increased by employing two groups of tabulated values of $K_i^{PID/FID}$,[75] which assigned the test substances to halogenoalkanes, alkanes, cycloalkanes, trimethylalkanes, alkynes, alkenes, aldehydes, ketones, arenes, halogenoarenes, and sulphur-containing hydrocarbons. The substances emerging from the column during the first 17 min were identified in terms of one group of values, while those eluted after 17 min were identified in terms of the second group. The values of $K_i^{PID/FID}$ for these substances are listed in Table 8.

The same workers used a parallel PID/FID combination for the determination of $C_1 - C_{10}$ hydrocarbons in air.[134] The impurities were concentrated from air in a cryogenic trap and were separated on a capillary column 60 m long with SE-30. Alkanes, alkenes, and arenes were differentiated.

2. The photoionistion detector/electron capture detector combination

The high sensitivity of the ECD to organic halogeno-compounds makes it irreplaceable in the determination of halogenohydrocarbons in the environment. It has been acknowledged that the PID/ECD combination is promising for the determination of chlorine-containing compounds in atmospheric waste.[133]

In the study of Jaramillo et al.,[133] as in those of Polotnyuk et al.[131] and Towns et al.,[132] the values of $K_i^{PID/FID}$ served as an additional factor for the identification of the individual compounds. The combination of PID with ECD makes it possible to differentiate chlorobenzenes in terms of the number of chlorine atoms in the molecule.[135] The difference is based on weak dependence of the sensitivity of the PID-10.02 on the chlorine content (Table 4) and on the appreciable increase in the ECD signal on passing from chlorobenzene to dichlorobenzene and further to hexachlorobenzene. Accordingly, the PID/ECD signal ratio varies from 4.0 and 0.03. The values of $K_i^{PID/FID}$ are also used to identify hydrocarbons and their nitro-derivatives.[80,135] In this case, the sensitivities of the detectors change in the opposite direction. The values of $K_i^{PID/FID}$ are 25 – 78 for polyarenes, 0.3 – 0.6 for nitropolyarenes, 1 – 1.5 for nitrotoluenes, and 0.004 – 0.020 for dinitrotoluenes. Thus the identification of arenes and their nitro- and dinitro-derivatives is extremely reliable.

3. Combination of the photoionisation detector with electrical conductivity detector

Chlorine-containing compounds are detected selectively by the Hall or Coulson electrical conductivity detector (ECD). This feature of the ECD has been used to determine halogenohydrocarbons in

water, while light arenes were detected with a PID-10.2 connected in series with an ECD.[136] Three columns were used to separate halogenohydrocarbons and alkylbenzenes—the main column and the two special columns. The employment of selective detectors simplifies the chromatogram. Out of the 42 substances detected in the sample, the PID failed to detect 18 halogenohydrocarbons, while the ECD failed to detect nine alkylbenzenes. A similar problem was solved using the halogen variant of the ECD and a PID-9.5.[137] In a sample of soil water (volume 5 ml), it is possible to determine with the aid of the ECD chlorinated hydrocarbons at concentrations up to 0.6–4.0 μg litre^{-1}, while with the aid of the PID it is possible to determine C_6-C_8 arenes at concentrations up to 1.0–1.1 μg litre^{-1}.

Methods have been developed for the determination of volatile organic compounds in drinking water using gas extraction and concentration[138] and also in sewage on quartz capillary columns.[139] The influence of experimental parameters on the duration of analysis and the reproducibility of the determination of 36 chlorohydrocarbons and arenes in natural water using a series-connected combination of a PID and an ECD in capillary columns 0.32 and 0.53 mm in diameter has been investigated in detail.[140] It has been shown that the PID/ECD combination makes it possible to reduce the analytical time and the cost of analysis as a result of the high selective sensitivity of the PID to hydrocarbons and of the ECD to nitrogen-, sulphur-, and halogen-containing compounds.[141] The PID/ECD combination has been used successfully to determine DDT and DDE impurities (10 p.p.m.) in the presence of 1000 p.p.m. of toxaphene.[125] The use of a PID with a 9.5 eV lamp permitted the selective detection of *p,p'*-DDT and *p,p'*-DDE, which have aromatic rings in their structure, while the employment of the ECD permitted the detection of all the halogen-containing substances.

4. The combination of the photoionisation detector with other detectors

The series connection of PID with 10.2 and 8.3 eV lamps and of a thermionic detector tuned to determine nitrogen-containing compounds has been used for the structural identification of aromatic and aliphatic amines.[142] Fig. 7 shows that the combination of the PID-10.2 with a (N/P)-detector makes it possible to differentiate reliably hydrocarbons from amines, while the combination of the PID-8.3 with a (N/P)-detector makes it possible to differentiate primary amines from secondary and tertiary amines. The ratio of the PID signal to the signal of the (N/P)-detector is appreciably greater for tertiary amines compared with secondary amines (Table 9).

The development of an improved UV-detector based on the absorption of light in the far UV region and having a working chamber with a volume of 40 μl increased significantly the possibilities for its combination with PID fitted with 10.2 and 11.7 eV lamps.[143] The UV-detector detects certain Freons, methane, and water to which the PID-11.7 is almost insensitive. It is recommended that the PID/UV detector response ratio be used to identify low-molecular-weight hydrocarbons, aldehydes, alcohols, and sulphur-containing compounds.[86]

Combinations of PID fitted with lamps having different energies have been used to identify hydrocarbons. The PID-11.7/PID-10.2 response ratios proved suitable for the differentiation of alkanes, alkenes, cycloalkanes, and arenes.[72] The combination of PID fitted with 9.5 and 8.3 eV lamps is sensitive to the structure of polyarenes and can be used to differentiate isomers. For example, the PID-9.5/PID-8.3 response ratio is 13 for anthracene and 43 for phenanthrene.[144]

5. Combination of three detectors

The combination of PID with two detectors has been used to analyse organic impurities in air and different gases. The PID/FID/ECD combination has been used.[74,76,145,146] In this combination, the universal FID is designed to detect hydrocarbons, PID is designed to detect alkenes and arenes, and ECD is designed to detect halogenohydrocarbons, i.e. the entire set of the principal low-boiling compounds usually present in air.

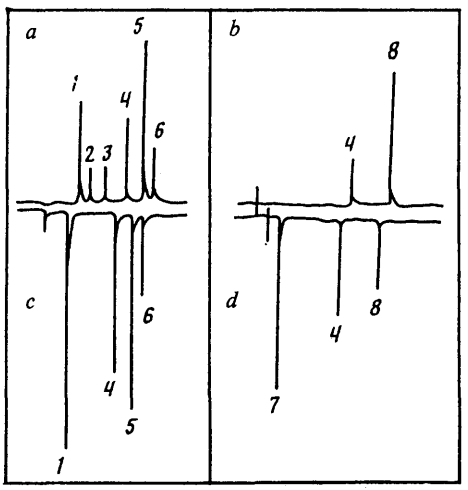

Figure 7. Chromatograms of amines obtained with a PID-10.2 (*a*), a PID-8.3 (*b*), and a (N/P)-detector (*c* and *d*); column 1.8 m long with Synerg C-AP at temperatures programmed from 80° to 190 °C at a rate of 15 K min^{-1} and with a helium carrier gas flow rate of 30 ml min^{-1}; *1*, n-heptylamine; *2*, n-dodecane; *3*, n-tridecane; *4*, di-n-hexylamine; *5*, dicyclohexylamine; *6*, dodecylamine; *7*, n-hexylamine; *8*, tri-n-hexylamine.[142]

Table 9. The ratio of the PID and (N/P)-detector signals for certain amines.

Compound	Signal ratio	
	PID-10.2 signal: (N/P)-detector signal	PID-8.3 signal: (N/P)-dector signal
Di-n-hexylamine	2.3	0.01
Tri-n-hexylamine	4.0	0.04
Dibenzylamine	6.4	0.004
Tribenzylamine	9.8	0.3

The stream of carrier gas emerging from the capillary column 60 m long and containing Al_2O_3/KCl was divided in proportions of 1 : 5 between ECD and PID + FID.[76] The impurities from one litre of air were concentrated in a cryogenic accumulator and C_1-C_2 halogenohydrocarbons were determined by the ECD with a DL in the range $1 \times 10^{-10}-9 \times 10^{-9}$%; benzene, C_3-C_8 alkenes and

alkanes, and C_1-C_3 chloroalkenes were determined by the PID-10.2 with a DL in the range $5 \times 10^{-12}-1 \times 10^{-8}$%, and C_2-C_8 aliphatic hydrocarbons and benzene were determined by the FID and a DL of $(1.2-5) \times 10^{-9}$%. A trap cooled to −173 °C was also used by Rudolph and Jepsen.[74] The detectors were connected in series. For an air sample volume of one litre, the DL for the detection of C_1-C_2 halogenohydrocarbons and CS_2 by the ECD was $2 \times 10^{-11}-3 \times 10^{-10}$%, the DL for C_3-C_6 hydrocarbons and certain chloroalkanes detected by the FID was $5 \times 10^{-10}-5 \times 10^{-11}$%, the DL for C_3-C_6 hydrocarbons and halogenohydrocarbons detected by the PID-11.7 was $2 \times 10^{-10}-2 \times 10^{-9}$%, and the DL for propene, butadiene, benzene, trichloroethylene, and CS_2 detected by the PID-10.2 was $2 \times 10^{-11}-3 \times 10^{-10}$%. The three detectors indicated made it possible to identify twenty organic compounds out of the 150 found in air.[146] The identification was based on the retention times and the detector response ratios. The advantages of the series connection of a UV-detector, a PID, and an FID have been examined.[147] The detector system has been recommended for the analysis of industrial gaseous waste and smoke and exhaust gases. It has been suggested that a combination of a PID, an ECD, and an ultrasonic detector be used for the determination of impurities comprising inert, corrosive, and combustible substances (at the level of p. p. m.) in different gases.[148] The characteristics of the detection of nitrogen, argon, hydrogen, oxygen, methane, ammonia, silanes, phosphine, arsine, etc. by the ultrasonic detector have been examined.

6. Devices for multidimensional detection

The combinations examined represent mechanical combinations of standard detecting devices. Multidimensional detectors, in which there are one or several detection zones combined in a single shell while the output signals reflect different properties of the detected molecules, have been developed vigorously recently. A design has been proposed for a detector with two chambers separated by a LiF or MgF_2 window in which the ionisation current and non-absorbed photons are recorded.[149] An example of a multidimensional detector, in which photoionisation is used and there is one detection zone, is provided by a device where the principal element is an evacuated chamber and a laser beam is used to ionise the compounds emerging from the column and entering the chamber and to excited their fluorescence.[150] The total electron current is measured with the aid of an electrode placed in the chamber. The fluorescence emitted is detected by a photomultiplier. Positive ions enter a time-of-flight mass spectrometer tuned to a specific mass. Thus the device ensures the detection of three different angles. Its operation was tested on a model mixture of 64 compounds. The sensor measuring the total electron current detected 24 compounds, predominantly of an aromatic character, with a detection limit of 6−500 pg. The mass detector had a significantly greater sensitivity: the detection limit varied from 1 to 63 pg. The fluorescence signal arose from 15 substances. The use of a controllable vacuum UV laser is in general extremely promising for photoionsation detection, because it increases the spectral selectivity and ionisation efficiency, reduces the detection volume, and creates the possibility of measuring the ionic mobilities. The PID constructed on the basis of these principles make it possible to detect polycyclic arenes with the detection limit of 0.3−50 pg.[151]

---o0o---

Photoionisation sensors are some of the principal detectors in gas chromatographs together with FID, ECD, (N/P)-detectors, and the katharometer. The high sensitivity to many organic and inorganic compounds (the sensitivity is in fact highest to certain classes of compounds) together with a pronounced selectivity and a wide linear dynamic range constitute the advantages of the use of PID in gas-chromatographic analysis. Important features of PID are the possibility of the specific regulation of the selectivity by employing UV lamps with different emission energies and also an increased sensitivity to the structure of the carbon skeleton of the molecule. The use of new materials, the improvement of the design, and an increase in the operating life of the lamps are the principal ways of improving the operating characterisics of PID and of securing reproducible detector signals. The development of detectors based on laser multiphoton ionisation is also promising.

Modification of polymers by polymeric additives

A E Nesterov, E V Lebedev
Institute of the Chemistry of Macromolecular Compounds, Kiev

ABSTRACT. The conditions for the thermodynamic compatibility of polymers and methods for its enhancement are examined. The study of the influence of various factors on the concentration-temperature limits of compatibility, dispersion stabilisation processes, and methods for the improvement of adhesion between phases in mixtures of thermodynamically incompatible polymers is described. Questions concerning the improvement of the physicomechanical characteristics of polymer dispersions are considered.

The bibliography includes 200 references.

IV. Conclusion 803

I. Introduction

The acceleration of scientific and technical progress requires the creation of new materials with the needed set of properties. Composite materials incorporating polymers containing a wide variety of fillers, mixtures and blends of two or more polymers, etc. have been acquiring an increasing role in the solution of this problem at the present time.

Since the preparation of new polymeric materials with the required properties can no longer be wholly based on the synthesis of new high-molecular-weight compounds, the era of problems concerning the modification of polymers already produced by industry and the preparation of materials with the required properties on their basis has now dawned. One of the most readily available and economically favourable modification procedures involves the preparation of mixtures and blends of two or more polymers, interpenetrating networks, etc. The properties of such systems are determined by their structure, whose formation is associated with the thermodynamic compatibility or incompatibility of the components and mechanism of phase separation under the conditions of the preparation of the composition and its conversion into finished articles. The practical experience gained in the preparation and use of finished articles made from such materials has shown that, in order to obtain the desired properties, thermodynamic compatibility of the components is needed in some cases, whilst in others it is in fact undesirable. For example, the view has been expressed[1] that, in terms of their mechanical properties, two-phase mixtures are superior to single-phase mixtures and that the subdivision of systems into thermodynamically compatible or incompatible has no great practical value. On the other hand, analysis of literature data has led Paul and Barlow[2] to the conclusion that materials obtained from compatible systems have on the whole better properties. A truly homogeneous product can be obtained from thermodynamically compatible polymers. In the case of compatible systems, a synergism is observed in a series of important physicomechanical properties such as moduli and strength, the transparency of the materials is ensured, and there are other advantages.[3–8] The compatibility of polymers guarantees also the operational reliability of the articles made from them, especially under the conditions of variable loads and in different temperature regimes. Much attention has therefore been devoted in recent years, particularly abroad, to the search for thermodynamically compatible pairs and significant progress on these lines has been achieved: about 300 thermodynamically compatible polymer pairs have now been discovered.[8–12]

In those cases where for the attainment of the required properties mixtures of thermodynamically incompatible polymers are used (impact-resistant plastics, certain adhesives), it is essential to stabilise the dispersion because, owing to the weak adhesion between the phases in such cases, difficulties arise in the attainment of the required degree of dispersion of the mixture components during their processing and their stability is impaired both during preparation and during use.[3] In many instances the weak adhesion between the phases impairs the mechanical properties.[3,13–16] Much attention has therefore been devoted nowadays to problems of the stabilisation of mixtures of this kind, the improvement of adhesion between the phases, etc.

This review surveys the literature data on the compatibility of polymers and on its dependence on various factors. Questions concerning the stabilisation of dispersions and the regulation of the properties of materials made from mixtures of thermodynamically incompatible polymers are also considered.

II. The compatibility of polymers and methods for its regulation

A large number of both original publications and reviews and monographs have been devoted to problems of the compatibility of polymers and the search for thermodynamially compatible polymer systems.[2,8,12,17,18] The study of the thermodynamic compatibility of polymers has led to the conclusion that in the vast majority of cases it is determined by specific interactions, which ensure the exothermicity of the mixing process, i. e. lead to a negative enthalpy of mixing.[3,10,18–22] It has been demonstrated for the first time by Tager and co-workers[23,24] that the entropy of mixing of thermodynamically compatible polymers is also negative. On this basis, the requirement that $\Delta S < 0$ has been put forward as one of the conditions for the compatibility of polymers.[25] Since the enthalpy

and entropy of mixing of compatible systems are negative, these systems should separate into layers on heating, i.e. should be characterised by the presence of a lower consolute temperature (LCT). Indeed the majority of the thermodynamically compatible polymer pairs found hitherto do have a LCT.[9-11] Upper consolute temperatures (UCT) are characteristic mainly of oligomer–oligomer and oligomer–polymer mixtures, mixtures of polymers with plasticisers, and mixtures of certain homopolymers with copolymers.[11,26-30]

In order to account for the exothermicity of the mixing process, the concept of the "mutually complementary difference" was put forward,[17] whose essential feature is that the macromolecules of the mixed polymers should contain groups complementing one another and capable of forming hydrogen bonds with one another or electron donor–electron acceptor complexes. This concept actually constitutes the basis of the study of polymer solutions.[31] A somewhat different approach has been used[32] to describe processes involving the mixing of homopolymers with variable-composition copolymers (binary interactions model). We shall consider these approaches in relation to specific examples.

1. The formation of ion pairs

Polystyrene is known to be incompatible with polyacrylate and polyisobutylene.[33] Nevertheless, polystyrene modified by a sulphonic acid or 4-vinylpyridine is compatible with the above polymers provided that polyacrylate, for example, is modified by 4-vinylpyridine, while polyisobutylene is modified by a sulphonic acid.[34] Such mixtures are compatible over the entire range of compositions, provided that the number of modifying groups in each polymer exceeds 5%.[34] The compatibility is caused by the formation of ion pairs as a result of the protonation of the pyridine ring by the sulphonic acid group. The Coulombic interaction between the ions is sufficient to ensure compatibility. Similarly the formation of stable intermolecular pyridine–carboxylate bonds (ion pairs) ensures the compatibility of oppositely charged polyelectrolytes such as the butadiene–methacrylic acid copolymer and the butadiene–2-methyl-5-vinylpyridinium iodide copolymer.[35,36] The formation of ion pairs leads to the compatibility of the lithium salts of the styrene–methyl methacrylate copolymer with poly(ethylene oxide) and poly(propylene oxide) [37-39] and also of the lithium salts of the ethyl acrylate–acrylic acid copolymer with polyethyleneimine.[40] It has been shown[38] that an increase in the radius of the cation (the replacement of Li by K or Na) in the salts of the styrene–methyl methacrylate copolymer containing 10.4 mol% of acrylate reduces the phase separation temperature of its mixtures with poly(ethylene oxide) and poly(propylene oxide) (systems with a LCT).

2. Other specific interactions

Polyolefins with high molecular weights are as a rule incompatible with other polymers.[33] However, chlorination of polyethylene, for example, makes it compatible with poly(vinyl chloride),[41-43] poly(methyl methacrylate) (when polyethylene contains between 27 and 50% of chlorine),[44-46] polycaprolactone (when polyethylene contains more than 25% of chlorine),[47] and poly(neopentyl glycol adipate) (when polyethylene contains between 42 and 48% of chlorine).[48] The compatibility of chlorinated polyethylene for example, with poly(methyl methacrylate) has been explained by the negative enthalpy of mixing, which can be caused by the formation of hydrogen bonds between the α-hydrogen atoms of polyethylene and the C=O groups of poly(methyl methacrylate) or by dipole–dipole interactions of the type C=O...Cl–C.[44] In particular, the compatibility of chlorinated polypropylene with polyesters has been explained[49] by dipole–dipole interactions of the type C=O...Cl–C, because the chlorinated polypropylene used in the above study did not have sufficient α-hydrogen atoms for the formation of hydrogen bonds with the C=O groups of the polyesters.

The method involving the Fourier transformation of IR spectra has been widely used in recent years to detect the occurrence of specific interactions (for example, hydrogen bonding).[50-62] It has been shown for mixtures of poly-4-vinylphenol with ethylene–vinyl acetate copolymers[52] that this method makes it possible to estimate even quantitatively the strength and number of intermolecular bonds and their temperature dependence. Measurements of the absorption band intensities in the region of 1738 and 1708 cm^{-1} (the frequencies of the free and hydrogen-bonded C=O groups) have been used[52] to estimate the fraction of carbonyl groups participating in the formation of hydrogen bonds and the heats of formation of the complex. The calculations were performed for two specimens: one of them was obtained from solution and dried at room temperature, while the other was first heated to 463 K. The spectra of the first specimen were obtained on heating and those of the second on cooling. In the former case, the free carbonyls participated in the formation of hydrogen bonds. If the intensities (areas) of the absorption bands near 1738 and 1708 cm^{-1} of the dried film obtained from the solution are designated by I_1 and I_2 respectively and those of the bands of the heated film are designated by I_1' and I_2', then

$$a_2(I_1 - I_1') = a_1(I_2' - I_2),$$

whence

$$a_1/a_2 = (I_1 - I_1')/(I_2' - I_2),$$

where a_1 and a_2 are the absorption coefficients for 1738 and 1708 cm^{-1} bands respectively. Having determined the ratio a_1/a_2, it is possible to calculate the fraction of carbonyl groups involved in the formation of hydrogen bonds.

In order to calculate the intermolecular interaction forces, the 1 : 1 complex is represented as a mixture of poly-4-vinylphenol with the ethylene–vinyl acetate copolymer at molar concentrations designated by [–OH] and [–C=O] respectively. The concentration of carbonyl groups involved in the formation of hydrogen bonds is designated by x. We then have in a simplified form

$$\text{—OH} + \text{—C=O} \overset{K}{\rightleftarrows} \text{—OH...O=C—},$$
$$K = x/([\text{—OH}] - x)([\text{—C=O}] - x),$$
$$\ln K = (-\Delta H/RT) + C,$$

where K is the equilibrium constant and ΔH the enthalpy of formation of the complex.

The dependence of $\ln K$ on $1/T$ is illustrated in Fig. 1, which shows that, below the glass point of the system (T_g = 360 K), the dependence of $\ln K$ on $1/T$ becomes non-linear, which may be associated with the non-equilibrium nature of the system. The values of ΔH and C were determined from the initial section of the $\ln K = f(1/T)$ relation and were found to be 21.4 kJ mol^{-1} and −6.55 respectively. Using these values as a basis, Moskala et al.[52] calculated the fraction of carbonyl groups participating in the formation of hydrogen bonds and found that at temperatures below T_g it exceeds the experimental value (curves *2* and *5* in Fig. 2). This is evidence that below T_g the system is indeed in a state of non-equilibrium possibly because of the low mobility of the

macromolecules under these conditions. With increase in the vinyl acetate content in the system, the consolute temperature increases, i.e. hydrogen bonding becomes possible at a higher temperature (Fig. 2). It has also been suggested that the LCT be estimated approximately from the temperature variation of the shift of the stretching vibration frequency of the C=O groups.[53] For example, it has been shown by this method[53] that the LCT should be observed in the temperature range 363–383 K for mixtures of chlorinated poly(vinyl chloride) with the ethylene–vinyl acetate copolymer and in the range 383–403 K for mixtures of poly(vinyl chloride) with the ethylene–vinyl acetate copolymer.

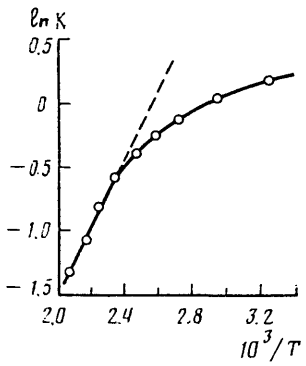

Figure 1. Dependence of $\ln K$ on $1/T$ for an 8 : 8 mixture of poly-4-vinylphenol with the ethylene–vinyl acetate copolymer (45% of vinyl acetate).[52]

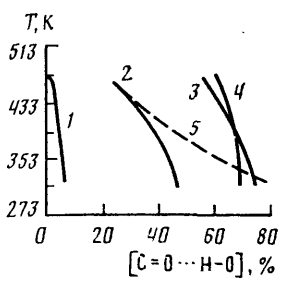

Figure 2. Temperature dependence of the fraction of C=O groups participating in the formation of hydrogen bonds for mixtures of poly-4-vinylphenol with 8 : 2 ethylene–vinyl acetate copolymers for different contents of vinyl acetate in the copolymer:[52] *1*–*4*, experimental data; *5*, calculation. Content of vinyl acetate in the copolymer (%): *1*, 25; *2* and *5*, 45; *3*, 70; *4*, 100.

A shift of the absorption bands of the hydroxy-group (3100–3700 cm^{-1}) has been observed in mixtures of poly(methyl vinyl ether) with polycaprolactone [57] and of poly(methyl vinyl ether) with the polyhydroxylated ether of bisphenol A with increase in the content of the second component.[58] The occurrence of specific interactions has been observed by this method also in mixtures of polycarbonate with poly(hexamethylene adipate),[59] of polycaprolactone with poly(vinylidene fluoride)–vinyl chloride and vinylidene chloride–acrylonitrile homopolymers and copolymers,[59,60] of poly(vinyl chloride) with poly-ε-caprolactone,[51] of poly(vinyl chloride) with poly-α-methyl-α-n-propyl-β-propiolactone and poly-β-valerolactone,[50] of poly(vinyl chloride) with ethylene–dimethacrylamide ethylene dimethacrylate–ethyl acetate–CO, ethylene dimethacrylate–vinyl acetate–CO, and ethylene dimethacrylate–ethylhexyl acrylate–CO copolymers,[62] of poly(vinyl chloride) with ethylene–vinyl acetate copolymers,[53] of poly(vinylidene fluoride) with poly(methyl methacrylate),[52] and also of the styrene–allyl alcohol copolymer with poly(vinyl acetate), polycarbonate, and poly(methyl methacrylate) with different degrees of stereoregularity.[61] In mixtures of the styrene–allyl alcohol copolymer with polycarbonate, the maximum degree of compatibility was attained when the content of OH groups in the copolymer was approximately 9%, while in its mixtures with polycaprolactone the dependence of the thermodynamic interaction parameter on the content of the OH groups passed through a minimum whose position corresponded to an approximately 3% content of these groups in the copolymer.[61,63] The formation of hydrogen bonds is the cause of the compatibility of polyhexafluoromethylvinylcarbinol and its copolymers with styrene (for styrene contents from 0.1 to 12%), poly(methyl methacrylate), poly(ethyl methacrylate), and poly(butyl methacrylate), polycaprolactone, and poly(methyl vinyl ether),[55] and also with poly-2,6-dimethyl-1,4-phenyleneoxybisphenol A carbonate.[56] In these systems, the hydrogen of the hexafluorocarbinol group forms a hydrogen bond with the carbonyl, ether, and carbonate groups of the polymeric admixtures. Under these conditions, an increase in the content of the OH groups in the copolymer raises the phase separation temperature (systems with a LCT).

Numerous studies have been devoted to the compatibility of poly(vinyl chloride) with other polymers.[64–84] A characteristic feature of these mixtures is that hydrogen and electron donor–electron acceptor bonds can be formed in them.[18,85,86] Poly(vinyl chloride) is compatible with poly(alkyl acrylates) when the number of carbon atoms in the alkyl group is less than 4 and with poly(alkyl methacrylates) if the number of carbon groups is less than 6. Thus it follows that poly(vinyl chloride) should mix with poly(methyl methacrylate). In practice, contradictory results have been obtained for this system. Thus the presence of a LCT has been observed,[67] while in other studies[83,84] a HCT has been noted! These contradictions have been explained[67] by the non-equilibrium nature of the system. The results of the study[87] in which the compatibility of poly(vinyl chloride) with poly(alkyl acrylates) and poly(alkyl methacrylates) was investigated are of interest from this point of view. It was observed that the curve relating the Flory–Huggins thermodynamic interaction parameter χ_{12} to the length of the alkyl group in poly(alkyl methacrylates) and poly(alkyl acrylates) passes through a minimum, i.e. there is a minimum concentration of ester groups at which these polymers mix with poly(vinyl chloride). An attempt was made to explain this finding by the relative contributions of the specific and dispersion interactions.[87] For this purpose, the heats of mixing were measured for the oligomers modelling the polymethacrylates and polyacrylates (M = 1000 to 3000) with chlorinated paraffin (M = 437, chlorine content 53.1%), modelling poly(vinyl chloride). The heats (enthalpies) of mixing, measured calorimetrically, proved to be negative in all cases, with the exception of the mixture with oligomethacrylate. The contributions to the heat of mixing by dispersion interactions, calculated on the

basis of the theory of solubility parameters, and by specific interactions (the difference between the overall and calculated heats of mixing) were estimated and it was noted that, in order to ensure compatibility, it is essential that the specific interactions should overlap the dispersion interactions. The heats of mixing of model compounds were clearly correlated with the compatibilities of the corresponding high-molecular-weight components. However, a reliable correlation was not observed between the heats of mixing and the thermodynamic interaction parameters χ_{12}, which can apparently be due to the contribution of the non-combinatorial entropy of mixing to the parameter χ_{12}.[18]

In connection with the use in a number of studies of model low-molecular-weight analogues, mention should be made of the method, proposed by Ebert et al.,[88] for the determination of the heats of mixing of compatible polymers by measuring the heats of the phase separation process. Differential scanning calorimetry (DSC) is used for such measurements. The sign of the DSC peak depends on the sign of the heat of mixing: an endothermic heat of phase separation corresponds to an exothermic heat of mixing and conversely. The size of the DSC peak, which is proportional to the integral heat of phase separation, corresponds approximately to the overall heat of mixing. The method has been tested in relation to a mixture of poly(ethyl acrylate) with poly(vinylidene fluoride). The heats of mixing found by this method agree with the corresponding values for oligomeric mixtures of the same type obtained calorimetrically.

The thermodynamic compatibility of chlorinated poly(vinyl chloride) (chloride content 67.2%) with polycaprolactone, poly(hexamethylene sebacate), poly-α-methyl-α-n-propyl-β-propiolactone, polyvalerolactone, poly(ethylene adipate), poly(ethylene succinate), and poly-β-propiolactone has been explained by specific interactions.[65,69] It has been shown in relation to a mixture of poly-ε-caprolactone with α-deuteriated poly(vinyl chloride) and solutions of polycaprolactone in carbon tetrachloride, tetrahydrofuran (THF), and chloroform and of methyl acetate (as a model analogue of ester groups) in pure water and in solution in carbon tetrachloride, that $-CH\ldots OOC-$ interactions between the $-CH(D)$ groups of poly(vinyl chloride) and the $-COO$ groups of polycaprolactone take place in systems of the poly(vinyl chloride)–polycaprolactone type.[54] The compatibility of the vinylidene chloride–acrylonitrile (20%), vinylidene chloride–vinyl acetate (20%), and vinylidene chloride–vinyl chloride (12%) copolymers with polycaprolactone, poly(hexamethylene sebacate), poly-α-methyl-α-n-propyl-β-propiolactone, and poly(ethylene adipate) is determined by the interaction of the C=O and C–Cl dipoles.[89] The altered thermodynamic interaction parameter is then a function of mixture composition. It is of interest that polylactones are incompatible with poly(vinyl fluoride) and poly(vinylidene fluoride).[79] It has been suggested[79] that this is associated with the significant difference between the electronegativities, atomic radii, and molar attractions of the chlorine and fluorine atoms (fluorine is more negative than chlorine, as a result of which it forms stronger chemical bonds with other atoms[90]). The compatibility of polylactones with poly(vinyl bromide) is greater than with poly(vinyl chlorides). On the other hand, poly(vinylidene fluoride) is compatible with many poly(alkyl methacrylates) and poly(alkyl acrylates) [98] containing short alkyl groups.

The compatibility of chlorinated polymers [poly(vinyl chloride), chlorinated poly(vinyl chloride), chlorinated polyethylene] with poly(ethylene terephthalate), poly(butylene terephthalate), and poly(hexamethylene terephthalate) and also of polyesters of the type of polycaprolactones, poly(2,2,-dimethyl-1,3-propylene adipate), poly(1,4-cyclohexanedimethylene succinate), and poly(2,2-dimethyl-1,3-propylene succinate) with chlorinated polymers has also been explained by the interaction of chlorine atoms with C=O groups.[93–96] Compatibility is achieved for a high chlorine content and for a definite concentration of C=O groups in the polymers.[97] The region corresponding to the compatibility of the hydroxyethyl ether of bisphenol A with aliphatic polyesters,[96] of chlorinated poly(vinyl chloride) with polyesters,[69] of poly(2,6-dimethyl-1,4-phenylene oxide) with aliphatic polyesters, etc.[98] is determined by the CH_3/COO ratio. Consequently it might have been expected that the introduction of C=O groups into the corresponding polymer or copolymer should have ensured its compatibility, for example, with chlorinated polymers, which has in fact been confirmed experimentally.[62,99,100] It has been suggested that in all the examples quoted the compatibility is determined by the formation of hydrogen bonds between the α-hydrogen atoms of poly(vinyl chloride) and the C=O groups of the added polymers or copolymers.

Interesting results have been obtained in the study of the influence of the position of the substituent on the compatibility of poly(2,6-dimethyl-1,4-phenylene oxide) with halogen-substituted styrene copolymers.[101–103] The above polymer is known to be compatible with polystyrene,[33] but is not compatible with poly-*o*-chlorostyrene, poly-*p*-chlorostyrene, or poly-*o*-fluorostyrene.[101,102] Poly(phenylene oxide) is compatible with styrene–halogenostyrene copolymers only for certain contents of halogenostyrene.[105] Thus poly(phenylene oxide) is compatible with *o*-chlorostyrene–*p*-chlorostyrene copolymers for a *p*-chlorostyrene content in the copolymer from 23 to 65%. It is also compatible with *o*-fluorostyrene–*o*-chlorostyrene copolymers for a *o*-chlorostyrene content between 15 and 36% and with *o*-fluorostyrene–*p*-chlorostyrene copolymers for a *p*-chlorostyrene content from 5 to 80%.[102] However, poly(phenylene oxide) is incompatible with the *p*-chlorostyrene–*p*-fluorostyrene copolymer of any composition.[102,103] The authors believe that in the examples quoted the compatibility is determined by repulsion effects, while incompatibility is determined by the specific interaction between different covalently linked comonomers.[103] The halogen content in the styrene–halogenostyrene copolymer for which poly(phenylene oxide) is compatible with the copolymer depends under these conditions on the type of halogen and increases in the following sequence: *o*-Br < *p*-F < *p*-Br < *o*-Cl < *o*-F.

It is noteworthy that in mixtures of homopolymers with copolymers the transition from compatibility to incompatibility occurs much more abruptly after a slight change in the composition of the copolymer.[96,104–106] A general characteristic feature of such mixtures is the presence of the so called "compatibility windows" which are observed also when the corresponding homopolymers are incompatible. For example, neither polystyrene nor polyacrylonitrile are compatible with poly(methyl methacrylate) and poly(ethyl methacrylate). However, the styrene–acrylonitrile copolymer is compatible with them.[107,108] The ethylene–vinyl acetate and butadiene–acrolynitrile copolymers are compatible with poly(vinyl chloride), but the corresponding homopolymers are incompatible with the latter.[73]

Clearly, such behaviour of systems of this kind cannot be accounted for by purely specific intermolecular interactions. In order to describe the thermodynamic behaviour of such systems, a binary interaction model has been proposed,[32] which includes intramolecular and intermolecular interactions. In this model, a mixture of a copolymer with a homopolymer is regarded as a ternary system incorporating as components the comonomers 1 and 2 of the

copolymer with volume fractions φ'_1 and φ'_2 respectively and the homopolymer 3, whose composition differs from those of the comonomers. Account is taken of three types of interactions: 1 with 2, 1 with 3, and 2 with 3. The parameter B_{ij} is used as the characteristic of the interactions. It is related to the usually employed Flory–Huggins thermodynamic interaction parameter χ_{ij} by the expression

$$\frac{B_{ij}}{RT} = \frac{\chi_{ij}}{V_i} = \frac{\chi_{ji}}{V_j} = \bar{\chi}_{ij},$$

where V_i and V_j are the molar volumes of the units of components i and j. For the effective interaction parameter, one can write

$$B = B_{13}\varphi'_1 + B_{23}\varphi'_2 - B_{12}\varphi'_1\varphi'_2, \qquad (1)$$

where B_{12} is the parameter of the interaction between the copolymer components 1 and 2 and B_{13} and B_{23} are the parameters of the interaction of the comonomers (1 and 2) of the copolymer with the monomeric units of the homopolymer (component 3). The first two terms of Eqn. (1) characterise the additional interaction of the polymer 3 with the comonomers 1 and 2, while the third term characterises the interaction between the comonomers 1 and 2 in the copolymer. It is seen from Eqn. (1) that, if $B_{12} > 0$, then the comonomers 1 and 2 are "unlike"[18] and the repulsion forces between them lead to values of B smaller than the additive values. On the other hand, if $B_{12} < 0$, then the values of B are greater than the additive values. Fig. 3 illustrates schematically the possible situation arising for different values of the parameters B_{ij}. The case presented in Fig. 3*b*, where all the B_{ij} are positive, is of interest. In this case the polymer 3 is not miscible with either comonomer 1 or 2. However, if the parameter B_{12} is fairly large, namely

$$B_{12} > (\sqrt{B_{13}} + \sqrt{B_{23}})^2,$$

a range of copolymer compositions φ'_1 arises in which $B < 0$ and this copolymer is compatible with the polymer 3. This apparently in fact accounts for the existence of the "compatibility windows" in many systems: the addition of the polymer 3 to the copolymer "dilutes" the unfavourable interactions between the comonomers 1 and 2 of the copolymer, creating "pure" exothermic conditions even when the binary interactions of the monomer 1 with the monomer 2 are endothermic, i. e. there are no specific interactions between the components.

Fig. 3 also illustrates other possible variants, which may lead to either the compatibility or the incompatibility of the components. For example, Fig. 3*c* illustrates the case where all the binary parameters are negative, i. e. any pair of the three mixture components is compatible. However, the model predicts that, for certain copolymer compositions, the latter will be incompatible with the homopolymer 3. Fig. 3*a* presents the standard situation in which the comonomer 2 of the copolymer mixed exothermically with the homopolymer 3, while the comonomer 1 is immiscible with the homopolymer 3. With increase in the fraction of the comonomer 1 in the copolymer, conditions for endothermic mixing are attained, the point corresponding to the transition from the exothermic to endothermic mixing then depending on the sign and magnitude of the parameter B_{12}.

The proposed model has been used[32] to describe the thermodynamic behaviour of mixtures of copolymers of different composition with other copolymers and homopolymers. For example, mixtures of the hydroxyethyl ether of bisphenol A with a series of polycarbonates, including also their low-molecular-analogues (the CH_x and CO groups), which were regarded as "comonomers", have been investigated.[32] Fig. 4 presents the dependence of the effective interaction parameter B, determined by various methods (calorimetry, melting point depression, sorption), for these mixtures on the volume fraction of the CH_x groups. By combining the parameters B_{ij}, it is possible to obtain with the aid of Eqn. (1) a curve which describes most effectively the experimental data. The continuous curve in Fig. 4 was obtained for $B_{12} = 1050$, $B_{13} = 350$, and $B_{23} = 700$ J cm^{-3}. It is striking that all three interaction parameters proved to be positive, i. e. in this case there are no specific interactions. When a number of other systems were considered, a satisfactory correlation was also found between the predictions of the model and experimental data.[109,110] For example, the model describes satisfactorily the results of the study of the compatibility of chlorinated poly(vinyl chloride) with ethylene–vinyl acetate copolymers[109] and of poly(tetramethylbisphenol A carbonate) with styrene–methyl methacrylate copolymers.[110] Apparently this model can be used to describe the thermodynamic behaviour of mixtures of three polymers and the interaction parameters can be determined using model oligomers.[111]

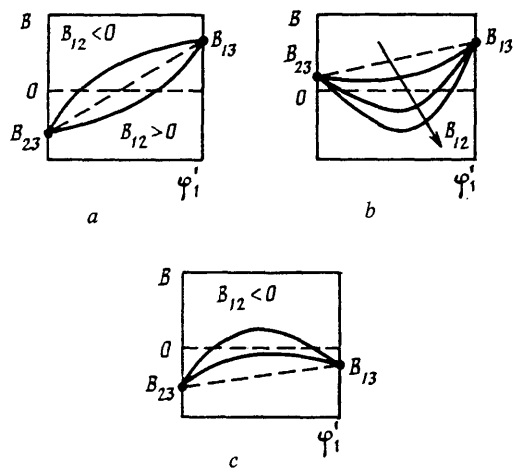

Figure 3. Schemes illustrating the concentration dependence of the effective interaction parameter B in mixtures of a homopolymer with variable-composition copolymers for different ratios of the binary interaction parameters:[32] *a*, B_{12} and $B_{23} < 0$ while $B_{13} > 0$ (upper curve) or B_{12} and $B_{13} > 0$ while $B_{23} < 0$ (lower curve); *b*, all three binary parameters (B_{12}, B_{13}, and B_{23}) are positive; *c*, all three binary parameters (B_{12}, B_{13}, and B_{23}) are negative. The curves in Fig. 3*b* are displaced downwards with increase in the parameter B_{12} and those in Fig. 3*c* are displaced upwards with increase in the parameter B_{12} in absolute magnitude [see Eqn. (1)].

3. The influence of other factors on the compatibility of polymers

(a) The introduction of a third component into a mixture of two polymers. If a third component (a polymer or copolymer), compatible with each of the polymers being mixed, is introduced into a mixture of two incompatible polymers, then such a ternary mixture becomes compatible.[112–116] Thus, when poly(vinylidene fluoride),

which is compatible with poly(methyl methacrylate) and poly(ethyl methacrylate) but the latter are incompatible with one another, is introduced into their mixture, the resulting ternary mixture proves to be compatible.[112] The mixture of poly(vinyl chloride) with the SKN-40 copolymer is compatible, while its mixture with the vinylidene chloride–vinyl chloride copolymer is incompatible.[115] On the other hand, the ternary mixture is compatible. However, the replacement of SNK-40 by SKN-30 makes all three pairs incompatible. Nevertheless, the ternary system is compatible.

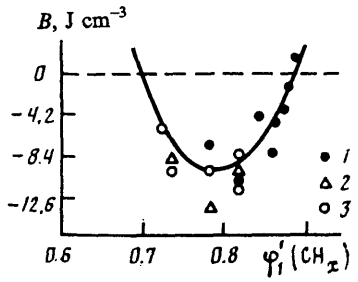

Figure 4. Interaction parameters for mixtures of aliphatic polyesters and their low-molecular-weight analogues with the polyhydroxylated ester of bisphenol A obtained by the calorimetric (*1*), melting point depression (*2*), and sorption (*3*) methods.[32]

Mixtures of polycarbonate with styrene–acrylonitrile copolymers containing 13 or 25% of acrylonitrile in the copolymer are incompatible.[116] However, the addition of even 1% of a polyester of the type of poly(1,4-butylene adipate), poly(1,4-cyclohexane-dimethylene succinate) or poly-ε-caprolactone is sufficient to obtain a single-phase mixture with polycarbonate : copolymer ratios of 1 : 1 or 1 : 3. The region of compatibility in the ternary mixture then increases with increase in the acrylonitrile content in the copolymer from 13 to 25%. The introduction of butadiene and styrene copolymers respectively into a mixture of polybutadiene and polystyrene oligomers lowers the phase separation temperature (system with a UCT).[114]

(b) Deuteriation of one of the mixture components. The temperature and concentration ranges corresponding to the miscibility of two copolymers can be altered by deuteriating one of the components. For example, non-ideal mixing is observed in mixtures of deuteriated and non-deuteriated polystyrenes.[117] Deuteriation of polystyrene increases the phase separation temperature of its mixtures with poly(vinyl methyl ether) (a system with a LCT).[118,119] The replacement of hydrogen by iodine in polystyrene makes the polystyrene–iodine-containing polystyrene system incompatible.[120] The UCT is increased similarly in the polystyrene–polybutadiene system on deuteriation of polybutadiene.[118] The change in compatibility in such systems has been explained by the change in the chain conformation on deuteriation.[118,119]

(c) The influence of the stereoregularity of one of the components. The stereoregularity of one of the mixture components has a significant influence on compatibility.[61,121,122] Thus, according to the results of Fourier transform IR spectroscopic analysis, maximum intermolecular interaction is observed in a mixture of the styrene–allyl alcohol copolymer with syndiotactic poly(methyl methacrylate), while in the mixture with the isotactic homopolymer the interaction is a minimum.[61] Isotactic poly(methyl methacrylate) is incompatible with poly(vinyl chloride) over the entire range of compositions, whereas with the syndiotactic homopolymer it forms a compatible system when the latter contains up to 60% of the syndiotactic polymer. For higher contents of syndiotactic poly(methyl methacrylate) (>60%), the system separates into two phases, one of which contains the pure syndiotactic poly(methyl methacrylate) while the other is a 60 : 40 mixture of syndiotactic poly(methyl methacrylate) and poly(vinyl chloride).[78] The influence of the stereoregularity of poly(methyl methacrylate) and its compatibility with poly(vinylidene fluoride) can be inferred from the Flory–Huggins thermodynamic interaction parameter χ_{12}, which is −0.13, −0.10, and −0.06 for mixtures with isotactic, atactic, and syndiotactic poly(methyl methacrylates) respectively.[122]

(d) The influence of the solvent. In many cases mixtures of polymers are obtained from their solutions in a common solvent.[33] It has been demonstrated experimentally and theoretically[17,123,124] that the compatibility of polymers in a common solvent depends on the difference between the parameters of the thermodynamic interaction of the solvent with each polymeric component (the so called "$\Delta\chi$ effect"[123]). Hence errors may arise in the assessment of the compatibility of two polymers isolated from a common solvent. For example, polystyrene is compatible with poly(vinyl methyl ether),[11] but in solvents with different affinities for the two polymers "closed regions" of incompatibility may be observed.[124] The films obtained from such solutions may contain microheterogeneous regions because during the evaporation of the solvent the system passes through a region of incompatibility and the structure formed in this composition range is retained, since the viscosity of the mixture increases significantly under these conditions.[125]

Thus the compatibility or incompatibility of polymers in solution does not alone guarantee their compatibility or incompatibility after the removal of the solvent. A mixture of poly(bisphenol A carbonate) with poly(methyl methacrylate), which many workers have regarded as incompatible,[11,126] may serve as a typical example. It has been shown[127] that in a number of instances the mixture separates into two phases: for example, if it has been obtained from solution in methylene chloride and THF by evaporating the solvent or by precipitating the polymers from the solution with methanol and also if it has been prepared from the melt. On the other hand, the system obtained by precipitating the same polymers from the same solvents with heptane is compatible over the entire range of compositions and it has a LCT. This must be borne in mind in considering systems in which both a LCT and a UCT are observed.

The influence of the difference between the affinities of the solvent for each polymer can exceed the influence of the interaction between the polymers on their compatibility in solution. For example, in a study of mixtures of poly(ethylene oxide) with the styrene–methacrylic acid copolymer,[128] it was observed that the compatibility of these polymers in benzene increases with increasing content of methacrylic acid in the copolymer (up to 8 mol%) as a consequence of weak specific interactions beween the polymers. The same effect is observed in THF but it is weaker, while in chloroform the polymers are incompatible.

The study of the influence of the affinity of plasticising agents on the compatibility of polychloroprene and butadiene-styrene rubbers[129] showed that the compatibility of the rubbers is impaired

in the presence of plasticisers which are good solvents for both rubbers (dibutyl sebacate and MP-604 oil), while after the introduction of a poor solvent (stabiloil-18) it hardly changes. The reduction of the compatibility of rubbers after the introduction of a good solvent has been explained[129] by the shielding of the functional groups of the rubbers as a result of the solvation of their macromolecules by the plasticisers. On the other hand, it has been shown[111] that, after the introduction into a mixture of two thermodynamically compatible polymers of a third polymer, which forms mixtures with each of the remaining polymers having similar consolute temperatures, the compatibility of the latter polymers increases. A significant decrease in compatibility occurs when the consolute temperatures for mixtures of the added third polymer with each of the blended polymers differ significantly. We may note that this system can be described satisfactorily within the framework of the binary interactions model.[32]

Apart from the factors enumerated, the consolute temperature is influenced significantly also by applied pressure.[130-135] Thus it has been observed for mixtures of poly(ethyl acrylate) with poly(vinylidene fluoride)[130] that, when the content of the latter in the mixture is up to 30%, the turbidity point for the system initially decreases with increase in pressure, then passes through a minimum, and finally increases. With increase in the content of poly(vinylidene fluoride) in the mixture (in excess of 40%), the turbidity point monotonically increases with increasing pressure (system with a LCT). In mixtures of poly(2,6-dimethyl-1,4-phenylene oxide) with styrene–*p*-fluorostyrene copolymers, the LCT increased with increasing pressure over the entire range of the latter.[131] In mixtures having a UCT (mixtures of oligostyrenes with oligobutenes and oligopropylenes),[132] an increase in pressure results in an increase in the UCT.

Whereas the parabolic dependence of the consolute temperature on pressure predicted by the theory for polymer solutions[17] has been confirmed experimentally,[133] for mixtures of polymers the available experimental data are insufficient to reach general conclusions. It is only known that the application of an electric field increases the LCT.[136]

III. The stabilisation of dispersions and regulation of the properties of materials based on mixtures of thermodynamically incompatible polymers

Typical examples of the modification of one polymer by the addition of another are provided by the preparation of rubber-reinforced glass plastics,[137,138] epoxide resins,[139] rubbers reinforced by thermoplastics and thermoreactive resins, etc.[140] All these systems are multiphase. Important factors determining the properties of such systems are the degree of dispersion of the additive in the matrix of the other polymer, adhesion at the interface, and the structure and properties of the interfacial layer.[3,141] The adhesion between the phases is especially important, because, for example, under the conditions of poor adhesion, the mechanical stresses in one phase are not transmitted effectively to the second phase, as a result of which the mechanical properties of the system may be impaired.[3] Consequently, with the exception of certain special cases,[142] a good adhesion between the phases is essential in multiphase mixtures. For this purpose, one introduces the so called "compatibility inducers", which may be block or graft copolymers having blocks with the same chemical composition as the blended polymers,[3,143] as well as other polymers improving the compatibility of the initial components.[144] The mutual binding of the phases can also be improved by creating interphase cross-links[145-148] and by generating interpenetrating networks.[149]

In this review we shall consider mainly the results of the latest studies on dispersion stabilisation processes and methods for the regulation of properties of systems obtained from thermodynamically incompatible polymers.

1. Introduction of compatibility inducing additives

One of the ways of solving the problem of the stability of mixtures of incompatible polymers involves the wide scale employment of block and graft copolymers,[3,143] constituting compatibility inducing additives, especially in the preparation of impact-resistant compositions.[3] It has been shown in a number of studies[150-153] that the introduction of a graft copolymer such as hydrogenated butadiene–styrene into a mixture consisting of low density polyethylene and polystyrene increases the tensile strength but the elongation at rupture remains small. On the other hand, when 9% of a diblock copolymer with an equivalent composition is introduced into the mixture, then the tensile strength, elongation at rupture, and Young's modulus all increase and other system characteristics are also improved. With increase in the molecular weight of the copolymer, these characteristics are improved and even synergism of the properties is observed. A similar effect has been noted also after the introduction of such a copolymer into a mixture of high density polyethylene with polystyrene.

Comparative studies of the morphology and mechanical properties of polyethylene–polystyrene mixtures have shown that the introduction into them of a styrene–butadiene block copolymer whose blocks are separated by a styrene–butadiene statistical copolymer [for example of the type PS–$(PS/PBD)_{stat}$–PBD] induces a greater effect than introduction of the simple diblock copolymer.[153] The authors believe[153] that the unique effect of this copolymer is caused by its partial compatibility with polystyrene and polyethylene at the interface, i.e. it behaves as a stabilising agent for the homopolymers and promotes the creation of a "stepwise" modulus responsible for the improvement of the mechanical properties. Furthermore, after the introduction of such a block copolymer there is a significant increase in the dispersion of this system and synergism of the properties is manifested in the range of compositions where the mixture is enriched in the polymer matrix. When the mixture contains up to 80% of polystyrene, a system with a structure of the "network in network" type is produced. The introduction of the α-methylstyrene–methyl methacrylate block copolymer into a mixture of poly(vinylidene fluoride with poly-α-methylstyrene also leads to a decrease in the size of the dispersed particles and to an increase in tensile stress and Young's modulus.[151] The ethylene–propene copolymer, introduced into a mixture of polyethylene with polypropylene, also has an emulsifying effect.[154-157] The introduction of a copolymer increases the affinity between the components, which is manifested by a more effective homogenisation of the mixtures.[154] As a result, the mixtures are deformed more uniformly and are characterised by greater elongations with rupture. In the given instance, the macromolecules of the copolymer, dispersed in amorphous regions of polyethylene and polypropylene, ensure high degrees of interpenetration of the components.[154] Polyethylene and polypropylene are partially compatible in the melt,[155,156] but the introduction of the copolymer stabilises the two-phase structure of the melt.

An emulsifying effect has been observed also after the introduction of the α-methylstyrene–graft methyl methacrylate copolymer into a mixture of poly(vinylidene fluoride) with poly-α-methylstyrene.[157] In particular, the size of the particles diminished significantly in this system, a maximum appeared on the relation between the tensile strength and composition for a 70% content of poly(vinyl fluoride), and additivity of Young's moduli was observed. On the other hand, in the absence of the copolymer, the tensile strength and Young's moduli were described by curves with a minimum.

Other examples of the use of block or graft copolymers as compatibility inducing additives may be found in a review.[3] The choice of the appropriate copolymer should be based, according to Paul and Newman,[3] on the following requirements: (1) it must reduce the interfacial energy, (2) it must promote a finer dispersion of the components during the mixing process, (3) it must stabilise the mixture and prevent the separation of the components, and (4) it must improve the adhesion between the phases. The desired effects can be attained when the appropriate copolymer is located on the interface between two phases.[3]

The compatibility inducing agent may be also a third polymeric component introduced into a mixture of two thermodynamically incompatible polymers.[158–161] For example, in order to improve the properties of mixtures of low density polyethylene with other polymers [polystyrene poly(vinyl chloride), polypropylene], additives such as the ethylene–propene copolymer, natural rubber, polybutadiene, the acrylonitrile–butadiene–styrene ternary copolymer (ABS resin), copolymers of the butadiene–styrene type with a 72% content of butadiene, chlorinated polyethylene containing 42 and 20% of chlorine, and polyurethane containing ethylene adipate blocks.[161] It has been shown that the introduction of a third component into 1 : 1 mixtures improves the mechanical properties and that the increase in impact resistance is accompanied by an increase in elongation at rupture. Particularly high impact resistances and elongations at rupture have been observed after the introduction of the butadiene–styrene rubber into a mixture of polystyrene with polyethylene. The improvement of the properties of such systems can be accounted for by the formation of an elastomeric layer at the interface and by the dispersing capacity of the modifying additives. The improvement of the interfacial interaction and hence the improvement of the physicomechanical properties of mixtures of various rubbers (strength, ozone and weather resistance, resistance to thermal ageing, reduction of the embrittlement temperature, and reduction of the density of vulcanising agents) is promoted by the introduction of chlorinated polymers into such rubbers.[143] The modifying effect of additives of this kind is mainly determined by their polarity. Thus the modification of a mixture of thermoplastic polyurethane with poly(vinyl chloride) by a more polar rubber leads to the formation of compositions with high strength parameters.[162] The interaction between the components of a heterogeneous mixture of two polymers intensifies also after the introduction of surfactants of different classes,[163] for example, after the introduction of ionogenic surfactants into mixtures of poly(vinyl chloride) with natural rubbers. The introduction of a surfactant into a mixture of an epoxide resin and silicone rubber ensures the appearance of a region of compatibility in oligomer–natural rubber systems.[164] The factor determining the properties of mixtures of poly(vinyl chloride) with chlorinated polyethylene is the compatibility of the added oligomer (high-molecular-weight oligobutadienes and oligobutadienes with OH and CN groups) with each mixture component.[159] In certain cases, the additives introduced increased the rate of "dissolution" of, for example, rubbers in one another at the same temperature of the treatment of the mixture, which is important for the preparation of layered (doubled) compositions (the introduction of peroxides into a mixture of polybutadiene with butadiene–styrene rubber[165]).

2. The role of interphase cross-links

One of the effective ways of stabilising mixtures of incompatible polymers is interphase cross-linking.[145–148] Thus cross-linking has been used to increase the stability of mixtures of polyethylene with poly(vinyl chloride).[145] The cross-linking of poly(vinyl chloride) was achieved by introducing 6-diallylamino-1,3,5-triazine-2,4-dithiol (DAATD) and polyethylene was cross-linked by introducing a mixture of DAATD with peroxides of different types. It has been shown that the more intense the adhesion interaction between the components, the better the mechanical properties of the system (strength and elongation at rupture). Nakamura et al.[145] attribute this effect to the formation of chemical bonds between poly(vinyl chloride) and polyethylene phases during the mixing process and after pressing. The introduction of the same cross-linking agent (DAATD) into a mixture of fluororubbers based on vinylidene fluoride or hexafluoropropene with epichlorohydrine and polyisoprene led to the formation of vulcanised rubbers with a high degree of cross-linking and good adhesion and mechanism properties. In a pure form, these rubbers are incompatible, but the introduction of the additive leads to a high degree of covulcanisation of individual rubbers at the interface.[146] Heating of the system or the addition of tetraalkylammonium bromide together with DAATD facilitates significantly the formation of cross-linked at the interface.

The modification of polystyrene by peroxide, dithiocarbamate, or perthiocarbamate groups ensures its mixing with natural rubber, the ethylene–propylene copolymer, butadienenitrile rubber, polypropylene, and polybutadiene.[147] The vulcanised mixtures of modified polystyrene with, for example, polybutadiene behave under dynamic conditions similarly to three-block copolymers. Polystyrene modified by groups which react with the double bonds of the elastomer reinforces the elastomer matrix.[147,148]

3. Specific interfacial interactions

Specific interactions at the interface also promote the stability of two-phase polymer mixtures.[166–170] For example, mixtures of poly(urethane-urea) with poly(vinyl chloride) are incompatible, but the formation of hydrogen bonds between the α-hydrogen atoms of poly(urethane-urea) and the chlorine atoms of poly(vinyl chloride) ensures effective interfacial adhesion.[166] The impact strength of the system passes through a maximum for a 7.5–15% content of poly(urethane-urea).

The adhesion between phases increases when electron donor–electron acceptor bonds are formed at the interface.[167,168] Such bonds are formed in mixtures of electron-donating and electro-accepting polycarbonates, polyterephthalates, or polyisophthalates obtained from 2-(*p*-dimethylaminobenzyl)propane-1,3-diol (donor) and 2-(3,5-dinitrobenzyl)propane-1,3-diol (acceptor)[168] and also from poly[*N*-(2-hydroxyethyl)carbazolyl methacrylate] (donor) and poly(methacryloyloxy-β-hydroxyethyl-3,5-dinitrobenzoate) (acceptor).[169] In the latter case the intermolecular complex formation increases the modulus of the mixture in the region of low-frequency dynamic loads and high temperatures by three orders of magnitude compared with the pure components. It is believed[169] that intermolecular complex formation leads to the formation of thermoreversible networks with an unusual topology which results in

the expansion of the frequency range of the elastic response of the mixtures. The presence of a maximum in the dependence of the decomposition energy on the composition of mixture of the sodium and zinc salts of an ethylene ionomer with rubbers (acrylonitrile or carboxylated acrylonitrile rubbers) has also been explained by the ionic interaction of polar phases.[170] A tenfold increase in the impact resistance of powdered mixtures of poly(phenylene oxide) (50 parts), the zinc salt of sulphonated (1.4 mol% of sulphur), polystyrene (9 parts), sulphonated (0.6 or 1.4 mol% of sulphur) polystyrene (9 parts), the ethylene–propylene copolymer (9 parts), and zinc stearate (9 parts) in the presence of triphenyl phosphate (14 parts) is also caused by the interaction at the interface.[167] (The mixtures were obtained by dry blending with subsequent extrusion at 453–523 K.)

4. The addition of small amounts of one polymer to another

Numerous studies devoted to the influence of the addition of small amounts of one polymer to another on the physicomechanical and physicochemical properties of the systems, especially on their viscosity, have been published in recent years.[171–181] Viscosity is an important technological parameter and the characteristic features of its variation with composition have been examined in particularly great detail. Attention has been concentrated on the elucidation of the mechanism of the influence of additives on the viscosity.[172,181] A series of anomalies in the concentration dependence of the viscosities of melts of mixtures of polymers (over a narrow range of concentrations, predominantly for a low content of one of the components) have been discovered.[181] As a rule, at low concentrations of the additives a sharp decrease in viscosity is observed. For example, the viscosity of the incomptible thermoplastic polyamide–liquid crystal copolyester system based on 6-hydroxy-2-naphthoic and *p*-hydroxybenzoic acids diminishes sharply in the presence of small amounts of a copolymer in the mixture.[174] The addition of vinyl chloride–vinyl acetate or vinyl chloride–propylene copolymers reduces the viscosity of poly(vinyl chloride) and facilitates its treatment.[175] The greatest effect is then exhibited by copolymers with a low molecular weight. The addition of 10% of butadiene-styrene rubber to the butadiene–styrene–butadiene copolymer diminishes the viscosity of the latter almost by a factor of 2,[176] which has been explained by the localisation of the added rubber with short chains at the interface and the consequent facilitation of the flow of the copolymer. The similar introduction of small amounts of the styrene–maleic anhydride (14% of the anhydride) copolymer reduces significantly the fluidity of poly(bisphenol A polycarbonate).[177]

It is possible to quote very many similar examples.[182–186] In our view, among the existing explanations of the observed anomalies, that according to which their appearance is associated with the transition of the system from the single-phase state to the two-phase state and conversely can be regarded as the most acceptable.[180,181] This was first demonstrated in a study where the concentration dependence of the viscosity was compared with the Flory–Huggins prameter χ_{12} of the thermodynamic interaction between the mixture components in melts at identical temperatures. Satisfactorily parallel concentration variations of the viscosity and the parameter χ_{12} were observed. In particular, for positive values of χ_{12} (thermodynamically incompatible system), the viscosity proved to be less than the additive value, while for negative values (compatible system) it proved to be higher than the additive value. It was concluded that a sharp fall of the viscosity of melts of polymer mixtures at low concentrations of the added polymer occurs when the system passes from the single-phase to the two-phase state.[179] The form of the phase diagram apparently make it possible to predict the concentration and temperature dependences of the viscosities of melts of polymer mixtures. Hitherto, such comparison of the concentration variation of the viscosity with the phase diagram has been achieved in only one study.[179]

Extremum changes have been observed also in a number of other physicochemical and physicomechanical characteristics of systems at low concentrations of the added polymer.[187–200] Thus the improvement of high density polyethylene after the introduction into the latter of small amounts of thermoelastoplastics has been explained by the latter being distributed in the non-ordered regions of the polyethylene with retention of the primary crystalline state.[191]

It has been suggested that the increase in strength on extension of polypropylene containing small amounts of a thermoelastoplastic (up to 1%) occurs as a result of the surface interaction of the polystyrene units with the structural formations in polypropylene, which leads to the joint orientation of polypropylene and the thermoelastoplastic.[193] The authors[191] concluded that the micro-additives play the role of a filler of the structural defects, facilitating the plastic deformation and ensuring the formation of a finer and uniform structure. The reason why the strength properties of the systems are impaired on further increase in the amount of the additives are still not understood.

The high tensile strength (above the additive value) of low density polyethylene with added ethylene–propylene copolymer has been explained[195] by the partial compatibility of the copolymer with polyethylene in the melt: on cooling the mixture of polyethylene with the crystalline copolymer (with a degree of crystallinity from 1 to 20%), a cross-linked matrix is formed as a result of the joint crystallisation. The synergism of the properties of mixtures of high density polyethylene with the ethylene–propylene copolymer and also of isotactic polypropylene with the same copolymer has been explained by partial compatibility.[196] The strength properties are improved with increase in the compatibility of the modifying additive and the polymers. This is achieved, for example, by increasing the content of the component A in a copolymer of the A–B type when it is mixed with the corresponding type A homopolymer. The necessity for the partial compatibility of the components in order to achieve a high impact strength was also noted in a study of mixtures of poly(bisphenol A carbonate) with the styrene–acrylonitrile copolymer and the same copolymer grafted on polybutadiene.[197] The change in the position of the mechanical losses peak and of the complex shear modulus for a styrene block copolymer modified by resins has also been explained by the compatibility of the modifying additive with the polymer matrix.[198]

It is known that an excess volume of mixing obtained for compatible systems, i.e. $\Delta V = V_{mix} - \Sigma\varphi_i V_i < 0$. This reduces the number of external degrees of freedom[18] and hence lowers the mobility of the chains and increases the packing density. Partial compatibility ensures the mutual binding of the phases, i.e. interfacial adhesion as a result of which the physicomechanical characteristics of systems of this kind are improved.[3]

IV. Conclusion

The examples examined in the review indicate convincingly that polymers differing in chemical structrure and involving opposite principles, which complement one another, are most effectively miscible[10] (the concept of "the mutually complementing difference"

already mentioned[17]). Since in such cases the enthalpy of mixing is negative, systems of this kind should be characterised by a LCT. Indeed, according to Krause,[9] among the known thermodynamically compatible polymer pairs, 75% have a LCT. Consequently, in order to ensure thermodynamic compatibility it is essential to select components such that their functional groups are capable of strong interaction or one or both components must be modified in such a way that the "mutually complementing differences" are ensured.

In devising compositions which need not satisfy the requirement of thermodynamic compatibility, it is necessary to solve the problem of the stabilisation of the dispersion by introducing "compatibility inducing additives", by organising interphase cross-links, or by ensuring partial compatibility of the components both in the preparation of the composition and in its conversion into finished articles. In other words, it is essential to ensure a satisfactory interfacial adhesion at least in those cases where the system must have a high strength.

Leningrad State University

ABSTRACT. The problem of identifying halogen-containing organic compounds in their gas-chromatographic and gas-chromatographic–mass-spectrometric (GC-MS) determination in different materials has been examined. Particular attention has been paid not to the complete characterisation of methods for carrying out this analysis but to the most important problem of increasing the selectivity at the stages of sampling, separation, and interpretation of the gas-chromatographic and GC-MS information.

The bibliography contains 292 references.

III. The mass-spectrometric characterisation and identification of halogen derivatives 814

I. Introduction

The examination of the gas-chromatographic and mass-spectrometric analysis of halogen-containing organic compounds (HOC) is important, since these compounds are widely used in industry, agriculture, medicine, and everyday life. Since only a few compounds of this class are found in natural materials, and most are manufactured by man, the analysis of materials of this kind often requires their selective determination in much larger quantities of a large number of compounds of other classes. Thus the problems of selective sampling, separation, detection, and the reliable interpretation of the data are extremely important for halogen derivatives.

Published data on methods for analysing halogen-containing compounds in various materials, developed up to the early nineteen-eighties, have been summarised in various reviews[1–3] and monographs.[4–6] Special sections in handbooks[7,8] have been devoted to the determination of traces of HOC in the air of industrial plants and in the atmosphere.

Several hundred studies of different aspects of the analysis of HOC are now published every year, and these data require systematisation. In addition to an increase in the range of substances determined, there is a tendency towards a more rigorous characterisation of procedures in order to increase the accuracy and selectivity of analysis and to simplify methods of sampling. A number of topics, in particular the selection of sorbents for concentrating traces of substances to be analysed and the conditions for their gas-chromatographic separation, to which particular attention was paid in earlier reviews,[1–7] do not now require examination, since the corresponding procedures have been systematised and standardised.[9] Thus in the present review particular attention is paid not to a detailed description of specific procedures for analysing HOC in different materials but to the presentation of the general principles of their gas-chromatographic and mass-spectrometric identification, quantitative analysis, and methods for increasing the selectivity of the determination by using special methods of detection.

In recent years, more accurate data have been obtained on the high toxicity of various halogen-containing compounds.[10–12] Mutagenic activity has been noted for 40 substances of this type used in industry.[13] Thus it is necessary to develop reliable highly sensitive procedures for determining HOC in the atmosphere, water and effluents, soils, biological materials, foodstuffs, and other substances.

The large number of HOC produced on the industrial scale can be classified in two groups, according to their physicochemical properties. The first group consists of volatile polyhalogenocarbons, Freons, halogen-containing monomers, and solvents. The second group consists of high-boiling polychlorinated hydrocarbons, pesticides, the starting materials for their synthesis, and metabolism products. The particular danger of the contamination of the environment by materials of the first group (in particular the simplest polychlorofluorocarbons) is now considered to be the possible destruction of the ozone layer in the atmosphere as a result of photochemical reactions involving Hal' radicals, first noted in 1974 [14,15] (these questions have been discussed in detail[8]). Until recently it was considered that these compounds are produced exclusively by man, but in 1985, chloro- and chlorofluoromethanes were detected in volcanic gases.[16,17] Previously, only the natural production of CH_3Cl,[16] CH_3Br, and, possibly, CF_4,[18] had been noted. The existence of natural sources of HOC may lead to a re-examination of estimates of the potential danger of these substances for the ozone layer of the atmosphere.

Polychlorinated aromatic hydrocarbons, chlorine-containing pesticides, and other compounds of this kind are not highly volatile, so that they are concentrated in condensed media.[19–21] Nevertheless, they are detected at considerable distances from their sites of use (as far as the Arctic regions).[22–26] The global contamination of the biosphere by chlorine-containing compounds makes it important to control their concentration in compounds of food chains[27] and biological materials.[28]

The most toxic representatives of this group of HOC are polychlorinated dibenzo-*p*-dioxins, dibenzofurans, diphenyl ethers, and similar substances having a teratogenic action. The intensive study of methods for detecting and identifying these compounds began after the chemical plant disaster in Seveso (Italy) in 1976, which led to the sudden release of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, long-term contamination of the environment, and cases of acute poisoning.[29] Polychlorodibenzodioxins and -furans may be formed by the oxidation of polychlorobiphenyls (added to pesticides)[30] or by the oxidative chlorination of aromatic compounds by HCl in air,[31] but most of these compounds released into the atmosphere are produced by the thermal treatment of chlorine-containing polymers, including the combustion of household refuse.[32–35] The chlorination of drinking water leads to the appearance in it of traces of polychloro-aromatic hydrocarbons and phenols,[36,37] whose concentration also requires effective control.

II. Basic principles of the separation, selective detection, and gas-chromatographic identification of halogen-containing substances

One of the most important tasks in the gas-chromatographic analysis of HOC is to achieve the maximum selectivity with respect to compounds of this type, in order to eliminate the influence of interfering components and to increase the reliability of identification and quantitative analysis. The possibilities for achieving this are different at the stages of sampling and preparing specimens for analysis, chromatographic separation, and detection of the substances being determined.

1. Sampling and preparation of specimens for analysis

The reactivity and specific chemical properties of halogen-containing compounds generally do not differ significantly from those of their analogues not containing halogens. For this reason, the selective extraction of HOC from specimens being analysed at the stages of sampling and specimen preparation is usually impossible. Only isolated examples of this selectivity are known, based on specific reactions of the substances being analysed. Thus a method for determining hexachloroacetone in air[38] is based on its absorption by anhydrous methanol, which is accompanied by the quantitative reaction:

$$(CCl_3)_2CO + CH_3OH \rightarrow CCl_3CO_2CH_3 + CHCl_3.$$

Both reaction products are determined in the subsequent gas-chromatographic analysis of the solution obtained. The detection limit using an electron capture detector is 3 μg m^{-3}.

The same principle (trapping in liquid absorbers which react with specific substances) is used successfully in the analysis of free halogens and hydrogen halides in air.[1,39–42]

The anlaysis of traces of organic halogen-containing compounds in gases at the level of several p. p. t. (parts per trillion by volume) is carried out by the direct introduction of large gas specimens using highly sensitive selective detectors,[43,44] or cryogenic concentration in special traps or preliminary columns not selective with respect to substances of other classes,[18,45,46] or trapping on solid sorbents. The subsequent desorption of the substances being determined is carried out thermally, directly in the analytical column, or by treating the sorbent with organic solvents and analysis of the eluate.[47] The desorption of halogen-containing compounds from active carbon by water vapour is possible in principle.[48] To trap the most volatile compounds, including perfluoroalkanes, Freons, etc., active carbons with a specific surface of up to 1000 m^2 g^{-1} [47,49-52] or graphitised carbon black (Carbopack B type) with a specific surface of about 100 m^2 g^{-1} [53] are used. The thermally stable polymeric sorbent Tenax (poly-*p*-2,6-diphenylphenylene oxide) is effective not only for concentrating low-boiling halogenoalkanes and chlorinated aromatic hydrocarbons[54–57] but also chlorine-containing pesticides.[58] The carbon sorbent Ambersorb XE-340 is used for the same purposes.[59]

In thermal desorption from carbon sorbents and even the chemically most inert Tenax, however, it is necessary to take account of the possible thermal decomposition of primarily high-boiling halogen-containing compounds as a result of their dehydrohalogenation. Thus the recovery of various pesticides in desorption from 0.11 g of Tenax at temperatures of 250–325 °C and a carrier-gas (helium) velocity of 11.2 ml min^{-1} has the following values (% of the original quantity)[58]:

α-$C_6H_6Cl_6$	97±8	*pp'*-DDT	60±2
Heptachlor	26±5	*pp'*-DDT	20±1
Dieldrin	120±3	perylene (for comparison)	82±2 .

Another factor responsible for the loss of compounds being analysed and distortion of the results of a quantitative analysis may be incomplete trapping in the cryogenic trap, particularly for low-boiling compounds.[60]

When working with polymeric sorbents, it is necessary to take account of the presence of traces of halogen-containing substances in the background emanation of the polymer itself.[61,62] To prevent the incomplete trapping of low-boiling compounds, polymeric sorbents with a specific surface of up to several hundred m^2 g^{-1} are used (Chromosorbs 101, 103, 107, Porapaks M, Q, T, Cekachrom 2, 3, CE-1, CE-2, etc.).[63–65] The basic characteristics of all solid sorbents are the specific retention volumes of each of the substances being determined at the sampling temperature (V_g, litre g^{-1}) and the maximum sample gas volumes, related to V_g by the simple expression $V_g^{max} \simeq V_g(1 - 2/\sqrt{N})$,[7] where N is the efficiency of the sorption tube in theoretical plates. These data have been published for the simplest HOC.[63,64]

In the study of the concentration of volatile halogen-containing compounds in liquid specimens (including aqueous solutions), the best method is apparently vapour-phase analysis (VPA),[66] which is based on information on the composition of the condensed phases obtained by analysing the gaseous media present in contact with them. The possibilities provided by the method are determined by the distribution coefficients of the substances being analysed between the liquid and gas phases. In some cases the differences in these coefficients for different substances make it possible to increase the selectivity. In general, the term vapour-phase analysis includes both the analysis of the equilibrium or non-equilibrium gas phase above the specimen[66] and the complete sweeping of the components being determined from solutions by a stream of carrier gas followed by their sorption.[55,67] The detection limit of the method can be varied by changing the temperature of the analysis and by adding salting-out agents. For example, the addition of sodium sulphate (20 g) to an aqueous solution (50 ml) when capillary columns and an electron capture detector are used lowers the detectable concentrations of CH_3Cl from 1.6 p. p. m. to 1.3 p. p. m., $CHCl_3$ from 2.4 p. p. m. to 0.9 p. p. m., and C_6H_5Cl from 1.5 p. p. m. to 0.4 p. p. m.[68]

Vapour-phase analysis is effective in the determination of a wide range of chlorine and bromine derivatives of methane and ethane in drinking water,[69–73] traces of chloroform in blood plasma,[74]

monomer residues in polymeric materials (for example vinyl chloride in polyvinyl chloride[75,76]), solvents in foodstuffs,[77] traces of volatile halogen-containing substances in organic electrolytes,[78,79] etc. Of particular interest is the vapour-phase analysis of specimens which cannot be introduced into a chromatographic column because of their thermal instability, reaction with a phase, etc. This method has been used to determine traces of polychlorinated C_1-C_3 hydrocarbons in $SiCl_4$, $POCl_3$, $GeCl_4$, BBr_3, and BCl_3.[80]

The extraction of solid or liquid specimens by organic solvents (usually with boiling points not higher than 100 °C) is most frequently used in the analysis of less volatile halogen-containing organic compounds: herbicides,[81] chlorobenzenes, chlorotoluenes, hexachlorobutadiene, and polychlorobiphenyls,[82,83] chlorostyrenes,[84] and polychlorodibenzo-*p*-dioxins.[85,86] After concentration of the extract, it is possible to achieve a degree of enrichment of up to $(1-3) \times 10^3$ with a degree of extraction of 50–98%. Light halogenomethanes can be analysed in this way only by electron capture detectors and solvents with respect to which their sensitivity is low.[81,87] Concentration in this case becomes impossible, and direct VPA of the original specimens is preferable.

The large number of preliminary stages in the analysis of traces of HOC in dilute solution (gas or liquid extraction, concentration on solid sorbents) leads to a slight regular decrease in the accuracy of quantitative determinations as a result of the accumulation of both random and systematic errors. Thus in a number of cases the direct introduction of the specimens being analysed into packed or capillary columns with grafted stationary phases is more appropriate. For example, when this method is used to analyse aqueous solutions, it is possible to achieve detection limits of 2 p. p. b. for CH_2Cl_2, 0.1 p. p. b. for CH_3CCl_3, 0.15 p. p. b. for $CCl_2=CHCl$, and 0.1 p. p. b. for C_2Cl_4.[88] A similar method has been used not only for aqueous solutions but also for dilute solutions in organic solvents.[89,90]

A particular case of the special treatment of specimens of non-volatile or thermally unstable compounds for analysis involves the preparation of derivatives suitable for gas-chromatographic analysis.[91] If these derivatives contain halogen atoms, the problem of increasing the selectivity of detection is solved simultaneously (see above). For compounds containing active hydrogen atoms (NH, OH, SH groups), the derivatives are most frequently heptafluorobenzoates, trifluoroacetates, pentafluoropropionates, and heptafluorobutanoates. This method is used to analyse amino-acids,[92–94] dipeptides,[95] mono-, di-, and oligosaccharides,[96–99] aromatic amines,[100,101] β-arylamines, their metabolites, and aliphatic diamines,[102–104] ethylene glycol in blood serum,[105] the oxidation products of coal[106] (in the last case, use is made of peroxotrifluoroacetic acid, which acts simultaneously as oxidant and as reagent for derivative formation), etc. The analysis of organic acids as their hexafluoroisopropyl esters after treatment with $(CF_3)_2CHOH$ has been recommended.[107]

Various halogen-containing compounds (the halides of silicon, boron, etc.) are highly reactive and unstable under the conditions of gas-chromatographic analysis. Special methods for dealing with compounds of this kind have been described.[108]

2. The gas-chromatographic separation of halogen-containing compounds

The conditions for the optimum gas-chromatographic separation are different for volatile halogen derivatives and high-boiling polychlorinated aromatic compounds. The analysis of substances of the first group is usually carried out on packed columns with a high concentration of the stationary phases[69,81] or on polymeric or inorganic sorbents modified by various additives. Thus a column containing Carbopack B treated with 0.5% SP-1000 (3 m) is effective for separating halogen derivatives with boiling points from –24 °C (CH_3Cl) to 121 °C (C_2Cl_4).[109] A packing with similar characteristics consisting of 0.2% of polar Carbowax 1500 on Carbopack C (specific surface about 10 $m^2\ g^{-1}$) is effective for the temperature-programmed separation of a mixture of substances with boiling points from 40 °C (CH_2Cl_2) to 132 °C (chlorobenzene), that is practically all aliphatic C_1 and C_2 chlorine derivatives.[110] Combined colums with polar and non-polar stationary phases,[69] molecular sieves,[109] or silica gels[52] are sometimes used.

Gas-adsorption capillary columns with a coating of aluminium oxide or silica gel are effective for separating low-boiling halogen-containing compounds.[18,111]

Compounds of the second group are usually analysed on glass or quartz capillary columns containing high-temperature silicone stationary phases with low or medium polarity,[30,43,46,83,85,112–120] or on packed columns with a low concentration (not more than 5%) of similar phases.[81,110,121] Since polychlorinated biphenyls, dibenzo-*p*-dioxins, dibenzofurans, and other representatives of this group of compounds are specific materials distinguished by the simultaneous presence of a large number of similar substances, including isomers (polychlorobiphenyls, for example, form a "group" of 209 theoretically possible compounds), in a number of cases special optimisation of the temperature conditions of the analysis is appropriate, to increase the efficiency of their separation.[122] This analysis requires high temperatures (150–300 °C), at which it is necessary to take account of the possible decomposition of various substances in the chromatographic column. Thus dehydrochlorination of chlorine-containing pesticides has been observed on glass columns with surfaces modified by $BaCO_3$.[123]

An increase in the selectivity of the determination of halogen-containing compounds at the separation stage is possible by using reaction gas chromatography,[1] including the removal of interfering components in preliminary or subsequent columns. This method is effective for determining traces of CH_3Cl, CH_3Br, and C_2H_5Cl in CH_3OH using a capillary column. The solvent is trapped selectively at the column outlet in a trap containing activated Al_2O_3 at 30 °C, which is heated to 200 °C when the analysis is complete.[124] For chlorine-containing pesticides, polychloroaromatic compounds, etc., a useful version of reaction chromatography involves their catalytic hydrogenation to hydrocarbons with preservation of the carbon framework of the molecules (the so-called "carbon skeleton chromatography"),[1,125] carried out in a preliminary column reactor by means of the hydrogen used as carrier gas. This method makes it possible to lower the temperature and time of the analysis, and does not require the use of selective detectors.

Other effective methods for separating mixtures of polychloroaromatic compounds are liquid[126,127] and "fluid"[128,129] chromatography (in a stream of non-ideal eluants at pressures and temperatures in the column exceeding the critical parameters of the eluant).

3. Methods for detecting halogen derivatives

The maximum selectivity in the analysis of halogen-containing compounds is achieved at the stage of their detection using selective gas-chromatographic detectors or mass spectrometers. The widely used electron capture detectors (ECD) solve this problem effectively, but increasing use is being made of mass spectrometers, which provide much greater possibilities and a controllable selectivity of detection.

Chromatographic detectors based on the general principle of the change in the electronic conductivity of the gaseous medium in the presence of halogen-containing substances (electron capture and constant recombination) are fairly simple to use, and have been employed in a large number of studies of the analysis of varied halogen-containing compounds, for example free iodine,[130] volatile halogenocarbons in water and in air,[38,47,57,81,88,131,132] 1-bromo-1-chloro-2,2,2-trifluoroethane (Halothane) in air,[133] chlorobenzenes,[82] polychlorophenols,[134] halogen-containing pesticides,[81,89,135] etc. Signals from three detectors have been recorded simultaneously to increase the selectivity of the determination of halogen-containing substances in air.[136]

Important features of electron capture detectors are the comparatively short linear range (about two orders of magnitude),[137] which makes it difficult to carry out quantitative analysis, and the marked dependence of the relative response of the detector on the nature, number, and even the position of the halogen atoms in the molecule. The use of these detectors therefore requires the constant application of specially prepared calibration mixtures of the compounds being analysed.[138–140] The dependence of the relative response of ECD on the number of chlorine atoms in a series of chlorobenzenes is illustrated by the results of a study[141] given in Table 1. Since the relative sensitivity coefficients depend on the operating conditions of the detector and differ considerably even for isomers, in quantitative analysis it is necessary to have standard specimens of all the substances being determined. A practical consequence of this is a difference in the detection limits for chlorobenzenes using ECD. For example, when aqueous solutions are extracted with pentane, about 0.01 ng litre^{-1} penta- and hexachlorobenzenes can be determined, whereas the corresponding value for the mono-substituted compound is only 500 ng litre^{-1}.[82] It is not yet possible to calculate the relative sensitivity coefficients for ECD. These parameters of halogen derivatives can be calculated by an additive scheme only for thermal conductivity detectors.[142]

Table 1. Relative response of the electron capture detector for chlorobenzenes.[141]

Degree of substitution	Relative response	Degree of substitution	Relative response
Monochlorobenzene	1	Tetrachlorobenzenes	
Dichlorobenzenes		1,2,3,4-	$12\cdot10^3$
1,2-	550	1,2,3,5-	$10\cdot10^3$
1,3-	610	1,2,4,5-	$5.8\cdot10^3$
1,4-	280	Pentachlorobenzene	$23\cdot10^3$
Trichlorobenzenes		Hexachlorobenzene	$30\cdot10^3$
1,2,3-	$7.2\cdot10^3$		
1,2,4-	$4.0\cdot10^3$		
1,3,5-	$4.5\cdot10^3$		

The low sensitivity of ECD to compounds containing one fluorine or chlorine atom explains the observed[1] difficulty of determining vinyl chloride. Thus for substances of this kind, it is preferable to use flame ionisation[76] or photo-ionisation[143,144] detectors. It has been reported,[145] however, that the sensitivity of ECD to vinyl chloride increases by a factor of about 10^3 (from 1 ng to 1.4 pg) when N_2O (10–50 p.p.m.) is added to the gas (nitrogen) passing into it. The observed effect is due to the appearance in the gas phase of O^- ions, formed by the reaction of N_2O with thermal electrons. A chromatograph with a detector modified in this way, when 1 cm^3 of air is introduced directly, can determine vinyl chloride at a concentration of about 0.5 p.p.m. (1.4 mg m^{-3}), which, however, is higher than the level officially established in the USSR for the limiting permissible concentrations of this substance (0.1 mg m^{-3} for a working area, and 0.005 mg m^{-3} for atmospheric air).

The mass spectrometer, used as a chromatographic detector under total ion current recording conditions or under the conditions of mass fragmentography (detection of the signals of ions with previously specified mass numbers), has a longer linear range than ECD.[146] An additional advantage of the mass spectrometer is that it is possible to carry out a quantitative analysis not only by absolute calibration but also by isotopic dilution. Thus in the determination of the isomers of hexachlorocyclohexane, known quantities of its completely deuteriated analogue $C_6D_6Cl_6$ were added to the specimens.[146] Analysis by absolute calibration or mass-spectrometric detection is complicated by the difficulty of determining the ionisation cross-sections of different substances, but according to recent data, they can be calculated by additive schemes to within about 5%.[147]

Gas chromatographic–mass-spectrometric (GC-MS) analysis is widely used in the selective determination of poly-chlorinated aromatic hydrocarbons and their derivatives in complex mixtures with ionisation by electron impact[148–151] and with chemical ionisation.[152,153] The method involving the detection of the negative ions formed in chemical ionisation is particularly important for determining traces of the most toxic chlorinated dibenzo-*p*-dioxins, dibenzofurans, etc., since it has the lowest detection limit (down to 10^{-18} g according to some estimates).[154–161] The method involving ionisation at atmospheric pressure has similar advantages.[162,163]

Because of the importance of the selective detection of HOC, detectors of other types are used for their determination. It has been shown possible to identify halogens in organic compounds and to determine their mass fractions to within 3–6 rel. % with a detection limit down to 1 pg s^{-1} using detection in a corona discharge [a helium plasma with an electronic temperature of $(5-7)\times10^3$ K] from the wavelengths and intensities of the lines of the atomic emission of free halogen atoms in both the microwave[164,165] and near infrared[166] ranges. These plasma detectors are fitted with monochromators (usually diffraction gratings) and a set of recording assemblies, making it possible to determine several elements simultaneously (C, H, N, O, F, Cl, Br, I, S) [165,166] and to establish the empirical formulae of the compounds being analysed. The construction of detectors of this kind designed for capillary columns has been described.[167,168]

The possibilities provided by molecular emission spectroscopy have made it possible to produce another type of selective gas-chromatographic detector having a long linear range and a low noise level. The halogen-containing compounds leaving the packed column react with metallic indium in a hydrogen flame, after which the molecular emission signals of the indium halides are recorded at 360 nm (chloride), 376 m, (bromide), or 410 nm (indium iodide).[169] An infrared detector with Fourier transformation has been used for the chromatographic determination of polychlorodibenzo-*p*-dioxins. New electrical conductivity detectors can be used even with capillary columns.[170,171] The construction of selective detectors based on the Hall effect has been proposed.[172,173]

In the analysis of traces of polychlorinated aromatic compounds, extensive use is made of mass spectrometers with several mass analysers, effective for the analysis of complex mixtures (MS-MS). In this case, the chromatographic separation need not be so efficient,[173–175] and this stage may even be eliminated completely.[175] The direct analysis of mixtures for individual components by MS-MS using comparatively simple instruments makes it possible to develop the most rapid methods for their determination.[176–178]

The possibilities provided by the use of resonance two-photon ionisation for the detection of halogen-containing compounds have been studied.[179]

When ionisation is carried out by electron impact, the most widely used method of selective detection is mass fragmentography, which is effective both for volatile halogen-containing compounds[180–182] and for polychlorinated aromatic hydrocarbons[183,184] and pesticides.[115] The mass numbers of the principal peaks in the spectra of each component (m/z), some of which are given in Table 2, are usually chosen for diagnostic purposes.

Table 2. Mass numbers of the principal peaks of the mass spectra for the detection of various halogen-containing compounds under mass-fragmentographic conditions.[180–182]

Compound	m/z	Compound	m/z
Methyl chloride	50	1,2-Dichloroethylene	61
Dichloromethane	49, 84	1,2-Dichloropropane	63
Trichloromethane	83	2,3-Dichloroprop-1-ene	75
Tetrachloromethane	117	1,3-Dichloroprop-1-ene	75
Freon 13	69	Dichlorobromomethane	83
Freon 12	85	Chlorodibromomethane	129
Freon 11	101	Tribromomethane	171
Freon 22	67	1,2-Dibromoethane	107, 108
Freon 114	85	Chlorobenzene	112
Freon 113	101	Chlorotoluenes	91
1,1,1-Trichloroethane	97	Dichlorobenzenes	146
Trichloroethylene	95	Dichlorotoluenes	125
Tetrachloroethylene	129, 166	Trichlorobenzenes	180
1,1-Dichloroethane	63	Fluorobenzene	96
1,2-Dichloroethane	62	Difluorobenzenes	95
1,1,2-Trichloroethane	97	Pentafluorobenzenes	168
1,1,2,2-Tetrachloroethane	129	Fluorobromobenzenes	95
1,1-Dichloroethylene	61	Lindane	181

If this method of detection is used with chemical ionisation, the signals of the protonated molecular ions $[M + H]^+$ are usually recorded.

In mass fragmentography, instruments with a low resolution $[(1-1.5) \times 10^3]$, calibrated from integral mass numbers, are most frequently used. Comparatively recently (1981), an improvement of this method, namely high-resolution mass fragmentography, was proposed for instruments with a resolving power of not less than 2.5–3 thousand.[185] The extremely high selectivity of this method of detection has proved useful in the analysis of halogen-containing substances.[109,186] This selectivity is based on the specific values of the mass "defects" (ΔM) for the halogens [the differences between the exact masses of the atoms and their integral (by definition) mass numbers], which distinguish them from other elements found in organic compounds:

Element	ΔM	Element	ΔM	Element	ΔM
^{19}F	−0.0015	^{12}C	0	^{28}Si	−0.0231
^{35}Cl	−0.0311	^{1}H	0.0067	^{32}S	−0.0279
^{79}Br	−0.0183	^{14}N	0.0031	^{31}P	−0.0262
^{127}I	−0.0553	^{16}O	−0.0051		

In this case the mass fragmentograms are recorded from the exact values of the masses of the characteristic ion detected, given in Table 3.

Table 3. Exact masses of halogen-containing ions for the detection of various compounds under the conditions of high-resolution mass fragmentography.[109]

Compound	Ions detected	Masses of the ions (a.m.u.)	Compound	Ions detected	Masses of the ions (a.m.u.)
CHF_2Cl	$CHF^{35}Cl$	66.975	$CFCl_3$	$CF^{35}Cl_2$	100.936
	$CHF^{37}Cl$	68.972		$CF^{37}Cl^{35}Cl$	102.933
CF_2Cl_2	$CF_2{}^{35}Cl$	84.967	$C_2F_3Cl_3$	$CF^{35}Cl_2$	100.936
	$CF_2{}^{37}Cl$	86.964		$CF^{35}Cl^{37}Cl$	102.933
$CHFCl_2$	$CHF^{35}Cl$	66.975	CH_3CCl_3	$C_2H_3{}^{35}Cl_2$	96.961
	$CHF^{37}Cl$	68.972		$C^{35}Cl_3$	116 906
CH_2Cl_2	$CH_2{}^{35}Cl_2$	83.953	CCl_4	$C^{35}Cl_3$	116.907
	$CH_2{}^{37}Cl^{35}Cl$	85.950	C_2HCl_3	$C_2H^{35}Cl_2$	94.945
$C_2F_4Cl_2$	$CF_2{}^{35}Cl$	84.967			
	$CF_2{}^{37}Cl$	86.964			

4. The gas-chromatographic identification of halogen-containing substances

The gas-chromatographic identification of organic compounds is based on the accurate measurement of the retention parameters, of which the most reproducible forms are interpolation relative quantities, called retention indices.[187] Under isothermal analysis conditions, Kovac's retention indices are generally used:

$$I = 100n + 100\,(\lg t'_x - \lg t'_n)/(\lg t'_{n+1} - \lg t'_n),$$

where t'_x, t'_n, and t'_{n+1} are the corrected retention times of the substance being determined and the nearest reference components (n-alkanes) containing n and $n + 1$ carbon atoms, and $t' = t - t_0$, where t_0 is the retention time of the non-sorbed gas.

There is as yet no single generally accepted system of retention indices for temperature-programmed conditions. Among different methods for calculating them, mention may be made of a recently proposed system of linear–logarithmic indices,[188] in which the uncertainties in their calculation are smaller than those for other methods.

When non-selective chromatographic detectors are used, the reliability of identification only from the indices is low. Any additional information increased considerably the reliability of the assignment. Detailed catalogues of retention indices[189,190] have now been produced, but successful identification from these data requires the maximum possible additional characterisation of compounds of different classes. This explains the appearance of a large number of special publications giving the results of the determination of the retention indices of series of compounds with similar structures, including homologues, on different stationary phases. Among halogen derivatives, data of this kind have been obtained for alkyl chlorides,[191] the alkyl esters of chloroacetic acids,[192] chloromethyl esters,[193,194] chloroethanols,[195] the corresponding carboxylates,[196] chloroalkyl acetates,[197] chloropropanoates and chlorobutanoates,[198,199] chloroalkyl chloroacetates,[200] methyl chloro-

propanoates,[226] and the products of the halogenation and hydrohalogenation of alkyl acrylates.[201] The following aromatic compounds have been characterised: alkyl chlorobenzoates,[202] chloroalkyl benzoates and nitrobenzoates,[203,204] halogen-substituted benzenes, toluenes, and anisoles,[205,206] chlorinated 4-hydroxybenzaldehydes,[207] isomeric chlorophenols,[208] and pentafluorobenzoates.[209] The relationship between the structure of chlorophenoxyalkanecarboxylic acids and their retention indices has been discussed.[210] The relative retention times of 39 polychlorodibenzo-*p*-dioxins on weakly polar polydimethylsiloxane stationary phases have been determined.[30,211] Among the isomeric tetrachlorodibenzo-*p*-dioxins, the shortest relative retention time is shown by the isomer with the chlorine atoms in positions 1, 3, 6, and 8 (0.55), and the maximum by the 1,2,8,9-isomer.[1,21] The retention time of the most toxic 2,3,7,8-tetrachloro-derivative is usually taken as unity.[30] The retention indices of these dioxins can be calculated using additive schemes.[212–214] The difficulty of the gas-chromatographic identification of the compounds of these groups, however, makes it necessary to develop more complex methods based on pattern recognition techniques.[215,216]

Data on the retention indices of a number of toxic substances, including halogen derivatives, were published only in 1985.[217] More than 600 compounds, including chlorine-containing pesticides, have been characterised by their so-called effective retention temperature.[218]

The low sensitivity of selective gas-chromatographic detectors towards reference n-alkanes makes it necessary to use other reference homologues. As compounds of this kind for use with ECD, the esters of trichloroacetic acid CCl_3CO_2R, where R = n-C_nH_{2n+1}, have been recommended; the esters are given standard values of $100n$.[219] The method of identification based on this system for calculating the indices has been used in the determination of chlorine-containing pesticides and polychlorobiphenyls.[219,220] This set of reference components cannot be used to analyse low-boiling polyhalogenomethanes and -ethanes, however, since the first member of the series of trichloroacetates in the n-alkane system has an index of about 900 on non-polar silicone phases, so that lower values of the indices cannot be determined. For this reason, n-alkyl bromides[222] and n-alkyl iodides[223] have also been recommended as reference halogen-containing compounds.

Thermospray detectors are suitable for the analysis of both halogen-containing compounds and N- and P-containing substances, so that the homologous series of tri-n-alkylamines can be used as reference components.[223] The proposed[224,225] "universal" reference homologous series of bis(trifluoromethyl)thiophosphonates $(CF_3)_2P(S)OC_nH_{2n+1}$ can be used with practically all types of chromatographic detector, since the molecules contain halogen, sulphur, and phosphorus atoms simultaneously.

III. The mass-spectrometric characterisation and identification of halogen derivatives

According to present-day ideas, the fragmentation of halogen-containing organic compounds on electron impact shows no specific patterns. The most general direction of the decomposition of the molecular ions of all compounds of this type is the formation of $[M - Hal]^+$ ions and, less frequently, $[M - HHal]^{\cdot +}$. The probability that Hal$^{\cdot}$ radicals are removed increases in the order F < Cl < Br < I (with decrease in the electronegativity of the halogen).[226] The presence of other functional groups in the molecule may suppress considerably the fragmentation with rupture of C–Hal bonds, particularly for fluorides and chlorides. This is related to the relatively high ionisation energies (IE) of the non-bonding molecular orbitals localised on the halogen atoms, and the high probability of removal of an electron from other orbitals. This can be illustrated by the ranges of the IE of aliphatic halides, 10.7 ± 0.2 eV. (chloroalkanes), 10.1 ± 0.2 eV (bromoalkanes), and 9.2 ± 0.2 eV (iodoalkanes), compared with –9.2 ± 0.4 eV for alkanes, –9.3 ± 0.2 eV for ethers, –8.4 ± 0.1 eV for sulphides, etc.[227] The ionisation potentials of fluorine-containing compounds with different structures are generally greater than 10 eV. The fragmentation shows specific regularities only for polyhalogeno-derivatives, in particular perfluorinated derivatives.

The mass-spectrometric study of halogen-containing compounds is complicated by the low intensities of the peaks of the molecular ions, which correlate with the electronegativities of the halogen atoms and decrease in the order I > Br > Cl > F. The greatest difficulties are encountered in the detection of the mono-isotopic iodine and fluorine in organic compounds. Iodo-derivatives with sufficiently intense molecular ion peaks (not less than 1% of the total ion current) can be recognised from the large negative values of the homologous increments in the intensities of the [M + 1] isotopic peaks,[227] whereas the analysis of the spectra of fluoro-derivatives, which rarely give signals of this kind, is one of the most complex problems in mass-spectrometric identification. A general structural requirement for the production of the signals of the molecular ions of all halogen derivatives is the presence in the molecule of a p-π conjugated system for example $\rangle C=C-Hal$.[227]

The most important characteristic of polychloro- and polybromo-compounds is the presence of specific multiplets of the isotopic peaks in the mass spectra.[226,227] Their appearance makes it possible to achieve selectivity in the detection of halogen deriatives during GC-MS analysis by another period. A specially developed computer program makes it possible to detect these multiplets and to obtain information on the number of chlorine atoms in an unknown compound.[228,229] In this case the selective detector is a "mass spectrometer + computer" combination.

The difficulty of interpreting the mass spectra of fluorine-containing compounds makes it important to develop algorithms based on new principles. These include a method which requires a two-stage analysis of the data.[227] In the first stage (group identification or classification), an unknown compound can be assigned to a definite homologous series or group of homologues according to the numbers of homologous groups of principal peaks in the mass spectrum or (and) the statistically treated spectra of ion series. The subsequent refinement of the structure of the substance in the second stage is carried out with allowance for the known regularities of the fragmentation of the given series, together with the gas-chromatographic retention parameters.

Algorithms for group identification based on the statistically treated spectra of ion series have been characterised in detail, and the data for 20 series of halogen-containing substances have been given.[227] The further extension of the data base is extremely important, primarily to decrease the number of errors in second-order identification (the assignment of unknown substances to one of the series already characterised).[227] Table 4 gives the spectra of the ion series for several groups of fluorine-containing compounds. This method makes it possible to describe series in which the compositions of the members differ not by a CH_2 group but by another homologous difference, for example CF_2 (mass number 50).

In this case, compounds belonging to different homologous groups are obtained in a single series $y_M \equiv M \pmod{14}$, and the spectra of the ion series have a slightly lower reproducibility, which does not prevent the practical utilisation of these data.

Table 4. Mass spectra of the ion series of various groups of organofluorine compounds.[227]

Class of compound	Homologous group y_M	I_y in order of increasing y from 0 to 13*
n-Alkyl fluorides	6	$25_4\ 30_8\ 1_1\ 3_1\ 2_1\ 6_3\ 0\ 0\ 0\ 0\ 0\ 4_2\ 2_1\ 27_7$
s- and t-Alkyl fluorides	6	$4_4\ 4_3\ 1_1\ 4_1\ 8_5\ 57_8\ 3_2\ 0\ 0\ 0\ 0\ 2_2\ 1_1\ 12_4$
gem-Difluoroalkanes	10	$0\ 2_2\ 1_1\ 8_2\ 2_2\ 16_9\ 1_1\ 0\ 3_2\ 62_{10}\ 2_2\ 0\ 1_1\ 2_2$
Aryl fluorides	12	$1_1\ 3_2\ 0\ 1_1\ 1_1\ 4_1\ 2_1\ 3_1\ 3_1\ 4_1\ 2_1\ 46_9\ 23_9\ 7_2$
Perfluoroalkanes	**	$0\text{-}4_4\ 4_3\ 4_1\ 0\ 4_4\ 0\ 13_8\ 3_2\ 1_1\ 0\ 1_1\ 0\ 66_7$
Perfluoroalkenes	**	$2_2\ 5_4\ 5_4\ 6_4\ 3_3\ 9_7\ 2_2\ 6_4\ 2_1\ 4_2\ 2_2\ 2_2\ 1_1\ 51_{13}$
Perfluorocarboxylic acids and their esters	**	$1_1\ 9_4\ 5_2\ 40_4\ 1_1\ 3_3\ 0\ 4_4\ 3_2\ 5_5\ 1_1\ 4_3\ 0\ 24_6$

* I_y represents the total intensities of the signals of the homologous group y as a percentage of the total ion current ($\Sigma I_y = 100\%$); the subscripts give the standard deviations characterising the scatter in these quantities for different compounds of the given group.
** The mass numbers of the homologues are compared with respect to the modulus 50 (homologous difference CF_2) and not 14 (CH_2 group), so that they relate to different homologous groups $y_M = M \pmod{14}$.

An increase in the reliability of mass-spectrometric identification requires the elimination of the principal sources of inter-laboratory uncertainties in the mass spectra and the observation of various critria proposed for estimating the "quality" of mass spectra.[230] The simplest method of verifying the operating conditions of an instrument involves recording the spectra of standard compounds and comparing the peaks with tabulated values. Recommended reference substances are phenylbis(pentafluorophenyl)phosphine and *p*-bromofluorobenzene,[182,231,232] the data for which are given in Table 5.

The mass-spectrometric characterisation of halogen-containing compounds which have not been studied before covers an extremely wide range of materials. Because of the objective characteristics of the dissociative ionisation of substances of this class, however, the specific characteristics of their fragmentation often are not related to the presence of the halogen atoms in the molecule, but are determined completely by other functional groups. The fundamental facts include a new skeletal rearrangement in the molecular ions of dichloro- and difluorosilanes, associated with the elimination of dichloro- and difluorosilenes respectively:

$$[RR'SiHal_2]^{+\cdot} \rightarrow [RR']^{+\cdot} + SiHal_2.$$

The structural requirement for this process is the presence of multiple bonds or heteroatoms in the groups R and R'.[233] General rearrangements take place in the molecular ions of the trimethylsilyl and t-butyldimethylsilyl ethers of chlorine-containing alcohols, accompanied by the migration of a Cl atom to silicon and leading to the appearance in the spectra of peaks due to the ions $[(CH_3)_2SiCl]^+$ with *m/z* of 93 and 95.[234,235]

Polychlorinated compounds have been studied in detail not only in the solution of special analytical problems[236–239] but also frequently in the development of methods of detection and the interpretation of the mass spectra of these substances in the determination of pesticides and insecticides,[240–242] toxic polychloro-aromatic compounds,[148–151,243–245] etc. An independent direction of mass-spectrometric studies involves the investigation of potential metabolites of halogen-containing drugs.[246] A large number of papers have been devoted to the analysis of the regularities of the fragmentation of halogen-containing cyclo- and polyphosphazenes $(-PR_2=N-)_{3-n}$, a new promising class of monomers for the preparation of polymeric materials.[247–255] The mass spectra of the adducts of unsaturated compounds with 5,5-dimethoxytetrachloro-cyclopentadiene, which is a specific reagent for GC-MS analysis, have been characterised to establish not only the positions of the double bonds in unknown compounds but also, in the opinion of the authors cited,[256] their configuration.

Table 5. Standard mass spectra of phenylbis(pentafluorophenyl)-phosphine and *p*-bromofluorobenzene for standardising mass spectrometers.[182,231,232]

$C_6H_5P(C_6F_5)_2$		BrC_6H_4F

444	[7—9		

*Relative to the intensities of the signals with the mass numbers indicated.

Chemical ionisation is most frequently used in mass fragmentography for detecting polyhalogeno-aromatic compounds.[152,153] Halogen-containing compounds are promising reagent gases for the selective detection of compounds of different chemical character. For example, the use of chlorobenzene (IE 9.04 eV) for this purpose in the analysis of mixtures of petroleum hydrocarbons makes it possible to record only the aromatic hydrocarbons (IE range 8.5 ± 0.3 eV), whereas alkanes (10.4 ± 0.5 eV) and cycloalkanes (10.1 ± 0.3 eV) are not detected.[257] The use of CH_3I leads to the formation in the gas phase of dimethyliodonium cations $[(CH_3)_2I]^+$, capable of effectively methylating the compound being analysed.[258] The characteristics of the production and reactivity of $[CCl_3]^+$ and $[CCl_3]^-$ ions under chemical-ionisation conditions have been discussed.[259,260]

The high electron affinity of halogen-containing compounds, compared with other organic compounds, is responsible for the large negative ion formation cross-section,[261] and makes negative ion mass spectrometry a promising method for detecting and identifying compounds of this type. In practice, anions are most frequently generated under chemical-ionisation conditions, when thermal electrons are present in the ion source. Under these conditions, aromatic compounds give intense signals due to the molecular radical-anions $M^{\cdot-}$ at a low fragmentation depth, and signals of the ions $[M - H]^-$ are typical of compounds not containing conjugated systems. Chemical ionisation with detection of negatively charged ions does not impose fundamental restrictions on the nature of the reagent gases (methane is usually employed), but in some cases, mixtures with halogen-containing substances, for example CH_3OH and $CHCl_3$ [262] or CH_4 and CH_2Cl_2,[263] are used. This method leads to the preferential formation of $[M + Cl]^-$ anions.

The mass spectra and optimum detection conditions for these ionisation conditions have been studied for a series of pentafluorophenyl compounds C_6F_5R (R = F, CH_3, NH_2, OH, SH, OCH_3, $OCOCH_3$, CHO, NO_2, and CN),[264] pentafluorobenzoyl derivatives of aminoacids,[92] chloro- and fluorochloroethylenes,[265,266] the pentafluoropropionates of hydroxylamine derivatives,[267] chloroglucuronides,[268] trifluoroacetyl derivatives of polyols (in particular myoinositol[269]), derivatives of α,β-difluorocinammic acids,[270] halogen-containing derivatives of dipeptides and their metabolites,[271] etc. The method is highly sensitive, since the efficiency of ionisation is high (close to 100%), and the spectra of the negative ions of the halogen-containing compounds in a number of cases have a high structural specificity, making it possible to distinguish isomers, which have similar positive-ion spectra. Only this method makes it possible to differentiate perfluorobuta-1,3-diene and the isomeric perfluorobut-2-yne and perfluorocyclobutene.[272] The high sensitivity of the method has led to its extensive application in the analysis of toxic polychlorinated aromatic compounds by GC-MS analysis.[154–161,273–277]

The detection of negative ions is also possible in so-called thermospray ionisation in liquid chromatograph–mass spectrometers used in the analysis of non-volatile or thermally unstable compounds, including pesticides.[278–280] The process of anion formation can be controlled by adding special halogen-containing additives to the eluant. For example, the addition of only 0.1–1% chloroacetonitrile increases considerably the sensitivity of the detection of phenols, as a result of the formation of $[M + Cl]^-$ ions.

Mass-spectrometric studies of one of the most important types of non-volatile compound, namely organic salts, including the large group of salts of hydrogen halides, have been reviewed.[281] The special methods of ionisation used to record the mass spectra of substances of this kind and high-boiling halogen derivatives include the field desorption of pesticides,[282] which may be combined with separation of the mixtures on a liquid chromatograph.[283] The mass spectra have been obtained under photo-ionisation conditions and analysed for halogenomethanes,[284] 1,1-difluoroethane,[285] 1,1-dichlorodifluoroethylene,[286] fluoroethylenes,[287] and 5-fluorouracil derivatives.[288] One of the promising methods of secondary ion emission with ionisation on solid supports, so-called fast atom bombardment (FAB), has been used to study fluoroalkyl sulphonates,[289] metabolites of 2-chloro-N-isopropylacetanilide,[290] iodoxamic acid and its dimethyl ester,[291] and the halides of various elements of Group IV of the periodic system.[292]

— o0o —

The variety of existing methods and the constant development of new methods for the chromatographic and mass-spectrometric identification and quantitative determination of halogen-containing organic compounds is related to the need to solve a number of fundamental urgent problems. One of these is the contamination of the environment by substances which are produced almost exclusively by man. There are no effective natural decomposition mechanisms for these substances, which accumulate in different materials and have a cumulative effect. The influence of the emission of volatile fluorochlorohydrocarbons into the atmosphere on the stability of the ozone layer is now a controversial topic. The reliable control of the concentration of aromatic polychlorinated organic compounds in foodstuffs, soils, natural waters, effluents, etc. is undoubtedly important.

The effective solution of these problems makes special demands on analytical methods for determining halogen derivatives. These requirements include ensuring the minimum detection limit, decreasing the systematic and random errors of the analysis, and achieving the maximum selectivity, discussed in the present review, of the determination of HOC against a background of predominant quantities of interfering components of different chemical character. In addition a completely unique type of problem involves increasing the efficiency of methods for interpreting the results of gas-chromatographic and GC-MS analyses to establish the composition and structure of unknown components in complex mixtures. The greatest difficulties are encountered in the structural analysis and identification of fluorine-containing compounds, and the improvement of the appropriate algorithms is an extremely urgent task.

The variety of methods and techniques for carrying out all stages of the gas-chromatographic and GC-MS analysis and identification of HOC in different materials, reflected in the present review, provides an objective prerequisite for the selection of the best methods for solving specific problems. This characterisation of the determination of HOC by means of the single most important criterion, namely the maximum selectivity, should not however be considered in isolation from other parameters of analytical procedures, in particular the reliability of the identification of these compounds.

The liquid-crystalline state of salt melts containing organic ions

T A Mirnaya, V D Prisyazhnyi, V A Shcherbakov
Institute of General and Inorganic Chemistry, Ukrainian SSR Academy of Sciences, Kiev

ABSTRACT. The present review deals with the latest achievements in the chemistry of ionic melts and liquid crystals (LC). New liquid crystals, formed by salt melts containing organic ions, have been described. The characteristics of their thermodynamic and transport behaviour, structure, and optical properties have been examined. The part played by electrostatic interactions and the parameters of the cations and anions in the stabilisation of the ionic mesophase has been demonstrated. The dependence of the production of liquid crystals in binary salt mesogenic systems on the nature of the interionic interactions has been analysed. The possible practical applications of this new class of liquid crystals have been discussed.

The bibliography contains 77 references.

I. Introduction

The most remarkable of the states of aggregation of matter, namely the liquid-crystalline state, is produced as a result of the specific breakdown of the crystal lattice on fusion (thermotropic LC) or solution (lyotropic LC) of a mesogenic substance.

The basic problem in the chemistry of liquid crystals is to determine which characteristics of the structure of the molecules of mesogens and their interactions determine the existence of the mesomorphic phase. Ionic liquid-crystalline melts, in which the principal role in the stabilisation of the liquid-crystalline state is played by the electrostatic factor,[1] are of particular interest in this connection.

The term melt is used to describe that part of the range of the liquid state of matter which can be described by the quasi-crystalline approach.[1,2] The structure and properties of salt melts consisting of simple ions have been studied in detail. They can be regarded as unique model systems, but the intensive study of melts containing monatomic ions has been stimulated not only by the possibility of carrying out simple experiments and the unambiguous interpretation of the results, but also by their extensive practical application.[2,3] Physical chemists have recently begun to study salt melts containing polyatomic ions. This has been due not only to the necessity of developing the theory of the liquid state but also to a number of technological requirements of modern industry. Research workers have been attracted by the low melting points, the ease of formation of salt glasses, and other properties of melts containing complex ions.[4–6]

Until recently, mainly inorganic salt melts were studied although organic salts provide a much wider and more varied range of materials for study and application. Since the shape and size of the repulsion envelope of the organic ion,† and the magnitude and distribution of the density of the Coulombic charge on it, can be easily varied, organic salt melts make it possible to obtain liquids with different inter-particle interactions, with expected and sometimes unusual properties.

The main obstacle to the extensive study and application of organic salt melts has been their low thermal stability. The instability of salt melts is both "internal", determined by the energy of the interatomic bonds within the ion, and "external", determined by the perturbing influence of impurity ions, molecules, and atoms.[4]

In most cases, the instability of organic ionic melts is "external", so that it can be avoided. Ubbelohde and co-workers[7,8] determined various impurities influencing the stability of melts containing organic ions, and formulated the requirements to be satisfied in the synthesis and study of these salts. Thus the basic conditions for working with molten organic salts include the absence from the melt of molecular or atomic oxygen and impurity transition metal ions and OH^- ions.

Thorough precautions in experiments with organic salt melts have made it possible to accumulate fairly extensive data on their physicochemical properties.[9–12]

Melts formed by the salts of n-alkanoic acids have been studied most systematically. Many representatives of this class of salt show unique properties. Thus in a definite temperature range, from the melting point (T_f) to the clearing temperature of the mesophase (T_{cl}), most of them exist in a viscous optically anisotropic state completely analogous to liquid crystals.[13]

A liquid crystal is a liquid with a constant anisotropy of the physical properties, having one-dimensional (nematic, cholesteric) or two-dimensional (smectic) order in space.

Liquid crystals play an important role in present-day science and technology.[14–27] Considerable interest is shown in all new data on liquid-crystalline substances, particularly data refuting the previously accepted view that the ability to form liquid crystals or mesophases

†The repulsion envelope of a polyatomic ion is the surface extending round the spheres of repulsion of the outer atoms in the complex ion; the radius of the sphere of repulsion of an atom, according to Ubbelohde, is equal to its crystal-chemical radius for the given type of bond and coordination (see the bibliography in Ubbelohde's book[1]).

is shown only by complex organic molecules with clearly defined anisometry.[14,15]

In fact, mesogens (that is substances forming liquid crystals or mesophases) are most frequently long rod-shaped or cylindrical, and also disc-shaped, molecules. At an early date, however, Frederiks,[16] one of the founders of the physics of liquid crystals, warned against overestimation of the part played by the anisometry of mesogens: "... since there are known cases of liquids with long molecules which do not form an anisotropic liquid phase, a comparatively elongated molecule is undoubtedly not a sufficient condition for the existence of an anisotropic phase. In fact, it cannot even be stated that this is a necessary condition".

Mesogenic substances with non-traditional structure and molecular shape, such as organic and inorganic compounds with ionic structures, are now increasingly encountered among liquid crystals.[1,13,20,21] These mesogens are extending the range of existence of mesogenic substances from organic into inorganic chemistry.

The liquid-crystalline properties of salts of carboxylic acids were detected as early as 1910 by Vorlaender on fusion of the long-chain homologues of soaps.[14] The mesophases of these salts are similar to liquid soaps, and by analogy were called smectic, from the Greek work "smektos"—soap-like. It was later found that the smectic form of liquid crystals is often encountered in substances of other (non-salt-forming) classes. Having given their name to the type of liquid-crystalline system showing two-dimensional order, however, the carboxylic acid salt mesophases themselves subsequently attracted practically no attention from research workers for many decades. Many aspects of the structure of the mesophases and the mechanism of fusion of the salts of the higher homologues of aliphatic acids became clear only after the work of Vold and co-workers[28,29] and Skoulios and co-workers.[30–33]

The liquid crystals formed by soaps show no distinctive features compared with smectic liquid crystals of other types, and show the same regularities; their molecules have clearly defined anisometry (the length to width ratio is greater than 5) and have a constant dipole at right angles to the long axis of the molecule.[14]

Ubbelohde's discovery[34] of the liquid-crystalline properties of the salts of the lower homologues of the alkanoic acids (from propanoic to octanoic) was unexpected and even sensational.

Table 1. Characteristics of the polyatomic anions of various mesogenic and non-mesogenic salts.[8]

Anion	Radius of repulsion envelope, Å	Charge/(number of atoms) ratio
SCN^-	2.20	1:3
NO_3^-	2.32	1:4
ClO_4^-	2.36	1:5
$CH_3CO_2^-$	2.60	1:7
$C_2H_5CO_2^-$	2.82	1:10
$n\text{-}C_3H_7CO_2^-$	3.04	1:13
$iso\text{-}C_4H_9CO_2^-$	3.28	1:16

Firstly, the particles making up these mesophases are quasi-globular ions: inorganic cations and carboxylate anions, whose length to width ratio does not exceed 2. Thus the principal geometric requirement satisfied by the particles of all previously known mesogenic substances[14] is not satisfied in this case.

Secondly, in contrast to the classic liquid crystals formed by electrically neutral molecules, the salt mesophases have a high ratio of the electrostatic charge to the total number of atoms. Moreover, the radii of the repulsion envelopes of the carboxylate anions of the group of salts being considered differ little from those of the polyatomic anions of inorganic non-mesogenic salts (Table 1). Thus salt mesophases are anisotropic ionic melts.

Thirdly, in most cases there is a marked difference in the radii of the repulsion envelopes of the cations and the carboxylate anions, that is $r_c/r_a < 1$ (Table 2). By analogy with inorganic salts, this ratio of the dimensions of the cation and the anion should favour the stepwise positional ordering of first the cation sub-lattice and then the anion sub-lattice of the crystal, and hence lead to the existence of a highly conducting solid phase (solid electrolyte).

Table 2. Ratio of the radii of the cation and the anion and the difference in the specific conductance of the melt and the crystal at T_f for non-mesogenic salts and T_{cl} for mesogenic salts.[8]

Salt	r_c/r_a	γ_l/γ_s	Characteristic of thermal behaviour
AgCl	0.62	30	solid electrolyte
AgBr	0.57	20	ditto
$C_2H_5CO_2Na$	0.35	13	mesogenic salt
$iso\text{-}C_4H_9CO_2Na$	0.30	8	ditto
$n\text{-}C_3H_7CO_2Na$	0.32	—	»

These facts, together with electrical conductivity data (Table 2), led Ubbelohde[8] to suggest that the mesophases of the salts of the lower carboxylic acids are not true liquids but highly plastic solid forms in which only the anions are organised in a crystal lattice, while the cation sub-lattice is disordered. Measurements of the shearing stresses showed unambiguously,[35] however, that salt mesophases are true liquids throughout the temperature range of their existence from T_f to T_{cl}, and that they are liquids with constant anisotropy of the physical properties. Similar anisotropic melts with the structure of the smectic form of type A were subsequently detected among salts of aromatic acids and alkali metals[36] and the lower homologues of n-alkylammonium halides.[37]

Ionic anisotropic melts have been called ionic liquid crystals (ILC). They could be defined as thermodynamically equilibrium liquids with constant anisotropy of the physical properties, consisting of oppositely charged ions. The basic structural unit of ILC, in contrast to molecular LC, is a mesogen ion, and not a mesogen molecule. Since the existence of a mesophase requires clearly defined anisotropy of the inter-particle interactions,[15] it follows that in molecular liquid crystals, in which the predominant intermolecular interaction is van der Waals interaction, an anisotropic shape is a necessary characteristic of the mesogen molecule, whereas in ILC, in which the predominant inter-particle interaction is electrostatic, the necessary characteristic of the mesogen ion should be the anisotropy of the distribution of the Coulombic charge, and the geometry of the ion is now not the decisive factor.

Table 3. Parameters of the fusion and clearing of non-mesomorphic and mesomorphic salts and classic LC.

Cadmium myristate	374	400	43.0	1.6	115.0	4.0				[38]

Note. $\Delta V_f = V_m - V_s$, where V_m is the volume of the mesophase at T_f, and V_s the volume of the solid phase at T_f; $\Delta V_{cl} = V_l - V_{lc}$, where V_l is the volume of the isotropic melt at T_{cl}, and V_{lc} the volume of the mesophase at T_{cl}; $\Delta V^* = V_l - V_s$.

The properties of this new class of liquid crystal, the structural characteristics of typical representatives, and the relationship between the mesomorphism and the nature of the ionic components of the melt can now be considered.

II. The thermodynamic properties of ionic mesogens

The study of the thermodynamic functions of liquid crystals and the changes which they undergo in mesomorphic phase transformations is an important step in the determination of the nature of the inter-particle interactions and the mechanisms of the phase transformations. Most available data on the thermodynamic properties of organic salts have been fully dealt with in a review by Franzosini and Sanesi.[12] Nevertheless, the tendency of most salts with organic ions to form supercooled and metastable states complicates considerably the interpretation of the thermodynamic data obtained; a large number of ambiguous results and results which have not been reproduced have been published.

The temperatures of the phase transformations have been most fully studied; this applies to the homologous series of the alkanoates of the alkali metals, thallium, ammonium, various metals of the second main group of the periodic system, and various transition metals (zinc, cadmium, lead, manganese, etc.), and various salts of aromatic carboxylic acids.[12,36] The enthalpies and entropies of the fusion and clearing of the mesophase have been studied for the alkanoates of the alkali metals, thallium, and various transition metals, and for mono-substituted n-alkylammonium chlorides,[12,37–41] but a complete picture of the thermal change in the thermodynamic properties has been obtained for only two salts from the ILC group, sodium isovalerate and butyrate.

A comparative analysis of the parameters of the fusion and clearing of the mesophase (Table 3) for three groups of substance, namely non-mesogenic inorganic salts, ILC, and molecular LC, leads to several important conclusions.

1. Ionic mesogens have relatively low enthalpies of fusion, like molecular LC and salts without conformationally flexible chains.[42]

2. The values of ΔS_f for ionic mesogens are extremely low (9–20 J mol^{-1} K^{-1}) compared with ΔS_f for molecular LC ($\sim$70 J mol^{-1} K^{-1}) and inorganic salts ($\sim$25 J mol^{-1} K^{-1}). They are often even lower than ΔS_f for the inert gases ($\sim$14 J mol^{-1} K^{-1}).

3. The values of ΔH_{cl} and ΔS_{cl} for ILC are of the same order of magnitude as for ordinary LC.

4. The values of ΔS_{Cl} for ILC are lower than ΔS_f by factors of 2–5.

5. The relative changes in volume in the fusion and clearing of ILC are approximately equal, whereas for molecular LC the relative change in volume at T_{cl} is smaller by an order of magnitude than that at T_f. The relative change in the volume of ionic mesogens in the transformation between the crystal and the isotropic melt via the mesophase ($\Delta V^*/V_s$, see Table 3) is of the same order of magnitude as the relative change in volume in the transformation between the crystal and the isotropic melt for ordinary inorganic salts.

The low enthalpy and entropy of fusion of ILC are indications of positional ordering, characteristic of a crystal containing quasi-spherical molecules consisting of a small number of atoms.[42] However, the fact that ΔS_f for ionic liquid crystals is often lower than the value 14 J mol^{-1} K^{-1} characteristic of the formation of simple positional defects apparently indicates cooperative positional disordering of the crystal lattice at T_f.[42]

In the fusion of ionic mesogens, the features of the cooperative positional disordering may be that each group of neighbouring ions and their component atoms are displaced collectively from their equilibrium positions in the crystal, forming local structures or domains with liquid-crystalline ordering. If smectic ILC are formed on fusion, the arrangement of the ions in these domains should preserve the long-range orientational order combined with translational periodicity in two dimensions. An indirect thermodynamic indication of the preservation of partial positional

order in ILC is the extremely marked increase in volume of T_{cl} for sodium butyrate and isovalerate, comparable with the change in volume on fusion.

A characteristic feature of the ILC studied is the absence of mesomorphic polymorphism (only one LC phase exists).

The influence of the length of the aliphatic chain of the anion or cation on the thermodynamics of the mesomorphic state has been studied for the homologous series of n-alkanoates of the alkali metals, thallium, and various transition metals, and for mono-substituted n-alkylammonium chlorides.[12,36-41]

Fig. 1 gives the dependence of the thermodynamic parameters of the phase transformations (T_{cl}, ΔS_f, ΔS_{cl}) on the length of the aliphatic chain of the mesogen ion (n) in various homologous series of ILC. Analysis of these data shows that:

1) there is an odd–even alternation of the thermodynamic parameters of the transformation betweeen the ILC and the isotropic melt, which is smoothed out with increase in the length of the alkyl chain n;

2) the dependence of T_{cl} on n shows a flat maximum at n = 5–8;

3) there is no simple dependence of ΔS_f on n;

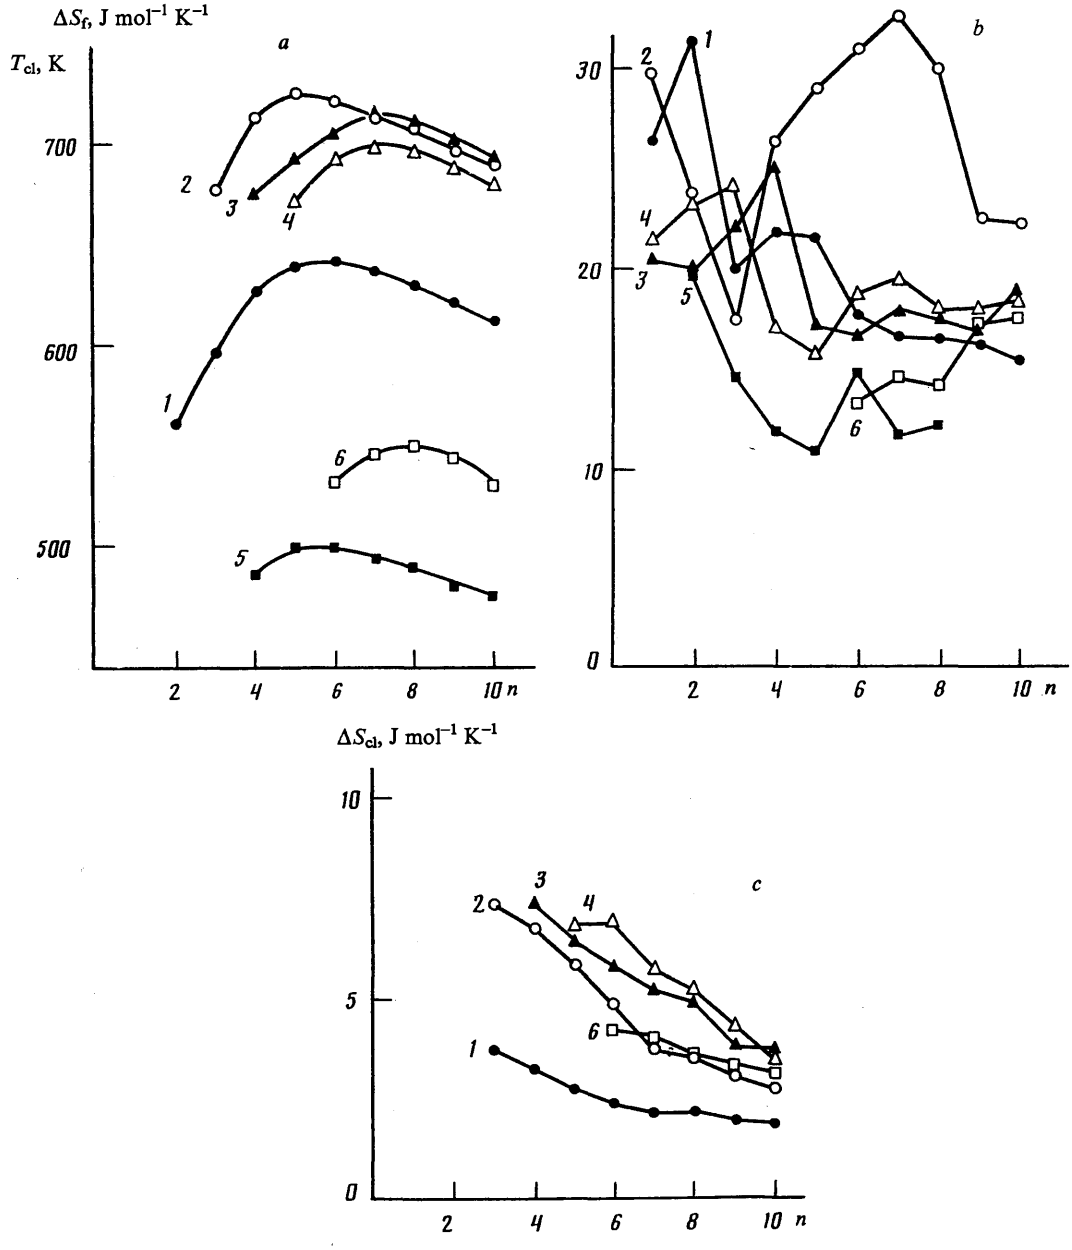

Figure 1. Dependence of the clearing temperature (*a*), the entropy of fusion (*b*), and the entropy of clearing (*c*) of the mesophase on the number of carbon atoms in the aliphatic chain of the mesogen ion for homologous series of salts: *1*, $C_nH_{2n+1}CO_2Na$; *2*, $C_nH_{2n+1}CO_2K$; *3*, $C_nH_{2n+1}CO_2Rb$; *4*, $C_nH_{2n+1}CO_2Cs$; *5*, $C_nH_{2n+1}CO_2Tl$; *6*, $C_nH_{2n+1}NH_3Cl$.[12,37]

4) ΔS_{cl} and ΔH_{cl} decrease regularly with increase in the length of the alkyl chain of the mesogen ion.

These regularities are qualitatively the same as the general regularities in the thermodynamic behaviour of known homologous series of classic smectic liquid crystals,[43] since in all cases a decisive role is played by the dimensions of the alkyl group. Thus the odd–even alternation is a consequence of the difference between the contributions of an odd and an even carbon atom to the length and polarisability of the hydrocarbon chain of the ion or molecule.

The decrease in ΔS_{Cl} and ΔH_{Cl} with increase in n may be due either to a relative increase in the ordering of the isotropic melt or to a decrease in the ordering of the mesophase close to T_{cl}. X-Ray diffraction data for thallium alkanoates[44] indicate an increase in the ordering of the alkane chains of the anions in the mesophase close to T_{cl} with increase in n.

The few published studies of the total change in the entropy of organic salts on going from the crystalline state at 0 K or 298 K to the isotropic liquid state indicate a definite increase in $\Sigma\Delta S$ with increase in the length of the alkyl group.[40] This increase in the total entropy in homologous series of flexible molecules is due predominantly to the increase in the configurational component of the entropy. Thus for the long-chain homologues of alkanoates and alkylammonium salts, the main mechanism of fusion involves disordering of the alkane chains.

For the homologues of salts with short alkyl groups ($n \leqslant 7$), in which the predominant interionic interaction is electrostatic, the mechanism of fusion is apparently slightly different, and will be discussed later in relation to structural data for ILC. The fact that the electrostatic interaction makes the principal contribution to the total energy of stabilisation of the ionic mesophase explains the high sensitivity of the thermal stability of ILC to the nature of the component ions. Thus Fig. 1*a* shows that the LC state is not realised in lithium carboxylates; in the homologous series of the salts of the other alkali metals, the existence of the mesophase depends on the length of the alkyl group; for example, the salts form a mesophase at $n \geqslant 2$ for sodium, at $n \geqslant 3$ for potassium, at $n \geqslant 4$ for rubidium, and at $n \geqslant 5$ for caesium.

Parameters of the cations and the carboxylate anions making up the salt mesophase, namely the polarising power of the cations z_c/r_c^2 and the ratio of the radii of the cations and anions r_c/r_a, have been analysed.[45] This analysis made it possible to formulate the following empirical relationship: an ionic mesophase can exist in molten salts of alkanoic acids if

$$z_c/r_c^2 \leqslant 1.05 \text{ and } r_c/r_a \leqslant 0.4. \quad (1)$$

This relationship is naturally approximate, but it applies satisfactorily to 12 homologous series of monovalent and divalent metal n-alkanoates.[45] The main value of the expressions (1) is that they show the relationship between the possible production of LC ordering in a salt melt and the nature of cations and anions.

III. The structure and optical properties of ionic mesogens

Although the structure of ILC has not yet been established in sufficient detail, a model of the structure of the ionic mesophase has now been proposed, based on the results of polarisation, X-ray diffraction, and NMR studies of sodium butyrate and isovalerate,[46–48] potassium hexanoate,[49] thallium and sodium n-alkanoates,[44,50–52] and sodium methylpentanoates.[53]

Optical polarisation studies have established unambiguously that the mesophases of the salts of lower alkanoic acids are homogeneous liquid-crystalline phases of the smectic A type;[44,48] the existence of only one smectic phase throughout the temperature range of stability of the ILC is also indicated by the ^{23}Na NMR spectra of sodium alkanoates. Thus in all the sodium salts studied, the quadrupole coupling constant, calculated from the first-order quadrupole splitting of the ^{23}Na NMR spectrum, shows a smooth temperature dependence.[47,51,53]

The basic principle of the arrangement of the ions of the salts of carboxylic acids in the condensed state is determined by the combination of the strong electrostatic interactions of the cations and the anions and the weak van der Waals interactions of the organic chains of the anions. The ionic groups should be in contact with one another, but in such a way that the bulky non-polar organic parts of the carboxylate anions are close-packed. This condition is satisfied by electrostatic "sandwich" layers of metal cations, situated close to the negatively charged carboxyl groups of the alkanoate anions (Fig. 2). This layer segregation of the ions practically excludes the unfavourable interaction of the Coulombic charges with the aliphatic chains, whose dielectric constants are low

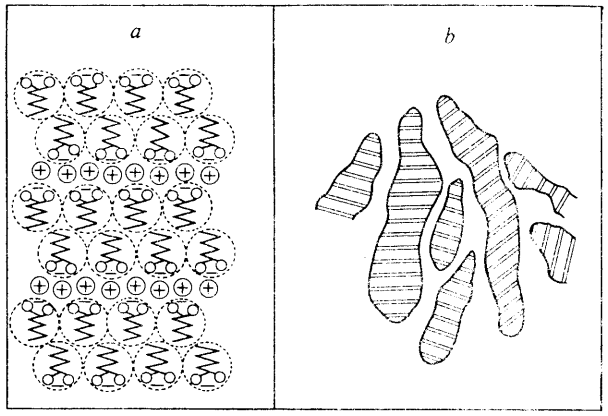

Figure 2. Schematic representation of the layer structure of an ionic liquid crystal (from published data[46–48]): *a*, relative arrangement of the carboxylate anions and the metal cations in LC domains; *b*, possible preferred orientation of the cation–anion layers forming the domains in the ionic mesophase.

Thus in a liquid-crystalline carboxylate melt, the first coordination sphere of the cation contains only anions, in accordance with Temkin's model of the structure of ionic melts,[42] whereas the first coordination sphere of the anion contains both cations and anions. The energy of the Coulombic interaction of two adjacent cations in the same electrostatic layer will naturally be much greater than the energy of this interaction between the cations belonging to two neighbouring electrostatic "sandwiches".

The arrangement of the electrostatic "sandwiches" in space may be different in different salts, since the packing of the ions is determined by the Coulombic forces acting both [illegible] sandwich"

and between neighbouring "sandwiches". The magnitude of these forces should apparently depend both on the nature of the metal cations and on the size of the hydrocarbon chain of the carboxylate anion, shielding the electrostatic interactions between neighbouring "sandwiches". In ionic liquid-crystalline melts, the Coulombic interactions involve more than ten thousand ions,[8] and this facilitates their mutual ordering. Thus the strength of the electrostatic interactions should also influence the size of the LC domains in salt melts, and the parameters of the order in the ILC.

Optical polarisation studies of lower sodium carboxylates[48] have shown that in the series of homologues from sodium butyrate to sodium heptanoate there is a considerable change in the size of the LC domains (Table 4). The size of the domains decreases with a relative increase in the organic part of the carboxylate anion in the series of related compounds, reflecting the increase in the shielding of the electrostatic field. No obvious simple criteria have yet been found, however, for estimating the absolute dimensions of the LC domains in other homologous series. Thus no complete explanation has yet been given for the marked increase (by a factor of ~ 25) in the size of the domain on going from sodium butyrate to sodium isovalerate, which is similar in many respects but which has a lower mesophase thermal stability (Table 4).

Table 4. Size of the LC domain and the thermal stability of the ionic mesophase of sodium carboxylates.

Salt	Size of domain $\times$ 10^6, m (Ref.48)	T_{cl}, K (Ref.12)
iso-$C_4H_9CO_2Na$	500	556
n-$C_3H_7CO_2Na$	20	597
n-$C_4H_9CO_2Na$	15	626
n-$C_5H_{11}CO_2Na$	10	631
n-$C_6H_{13}CO_2Na$	7	634

A characteristic feature of salt mesogens is the preservation of the long lattice constants of the crystals (d) on fusion. Thus non-branched sodium and thallium alkanoates[44,46] show an abrupt decrease in d at the melting point, and further increase in temperature leads to an even greater gradual compression of the cation–anion layers. Sodium isovalerate at the melting point shows a sharp increase in the long period, which in the mesophase remains constant and independent of temperature (Fig. 3).

According to Duruz and Ubbelohde,[46] the difference in the thermal behaviour of the long periods d of the mesophases of sodium butyrate and isovalerate is due to a difference in the thermal flexibility of the two alkane chains and the difference in their reaction to increasing torsional thermal vibrations with increase in temperature. Using data on the molar volume V, the authors cited[46] estimated the area occupied by the electrostatic cation–anion layers ($A = V/d$) in sodium butyrate and isovalerate, with the approximate assumption that these layers are packed in columns with no spaces between them. It was found that if one imagines cylinders being cut from the sequence of layers formed by identical numbers of cations and anions in the structures of the two salts, then at a temperature slightly below T_f the butyrate cylinder will be higher and will have a smaller basal area than the isovalerate cylinder. At T_f, the area of the base of the butyrate cylinder increases abruptly (by $\sim 8\%$), and its length decreases (by $\sim 1.6\%$). For the isovalerate cylinder, however, the length increases abruptly (by $\sim 7\%$), and the area of the base decreases (by $\sim 2.2\%$). Further increase in temperature from T_f to T_{cl} leads to a gradual increase in the area of the base of both cylinders, while the length of the isovalerate cylinder remains constant and that of the butyrate cylinder gradually decreases.

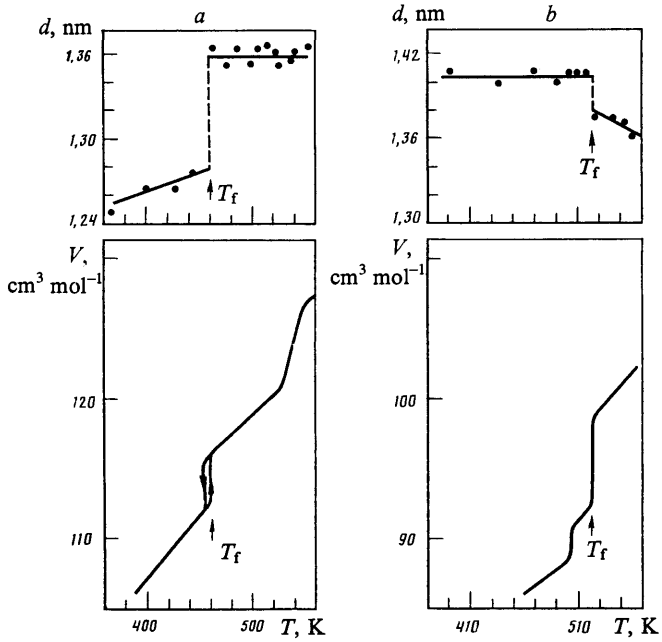

Figure 3. Temperature dependence of the lattice parameter d and molar volume V in the crystal and mesophase of sodium isovalerate (a) and butyrate (b).[46]

Thus a common feature of the thermal behaviour of salt mesophases containing organic ions is that the packing of the ions is loosened in a direction parallel to the plane of the electrostatic layers. In the direction at right angles to the plane of the smectic layers, however, the strong electrostatic attraction tends to compress the layers. The greater the possibility of a configurational change in the alkane chains of the mesogen ion, the greater the relative compression of the cation–anion layers in the mesophase. Thus for the homologous thallium n-alkanoates, the relative compression of the layers in the mesophase β ($\beta = (2L - d)/2L$, where L is the length of the carboxylate anion) is directly proportional to the length of the alkane chain of the anion n.[44] When a configurational change in the alkane chain of the anion is hindered, as in sodium isovalerate,[46] the inter-layer distance in the mesophase remains practically unchanged with increase in temperature.

The results of structural and thermodynamic studies of ILC indicate that the mechanism of the fusion of ionic mesogens involves cooperative positional disordering of the crystal lattice of the salt, accompanied by configurational ordering of the alkane chains of the

mesogen ions, and at T_{cl} the electrostatic layers probably undergo positional and other types of ordering.

A molecular model of the structure of ILC, essentially quasicrystalline, was first proposed by Ubbelohde and Duruz,[46] and was later developed in more detail from the results of polarisation and NMR studies by Jonas and co-workers.[47,48,51–53] According to this model, the structure of smectic ILC is described by a space filled by sequences of parallel cation–anion layers forming LC domains (see Fig. 2). These domains may take all possible configurations and be subjected to the orienting influence of different fields. In the opinion of Jonas and co-workers,[52] the organic chains of the anions in the LC domains either rotate "in a cone" with angle of 35° about the normal to the cation–anion layer or are ordered along the normal to the charged layer, but undergo *trans–gauche* isomerisation. Local structure formation, corresponding to the isotropically oriented layer domains, are preserved in the isotropic melts.[53] The type of ordering of the carboxylate anions in the layers may apparently be different for different salts, and, as noted by Jonas and co-workers,[53] is determined by the size and structure of the crystal lattice defects, and also by the structure of the carboxylate anions. No change in the size of the domains in carboxylate ILC with change in temperature was observed.[48]

In contrast to the above quasi-crystalline model of the structure of the mesophases of molten salts of alkanoic acids, an attempt has been made to describe them using the so-called R-theory of aqueous amphiphilic mesophases.[39] The basic postulates of this theory were analysed by Winsor.[24] The R-theory describes the structure of the mesophases on the basis of the balance between intermolecular forces which tend on the one hand to make the amphiphilic layer of molecules convex with respect to the lypophilic environment, and on the other hand to make it convex with respect to the polar medium. The postulates of this theory can obviously be applied satisfactorily only to systems with a low density of Coulombic charges, for example to the molten salts of the higher homologues of n-alkanoic acids. In ILC, where powerful Coulombic forces operate, this balance of intermolecular forces apparently does not play a decisive role in the stabilisation of the LC order.

An important characteristic of LC is the degree of long-range orientational order or the order parameter S, introduced by Tsvetkov[25] and defined by the equation:

$$S = {}^1/_2(3\overline{\cos^2\theta} - 1),$$

where θ is the angle between the direction of the director‡ of the LC and the long axis of the molecule, and $\cos^2\theta$ is the value obtained by averaging over all orientations of the molecules. In an ideal crystal, $S = 1$, and in an isotropic liquid, $S = 0$. For molecular LC, the maximum value of S in nematic crystals is 0.6–0.8, and the value for smectic crystals reaches 0.9 and changes little with change in temperature.

In the ionic smectic melts of sodium isovalerate and n-alkanoates, the order parameter is much smaller than in molecular smectics, and depends on temperature. Thus with increase in temperature from T_f to T_{cl}, the value of S changes from 0.65 to 0.1 in sodium isovalerate and from 0.38 to 0.1 in sodium butyrate.[47,48]

‡The director of the LC is the unit vector which indicates the direction of the preferred orientation of the long molecular axes, coinciding with the optical axis of the LC (for more details see Pikin's book[26]).

A characteristic feature of ILC is negative birefringence.[48,50] Pelzl and Sackmann[50] studied the birefringence of the LC phases formed by homologous thallium n-alkanoates. They established that the lower homologues (n = 5–9) show negative birefringence, which decreases with increase in the length of the alkane chain and with decrease in the temperature of the mesophase. For the middle homologues (n = 10–12), the sign of the birefringence changes from negative to positive. The higher homologues ($n > 12$) show only positive birefringence, which increases with increase in the length of the alkane chain of the anion and with decrease in the temperature of the mesophase. The difference between the optical behaviour of the lower and higher homologues of the n-alkanoates can be attributed to the characteristics of the structures of their smectic mesophases.

The magnitude and sign of the birefringence of LC are determined by the magnitude of the anisotropy of the polarisability. For salt mesophases, the anisotropy of the polarisability is determined by two structural factors: 1) the monoaxial layer arrangement of the polar groups, and 2) the group and mutually consistent configuration of the alkane chains between the cation–anion planes. The first factor determines the negative anisotropy of the polarisability, that is the polarisability in a direction perpendicular to the optical axis ($\alpha_\perp$), which is greater than the polarisability in a direction parallel to the optical axis ($\alpha_\parallel$), that is $(\alpha_\parallel - \alpha_\perp) < 0$, and the second factor determines the positive anisotropy of the polarisability, that is $(\alpha_\parallel - \alpha_\perp) > 0$.[50] In ILC, where the ratio of the charge to the number of atoms is high, the first factor predominates, so that negative birefringence is observed, whereas for the long-chain homologues of thallium alkanoates, the second factor is decisive, and positive birefringence is observed.[50]

As already noted, increase in the temperature of the mesophase of the salts of n-alkanoic acids leads to compression of the cation–anion layers and to loosening of the packing of the ions in a direction parallel to the cation–anion layers, and this leads to a decrease in $\alpha_\parallel$ and an increase in $\alpha_\perp$. Since the refractive index for the extraordinary ray n_e is directly proportional to $\alpha_\parallel$, and the refractive index for the ordinary ray n_o is directly proportional to $\alpha_\perp$, increase in temperature leads to an increase in the negative value of the birefringence $(n_e - n_o)$ for ILC, and to a decrease in its positive value for the LC phases of the higher homologues of thallium alkanoates. Thus the optical behaviour of ionic mesophases is described satisfactorily in terms of the above quasi-crystalline model of their structure.

IV. The transport properties of ionic mesophases

The transport properties of LC materials are very sensitive to their anisotropy and orientation. Unfortunately, for ILC there are practically no published data on completely oriented single-domain specimens, although these studies are necessary to establish the relationship between the dynamics and structure of the ionic mesophases.

Viscosity. ILC apparently have very high viscosities, since they are smectic forms (usually type A). Approximate data are available for only two mesophases, sodium butyrate and isovalerate.[12] Close to T_{cl}, the viscosity of both mesophases is ~10 Pa.s; on going to the isotropic melt, the viscosity decreases to ~0.04 Pa.s for sodium isovalerate and to ~0.01 Pa.s for sodium butyrate. Thus the viscosities of the isotropic melts of ionic mesogens are comparable with those of molten inorganic salts.[1,2,5]

Nuclear magnetic relaxation times and diffusion. Jonas, Bonekamp, and co-workers[47,51–54] have carried out NMR studies (^{1}H, ^{2}H, ^{23}Na) of the smectic mesophases of molten sodium carboxylates throughout the temperature range of stability of the LC phases. It was established that the mechanism of proton relaxation in the salt mesophase reduces to the self-diffusion of the anions and fluctuations in the ordering of their orientation; the first mechanism determines the frequency dispersion of the spin–lattice proton relaxation time T_1, and the second determines that of the spin–rotation relaxation time $T_{1\rho}$. The values of the self-diffusion coefficients D for the butyrate and isovalerate anions in the mesophase, estimated by the authors cited, are about 10^{-7} to 10^{-6} cm^2 s^{-1}, which coincides with the values predicted by theory for smectics of type A.[55]

The temperature dependence of the coefficients of self-diffusion of the anions in the mesophase and in an isotropic melt obey the Arrhenius law, with a break at T_{cl}. The NMR data can be used to estimate the averaged coefficient of three-dimensional diffusion.[54] It is assumed, however, that in smectic domains there is two-dimensional diffusion, which, according to the calculations,[54] is characterised by a value of D 1.5 times that measured by NMR. These differences in the absolute values of the diffusion coefficients, however, do not influence the estimation of the activation energy of diffusion, which has the values 37.7 kJ mol^{-1} and 37.2 kJ mol^{-1} for the butyrate and isovalerate anions respectively.

For sodium isovalerate, good agreement was established between the activation energies of viscosity and diffusion in the isotropic melt (50.6 kJ mol^{-1} and 48.1 kJ mol^{-1} respectively).

The absolute value of D calculated from the viscosity data using the Stokes–Einstein equation is smaller by two orders of magnitude than the values of D measured by NMR.[54] The explanation apparently is that the viscosity of the salt mesopahse is determined by slow interactions between the LC domains, whereas the rate of NMR relaxation reflects the rapid diffusion within domains of macroscopic dimensions.

The spin–lattice relaxation times T_1 (^{23}Na NMR) in the mesophases of molten sodium carboxylates increase regularly with increase in temperature, and have values of 10^{-4}–10^{-2} s. Because of the large difference in the dimensions of the carboxylate anion and the sodium cation, the correlation times (τ_c) for the fluctuations in the electric field gradient at the sodium cation, calculated by Bonekamp and co-workers,[47] reflect the fluctuations as a consequence of the diffusion of the sodium cation, and not the anion. The values of the activation energy for τ_c (16.7 kJ mol^{-1} for sodium butyrate and 32.3 kJ mol^{-1} for sodium isovalerate), obtained by Bonekamp and co-workers,[47] are much smaller than the values of the activation energy of diffusion of the anion. Thus the principal charge carrier in the ionic mesophases of molten carboxylates is the cation, and the conductivity in the mesophase of sodium butyrate should be higher than that in the mesophase of sodium isovalerate.

Electrical conductivity. A basic characteristic of the liquid-crystalline phases of salt melts is their intrinsic ionic conductivity.[8,56–59] In the isotropic melts of the carboxylates of monovalent and divalent metals, the activation energy of the electrical conductivity is not sensitive to change in the length of the alkane chain of the anion n.[57,58,60] At the same time, the absolute value of the electrical conductivity of the melt (measured at a temperature 5 K above T_{cl}) decreases regularly with increase in n.[57] These data indicate that the predominant charge carriers in carboxylate melts are the metal cations. This is also indicated by the size of the ionic components and by the NMR relaxation data for the salt mesophases. In the isotropic melt–mesophase and mesophase–crystal transformations, there is an abrupt change in the electrical conductivity, and the magnitude of these sharp stepwise changes depends on the length of the alkane chain of the anion and is greatest for the lower homologues of the alkanoates.[56,57]

The values of the specific conductance of the ILC studied are 10^{-1}–10 S m^{-1}, but most published electrical conductivity data relate to multi-domain non-oriented LC specimens. The results obtained by Duruz and Ubbelohde,[61] and also by Meisel and co-workers,[56,57] indicate marked anisotropy of the electrical conductivity of ILC. Thus the electrical conductivity of the mesophase of sodium isovalerate, obtained by cooling the isotropic melt with the application of a magnetic field ($\sim$10 kG) perpendicular to the electrical field, was found to be twice that of the mesophase obtained by cooling the isotropic melt in the absence of a magnetic field.[61] It has been shown[57] that the electrical conductivity of thallium carboxylates is influenced by differences in the degree of orientation of the LC phase, obtained by applying mechanical shearing stresses to the mesophase or by producing it in the field of a varying temperature gradient.

The most convincing proof of the anisotropy of ion transport, however, was obtained by Meisel and co-workers,[57] who determined the electrical conductivity of a homeotropically oriented (smectic layers parallel to the supports) LC specimen of thallium laurate in two mutually perpendicular directions. According to their data, the electrical conductivity of the mesophase in a direction parallel to the smectic cation–anion layers was much greater than that in the perpendicular direction (by a factor of $\sim$3). The electrical conductivity along the cation–anion layers in the oriented single-domain salt mesophase was found to be even higher than in the isotropic melt at a higher temperature, and at the point corresponding to the change from the mesophase to the isotropic melt, a marked abrupt decrease in the electrical conductivity was observed. In the direction perpendicular to the smectic layers, however, the electrical conductivity in the mesophase was much lower than that in the isotropic melt, and on going from the mesophase to the isotropic melt the usual abrupt increase in conductivity was observed. These data, and the values of the activation energies of the electrical conductivity in the salt mesophase (in the case of isovalerate, 7.6 kJ mol^{-1} for the non-oriented mesophase and <4 kJ mol^{-1} for the oriented mesophase), lead to the following conclusions.[61]

1. Charge transfer in the salt mesophases apparently involves the movement of ions along channels in the electrostatic layers.
2. The barriers preventing this movement are due to changes in the local electrostatic potential, so that they are extremely low (<4 kJ mol^{-1}) and comparable with the barriers controlling the migration of the ions in aqueous electrolytes.
3. The less oriented the LC specimen, the higher the activation energy of the electrical conductivity, as a consequence of the additional barriers preventing the transfer of ions from one LC domain to another.

The fact that the electrical conductivity in the oriented single-domain mesophase in a direction parallel to the smectic layers is higher than that in the less viscous isotropically-liquid phase at a higher temperature is apparently due to the marked difference in the heights of the energy barriers controlling ion migration in these two phases (the activation energy of the electrical conductivity in the isotropic carboxylate melt is $\sim$28 kJ mol^{-1}).

The further study of the anisotropy of the electrical conductivity of oriented thin-layer single-domain ILC specimens will yield new data on the dynamics and structure of this unusual class of LC materials, which will be useful for their practical application.

V. Binary systems of ionic mesogens

As already noted, a characteristic of the ionic mesophase is that its stabilisation depends to a considerable extent on electrostatic factors. For salts of carboxylic acids, it follows from Fig. 1*a* and the empirical relationship (1) that a decisive role in the stabilisation of the mesophase is played by the size of the ions and the polarising power of the cation. The relationship between the nature of the interionic interactions in the salt melt and the stability of the mesophase is most clearly revealed in binary salt systems, in which the formation of mixed melts is accompanied by a change in the nature of the interionic interactions.[45]

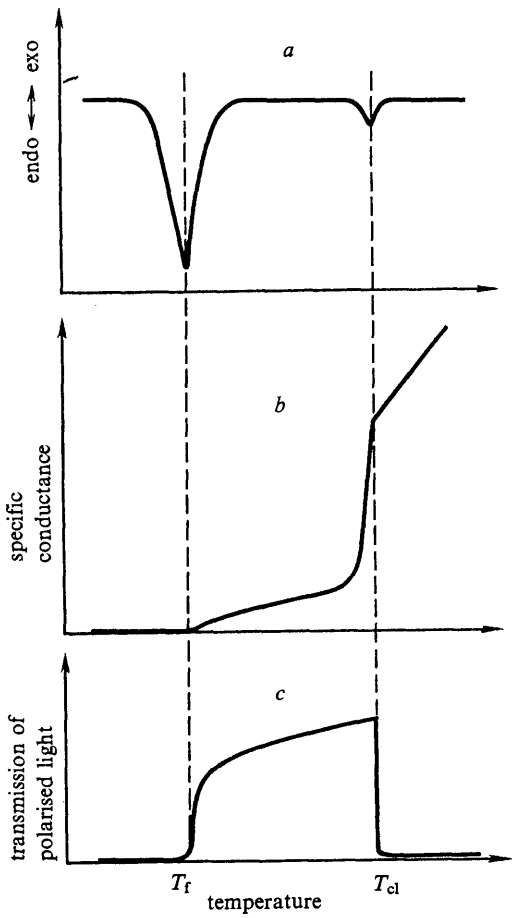

Figure 4. General form of the temperature dependence of the physicochemical properties of ionic mesogenic systems observed on heating; thermodynamic transitions from the crystal to the mesophase at T_f and from the mesophase to the isotropic melt at T_{cl}: *a*, differential thermal analysis curve; *b*, temperature dependence of the specific conductance; *c*, temperature dependence of the intensity of polarised light passed through a specimen of a salt LC system.[45]

In general, the formation of multicomponent systems provides interesting possibilities for extending the range of existence of the LC phase and even for the production of a mesophase in mixtures of components which are potentially mesogenic but individually non-mesomorphic, as a result of a marked decrease in T_{cl} for the system.[23] This last feature was first pointed out and confirmed experimentally in the early nineteen-huundreds by Bogoyavlenskii and Vinogradov.[62,63] Fifty years later, it was confirmed repeatedly by many workers.[23] The study of the stability of the mesophase with change in the ionic composition of the LC melt is of particular interest.

Mirnaya[45] studied the temperature range of existence of a binary salt mesophase by three independent methods: by studying the differential thermal analysis (DTA) curve, the temperature dependence of the specific conductance, and the transmission of polarised light by the LC specimen. Fig. 4 shows that all three methods made it possible to determine reliably the melting point of the crystal and the clearing temperature of the mesophase; DTA gives T_{cl} most accurately, and the other two methods are highly sensitive to the change from the isotropic liquid to the mesophase.

Unfortunately, very few binary salt mesogenic systems have been studied, and most of these contain the butyrate anion as the mesogen ion. All the salt LC systems studied can be provisionally divided into two groups.

The first group consists of systems in which continuous LC solutions are formed. They are characterised by a smooth change in T_{cl} with change in concentration, with positive or *S*-shaped deviations from additivity. These systems include binary mixtures of salts with a common mesogen anion and symmetrically charged cations, for example Na, K$|C_3H_7CO_2$; Na, Cs$|C_3H_7CO_2$; Cs, $NH_4|C_3H_7CO_2$; and Na, Tl$|C_3H_7CO_2$ (Fig. 5).

The second group consists of systems in which the formation of the mixed melt leads to marked destabilisation and disappearance of the mesophase. These systems include binary systems with a common mesogen anion and asymmetrically charged cations, for example K, Zn$|C_3H_7CO_2$; Na, Mg$|C_3H_7CO_2$, and also systems with a common cation, for example Na$|C_3H_7CO_2$, NO_3; Na$|C_3H_7SO_2$, SCN (Fig. 6).

In the ionic mesogenic systems studied, T_{cl} in most cases deviates considerably from additivity, whereas in molecular LC systems of two components without specific interaction, T_{cl} obeys the additivity law, that is it is a linear function of the composition:[14,24]

$$T_{cl} = T_1 + x_2(T_2 - T_1),$$

where T_1 and T_2 are the clearing temperatures of the mesophases of the individual components, and x_2 the mole fraction of the second component. In only a few cases are slight deviations from additivity ΔT_{cl} (mainly negative) observed, when the molar volumes of the components differ considerably. This behaviour of molecular LC mixtures is described satisfactorily by the statistical theory of Luckhurst and Humphries.[64]

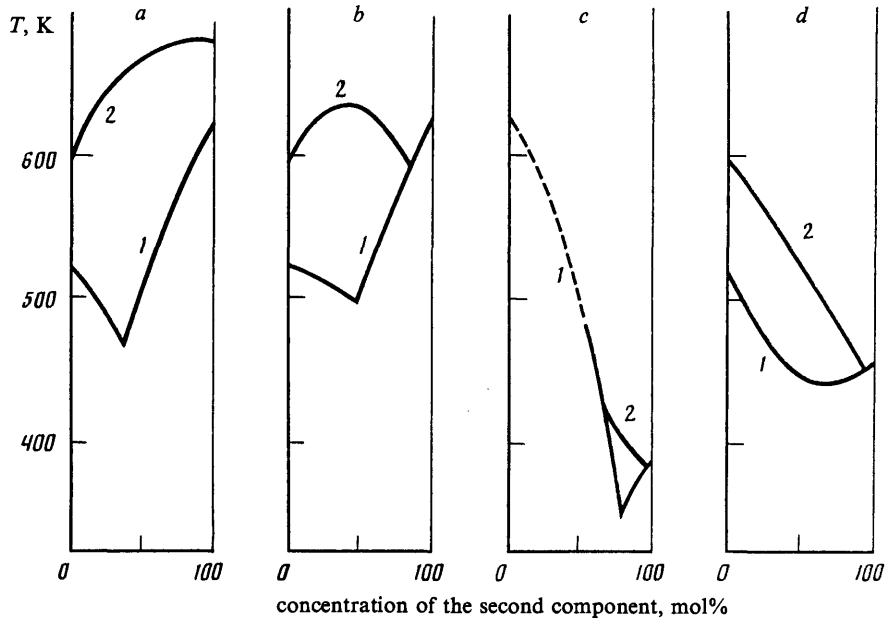

Figure 5. Melting point (*1*) and clearing temperature (*2*) of the mesophase in binary salt systems: *a*, $C_3H_7CO_2Na-C_3H_7CO_2K$; *b*, $C_3H_7CO_2Na$–$C_3H_7CO_2Cs$; *c*, $C_3H_7CO_2Cs$–$C_3H_7CO_2NH_4$; *d*, $C_3H_7CO_2Na$–$C_3H_7CO_2Tl$.[45]

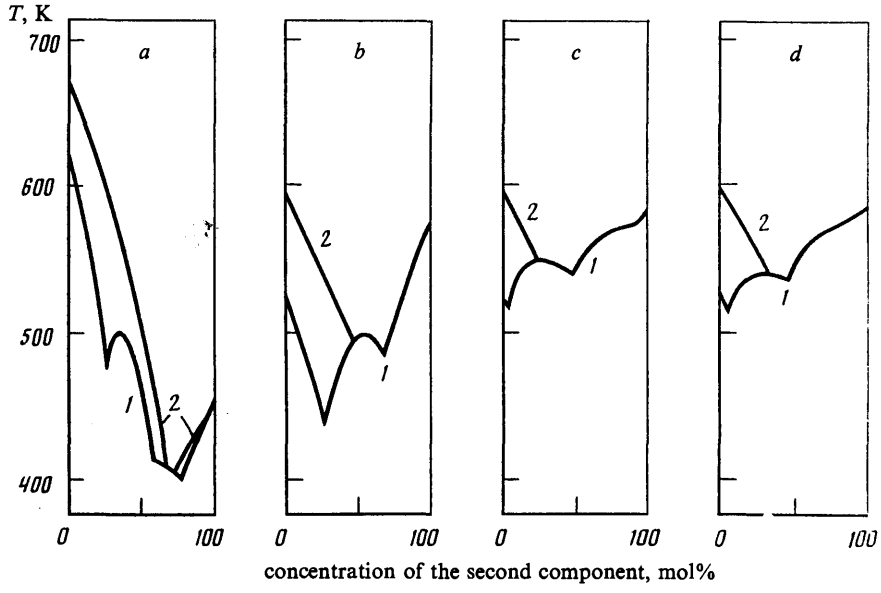

Figure 6. Melting point (*1*) and clearing temperature (*2*) of the mesophase in binary salt systems: *a*, $C_3H_7CO_2K$–$(C_3H_7CO_2)_2Zn$; *b*, $C_3H_7CO_2Na$–$(C_3H_7CO_2)_2Mg$; *c*, $C_3H_7CO_2Na$–$NaNO_3$; *d*, $C_3H_7CO_2Na$–NaSCN.[45]

The formation of continuous LC solutions in salt systems of the first group made it possible to estimate the thermal stability of a mixed ionic mesophase using the approximate model of ionic solid solutions.[65] This approach led to the following expression:

$$\Delta T_{cl} = 2x_1x_2E/R,$$

where R is the universal gas constant, and E the energy of stabilisation of the mesophase, which is the orientational component of the enthalpy of mixing of the system corresponding to one mole of the vapour of the interacting non-equivalent cations.

In systems in which one or both of the components containing the mesogen ion are individually non-mesomorphic, ΔT_{cl} was estimated using the values of the latent T_{cl}, determined by extrapolation.[45,66]

The value of E is extremely sensitive to the nature of the interionic interactions in the mesomorphic systems. Thus in the systems formed by alkali metal carboxylates with a common mesogen anion, for example Na, K|$C_3H_7CO_2$ or Na, Cs|C_3H7CO_2, where the predominant type of inter-particle interaction is the Coulombic interaction of the non-equivalent cations, $E > 0$. This leads to a unique characteristic of systems of this type, namely the marked positive deviation of T_{cl} from additivity, reaching several tens of degrees. The energy of stabilisation in these systems is practically independent of the concentration of the components, and shows a linear correlation with the parameter of the interionic interactions Δ^2 [$\Delta = (r_1 - r_2)/(r_1 + r_2)$, where r_1 and r_2 are the cation–anion distances in the individual components].[65] The authors cited[65] established the interesting fact that the stabilisation of the ionic mesophase in the binary system, is higher, the greater the difference in the sizes of the metal cations of the two salts.

For salt melts, the parameter of the interionic interactions determines the intensity of the enthalpy changes on formation of the mixed melt,[67] so that the stabilisation of the carboxylate mesophase takes place as a result of the enthalpy factor, that is the increase in the energy of the orientational interaction of the non-equivalent ions relative to the energy of their thermal motion.

Another type of binary mesogenic system in the first group corresponds to the systems formed by monovalent metal and ammonium carboxylates with a common mesogen anion, for example Ca, $NH_4|C_3H_7CO_2$ (see Fig. 5). A distinguishing feature of interionic interactions in these systems is the formation of hydrogen bonds (H-bonds) between the ammonium cations and the carboxylate anions. A linear change in E with change in concentration was established for systems of this type.[68] The relative increase in the concentration of the monovalent metal cation in the mixed melt leads to an increase in E, and a directly proportional relationship is observed between the value of E and the increase in the ^{1}H NMR chemical shift (δ) of the ammonium ion as a result of the formation of H-bonds in the system.[45]

Thus the energy of stabilisation of the mixed salt mesophase is higher, the greater the number of ions forming H-bonds in the melt, and the greater strength of these bonds.[45,68] Naturally, the formation of H-bonds in the salt melt will facilitate the production of LC order only if appreciable anisotropy of the electrostatic interactions is preserved or created in the system.

In the systems formed by ammonium and monovalent metal butyrates, the values of the energies of formation of the H-bonds and the stabilisation of the mesophase are determined by the nature of the metal cation. The strength of the H-bond between a carboxylate anion and the ammonium cation in a salt melt is a complex function of two parameters of the metal cation, namely its size and its polarising power.[69] Increase in the polarising power of the metal cation is accompanied by a decrease in the strength of the H-bond as a result of the decrease in the electron-donor power of the carboxyl group of the anion, and increase in the size of the metal cation is accompanied by an increase in the steric barriers preventing the formation of the H-bond. According to Mirnaya and co-workers,[68] in the salt mesophases studied the last factor predominates, and with increase in the size of the metal cations in the LC melt, the energy of stabilisation of the mesophase generally decreases.

The first group of salt mesogenic systems also includes the binary systems formed by thallium and alkali metal carboxylates with a common mesogen ion, for example Na, Tl|$C_3H_7CO_2$ (see Fig. 5). In these systems, one component, namely the thallium(I) carboxylate, provides a non-Coulombic component of the cation–anion bond, so that their behaviour is determined by both the Coulombic and the exchange repulsion interaction. In the presence of the strongly polarising lithium and sodium cations, the covalent character of the bond formed by the thallium cation with the counter-ion decreases, whereas in the presence of other alkali metal cations it increases, the increase being greater, the larger these cations.[70] The increase in the covalent character of the bond formed by the thallium cation with the butyrate anion in the salt mesomorphic melt is equivalent to an increase in the probability of formation in the melt of long-lived paired cation–anion associates, that is uncharged quasi-globular particles, which decrease the electrostatic stabilisation of the LC phase; E may then have negative values and actually determine the energy of destabilisation of the mesophase. It is this factor which apparently is responsible for the destabilisation of the ionic mesophase observed in the systems formed by thallium and alkali metal carboxylates,[45] since the stability of the mesophase decreases with increase in the size of the alkali metal cation (Fig. 7). With increase in the concentration of the alkali metal salts in systems of this type, stabilisation of the ionic mesophase takes place in addition to its destabilisation. The stabilisation is due to an increase in the anisotropy of the electrostatic interactions with increase in the total number of Coulombic charges, and also to the decrease in the total energy of the system. At definite component ratios in the systems formed by thallium and alkali metal carboxylates, the stabilisation of the salt mesophase predominates, so that the overall concentration dependence of E is S-shaped (Fig. 7).

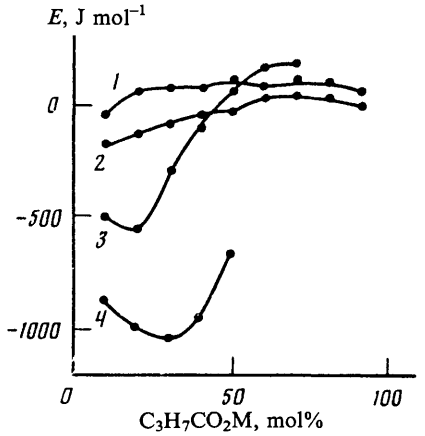

Figure 7. Concentration dependence of the energy of stabilisation of the ionic mesophase in the binary systems $C_3H_7CO_2Tl$–$C_3H_7CO_2M$, where M = Na (*1*), K (*2*), Rb (*3*), Cs (*4*).[45]

Unlike the mesogenic systems of the first group, where the formation of the mixed mesophase in most cases stabilises the LC phase, the mesogenic systems of the second group are characterised by breakdown of the LC order when the components are mixed. This behaviour is similar to that of molecular LC systems with one non-mesomorphic component. For the latter, the decrease in the thermal stability of the mesophase when the

non-mesomorphic component is added is greater, the greater the volume and mass and the smaller the anisometry of the non-mesogen molecules.[23,43]

In salt mesogenic systems with a common cation, for example $Na|C_3H_7CO_2$, NO_3 or $Na|C_3H_7CO_2$, SCN (see Fig. 6), the introduction of the anions of the second component into the cation–anion layers of the LC domains depresses T_{cl}. The rate of the decrease in the thermal stability of the salt mesophase is greater, the higher the symmetry and the larger the size of the added anion. Thus the anions studied[45] can be arranged in the following order of increasing ability to break down the LC order in molten sodium butyrate:

$$iso\text{-}C_4H_9CO_2^- < C_2H_5CO_2^- < SCN^- < NO_3^- < CH_3CO_2^-.$$

The mechanism of the observed breakdown in the LC order in the binary systems formed by carboxylates with a common mesogen anion and asymmetrically charged cations, such as K, $Zn|C_3H_7CO_2$ or Na, $Mg|C_3H_7CO_2$ (Fig. 6), is apparently the same as in systems with a common cation. This is due to appreciable local ion association and complex formation in these salt melts.[45] Thus as a result of the formation of the fairly stable anionic complexes $[Zn(C_3H_7CO_2)_4]^{2-}$, the K, $Zn|C_3H_7CO_2$ system can be regarded as a system with a common cation, in which one anion is the mesogenic butyrate anion, and the other the non-mesogenic anionic complex, that is $K|C_3H_7CO_2$, $[Zn(C_3H_7CO_2)_4]$.

The non-mesogenic character of the ionic complexes formed in salt melts is related to their quasi-globular form and the isotropic distribution of the Coulombic charge. These factors are responsible for the fundamental difference between ionic mesogenic systems and molecular systems in relation to the influence of complex formation on the thermal stability of the LC phase. In molecular LC systems with donor–acceptor interaction between the components, the thermal stability of the mesophase increases, apparently as a result of the increase in the anisotropy of the intermolecular interactions when molecular complexes with a higher anisotropy of the molecular form,[71,72] compared with the individual components, are formed. In individual cases, the donor–acceptor interaction between the components may be insufficient for the formation of a molecular compound, but when the nematic or isotropic solution is cooled, this interaction may lead to partial ordering of the molecules and to the formation of smectic or nematic phases, not observed for the components.[73,74] Thus complex formation in binary molecular systems makes it possible not only to obtain new LC phases but also to increase their stability.

Molten salt systems in which the ionic complex formed is mesogenic can also probably exist, and this should lead to an increase in the stabilisation of the ionic mesophase or to the appearance of LC order in a salt melt consisting of two individually non-mesomorphic components. Salt systems of this kind are not yet known, although searches are being carried out in this direction.[45,75]

Glass formation is an interesting characteristic of LC melts of salts of carboxylic acids with asymmetrically charged ions.[45] Among the great variety of problems in the physics and chemistry of liquid crystals, a unique position is now occupied by the problems of obtaining and detecting metastable LC phases, or, in Shubnikov's words, the problems of "obtaining homogeneous mesomorphic systems of sufficiently large volume in the supercooled vitreous solid state".[76] The aim in the production of these LC glasses is to extend the range of the practical application of LC to lower temperatures, and also to study the fundamental properties of the LC state.[26,77] The research interest is due to the fact that in LC glasses, all the characteristics of the macro-structure corresponding to the mesomorphic form will be revealed more clearly as a consequence of the marked decrease in the mobility of the LC molecules. The preparation and study of known molecular LC glasses is complicated, however, by the fact that their softening temperatures are usually much lower than room temperature.[26] In contrast to molecular systems, in ionic LC systems LC glasses with high softening temperatures (> 300 K) are formed.[45]

—o0o—

In conclusion it should be noted that binary ionic systems provide additional possibilities for controlling the stability of the ionic mesophase and for the production of new LC phases as a consequence of the high sensitivity of the salt mesophase to the nature of its component ions. High- and medium-temperature smectic ILC (range of existence 313–673 K) have now been studied, but it is also possible to produce low-temperature ILC using an appropriate combination of cations and anions in the salt melt.

It is not difficult to predict the future practical applications of this new class of LC. In contrast to classic smectics, ionic smectic LC should show optical sensitivity with respect to even weak electric fields. This is due to the high values of the components of the dielectric constant tensor of the ionic melt, the appreciable anisotropy of the electrical conductivity, and the small size of the cations and anions making up the ILC. In addition to the long-term memory and the possibility of local erasure of information,[18] characteristic of ordinary smectics, a basis for new non-traditional applications of ILC should be provided by the characteristic ionic channel electrical conductivity and its sensitivity to the degree of orientation of the LC specimen, and also by the possibility of controlling the optical properties of ILC by ion exchange and electrochemical transformations. The use of ILC as an anisotropic medium for the synthesis of organic and inorganic compounds, and also as an isotropic vitreous matrix for various spectroscopic purposes, is also of interest.

Thermodynamics of extraction by solutions of amines and salts of substituted ammonium bases

A V Ochkin, V V Sergievskii
Mendeleev Moscow Institute of Chemical Technology
Moscow Institute of Engineering Physics

ABSTRACT. Extraction systems containing amines and their salts are widely used to concentrate and separate metals. From the theoretical viewpoint, these systems are among the most complex, because of the variety of intermolecular interactions in the organic phase. The explanation and quantitative description of the observed regularities of extraction became possible only as a result of progress in the study of the thermodynamics of binary and multicomponent solutions of salts of substituted ammonium bases in non-polar organic solvents, which make it possible to distinguish the contribution of each type of interaction to the non-ideal character of the solutions. All known "anomalous" features are due to the influence of the hydration of the salts of the substituted ammonium bases on their activity.

I. Introduction

The extraction of acids and metal salts by solutions of substituted ammonium bases is widely used in the processing of irradiated nuclear fuel, in hydrometallurgy, and in the analytical chemistry of various elements. The extensive published experimental material on extraction equilibria in various systems has been summarised in monographs,[1–7] reviews,[8–21] and reference works.[22,23] At the same time, systems containing the salts of substituted ammonium bases are very complex, and until recently for a number of systems there was even lack of agreement about the composition of the compounds extracted; contradictory data have been published on the state of the retracting agents in organic solvents, obtained from inter-phase distribution data and from independent physicochemical measurements.

An examination of the results of a large number of studies of the extraction properties of amines and their salts, and also the properties of solutions of salts of substituted ammonium bases in organic solvents, shows that the principal reason for these discrepancies is the lack of data on the influence of various factors on the activity of the salts.

The present review examines the thermodynamics of solutions of salts of substituted ammonium bases in organic solvents, the influence of various factors (molecular association, hydration, and solvation) on the activity coefficients of the salts, and the use of the observed regularities for the explanation and quantitative description of the extraction equilibrium. The review does not deal with molecular-statistical models of the solutions, except for models of an ideal associated solution (IAS), which can be regarded as one of the methods for describing deviations from ideal behaviour, so long as no physical significance is assigned to the calculated values of the association constants.

The thermodynamic methods for describing the deviations from ideal behaviour in solutions of substituted ammonium bases are general, and make it possible to predict the equilibrium in extraction systems containing reagents of different classes. The material in the present review is useful for explaining the properties of ion-selective electrodes with liquid and solidified membranes based on the salts of completely substituted onium bases, and also for describing the kinetics of the reactions taking place in the synthesis of organic compounds in two-phase systems containing inter-phase transfer catalysts.

II. Regularities of the extraction of acids and metal salts

The extraction of acids and metal salts by solutions of amines in organic solvents usually involves chemical reactions between molecules of the extracting agent and the substance being extracted. A knowledge of the stoichiometry of the reaction involved in the formation of the compound being extracted is a necessary condition for an understanding of the regularities of the extraction and the description of the extraction equilibrium.

The extraction of monobasic inorganic acids from their sufficiently dilute aqueous solutions by solutions of amines in non-polar solvents, when the electrolytic dissociation of the salt formed in the process can be neglected, is usually described by the reaction

$$R_3N(org) + H^+ + X^- \rightleftarrows R_3NHX(org), \quad (1)$$

where R represents an organic group or a hydrogen atom, and X^- an anion. In the extraction of polybasic acids H_mX, normal $(R_3NH)_mX$ and acid R_3NH_mX salts are formed, the concentration of which depends on the equilibrium acidity, the nature of the organic solvent, and the strength of the acid and the base. For example, in the extraction of phosphoric acid by solutions of primary amines, normal phosphates are formed, whereas in extraction by tertiary amines, normal phosphates are not formed.[4] In the extraction of sulphuric acid by solutions of N,N-dioctylaniline, only the hydrogen sulphate $R_3NH_2SO_4$ is formed,[24] whereas in the extraction of sulphuric acid by the more basic tri-n-octylamine (TOA), various physicochemical methods have detected not only TOA sulphate and hydrogen sulphate

but also a compound with the intermediate composition $(R_3N)_3.(H_2SO_4)_2$.[25] Compounds with complex compositions are also formed in various other cases. Micro-quantities of peroxomolybdates are extracted by a trialkylmethylammonium sulphate as R_4NHMoO_6. The composition of the complex extracted at high molybdenum concentrations corresponds to the formula $(R_4NHMoO_6)_2H_2MoO_6$.[26]

The kinetics of the extraction of hydrochloric, perchloric, and sulphuric acids by solutions of TOA, tri-n-decylamine, and tri-n-laurylamine have been studied using a diffusion cell with stirring and with brief contact between the phases.[27] Since the rate of extraction is independent of the pH of the aqueous solutions and the concentration of the anion of the acid, it was concluded that the reversible protonation of the amine takes place at the inter-phase boundary.

The extent of the extraction of acids according to reaction (1) increases in the order $HCl < HBr < HI < HClO_4$, that is with decrease in the proton affinity and the hydration energy of their anions in aqueous solution. When different amines are used, the extraction of the acids decreases with increase in the degree of substitution: primary > secondary > tertiary amine.[28] Since the electronegativity of the hydrogen atom is lower than that of alkyl groups, the observed order of extractability is the opposite of that expected.[29] This contradication is apparently due to association of the amine salts as a result of the formation of hydrogen bonds between the non-substituted hydrogen atoms of the bases and the anions of the other salts. The existence of these interactions in solution has not yet been confirmed experimentally, but X-ray diffraction studies of crystals of the salts showed that they contain intermolecular hydrogen bonds.[29] Moreover, it has been established spectrophotometrically that hydrogen bonds are formed between the N–H groups of primary amines and the anions of the salts of quaternary ammonium bases R_4NX.[30]

The extraction of acids is influenced considerably by the nature of the organic diluent used and by the presence in the systems of a modifier (usually an alcohol or tri-n-butyl phosphate) added to prevent the formation of a second organic phase in the extraction. The distribution coefficients of acids usually increase with increase in the polarity of the organic solvents. Alcohols and other protogenic solvents generally facilitate the extraction of acids when normal salts are formed, and lower the distribution coefficients slightly when acid salts are formed.

The description of the extraction equilibrium is complicated considerably by the extraction of super-stoichiometric quantities of acid by the amine salts according to the equation

$$R_3NHX(org) + lH^+ + lX^- \rightleftarrows R_3NHX.lHX(org). \quad (2)$$

In the extraction of weak acids, for example hydrofluoric acid, the ratio of the concentrations of the acid and the amine in the organic phase increases continuously with increase in the concentration of the acid in the aqueous phase. A similar phenomenon is observed in the extraction of strong acids from their concentrated solutions. In this case, however, the extraction isotherm usually shows a clearly defined inflection corresponding to the point of complete neutralisation of the mine according to reaction (1). The extraction of super-stoichiometric quantities of the acid increases with decrease in the radius of the anion of the acid in the order perchlorate < iodide < bromide < chloride, and also on going from the salts of secondary amines to the salts of quaternary ammonium bases. Similar regularities are characteristic of the extraction of water by solutions of ammonium salts.

In the extraction of mineral acids by salts of onium bases, containing the anions of organic acids (HA), according to the reaction

$$R_4NA(org) + H^+ + X \rightleftarrows R_4NX(org) + HA(org) \quad (3)$$

the organic acid and the salt R_4NX are formed.[31,32] There is a close analogy between the regularities of the distribution of mineral acids in systems containing R_4NA and the regularities of extraction by neutral reagents with dissociation of the compound extracted in the organic phase.[33] By changing the nature of the components and the composition of the organic phase, it is possible to control the values of the distribution coefficients of inorganic acids and metal salts over a wide range at the stages of extraction and re-extraction. In particular, mixtures of TOA chloride with various acids (*p*-t-butylphenol, octanoic acid, di-2-ethylhexyl hydrogen phosphate, 5-t-butyl-2-hexadecylbenzenesulphuric acid) effectively extract H_2PtCl_6 and H_2PdCl_4. Conditions under which platinum and palladium in these systems can be re-extracted with water have been found.[34]

When aqueous solutions containing the anions of a mineral acid HY are treated with solutions of ammonium salts, anion exchange takes place:

$$R_4NX(org) + Y^- \rightleftarrows R_4NY(org) + X^-. \quad (4)$$

The degree of extraction of the ions of monobasic acids decreases in the order $ClO_4^- > I^- > NO_3^- > C_6H_5COO^- > Br^- > Cl^- > HSO_4^- > HCO_3^- > CH_3COO^- > F^- > OH^-$.[10] A similar lyophilic series is observed for liquid and solidified ion-selective electrodes based on quaternary ammonium salts.

Reaction (1) usually precedes the extraction of metal salts by ammonium salts, which may involve addition

$$qR_3NHX(org) + M^{z+} + zX^- \rightleftarrows (R_3NH)_qMX_{z+q}(org), \quad (5)$$

or anion exchange

$$qR_3NHX(org) + MX_{z+q}^{q-} \rightleftarrows (R_3NH)_qMX_{z+q}(org) + qX^-. \quad (6)$$

The final equilibrium products of reactions (5) and (6) are identical, that is these reactions are thermodynamically indistinguishable. Studies of the kinetics of extraction showed that it takes place according to reaction (6) when acido-complexes of the metals predominate in the aqueous phase, and according to reaction (5) in their absence.[13,17] From an analysis of data on the extraction of uranyl chloride by solutions of trioctylmethylammonium chloride it was suggested that metals may be extracted by a cation-exchange mechanism by molecules of the extracting agent combined with super-equivalent acid.[35]

Equilibria (5) and (6) are influenced considerably by the nature of the organic diluent. The influence of the diluent on the distribution coefficient of the metal salt depends markedly on the nature of the cation and anion of the onium salt.

Metal salts may also be extracted by other mechanisms. Thus in the extraction of the platinum metals, the amines are coordinated to the metal atoms.[2] The formation of bonds between the nitrogen atoms of the amines and the metal being extracted is most characteristic of primary amines. In particular, it has been established by different methods that in the extraction of divalent zinc from thiocyanate solutions by primary amines, the amine complexes $(RNH_2)_2Zn(SCN)_2$ are formed.[36] Long-chain primary aliphatic amines, unlike tertiary and secondary amines, effectively extract hydrolysed forms of aluminium sulphate.[37] In the systems formed by R_3NHX and R_4NX with platinum metals, the extraction equilibrium is often displaced towards the formation of polynuclear complexes, whose concentration increases with decrease in the concentration of the extracting agent.[38] The extraction of alkali metal carbonates by solutions of quaternary ammonium carbonates is accompanied by appreciable inter-phase distribution of water, and this has been attributed to the extraction of the salts by a hydrate–solvate mechanism.[39]

A characteristic feature of extraction systems containing salts of substituted ammonium bases is the marked positive deviations of the organic phase from ideal behaviour, due to molecular association and solvation of the salts. Until recently there was no method for taking account of the influence of various interactions on the activity of the components of the organic phase, so that extraction isotherms had been described only for various simple systems, and many observed phenomena could not be explained even qualitatively.

The extraction constant for the extraction of acids according to Eqn. (1) is given by the expression

$$K = \frac{\overline{C}_s \overline{y}_s}{\overline{C}_a \overline{y}_a a_{HX}} = \frac{\overline{y}_s}{\overline{y}_a}, \qquad (7)$$

where C represents the molar concentrations of the components, K and $\tilde{K}$ the thermodynamic and effective extraction constants respectively, y the activity coefficient, a_{HX} the activity of the acid in the aqueous solution, the subscripts s and a denote the amine salt and the amine respectively, and the bar above the symbols denotes the concentrations and activities of the components of the organic phase. Data on the activity of water (a_w) and the activity coefficients of electrolytes in aqueous solution are given, for example, by Mikulin.[40] The characteristics of the calculation of the activity of the components in mixed electrolyte solutions have been examined by a number of authors.[40–43]

The extraction constant for the extraction of metals according to reaction (5) can also be written as

$$K = \frac{\overline{C}_c y_c}{\overline{C}_s^q \overline{y}_s^q a_{MX_z}} = \tilde{K} \frac{\overline{y}_c}{\overline{y}_s^q} = \overline{K} \frac{\overline{y}}{\overline{y}_s^q \gamma_\pm^{z+1}}, \qquad (8)$$

where $\overline{K}$ is the apparent constant calculated without allowance for the mean ionic activity coefficients in the aqueous phase $\gamma_\pm$, a_{MX_z} the activity of the metal salt in the aqueous phase, and the subscript c denotes the metal complex extracted.

The stoichiometric coefficient q is often determined by studying the extraction of micro-quantities of the metal at a constant composition of the aqueous phase and varying concentration of the extracting agent $\overline{C}_s$. Eqn. (8) then becomes

$$\lg D = \text{const} + q \lg \overline{C}_s + \lg(\overline{y}_s^q / \overline{y}_c), \qquad (9)$$

where D is the distribution coefficient of the metal, and const $= \lg(K[X^-]^z \gamma_\pm^{z+1})$. The plot of $\lg D$ against $\lg \overline{C}_s$ will obviously be linear, with slope q, only if the ratio of the activity coefficients $\overline{y}_s^q / \overline{y}_c$ remains constant in the range of concentrations $\overline{C}_s$ studied.

To understand the influence of macro-components on the extraction of micro-quantities of substances by solutions of quatarnary ammonium salts, it is of fundamental importance to take account of the electrolytic dissociation of the salts and the complexes formed in the organic phase.[44] The dissociation constants of simple and complex high-molecular-weight ammonium salts in benzene and nitrobenzene have been determined and tabulated.

Experimental data on the extraction of mineral acids by amine solutions show that the effective extraction constants depend markedly on the concentration $\overline{C}_s$.[20] It is usually assumed that the values of $\overline{y}_a$ are close to 1, and the increase in $\tilde{K}$ with increase in the concentration of the amine salt is attributed to the decrease in $\overline{y}_s$ as a result of association of the salts:

$$n R_3NHX(org) \rightleftarrows (R_3NHX)_n(org). \qquad (10)$$

The association constant is

$$\beta_n = \overline{C}_s(n) / [\overline{C}_s(1)]^n, \qquad (11)$$

where $\overline{C}_s(1)$ and $\overline{C}_s(n)$ are respectively the concentrations of the monomer and the n-mer of the amine salt. The association constants have been determined either from independent data (cryoscopic, ebullioscopic, etc.) or from distribution data (two-phase potentiometric titration). In the last case, the following equilibrium was studied[16]

$$n R_3N(org) + n H^+ + n X^- \rightleftarrows (R_3NHX)_n(org), \qquad (12)$$

with equilibrium constant

$$K_n = \overline{C}_s(n) / \overline{C}_a^n a_{HX}^n = K^n \beta_n. \qquad (13)$$

The concentration of the amine salt is

$$\overline{C}_s = \sum_n \beta_n [\overline{C}_s(1)]^n = \sum_n K^n \beta_n \overline{C}_a^n a_{HX}^n. \qquad (14)$$

The extraction of sulphuric acid has been studied in most detail. The earliest study of the extraction of sulphuric acid by benzene solutions of TOA[45] established that the effective extraction constant remains constant only as far as a TOA sulphate concentration of 0.02 M, after which it increases. The deviations from ideal behaviour were attributed to the "polymerisation" of TOA sulphate in benzene.

The use of the equilibrium-displacement method to determine the composition of the compound formed in the extraction of uranyl sulphate by amine sulphates[13,14] established that the distribution coefficient of uranium is proportional to the concentration of "free" amine sulphate to the approximate power 0.5. At the same time, according to saturation data, one molecule of uranyl sulphate reacts with two molecules of TOA sulphate.[18,46] This discrepancy was also attributed to the formation of associates, present in a stable colloidally dispersed state. Independent physicochemical studies showed, however, that in anhydrous benzene solutions, TOA sulphate is monomeric[25,47] and undergoes association to only a slight extent when water is added to the organic phase.[48,49] This weak association can explain only a small fraction of the deviation from ideal behaviour in the organic phase of the extraction systems studied.

The effective extraction constants for the extraction of monobasic inorganic acids by amine solutions also depend markedly on the concentration of the ammonium salts formed. The experimental data are often represented on coordinates $\lg \overline{C}_s$–$\lg(\overline{C}_a a_{HX})$. If it is then assumed that the deviations from ideal behaviour are due only to the association of the amine salt in the organic phase and that Eqns. (10) to (14) are applicable, then for the slope of the tangent to the curve on these coordinates it is possible to write

$$\frac{\partial \lg \overline{C}_s}{\partial \lg(\overline{C}_a a_{HX})} = \frac{\sum_n n K^n \beta_n \overline{C}_a^n a_{HX}^n}{\sum_n K^n \beta_n \overline{C}_a^n a_{HX}^n} = \overline{n}, \qquad (15)$$

where $\overline{n}$ is the average degree of association of the amine salt in the organic phase.

Experimental data[8,20] show that at low concentrations of the ammonium salt, the slope is close to 1 (linear section), that is there is no association. With further increase in $\overline{C}_s$, the slope gradually begins to increase, and at a certain concentration the tangent becomes perpendicular to the abscissa. From this it was concluded that the average degree of association had become infinite, and this was interpreted as corresponding to the formation of a colloidal solution. With further increase in $\lg(\overline{C}_a a_{HX})$, however, the curve deviates to an even greater extent towards the ordinate, and the slope becomes negative, indicating that Eqn. (15) and the entire concept developed cannot be used to describe the extraction in this range. According to

independent data,[20] at concentrations corresponding to the vertical position of the tangent the average degree of association is not even close to infinity.

For a long time there was no accepted explanation for this phenomenon. For example, Diamond[8] suggested that the "anomalous" relationships are due to a change in the properties of the pure solvent resulting from the presence of a large number of ions, so that the solvent acquires the properties of a completely new substance with better extraction characteristics. Later,[50] he concluded that the "anomalous" relationship is due entirely to the behaviour of the "free" amine, and that increase in the concentration of the salt leads to an increase in the activity coefficient of the amine and a marked decrease in the ratio of the activity coefficients of the components of the organic phase. Others[51] suggested that "the increase in the dielectric constant of the solution with increase in the concentration of the ammonium salt leads to a decrease in the association and an increase in the extraction constant. The superposition of these effects gives different curves, including the anomalous curve".

Similarly, no unambiguous explanation was found for the nature of the dependence of the extraction of metal salts on the structure of the cations of the substituted ammonium salts. The extraction of metal salts from nitric acid solutions increases in the order primary < secondary < tertiary < quaternary alkylammonium.[5] In sulphuric acid solutions, at least for the actinides(IV) and (VI), the opposite relationship is observed, and was described as "curious".[19]

The influence of modifiers on the extraction equilibrium is often examined using the model of an ideal associated solution. According to this model, the deviations of the solutions from ideal behaviour are due to the formation of associates or solvates, whose solution behaves as an ideal solution, and the equilibria between them obey the law of mass action. Thus it is assumed that in the presence of alcohols or other solvating additives (B), mixed associate–solvates are formed

$$n\mathrm{R_3NHX(org)} + p\overline{\mathrm{B}} \rightleftarrows (\mathrm{R_3NHX})_n\mathrm{B}_p\mathrm{(org)}. \qquad (16)$$

and the equilibrium constant is written as

$$\beta_{np} = \frac{[(\mathrm{R_3NHX})_n\mathrm{B}_p]}{[\overline{C}_s(1)]^n[\overline{C}_B(1)]^p}. \qquad (17)$$

Eqns. (16) and (17) are more general than Eqns. (10) and (11). Similar equations can be written for the extraction of metals. This approach has not yet been used systematically to describe the influence of modifiers on extraction by amines. Eqns. (16) and (17) are most frequently used when $n = 1$.[14,15] These equations, however, can hardly explain various "anomalous" features of extraction, for example the fact that the distribution coefficient of the metal passes through a maximum with increase in the alcohol concentration.[52]

An explanation of these and various other "anomalous" features became possible after the development of methods for taking systematic account of the influence of various interactions on the activity of the salts of substituted ammonium bases.

III. Determination of the activity of the components in ammonium salt solutions

The organic phase of amine extraction systems is a multicomponent solution, which in the general case contains a diluent, an amine, neutral and acidic amine salts, water, a modifier, and the metal complexes extracted. A characteristic of these solutions is that the amines and the ammonium salts formed in the extraction are non-volatile substances, sparingly soluble in water. There are at present no direct methods for determining the thermodynamic activity of substances of this kind. The activity of the ammonium salts is therefore usually determined by indirect methods from the activity of the other components of the solution.

1. Experimental methods

Most frequently, in solutions of ammonium salts, the activity of the solvent is determined. Since existing methods are not of equal value, it is necessary to consider them briefly. The direct method involving measurement of the vapour pressure of the solvent is rarely used,[53,54] since it requires extremely complex apparatus and does not make it possible to study sufficiently dilute solutions in which the mole fraction of the solute $x_2 < 0.01$. The most accurate and sensitive method for determining the activity of the solvent is apparently the cryoscopic method. It has been used to study solutions in benzene with a molality down to 0.0003.[55–57] The chief disadvantage of the cryoscopic method is the need to carry out the studies at the freezing point of the solvent. It is thus practically impossible to determine the influence of the nature of the solvent and temperature on the activity of the components of the solution. Of the diluents usually employed in extraction, only benzene is widely used for cryoscopic measurements. Isolated studies have been carried out using cyclohexane and *p*-xylene.[58]

The ebulliometric method using a manostat has the advantage over the cryoscopic method that it makes it possible to carry out studies with a large number of volatile solvents at different temperatures. Ebulliometry is widely used to study solutions of polymers. The instruments developed for these purposes make it possible to carry out measurements in solutions with solute concentrations down to 0.0003 mol kg^{-1} and even lower.[59–61]

Isothermal distillation, and the isopiestic method, are applicable only to solutions with concentrations not lower than 0.01 mol kg^{-1}. Studies by these methods were previously carried out at temperatures close to room temperature (25–50 °C) using the solvents benzene, tetrachloromethane, cyclohexane, and chloroform.[20,62–64] Methods of measurement were subsequently developed for studying solutions in less volatile solvents (toluene, chlorobenzene, butylbenzene, and chloronaphthalene) at temperatures up to 130 °C.[65]

The above methods make it possible to determine directly only the activity of the solvent a_1. Nevertheless, in many papers, the experimental data are given as the average degrees of association of the solute $\bar{n}$:

$$\bar{n} = \ln x_1/\ln a_1 = 1/\varphi, \qquad (18)$$

where x_1 is the mole fraction of the solvent, and φ the osmotic coefficient. The values of $\bar{n}$ give a clear picture of the deviations from ideal behaviour in solution, and are widely used in the theory of IAS. This theory has been justifiably criticised for the insufficient clarity of the physical ideas on which it is based. However, so long as a physical significance is not given to the association (solvation) constants calculated from Eqns. (11), (13), and (17), then the theory of IAS can be regarded as a method for describing deviations from ideal behaviour, where the activity of the solute is equal to the concentration of its monomer.

Another component of the organic phase of amine extraction systems whose activity can easily be determined is water. In practice, however, the opposite approach is used; the dependence of the concentration of water in the organic phase on its activity a_w is determined. Titration with the Karl Fischer reagent is usually employed for this purpose, although other methods are also known. The saturation of the organic phase with water at a definite water activity is often carried out by the isopiestic method with

thermostatting.[12] The previously popular method involving the equilibration of the organic phase with an aqueous salt solution with known a_w has a number of unsatisfactory features, and is now seldom used.

The activity of the other components of the organic phase of amine extraction systems has not yet been determined experimentally. The determination of the activity of a number of susbstances used as modifiers is possible in principle.

2. Methods for calculating the activity of the components

The activity of the components of the solution is most frequently calculated from the activity of the solvent using the Gibbs–Duhem equation in the form

$$\frac{10^3}{M_1} d\ln a_1 + \sum_{i=2}^{n} m_i d\ln a_i = 0 \qquad (19)$$

or

$$\frac{10^3}{M_1} d\ln f_1 + \sum_{i=2}^{n} m_i d\ln f_i = 0, \qquad (20)$$

where m_i, a_i, and f_i represent respectively the molality, activity, and molar activity coefficient of the ith component of the solution, the subscript 1 refers to the solvent, and M_1 is the molecular mass of the solvent.

For binary solutions, integration of Eqn. (20) gives the expression

$$\ln f_2/f_2^0 = -\frac{10^3}{M_1}\int_0^{m_2} \frac{1}{m_2}\frac{\partial \ln f_1}{\partial m_2} dm_2, \qquad (21)$$

where $f_2^0$is the activity coefficient in the infinitely dilute solution. The absolute activity coefficients (standard state the pure substance) of the solute cannot be determined using the Gibbs–Duhem equation, so that the concentration activity coefficients are generally determined using $f_2^0 = 1$.

Eqn. (21) is practically never used to calculate activity coefficients, since as $m_2 \to 0$, the right-hand side becomes indeterminate. To avoid this difficulty, the concept of osmotic coefficient is used. Substituting Eqn. (18) in Eqn. (20) and integrating gives the following equation for the concentration activity coefficient:

$$\ln f_2 = \varphi - 1 - \int_0^{m_2} \frac{1-\varphi}{m_2} dm_2. \qquad (22)$$

The calculation of the activity coefficients from Eqn. (22) is usually carried out by graphical integration of the function $(1 - \varphi)/m_2$, extrapolating it to $m_2 = 0$.

The use of cross relationships has been proposed[66] for calculating the activities of the components in muiltcomponent solutions. Thus for solutions with components i, j, and k it is possible to write

$$\left(\frac{\partial \ln a_i}{\partial r_{kj}}\right) r_{ij} = \left(\frac{\partial \ln a_k}{\partial r_{ij}}\right) r_{kj} \qquad (23)$$

and

$$\left(\frac{\partial \ln f_i}{\partial r_{kj}}\right) r_{ij} = \left(\frac{\partial \ln f_k}{\partial r_{ij}}\right) r_{kj}, \qquad (24)$$

where $r_{ij} = x_i/x_j$ is the relative concentration. A particular case of r_{ij} is the molal concentrations

$$m_i = \frac{10^3}{M_1} r_{i1} = \frac{10^3}{M_1}\frac{x_i}{x_1}.$$

The method involving the calculation of the Gibbs free energy of the solution from the partial molar Gibbs free energy of one of the components,[67] and various other methods,[68–70] have been used in the calculation of the activities of the components of metallic alloys, but have not yet been used to interpret the results of the study of an extraction equilibrium.

It should be emphasised that different methods of calculation should theoretically give the same results. In practice, however, errors which are different for different methods are unavoidably introduced in the calculations. The well-founded selection of a method of calculation applicable to the systems being discussed in order to achieve the smallest uncertainty is as yet impossible, because of the lack of accurate experimental data.

3. Binary solutions

A knowledge of the activities in binary solutions is necessary for calculating the activities in more complex systems. Of the large number of binary solutions which may be formed with the participation of the components of the organic phase of amine extraction systems, only solutions of the amine salt (or amine)–non-polar solvent type have as yet been studied.

Only slight deviations from ideal behaviour have been observed in solutions of water[71] and amines[20,62] in non-polar organic solvents, so that the concentration activity coefficients of these substances in the binary solutions can be taken as 1.

Appreciable association takes place in solutions of alcohols in non-polar organic solvents. The activity coefficients of alcohols in binary solutions can be readily calculated from experimental data using Eqn. (22). A large number of studies have been devoted to binary solutions of substituted ammonium salts, whose degree of association varies over a wide range. Analysis of the experimental data[15] has shown that the association of ammonium salts increases in the following cases: 1) with increase in the radius of the anion (for a given cation) in the order fluoride < chloride < bromide < thiocyanate < nitrate < iodide < perchlorate; 2) with decrease in the length of the group of the ammonium cation; 3) with decrease in temperature; 4) with decrease in the dielectric constant of the solvent in the order of nitrobenzene > chloroform > benzene > xylene > tetrachloromethane > cyclohexane > alkanes; and 5) with decrease in the degree of replacement at the nitrogen atom for salts with a given anion in the order tertiary < secondary < primary amines. The salts of quaternary ammonium bases occupy an intermediate position between the salts of tertiary and secondary amines. Since the publication of the review cited,[15] a large number of new studies[1,3,5] of the association of ammonium salts have been published, confirming the above features.

It is assumed that the formation of intermolecular hydrogen bonds generally facilitates the association of salts of primary and secondary amines. The main factor responsible for the association of the salts of tertiary amines and quaternary ammonium bases, which have extremely high dipole moments,[1] is the electrostatic attraction between the molecules (chiefly dipole–dipole interaction), although in some cases (acid salts) intermolecular hydrogen bonds are also probably formed. Thus the dipole moments of the molecules of the hydrogen sulphates of tertiary amines are lower than those of the molecules of the chlorides or bromides of the same amines, although the latter are associated to a smaller extent than the hydrogen sulphates.[1,72]

There are comparatively few published data on the association of complex ammonium salts with metal salts in binary solutions. This is partly due to the insufficient stability of many complex salts, as a consequence of which it is necessary to introduce simple ammonium salts to displace the equilibrium in the solution. For stable complex

salts, the degree of association varies over a wide range, from 1 for the complex of uranyl sulphate with trioctylammonium sulphate in benzene[72] to 10 or more for tetraheptylammonium tetrachloro- and tetrabromoferrates.[62] NMR[73] has established that the association of the acido-complexes of lanthanide nitrates with the nitrates of tertiary amines increases with decrease in the length of the n-alkyl groups in the cations of the salts, and also on going from symmetrical to unsymmetrical cations.

A high degree of association makes it difficult to calculate the activity coefficients of ammonium salts from Eqn. (22). Thus in solutions of tridodecylammonium bromide in cyclohexane at a minimum concentration of 0.0077 M, the average degree of association $\bar{n} = 1.83$,[62] which corresponds to $\varphi = 0.546$. At the same time, for reliable extrapolation to infinite dilution in the calculation using Eqn. (22), it is necessary that the values of φ be close to 1 or at least greater than 0.9 at the minimum concentration of the solute. In the study of binary solutions of ammonium salts, this condition can be satisfied extremely rarely (the measurements have to be carried out in the concentration range 10^{-4}–10^{-3} M). Attempts have therefore been made to approximate the dependence of $\ln f_1$ or φ on the concentration of the solute by various functions, and then to carry out the integration of Eqns. (21) and (22).

For this purpose, the following polynomial expansion has been used[62]

$$\lg f_2 = A + Bm_2 + Cm_2^2 + Dm_2^3, \qquad (25)$$

where the subscript 2 refers to the ammonium salt, and the coefficients A, B, C, and D are non-zero. Since it follows from the definition of the concentration activity coefficient that $\lg f_2 = 0$ for $m_2 = 0$, Eqn. (25) can be regarded as an interpolation equation, applicable only in the range of concentrations studied in the work cited.[62] As noted by the authors cited,[62] the values of $\lg f_2$ calculated from Eqn. (25) may differ from the true values by a certain constant amount as a consequence of the inaccuracy of the extrapolation to infinite dilution in the integration of the Gibbs–Duhem equation. The value of $\Delta \lg f_2$ may reach about 0.15.[74]

A different approach was used by Gal and co-workers,[63] who represented the function under the integral sign in Eqn. (22) in the form of the polynomial

$$\frac{1-\varphi}{m_2} = A + Bm_2 + Cm_2^2 + Dm_2^3 + Em_2^4. \qquad (26)$$

This expansion is obviously preferable to that in Eqn. (25), since substituting Eqn. (26) in Eqn. (22) and integrating gives for $\lg f_2$ a polynomial which becomes zero for $m_2 = 0$. The dependence of $(1-\varphi)/m_2$ on m_2, however, is given by a curve resembling a hyperbola. For these relationships, the approximation by the polynomial is not effective, and the values of the coefficients of the polynomial are extremely sensitive to change in the range of the approximation. An extensive verification of the applicability of Eqn. (26) has not yet been carried out. It may be noted that the inverse function $m_2/(1-\varphi)$ is close to linear.

The following equation has been proposed[75] for solutions of ammonium salts in non-polar solvents

$$m_2^2/\ln f_1 = b_0 + b_1 m_2. \qquad (27)$$

This equation is useful for extrapolating data to infinitely dilute solutions, since significant deviations from linearity are observed only at high concentrations. Substituting Eqn. (27) in Eqn. (21) and integrating gives the equation

$$\ln f_2 = -\frac{10^3}{M_1 b_1}\left[\ln\left(1 + \frac{b_1}{b_0} m_2\right) + \frac{b_1 m_2}{b_0 + b_1 m_2}\right]. \qquad (28)$$

Thus the calculation of the activity coefficients in binary solutions of ammonium salts reduces to the determination of two empirical parameters, b_0 and b_1. This makes Eqns. (27) and (28) preferable to other equations used to describe the thermodynamic functions in these solutions. The values of the parameters b_0 and b_1 for a number of solutions have been published.[1] When $m_2 \ll 10^3/M_1$, Eqn. (27) becomes

$$\frac{m_2}{1-\varphi} = \frac{M_1}{10^3}(b_0 + b_1 m_2). \qquad (29)$$

Many authors use the theory of IAS to describe the deviations from ideal behaviour in binary solutions of ammonium salts. The calculation of the association constants for the same solutions using this theory leads to ambiguous results, however. For example, two alternative descriptions of the tridodecylammonium chloride–*o*-xylene system have been published.[76,77]

The activity coefficients (or the association constants, which to some extent are equivalent) in binary solutions are often used to describe the extraction equilibrium. This approach has been successful in a number of cases.[78] To avoid errors, however, before using the activity coefficients found in binary solutions, it should be established that the introduction of other components into the solution does not influence the values of the activity coefficients. For this it is necessary to develop methods for calculating the activity coefficients in multicomponent solutions of ammonium salts.

4. Calculation of the activities of solutes from the activities of the solvent in multicomponent solutions

The most complex problem is the calculation of the activities of substances in multicomponent solutions from the activities of the solvent. This problem can be simplified and reduced to the calculation of the change in the activity of a solute when another substance is added to the solution. The two most important cases may be noted. To explain the "anomalous" dependence of $\lg \bar{C}_s$ on $\lg(\bar{C}_a a_{HX})$ it has been suggested that the activity coefficient of the amine $\bar{y}_a$ increases when an amine salt is added to the solution.[50] Experimental data also indicate that the metal complex extracted may react with the amine salt in the organic phase. This interaction must be taken into account in the determination of q by the equilibrium-displacement method.

In the extraction of iron(III) chloride, only tetrachloroferrate ions $FeCl_4^-$ are present in the organic phase.[79] The values of q found by the equilibrium-displacement method, however, depending on the conditions of the experiment, lie in the range 1–2, due to the formation of $FeCl_5^{2-}$ ions or to the reaction of the tetrachloroferrate and the amine chloride.

In the extraction of lanthanide nitrates by amine nitrates, the dependence of $\lg D$ on $\lg \bar{C}_s$ is not linear,[80] and the deviation from linearity cannot be attributed entirely to the change in the activity coefficients of the salt $\bar{y}_s$. Finally, in some cases, reaction between the extracted complexes of different metals is possible.

The following equation was obtained[81] for calculating the activity coefficients in these systems by transforming the Gibbs–Duhen equation and the cross relationship (23)

$$\ln \gamma_2 = -\frac{10^3}{M_1}\int_0^{m_3}\frac{1}{m_3}\left[\frac{M_1}{10^3} + \left(\frac{\partial \ln a_1}{\partial m_2}\right)_{m_3=0;m_2}\right] dm_3, \qquad (30)$$

where γ is the activity coefficient when the concentration is expressed as the molality, and the subscript $m_2 = 0$ indicates that the derivative is taken as the concentration $m_2 \to 0$. Eqn. (30) can be used to calculate the change in the activity coefficients of micro-quantities of a solute when a third component is introduced.

Eqn. (30) has been used to determine the influence of an amine salt on the activity of an amine.[82] Three-component tetrachloromethane–tridodecylamine–tridodecylammonium bromide solutions were chosen as model systems; for these solutions, the slope of the plot of $\lg \overline{C}_s$–$\lg(\overline{C}_a a_{HX})$ becomes equal to infinity at $0.05\ M < \overline{C}_s < 0.1\ M$.[20]

Ebulliometric measurements showed that at a concentration $m_s = m_3 = 0.0482$ mol kg^{-1}, the expression in square brackets under the integral sign in Eqn. (30) is practically equal to zero, and the activity coefficients $\gamma_2 = \gamma_a$ do not differ significantly from 1. Thus the suggestion by Diamond and Bucher[50] that γ_a depends significantly on the concentration of the amine salt is not confirmed in this system, and it is necessary to look for another explanation of the anomalous dependence of $\lg \overline{C}_s$ on $\lg(\overline{C}_a a_{HX})$.

The ebulliometric method has been used to study the chloroform–tridodecylammonium chloride–tridodecylammonium tetrachloroferrate system.[83] The binary solutions based on these components are close to ideal, but in the ternary solutions, strong interaction between the solutes is observed. Thus the activity coefficients of micro-quantities of the amine tetrachloroferrate γ_c, calculated from Eqn. (30), decrease rapidly with increase in the concentration m_s, and at $m_s = 6 \times 10^{-3}$ mol kg^{-1}, $\gamma_c = 0.49$.

The systems formed by a solvent (tetrachloromethane or benzene) with tridodecylammonium nitrate and the complex of cerium or europium nitrate with tridodecylammonium nitrate have been studied in most detail.[85] Eqn. (30) was used to calculate the dependence of the activity coefficients of micro-quantities of the complex salts γ_c on the concentration of the amine nitrate, and it was shown that γ_c is smaller for the europium salts than for the cerium salts.[84] The values of γ_c were then used to describe the dependence of the distribution coefficient of micro-quantities of cerium and europium on the tridodecylammonium concentration at a constant composition of the aqueous phase. The extraction constants (more accurately, the products $K\gamma_{\pm}^4$) remained practically constant with change in the concentration of the extracting agent by a factor of 20, whereas neglect of γ_c led to a systematic drift of the constants (for example, in the extraction of europium, the apparent extraction constant changed by a factor of 2–3 in the concentration range studied).

Eqn. (30) can be used to calculate the activity coefficients of a solute only when its concentration is very low (micro-component). An equation has been derived,[85] making it possible to calculate the change in the activity coefficients of a solute when another substance is introduced into the solution over a wide range of concentrations For this purpose, the cross relationship (24) was intregated with replacement of the variables r_{12} and r_{13} by m_2 and m_3 respectively:

$$\ln f_2 = -\frac{10^3}{M_1}\int_0^{m_s}\left(\frac{\partial \ln f_1}{\partial m_2}\right)_{m_s}\frac{dm_3}{m_3}. \qquad (31)$$

It can be shown that as $m_2 \to 0$, Eqn. (31) becomes Eqn. (30). The calculation using Eqn. (31) is difficult, since the dependence of $\ln f_1$ on m_2 in solutions of amine salts is not linear. To eliminate this difficulty, Eqn. (31) was transformed to the equation[85]

$$\ln f_2 = \ln f_2^0 - \frac{10^3}{M_1}\int_0^{m_s}\left[\frac{\partial \ln (f_1/f_1^0 f_1^*)}{\partial m_2}\right]_{m_s}\frac{dm_3}{m_3}, \qquad (32)$$

where the superscripts 0 and * indicate that the activity coefficients were determined for binary solutions with $m_3 = 0$ or $m_2 = 0$. Eqn. (32) has been used to calculate the activity coefficients γ_c of the complexes of cerium and europium nitrates with tridodecylammonium nitrate. When the amine salt is added in the concentration range studied, γ_c is independent of the metal concentration.[85]

Allowance for the intermolecular association of the amine salts in the IAS model made it possible to develop mathematical models for the extraction of lanthanides from nitric acid solutions containing a salting-out agent by solutions of the nitrates of tertiary amines[86] and quaternary ammonium bases.[87]

IV. The influence of solvation of the extraction equilibrium

The solvation of ammonium salts by protogenic solvents in non-polar media has been studied in sufficient detail,[1,5,12,15] For example, infrared spectroscopy has shown that the reaction of the molecules of alcohols or water with the anions of the salts increases with increase in the degree of replacement at the nitrogen atom of the bases, and also with increase in the proton affinity of the anions.[88,89] Allowance for the influence of solvation on the extraction equilibrium using IAS theory does not explain the "anomalous" extraction relationships. The concepts of non-stoichiometric hydration and solvation of the salts[1] have proved to be more fruitful for describing the extraction equilibrium and understanding the essential features of the inter-particle interactions accompanying the extraction of acids and metal salts in systems containing solutions of amines and ammonium salts.

1. The hydration of ammonium salts

For many systems containing ammonium salts, in which the solubility of water (m_w) is relatively high, the distribution of water is described by the equation[90]

$$m_w = m_w^0 a_w (1 + k_r m_2), \qquad (33)$$

where m_w^0 is the solubility of water in the pure solvent at an equilibrium activity of water $a_w = 1$, and k_r the hydration parameter, related to the degree of hydration h by the expression

$$h = k_r m_w^0 a_w. \qquad (34)$$

An equation describing the activity of a solute in a ternary solution[1] was obtained from Eqn. (34) using cross relationships of the type (23) and (24):

$$\ln a_2 = \ln a_{20} - k_r m_w^0 a_w = \ln a_{20} - h, \qquad (35)$$

where a_{20} is the activity of the solute in the binary ammonium salt–solvent solution not containing water. Eqn. (35) was previously obtained by other methods.[91–93] Eqns. (33) and (35) were generalised to the case of multicomponent solutions.[94]

Thus the degree of hydration is a quantitative measure of the influence of the hydration of a solute on its activity on going from the binary solutions to solutions saturated with water at an equilibrium a_w. For the case being considered, where the distribution of water in the pure solvent and in the solution of the extracting agent obeys Henry's law, it is possible to write:

$$\Delta\mu_{2,hydr} = -RTh, \qquad (36)$$

that is the degree of hydration reflects the change in the partial molar Gibbs free energy of the ammonium salt when the solute is transferred from its dry solution to a solution containing water. Eqn. (35) can be transformed to the equation

$$\gamma_{hydr} = \exp(-h). \qquad (37)$$

It follows from Eqn. (37) that hydration lowers the activity coefficient of solutes if solutions of unit molality with the properties of infinitely

dilute solutions in the dry solvent are taken as the standard state. For the case being considered, the degree of hydration h is equal to the number of water molecules combined with a molecule of the solute in the organic solvent.[95] Thus for given values of m_w^0, hydration leads to lower values of γ_{hydr}, the higher the solubility of water in the organic phase of the extraction system.

In a number of cases it is more convenient to take as standard state a solution with the properties of an infinitely dilute solution, saturated with water at $a_w = 1$. The dependence on a_w of the activity coefficient γ_{21}, determined relative to this standard state, then has the form

$$\gamma_{21} = \gamma_2 \exp[h_\infty(1 - a_w)], \quad (38)$$

where h_∞ is the degree of hydration in the infinitely dilute solution at $a_w = 1$. In other words, the concentration activity coefficients in solutions saturated with water at $a_w = 1$ are equal to the concentration activity coefficients in the binary dry solutions. The equality of the activity coefficients determined in this way was established experimentally in a study of the extraction of hydrochloric and hydrobromic acids by trilaurylamine solutions.[78] This equality is observed in a relatively narrow range of change in the concentration of the trilaurylammonium salt, in which the distribution of water obeys Henry's law satisfactorily. The applicability of Eqns. (35)–(38) to ammonium salt solutions was confirmed by determining the activity of the salts in ternary solutions.[12,91] The range of change in h for the salts studied is fairly large. The greatest decrease in activity (by five orders of magnitude) was observed when water was added to solutions of methyltrioctylammonium sulphate.

Published data on the hydration of ammonium salts have been summarised.[1] The molar ratio of the concentrations of water and the salt in the solutions saturated with water depends on many factors. For quaternary ammonium salts it varies from 2 to 15, increasing with decrease in the molecular mass and symmetry of the cation.[96] In solutions of TOA sulphate and the salts of unsymmetrical ammonium bases, in which the solubility of water is high, the distribution of water shows appreciable deviations from Henry's law. These deviations are also observed in solutions of weakly hydrated amine salts, but at high concentrations of these salts. The deviations increase with decrease in the polarity of the organic solvents used.[90,91]

When there are deviations from Henry's law, the isotherm for the distribution of water can be described by the equation

$$m_w = \sum_{n_1,n_2} b_{n_1,n_2} a_w^{n_1} m_2^{n_2}, \quad (39)$$

where b_{n_1,n_2} is an empirical coefficient.

Substituting Eqn. (39) in the cross relationship (23)

$$(\partial \ln a_2/\partial \ln a_w) = -(\partial m_w/\partial m_2)_{a_w} \quad (40)$$

and integrating gives the expression

$$\ln a_2 = \ln a_{20} - \sum_{n_2,n_2} \frac{n_2}{n_1} b_{n_1,n_2} a_w^{n_1} m_2^{n_2-1}. \quad (41)$$

If all the terms with $n_1 \gg 2$ and $n_2 \gg 2$ are neglected, Eqn. (41) becomes Eqn. (35). For practical calculations, in the description of the influence of "non-linear" hydration, the following semi-empirical equation[97] is used instead of Eqn. (41)

$$\gamma_2 = \gamma_{20} \exp(-h_{int}), \quad (42)$$

and the integral degree of hydration h_{int}, reflecting the actual contribution of hydration to the decrease in the activity of the solute, is calculated from the isotherms for the distribution of water into the solution of the salt and into the pure solvent. With allowance for Eqn. (42), Eqn. (38) becomes

$$\gamma_{21} = \gamma_2 \exp(h_\infty - h_{int}). \quad (43)$$

Thus by using the values of h_{int} and h_∞ it is possible to change from the activities determined relative to solutions in the dry solvent to the activities determined relative to solutions saturated with water at a water activity a_w. In general, $h_{int} \geqslant h_\infty$, and the value of γ_{hydr} decreases with increase in the concentration of the salt.

Eqns. (35)–(43) make it possible to determine the regularities of the influence of hydration on the extraction equilibrium. Thus hydration is revealed most strongly in systems which include polybasic acids, and also ammonium salts containing methyl substituents. The contribution of hydration to the non-ideal behaviour of the organic phase of extraction systems decreases with decrease in the concentration of the salts and the proton affinity of their anions and with increase in the polarity of the solvents used.

As noted in section II, the most familiar "anomalous" relationship in extraction by amines is the discrepancy between the data on the degree of association of the ammonium salts obtained by analysing the distribution on the one hand, and independent physicochemical measurements on the other. The anomalies found[20] in the analysis of data on the extraction of monobasic acids by solutions of trilaurylamine on coordinates $\lg \overline{C}_s$–$\lg(\overline{C}_a a_{HX})$ are observed to an even greater extent[91] for the sulphuric acid–water–benzene–TOA system, that is the anomalies increase with increase in the solubility of water in the extracts. The solubility of water in solutions of TOA sulphate does not obey Henry's law even for dilute solutions, and the integral degree of hydration increases with increase in the salt concentratrion. For this system over a wide range of change in the salt concentration, $\gamma_{20} \simeq 1$. The activity coefficient of TOA sulphate in the ternary solutions was determined by two methods: from the combined results of cryoscopic and isopiestic measurements, and also by calculation using Eqn. (42) and the isotherms for the distribution of water in salt solutions with different concentrations.[12] The extraction constants for the extraction of sulphuric acid by benzene solutions of TOA, calculated with allowance for the values of γ_2, are practically constant. This shows that in the sulphuric acid–water–benzene–TOA extraction system at low concentrations of the acid, the main factor responsible for the non-ideal behaviour of the organic phase is the hydration of TOA sulphate.[91]

The solubility of water increases considerably with increase in the concentration of trilaurylammonium halides. Thus the "anomalous" relationships observed by Mueller and Diamond[20] are also apparently due to hydration of the salts, and not their association.

Allowance for the influence of hydration on the activity of TOA sulphate also made it possible to eliminate the contradiction between data on the composition of the extracted complex of uranyl sulphate obtained by the saturation and equlibrium-displacement methods.[98] The slope of the plot of $\lg D$ against $\lg a_2$ is close to 2, indicating the formation of the complex $(R_3NH)_4UO_2(SO_4)_3$ in this system. The composition of the complex found in this way is identical to that established by the saturation method.

In a number of studies,[99–101] the activity coefficients of various ammonium salts were found from the isotherm of the surface pressure at the interface between water and a solution of the salt in an aromatic hydrocarbon. With change in the anion of the salt R_3NHX, the values of γ_2 decrease in the order perchlorate < iodide < bromide < chloride. From this it was concluded that the salts whose anions are least effectively extracted are most highly associated.[17,18] This does not agree, however, with data on the association of the salts in dry solutions, obtained by independent methods.[99] It is understandable that

the inversion of this series is due to hydration of the salts, which increases sharply with increase in the proton affinity of their anions and which makes a larger contribution to the non-ideal behaviour of the solutions than association of the salts.

The inversion of the order of activity of the salts in ternary solutions compared with the binary solutions is also observed in other cases. Thus as a consequence of the marked differences in the hydration of ammonium salts with different degrees of substitution, the observed extraction features often cannot be explained on the basis of the reactivity of the amines and the ammonium salts in their dry solutions.

It was pointed out above that the extraction of metals from sulphuric acid solutions increases in the order quaternary < tertiary < secondary alkylammonium. At the same time, spectroscopic studies show that the electron-donor properties of the anions of ammonium salts increase with increase in the degree of substitution at the nitrogen atom of the bases.[102] This "anomalous" dependence of the extraction of metal salts from sulphuric acid solutions on the nature of the cation of the ammonium salt is often related to a steric effect.[8,9] It has been shown, however, that the observed regularity is also due to the influence of hydration on the activity of the ammonium salts.[1] Thus at identical concentrations of secondary and quaternary alkylammonium sulphates, their degrees of hydration differ by approximately 7 units. From the stoichiometry of the complex formed, it can be shown that a decrease in the distribution coefficient should be observed in this order as a result of the difference in the hydration of the salts. For uranyl sulphate, for example, it decreases by a factor of approximately 10^6.[103] The difference actually observed in the extracting power of ammonium salts of the series being considered is appreciably lower, because of the increase in reactivity with increase in the degree of replacement at the nitrogen atom of the bases.

Methyldialkylamines and dimethylalkylamines are weaker bases than trialkylamines, so that the extraction constants for the extraction of acids by these compounds should be slightly lower. In fact, the extraction constant for the extraction of nitric acid by TOA solutions is slightly higher than that for extraction by solutions of methyldioctylamine.[104] The opposite picture is observed, however, for the extraction of hydrochloric and sulphuric acids.[5] The "anomalous" increase in the extraction constants for extraction by methyl-substituted tertiary amines corresponds quantitatively to the difference in the degrees of hydration of the chlorides and sulphates of these amines and those of the corresponding TOA salts in non-polar solvents.[12]

Thus the "anomalous" features observed up to the present in systems containing amines and ammonium salts can be explained only by taking account of the influence of hydration on the activity of the components of the organic phase. In extraction systems containing amines, the part played by hydration generally increases with decrease in the intensity of the acid–base reaction between the components. Hydration has a levelling action on the extraction of inorganic acids. The distribution of the salts between the phases is usually accompanied by displacement of water from the organic phase. Thus hydration facilitates the extraction of inorganic acids by amines, but depresses the extraction of metal salts.

2. The solvation of ammonium salts

To interpret data on the extraction equilibrium in systems containing modifiers, it is necessary to have data on the activity of the components in ternary solvent–ammonium salt–alcohol and solvent–alcohol–water systems and in quaternary solvent–ammonium salt–water–alcohol systems.

In the thermodynamic study of ternary solvent–ammonium salt–alcohol solutions, usually only the activity of the solvent is determined, and the activity of the salt is calculated using the cross relationships (23) and (24). The close analogy between the phenomena of the hydration of ammonium salts and their solvation by alcohols makes it possible to simplify the calculation of the activity of the salt. Eqn. (33) can then be written as:[105,106]

$$m_{al}\gamma^*_{al} = a_{al}(1 + k_s m_2), \tag{44}$$

where a_{al} and m_{al} represent respectively the activity and molality of the alcohol in the ternary solution, γ^*_{al} the activity coefficient of the alcohol in the binary solution ($m_2 = 0$) at the same concentration m_{al}, and k_s the solvation parameter.

Since it is difficult to determine the activity of alcohols in ternary solutions, Eqn. (44) cannot be confirmed experimentally. Only the equations for the activity of the ammonium salt and the solvent, obtained using Eqn. (44), can be verified.

In the derivation of the equation for the activity of the ammonium salt,[105] the cross relatonship (23) was used in the form

$$(\partial \ln a_2/\partial m_{al})_{m_2} = (\partial \ln a_{al}/\partial m_2)m_{al}. \tag{45}$$

Differentiating Eqn. (45) with respect to m_2 and integrating with respect to m_{al} gave the equation

$$\ln a_2 = \ln a_2^0 - \frac{k_s}{1 + k_s m_2} m_{al}. \tag{46}$$

Substituting Eqns. (44) and (46) in the Gibbs-Duhem equation (19) and integrating gives the following equation for the activity of the solvent.[106]

$$\frac{10^3}{M_1} \ln \frac{a_1}{a_1^0 a_1^*} = \frac{k_s m_s m_{al}}{1 + k_s m_2}, \tag{47}$$

where a_1^0 and a_1^* are the activities of the solvent in the corresponding binary solutions for $m_{al} = 0$ and $m_2 = 0$. Eqns. (44), (46), and (47) have been generalised to multicomponent solutions.[94]

Eqn. (47) has been used for the treatment of the results of cryoscopic measurements[49] in the three-component benzene–trioctylammonium sulphate–n-octanol and benzene–trioctylammonium sulphate–methanol systems by the isomolar-series method. These results were prevoiusly described assuming that a trioctylammonium disolvate is formed.[49] The calculated values of the stability constants of the disolvates varied from 393 to 783 for the first system, and from 1020 to 4800 for the second. The range of change in the solvation parameters k_s calculated from the same data was much smaller: from 11.6 to 17.1 for the first system, and from 21.1 to 25.4 for the second. Thus Eqn. (47) provides a better description of the experimental data on the solvation of the ammonium salts than equations based on stoichiometric considerations.

At low alcohol concentrations, Eqn. (47) is simplified and becomes

$$\frac{10^3}{M_1} \ln \frac{a_1}{a_1^0} = -\frac{m_{al}}{1 + k_s m_2}. \tag{48}$$

Eqn. (48) has been used to calculate solvation parameters from ebulliometric data. The results, given in Table 1, show that the solvation parameters of the ammonium salts decrease with increase in temperature, and also with increase in the radius of the anion and the length of the alkyl group of the cation of the salt. To compare data on the influence of "inert" solvents, the solvation parameters of the salts were calculated on the molar concentration scale $k'_s = k_s/d_0$, where d_0 is the density of the solvent. With change in the solvent, the values of k'_s decrease in the order n-pentane < cyclohexane < tetrachloromethane < benzene, that is with increase in the polarity of the solvent. Similar relationships were previously observed for the hydration of ammonium

salts,[15,90] indicating that the phenomena of solvation and hydration are similar. Certain differences are also observed, however; in the solvation by alcohols of trioctylammonium sulphate and methyldioctylammonium and tetrapentylammonium chlorides, a phenomenon analogous to the non-linear hydration detected for these systems is not observed.

Table 1. Solvation parameters k_s of ammonium salts by n-tetradecanol.

*1Solvation by n-decanol; *2by n-hexadecanol; *3by n-octanol; *4by methanol.

There are few published data on the hydration of alcohols in non-polar solvents. The solubility of water increases slightly in the presence of alcohols. The distribution of water at relatively low alcohol concentrations is described by Eqn. (33), and the degree of hydration of the alcohols is usually low. Thus for $a_w = 1$, the degree of hydration of n-octanol h_{al} in benzene is 0.052[110] or 0.049,[107] and that in tetrachloromethane is 0.043.[110] These data show that the addition of alcohols to non-polar solvents does not lead to a significant change in the activity of water in the organic phase.

The Gibbs–Duhem equation for a four-component solvent–ammonium salt–water–alcohol system can be written as

$$\frac{10^3}{M_1}\frac{\partial \ln a_1}{\partial m_{al}}dm_{al}+m_2\frac{\partial \ln a_2}{\partial m_{al}}dm_{al}+m_w\frac{\partial \ln a_w}{\partial m_{al}}dm_{al}+m_{al}\frac{\partial \ln a_{al}}{\partial m_{al}}dm_{al}=0, \quad (49)$$

The possibility of transforming this equation to a form convenient for calculations is determined by the nature of the dependence of the solubility of water on the alcohol concentration. The experimental study of the hydration of ammonium salts in the presence of alcohols shows the existence of two types of dependence of m_w on m_{al}.[107,110–112] For some systems at low alcohol concentrations and a constant activity of water the following equation is applicable:

$$m_w = m_w^0 + hm_2 + h_{al}m_{al}. \quad (50)$$

For other systems, when an alcohol is added, m_w decreases at first, after which it passes through a minimum and then increases slowly. The degree of displacement of water by the alcohol increases with increase in the proton affinity of the anion of the salt.[112] The last section of the curve can be described by Eqn. (50). In systems of the first type, $h \leqslant 1$, whereas in systems of the second type, the minimum solubility of water corresponds to $h \simeq 1$.

For systems in which the hydration of the salts is described by Eqn. (50), the derivative $\partial \ln a_w/\partial m_{al} \simeq 0$, since the values of h_{al} are usually low. In this case, Eqn. (49) becomes the Gibbs–Duhem equation for a three-component system. This means that in these sysems, the hydration and solvation of the ammonium salts take place independently of one another, and in the calculation of the influence of alcohols on the activity of the ammonium salts in the presence of water it is possible to use the same equations and solvation parameters as for anhydrous solutions.

The solubility of water in solvent–ammonium salt–metal complex–alcohol systems can also in a number of cases be described by Eqn. (50). The following equation has been proposed[107] for the description of the influence of solvation on the activity of the components in systems of this kind:

$$m_{al}\gamma_{al}^* = a_{al}(1 + k_{2s}m_2 + k_{3s}m_3), \quad (51)$$

where k_{2s} and k_{3s} are the solvation parameters of the ammonium salt and the metal complex respectively. This equation has been used[107,113] for the description of the extraction of micro-quantities of metals, and this has made it possible to eliminate the influence on the equilibrium of the change in the concentration of the extracting agent as saturation takes place. In this case, $m_3 \to 0$, and from Eqn. (51), using the cross relationship (45), it is possible to obtain the expressions

$$\ln(a_2/a_2^0) = -k_{2s}m_{al}/(1 + k_{2s}m_2) = \ln(\gamma_2/\gamma_2^0) \quad (52)$$

and

$$\ln(a_3/a_3^0) = -k_{3s}m_{al}/(1 + k_{2s}m_2) = \ln\gamma_3, \quad (53)$$

where γ_2 and γ_3 are the activity coefficients of the ammonium salt and the metal complex respectively in the presence of the alcohol, γ_2^0 the activity coefficient of the ammonium salt in the binary solution, and $\gamma_3^0 = 1$. At a constant composition of the aqueous phase and a constant concentration of the ammonium salt, substituting Eqns. (52) and (53) in Eqn. (9) gives the equation

$$\ln D = \ln D_0 - \frac{qk_{2s} - k_{3s}}{1 + k_{2s}m_2}m_{al}, \quad (54)$$

where D_0 is the distribution coefficient of micro-quantities of the metal in the absence of the alcohol.

Eqn. (54) has been used to describe the influence of n-tetradecanol on the extraction of micro-quantities of iron(III), cobalt(II), and zinc chlorides by solutions of tridodecylammonium chloride in tetrachloromethane.[107,113] In these systems the introduction of the alcohol has practically no influence on the hydration of the extracting agent. The

treatment of the experimental data was carried out using the linear regression equation

$$\ln D = \ln D_0 - bm_{al}. \quad (55)$$

The calculation using Eqn. (55) and the solvation parameters given in Table 1 gives values of b which are practically identical to those obtained from experimental distribution data.

The description of systems in which the addition of an alochol leads initially to a decrease in the hydration of the ammonium salt is even more complex.[52] In this case the distribution coefficient of the metal salt passes through a maximum with increase in the alcohol concentration. The position of the maximum coincides with the position of the minimum on the curve giving the dependence of the concentration of water in the organic phase on the alcohol concentration. The ascending branch of the dependence of the distribution coefficient of the metal salt on the alcohol concentration is due to the increase in the activity of the ammonium salt as a result of the decrease in its hydration when the alcohol is added, and the descending branch is due to the decrease in the activity of the salt as a result of its solvation. This descending branch of the curve is described by equations of type (54) and (55). The calculated increase in the activity of the ammonium salt corresponds to the observed increase in the distribution coefficient of the metal salt.

Thus the non-stoichiometric model of the hydration and solvation of ammonium salts developed by the present authors makes possible a fairly simple description and interpretation of data on the extraction equilibrium. The results obtained using this model are consistent with the results of independent physicochemical measurements.

α-Halo-α-nitrocarboxylic acids and their derivatives

I V Martynov, A I Yurtanov
Institute of Physiologically Active Compounds, USSR Academy of Sciences, Chernogolovka

ABSTRACT. The methods for synthesising α-halo-α-nitrocarboxylic acids and their functional derivatives are reviewed. Reference is made to IR, NMR, and Raman spectroscopic data, calculation methods, and X-ray diffraction analysis, and information on the acidity and electron- and proton-donor capacities of the compounds is given. Reactions involving C–H and C–Hal bonds, carboxyl and nitro groups, the mechanisms of the most important reactions, and data on the toxicity and physiological activity are discussed.

The bibliography includes 196 references.

I. Introduction

α-Halo-α-nitrocarboxylic acids and their derivatives are polyfunctional compounds which are interesting from the point of view of studying the relationship between structure and properties. Distinctive (anomalous) behaviour of fluorine, chlorine, and bromine atoms on the carbon atom bonded to the nitro group has been found and elucidated for these compounds. A nontrivial mutual effect between the nitro and carboxyl groups and halogens, which manifests itself in the spectroscopic characteristics, structure, and chemical properties of these compounds, has been demonstrated. They have proved to be successful model compounds for studying the mechanisms of decarboxylation and the formation of halo-oximes, nitroso compounds, and phosphoryloximes. Reactions typical for them are the reductive decarboxylation with elimination of a single oxygen atom from the nitro group, deuterium exchange between cyclic transition states, the formation of heterocycles with complete or partial conversion of functional groups, redox phosphorylation, sulphonation–dehalogenation, etc.

Compounds of this group have become readily available as a result of the development of convenient methods for preparing them from accessible feedstocks. There are extensive possibilities for converting them to various nitro and nitroso compounds, oximes, hydroxylamines, amines, amino acids, and other compounds that have various properties of use for practical application and are difficult to synthesise by other methods. As a result of this, they have attracted the attention of chemists in recent years.

Compounds of this group include fungicides, insecticides, bactericides plant growth regulators, and also compounds that possess anti-choline esterase and hypotensive activity, amine oxidase inhibitors, and certain other physiologically active compounds that have potential for introduction into the national economy. All this is an indication of their important practical significance.

The first examples of this series of compounds were obtained at the beginning of the century. However, a systematic study of them was only carried out during the last 30 years because of the development of practicable synthetic methods. Specific information about α-halo-α-nitrocarboxylic acids and their derivatives is given in monographs[1–4] and review articles.[5–7] However, there are no reviews in the literature specially devoted to such an important group of compounds. The present article is the first attempt to correlate the studies on the preparative methods, properties, and use of α-halo-α-nitrocarboxylic acids and their derivatives. Literature sources from the last 30 years as well as earlier studies are covered here.

II. Synthetic methods

1. Replacement of a hydrogen atom in α-nitrocarboxylic acid derivatives by chlorine

Halogenation of salts of *aci*-nitro compounds is a general method for the preparation of α-halonitrocarboxylic acid derivatives and halonitroalkanes.[4,7,8]

$$O_2NCHY + MOH \rightarrow M^+[O_2N{=}CY]^- \xrightarrow[-MX]{X_2} O_2NCXY,$$

R = H, alkyl, NO_2, halogen; X = F, Cl, Br;
Y = CO_2R, CN, $CONH_2$ etc.; M = Na, K, NH_4, Ag etc.

When salts of *aci*-nitrocarboxylic acid derivatives are treated with bromine or chlorine, bromodinitroacetonitrile,[9] methyl bromonitroacetate,[10] dimethyl and diethyl bromonitromalonates,[11] dibromonitroacetonitrile,[12] ethyl bromo-, chloro-, dibromo-, and bromochloro-nitroacetates, ethyl α-bromo- and α-chloro-α-nitropropionates and -butyrates,[13] dichloronitroacetonitrile,[14,15] and α-bromo- and α-chloro-α-nitropropionamides[16] are obtained. Bromonitromalonamide, *N*-methylbromonitroacetamide, and dibromonitroacetamide were synthesised by treatment with bromine water.[17] It was shown subsequently using IR spectroscopy that *N*,α-dibromonitroacetamide rather than α,α-dibromonitroacetamide is formed under these conditions.[18] Dichloronitroacetamide[19] and ethyl chloronitromalonate[20] are obtained in a similar manner. The bromination of the sodium salt of dinitroacetonitrile was successfully carried out using bromine in a mixture of water and dichloromethane, while chlorination of the same salt could only be achieved using hydrochloric acid and hydrogen peroxide.[21] Treatment of the sodium salts with chlorine led to the synthesis of chloronitromalonamide,

chloronitroacetamide, fluorochloronitroacetamide, and ethyl fluoro-chloronitroacetate.[22] It was possible to obtain methyl α-bromo-α-nitropropionate and methyl α-bromo-α-nitro-β-phenylpropionate as well as ethyl α-bromo-α-nitrobutyrate in methanol solution.[23] When halogenation was carried out in a water–methanol solution, it was possible to increase the yields of ethyl dichloro- and bromo-chloro-nitroacetates.[24] Ethyl bromonitroacetate was synthesised in high yield in an alcohol–ether mixture.[25] Bromination of the potassium salts of dinitrodicarbonitriles in an ether–CCl_4 mixture at 0 °C gave a number of dibromodinitrodinitriles.[26,27]

$$\left[\begin{array}{cc} NO_2 & NO_2 \\ \| & \| \\ NCC(CH_2)_n & CCN \end{array}\right]^{2-} 2K^+ \xrightarrow[-2KBr]{2Br_2} NCCBr(NO_2)(CH_2)_nC(NO_2)BrCN,$$
$n = 2, 4, 6$.

The diastereomers were separated by fractional crystallisation from aqueous ethanol. α-Bromo-α-nitrobutyronitrile and α-bromo-α-nitrocapronitrile were obtained in a similar manner. Bromination of the dipotassium salt of α,α′-dinitroadiponitrile in an alkaline medium at the same temperature followed by acidification was accompanied by elimination of one nitrile group and hydrolysis of the other to an amide.[27] The same product is formed by alkaline hydrolysis of α,α′-dibromo-α,α′-dinitroadiponitrile.

$$\left[\begin{array}{cc} NO_2 & NO_2 \\ \| & \| \\ NCC(CH_2)_2 & CCN \end{array}\right]^{2-} 2K^+ \xrightarrow[-2KBr]{2Br_2} \begin{array}{cc} NO_2 & NO_2 \\ | & | \\ NCCBr & (CH_2)_2CBrCN \end{array}$$
$$\xrightarrow{1)\ Br_2,\ OH^-,\ 0°;\ 2)\ H^+\ 1)\ KOH\ aq.;\ 2)\ H^+}$$
$$O_2NCHBr(CH_2)_2CBr(NO_2)CONH_2$$

The bromination of $K^+[C_2H_5C(NO_2)CONH_2]^-$ and $[CH_2CH_2C(NO_2)CONMe_2]_2^-2K^+$ salts under similar conditions gives the corresponding α-bromo-α-nitroamides, while the potassium salt of *N,N*-dimethylnitroacetamide is converted to a dibromo-substituted product. Formation of the latter is accounted for by the following scheme:[28]

$$K^+[O_2N{=}CHCONMe_2]^- \xrightarrow[-KBr]{Br_2} O_2NCHBrCONMe_2 \xrightarrow[-O_2NCH_2CONMe_2]{K^+[O_2N=CHCONMe_2]^-}$$
$$\rightarrow K^+[O_2N{=}CBrCONMe_2]^- \xrightarrow[-KBr]{Br_2} O_2NCBr_2CONMe_2.$$

Bromination of the sodium salt of ethyl α-nitro-β-hydroxypropionate has been reported.[25]

$$Na^+[O_2N{=}C(CH_2OH)CO_2Et]^- \xrightarrow[-NaBr]{Br_2} O_2NCBr(CH_2OH)CO_2Et.$$

Ethyl dibromonitroacetate was obtained when the mercury salt of ethyl nitroacetate was treated with bromine.[29] Treatment of the Na and K salts of dinitroacetonitrile with equimolar quantities of chlorine fluorosulphate gives chlorodinitroacetonitrile.[30]

$$[NC(NO_2)_2C]^-M^+ + ClOSO_2F \xrightarrow[-MCl]{} NC(NO_2)_2CCl.$$

When a twofold excess of chlorine fluorosulphate is used, a product derived from addition to the C≡N bond is formed, and this undergoes methanolysis to give methyl chlorodinitroacetate.[30] The fluorinated analogue of a chlorodinitroimidate is obtained by reaction between fluorodinitroacetonitrile and chlorine fluorosulphate.

$$[C(NO_2)_2CN]^-Na^+ + 2\,ClOSO_2F \rightarrow ClC(NO_2)_2C(NCl)—OSO_2F \xrightarrow{MeOH}$$
$$\rightarrow ClC(NO_2)_2CO_2Me,$$
$$FC(NO_2)_2CN + ClOSO_2F \rightarrow FC(NO_2)_2C(NCl)—OSO_2F.$$

Reaction of chlorine fluorosulphate with ethyl dinitrocyanoacetate leads to replacement of the CN group by Cl:

$$NCC(NO_2)_2CO_2Et + ClOSO_2F \xrightarrow{-20\ to\ -30°} ClC(NO_2)_2CO_2Et.$$

A halogenation method using *N*-chloro- or *N*-bromo-succinimide is also known.[31]

$$O_2NCH(Me)CO_2Et \xrightarrow[dioxan–water]{O,\ argon} O_2NCCl(Me)CO_2Et.$$
70%

Fluorination of alkali salts of carboxylic acid nitro derivatives has been used less frequently. Fluorodinitroacetate esters are formed when salts of dinitroacetate esters are treated with fluorine over KF. Under the same conditions nitroacetate esters give a mixture of three products.[32]

$$[O_2N{=}CHCO_2Et]^-Na^+ \xrightarrow[-NaF]{F_2} O_2NCF_2CO_2Et + O_2NCHFCO_2Et +$$
$$+ O_2NCH_2CO_2Et.$$

This process results from the intermediate formation of the sodium salt of fluoronitroacetate ester and its reaction with fluorine.

$$[O_2N{=}CHCO_2Et]^-Na^+ + O_2NCHFCO_2Et \rightarrow O_2NCH_2CO_2Et +$$
$$+ [O_2N{=}CFCO_2Et]^-Na^+,$$
$$[O_2N{=}CFCO_2Et]^-Na^+ \xrightarrow[-NaF]{F_2} O_2NCF_2CO_2Et.$$

When similar conditions are used over CaF_2 fluorodinitroacetonitrile is obtained in 70% yield,[33] having been synthesised previously in low yield when an aqueous solution of the potassium salt of dinitroacetonitrile was treated with F_2.[34]

Fluorination of the potassium salt of ethyl dinitroacetate with a mixture of fluorine and nitrogen gave ethyl fluorodinitroacetate with a small amount of fluorodinitromethane.[35]

$$[(O_2N)_2CCO_2Et]^-K^+ \xrightarrow{F_2} (O_2N)_2CFCO_2Et + (O_2N)_2CHF.$$

Fluoronitromalonate ester is obtained by fluorination of the potassium salts of oximes with perchloryl fluoride[36]

$$KON{=}C(CO_2R)_2 + FClO_3 \rightarrow O_2NCF(CO_2R)_2.$$

The ammonium salts of dinotroacetamides are converted to fluorinated products in low yield.[37,38]

$$[(O_2N)_2CCONH_2]^-NH_4^+ \xrightarrow{FClO_3} (O_2N)_2CFCONH_2,$$
5.6%
$$[(O_2N)_2CCONHEt]^-\overset{+}{N}H_3Et \xrightarrow{FClO_3} (O_2N)_2CFCONHEt.$$
14%

Fluorination of dinitronitrile salts in Cellosolve gives a product from fluorination and addition to the C≡N group. It is thought that the process takes place via the formation of dinitrofluoroacetonitrile.[38]

$$[(O_2N)_2CCN]^-Na^+ \xrightarrow{FClO_3} [(O_2N)_2CFCN] \xrightarrow{HOCH_2CH_2OMe}$$
$$\rightarrow (O_2N)_2CFC(NH)—OCH_2CH_2OMe.$$

The potassium salts of nitroacetic acid derivatives can be fluorinated with both fluorine and perchloryl fluoride[39]

$$[O_2N{=}CRCO_2R']^-K^+ \xrightarrow{F_2(FClO_3)} O_2NCFRCO_2R',$$
$R = H,\ SAr;\ R' = Et,\ PhCH_2$.

A satisfactory result was obtained when diethyl nitromalonate was fluorinated in DMF in the presence of sodium hydride.[40]

$$O_2NCH(CO_2Et)_2 + NaH + FClO_3 \xrightarrow{DMF} O_2NCF(CO_2Et)_2.$$

2. Nitration of halo-olefins

The synthesis of α-halo-α-nitrocarboxylic acids and their derivatives by nitration of halo-olefins with mixtures of nitric and sulphuric acids is a more versatile and practicable method.

$$X^1X^2C{=}CX^3X^4 \xrightarrow{HNO_3/H_2SO_4} O_2NCX^1X^2C(=O)Y,$$

X^1, X^2, X^3, X^4 = H, F, Cl or Br; Y = F, Cl, Br or OH.

Nitration of a number of halo-olefins with a small excess of a mixture of nitric and sulphuric acids in the molar ratio 1 : 1 at 15–60 °C results in the formation of α-halo-α-nitrocarboxylic acids or their chlorides in 35–85% yield.[41–46] Nitration of trichloroethylene, giving chloronitroacetyl chloride, is accompanied by the formation of chlorocyanogen, dichloroacetyl chloride, and pentachloroethane.[42,43] Fluorochloronitroacetic acid is obtained from symmetrical difluorodichloroethylene.[44] Nitration of $ClF_2CCCl{=}CCl_2$ and $F_3CCCl{=}CCl_2$ gives the acid chlorides $ClF_2CCCl(NO_2)COCl$ and $F_3CCCl(NO_2)COCl$. The accumulation of chlorine atoms at the "allyl" position of 1,1,2-trichloropropylene results in a competing reaction—the formation of trichloroacrylic acid.[45]

$$Cl_2C{=}CClCCl_2F \rightarrow Cl_2C{=}CClCO_2H.$$

For perchloropropylene this reaction becomes the main process. Nitration of tetrafluoroethylene and trifluorochloroethylene leads to difluoronitroacetic acid.[46] Under these conditions perchloroethylene is converted to trichloroacetyl chloride,[46] while 1-fluoro- and 1-bromo-2,2-dichloroethylene are converted to fluoro- and bromonitroacetyl chloride respectively.[47,48] The nitration of vinylidene chloride, which leads to nitroacetyl chloride, requires an excess of the olefin undergoing nitration and cooling to –5 to 0 °C.[49]

The use of a nitric–sulphuric acid mixture comprising 5–10% nitric acid and not containing radical species, according to EPR data, creates favourable conditions for conducting an ionic reaction. It was possible to carry out the nitration of perchloroethylene to dichloronitroacetyl chloride under these conditions and to increase the yield of fluoronitroacetic acid and difluoronitroacetic acid to 85 and 92% respectively.[50] 1,1-Dichloropropene, 1,1-dichloro-3-methylbutene, and 1,1,1-trichloro-3-methylbutene have been nitrated using such a mixture.[51] Pure chloronitroacetyl chloride is obtained from trichloroethylene using a nitration mixture prepared from 60% HNO_3 and oleum.[52]

According to kinetic data, the rate of nitration is affected by the composition of the nitration mixture, the temperature, and the intensity of mixing.[53] A nitric acid content of 10–20% in the nitration mixture achieves the highest rate of reaction. According to the data of vibrational spectroscopy and ^{14}N NMR spectroscopy, at such a proportion HNO_3 is completely converted to a nitronium cation NO_2^+.[50,54–56] The process occurs at the phase boundary and can be given by a first-order equation (with respect to consumption of trichloroethylene and liberation of heat). The high value of the energy of activation (16.7 kcal mol^{-1}) indicates that a process with an ion-molecular mechanism is taking place. The proposed mechanism of ionic nitration appears to be a general one for the nitration of unsaturated compounds and is distinct from the nitration of aromatic compounds, which takes place with zero kinetic order with respect to the contents of the nitration mixture.[57–59] The process can be represented by the following scheme:[41,42,53]

$$ClHC{=}CCl_2 \xrightarrow{NO_2^+} [ClHC{=}CCl_2] \rightarrow [ClHC(NO_2){-}\overset{+}{C}Cl_2] \xrightarrow{H_2SO_4}$$
$$\rightarrow [ClHC(NO_2){-}CCl_2OSO_3H] \xrightarrow{-HOSO_2Cl} O_2NCHClCOCl.$$

The reaction starts with attack by the nitronium cation on the double bond (nitration with nitric acid gives trichloronitroethylene[60]). The carbocation formed is stabilised by the addition of bisulphate anion, and the subsequent elimination of chlorosulphonic acid gives chloronitroacetyl chloride.

3. Preparation of α-nitroperfluorocarboxylic acids from the products of nitration of fluoro-olefins with nitrogen dioxide

The hydrolysis and alcoholysis of 2-nitroperfluoroalkyl nitrites, obtained by nitration of perfluoroalkenes with nitrogen dioxide, is the most studied and most frequently used method for obtaining α-nitroperfluorocarboxylic acids and their derivatives.[6,61–70]

$$F_2C{=}CFX \xrightarrow{N_2O_4} O_2NCF_2CFXONO \rightarrow O_2NCF_2COF \rightarrow$$
$$\xrightarrow[(ROH)]{H_2O} O_2NCF_2COOH\,(R).$$

Difluoronitroacetic acid is formed by nitration of both perfluoroethylene and trifluorochloroethylene.[61] The process is a free-radical one. Reaction of 2-nitroperfluoroethyl nitrite with sulphuric or chlorosulphonic acid gives difluoronitroacetyl fluoride, which is also an intermediate in the hydrolysis and alcoholysis of 2-nitrotrifluoroethyl nitrite.[63]

$$O_2NCF_2CF_2ONO \xrightarrow{H_2SO_4,\ ClSO_3H} [O_2NCF_2CF_2OH] \rightarrow$$
$$\rightarrow O_2NCF_2COF \xrightarrow[(ROH)]{H_2O} O_2NCF_2CO_2H\,(R).$$

Hydrolysis and alcoholysis of nitroperfluoropropyl nitrite does not give the expected α-nitroperfluoropropionic acid or its esters but yields nitroperfluoroacetone hydrate or its hemiketals.[65] Difluoronitrothioacetic acid and difluoronitroacetate thioesters are also obtained when 2-nitrotetrafluoroethyl nitrite is treated with hydrogen sulphide or mercaptans.[68–70]

$$O_2NCF_2CF_2ONO + HSR \rightarrow O_2NCF_2COSR + HF + FNO.$$

Hydrolysis of the reaction products gives difluoronitroacetic acid.

Reaction of 2-nitronitrosotetrafluoroethane with hydroxylamine also gives difluoronitroacetic acid.[71,72] The reaction takes place with evolution of HF and N_2.[72,73]

$$O_2NCF_2CF_2NO + H_2NOH \rightarrow [O_2NCF_2CF_2N(OH)NHOH \xrightarrow{-H_2O}$$
$$\rightarrow O_2NCF_2CF_2N{=}NOH \xrightarrow{-N_2} O_2NCF_2CF_2OH \xrightarrow{-HF}$$
$$\rightarrow O_2NCF_2COF] \xrightarrow[-HF]{H_2O} O_2NCF_2CO_2H.$$

Alkaline hydrolysis of 2-nitronitrosotetrafluoroethane is accompanied by the formation of 1,2-dinitrotetrafluoroethane.[74]

$$O_2NCF_2CF_2NO \xrightarrow{OH^-} O_2NCF_2CO_2H + O_2NCF_2CF_2NO_2 + N_2 + F^-.$$

Difluoronitroacetyl fluoride is formed in small quantities during the nitration of perfluorobutadiene.[74]

$$F_2C{=}CFCF{=}CF_2 \xrightarrow{N_2O_4} O_2NCF_2CF{=}CFCF_2NO_2 \xrightarrow{N_2O_4} O_2NCF_2COF.$$

Difluoronitroacetic acid is isolated in the oxidation of 1,4-dinitro-1,1,4,4-tetrafluoro-2-butene. Addition of alkali gives difluoronitromethane.[76]

$$O_2NCF_2CH{=}CHCF_2NO_2 \xrightarrow[\text{KOH}]{H_2O,\ KMnO_4} O_2NCF_2COOH,\ O_2NCF_2H$$

Reaction of α-ethoxy-β-nitroperfluoropropane and α-ethoxy-β-nitroperfluoroisobutane with $AlCl_3$ followed by treatment with ethanol gives ethyl α-nitroperfluoropropionate and ethyl α-nitroperfluoroisobutyrate.[77,78]

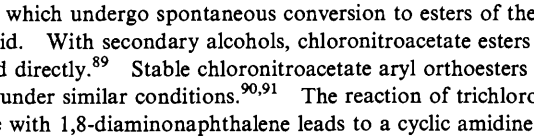
$$CF_3CX(NO_2)CF_2OEt \xrightarrow{AlCl_3} CF_3CX(NO_2)COX \xrightarrow{EtOH} CF_3CX(NO_2)CO_2Et,$$
$$X = F,\ CF_3.$$

Various esters and amides of α-halo-α-nitrocarboxylic acids are synthesised by esterification or aminolysis of acid halides or esters obtained by nitration of halo-olefins.[1,3,43,44,46–49,51,62–64,67,77–86]

4. Other methods for synthesising functional derivatives of α-halo-α-nitrocarboxylic acids

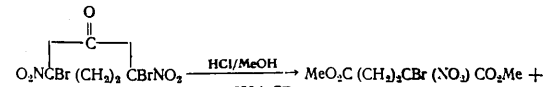
The prolonged passage of nitryl chloride through a cooled ether solution of ethyl diazoacetate yields ethyl chloronitroacetate.[82]

$$N_2CHCO_2Et + O_2NCl \rightarrow O_2NCHClCO_2Et.$$



Certain problems have arisen in the preparation of halo-nitroacetate aryl esters. Difluoronitroacetate phenyl esters are not formed from 2-nitrotetrafluoroethyl nitrite and they were obtained from difluoronitroacetyl chloride.[79] Because it was not possible to obtain bromo- and chloro-nitroacetate phenyl esters by esterification of acid chlorides or by transesterification of their alkyl esters, they were synthesised from the corresponding nitroacetate esters, which in turn were obtained by nitration of acetoacetate esters synthesised from phenol and diketene.[87]

$$CH_2{=}C(O){-}CH_2{-}C(=O) + HOPh \rightarrow CH_3COCH_2CO_2Ph \xrightarrow{HNO_2}$$
$$\rightarrow O_2NCH_2CO_2Ph \xrightarrow{X_2} O_2NCHXCO_2Ph$$
$$X = Cl \text{ or } Br.$$



Chlorination of α-nitrocarboxylic acid hydrazides or their derivatives gave chlorodinitroacetyl and α-chloro-α-nitropropionyl chlorides, which were converted to methyl esters.[81]

$$[O_2N{=}CRCONHNH_2]^-H_3^+NNH_2 \xrightarrow{Cl_2} O_2NCClRCOCl \xrightarrow{MeOH} O_2NCClRCO_2Me.$$

The reaction of α-oximinocarboxylate esters with nitrosyl chloride leads to a mixture of chloronitrocarboxylate esters and chloronitroso esters.[88] When ethyl α-chloro-α-nitrosopropionate and ethyl α-chloro-α-nitrosobutyrate are oxidised with peroxytrifluoroacetic acid, the corresponding α-halonitro esters are isolated in good yield.[88] Chloronitroacetamide is obtained by alkaline hydrolysis of chloronitromalonamide, while fluorochloronitroacetamide is obtained by aqueous hydrolysis of the intermediate fluorochloro-nitromalonamide.[22] When trichloronitroethylene is reacted with primary alkoxides, unstable orthoesters of chloronitroacetic acid are formed, which undergo spontaneous conversion to esters of the same acid. With secondary alcohols, chloronitroacetate esters are obtained directly.[89] Stable chloronitroacetate aryl orthoesters are formed under similar conditions.[90,91] The reaction of trichloronitro-ethylene with 1,8-diaminonaphthalene leads to a cyclic amidine.[92]

Treatment of cyclic α,α′-dinitroketone with a methanol solution of hydrogen chloride gives a mixture of dimethyl 2-bromo-2-nitro-glutarate and methyl 2,5-dibromo-2,5-dinitropentanoate.[93] It has been suggested that the first product is formed from the second by a modified Nef reaction.

Reaction of dichloro- and dibromo-nitroacetamides with PCl_5 gives a number of *N*-phosphorylated amides and imidoyl chlorides of dichloro- and dibromo-nitroacetates — $Cl_2C(NO_2)CONHPOCl_2$, $Cl_2C(NO_2)CONHPO(OEt)_2$, $Br_2C(NO_2)CONHPOCl_2$, $Cl_2C(NO_2)CCl{=}NPOCl_2$, and $Br_2C(NO_2)CCl{=}NPOCl_2$.[19]

When difluoronitroacetic acid is treated with SO_3, the mixed anhydride $O_2NCF_2COOSO_3H$ is formed, and it undergoes alcoholysis to give difluoronitroacetate esters.[94,95] The mixed anhydride synthesised by the reaction of 2-nitrotetrafluoroethyl nitrite with glacial acetic acid is converted on treatment with alcohols to acetates and difluoronitroacetic acid.[96,97]

α-Nitroperfluoropropionate esters are synthesised by oxidation of α-nitrosoperfluoropropionate esters.[78]

$$ONCF(CF_3)CO_2Et \xrightarrow{N_2O_5} CF_3CF(NO_2)CO_2Et.$$

Polyfluorinated alcohols deposited as a thin layer on the surface of inert supports (NaF or CaF_2) when treated with dilute fluorine (−15 to −10 °C) form a mixture of aldehydes and esters.[98]

$$O_2NCF_2CH_2OH \xrightarrow{F_2} O_2NCF_2CHO + O_2NCF_2CO_2CH_2CF_2NO_2.$$

Amidines[99] and oximes[100] are obtained by aminolysis of nitroperfluoroalkyl nitrites. Corresponding esters are synthesised when difluoronitroacetic anhydride is treated with dihydric alcohols.[101]

The silver[6] and mercury[102–104] salts of difluoronitroacetic acid are known. The former, in contrast to the latter is unstable on standing and is rapidly decomposed with water.

$$O_2NCF_2COOH + Ag_2CO_3 \rightarrow O_2NCF_2COOAg,$$
$$O_2NCF_2COOH + HgO[(CH_3COO)_2Hg] \rightarrow (O_2NCF_2COO)_2Hg.$$

III. The use of physicochemical methods for studying the structure and properties

1. Vibrational spectroscopy

It is infrared spectroscopy that is usually used to confirm the structure of synthesised α-halo-α-nitrocarboxylic acids and their derivatives.

An accumulation of electronegative substituents (NO_2, halogen, CN, COOR) results in a shift of the absorption bands of the nitro group to shorter wavelength. Alkyl substituents give the reverse effect (Table 1). This type of shift is also typical for absorption bands from the carbonyl group. The presence of alkyl groups on the α-carbon atom decreases the difference Δν between the absorption frequencies of asymmetric and symmetric stretching vibrations of the NO_2 group. In the IR spectrum of the mercury salt of difluoronitroacetic acid there are shifts of ν(CO) and $\nu_{as}(NO_2)$ to higher absorption frequency by ~150 and ~40 cm^{-1} respectively compared to the acid and its esters.[64,107] However, the existing data

Table 1. Wavenumbers of stretching vibrations (cm^{-1}) of α-halo-α-nitrocarboxylic acid derivatives.

Compound	NO_2, as	NO_2, s	C=O	Other functional groups	Refs.

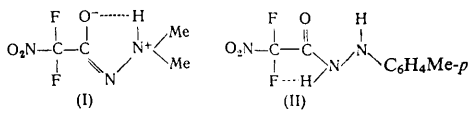
are not sufficient to make a reliable assessment of the mutual effect from the functional groups. Raevskii et al.[105] undertook such an assessment in the case of a number of chloronitroacetate esters. The absorption region of the "acidic" proton was established (C—H group, 2932—2965 cm^{-1}) from comparative data and the spectrum of the deutero analogue. The strong absorption band in the region 1774—1763 cm^{-1} corresponds to a stretching vibration of the C=O group. Polarised Raman lines correspond to the same regions. The absorption frequencies of $NO_{2,as}$ (1592—1589 cm^{-1}) and $NO_{2,s}$ (1352—1347 cm^{-1}) have been determined. The vibration frequencies of the NO_2 and CO groups differ from those of ethyl nitroacetate (1382, 1562, and 1745 cm^{-1}). The narrow intervals of three absorption bands at 740—726, 670—657, and 580—568 cm^{-1}, the constant ratio of their intensities, and the absence of other bands in these regions can be of use analytically as a spectroscopic characteristic of the chloronitro group (together with asymmetric NO_2).

2. NMR spectroscopy



In order to investigate the possibility of self-association and association with an oxygenated solvent, ^1H NMR spectra were obtained for a number of chloronitroacetate esters in a pure form and in solution.[83,108] The signals from the α-CH protons of the pure products appear as singlets downfield (δ 6.36—6.47, HMDS). In the spectra of the same esters in oxygenated solvents—acetone-d_6 and dimethyl sulphoxide-d_6—the "acidic" protons were displaced further downfield the higher the ε value of the solvent, which is related to the formation of hydrogen bonds in which the CH proton and the oxygen atoms of the solvents participate. This is supported by the dependence of the chemical shift on the concentration of solutions. The magnitudes of the chemical shifts of the CH protons give a poor correlation with pK_a values in the series of chloronitroacetate esters.[108] The chemical shifts of the CH protons of chloronitroacetyl chloride (δ 6.67, TMS),[52] chloronitroacetamide (δ 6.56, 50% CD_3CN), and ethyl chloro- and bromo-nitroacetates (δ 6.56 and 6.66 respectively) were determined.[108] The ^{13}C NMR data of chloronitroacetyl chloride are: δ 90.33 p.p.m. (O_2NCHCl) and 161.78 p.p.m. (CO).[52] By studying the ^{13}C and ^{19}F NMR spectra of fluoronitroacetic acid, its propyl ester, and methyl chloronitroacetate, together with other halonitro and halonitroso compounds, it was demonstrated using mathematical calculations that the values of the chemical shifts give an unsatisfactory correlation with the sum of the Swain—Lupton constants (field constants) and correlate well with the charges on the carbon atom, calculated using the RMX [? Ed. of Translation] method (correlation coefficient 0.978). In the case of ^{19}F NMR spectra the paramagnetic contribution to the magnetic shielding constant is important.[109] The signal in the ^{19}F NMR spectrum of the mercury salt of difluoronitroacetic acid is displaced downfield relative to the spectra of other derivatives of this acid. This phenomenon, together with the IR spectroscopy data (see above), indicates that there is a strong donor-acceptor interaction between the Hg atom and the $O_2NCF_2COO_2$ group, with the Hg atom acting as an electron acceptor.[102]

3. Other methods

In order to confirm the structure of chloronitroacetic acid derivatives and to study their reactivity and reaction mechanism, use has been made of mass spectrometry,[52,83,107] EPR specroscopy,[83] calculation methods,[108,111] and electron-diffraction[112] and thermographic[113] methods. X-Ray diffraction analysis was used to study the structure of *aci*-ethyl chloronitroacetate[114] and *aci*-chloronitroacetamide anions.[115] The $O_2^-N{=}CClCOOC_2H_5$ anion is perfectly planar, while the $O_2^-N{=}C^1ClC^2ONH_2$ anion is almost planar. The lengths of the C—Cl bonds (1.711 and 1.713 Å respectively) have values that are intermediate between the bond lengths of C(sp^2)—Cl (1.72 Å) and C(arom)—Cl (1.70 Å).[116] Formally the N=C double bond (1.45 and 1.334 Å) is considerably longer than normal double bonds.[116] The length of the C=O bond in the ester anion is normal while in the amide anion it is extended (1.259 Å). Formally the N—C(2) single bond (1.323 Å) in the amide anion is formally shorter than an N = C double bond. The

C(1)–C(2) (1.465 Å) and N–C(2) bonds are very much shorter compared to single bonds (1.541 and 1.472 Å).[116] The distribution of bond lengths and the planarity of the anions indicate that conjugation occurs in them.

Difluoronitroacetic acid *N,N*-dimethylhydrazide has the zwitterion structure (I). In the case of aryl-substituted hydrazides, a form with a CF–HN hydrogen bond (2) occurs.[80,117]

(I) (II)

4. Acid-base properties

The introduction of chlorine atoms into molecules of nitrocarboxylic acid derivatives gives rise to a significant increase in CH-acidity (Table 2).[108,118–120] The introduction of fluorine atoms, on the other hand, reduces the acidic properties. This phenomenon is due to the destabilising effect of fluorine in the planar anion of the *aci*-form of the nitro compound, which manifests itself as "anticonjugation" (α-effect through the C=N double bond). This effect must assist the carbanion in adopting a pyramidal structure, which would lead to a partial disruption of conjugation, in other words, to destabilisation of the anion.[120] The planar configuration of the anions of ethyl chloronitroacetate and chloronitroacetamide to a certain extent confirms such a hypothesis.[114,115] An X-ray diffraction study of anions of α-fluoronitroalkanes or fluoronitroacetic acid derivatives would help to answer this question.

Table 2. CH-Acidity of α-halonitrocarboxylic acid derivatives (water, 25 °C).

Compound	pK_a	Refs.	Compound	pK_a	Refs.
$O_2NCH_2CO_2C_2H_5$	5.82	[121]	$O_2NCHClCO_2(CH_2)_2CH_3$	4.21	[108]
$O_2NCHFCO_2C_2H_5$	6.28	[118]	$O_2NCHClCO_2(CH_2)_3CH_3$	4.23	[108]
$O_2NCHClCO_2C_2H_5$	4.16	[118]	$O_2NCHClCO_2CH(CH_3)_2$	4.37	[108]
$O_2NCH_2CONH_2$	5.18	[118]	$O_2NCHClCO_2CH_2C(CH_3)_3$	4.32	[108]
$O_2NCHFCONH_2$	5.89	[118]	$O_2NCHClCO_2CH_2CH(CH_3)_2$	4.21	[108]
$O_2NCHClCONH_2$	3.60	[118]	$O_2NCHClCO_2CH(CH_3)CH_2CH_3$	4.42	[108]
$O_2NCHClCO_2CH_3$	4.02	[108]	$O_2NCHClCO_2CH_2CH_2Cl$	3.92	[108]

The nature of the alkyl substituent in the ester group has a weak effect on the change in CH-acidity in a series of chloronitroacetate esters.[108] A satisfactory relationship has been found between pK_a values and the Taft σ* constants of substituents for eight chloronitroacetate esters $O_2NCHClCOOR$ (R = Me, Et, Pr, Bu, iso-Bu, neopentyl, sec-Bu):[108] $pK_a = 3.98 - 1.94\sigma^*$; n = 8, $r = 0.98$, $s = 0.03$; $F = 143.5$. The acidic properties of α-bromo-α-nitrocarboxylic acid derivatives are not known. Determination of the dissociation constants showed that difluoronitroacetic acid is a stronger acid than trifluoroacetic acid (K_a 9.7 × 10^{-1} and 5 × 10^{-1} respectively).[62]

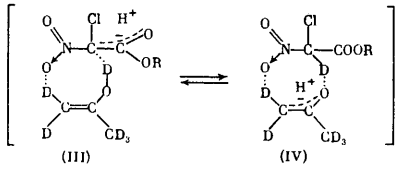
In terms of proton-donor properties the C–H bond of chloronitroacetate esters considerably surpasses the C–H bond in chloroform, acetylene derivatives, *o*-carborane, and it resembles the N–H bond.[105] Calorimetry was used to establish the proton-donor capacity of ethyl chloronitroacetate, which exceeds that for chloroform by a factor of 1.5. The thermodynamic constants of the hydrogen bond with trimethyl phosphate were determined and the enthalpy and autoassociation constant of this ester in CCl_4 were calculated.[122] The *P*-factor of methyl chloronitroacetate proved to be equal to the *P*-factor of *N*-methylaniline.[105] In the case of the reaction between ethyl chloronitroacetate and phenol in CCl_4 it was shown using IR spectroscopy that the electron-donor capacities of the CO and NO_2 groups were approximately equal and reduced by the mutual effect of the electronegative groups.[105]

IV. Chemical properties

1. Reactions involving the α-CH proton

As aliphatic nitro compounds that contain an active hydrogen atom at the α-position relative to the nitro group, α-halo-α-nitrocarboxylic acid derivatives react with bases to form salts of nitro compounds

$$O_2NCHXCOR \xrightarrow{:B} BH^+O_2^-N{=}CXCOR,$$



R—residues from alcohols, amines, etc.

Despite the frequent use of these salts in synthesis,[12–14,22,23,25,43,48,106,122] their stability on standing has hardly been discussed at all. Some chloronitroacetic acid derivatives, in particular the salts mentioned above,[114,115] do not decompose over a period of 1–2 months.[107] The sodium salt of benzyl chloronitroacetate[106] (5–10 g) can be stored at room temperature for 2–3 months without decomposition. Other derivatives are stable from several hours up to several days. On the whole, compounds such as salts of aliphatic nitro compounds cannot be stored for a long period because of their tendency to undergo spontaneous decomposition.

Bromo- and chloro-nitroacetate esters readily undergo the Henry reaction with aldehydes in the presence of calcium hydroxide[43] or potash.[48] The use of sodium acetate as a catalyst increased the yield of α-chloro-α-nitro-β-hydroxycarboxylic acids.[106]

$$O_2NCHXCO_2R \xrightarrow{R^1CHO} O_2NCXCO_2R,$$
$$\quad\quad\quad

suggested that deuterium exchange takes place via the highly unstable eight-membered transition states (III) and (IV).

(III) (IV)

Deuterium exchange takes place by a mechanism involving the concerted "departure" of a proton via the COOR group of (III) or the CO group of acetone in (IV) and arrival of a deuterium ion via the NO_2 group,[108] which is borne out to a certain extent by the approximately equal electron-donor capacities of the CO and NO_2 groups in chloronitroacetate esters.[105] Since a correlation exists between $T_{1/2}$ and the Taft σ^* constants of unbranched substituents, this type of deuterium exchange can serve as a method for measuring the relative mobility of protons in CH-acids.

The involvement of calculation methods for determining the charge distribution in anions that are formed by deprotonation of chloronitroacetate esters made it possible to propose an almost planar structure for the anion,[108] which was subsequently confirmed by X-ray diffraction analysis.[114]

2. Reactions involving the C—Hal bond

The presence of a nitro group at the α-position relative to a bromine atom activates the latter in a reaction with aqueous hydrazine. Diethyl bromonitromalonate is reduced more rapidly than diethyl bromomalonate.[123]

$$O_2NCBr(CO_2Et)_2 + H_2NNH_2 \rightarrow O_2NCH(CO_2Et)_2 + N_2 + HBr,$$
$$BrCH(CO_2Et)_2 + H_2NNH_2 \rightarrow CH_2(CO_2Et)_2 + N_2 + HBr.$$

The nitro group has a lesser effect on the mobility of halogen atoms in this reaction than keto or carbethoxy groups, as can be seen from the examples of the reduction of hydrazine hydrate given below.[13]

Halogen is reduced	Halogen is not reduced
$RCOCHClCO_2Et$, $RCOCRClCO_2Et$, $RCOCCl_2CO_2Et$, $CHCl(CO_2Et)_2$, $RCCl(CO_2Et)_2$, $CCl_2(CO_2Et)_2$	$O_2NCHClCO_2Et$, $O_2NCRClCO_2Et$, $O_2NCCl_2CO_2Et$

This is also confirmed by the ready reduction of ethyl bromonitroacetate, in contrast to bromonitroethane.

Bromonitrocarboxylate esters are reduced more readily than their chlorine analogues. Thus, ethyl α-chloro-α-nitropropionate and ethyl α-chloro-α-nitrobutyrate are not reduced, in contrast to their bromine analogues.

Esters of chloro-, bromochloro- and fluorochloro-nitroacetic acids when reacted with triphenylphosphine in benzene—methanol solution replace a bromine or chlorine atom with a hydrogen atom.[24] A change to a benzene medium reduced the yield of ethyl nitroacetate from ethyl chloronitroacetate from 71 to 20%.

$$O_2NCX_2COOR \xrightarrow[\text{benzene}]{Ph_3P,\ MeOH} O_2NCHXCOOR + Ph_3PO + Ph_3PO\cdot HX,\ X = H,\ Cl \text{ or } Br.$$

Hydrodechlorination of bromo- and chloro-nitroacetate esters can take place when sodium dithionite is used in aqueous alcohol.[86]

$$O_2NCHXCOOR \xrightarrow{Na_2S_2O_4} O_2NCH_2COOR.$$

3. Reactions involving the carboxyl group

Fluoronitroacetic,[50] difluoronitroacetic,[61,62] and fluorochloronitroacetic[44] acids have been obtained in a pure form. Difluoronitroacetic acid is stable in aqueous solution.[61,62] The remaining α-halo-α-nitrocarboxylic acids have only been determined as derivatives: esters, amides, acid chloride, etc. Bromo- and chloro-nitroacetic acids were determined in ether solution using IR spectroscopy.[86]

Table 3. Decarboxylation of α-halo-α-nitrocarboxylic acids and their chlorides to nitroso compounds or oximes.

A large number of studies have been devoted to the decarboxylation of α-halo-α-nitrocarboxylic acids as a method for obtaining various halonitro-, halonitroso-, and halonitronitrosoalkanes.[44,52,66,124–132] Depending on the nature of the acid and reagents and the temperature of the medium, α-halo-α-nitrocarboxylic acids (or their acid chlorides) form halonitro, halonitroso, or halonitronitroso compounds (Tables 3 and 4). The conversion of α-nitro-α,β-dichloro-β,β-difluoropropionyl chloride to chloronitromethane when treated with water[124] is accounted for by the following reaction scheme:

$$ClCF_2CCl(NO_2)COCl \rightarrow ClCF_2CClNO_2^- \xrightarrow[-Cl^-]{} CF_2{=}CClNO_2 \xrightarrow{H_2O} \rightarrow HOCF_2CHClNO_2 \xrightarrow[-HF]{} FCOCHClNO_2 \xrightarrow[-HF]{H_2O} \rightarrow O_2NCHClCOOH \xrightarrow[-CO_2]{} O_2NCH_2Cl.$$

There is no common view on the mechanism of decarboxylation of α-nitrocarboxylic acids and their derivatives.[52,124,125] Evidently the solvating capacity and polarity of the reaction medium as well as the nature of the nitrocarboxylic acid and other reactants affect the course of the reaction and the nature of the products.

In effectively solvating polar media, *aci*-nitrocarboxylic acid is formed, undergoing decarboxylation.

$$HO_2N{=}CRCOOH \xrightarrow{-CO_2} HO_2N{=}CHR \rightarrow O_2NCH_2R.$$

Depending on the nature of the radical R, the decarboxylation product can be converted to a nitro compound or, after protonation, dehydration, and addition of an anion, to a nitroso compound (or oxime).

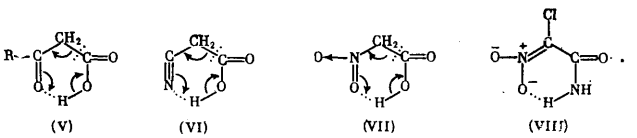
$$HO_2N{=}CRR' \rightleftharpoons O_2NCHRR'$$
$$\downarrow HCl$$
$$HO\diagdown \overset{+}{N}{=}CRR'Cl^- \xrightarrow{-H_2O} O{=}NCClRR'$$
$$HO\diagup$$

The course of the reaction will most likely be mainly affected by the lifetime of the *aci*-nitro compound and its concentration. The amount of *aci*-form is known[133] to vary according to the series (%): CH_3NO_2 (0.000011) < $C_2H_5NO_2$ (0.0085) < iso-$C_3H_7NO_2$ (0.275).

The presence of the electronegative substituents COOH, COOR, or halogens at the α-position of nitroalkanes evidently substantially reduces the percentage of the *aci*-form. This can explain the conversion of salts of 2-nitropropane, nitrocyclohexane,[131] and ethyl nitroacetate[134] to the corresponding chloronitroso compounds on treatment with anhydrous HCl in ether and the absence of such a reaction for diethyl nitromalonate, nitroform,[131] and ethyl chloronitroacetate.[52]

In weakly solvating nonpolar media, where the probability of a sufficiently long lasting protonated nitro group is low, an intermolecular redox decarboxylation can take place.[52,125]

$$O_2NCHClCOCl \xrightarrow[\text{base}]{\text{acid or}} \left[O{=}\overset{+}{N}{-}CHCl \;\rightleftharpoons\; O{=}\overset{+}{N}{-}CHCl \right] Cl^- \xrightarrow{-CO_2}$$
$$\longrightarrow ONCHCl_2 \longrightarrow HON{=}CCl_2.$$



The course of the reaction is evidently also affected by the temperature, phase state, and steric and other factors. For example, difluoronitroacetic acid, as one of the strongest organic acids, can act as a base towards stronger acidic reagents.

Esters are apparently decarboxylated in the same way as acids. Thus, ethyl esters of chloro- and dichloro-nitroacetic acid,[132] and also of difluoronitroacetic acid[131] when reacted with hydrochloric acid form the corresponding halonitromethanes. Ethyl perfluoronitropropionate is converted under similar conditions to α-chloroperfluoronitrosoethane.[78]

$$O_2NCF(CF_3)CO_2C_2H_5 \xrightarrow{HCl} ONCFClCF_3 + EtOH + CO_2 + H_2O.$$

Since the values of the dissociation constants of trifluoro- and trichloro-nitroacetic acids are comparable and the stability of the former is higher, the greater stability of difluoronitroacetic acid compared to other α-nitrocarboxylic acids can be accounted for by the electron-donor properties of fluorine atoms. A series of acid stabilities has been put forward:[135] O_2NCF_2COOH > $O_2NCFClCOOH$ > $O_2NCHFCOOH$ > O_2NCH_2COOH > $O_2NCHClCOOH$.

Decarboxylation of α-substituted carboxylic acids results from the formation of six-membered transition states (V)–(VII) [136]

(V) (VI) (VII) (VIII)

The stability functions of such transition states will be mainly the planarity and solvation. In the case of fluorinated nitroacetic acids, there is evidently an affect from the same factors that determine CH-acidity, that is, repulsion beween the *p*-orbitals of the fluorine atom and the π-systems involving the central carbon atom, nitro group, and carboxyl group (covalent radii F 0.64, Cl 0.99, Br 1.14 Å). In other words, the fluorine atoms inhibit the formation of a planar six-membered transition state and thus inhibit the decarboxylation of fluoronitroacetic acids. It appears that proton solvents can form such a transition state through hydrogen bonding, as a result of which fluoro- and fluorochloro-nitroacetic acids, which are stable in a pure form, are readily decarboxylated in water. As was mentioned above, anions of chloronitroacetic acid derivatives are planar,[114,115] and evidently as a result of this, chloronitroacetic acid is readily decarboxylated. The anion of chloronitroacetamide (VIII) has a structure which resembles the hypothetical transition states (V)–(VII), which to a certain extent is an argument in favour of their possible formation.

Esterification of α-halo-α-nitrocarboxylic acid chlorides with aliphatic alcohols occurs in the normal way. However, it is better to obtain benzyl chloronitroacetate[83] by using sodium benzylate in benzyl alcohol in order to avoid decomposition of benzyl chloronitroacetate with HCl that is formed during the reaction.

$$O_2NCHClCO_2CH_2Ph \xrightarrow{HCl} O_2NCHClCOOH \xrightarrow{-CO_2} O_2NCH_2Cl.$$

By reacting chloronitroacetyl chloride with benzenediazonium chloride, the α-chloro derivative of nitroformaldehyde phenylhydrazone is formed in high yield[137]

$$O_2NCHClCOCl \xrightarrow{NaHCO_3,\ H_2O,\ PhN_2^+Cl^-} O_2NCCl{=}NNHPh.$$

However, there is no conclusive evidence in this study that benzenediazonium chloride reacts with disodium chloronitroacetate $2Na^+[O_2N{=}CClCOO]^{2-}$ rather than the sodium salt of chloronitromethane $Na^+[O_2N{=}CClH]^-$ which is formed from it by decarboxylation.

Difluoronitroacetyl fluoride and chloride form various products with trimethylsilane.[138]

$$O_2NCF_2COF + HSiMe_3 \rightarrow O_2NCF_2CO_2CH_2CF_2NO_2 + FSiMe_3,$$
$$O_2NCF_2COCl + HSiMe_3 \rightarrow O_2NCF_2CH_2OSiMe_3 + ClSiMe_3.$$

Treatment of difluoronitroacetyl fluoride with methyltrichlorosilane gives difluoronitroacetyl chloride.[138]

$$O_2NCF_2COF + MeSiCl_3 \rightarrow O_2NCF_2COCl + MeSiFCl_2.$$

An attempt to obtain the mercury salt from fluorochloronitroacetic acid and mercuric oxide gave di(fluorochloronitromethyl)-mercury.[139,140] It was suggested that the reaction takes place via the mercury salt of fluorochloronitroacetic acid, which is unstable to decarboxylation, in contrast to the mercury salt of difluoronitroacetic acid.[102,104]

Alkyl difluoronitroacetates and difluoronitroacetyl halides undergo aminolysis with ammonia and aniline without complications, giving amides and anilidies.[62,77,78] Derivatives of other α-halo-α-nitrocarboxylic acids react in more than one way. On treatment with ammonia, ethyl perfluoronitropropionate decomposes to α-hydroperfluoronitroethane and urethane.[77,78]

$$O_2NCF(CF_3)COOEt \xrightarrow{NH_3} CF_3CHFNO_2 + H_2NCOOEt.$$

Reaction of ammonia with methyl α-chloro-α-nitrotrifluoropropionate at −30 °C gives an amide which is unstable at room temperature.[141] The presence of methyl carbamate in the reaction mixture is an indication that a haloform decomposition is taking place at the same time.

$$O_2NCCl(CF_3)COOMe + NH_3 \rightarrow O_2NCCl(CF_3)CONH_2 + H_2NCOOMe.$$

At room temperature haloform decomposition is the main process.

$$O_2NCFClCOOMe + Et_2NH \rightarrow CHFClNO_2 + Et_2NCOOMe,$$
$$O_2NCCl(CF_3)COOPr\text{-}n + NH_4OH \rightarrow H_2NCOOPr\text{-}n.$$

Reaction of ethyl bromo- and chloro-nitroacetates with aqueous ammonia at 50−60 °C leads to the ammonium salts, which are acidified to give the amides. Hydrazinolysis can be achieved over a period of days at room temperature.[107]

$$O_2NCHXCOOEt + H_2NR \rightarrow H_3\overset{+}{N}R[O_2N{=}CXCONHR]^- \xrightarrow{H^+} O_2NCHXCONHR,$$
$$X = Br, Cl;\ R = H, Me, NH_2.$$

When the temperature is increased to 80−100 °C, decomposition of the initial esters occurs with formation of ammonium halides. When bromo- and chloro-nitroacetate esters are treated with aqueous solutions of sterically hindered amines and also alcohol and ether solutions of ammonia or amines, ammonium salts are also formed. This occurs because of the instability of the ammonium salts of the nitro compounds formed, as a result of their insufficient solvation, and leads to elimination of halogen and subsequent decomposition of the nitroester.[107]

Reaction of methyl difluoronitroacetate with sodium borohydride gives a mixture of difluoronitroacetaldehyde and its hemiacetal.[142]

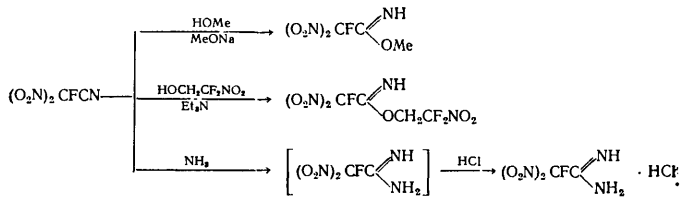
$$O_2NCF_2COOMe + NaBH_4 \rightarrow [O_2NCF_2\overset{O^-}{\overset{|}{C}}HOMe(BH_3Na)^+] \rightarrow$$
$$\xrightarrow{H_2O} O_2NCF_2CH(OH)OMe + O_2NCF_2CHO.$$

When diethyl fluoronitromalonate is treated with alcoholic alkali and subsequently acidified, fluoronitromethane is obtained.[40] It has been suggested that the disodium salt of fluoronitromalonic acid is formed as an intermediate.

$$O_2NCF(COOEt)_2 \xrightarrow{EtOH,\ NaOH} [O_2NCF(COONa)_2] \xrightarrow[H_2O]{ClCH_2COOH} O_2NCH_2F.$$

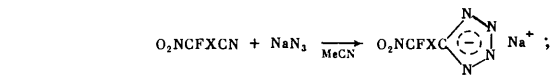
In contrast, for example, to nitroacetic acid, difluoronitroacetic acid is not fluorinated on treatment with SF_4, which is due to a combination of the electron-acceptor effect of the fluorine atoms on fluorination and the ease of undergoing decarboxylation.[143]

$$O_2NCF_2COOH \xrightarrow[130°C]{SF_4} O_2NCF_2CF_3,$$
$$O_2NCH_2CO_2H \xrightarrow{SF_4} O_2NCH_2CF_3.$$



The reaction of chlorine fluorosulphate with ethyl chlorodinitroacetic acid is accompanied by displacement of the carbethoxyl group.[30]

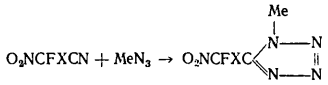
$$(O_2N)_2CClCOOEt + ClOSO_2F \rightarrow (O_2N)_2CCl_2.$$



The reaction of difluoronitroacetyl fluoride with acetone and methyl ethyl ketone results in the formation of 1,1-difluoro-1-nitropentane-2,4-dione and 1,1-difluoro-1-nitro-3-methylpentane-2,4-dione.

$$O_2NCF_2COF + RCH_2COCH_3 \rightarrow O_2NCF_2COCHRCOCH_3.$$
R=H, CH_3.

The presence of two nitro groups in fluorodinitroacetonitrile increases the electrophilic nature of the nitrile group. Reaction of this compound with alcohols gives imidates,[33,145] while with ammonia an amidine is formed.[33]



The reaction of difluoronitro- and fluorodinitro-acetonitrile with sodium azide is not so vigorous as for CF_3CN. This is because the nitro group shields the carbon atom of the nitrile group and hinders attack by azide ion.[146]

X = F, NO_2.

1,5-Disubstituted tetrazoles are synthesised by a reaction with methyl azide.[146] Reactions of trifluoroacetonitrile and chlorinated acetonitriles with MeN_3 take place with considerably greater difficulty, which is related to the strong electron-acceptor effect of the NO_2 group, which assists 1,3-cycloaddition.

By studying the kinetics of the addition of the radical $CH_3^{\cdot}$ to a number of perfluorocarbonitriles and α-nitroperfluorocarbonitriles in relation to the rate of elimination of H from iso-octane it was established that fluoronitronitriles are more reactive. Thus, O_2NCF_2CN adds on a methyl radical four times as fast, and $(O_2N)_2CFCN$ ten times as fast, as does CF_3CN. This phenomenon is due to the increased electrophilicity of the carbon atom of the nitrile group as a result of the strong electron-acceptor effect of the fluoronitro groups. The linear correlation of the ratio k_2/k_1 and σ^* indicates that the inductive effect mainly contributes to the reactivity of nitriles of this series towards a methyl radical.[147]

The mercury salt of difluoronitroacetic acid decarboxylates in the presence of strong bases.[102]

$$(O_2NCF_2COO)Hg \xrightarrow[or\ NaOH,\ H_2O]{Na_2CO_3,\ H_2O} O_2NCF_2H.$$

In ether it readily reacts with alkyl iodides and lower alkyl bromines.[102,103]

$$(O_2NCF_2COO)_2Hg + RX \xrightarrow[-HgCl_2]{ether} O_2NCF_2COOR + O_2NCF_2COOEt + ROEt,$$
$$R = Me, Et, Pr\text{-}n, Bu\text{-}n;\ X = Br, I.$$

The formation of ethyl esters as by-products, in quantities which increase as the activity of the alkyl halides decreases, occurs because

the salt undergoes reaction in solvated forms. With benzyl bromide and benzyl chloride the reaction takes place without by-products.

$$(O_2NCF_2COO)_2Hg + PhCH_2X \xrightarrow[-HgX_2]{ether} O_2NCF_2COOCH_2Ph.$$

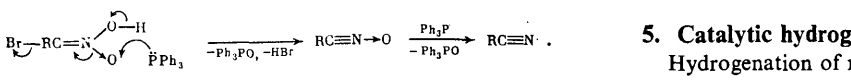
In acetonitrile alkylation is also unaccompanied by side-reactions. The reaction in THF mainly leads to ring-opening.[103,104] The quantity of decomposition products from THF rises as the strength of the acid increases.[103]

$$(RCOO)_2Hg + MeI \xrightarrow[-HgI_2]{THF} RCOOMe + RCOO(CH_2)_4OMe,$$
$$R=O_2NCF_2,\ CF_3,\ Me,\ 2,4,6\text{-}Cl_3C_6H_2OCH_2.$$

The explanation that side-reactions occur because of solvation is not entirely convincing. The overall logic of these studies[102–104] indicates that two independent processes are taking place under these conditions — alkylation of the salts with alkyl halides and decomposition of ether or THF by difluoronitroacetic acid derivatives formed during reaction.

4. Reaction of α-halo-α-nitrocarboxylic esters with trivalent phosphorus compounds

The reaction of α-halonitrocarboxylic acids with trivalent phosphorus compounds, as a special case of the reaction of aliphatic and alicyclic α-halo-α-nitro compounds with phosphines and phosphites, is the most characteristic feature of these compounds.[23,24,148–154] The reaction has been studied in the case of α-bromo- and α-chloro-nitro compounds. The products of the reaction between α-halonitro compounds and triphenylphosphine and triphenyl phosphite, as a rule, are of differing types.

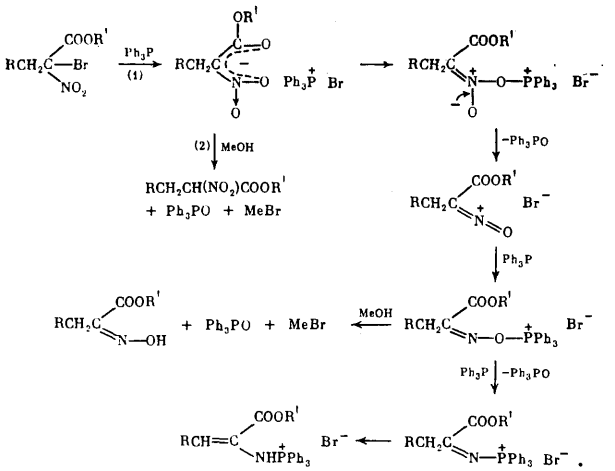


In a study of the reaction of triphenylphosphine with a number of α-bromonitro compounds it was found[148,149] that bromonitromethane and 1-bromo-1-nitroethane form quaternary salts which do not react with a further portion of triphenylphosphine.

$$Ph_3P + BrCRHNO_2 \rightarrow Ph_3\overset{+}{P}\text{—}CR{=}NO_2H\ Br^-.$$

At the same time, 1-bromo-1-nitropropane, ethyl bromonitroacetate, 1-bromo-1-nitro-octane, and bromonitrophenylmethane with twice the amount of triphenylphosphine give nitriles with yields of 63, 50, 72, and 75% respectively.

$$2Ph_3P + BrCRHNO_2 \rightarrow RC{\equiv}N.$$



In the opinion of Trippet and Walker,[149] in the latter cases attack by Ph_3P occurs on the oxygen atom of the nitrile group.

Subsequently, reaction of 1-bromo-1-nitroalkanes with twice the amount of Ph_3P gave salts of phosphonium-substituted oximes, whose structure was confirmed by elemental analysis and IR and ^1H NMR spectroscopy.[150]

$$2\,Ph_3P + BrCRHNO_2 \rightarrow Ph_3\overset{+}{P}CR{=}NOH\ Br^- + Ph_3PO,$$
$$R=H,\ Me,\ Et..$$

The various stages were studied in the case of the reaction of a number of α-bromo-α-nitrocarboxylate esters with triphenylphosphine, with determination of the intermediate and final products, which to a considerable extent clarified the reaction route.[23]

Chloro-, fluorochloro-, and dichloro-nitroacetate esters react with triphenylphosphine in a similar manner according to reactions (1) and (2).[24]

The reaction of bromo-, chloro- and fluorochloro-nitroacetic acids and α-chloro-α-nitrotrifluoropropionic acid with triethyl phosphite gives phosphorylated oximes.[151,153]

$$O_2NCRXCOOR' + (EtO)_3P \rightarrow (EtO)_2\overset{O}{\overset{\|}{P}}\text{—}O\text{—}N{=}CRCOOR'.$$

The same products are obtained by counter synthesis from the ammonium salts of *aci*-nitrocarboxylate esters and diethyl phosphorochloridite.[152]

$$(EtO)_2PCl + NH_4^+[O_2N{=}CXCOOR]^- \rightarrow (EtO)_2\overset{O}{\overset{\|}{P}}\text{—}O\text{—}N{=}CXCOOR,$$
$$X=H,\ Cl,\ Br.$$

Phosphoryloximes were obtained for the first time by Allen[154] in the reaction of triethyl phosphite with 2-chloro-2-nitropropane and 2-chloro-2-nitrosopropane.

Methyl diphenylphosphinite also reacts to form a phosphorylated oxime.[23] This reaction, in principle, is a link that connects the reactions of α-halo-α-nitro compounds with triphenylphosphine and trialkyl phosphites into a single whole.

5. Catalytic hydrogenation

Hydrogenation of methyl and ethyl chloronitroacetates over palladium catalysts gives glycine ester hydrochlorides.[86,113]

$$O_2NCHClCOOR + H_2 \xrightarrow[EtOH]{Pd} HCl \cdot H_2NCH_2COOR.$$

A study of the kinetics of the process using thermography showed[113] that the main quantity of hydrogen is absorbed at the initial stage. It is possible to conclude from the decrease in reaction heat effect and small absorption of hydrogen at high degrees of conversion that at 40–50 °C decarboxylation starts to play a significant role. This conclusion is also supported by the fact that carbon dioxide has been detected in excess hydrogen removed from the reaction. Decarboxylation may take place because of the accumulation of water and hydrogen chloride during reduction, which increases the probability of hydrolysis of the initial ester to chloronitroacetic acid. This is one of the possible reasons for the low yields of final products (up to 65%).

V. Physiological activity

Bromine- and chlorine-containing α-halonitroacetate esters acquire a yellow colour and sharp odour on standing as a result of partial decomposition. Methyl bromonitroacetate has an irritating effect on the eyes and cause irritation on skin contact.[10] According to the WHO classification, chloronitroacetate esters are classed as compounds with moderate and low hazards. For peroral administration to mice, the acute toxicity amounted to 830 to 2300 mg kg^{-1} (2.3–9.1 mmol kg^{-1}) and for skin application it was 6000–8100 mg kg^{-1}.[85,155] Introduction of additional halogen atoms into the different parts of the molecules of these compounds increases the toxicity by a factor of 3–10.[85] The toxicity of fluorochloronitroacetate esters is higher than for esters of chloro-, dichloro-, and bromochloro-nitroacetic acids.[156] In working with difluoronitroacetic acid and its derivatives it is recommended to use care because of the known toxicity of these compounds.[62,66]

Chloronitroacetate esters at concentrations of 0.5–3 μM increase the ionic permeability of mitochondria, in other words, they act as decouplers of oxidative phosphorylation. Their effective concentrations are 10–15 times higher than for the traditional decoupler—2,4-dinitrophenol.[155] At minimum concentrations they inhibit the activity of mitochondrial succinate oxidase.[155]

Propyl and butyl chloronitroacetates have insecticidal activity.[85] Various esters of the same acid have suppressed the growth of bacteria of fungal mycelia and also the development of plant diseases.[85] Growth-regulating activity has been found in them, according to the results of initial experiments.[85]

Fluorochloronitroacetate esters have an anti-choline esterase action.[84,156–158] The most active is the butyl ester. The bimolecular constants for irreversible inhibition (k_2) of acetyl- and butyryl-choline esterase are $(3 \pm 0.7) \times 10^{-4}$ and $(5.1 \pm 0.5) \times 10^{-5}$ litres mol^{-1} min^{-1} respectively.

The effect of chlorine- and fluorine-containing nitroacetate esters on the morphology of mouse liver has been studied.[159] α-Fluoro-nitrocarboxylic acid hydrazides inhibit monoamine oxidase and have hypotensive properties.[160]

—o0o—

During preparation of the manuscript for printing, a number of publications whose contents considerably complement the present review have appeared.

The bromination of nitroacetonitrile with bromine has been carried out without using bases.[161] Dinitroacetonitrile anion is almost quantitatively chlorinated on platinum, graphite, and ruthenium oxide-titanium anodes.[162] α-Fluoro-α-nitrocarboxylate esters can serve as initial reactants for the synthesis of various fluorine-containing synthons.[163] Nitration of symmetric difluoro-dichloroethylene and fluoro-1,2-dichloroethylene with a nitration mixture containing added SO_3 gives fluorochloro- and chloro-nitroacetyl fluorides respectively.[164] 1,1-Dichlorodifluoro-1,2-dinitroethane, in addition to difluoronitroacetyl chloride, is found amongst the products from the gas-phase nitration of 1,1-difluorodichloroethylene.[165] The conversions of alkyl fluoronitroacetates have been studied in Henry and bromination reactions.[166] Treatment of diethyl 2,5-dinitroadipate with excess aqueous KOBr gives diethyl 2,5-dibromo-2,5-dinitroadipate.[167] When treated with xenon difluoride, difluoro- and fluorochloro-nitroacetic acids can undergo halo- and nitro-decarboxylation.[168,169] The same system can be used for the halonitromethylation of benzene derivatives.[170–172] Primary and secondary amines can aminolyse methyl difluoro- and fluorochloro-nitroacetates.[173,174] Chloronitroacetic acid derivatives readily undergo sulphonation and dehalogenation with sodium sulphite, hydrosulphite, and dithionite.[175–178] Replacement of the chlorine atom is accompanied by oxidation of S(IV) to S(VI). Treatment of anhydrous ammonium salts of halonitroacetic acid derivatives with thionyl chloride gives the corresponding halo-oximinoacetic acid derivatives.[178,179] Chloronitroacetic acid derivatives coordinate with Cu(II) and Ni(II) ions.[180,181] The minimum negative charge on the chlorine atom in chloronitroacetic acid derivatives has been established using ^{35}Cl NQR and quantum-chemical calculations. The composition and molecular structures of chloronitroacetanilide,[183] dichloronitroacetamide,[184] bis(chloronitro-acetamidato)tetra-amminecopper(II),[185] and the hydrazine salt of 1-difluoronitroacetyl-2-acetylhydrazide[186] have been studied using X-ray diffraction analysis. On changing from esters to thioesters of fluorochloronitroacetic acid, their anti-choline esterase activity is markedly reduced.[187] Chloronitroacetamide has a retardant effect on wheat plants.[188] Detailed information on the synthesis and relationship between the hypotensive and anti-monoamine oxidase activities of difluoronitroacetic acid hydrazides has been published.[189–191] The synthesis of chiral α-substituted fluoronitro-acetates has been carried out and the racemates have been separated.[192–194] The absolute configuration of their optical isomers has been established by X-ray diffraction analysis.[195] The formation of isoxazoline-*N*-oxide from dibromonitroacetonitrile and tetramethylethylene has been reported.[196]

Extraction with thio and dithio phosphorus acids

I P Alimarin, T V Rodionova, V M Ivanov
Lomonosov Moscow State University

ABSTRACT. The main physicochemical characteristics of thio and dithio phosphorus acids—acid and redox properties, stability in solution, tautomerism, association and solubility in nonaqueous media, distribution in water–organic solvent systems—are reviewed. The effect of the structure of the reagents on their properties is analysed. The optimum conditions and chemical nature of extraction, the effect of substituents and diluents on the extract of metal dialkyldithiophosphates is discussed. Examples are given of the effective use of thio and dithio phosphorus acids for the separation of elements and the isolation of Cu, Hg(II), Tl(I), Sn(II), As(III), and Bi from other elements. The potential application of the extraction of elements with thio and dithio phosphorus acids is examined.

The bibliography includes 157 references.

I. Introduction

There is no standard nomenclature for dithio phosphorus acids. In the English literature dithio phosphorus acids are more frequently called dialkyldithiophosphoric acids or dialkyl dithiophosphates. The term "dialkyl dithiophosphates" emphasises that they are classed as partial esters of dithiophosphoric acid. Correspondingly for thio acids, the terms dialkylthiophosphoric acids and dialkyl thiophosphates are more widely used. In the German literature these reagents are called dithiophosphate esters. In the Russian literature the terms dialkyl- and diaryl-dithiophosphoric acids have become established, *O*,*O*-dialkyl- and *O*,*O*-diaryl-dithiophosphoric acids are to be found less often. In the Russian literature the term dialkyldithiophosphates relates to complex compounds such as nickel diethyldithiophosphate, etc. In this review we have used the terms dialkyl- and diaryl-dithiophosphoric acids and dialkyl- and diaryl-thiophosphoric acids respectively. Complex compounds of elements with these reagents are to be known as dialkyldithiophosphates.

The ability of complex compounds of metals with organic thio and dithio phosphorus acids to be extracted into various solvents was established back in 1949,[1,2] and in 1965 a review on the extraction of these complexes was published.[3] A large amount of material on the extraction of thiophosphates and dithiophosphates has been collected up to the present time and it requires classification. The range of extractants has been extended, the mechanism of extraction has been studied, and schemes for the separation of elements have been developed. In particular, the optimum conditions for extracting many elements with diethyldithiophosphoric acid (DEDTPA),[3–9] di-n-butyldithiophosphoric acid (DBDTPA),[5,6] diphenyldithiophosphoric acid (DPDTPA),[10] and di-2-ethylhexyldithiophosphoric acid (D2EHDTPA)[5,7] have been found. For the extraction of heavy metals, salts of dialkyldithiophosphoric acids have also been used; these contain alkali metals,[9,11] zinc,[12] and nickel.[12,13] Metal dialkyldithiophosphates are more stable than the corresponding acids both in aqueous solution and in organic solvents, and they are also more selective, so their future use is promising.

In addition, the possible use of full esters of dialkyldithiophosphoric acids—*O*,*O*,*S*-trialkyl dithiophosphates,[14–17]—amides,[28,29] bis(dialkyldithiophosphoryl) disulphide,[30] and other derivatives as extractants has been examined.

The use of the extraction of dithiophosphates in a large group of combined methods is of interest.

Almost all dialkyldithiophosphates do not absorb light in the visible or near UV region of the spectrum. This is the reason why extraction spectrophotometry has not been widely developed. Only the determinations carried out on different compounds of copper,[31,32] bismuth,[33,34] and palladium,[35,36] which are based on the ability of Cu(II), Bi(III), and Pd(II) dialkyldithiophosphates to absorb in the visible region of the spectrum, constitute an exception.

The extraction of dithiophosphates is used on a large scale in extraction polarography. By combining extraction with polarography it is possible to determine metals that are present together without initially separating them. Thus, for example, Zn, Co(II), and Ni dithiophosphates are co-extracted, but they can be determined separately by polarography in a benzene–ethanol mixture with 0.2 M $LiClO_4$ as the supporting electrolyte.[37] The polarographic properties of the diethyldithiophosphates of Zn, Cd, Sb(III), Bi(III), Cr(III), U(VI), Mn(II), Fe(II), Ni,[38] Cu(II)[39,40] Pb(II), ^{12}Fe(II)[41], and Pd[42] have been studied. Complexes of elements with full d^{10} shells give reversible polarographic waves in the solvent mixture benzene–ethanol.

The electrolytic oxidation of heteroligand complexes of Cu, Co(II), and Ni with diethyldithiophosphoric acid and bases—2,2′-dipyridyl, 1,10-phenanthroline, and aminopyridine[43,44]—has been studied. Extraction polarography has been widely applied; the main theoretical conclusions and practical recommendations for its use are covered in a review.[45]

The trends towards the use of dialkyldithiophosphoric acids in extraction atomic absorption analysis have been outlined. Elements are determined after their initial extractive or adsorptive concentration (on active carbon) as dialkyldithiophosphates.

Diethyldithiophosphoric acid has been used for extractive concentration of As, Sb, and Bi from industrial nickel electrolytes,[46] for concentration of Cd, Pb, and Bi from sea-water on active carbon,[47] and of Cu, Cd, In, Tl, and Bi in the analysis of metallic aluminium and gallium.[48] Dibutyldithiophosphoric acid is a good reagent for the combined extraction and adsorptive concentration from sea-water of Cu, Zn, Cd, Pb, and Bi, which are then determined by atomic absorption spectroscopy.[49,50]

The first studies on the use of dialkyldithiophosphates in high-performance liquid chromatography indicate that it is possible to use the most stable of them, for example, silver dialkyldithiophosphates,[51] for concentration and separation from associated ions.

The aim of the present review is to correlate the data on the extraction of dithio- and thio-dithiophosphates and to identify the most important aspects of using them in analytical chemistry and the ways of developing them further.

II. Properties of thio and dithio phosphorus acids

1. Acid properties

Thio and dithio phosphorus acids are quite strong acids.[11,52–57] Aqueous solutions of recrystallised dialkyldithiophosphates of alkali and alkaline earth metals have a pH of 7, and as salts of strong acids, they are virtually unhydrolysed.[54] An aqueous 0.109 M solution of DEDTPA has a pH of 1, $K_a = 2.4 \times 10^{-2}$. The potentiometric titration curve of an aqueous solution of DEDTPA against a solution of NaOH is characteristic of strong monobasic acids. The centre of rapid change in potential corresponds exactly to pH 7. Potentiometric titration curves of aqueous solutions of DEDTPA and H_2SO_4 with the same molarity against a solution of NaOH virtually coincide in form and magnitude of sudden change at the equivalence point.[11]

Substituents on the phosphorus atom have little effect on the pK_a values of dialkyldithiophosphoric acids.[56–58] It was found by pH titration of dithio acids in aqueous ethanol solutions containing 40 vol. % ethanol with a constant ionic strength of 0.3 (KNO_3) and at a temperature of 25 ± 0.1 °C that the pK_a values of dithio acids have virtually no dependence on the nature of the substituents, and they are equal to 2.00–2.25.[58] The lack of dependence of the acid strength on the structure of alkyl and alkoxyl groups has been confirmed by a determination of pK_a in aqueous isopropanol solutions containing 90 vol. % isopropanol (pK_a values vary from 2.75 to 2.85).[59] According to other results the pK_a values of acids that have different substituents do not remain constant. Thus, an increase in the length of carbon chain of the substituents leads to a reduction in the acid strength: for DEDTPA $pK_a = -1.10$, while for DBDTPA $pK_a = 0.22$.[62] In absolute ethanol and aqueous ethanol mixtures the solvation conditions are not the same, causing a variation in acid strength by a factor of almost $10^{2.5}$ [53,60] (Table 1). Moreover, the difference in acid strengths may partly be due to a change in function of the glass electrode in absolute ethanol. The pK_a values of some dithio acids have also been determined in other solvents—for aliphatic dithio phosphorus acids they range from 3.60 to 4.40 in benzene and from 2.30 to 2.90 in anisole.[63] Acids with cyclic substituents on the phosphorus atom in benzene ($pK_a = 1.90–3.23$) or anisole ($pK_a = 0.62$-1.65) are stronger than acids that contain aliphatic groups.[63,64]

The dissociation constants of some acids in the presence of different salts ($NaClO_4$, NaCl) were determined spectrophotometrically. It was recorded[65] that compounds containing $P(S)S^-$ have a maximum absorption at 225 nm. A study of the absorption spectra of potassium dibutyldithiophosphate in perchloric and hydrochloric acid in relation to the acidity of the aqueous solution showed that the intensity of light absorption at 225 nm decreases as the concentration of mineral acid increases; this is due to the equilibrium being shifted towards formation of the undissociated form (HA) of the acid. The undissociated form (HA) and the conjugated form—dibutyldithiophosphate ion (A^-)—have different molar absorption coefficients ($\varepsilon_{HA} = 3.9 \times 10^3$ and $\varepsilon_{A^-} = 4.15 \times 10^3$). The average molar absorption coefficients of DBDTPA at 225 nm in solutions of different acidity ($\mu = 1.0$; $NaClO_4$) are given below:[65]

c_{H^+}, M	1.03	0.72	0.31	0.185	0.103
$\bar{\varepsilon}$	4039	4062	4097	4116	4130 .

Table 1. Dissociation constants of dithio and thio phosphorus acids in aqueous ethanol solutions and in anhydrous ethanol.

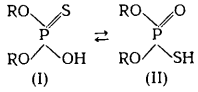
In $HClO_4$ the dissociation constant of DBDTPA is equal to −0.24 and in HCl it is equal to −0.09 (in pK_a units) (spectrophotometric determination).[65] These values are not in agreement with those found by the distribution method: 0.28 and 0.22 in $HClO_4$ and HCl respectively.[65,66] For dimethyldithiophosphoric acid (DMDTPA), $pK_a = -0.33$.[67]



2. Stability in solution

Dialkyldithiophosphoric acids can decompose in aqueous solution with elimination of H_2S and alcohol, but they are more stable than diethyldithiocarbamic acid and xanthic acid.[11] It is assumed that thio phosphorus acids in aqueous solution are hydrolysed on the thiol group. The salts of these acids in aqueous solution are more stable. Thus, the concentration of the sodium salt of DEDTPA remains constant (120 μg ml^{-1}) for a month, while there is 9% decomposition of DEDTPA during this time. In 1 M HCl the decomposition half-life of DEDTPA is 250 h[11] while in 10 M HCl it is 4.8 h. For comparison, diethyldithiocarbamic acid has a decomposition half-life of 1–2 h. DEDTPA decomposes

more slowly in sulphuric acid than in hydrochloric acid of the same concentration.[11,68] Diphenyldithiophosphoric acid does not decompose in neutral or acidic solutions over a period of two months.[69] The decomposition of dialkyldithiophosphoric acids is a first-order reaction. Dialkyldithiophosphoric acids are stable in organic solvents.[11]

3. Tautomerism

A tautomeric conversion of the thione form (I) ⇄ thiol form (II) is characteristic of thio phosphoric acids:[53]

(I) (II)

In aqueous solution the equilibrium is shifted towards the thiol form; in ethanol the thione form predominates.

4. Distribution in the system water–organic solvent

The behaviour of dithio acids in water–organic solvent systems has not been studied in sufficient detail and is only known for acids that are used as extractants. In particular, the extraction of diethyl–, diisopropyl-, di-n-butyl-, diisobutyl- and di-2-ethylhexyl-dithiophosphoric acids has been studied.[52,70] The acid distribution constants and the acidic dissociation constants have been determined in the system HCl–CCl_4 (Table 2). An increase in the length of the hydrocarbon group leads to some reduction in acidic properties, which is in agreement with other results;[62] this applies particularly to DEDTPA and D2EHDTPA (Table 2).

Table 2. Distribution constants and dissociation constants (in pK_a units) of some dialkyldithiophosphoric acids when $\mu = 1$ at 25 °C.[52,70]

Alkyl group	Solvent	$pH_{1/2}$*	$\lg K_D$	pK_a**
Ethyl-	Carbon tetrachloride	0.35	0.45	−0.10
Isopropyl-	"	1.89	1.90	0.00
n-Butyl-	"	2.70	2.52	−0.22
	Methyl isobutyl ketone	2.77	2.54	−0.25
	n-Amyl acetate	2.40	2.23	−0.18
Isobutyl-	Carbon tetrachloride	2.74	2.63	−0.10
2-Ethylhexyl-	"	4.17	5.42	−1.25
	n-Heptane	—	5.43	—
	Benzene	—	5.39	—

*$pH_{1/2} = pK_a + \log K_D$, where K_D is the distribution constant of dialkyldithiophosphoric acid (organic phase saturated with the aqueous phase and aqueous phase saturated with the organic phase); **K_a is acid dissociation constant in water saturated with the organic solvent.

The extraction of DBDTPA into CCl_4 decreases at an acid concentration of 6 M regardless of the nature of the mineral acid (HCl, HBr, H_2SO_4, $HClO_4$, HNO_3).[52] The effect of ionic strength on the distribution of dithio acids is complex in nature. For example, in the extraction of DBDTPA from solutions with a constant HCl content, the addition of NaCl initially leads to a reduction and then to a marked increase in distribution coefficient of the reagent.[52] Dithio acids are not extracted from weakly alkaline and neutral solutions; this is due to the formation of dithiophosphate anions. The extraction of DPDTPA from solutions of HCl, HNO_3, and H_2SO_4 has been studied. It is at a maximum when 2–7 M solutions are used. However, the distribution constants and dissociation constants have not been determined.[10] These values are generally difficult to determine separately for dialkyldithiophosphoric acids, therefore the ratio K_D/K_a, that is, the two-phase stability constant, is frequently determined (Tables 3 and 4).

Table 3. Logarithms of two-phase stability constants $\log(K_{D,HA}/K_{a,HA})$ of dithio phosphorus acids $(RO)_2P(S)SH$ in the system water–nonpolar organic solvent[71,72]

R	$\lg(K_{D,HA}/K_{a,HA})$ in

5. Polymerisation and solubility in nonaqueous media

Dialkyldithiophosphoric acids, in contrast to phosphoric acids, have no tendency to polymerise in nonaqueous media.[73] However, the association of dithio and thio phosphorus acids in nonaqueous solvents has not been studied in sufficient detail. It is known that DBDTPA does not form dimers or polymers in CCl_4, methyl isobutyl ketone, and amyl acetate.[52] It was also established by cryoscopy that there were no dimers or more complex associated forms of DEDTPA in benzene.[74] D2EHDTPA also does not polymerise in nonaqueous media.[74] An analysis of the IR spectra of DMDTPA and DEDTPA showed that in dilute solutions in CCl_4 these acids were present to a considerable extent as

monomers.[75]

On the basis of the results of a two-phase titration of DBDTPA and methylheptyldithiophosphoric acid (MHDTPA) in cyclohexane and dodecane, a solubility parameter was calculated, which can be applied to all acids with unbranched groups when the number of carbon atoms does not exceed eight.[76] Compounds with a P(S)SH group are characterised by a lower intermolecular interaction energy than the corresponding oxygen-containing compounds. Thus, dithio phosphorus acids have a lower tendency to dimerise through formation of intermolecular hydrogen bonds than, for example, dibutylphosphoric acid.[73] However, the high polarisability of the sulphur atoms assists the interaction of dithio acids with a polar solvent. Therefore, it may be assumed that it is possible to determine solubility parameters more accurately in a nonpolar solvent than in a polar one which is subject to the inductive effect.[76]

6. Redox properties

Dialkyldithiophosphoric acids exhibit reducing properties and are readily oxidised with mild oxidising agents such as iodine to form bis(dialkyldithiophosphoryl) disulphides $[(RO)_2P(S)S]_2$, which are solid, low-melting compounds that are slightly soluble in water.[77] For example, the solubility of bis(dimethyldithiophosphoryl) disulphide in water at 25 °C is 4×10^{-5} M.[78] When dithio acids are treated with chlorine, the following reaction occurs[79]

$$2\,(RO)_2P\begin{matrix}\diagup S\\ \diagdown SH\end{matrix} + 3\,Cl_2 \rightarrow 2\,(RO)_2P\begin{matrix}\diagup S\\ \diagdown Cl\end{matrix} + S_2Cl_2 + 2\,HCl.$$

Anions of dialkyldithiophosphoric acids are oxidised on dropping mercury and platinum electrodes. The half-wave potential for diethyldithiophosphate ion (10^{-3} M) is -0.062 V on a dropping mercury electrode (relative to a saturated calomel electrode) and $+0.696$ V on a rotating platinum microelectrode.[80]

Dialkyldithiophosphate ions and their oxidation products form reversible redox systems for which the Nernst equation is valid.[78] Their reduction takes place in accordance with the following equation:

$$(RO)_2P(S)S{-}{-}S(S)P(OR)_2 + 2e \rightleftarrows 2\,(RO)_2P(S)S^-.$$

The potential of a system containing dialkyldithiophosphate ions and their insoluble oxidation products is given by the following equation:

$$E = E_0 - 0.058 \lg a_{(RO)_2P(S)S^-}.$$

As bis(dialkyldithiophosphoryl) disulphides are only slightly soluble in water, their saturated solution can be readily obtained by the addition of small quantities of iodine or previously synthesised bis(dialkyldithiophosphoryl) disulphide to a solution of dithiophosphate ions. In practice there is no need to introduce the oxidation product of dialkyldithiophosphate since the platinum electrode maintains a constant potential even in freshly prepared solutions of dialkyldithiophosphates; this is probably due to the presence of traces of reagent oxidation products in them. The measurement of redox potentials by a balancing method in the circuit

$$Pt\,|\,KS(S)P(OR)_2\ (m)\ |\,[(RO)_2P(S)S]_2\ (s),\ 0.1M\ KCl\,\|\,0.1\ M\ KCl,\ Hg_2Cl_2\,|\,Hg$$

gave the following results:[78]

R	E_0, V	R	E_0, V
CH_3	+0.315	C_6H_{13}	−0.015
C_2H_5	+0.255	iso-C_3H_7	+0.196
C_3H_7	+0.187	iso-C_4H_9	+0.158
C_4H_9	+0.122	iso-C_5H_{11}	+0.086
C_5H_{11}	+0.050		

As the length of the carbon chain of the RO group increases, the redox potential of the acid decreases. Dithio acids with branched substituents and also with a long unbranched chain are oxidised with somewhat greater difficulty than dithiophosphates with a small unbranched carbon chain.

The redox potentials found from potentiometric titration of aqueous ethanol solutions of dithiophosphinic acids against a 0.1 M solution of I_2 in 40% ethanol at pH 6.5 (phosphate buffer solution) have been determined.[61]

III. Extraction with thio and dithio phosphorus acids

1. Reagents used and optimum extraction conditions

The use of DMDTPA as an extractant has been studied less than the others. It is the most soluble in water and passes into the organic phase less effectively than the other acids. Moreover, DMDTPA complexes with metal ions are the least stable and are fairly readily soluble. This is likely to account for the limited use of DMDTPA in extraction chemistry.

A study of the extraction of nickel dimethyldithiophosphate $Ni[S_2P(OCH_3)_2]_2$ with toluene from a 1 M solution of a mixture of $Na[S_2P(OCH_3)_2]$ and $NaClO_4$ showed that the distribution coefficients of the complexes were low and varied from -2 to $+1$ (in $\log K_D$ units).[67] In the system water–toluene the equilibrium stops after 30 min. In the opinion of Wingefors[67] the extraction of nickel dimethyldithiophosphate from weakly acidic solutions is effected because of the large value of the distribution constant of the complex ($\log K_{D,2} > 2$). The complex is not associated in the organic phase even when there is a large concentration of nickel in the initial aqueous solution.

DMDTPA forms a complex with palladium that is insoluble in water but soluble in CCl_4, diethyl ether, and chloroform[35] and which is suitable for the extraction and photometric determination of palladium. The same acid can be used to extract uranyl ions from 0.005–0.01 M $HClO_4$ into benzene, but the distribution coefficients of the complex are very low.[81]

The extraction of diethyldithiophosphates of copper,[13,82,83] silver and gold,[9,82,84,85] bismuth,[86] iron(III),[83] noble metals,[9] ruthenium and osmium,[9,87] and palladium[42,88] has been extensively studied. The extraction conditions using DEDTPA from 0.1–10 M solutions of HCl and 0.05–7.5 M H_2SO_4 into CCl_4 for many elements have been described.[9]

Elements of Groups I–III as well as Zn, V(III), V(V), Nb, Ta, Sn(II), Cr(III), and rare earth elements do not form sparingly soluble compounds with DEDTPA and are not extracted.

Copper(II) is quantitatively extracted from 0.1–5 M solutions of HCl or 0.05–6 M solutions of H_2SO_4,[9] as well as from weakly acidic and neutral solutions.[13] At pH 9 it remains almost completely in aqueous solution. This was used as a basis for the successive extraction of copper and silver with a solution of DEDTPA into CCl_4.[2] Copper diethyldithiophosphate was used for a photometric determination of copper.[83] Silver was completely extracted with DEDTPA from a 0.1–3 M solution of HCl into CCl_4.[9] In a more recent study[82] it was shown that it can also be extracted from less acid solutions up to pH 11. Depending on the ratio of the component concentrations, gold(III) forms different products with DEDTPA. Gold(I) is completely extracted from acid

and neutral media, so DEDTPA has been used in an extraction-atomic absorption determination of gold (and silver) in natural water.[85]

Alkaline earth elements and zinc do not form complexes that can be extracted with DEDTPA. Cadmium is incompletely extracted from 0.1 – 10 M solutions of HCl or 0.05 – 5 M solutions of H_2SO_4, but is completely extracted from media with pH 3.0 – 7.0, and in the presence of 2,2′-dipyridyl it is extracted at pH 6.5 – 8.5.[41] Mercury(II) is quantitatively extracted from 0.1 – 5 M solutions of HCl or 0.1 – 7.5 M H_2SO_4, while mercury(I) is reduced to the metal.[9] A more recent study[89] showed that mercury(II) is extracted from media containing 5 M HCl (or 8 M H_2SO_4) up to pH 7. In this case the complex exists in the organic phase in monomeric form.

Indium is not completely extracted with DEDTPA from a 0.1 M solution of HCl, and thallium(I) is only extracted to the extent of 5%. Thallium(I) is readily extracted from weakly acidic solutions,[9] and in the presence of 2,2′-dipyridyl it is extracted at pH 6.5 – 7.0.[45] Thallium(III) is reduced to thallium(I) by the reagent (sometimes the reduction takes place over several hours).[9]

Germanium(IV) is not extracted from 3 M solutions of HCl, while from solutions with a lower HCl concentration the extraction is not quantitative.[9] Tin(II) and tin(IV) are also incompletely extracted from 0.1 – 10 M HCl or 0.05 – 5 M H_2SO_4.[9] Lead(II) is extracted with DEDTPA from acid, neutral, and alkaline solutions.[9]

Arsenic(III) is quantitatively extracted with DEDTPA from weakly acidic and strongly acidic solutions while arsenic(V) is not extracted under these conditions. Antimony(III) is effectively extracted from 0.1 – 12 M solutions of HCl or 0.05 – 2.5 M H_2SO_4; antimony(V) in this case is first reduced and then extracted as the diethyldithiophosphate.[4,9] Bismuth diethyldithiophosphate is extracted over an acidity range from 5 M HCl (2.5 M H_2SO_4) to pH 2.5.[9,34,86]

Selenium(IV) and tellurium(IV) are extracted with DEDTPA from weakly acidic and strongly acidic solutions. Selenium(VI) is only extracted from strongly acidic solutions, probably being reduced initially to selenium(IV). Tellurium(VI) is only 60% extracted even from a 10 M solution of HCl.[9] Uranyl ions are extracted from 0.0005 – 0.01 M solutions of $HClO_4$ into benzene in the form of uranyl diethyldithiophosphate with very low distribution coefficients.[81]

Rhenium(VII) is extracted as its diethyldithiophosphate to the extent of 20% from a 0.1 M solution of HCl to which has been added a 15% solution of $TiCl_3$, whereas it is not extracted at all from 6 M HCl. From a mixture of potassium perrhenate – sodium diethyldithiophosphate — $SnCl_2$ containing 1 – 3 M HCl, rhenium is extracted with benzene, chloroform, diethyl ether, ethyl acetate, isoamyl acetate, and isobutanol.[9]

Iron(III) is quantitatively extracted at pH 2 – 3 while at lower pH values it is reduced to iron(II).[9] In order to prevent the reduction of iron(III) the extraction is carried out in the presence of H_2O_2. The distribution constant of iron(III) diethyldithiophosphate for passage of the latter into hexane is equal to 51.9.[83] At low concentrations cobalt(II) does not react with sodium diethyldithiophosphate in aqueous solution, but on extraction from solutions with a high cobalt concentration the extract changes to a green colour[4] which is characteristic of a complex of cobalt(III) with DEDTPA. Cobalt(II) diethyldithiophosphate in the extract is oxidised with atmospheric oxygen after several hours.[9] In the presence of 2,2′-dipyridyl, cobalt(II) is extracted with DEDTPA at pH 5.5 – 10.0.[45] Nickel(II) is incompletely extracted from 50% CH_3COOH with sodium diethyldithiophosphate.[4] The extraction becomes quantitative when the operation is repeated four times. In the presence of 2,2′-dipyridyl, Ni(II) is extracted at pH 0.5 – 2.0.[41]

Ruthenium(III) is extracted with carbon tetrachloride at room temperature in the presence of diethyldithiophosphate ions from a 0.1 – 10 M solution of HCl or a 0.05 – 7.5 M solution of H_2SO_4.[9] Osmium(IV) is not quantitatively extracted with DEDTPA from a 0.1 – 8 M solution of HCl or a 0.05 – 6 M solution of H_2SO_4 into carbon tetrachloride. Iridium(III) and rhodium(III) are not extracted from media containing HCl or H_2SO_4.[9] Iridium(IV) is reduced by the reagent to iridium(III), but iridium(III) diethyldithiophosphate precipitates out incompletely. The precipitate is extracted with chloroform and carbon tetrachloride.[4]

Platinum(II) is effectively extracted from acid solutions.[4] If platinum(IV) is reduced to platinum(II) in the presence of diethyldithiophosphate ions using $SnCl_2$, it is rapidly extracted from 1 – 10 M solutions of HCl into CCl_4 as a complex with the ratio $Pt:A^- = 1:2$.[90] Palladium is extracted from neutral and weakly alkaline solutions.[4,9] The reagent has been used to determine palladium in ore.[88]

Diethyldithiophosphates form the following series of extractability: As(III) > Bi > Pb > Zn > Ni > Co > Cd.[9,61,73] However, this series, which corresponds to the optimum extraction conditions, needs to be adjusted (this concerns, for instance, the positions of Cd and Zn) and requires a quantitative characterisation.

Diisopropyldithiophosphoric acid (DIPDTPA), like the other acids, forms coloured compounds with Cu(II), Bi, Pd(II), and Pt(II) ion.[35] The extraction of copper with zinc diisopropyldithiophosphate into CCl_4 is quantitative from 0.1 – 5 M HCl, 0.05 – 2.5 M H_2SO_4, 0.1 – 5 M $HClO_4$, 0.1 – 1.5 M H_3PO_4, or 0.1 – 2 M HNO_3.[91] The extraction of copper from less acid solutions has not been studied. Bismuth diisopropyldithiophosphate is also extracted from acid solutions. The extracts are characterised by a maximum absorption of light at 350 nm. It is possible to determine photometrically 5 – 70 μg of bismuth in 5 ml of chloroform.[92] Uranyl ions are extracted with DIPDTPA from 0.0005 – 0.01 M solutions of $HClO_4$ into benzene but the distribution coefficients are very low.[81]

Dibutyldithiophosphoric acid (DBDTPA) has been studied as an extractant fairly comprehensively.[5] Out of 42 elements studied, 22 have been satisfactorily extracted from media containing 0.03 – 9 M HCl or 0.1 – 18 M H_2SO_4. The extraction only requires a few minutes and is carried out in a single operation. The concentrations of metal can vary over a wide range from submicrogram to milligram quantities per ml of solution.[5] Ag and Bi(III) ions are quantitatively extracted with DBDTPA even from 1×10^{-7} M solutions of their salts. The maximum extractable quantity of metal depends on the initial concentration of DBDTPA in the organic phase, the ratio of volumes of the phases, and the solubility of the complex formed in the organic solvent.

According to the results of Handley and Dean,[5] Ag and Hg(II) are extracted with DBDTPA from an acid medium up to pH 10. Copper(II) and palladium are extracted from ammonia solutions with pH 8. The extraction of silver and palladium cannot solely be attributed to an exchange reaction with DBDTPA and its salts.[6,8] Evidently a coordination and ionic interaction is also occurring in this case. The passage of zinc dibutyldithiophosphate into CCl_4 and heptane from perchloric acid[93] and hydrochloric acid[94] has been characterised in considerable detail (Table 5). For comparison, in the extraction of a complex of cadmium with DBDTPA using carbon tetrachloride from a 1 M solution of HCl with an ionic

strength of 1, $\log K_{ex} = 5.3$; $\log \beta_2 = 9.7$; $\log K_D = 0.9$; $\log(K_{D,2}\beta_2) = 10.6$ [here, $\log(K_{D,2}\beta_2)$ is the two-phase stability constant].[95]

Table 5. The distribution of zinc dialkyldithiophosphate in different systems.

Alkyl	lg K_{ex}	lg β_2	lg K_D	lg $(K_{D,2}\beta_2)$
	CCl_4–1 M HCl (Ref.94)			
Ethyl-	—10			—9.3
Butyl-	1.22	3.81	2.77	6.57
Isobutyl-	1.29	4.00	2.70	5.77
sec-Butyl-	1.37		2.77	
2-Ethylhexyl-	1.40		2.86	
	CCl_4–$HClO_4$ (Ref.93)			
Butyl-	1.67	2.27	5.37	6.05
	Heptane–$HClO_4$ (Ref.93)			
Butyl-	1.85	2.27	3.78	

Zinc dibutyldithiophosphate was used as an extractant for the extraction of mercury(II), which was then determined in the extract by polarography.[12] Nickel dibutyldithiophosphate is extracted into heptane with very high distribution coefficients ($\log D > 3$), but the extraction takes place slowly and re-extraction is not quantitative.[67] Uranyl ions can be extracted from perchloric acid solutions into benzene using DBDTPA.[81]

Dibutyldithiophosphate form the following series of extractability:[5,73]

$$\text{Pd(II)} > \text{Au(III)} > \text{Cu(I)} > \text{Hg(II)} > \text{Ag} > \text{Cu(II)} > \text{Sb(III)} > \\ > \text{Bi(III)} > \text{Pb} > \text{Cd} > \text{Ni} > \text{Zn}.$$

The use of zinc isobutyl-2-ethylhexyldithiophosphate in the form of a 50% solution in a mineral oil (industrial name DF-II) as an extractant for copper has been proposed. This compound is used as an oil additive.[96] The availability of the reagent, its high copper capacity, low viscosity, and good compatibility with kerosine have determined its use in hydrometallurgy.[96] In a single extraction the distribution coefficients of copper are higher by 3–5 orders than for associated elements.

The extraction metals with di-2-ethylhexyldithiophosphoric acid has been studied in the greatest detail. A considerable amount of attention has been given not only to the conditions but also the extraction mechanism, a determination of the extraction constants and distribution constants of the complexes, and the effect of diluents. The extraction of Cu(II),[97–101] Ag,[102] Au(III),[103] Ca,[104] In,[105,106] Tl(I),[107,109] As(III),[110,111] and Bi[112,113] has been studied.

Other dialkyldithiophosphoric acids with large alkyl groups—n-hexyl-, n-octyl-, dodecyl-, and isododecyl-dithiophosphoric acids, and other acids with unbranched C_9–C_{18} groups—have also been tested as extractants. These acids are virtually insoluble in water and in acid and alkali solutions. For example, the solubility of D2EHDTPA in water is 0.0088 g litre^{-1}, in 1 M H_2SO_4 it is 0.022 g litre^{-1}, and in 2 M NaOH 0.114 g litre^{-1}. Out of the acids listed it is best to use D2EHDTPA, since the extraction of metals with its solutions in organic solvents occurs with sufficient rapidity.[114] In contrast to acids synthesised from C_8–C_{18} alcohols, D2EHDTPA does not form stable emulsions. These extractants are not decomposed by solutions of 7–9 M HNO_3, H_2O_2 (in the presence of HCl or H_2SO_4), Br_2, Tl(III), and other oxidising agents.[114] In the absence of oxidising agents, solutions of D2EHDTPA are stable and their extractive capacity does not change with time.[114] The reagent D2EHDTPA forms such stable complexes with metal ions that even compounds of alkali and alkaline earth metals can be extracted. The extraction constants of ammonium and sodium ions into heptane ($\mu = 1$) are equal to -3.50 ± 0.06 and -3.70 ± 0.01 (in $\log K$ units) respectively.[115] The use of the polar solvent 2-ethylhexanol markedly improves the extraction of ammonium ions; in this case $\log K_{ex} = -1.55 \pm 0.10$. Systems with sodium ions separate into phases slowly (20–24 h) while with ammonium ions they separate after a few minutes. Sodium ions are evidently strongly hydrated in the organic phase. The solubility of D2EHDTPA in ammonia solutions is low. After mixing equal volumes of a 1 M solution of NH_3 and $(NH_4)_2CO_3$ with a 0.22 M solution of D2EHDTPA in heptane, 0.05 g litre^{-1} of D2EHDTPA and its anion is extracted into the aqueous phase.

Copper(II) is quantitatively extracted with solutions of D2EHDTPA in saturated hydrocarbons from media containing 0.05–11 M H_2SO_4, 0.1–8.7 M $HClO_4$, 0.1–12 M CH_3COOH, 0.1–12 M HCl, or 0.1–7 M HBr.[97,98] The extraction is virtually complete after 2 min. The extraction of copper with solutions of D2EHDTPA in the presence of diethylenetriaminepentaacetic acid has been studied.[9]

The extraction of copper(II) is made difficult by its partial reduction to copper(I).[100,116] This process has received very little study and is sometimes completely ignored. In dilute solutions reduction takes place quite slowly and after brief contact (30 s) of a solution of D2EHDTPA in toluene with a 1–2 M solution of $CuSO_4$, CuA_2 passes into the organic phase (pH of solution not specified). The electronic spectra of CuA_2 and CuA differ considerably. It is assumed that a dynamic equilibrium is established during extraction

$$2CuA_2 \rightleftarrows 2CuA + A_2.$$

The CuA complex is associated in solution (degree of association 4–5) when the concentration of Cu(I) is 1 mg ml^{-1}.

In the extraction of large quantities of Cu(II) the process can also be complicated by polymerisation of the CuA_2 complex in the organic phase.[97,117] Copper is not re-extracted with a 2.5 M solution of H_2SO_4 or with solutions of $Na_2S_2O_3$, $H_2C_2O_4$, and phosphoric acid salts.[101] Re-extraction can be carried out using 5 M NH_3 or 10 M HNO_3. NaOH solutions are unsuitable for re-extraction, 7–10% solutions of thiourea in 1–3 M solutions of a mineral acid are used for this purpose.[97]

Silver is completely extracted with a 0.01 M solution of D2EHDTPA in octane from media containing 0.1–8.7 M $HClO_4$, 0.05–9 M H_2SO_4 ($D > 2 \times 10^3$), 0.1–8 M HCl, or 0.1–3 M HBr.[102]

The extraction of gold(III) with the reagent D2EHDTPA from solutions of mineral acids has been studied. During extraction from HNO_3 solutions there is a sharply defined minimum when the concentration of acid is 9 M. Gold is extracted from solutions of mineral acids regardless of its form in the initial solution. The distribution coefficients of gold during extraction from HCl solutions are higher than from HBr solutions. They attain a maximum value when the concentration of mineral acids ranges from 0.1 to 10 M. The extractant is decomposed by the mixture

$HCl + H_2O_2$ (9:1); gold is not extracted from this mixture. Another good re-extraction agent is a 0.5 M solution of thiourea in 0.1 N HCl, HBr, or H_2SO_4.[103]

The extraction of calcium with solutions of ammonium di-2-ethylhexyldithiophosphate in heptane, octanol, TBP, and hexadecane has been studied.[104] The equilibrium stops after 2–3 minutes. In the extraction of calcium with this reagent from 0.5–4 M solutions of its salts, $\log K_{ex} = 0.73 \pm 0.05$. Calcium ions are extracted even more effectively with the sodium salt of the acid. The Ca–Na exchange constant is higher than the Ca–NH_4 exchange constant: $\log K_{Ca-Na} = 1.05 \pm 0.04$; $\log K_{Ca-NH_4} = 0.64 \pm 0.06$. D2EHDTPA appears to extract the ammonium ion more effectively than the sodium ion. A solution of D2EHDTPA in n-decane (0.1 M) extracts Mg, Ca, Sr, and Ba. The degree of extraction depends on the pH of the aqueous phase; at pH > 4 extraction is quantitative.[118]

The distribution coefficients of indium are sufficiently high to ensure its almost quantitative extraction with 0.3–0.5 M solutions of D2EHDTPA in saturated hydrocarbons (heptane, toluene, octane) from solutions of $HClO_4$ and H_2SO_4 of any concentration and from solutions of hydrohalic acids up to 3 M HCl, 4 M HBr, and 5 M HI. Extraction decreases in the series HCl > HBr > HI.[106] The extraction constant of indium ($\log K_{ex} = 10.3$) is very high. The distribution coefficients of indium remain high even for extraction with dilute solutions of D2EHDTPA (0.02 M) from solutions of oxoacids. Extraction decreases in the series $HClO_4$ > H_2SO_4 > H_3PO_4 > $H_2C_2O_4$. Indium is also extracted from alkaline and ammonia solutions. For media containing 0.5–5 M NH_3 or NaOH, the distribution coefficients of indium are constant, and they are much higher for the former than for the latter.

A solution of D2EHDTPA in decane (0.1 M) effectively extracts Tl(I) from solutions of oxoacids and from solutions of hydrohalic acids of low concentration. In extraction from isomolar solutions the distribution coefficients increase in the series $HClO_4$ > H_3PO_4 > H_2SO_4 > HNO_3 > HCl. The largest reduction in distribution coefficients occurs in the presence of chlorides; sulphates and phosphates have virtually no effect on this property. Thallium(I) can be re-extracted with an 8–9 M solution of HNO_3. High concentrations of oxalic and citric acids have comparatively little effect on the extraction of Tl(I). Thallium(I) is extracted with high distribution coefficients not only from buffer solutions with pH 5–10 but also from highly concentrated solutions of NH_3 and alkalis; $\log D$ has a constant value up to a concentration of 5 M NH_3 or NaOH.[107] Thallium(I) is quantitatively extracted with a 1 M solution of D2EHDTPA in 2-ethylhexanol from 0.05–2.5 M H_2SO_4.[108]

The extraction of tin(II) with solutions of D2EHDTPA has been studied in detail.[119,120] It occurs quantitatively over a wide concentration range of H_2SO_4 and from HCl solutions up to an acidity corresponding to 3 M HCl. Tin is quantitatively re-extracted with an 8–9 M solution of HCl. It was shown by saturation of the organic phase that the ratio of metal to reagent in the extract was 1:2. The distribution coefficient of tin when it is extracted from sulphuric and hydrochloric acid solutions and HBr solutions with a solution of D2EHDTPA in octane, decane, cyclohexane, benzene, toluene, CCl_4, and chloroform is directly proportional to the square of the concentration of extractant in the organic phase and inversely proportional to the square of the hydrogen ion concentration in the aqueous phase.

A solution of D2EHDTPA in octane (0.05 M) can quantitatively extract bismuth from a 0.1–8.7 M solution of $HClO_4$ and a 0.05–15 M solution of H_2SO_4; with a concentration of bismuth of 5×10^{-3} M, $\log D > 3$.[113] It is extracted in a more acidic medium from solutions of HCl or HBr. As the concentration of hydrohalic acid in the aqueous phase increases, the distribution coefficients are reduced, the decrease being more substantial in extraction from HBr solutions, which is due to the differing stabilities of halide complexes of bismuth.[113] From among cation-exchange extractants — dialkyldithiophosphoric, dialkylthiophosphoric, alkylphosphoric, and naphthenic acids, and alkyl mercaptans — the most effective for bismuth are D2EHDTPA and dioctylthiophosphoric acid. Bismuth is quantitatively extracted with a 0.05 M solution of D2EHDTPA in octane from media containing 0.1–6 M HNO_3 ($\log D > 3$).[112]

The extraction of arsenic(III) from solutions of HNO_3, $HClO_4$, H_2SO_4, HCl, and HBr over a wide concentration range with a solution of D2EHDTPA in decane has been studied.[110] Extraction from strongly acidic media ($\leqslant 5$ M H^+) is complete, while arsenic is not extracted from solutions with pH 6–7. Acetates, tartrates, fluorides, iodides, and EDPTA do not inhibit extraction.[110,121] The highest distribution coefficients are attained in extraction from media containing 8 M H_2SO_4 (up to pH 2) and from a 1–10M solution of HCl. A feature of the extraction of arsenic(III) is the increase in the distribution coefficient as the concentration of the acid in the aqueous phase increases. Levin et al[111] attribute this to the increase in concentration of the extractable species:

$$AsO_3^{3-} + 6H^+ = As^{3+} + 3H_2O.$$

The extraction of nickel and cobalt with solutions of D2EHDTPA in decane has been studied.[122] Nickel extracts have a green colour. The highest distribution coefficients occur in the extraction of nickel from solutions in the region of pH 2 to 0.5 M H_2SO_4 or 1 M HCl. Cobalt has lower distribution coefficients, its maximum extraction is reached at pH 1.6–1.2. The extraction constants of nickel and cobalt are equal to 1.4×10^3 and 0.9 respectively when $\mu = 4.8$; $\log K_{ex} = 2.29 \pm 0.07$. The elements are quantitatively re-extracted with 6-10 M HCl.

Solutions of D2EHDTPA have also been used for extraction of platinum metals. Palladium(II) forms a complex with D2EHDTPA in 2–3 M HCl without heating in the presence of acetone; the complex is quantitatively extracted into the organic solvent. Silver and gold are extracted under the same conditions, but platinum and rhodium are not extracted. After addition of 0.01 M $SnCl_2$ to an aqueous solution of this type, platinum and rhodium are extracted on standing for 2 h, but iridium is not extracted.[123] By using a 0.01 M solution of extractant in toluene it is possible to extract palladium almost completely from a 0.1–10 M solution of NH_3 or a 0.1–5.3 M solution of NH_4Cl. Toluene, CCl_4, and saturated hydrocarbons can be used as diluents. With a ratio of $V_{org}:V_{aq} = 1:50$ and a palladium concentration of 0.02 μg ml^{-1}, more than 98% of palladium was extracted from 1 M NH_3 and NH_4Cl.[124] The extraction constant of palladium with D2EHDTPA is very high ($\sim 10^{20}$). The inhibiting effect of Cu, Pb, Mn, and Co is eliminated by the addition of excess EDTA.[124]

Iridium(III) is quantitatively extracted into the organic phase from an aqueous solution containing 1–4 M HCl when a 100-fold excess of D2EHDTPA is used (when the concentration of iridium is 1×10^{-3} M) in the presence of acetone, heating being required in this case. The optimum extraction conditions are: 2–3 M HCl, 0.1 M solution of extractant in acetone, acetone content 50 vol. %, heating at 100 °C for 30–40 min. The extraction constant of the complex using chloroform is quite high ($\log K_{ex} = 4.41 \pm 0.1$).[123]

Iridium is not re-extracted with 6 M NaOH, 1 M EDTA, or hydrochloric or sulphuric acid solutions of thiourea because of the formation of kinetically inert iridium complexes. Under the optimum conditions the extraction of iridium is not inhibited by the presence of the following metals (in excess quantities): Fe(III) 20; Cu 3×10^3; Ni 1×10^4; Co 3×10^4. The extraction of iridium becomes complicated in the presence of tin(II), which under these conditions evidently forms tin chloride-containing complexes of iridium of different compositions.

The elements can be arranged in the following series in relation to their ability to be extracted with D2EHDTPA from HCl solutions:[125]

$$Bi > Cu(II) > Pb \geqslant As > Cd \geqslant In > Fe > Ni > Zn.$$

A more complete series based on extraction constants is given in another study[126]

$$Au(I) > Ag(I) > Hg(II) > Pt(II) > Pd(II) > Cu(II) > Ir(III) > > Bi(III) > As(III) > Ru(III) > In(III) > Pb(II) > Sn(II) > > Cd(II) > Fe(III) > Tl(I) > Ni(II) > Zn(II) > Co(II).$$

Table 6. Exchange constants and extraction from perchloric acid solutions.[125]

System M_1-M_2	$\log K_{exch}$	System M−H	$\log K_{ex}$
Zn^{2+}—In^{3+}	11.0±0.3	Zn^{2+}—H	2.25±0.03
Zn^{2+}—Ni^{2+}	0.75±0.03	Ni^{2+}—H	3.14

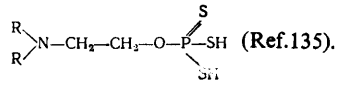
Fe^{3+}—In^{3+}	1.6±0.08	Pb^{2+}—H	8.09±0.05
As^{3+}—Cu^{2+}	12.94	As^{3+}—H	11.93
		Cu^{2+}—H	12.3
		Bi^{3+}—H	20.1±0.06

There is considerable interest in the exchange reactions of metal di-2-ethylhexyldithiophosphates in the presence of anions that have a tendency towards complex formation with exchangable cations. The extraction constants of metals that form complexes with anions of mineral acids and other complex-forming ligands are equal to $K/(1 + \beta_i c^i)$, where K is the extraction constant in the absence of complex-forming ligand, β_i is the stability constant of the ith complex, c is the concentration of ligand. Depending on the conditions, the exchange constants can vary over a wide range, as a result of which many metals alter their position in the exchange-extraction series. Table 6 lists the exchange constants and extraction constants of certain metals from perchloric acid solutions. In hydrochloric acid solutions these constants have different values.

The exchange constants of the pairs Bi−As and As−Cu when $\mu = 5$ (LiCl) and at an H^+ concentration of 1 M are 0.78 and 5.32 respectively, while the $\log K_{ex}$ values for bismuth and copper complexes are 11.5 and 10.01.[125] As arsenic does not form acido-complexes, the value of K_{ex} at a constant acidity of 1 M H^+ remains unchanged ($\log K_{As-H} = 11.9$) if the extraction is carried out from either perchloric acid or hydrochloric acid solutions.

The extraction of metals with diphenyldithiophosphoric acid (DPDTPA) has been well studied.[127] The latter can be used to extract Cu(II), Pd,[35] Bi,[92] and Pt(II).[128] For example, platinum(II) is quantitatively extracted from a 2.5 M solution of HCl or 1.25 M solution of H_2SO_4.[128] Selenium(IV) is extracted with DPDTPA in chloroform from solutions in the region pH 1 to 10 M HCl.[129] The extraction of cadmium from a 0.05 M solution of H_2SO_4 was used for a subsequent titrimetric determination of cadmium in the presence of Zn, Al, Cr, Co, Mn, and Fe(III).[130]



Amongst cyclic alkylidenedithiophosphoric acids, 1,3- and 2,3-butylenedithiophosphoric acids have been studied as extractants for the selective isolation of copper.[13] Solutions of these in chloroform (0.3 M) completely extract copper from acidic media ranging from 2.5 M H_2SO_4 to pH 5. The extraction time in the presence of extraneous elements is 30 min. Using these acids at pH 2, the following may be extracted (in %): Fe(III) 0.3−0.4; Co, Mn, Zn 0.1−0.2. These acids are more selective than isobutylethylhexyldithiophosphoric acid, a 0.15 M solution of which in chloroform at pH 2 extracts 46% iron(III) and 90% nickel. A 0.25 M solution of H_2SO_4 containing 0.5−11.0 M thiourea or a 0.025−0.1 M solution of EDTA in 5% ammonia are suitable for re-extraction of copper. In the presence of Na_2SO_3 copper(I) is quantitatively extracted while there is 1% extraction of iron(II). A 2.5 M solution of H_2SO_4 can be used to re-extract copper(I). The distribution coefficients of 1,3- and 2,3-butylidenedithiophosphoric acids in the system water−$CHCl_3$ at pH > 2 are very small and do not change as the pH increases, which is due to anions of the acids being present in aqueous solution.

Dibutylthiophosphoric acid has been studied from amongst thiophosphoric acids. The extraction of 30 elements using a 0.2 M solution of this acid in CCl_4 from sulphuric acid, hydrochloric acid,[132] and nitric acid[133] solutions has been studied. Ag, Au(I), Pb(II), Hg(II), Bi, and Pd(II) are effectively extracted from solutions of 0.005−5 M H_2SO_4 and 0.01−10 M HCl. Cadmium and zinc are completely extracted from solutions of sulphuric or hydrochloric acid with a concentration of less than 0.05 M. The extraction of As(III), In, Ga, Tl(I), Se(IV), Sn(II), and Fe(III) is characterised by high distribution coefficients. Y, La, Sb(III), Nb, and Mo(VI) are only slightly extracted and Cr(III), Mn(II), Fe(II), Co(II), Ni, alkali metals, and alkaline earth metals are not extracted at all.[132]

Extraction from nitric acid solutions is complicated by oxidation of the reagent, which is marked when the concentration of HNO_3 is more than 6 M. The extractant can be used to separate different groups of elements: Cu, Sc, Se(IV), Pd, Cd, Bi, Sb(V), Zn, In, Te(IV), Tl(I) are extracted from a 1 M HNO_3 solution; Cu, Sc, Se(IV), Pd, Cd, Sb(V), and Bi are extracted from a 3 M solution; and Pd, Bi, and Sb(V) are extracted from a 5 M solution.[133]

Cyclic pinacolinethiophosphoric acid in $CHCl_3$ quantitatively extracts palladium from 0.5−1.0 M HCl. On boiling the extract for 10−15 minutes, the complex decomposes to give PdS.[134]

There has been a qualitative study[135] of the extraction of heavy and platinum metals with dithiophosphoric acids $(RO)_2P(S)SH$, where R are unsaturated groups (allyl, β-methylallyl, propargyl) and also trithiophosphoric acid derivatives such as dimethyl-aminomethyl- and diethylaminoethyl-trithiophosphoric acids with the general formula

(Ref.135).

2. Chemical nature of extraction

Dialkyldithiophosphoric acids extract elements from acidic aqueous solutions by a cation-exchange mechanism, which has been studied in the greatest detail in the case of D2EHDTPA.[136–140] The absence of anions of mineral acids in the extract whatever the type of acid is typical for the extraction of Cu(II),[99] Ag,[102] Ca,[118] In,[105] Tl(I),[109] As,[111] Be,[113] U(VI),[81] Ni,[122] and Pd.[123,124] It has been established using a saturation method that compounds with the composition MA_n which are not solvated with molecules of free acid[99,105,113,122,124] and not hydrated[122,136] are extracted into the organic phase. However, in certain cases the complexes can add on molecules of free acid. For example, complexes of magnesium and alkaline earth elements are solvated with a single D2EHDTPA molecule.[118] The results of elemental analysis of complexes between iridium(III) and D2EHDTPA isolated using thin layer chromatography indicate that they have the composition $Ir_2A_3 \cdot HA$.[123]

The electronic spectra of the organic phases obtained by extraction of metals from solutions of different mineral acids ($HClO_4$, H_2SO_4, HCl, etc.) are identical whatever the nature of the diluent and the concentration of the acid.[105,109,111,113,119,124] The reduction in distribution coefficients as the concentration of acid in the aqueous phase increases [with the exception of As(III)[137]] suggests that there is a cation-exchange mechanism for extraction.

A detailed study of the IR spectra of metal-containing extracts obtained when D2EHDTPA and DPDTPA are used in saturated hydrocarbons also points to a cation-exchange mechanism for extraction. In the IR spectrum of pure D2EHDTPA there is a band with a maximum at 2460 cm^{-1} and two bands with maxima at 2560 and 2595 cm^{-1}. In nonpolar solvents the intensity of the latter two bands increases while the intensity of the band at 2460 cm^{-1} decreases. The bands at 2560 and 2595 cm^{-1} are attributed to (P)–S–H stretching vibrations of the monomeric acid molecules. In the spectrum of the deuterated extractant the $O_2P(S)SD$ maxima at 2560 and 2595 cm^{-1} are shifted to lower frequency. It is assumed that the band at 2460 cm^{-1} is an indication of the presence of dimeric acid molecules.[114] The presence of an asymmetric band with a maximum at 675 cm^{-1} is due to vibrations of the P=S group. Bands in the region 700–400 cm^{-1} are attributed to P–S vibrations, but their interpretation is ambiguous because these bands can correspond to the vibrations of a hydrocarbon group.[114]

In the IR spectrum of the pure acid there is a broad band at 2460 cm^{-1} and two sharp maxima at 2560 and 2595 cm^{-1} due to vibrations of the S–H group; these disappear if the extract contains Ag,[102] In,[105] Tl(I),[109] Sn(II),[119] As(III),[111] Bi,[113] and Pd.[114,124] This phenomenon indicates that the hydrogen ion of the S–H group is replaced by a metal ion, namely, that there is a cation-exchange mechanism for extraction.

The occurrence of an interaction between the sulphur atom of the P=S group and metal ions is supported by the change in position and shape of this band in the spectra of extracts containing complexes compared to its position and shape in the IR spectra of the pure acids. Instead of an intense band at 675 cm^{-1} due to asymmetric vibrations of the P=S group,[114] in the spectrum of an extract that contains bismuth a new band of medium intensity with two clearly defined maxima at 627 and 640 cm^{-1} appears.[113] In the spectrum of an extract of silver complex a band with a maximum at 635 cm^{-1} and a weak shoulder at 645–650 cm^{-1} appears.[124] Similar changes in the vibration bands of the P=S and (P)–S–H groups also occur in the IR spectra of extracts of other metals: In,[105] Tl(I),[109] Sn(II),[114,119] and As(III).[111]

A comparison of the IR spectra of solutions of the reagent in heptane and in TBP with the spectra of extracts saturated with calcium showed that the position of the absorption band due to the P=S group (681 cm^{-1}) did not change. Some broadening of the bands was an indication of a weak interaction between the thione sulphur of the P=S group and the metal.[104] The vibrational bands of the P–S bond (400–700 cm^{-1}) change considerably. The weak maxima at 600, 580, and 535 cm^{-1} and the shoulder at 490 cm^{-1} in the spectrum of the extract of free reagent are shifted to shorter wavelength at 610, 590, and 550 cm^{-1} respectively in the spectrum of the extract of bismuth while the shoulder maintains its position at 490 cm^{-1}.[113] The position of the bands from the P–S bond also change in the spectra of extracts of complexes of Ag,[102] Sn(II),[114,119] As(III),[111] and U(VI),[66] but an interpretation of these shifts is ambiguous.

An asymmetric band with a maximum at 1015 cm^{-1} and poorly defined shoulders at 985 and 1035 cm^{-1} is attributed to vibrations of the (P)–O–C bonds.[114] This band undergoes considerable changes in the spectra of extracts of complexes of Sn(II),[119] As(III),[111] Bi,[113] and other metals[66,114] compared to its position in the spectrum of the free acid. The nature of the changes depends on the degree of ionic character of the P–S–M bond.

The band due to asymmetric vibrations of Pd–S in the Raman spectrum of a complex of palladium with D2EHDTPA is situated at 330 cm^{-1} while in the spectrum of palladium diethyldithiophosphate it occurs at 317 cm^{-1}.[124]

The IR spectra of extracts of bismuth[111] and tin(IV)[119] after they have been diluted with free reagent have also been studied.

The IR spectra of complexes of iridium, rhodium, platinum, and palladium with D2EHDTPA are similar to the spectra of other dithiophosphates. The absorption bands due to vibrations from S–H groups (2560 and 2595 cm^{-1}) disappear, while the band from the P=S group at 673 cm^{-1} in the free reagent is shifted in complexes of these metals to lower frequency by 41, 42, 39, and 40 cm^{-1} respectively.[138] The band from the coordinate P=S group has a doublet structure for all dithiophosphates; this is due to the existence of two rotational isomers.[138] D2EHDTPA evidently acts as a bidentate ligand. However, it is thought that complexes that are solvated with molecules of free D2EHDTPA can also be extracted in small quantities. Such complexes are less mobile and are separated from the main component on silica gel.[123]

In the IR spectrum of free DPDTPA there is an absorption band from the P=S group at 665 cm^{-1}; in the case of the potassium salt of DPDTPA the absorption band from this group appears at 690 cm^{-1}. The absorption bands from the P=S group in diphenyldithiophosphates of Ag(I), Cd, Hg(II), Bi, Pb, and Ni, are shifted to longer wavelength by 5–15 cm^{-1} compared to the frequency of vibrations from this group in the free acid and by 15–60 cm^{-1} compared to the potassium salt. The vibration frequency of the P–O–C group at 1160 and 1025 cm^{-1} remains unchanged.[139] Shishkov and Busev[139] attribute this to the formation of a chelate with a four-membered ring.

Dialkyldithiophosphates are mainly extracted as monomeric compounds, but some of them are associated in the organic phase. The degree of association of gold when it is extracted with solutions of D2EHDTPA in heptane is 3, while mercury(II) dibutyldithiophosphate is extracted from sulphuric acid solutions into carbon tetrachloride as its tetramer.[89] Association also occurs

in the organic phase when large quantities of copper(II) are extracted with D2EHDTPA solution.[97] Ammonium dialkyldithiophosphate is highly associated in an inert solvent.[104] As a rule, unsaturated coordinate complexes are associated in the organic phase.[89,97,102]

Extraction from acidic aqueous solution that takes into account association is given by the following equation

$$mM^{n+} + \frac{m}{x}(n+s)(HR)_x + my\,H_2O \rightleftarrows (MR_n \cdot s\,HR \cdot y\,H_2O)_m + mn\,H^+.$$

The extraction constants are given in Table 6.

For some metals the extraction constants are very large and they cannot be calculated by the standard method based on the functions $\log D - \log[HA]_{org}$ or $\log D - \log[H^+]_{aq}$ because of the impossibility of determining very low concentrations of metal ($10^{-8}-10^{-7}$ M) in the aqueous phase after distribution.[140] Although dialkyldithiophosphoric acids are classed as strong acids and extract metals from acid media, there are results that indicate that dithiophosphates can also be extracted from weakly alkaline media. This relates to those that are most soluble in water (DMDTPA, DEDTPA, DPrDTPA, DBDTPA). Thus, DMDTPA extracts nickel from aqueous solution in the region of pH > 4:[66,81]

$$Ni^{2+}_{(aq)} + 2A^-_{(aq)} \rightleftarrows NiA_{2(org)}.$$

Uranyl ions are extracted with these acids in a similar manner. Extraction from alkaline media is particularly characteristic of metals that do not form very stable dithiophosphates (Zn, Co, Ni). Extraction of metal dithiophosphates in the presence of amines or donor-active added components is confirmation of the formation of complexes in aqueous solution in an alkaline medium.

Dithiophosphates of the transition metals Mn(II), Fe(II), and Co(II) in the presence of 2,2′-dipyridyl (Dipy) or 1,10-phenanthroline (Phen) are extracted in weakly alkaline media as mixed ligand complexes. The maximum degree of extraction of Mn(II), Fe(II), and Co(II) complexes is reached at pH 6–7 while for Ni(II) the maximum occurs at pH < 2. The pH region for extraction is very narrow as at pH 1–3 ligand exchange can occur because of the low stability of the dithiophosphates. At pH < 7 all of the amine is in the aqueous phase and at pH < 2.5 it is completely protonated. On the other hand, dialkyldithiophosphate ions are protonated at H < 2.7 and the acid concentration in the organic phase increases sharply. In the pH region 6–7 dialkyldithiophosphoric acids (HA) and the amine exist completely in the aqueous phase and the ratio of Dipy : HA that is conducive to extraction of Fe(II) is 3 : 2. The formation of complexes with HA and amine occurs in the aqueous phase and can be represented by the following scheme:

$$Fe(Dipy)^{2+}_3 + 2A^- \rightleftarrows [Fe(Dipy)_3A_2]_{(org)}.$$

In the absence of amine or dithiophosphate ion there is no extraction of Fe(II) complexes. Only the combined presence of both ligands leads to a considerable synergistic effect.[41]

3. Effect of substituents on the extraction of dialkyldithiophosphates

Interesting observations have been made in comparing the extractive capacity of different dialkyldithiophosphoric acids. It should be noted first of all that replacement of oxygen atoms by sulphur increases the extractive capacity of dialkyldithiophosphoric acids compared to dialkylphosphoric acids. Thus, for example, the extraction constant of bismuth with a solution of D2EHDTPA is 10^{16} times higher than the extraction constant of bismuth with di-2-ethylhexylphosphoric acid (D2EHPA);[113] the extraction constant of silver with D2EHDTPA is 2.1×10^{41}, while its extraction constant with D2EHPA is 1.4×10^{-2}. A similar phenomenon occurs in the extraction of indium.[105]

Bode and Arnswald,[9,11] who had studied the extraction of metals with only DEDTPA, proposed that the RO group on the phosphorus atom has little effect on the properties of the extractant. However, it was shown[5] that replacement of ethyl groups by n-butyl groups leads to an increase in the degree of extraction of elements. Moreover, the use of acids with a larger number of carbon atoms in the alkyl group of the acid increases the range of extractable elements. Thus, in contrast to DEDTPA, the dibutyl analogue completely extracts Zn, Tl(III), and Ni, and partially extracts Co(II) and Cr(III); Au(III) is extracted without reduction to elemental gold. Mercury and zinc are extracted more effectively with D2EHDTPA than with DBDTPA. Out of those studied, D2EHDTPA is the most effective extractant.[5] The effect of subsituents on the extractive capacity of dithio acids is noticeable in the case of the extraction of uranyl ions;[81] on increasing the carbon chain in dialkyldithiophosphoric acids the distribution coefficients of the complexes decrease in the series $2\text{-}(C_2H_5)C_6H_{12} > n\text{-}C_4H_9 > C_3H_7 \gg C_2H_5$.

It is interesting to monitor the effect of substituents on the phosphorus atom in the case of the extraction of certain dialkyldithiophosphates.[71,141] Extraction can be quantitatively characterised by the two-phase stability constant of extracted complex ($K_{D,2}\beta_n$). A variation in substituents substantially changes the two-phase stability constant of dialkyldithiophosphate. As the number of carbon atoms in the substituents increases, there is a trend towards an increase in $K_{D,2}\beta_n$ (Table 7),[141] which may be due to the effect of substituents on the distribution constants of the complexes and their stability constants.[142]

Table 7. Characteristics of the extraction of dialkyldithiophosphates with different solvents.[141]

Alkyl	Nickel in		Zinc in C_7H_{16}	Calcium in $C_6H_5CH_3$	Lead in CCl_4
	$CHCl_3$	C_6H_6			
Ethyl-	4.45	4.06	2.70	5.22	8.84
Propyl-	7.11 (2.3)	6.87 (2.9)	5.13 (1.7)	7.55 (3.8)	11.62 (7.6)
Isopropyl-	7.98 (2.6)	7.43 (3.0)	5.44 (1.5)	7.95 (3.7)	11.78 (6.9)

Note. $\log(K_{D,2}\beta_2)$ values are listed (those in brackets are $\log K_{ex}$ values).

The stability of the complexes increases with the introduction of a more electron-donating group into the ligand molecule, so complexes with dithiophosphinic acid derivatives are the most stable.[143] But an increase in stability of dialkyldithiophosphates is also due to the steric effects of substituents on phosphorus. A

linear correlation exists between the logarithms of the stability constants of the complexes and the sum of the steric constants of substituents on the phosphorus atom (E_s^0). However, in order to derive correlation equations it is also necessary to take into account the hydrophobic effects of the substituents, which affect the distribution constants of the complexes. In order to determine the two-phase stability constants of dialkyldithiophosphates, two-parameter equations that include the steric and hydrophobic effects of the substituents on the phosphorus atom have been propounded. Taft constants E_s^0 are used to determine the steric effect and the number of carbon atoms are used to determine the hydrophobic effect. Correlation equations for the determination of two-phase stability constants of nickel have been derived for the systems water–toluene, water–heptane, and water–carbon tetrachloride.[71]

The two-phase stability constants of the dithiophosphates of Zn, Cd, Pb, and Ni also rise with the increase in steric and hydrophobic effects of substituents on the phosphorus atom (Table 7).[71,141]

4. Effect of diluents on the extraction of dialkyldithiophosphates

This effect can be closely followed in the case of complexes of metals with D2EHDTPA. In the majority of studies unreactive organic diluents are used (Table 8).

Table 8. Extraction constants of bivalent elements ($\log K_{ex}$) with D2EHDTPA solutions in different diluents (μ = 5).[144]

Element	Octane	CCl_4	$CHCl_3$	MIBK	Octanol
Hg	40.18	39.02	38.62	39.62	35.12
Pt	24.11	33.00	22.60	20.85	19.05
Pd	20.10	18.94	18.54	16.54	15.04
Cu	12.06 (12.30)	11.50 (11.40)	10.50	8.80 (8.80)	7.00
Pb	8.55 (8.09)	7.39	6.99	5.29	3.49
Sn	7.55 (7.79)	6.39	5.99	4.29	2.49
Cd	7.55 (7.04)	6.39	5.99	4.29	2.49
Ni	3.09 (3.14)	1.87	1.37	−0.23	−2.03
Zn	2.02 (2.25)	0.86	0.46	−1.24	−3.04
Co	0.02	−1.14	−1.54	−3.24	−5.04
Fe	−3.00	−4.10	−4.56	−6.26	−8.06
Mn	−6.02	−7.17	−7.57	−9.27	−11.07

Note. Calculated values of $\log K_{ex}$ are listed (those in brackets are the experimental figures).

The extraction constants of tin(II) from solutions of HCl and HBr differ almost by a factor of 10, which is attributed[119] to a discrepancy in the data on the stability of chloride and bromide complexes of tin. The extraction constants from sulphuric acid solutions are less than from solutions of HCl and HBr. It was not possible to make a comparative determination of the extraction constants of tin with D2EHDTPA from perchloric acid solution because of the instability of tin(II) solutions in perchloric acid.

The extraction constants of bivalent metals with D2EHDTPA in different diluents as determined by calculation are in good agreement with the exeperimental values (Table 8).[144] By using the principle of strong and mild acids and bases (SMAB) as a basis for determining K_{ex} it is possible to calculate these values from three experimental quantities.

A comparison of the extraction constants of the di-2-ethylhexyldithiophosphates of silver,[102] tin(II),[119] and bismuth[113] in different diluents shows that inert diluents have little effect on the extraction of dialkylphosphorodithioates. Oxygenated solvents, such as tributyl phosphate (TBP) and trioctylphosphine oxide (TOPO), have a marked effect on extraction. Decane, benzene, CCl_4, and chloroform have little effect on the extraction constant of arsenic(III) with D2EHDTPA ($\log K_{ex}$ = 10.8), but methyl hexyl ketone, dibutyl ether, and dichloroethane decrease it by a factor of 100–1000.[111] On dilution with kerosene, the phases separate out slowly when these elements are re-extracted.[121]

Diluents affect the extraction of zinc and mercury(II) in quite different ways. The most complete extraction of zinc occurs when the extractant DBDTPA is diluted with n-heptane or carbon tetrachloride; amyl alcohol and amyl acetate cause extraction to be reduced. On the other hand, the distribution coefficients of mercury(II) when using oxygentaed solvents such as ethyl acetate and isopropyl ether are higher than when n-heptane, xylene, and toluene are used, particularly at a low acidity of the aqueous solution (0.1 M HCl).[5]

Table 9. Extraction constants of indium ($\log K_{ex}$) with D2EHDTPA solutions in different diluents (μ = 5).[105]

Diluent	$HClO_4$	H_2SO_4
Decane	(10.6)	(10.3)
CCl_4	9.6 (9.8)	9.3
Benzene	9.4 (9.5)	9.1
Chloroform	8.6 (8.2)	8.5 (8.3)
Dibutyl ether	7.1 (6.7)	6.8 (6.3)
Methyl hexyl ketone	6.6 (8.7)	6.3
TBP	5.1 (10.1)	4.8 (7.4)
Octanol	4.9	4.6 (7.4)

Note. Calculated values of $\log K_{ex}$ are listed (those in brackets are the experimental figures).

The experimental and calculated extraction constants of indium only coincide for solvents with low polarity (Table 9).[105] TBP can exert both an antagonistic effect and a synergistic effect depending on the concentration. The distribution coefficient of indium in extraction with a solution of D2EHDTPA in TBP initially decreases as the proportion of the latter increases and then, when the concentration of TBP is above 0.5 M, increases sharply, in all probability because a TBP molecule is being incorporated into the extracted compound.[105]

Diluents have a substantial effect on the distribution coefficients of thallium(I)[109] and relative to this factor are arranged in the series: alcohols > aromatic hydrocarbons > halogen derivatives > ethers > saturated hydrocarbons and cyclic hydrocarbons. The distribution coefficients are at a maximum when TBP is used as the diluent, but the solution of extractant changes its properties substantially on standing in this diluent. Thus, a freshly prepared 0.1 M solution of D2EHDTPA in TBP extracts thallium(I) from 0.1 M H_2SO_4 with a distribution coefficient of about 190, but on standing for two weeks this value decreases to 3. Such phenomena do not occur when other diluents are used.[107]

Oxygenated solvents have the strongest but an unequal effect on the extraction of low-stability complexes of cobalt and nickel (Table 10).[121] When TBP or 2-ethylhexanol are used, the distribution coefficients of cobalt are higher, while the distribution coefficients of nickel are lower, than when saturated hydrocarbons are used. For example, TBP and TOPO reduce the rate of extraction of nickel by a factor of 20.[145] According to the results of one study,[117] added quantities of 2-ethylhexanol and TBP increase the rate of extraction of nickel with a 1 M solution of D2EHDTPA in hexane from solutions of H_3PO_4, and instead of 12 h required for extracting nickel without donor-active components (DAC), in the presence of 20 vol. % 2-ethylhexanol nickel is completely extracted in 2 min. It has been proposed that the extraction of nickel is limited by surface reactions with a single rate-limiting stage. The kinetic functions in the extraction system nickel-D2EHDTPA are determined by the limiting role of chelate formation in the adsorbed layer on the phase interface. This process is represented hypothetically by the equations

$$[Ni(H_2O)_6^{2+}]_{(aq)} + R^-_{(s)} \rightleftarrows [Ni(H_2O)_{6-n}R]^+_{(s)} + nH_2O,$$
$$[Ni(H_2O)_{6-n}R]^+_{(s)} + R^-_{(s)} \rightarrow [NiR_2]_{(s)} + (6-n)H_2O,$$
$$[NiR_2]_{(s)} \rightleftarrows [NiR_2]_{(org)},$$

where the index s corresponds to the state of sorption at the phase interface.[146]

Table 10. Effect of diluents on the distribution coefficients of complexes of cobalt and nickel with D2EHDTPA.[121]

Diluent	Cobalt (0.25 M HA, 0.25 M $HClO_4$)	Nickel (0.1 M HA, 2.0 M $HClO_4$)
2-Ethylhexanol	12.0	0.81
Tributyl phosphate	8.7	1.72
Cyclohexane	4.3	2.12
Decane	3.5	14.2
Dibutyl ether	3.4	0.28
Carbon tetrachloride	1.5	3.66
Benzene	1.4	0.427
Chlorobenzene	0.96	0.56
Chloroform	0.4	0.66

Cobalt is oxidised during extraction with solutions of D2EHDTPA. The compound of cobalt(II) with D2EHDTPA that is extracted into the organic phase changes colour from blue at the start of extraction to dark brown on prolonged agitation. The Co(II) compound is rapidly extracted and then Co(II) in the organic phase is slowly oxidised to Co(III). This process is determined by an equilibrium that is slowly reached.[147] The time taken to establish equilibrium in the extraction of cobalt with a solution of D2EHDTPA in decane depends on the concentration of cobalt in the organic phase. At relatively high concentrations the equilibrium is established after 10 h. At a low concentration (less than 3×10^{-4} M), agitation is required for 45 h. If the concentration of cobalt(II) in the organic phase exceeds 1×10^{-3} M it is almost completely oxidised.[148] Added quantities of TBP and TOPO increase the rate of extraction of Co(II) and considerably reduce its rate of oxidation.[145] The latter phenomenon is due to formation of a mixed ligand complex Co–DAC–HA which is not oxidised in the organic phase.[145]

In general the effect of DAC on the extraction of cobalt and nickel is very complex and it depends on their concentration and nature (some added components inhibit extraction while others accelerate it) and also on the nature of the extracted complex. A reduction in time of phase contact, the introduction of DAC, and a lowering of the partial pressure enable cobalt and nickel to be separated.[145,149,150]

In the extraction of uranyl ions with solutions of diethyl-, di-n-propyl-, and di-n-butyl-dithiophosphoric acids in n-butanol, the distribution coefficients are higher than in benzene. It is thought[151] that n-butanol is incorporated into the extracted compound. The extraction constants of uranyl ions with solutions of 2DEHDTPA in different diluents are also dissimilar.[81] The values of $\log K_{ex}$ for different diluents are: benzene 0.37; chloroform 0.79; carbon tetrachloride 0.92; and cyclohexanol 0.28.[152]

IV. The use of dithio phosphorus acids for the separation of elements

There is virtually no information about the use of thio phosphorus acids for the separation of elements. It is only known that a solution of DBTPA in CCl_4 has been used for the extractive separation of the following element pairs in nitric acid solutions: Te(IV)–Se(IV), Au(III)–Tl(I), Pt(IV)–Pd(II), As(V)–In(III), As(V)–Sb(V), In(III)–Ga(III), and Bi(III)–As(V).[133] Apart from that, Te, Se, Bi, In, Zn, and Cu ions have been isolated from 0.3 M HNO_3 using a 0.3 M solution of DBTPA for their determination in pure silver.[153]

We will therefore examine below the separation of elements with dithio phosphorus acids, amongst which the main position is occupied by D2EHDTPA. In studying the extractive properties of this reagent, three groups of metal cations can be distinguished. The first is made up by elements that are effectively extracted from strongly acidic solutions—Ag(I), Au(I), Cu(I) and Cu(II), Hg(I) and Hg(II), Bi(III), Sb(III), As(III), Sn(II) and Sn(IV), Pb(II), and platinum metals. In the second group are elements that can only be slightly extracted (extracted at low concentrations of HCl or H_2SO_4)—Tl(I), Cd(II), In(III), Fe(III), Zn(II), Ni(II), and Co(II). The third group consists of unextractable elements: alkali metals, alkaline earth metals, Al, Ti(IV), Ga, Ga, Mn(II), Fe(II), Zr(IV), and Cr(III) and Cr(VI).[114,126] Different schemes for the separation of complex systems and methods for isolating elements using D2EHDTPA have been put forward.

1. Isolation of copper

Copper is isolated from unextractable elements and those of low extractability using D2EHDTPA solutions in inert diluents from solutions with a high concentration of H_2SO_4.[114] Ag, Au, Hg(II), In, Sb(III), and Bi are extracted together with copper. In, Sb(III) and Bi ions are re-extracted with conc. HCl[97] (copper is not re-extracted with solutions of acids, alkalis, or ammonia). Copper is slowly re-extracted only with solutions of oxidising agents that decompose the extractant[114] [in the re-extraction of copper(II) with an 85% solution of thiourea in 0.5 M H_2SO_4, 20–40% of D2EHDTPA is oxidised depending on the time of agitation[97]]. Because of the slow re-extraction of copper, it is possible to separate it from bismuth at this stage.

A number of ions remain in the aqueous phase when a metal dialkyldithiophosphate is used as the extractant, having an

extraction constant which is less than for copper but higher than for the remaining metals. Cadmium di-2-ethylhexyldithiophosphate is suitable for such a purpose (log K_{ex} = 10.67). In the extraction of copper(II) with a saturated solution of this extractant in a saturated hydrocarbon, Zn, Tl(I), Tl(III), Co, Ni, Sn(II) and (partly) In remain in aqueous solution.[97] Copper(II) is extracted almost completely from 1–6 M solutions of HCl with 0.05 M D2EHDTPA in heptane over a period of 2 min.[98] Under these conditions Pd(II), Sn(II), and Sn(IV) have very low distribution coefficients (D < 0.1). The small quantities of palladium which pass into the organic phase in the extraction of copper(II) do not interfere with a photometric determination of copper at 420 nm as the molar absorption coefficient of the palladium complex at this wavelength is a hundred times lower in magnitude. A 0.05 M solution of D2EHDTPA completely extracts palladium ($D > 5 \times 10^3$) from ammonium chloride solutions with a concentration of 0.5–6 M NH_3. In the presence of EDTA the distribution coefficient of copper is markedly reduced. In extraction from a 0.5–1 M solution of NH_3 containing 0.05 M EDTA, the partition coefficient of the Pd–Cu pair is 10^5, in other words, by adding EDTA to the ammonia solution it is possible to re-extract copper selectively.[98]

2. Isolation of mercury(II)

The use of a 0.05 M solution of D2EHDTPA in octane for extraction permits the complete extraction of 5×10^{-3} M Hg(II) from solutions containing 0.1–8.7 M $HClO_4$, 0.5–9 M H_2SO_4, 0.1–7 M HCl, or 0.1–2 M HBr ($D > 500$).[154] An increase in the concentration of hydrohalic acids sharply reduces the distribution coefficient of mercury, the reduction being more significant in extraction from HBr solutions than from HCl solutions. Mercury is effectively re-extracted with concentrated acid solutions of thiourea and NH_4SCN and concentrated solutions of HCl or HBr. The presence of a more than tenfold excess of tin(II) in the aqueous phase inhibits the extraction of mercury. The negative effect from the presence of tin can be eliminated by the addition of 1–2 ml of a 1% solution of NH_4F. Mercury is separated during extraction from elements of low extractability—Al, Ga, Ti(IV), Zr, Cr(III), Mn(II). In order to isolate it from the co-extracted elements—Zn, Cd, Sn, Pb, Tl(I), Ni, and As(III)—it is possible to use bismuth di-2-ethylhexyldithiophosphate. Mercury(II) is extracted with a 0.006–0.01 M solution of bismuth di-2-ethylhexyldithiophosphate in octane from 0.1–3 N mineral acids. Mercury is isolated from zinc and cadmium by extraction with a solution of DEDTPA in heptane; 2 M HCl or H_2SO_4 must be present in the medium. Cadmium is then separated from Hg(II) by re-extraction with a 1 M solution of HCl or it is directly determined with 1-(2-pyridylazo)-2-naphthol in the extract.[155]

3. Isolation of thallium(I)

Thallium(I) is separated from elements of low extractability by extraction with a solution of 1 M D2EHDTPA in 2-ethylhexanol from 1.5–2 M solutions of H_2SO_4.[108] Cu, Ag, Zn, As(III), Hg, Fe, Ni, and Sb(III) are extracted together with Tl(I). It is isolated from these elements by washing the organic phase with different complexing agents. Washing the extract with a 40% solution of diethylamine in 30% $(NH_4)_2SO_4$ leads to the re-extraction of Zn and Ni. A second component—pyro-2-ethylhexylphosphoric acid—is added to the organic phase in order to isolate Tl(I) from Sb and Fe. On shaking the mixed organic phase with an oxidising agent (8 M HNO_3), D2EHDTPA is decomposed and Tl(I) passes into the aqueous phase while Sb and Fe remain in the organic phase as the second component is not oxidised.

Ag and Hg(II) ions are not separated from Tl(I) on washing the organic phase with solutions of acids and bases or amines. But the oxidation product of D2EHDTPA—most probably bis(alkyldithiophosphoryl) disulphide—extracts silver and mercury with high distribution coefficients. Therefore, when D2EHDTPA is decomposed with a solution of HNO_3, Tl(I) passes into the aqueous phase while Ag and Hg remain in the organic phase.

Since the distribution coefficients of copper when it is extracted with D2EHDTPA are substantially higher than for Tl(I), copper readily displaces thallium from the organic phase.[108]

4. Isolation of tin(II)

Tin(II) is isolated from co-extracted metals by re-extraction with 3–5 M H_2SO_4 or 1–2 M HCl.[120] However, it is not possible to remove all the co-extracted elements in this manner but only Zn, Ni, Co, Fe(III), Sb(III), Mo(VI), and Tl(I). Cu, Ag, As, Bi, and Hg(II) are not separated even when the organic phase is washed with conc. H_2SO_4 or $HClO_4$, but Sn(II) is readily isolated by re-extraction with an 8 M solution of HCl. Bi and Sb(III) ions are re-extracted with HCl solutions of higher concentration, but As(III), Cu, and Hg are not re-extracted even with conc. HCl.[120]

5. Isolation of arsenic(III)

It is possible to separate As(III) from elements of low extractability—Mg, Mn, Cr, Ti, Zr, Al, rare earth elements—during extraction from acid solutions.[110] The separation of arsenic from metals that form anionic chloride complexes occurs when it is extracted from solutions with a high HCl content or after washing the extract with HCl. Solutions of the oxidising agents HNO_3, H_2O_2 + HCl, Tl(III), and Br_2, the most suitable of which is bromine,[156] can be used for the re-extraction of arsenic.

Arsenic can be extracted from sulphuric acid and hydrochloric acid solutions with nickel diethyldithiophosphate by means of exchange reactions. The exchange process between arsenic and nickel

$$3NiA_{2(org)} + 2As^{3+}_{(aq)} \rightleftarrows 2AsA_{3(org)} + 3Ni^{2+}_{(aq)}$$

is quite slow (about 2 h) and is very dependent on the pH of the solution. By using nickel diethyldithiophosphate it is possible to remove arsenic from a nickel electrolyte to a sufficient degree in two stages.[121]

6. Isolation of bismuth

In order to separate bismuth from elements of low extractability, it is extracted with a 0.01 M solution of D2EHDTPA in octane from 0.1–4 M $HClO_4$, H_2SO_4, HCl, or HBr and the organic phase is washed once with a 1.5–3 M solution of H_2SO_4.[157] Cu(II), Zn, Cd, In, Tl(I), Sn(II), Pb, As(III), Sb(III), Fe(III), Co, and Ni are extracted together with bismuth.[114] Bismuth is extracted almost quantitatively at any concentration of these elements and in addition it displaces them on extraction. Bismuth is separated from cobalt by extraction from 2.5 M H_2SO_4. Bismuth can be determined in the presence of the following elements (their admissible excess quantity relative to Bi is given in brackets): Zn, Cd (600); Ni (60); Sn(II) (8); Sb(III) (3). The adverse effect of Sn(II) is eliminated by washing the organic phase with 3–4 M HCl, since Sn(II) is re-extracted considerably less with concentrated HCl solutions than is bismuth.

Ag, Au, Hg, and Bi ions form strong thiourea complexes, but the latter do not interfere with the extraction of bismuth, so it can

be isolated from these elements. The product from oxidation of D2EHDTPA with nitric acid extracts Ag, Au, and Hg, but not Bi, with high distribution coefficients. Therefore, when the extract is washed with 6 M HNO_3, Ag, Au, and Hg ions remain in the organic phase while bismuth passes into the aqueous phase, where it can be determined using KI. Determination of bismuth is possible in the presence of a 20-fold excess of Ag and Au, and 10-fold excess of Hg.[157]

7. Separation of platinum metals

The scheme for separation of the platinum metals, Au, and Ag is based on a difference in the conditions for forming extractable di-2-ethylhexyldithiophosphates.[123,126] Ag, Au, and Pd and some of the class *a* metals are extracted under normal conditions without heating the aqueous solution in the presence of the reagent and acetone. After addition of 0.1 M $SnCl_2$ to the aqueous solution and allowing it to stand for 1 h, platinum and rhodium are extracted, the aqueous solution is then heated and iridium is extracted. Thus, D2EHDTPA can be used for the group concentration of platinum metals and for separations of the pairs palladium–platinum and rhodium–iridium.[123] Cu(I), Hg(I), As(III), Bi(III), and Sb(III) are extracted together with iridium. All of the metals apart from Cu(I) can be separated from iridium by re-extraction with a 10 M solution of HCl.

—o0o—

It should be pointed out in conclusion that there are no quantitative characteristics for determining the efficiency of the extraction processes involving dialkyldithiophosphates. A possible exception to this is D2EHDTPA, for which the extraction constants of metal cations are known. Nevertheless even for this the stability constants of the complexes are still unknown. In fact, a determination of extraction, stability, and distribution constants of complexes and also the two-phase stability constants provides material that serves as a basis for using dithio acids in analytical chemistry and therefore it is worthy of close attention.

Polycyclotrimerisation of cyanamides

V A Pankratov, A E Chesnokova
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The results of studies in the field of the synthesis of polymers with a network structure by the polycyclotrimerisation of cyanamides and oligomers containing cyanamide groups are surveyed and analysed. The prospects for the use of polymers based on compounds containing cyanamide groups in the preparation of various thermostable materials are discussed.

The bibliography includes 174 references.

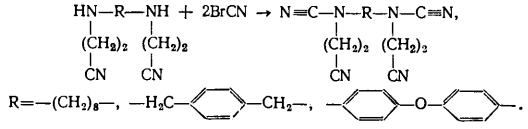
I. Introduction

The synthesis of structured polymers containing *sym*-triazine groups at the network nodes has recently attracted special attention since it is one of the promising ways of creating new polymeric materials.[1–17] The increase in thermal stability and the improvement of physicomechanical characteristics of such polymers are achieved as a result of the development of the highly selective polycyclotrimerisation and the elucidation of the influence of the heterounit structure of network systems on their properties. As a result of this, the polycyclotrimerisation reactions of monomers and oligomers containing the N ≡ C–NH and N ≡ C–NR functional groups are of great interest. They make it possible to obtain cross-linked polymers having a regular chemical structure with a definite specified size of the internodal fragments and stable *sym*-triazine rings at the network nodes. An advantage of this reaction, leading to the synthesis of network polymers, is that it proceeds without the evolution of low-molecular-weight products. Because of this, articles can be made from such polymers by polymerising monomers or oligomers prepared beforehand (which are as a rule low melting and are readily soluble in organic solvents), i.e. by the usual methods for the processing of thermoreactive polymers.

Numerous studies devoted to the characteristics of the cyclotrimerisation of cyanamides and related compounds, which merit a special survey in combination with earlier information,[1–4,8,10,11,13,15,16,18–21] have been published recently. Therefore the consideration of the advances in the synthesis, investigation, and applications of network polymers based on cyanamides and oligomers containing cyanamide groups has become the subject of the present review. Attention has been concentrated on the latest studies which have not been described in reviews published previously.[1–4,8,11,13,15,16,19–21]

II. The synthesis of N-substituted cyanamides

The commonest method of synthesis of cyanamides involves the interaction of the corresponding amines with halogenocyanogens (ClCN, BrCN):[8,11,19,21–30]

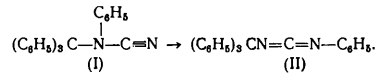


$$2\,R{-}NH_2 + HalCN \rightarrow R{-}NH{-}C{\equiv}N + R{-}NH_2 \cdot HHal,$$

R = alkyl or aryl.

It has also been suggested that cyanamides be synthesised in amide solvents, which play the role not only of solvents but also of acceptors of the hydrogen halides evolved, which makes it possible to increase by a factor of two the yield of cyanamides.[29] This method is convenient for the synthesis of cyanamides from primary amines.[11,28,29,31] In the synthesis of N-substituted cyanamides from secondary amines,[11,28,29] $NaHCO_3$ can be used as the acceptor.

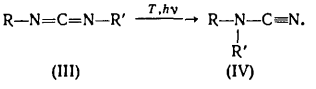
Certain other methods of synthesis of substituted cyanamides are also known.[32–34] The preparation of lower aliphatic cyanamides by the interaction of calcium hypochlorite with amine salts followed by the treatment of the resulting alkyl-disubstituted chloroamines with a solution of KCN or NaCN has been described.[32]



Cyanoethylated bis(cyanamides) have been obtained[35] by the interaction of cyanoethylated diamines with bromocyanogen in accordance with the scheme

The introduction of the cyanoethynyl group; as a substituent at the nitrogen atom lowers the melting point of the cyanoethylated bis(cyanamides) compared with the corresponding unsubstituted bis(cyanamides), which is especially important in the practical use of these compounds.

A specific property of cyanamides is the tendency towards tautomerisation,[36–40] which has a significant influence both on the chemical properties of cyanamides and on the mode of their cyclotrimerisation (on the structure of the products formed). Spectroscopic studies on cyanamide[41,42] have made it possible to establish unambiguously that this compound exists only in the form $NH_2{-}C \equiv N$ in the crystalline state, in aqueous solutions, and in certain organic solvents.

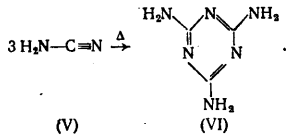


The isomerisation of *N*-phenyl-*N*-tritylcyanamide (I) to *N*-phenyl-*N'*-tritylcarbodiimide (II), observed both in the crystalline state and in solution, has been studied in detail:[43,44]

In both cases, the rate of the process depended on temperature: with increase in temperature, the isomerisation process was accelerated.

The rate of reaction also increases when a non-polar solvent is replaced by a highly polar one, which enabled the authors[43] to propose an ionic isomerisation mechanism.

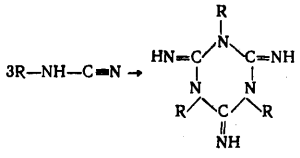
The reverse isomerisation of disubstituted carbodiimides (III) to the corresponding cyanamides (IV) is accelerated both thermally and photochemically, which has led to the conclusion[45,46] that this process has a radical mechanism:



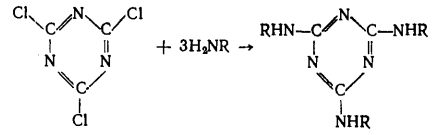
(III) (IV)

The possibility of finding the given compounds in different tautomeric forms depending on the reaction conditions has been confirmed by the results obtained in the study of the alkylation[43–48] and cyclotrimerisation of substituted cyanamides.[8,11,49–61] The alkylation of *N*-monosubstituted cyanamides afforded both *NN*-disubstituted cyanamides[43,44,47,48] and the corresponding carbodiimides[38,43,44,46,48] or mixtures of these products.[38,43,44,48]

III. Cyclotrimerisation of monocyanamides



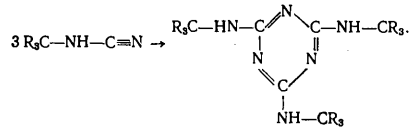
There are few literature data[62–64] on the cyclotrimerisation of cyanamide (V) (T_m = 42 °C) with formation of 2,4,6-triamino-1,3,5-triazine (melamine) (VI), because on heating above the melting point (80–130 °C) cyanamide as a rule dimerises with formation of dicyanodiamide $NH_2-C(=NH)-NHCN$:[50]



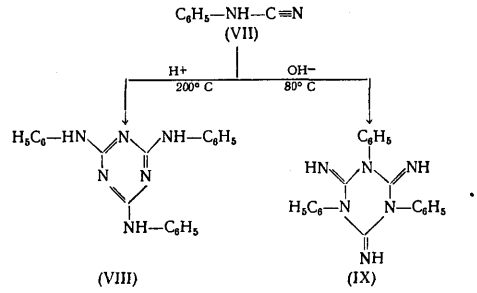
(V) (VI)

The cyclotrimerisation of cyanamide is carried out by heating the latter above 150 °C in solution in tetrahydronaphthalene, diphenyl ether, or a mixture of *m*- and *p*-cresols[62] and also in solution in dimethyl sulphoxide or sulpholan in the presence of an alkali metal or alkaline earth metal hydroxide.[63,64]

The cyclotrimerisation of substituted cyanamides has been frequently reported[49–57,65–67] but until recently the available literature data were contradictory. In some cases the cyclotrimerisation products were isomelamine derivatives,[51,52,55,56,65] whilst in others they were substituted melamines with the normal structure.[53,57,66,67] Thus the cyclotrimerisation of aromatic and aliphatic monocyanamides has been carried out in aqueous or alcoholic solution without a catalyst or in the presence of an alkaline catalyst.[22,49] In all cases, the trimerisation products were the corresponding trisubstituted isomelamines:



Substituted melamines with the normal structure could be obtained only by condensing cyanuric chloride with the corresponding amine:[22]

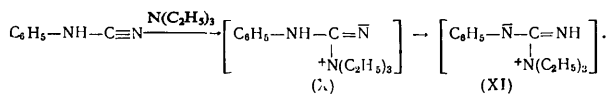


The formation of substituted isomelamines was also observed in the cyclotrimerisation of primary and secondary alkylcyanamides in solution in ethanol.[54] The cyclotrimerisation of compounds having the formula RCO–NR′–CN, where R, R′ = alkyl, arylalkyl, allyl, or methylallyl, in solution in aqueous ethanol in the presence of an alkaline catalyst also leads to the formation of substituted isomelamines.[65]

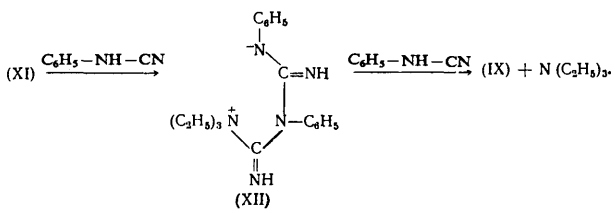
On the other hand, when the trimerisation of tertiary aliphatic cyanamides was carried out under similar conditions,[53] trisubstituted melamines with the normal structure were obtained:

These literature data permit the conclusion that 2,4,6-triamino-1,3,5-tri-azines are formed more readily if the substituting groups generate steric hindrance to attack by the NH group, as in the case of tertiary alkyls,[53,57,66] 1-adamantyl,[66] and *o*-substituted aryls.[67]

A series of studies have been published[8,11,13,58–61] in which the cyclotrimerisation of phenylcyanamide (VII) was investigated. It was found that, depending on the conditions in the cyclotrimerisation of compound (VII), triphenylmelamine (VIII) and triphenylisomelamine (IX) may be formed:

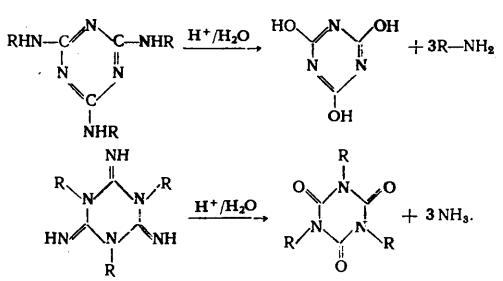


(VIII) (IX)



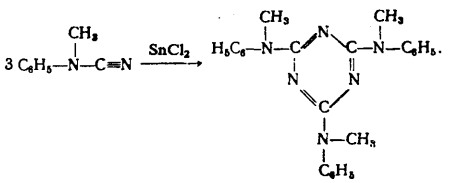
Thus compound (IX) is formed in the cyclotrimerisation of compound (VII) in the melt under mild conditions (20–80 °C), whereas at 200 °C the structure (VIII) is mainly produced.[52] The structure of the final product of the cyclotrimerisation of compound (VII) may be regulated also by the nature of the catalyst. Thus compound (VIII) is formed in the presence of Lewis acids ($SnCl_2$, $ZnCl_2$, $TiCl_4$, etc.), whereas on treatment with basic catalysts (triethylamine, pyridine, triphenylphosphine, etc.) the iso-form (IX) is produced. Lewis acids probably form adducts with compound (VII) having different degrees of substitution of the electron pair involved in the π-bond: ranging from molecular compounds of the type $C_6H_5-NH-CN.MX$ to the ionic structures $C_6H_5-NH-C \equiv N-\overline{M}X$. An increase in the polarisation of the $-C \equiv N$ group tends to accelerate the cyclotrimerisation of compound (VII) with formation of the structure (VIII).

The cyclotrimerisation of compound (VII) catalysed by triethylamine apparently gives rise to the complex of compound (VII) with $(C_2H_5)_3N$ as a reuslt of the nucleophilic attack by the carbon atom of

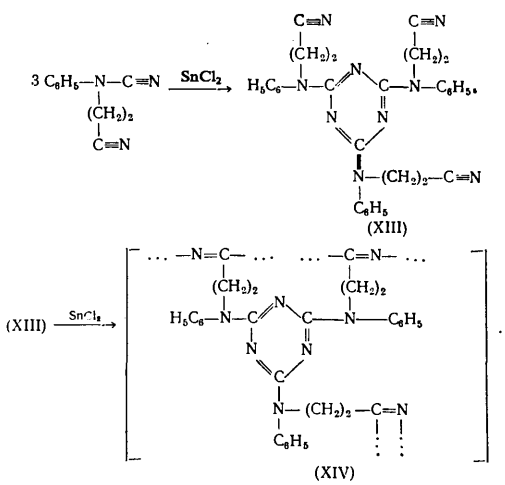


the nitrile group on the nitrogen atom of the tertiary amine:

Of the two tautomeric structures (X) and (XI), compound (XI) is probably more stable. This has been confirmed by IR spectroscopic data, since the intensity of the 2230 cm^{-1} absorption band, characteristic of the vibrations of the $-C \equiv N$ bond of cyanamides,[68] diminishes as triethylamine is added to a solution of compound (VII) in toluene and a band appears at 2130 cm^{-1}, corresponding to the vibrations of the carbodiimide group.[68] Subsequently the complex (XI) apparently combines with two further molecules of compound (VII), forming triphenylisomelamine (IX) via the transition state (XII):[60]



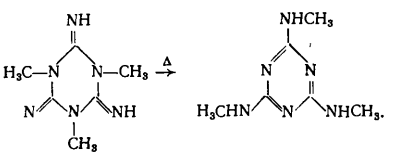
The fundamental difference between the compounds having the isomelamine and melamine structures, obtained as a result of the cyclotrimerisation reaction, is manifested in the products of their hydrolysis: melamine derivatives form, as a result of hydrolysis, cyanuric acid and the corresponding amine, while isomelamine derivatives give rise to the corresponding isocyanurate and ammonia:[11,50,58]



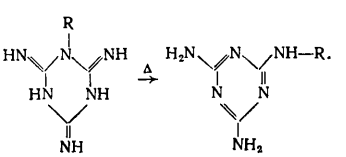
The trimerisation of disubstituted cyanamides was first described by Weith[69] in connection with the synthesis of hexaphenylmelamine by the reaction of diphenylamine with chlorocyanogen, which should proceed via an intermediate stage involving the formation of diphenylcyanamide. 2,4,6-Tri(1-pyrrolyl)-1,3,5-triazine has also been obtained by treating pyrrole with chlorocyanogen.[70]

The kinetics of the cyclotrimerisation of *N*-ethyl-*N*-phenylcyanamide have now been investigated[29] and it has been shown that the presence of the aliphatic substituent in the α-position relative to the nitrile group diminishes the reactivity of the cyanamide group, as a result of which the cyclotrimerisation of this compound proceeds only in the presence of cationic catalysts of the Lewis acid type and leads to the formation of 2,4,6-tris(*N*-ethylphenylamino)-1,3,5-triazine.

The cyclotrimerisation of *N*-methyl-*N*-phenylcyanamide and *N*-cyanoethyl-*N*-phenylcyanamide has also been investigated.[71,72] The cyclotrimerisation of *N*-methyl-*N*-phenylcyanamide[71] was achieved in the melt in the presence of $SnCl_2$:

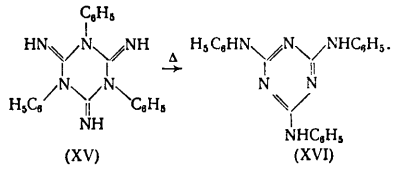


By studying the cyclotrimerisation of *N*-cyanoethyl-*N*-phenyl cyanamide in the presence of $SnCl_2$, the authors[71] showed that, depending on the reaction conditions, not only the corresponding trimer—2,4,6-tris(*N*-cyanoethylamino)-1,3,5-triazine (XIII)—but also the cross-linked polymer (XIV) is formed as a result of the polymerisation of compound (XIII) via the nitrile groups:



At 30 °C, compound (XIII) is formed preferentially, while at 150 to 280 °C the main product is compound (XIV). Heating of compound (XIII) in the presence of $SnCl_2$ affords compound (XIV).

Data concerning the isomerisation of isomelamine derivatives are of great interest.[11,19,56,58] Thus the isomerisation of trimethylisomelamine, synthesised by Hofmann's method,[73] to trimethylmelamine was carried out by heating trimethylisomelamine at the melting point:[56]



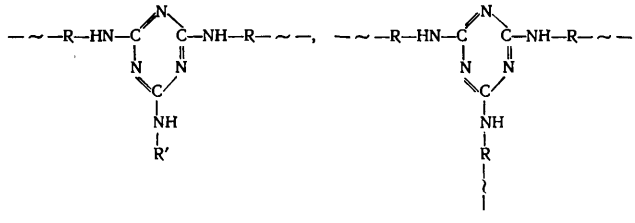
In a study of the influence of elevated temperatures on the reactivity of monosubstituted isomelamines, their conversion into monosubstituted melamines was observed:[74]

The isomerisation occurred in solution in a hydroxylated solvent at a temperature above 80 °C in the presence of 0.1 – 10% of an alkaline catalyst, the yield of the monosubstituted melamine being 95 – 97%.

It has been shown in a study[11,58] of the isomerisation of triphenylmelamine that the substituted isomelamine (XV) isomerises to the melamine (XVI) with the normal structure at a temperature above the

melting point (185 °C); the structure of compound (XVI) does not change on heating to the decomposition temperature. It has also been found that in solution the isomerisation of compound (XV) to (XVI) proceeds at appreciably lower temperatures:[58]

(XV) (XVI)



The characteristic features of substituted cyanamides and of the compounds formed on their cyclotrimerisation considered above must undoubtedly be taken into account in the synthesis and study of the properties of polymers based on cyanamides.

IV. Homopolymers of low-molecular-weight cyanamides

The first information about polymers obtained by the polycyclotrimerisation of substituted cyanamides appeared at the beginning of the 1960's and until the 1970's was limited mainly to patent data alone.[4,8,11,13,19,20,23–30,61–69,75]

The synthesis of polymers based on alkyldicyanamides, having the general formula $N \equiv C-NH-(CH_2)_n-NH-C \equiv N$, containing from 2 to 20 methylene groups, has also been described.[76–82] The polymerisation was carried out purely thermally or in the presence of alkaline catalysts by heating one alkyldicyanamide or a mixture of such compounds at the melting point of the monomers for 0.5–1 h.[76] The soluble oligomers thus formed were used as adhesives for the glueing of plastics, varnish coatings, etc. The final hardening was carried out by heating the oligomer to 100 °C. The structure of the polymers was not investigated.

The copolymerisation of bis(cyanamides) having the general formula $NC-NH-R-NH-CN$ with the monocyanamides $R'-NH-CN$ at 60–350 °C in the presence of acid or alkaline catalysts[83] yielded copolymers containing units with the following structure:

Depending on the ratio of the monocyanamide and the bis(cyanamide), both soluble and insoluble cross-linked polymers were obtained.[83]

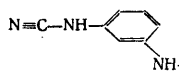
The polycyclotrimerisation of cyanamides obtained from primary and secondary aromatic diamines was first achieved by Korshak, Pankratov, Vinogradova and co-workers.[61] The principal characteristics of this process were determined[11,58,60] and various properties of network heat-resistant and thermostable polymers based on a large set of bis(cyanamides)[4,8,11,13,20,22,29,58–61,71,72,84–108] were investigated in the studies by these workers.

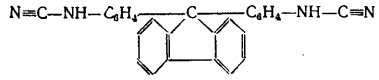
Investigation of polymers based on bis(4-cyanamidophenyl)-methane, obtained at different temperatures, by IR spectroscopy and also by analysing the hydrolysis products has made it possible to discover[11,84] two types of reactions, as for the model compound phenylcyanamide. At reaction temperatures below the melting point of the initial primary bis(cyanamide), mainly a polymer containing isomelamine fragments is formed, whereas at high temperatures the reaction product is predominantly a polymer having the normal melamine structure.

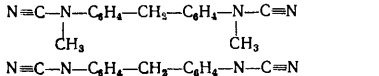
The polycyclotrimerisation in bulk of secondary N-substituted bis(cyanamides)—bis(4-*N*-methylcyanamidophenyl)methane and bis(4-*N*-ethylcyanamidophenyl)methane—leads to the formation of substituted melamines with the normal structure only, as for the model compound *N*-ethyl-*N*-phenylcyanamide.[11,84] Aliphatic substituents in the α-position relative to the nitrile group diminish the reactivity of the cyanamide group compared with primary N-substituted cyanamides. The polycyclotrimerisation of such compounds takes place in the presence of catalysts of the type of Lewis acids. In contrast to patent data,[75–77,79–81,83,109–118] from which it is difficult to derive a general idea about the influence of the chemical structure of the initial bis(cyanamides) on the properties of the polymers, a number of workers[4,8,11,13,20,28,29,58–61,84–108] carried out a series of systematic investigations in which the influence of the nature of the bridging group between the phenylene moieties and the substituents in the cyanamide group on a number of properties of the polymers was traced under comparable conditions.

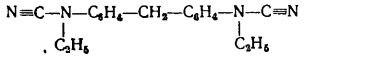
Table 1 compares certain properties of the polymers obtained. All the polymelamines investigated were infusible and insoluble close-network polymers, whose network nodes consisted of *sym*-triazine rings connected by the residues of the initial diamines. According to the results of dynamic thermogravimetric analysis of the polymelamines in air, the temperature of the onset of weight loss of these polymers lies within a fairly narrow range (400–420 °C). However, the subsequent course of the thermogravimetric curves of polymelamines with different structures is different. The highest thermal stability is characteristic of polymelamines containing the fluorene group between the phenylene moieties. The polymelamine based on 1,7-bis(4-cyanamidophenyl)carbaborane is characterised by a 5% weight loss on heating to 900 °C in an inert atmosphere.[11,86,87]

According to Hynds et al.,[109] the polymer based on 1,3-dicyanamidobenzene has a decomposition temperature of 464 °C [thermogravimetric analysis (TGA) at a rate of 6 K min^{-1}].









The polymer based on 4,4′-bis(*N*-methylcyanamido)diphenylmethane is characterised by a 50% reduction of weight after heating for 1200 h in air at 260 °C and has a modulus of elasticity equal to 28 800 of kgf cm^{-2}, which remains almost unchanged after 500 h at 260 °C.[111,112,116]

The study of the thermal stabilities of a series of polymers showed that in a helium atmosphere and in air the temperature of the onset of decrease in the weight of polymelamines is approximately the same. However, whereas polymelamines are degraded to the extent of 90% in air at 700 °C, in an inert atmosphere the coke residue at this temperature amounts to 60–80%.[8,11,84,86,87]

In order to deepen the understanding of the processes occurring in aromatic polymelamines on heating, a detailed study has been made also of the thermal degradation of the polymelamine based on bis-(4-cyanamidophenyl)methane and model compounds such as triphenylmelamine, triphenylisomelamine, and melamine.[11,20,88] The data obtained enabled the authors to postulate that the degradation of polymelamine proceeds not with the decomposition of the *sym*-triazine rings of the polymer but with formation of systems consisting of condensed *sym*-triazine rings.

The study of the character of the thermomechanical curves and of the regions corresponding to the useful employment of aromatic poly-

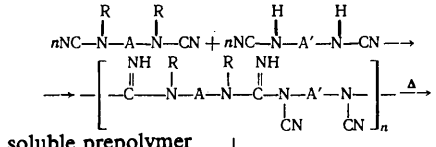
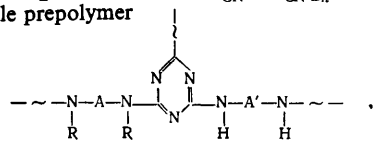
*The degree of conversion of the cyanamide groups in all the polymers investigated was 90%.

**T_{def} is the temperature corresponding to deformations determined from thermomechanical curves (0.8 kgf cm^{-2} load, heating rate 80 K h^{-1}).



***According to TGA data in air (the values obtained in a helium atmosphere are given in brackets) on heating to the corresponding temperatures (heating rate 4.1 K min^{-1}).

melamines[11,84] showed that these polymers are characterised by a high heat resistance, which is limited by their thermal stability.



According to X-ray diffraction data, polymelamines have basically an amorphous structure, but a certain amount of order has been observed in some of them (Table 1), which is also characteristic of polycyanurates obtained by the polycyclotrimerisation of the dicyanoethers of bisphenols.[119,120] Thus the presence of a rigid three-dimensional network, formed during the synthesis, in these polymers is not an obstacle to the appearance of ordered structures. Bearing in mind that the ordering of the structure in close-network polmers after the formation of a network is unlikely, it has been suggested that the structures of such polymers are formed during their synthesis.[11,84]

It has been shown[8,11,59,84,85] (Table 2) that polymelamines are also characterised by good physicomechanical parameters. Some of the aromatic polymelamines obtained have been tested as binders for anti-friction materials. It has been demonstrated that these materials have a stable coefficient of friction in the temperature range 200–300 °C.[87]

The synthesis of copolymers based on primary and secondary aromatic bis(cyanamides) has also been achieved in accordance with the scheme

soluble prepolymer

cross-linked polymer

Di(4-aminophenyl)methane was chosen as the starting material for the synthesis of primary and secondary bis(cyanamides). The use of secondary bis(cyanamides) in combination with primary bis(cyanamides) enabled Kray[121] to reduce the rate of polymerisation and to obtain linear prepolymers which can be effectively processed in solution and in the melt. The prepolymers have been used as binders for glass and foam plastics and cast resins and as a base for honeycomb systems.

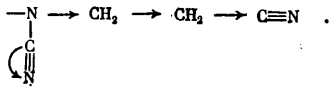


Table 2. Physicomechanical properties of aromatic network polymelamines.[99]

Initial arylbis(cyanamide)	σ_{comp}, kgf cm^{-2}	σ_i, kgf cm^{-2}	Ha_{Br}, kgf cm^{-2}	E_{comp} kgf cm^{-2}

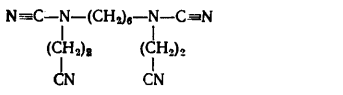
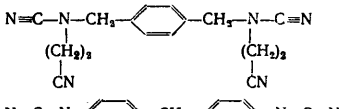
*Ha_{Br} is the Brinell hardness.

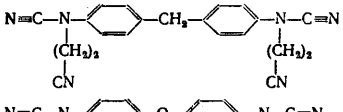
The characteristic features of the polycyclotrimerisation of cyanoethylated bis(cyanamides) of different chemical nature have been investigated.[72,91–94] The presence of the electron-accepting N ≡ C

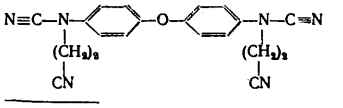
group in the β-position relative to the nitrogen atom of the cyanamide group somewhat increases, compared with *N*-alkylcyanamides, the reactivity of the cyanoethylated bis(cyanamides):

The improvement of the thermal and physicomechanical properties of polymers based on cyanoethylated bis(cyanamides) has been explained by the possibility of additional cross-linking by virtue of the presence of nitrile groups. Thus the impact strength of these polymers is 4–9 kJ m^{-2}, the Brinell hardness is 310–320 MPa, and the density is 1230–1238 kg m^{-3}.[93]









Bearing in mind the results of studies on model compounds, it has been suggested[91–94] that cyanoethylated bis(cyanamides) are polycyclotrimerised at 70–120 °C via the cyanamide groups, while the nitrile groups remain almost unchanged under these conditions. On raising the temperature (150–280 °C), the nitrile groups form polyconjugated

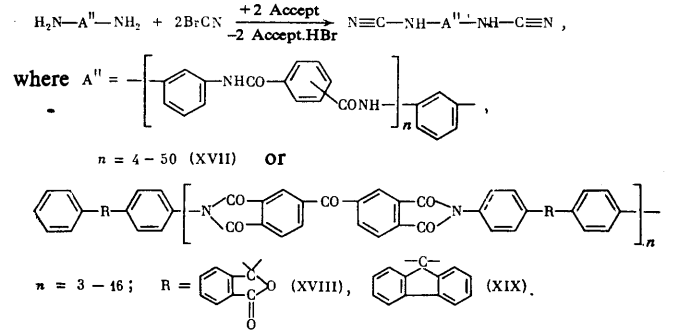
bonds.

Table 3 presents certain thermal characteristics of infusible and insoluble network polymers based on various cyanoethylated bis(cyanamides). The chemical nature of the internodal fragments has an appreciable influence on the properties of these polymers.[92–94]

Table 3. Cyanoethylated bis(cyanamides) and the thermal properties of the polymers based on them.[91–94]

Cyanoethylated bis(cyanamide) structure	Network polymers T_m, °C	n_D^{20}	T_{def}, °C*	$T_{o.d.w.}$, °C**
	—	1.4625	264	200
	—	1.4338	324	200
	65–66	—	300	400
	81–82	—	220	390

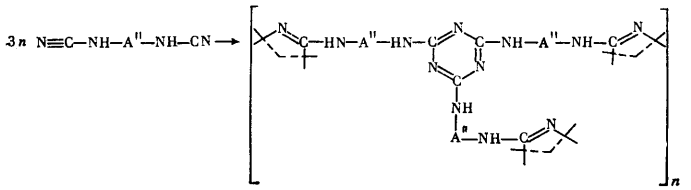
*T_{def} is the temperature of the onset of deformation according to thermomechanical studies.



**$T_{o.d.w.}$ is the temperature of the onset of decrease in weight in air according to TGA data.

The high heat resistance and thermal stability as well as good physicomechanical parameters of the polymers obtained and the ability to polymerise without the evolution of volatile products have made it possible to use cyanoethylated bis(cyanamides) as adhesive compositions with heat resistance up to 250–300 °C.[92–94]

V. Polycyclotrimerisation of oligomers with N ≡ C–NH and N ≡ C–NR functional groups



Some of the promising starting compounds for the synthesis of polymelamines by the polycyclotrimerisation reaction are oligomers containing cyanamide groups. Compared with monomeric unsubstituted bis(cyanamides) they have a lower concentration of functional groups and hence the rate of their polymerisation is lower. All these factors make it easy to monitor and to regulate their polycyclotrimerisation. The introduction of thermally stable fragments between the functional groups permits the synthesis of heat resistant and highly thermostable network polymers whose physicomechanical properties can be regulated by altering the length and nature of the oligomer chains.

The synthesis of the oligomers and their polycyclotrimerisation were first studied systematically and the properties of network polymers based on oligobis(cyanamides) were first investigated in Refs. 90, 95–108, 122, and 123. Korshak and co-workers[95–108] synthesised oligomeric bis(cyanamides) by the interaction of oligomers containing terminal NH_2 groups with bromocyanogen in *NN*-dimethylacetamide, which plays the role of both the solvent and the acceptor of the hydrogen bromide evolved, in accordance with the scheme

The properties and certain characteristics of the compounds obtained are presented in Table 4. It is seen from these data that oligomeric bis(cyanamides) have lower softening temperatures than their high-molecular-weight analogues.[124]

Polymelamines differing in the size and chemical nature of the internodal fragments have been synthesised by the polycyclotrimerisation of oligomeric bis(cyanamides) in accordance with the scheme

where A″ are oligomers having the structure shown in Table 4.[90,95–108]

The polycyclotrimerisation of oligoamidobis(cyanamides) was investigated by IR spectroscopy in relation to the oligomer with $n = 4$. The gradual decrease in the intensity of the absorption band of the N–C–NH groups was observed in the course of the polycyclotrimerisation of this compound and was accompanied by the appearance

of absorption bands in the region of 810 and 1560 – 1580 cm^{-1} referring to the vibrations of the *sym*-triazine ring.[105]

Since the concentration of the functional cyanamide groups per unit volume of the reaction system diminishes with increase in the molecular weight of the initial oligomeric bis(cyanamide), it is almost impossible to investigate in this way the cyclotrimerisation process by IR spectroscopy for oligomeric bis(cyanamides) with a higher molecular weight ($n > 10$). The influence of factors such as temperature, reaction time, pressure, and other conditions in processing by compression pressing on the polycyclotrimerisation of oligomeric bis(cyanamides) was therefore monitored from the yield of the gel-fraction of the polymers formed. The study was performed in relation to the oligoaminobis(cyanamide) with $n = 25$ (Table 4).[90,97,98,103,105] The authors recommend that the oligomeric bis(cyanamides) be processed by compression pressing at 320 °C and a pressure of 60 kgf cm^{-2}. The polymers based on other oligoamidobis(cyanamides), synthesised under the given conditions, contain between 93 and 99% of the gel-fraction depending on the length of the oligoamide chain between the cyanamide groups.

*T_{soft} is the softening temperature determined from thermomechanical curves.
**$T_{o.d.w.}$ is the temperature of the onset of decrease in weight according to TGA data.

The study of the rheological properties of oligoamidobis(cyanamide) melts subjected to a variable load on a capillary viscometer (Table 5) showed that these oligomers are promising materials, capable of being processed by casting under pressure.[98,99]

It has been found[97] that the deformational heat resistance of polymelamines based on oligoamidobis(cyanamides) depends on the size of the internodal network fragment, i.e. on the density of the network. For example, polymelamine based on oligoamidobis(cyanamide) with $n = 4$ softens in the same region as the high-molecular-weight aromatic polyamide with an analogous structure, while the cross-linked polymer has a softening temperature lying above the temperature of the onset of chemical decomposition.

Table 5. The properties of oligoamides with terminal NH_2 groups (a) and of oligoamidobis(cyanamides) (XVII) based on them (b).[98,99]

50	12 000	$0.16 \cdot 10^{10}$	$0.49 \cdot 10^6$

*From terminal NH_2 groups.
**η_{eff} is the effective viscosity of the melt at 320 °C and 6.7×10^7 dyn cm^{-2}.

For a more detailed investigation of the heat resistance of polymelamines, the regions corresponding to their useful employment have been determined for a number of them over a wide temperature range and over a wide range of mechanical stresses. It has been shown that the heat resistance of polymelamines depends on the molecular weight of the internodal network fragment, i.e. on the density of the network. Thus the polymelamine based on oligoamidobis(cyanamide) with $n = 4$ can be used at high mechanical stresses and temperatures in contrast to the other polymers investigated.[97]

Data obtained by dynamic thermogravimetric analysis in air (Table 4) show that the onset of the decrease in the weight of polymelamines based on oligoamidobis(cyanamides) is restricted to a fairly narrow range (400 – 410 °C). However, with increase in the density of the network, i.e. with decrease in the molecular weight of the internodal polymelamine fragments, the onset of the decrease in weight shifts towards higher temperatures.

A comparative study of the thermal stabilities of polymelamines in air and in an inert atmosphere has also been carried out. It has been shown that the temperature of the onset of the decrease in the weight of polymelamines in an inert atmosphere is in the same temperature range as in air. However, whereas in air polymelamine decomposes fully at 700 °C, in an inert atmosphere the amount of coke residue is 60 – 72%.[90,95–108]

The synthesis of polymelamines by the polycyclotrimerisation of bis(cyanamides) tends to form regularly cross-linked thermostable and heat resistant polymers. The polycyclotrimerisation of bis(cyanamides) is characterised by a high selectivity and a high degree of conversion of the cyanamide groups, which is nearly quantitative. The internodal fragments of these polymers are residues of the initial bis(cyanamides).[95–108]

The experimental and theoretically calculated structural parameters of polymelamines based on oligoaminobis(cyanamide) have been compared.[97] The method based on the statistical theory of high elasticity was used to calculate the parameters of the network structure of the polymelamine based on oligobis(cyanamide) with $n = 25$.[97] The experimental number-average molecular weight of the active chain (M_{ce}) and the concentration of the active chains per unit volume of the cross-linked polymer $(V_c/V)_{exp}$ were evaluated from the equilibrium modulus of elasticity E in extension.

*Ha_{Br} is the Brinell hardness.

Table 6 shows, in relation to the polymelamine based on the oligoamidobis(cyanamide) with $n = 25$, that the experimental quantities are virtually identical with the theoretically calculated values, which shows that the degree of completion of the polycyclotrimerisation reaction is nearly quantitative and that the cross-linked polymer formed contains an oligoamide with $n = 25$ as the internodal fragments.[97]

The packing coefficients K have been calculated for certain polymelamines based on oligoamidobis(cyanamides). It was found that the polymelamines have a packing coefficient (0.680–0.690) close to the value determined earlier for linear amorphous polymers ($K = 0.681$).[125] Presumably the polymelamines based on oligoamidobis(cyanamides) are just as close-packed as linear amorphous polymers regardless of the value of M_c.[97]

In order to elucidate the possibility of synthesising polymelamines with specified properties by varying the length of the chain in the initial oligoamidobis(cyanamides) and oligoimidobis(cyanamides),[97,107] the influence of the molecular weights of the internodal fragments on certain physicomechanical characteristics of polymelamines has been studied (Table 7).

The dependence of the electrically insulating properties of the oligoamidobis(cyanamide)-based polymelamines on the effect of temperature, ageing time at different temperatures, and the influence of tropical moisture has been investigated.[100,106,107] Thus the electrically insulating properties of polymelamines based on the oligoamidobis(cyanamides) with $n = 50$ have been investigated as a function of the thermal ageing time at 200° and 250 °C.[100] The studies showed that, after the thermal ageing at 200° and 250 °C for 30 days, the electrically insulating properties of the polymelamines do not change signficantly (Table 8) and that various heat resistant and thermostable articles, used in the electrotechnical industry, can be manufactured from these polymers.

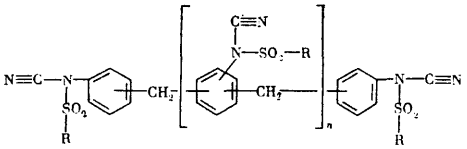
Table 8. Dependence of the electrically insulating properties of the polymelamine based on the oligobis(cyanamide) (XVII) ($n = 50$) on the ageing time.[100]

Conditions	T=200° C			T=250° C			E_{br}, kV mm^{-1}
	tan δ*	ε*	$10^{-15}\rho_V$, Ω cm	tan δ*	ε*	$10^{-15}\rho_V$, Ω cm	
Initial state	0.004	3.3	3	0,004	3.3	3	30
After ageing for							
10 days	0.004	3.6	2	0.004	4.6	5	—
20 days	0.003	3.4	3	0.006	5.1	2	—
30 days	0.004	3.7	1	0.008	5.2	2	25

*At a frequency of 1 MHz.

Table 9. Dependence of the electrically insulating properties of polymelamine based on the oligoamidobis(cyanamide) (XVII) ($n = 50$) on the effect of tropical moisture (38 °C, 98% relative humidity).[107]

Duration of exposure	tan δ*	ε*	$10^{-15}\rho_V$, Ω cm
Initial state	0.004	3.2	3
After exposure to tropical moisture for 10 days	0.007	3.7	8
30 days	0.02	3.7	8

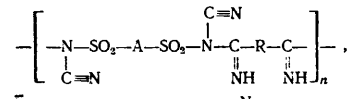


*At a frequency of 1 MHz.

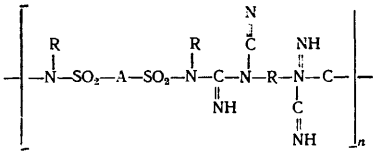
It has been found[100] that the electrically insultating properties of polymelamines based on the oligoamidobis(cyanamide) with $n = 50$ do not change when the polymers are used under the conditions of a tropical climate. The results of these studies are presented in Table 9. Thus the authors[100,106,107] note that the polymelamines investigated exhibit a high heat resistance and thermal stability and have good physicomechanical and electrically insulating parameters at an elevated temperature and under the conditions of a tropical climate and are therefore promising materials for practical use.

Polymelamines, especially aromatic polymelamines, are in most cases highly heat resistant thermostable polymers obtained from a readily available raw material, exhibit an effective adhesion to various materials, and can be readily converted into articles without the evolution of volatile substances.

The preparation of oligomers containing cyanamide groups has been described in a number of studies.[126–128] The authors[126,128] achieved the synthesis of the oligomers by condensing an excess of various diamines with cyanuric chloride, phosphorus trichloride, and phosphoryl chloride. Next the terminal amino-groups were treated with chlorocyanogen in order to obtain cyanamides. The thermoreactive oligomers obtained were cyclotrimerised by the cyanamide groups to prepare heat resistant binders in composite materials.[126–128]



The preparation of α-cyanosulphonamide oligomers having the general formula

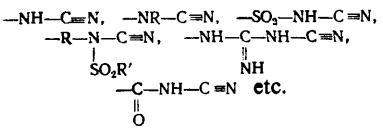


has been described in patents.[129–131] When these thermoreactive oligomers are hardened at 235 °C for 30 min, non-combustible heat resistant polytriazines with T_g = 275 °C are formed;[129] according to differential scanning calorimetric data, the heat of polymerisation is 60–63 cal g^{-1}.[130] The weight losses by the specimen of the composite material based on these oligomers (R = Ph, fillers—fused silica, glass fibre with a fibre length of 6 mm) are respectively 0.32, 0.57, and 4.38% after heating for 500 h at 200°, 225°, and 250 °C.[131]

Oligomeric aromatic polysulphones[132] and polyphosphazenes[133] containing cyanamide groups, and also copolymers of diallylcyanamide with vinyl monomers[134] have been described. Network polymers based on them are obtained by the cyclotrimerisation of the cyanamide groups.

Oligomers having the general formula

(Ref.135)



(Ref.136)

have been obtained by the copolymerisation of bis(*N*-cyanosulphonamides) with various bis(cyanamides).[135,136] These thermoreactive polymers, which can be effectively moulded in the melt, are hardened with formation of highly thermostable network polytriazines.

VI. Polymers based on cyanamides

Data are available, mainly of a patent character, for linear and network polymers based on various monomers with the following functional groups:

The polymers have been obtained by the copolymerisation of these monomers with bis(maleic amides),[137,138] diamines,[139–143] ε-caprolactone,[144] nitriles,[145] diamine salts,[146–148] triallyl cyanurate,[149] cyanates,[150–155] and phenols.[156]

There is also information in the patent literature about polymers obtained as a result of the interaction of cyanamides having different sructures with polyamidoacids, polybenzimidazoles, polyquinoxalines, polybenzothiazoles, polyamides, poly(aryl sulphones), and poly(phenylene sulphides), all containing terminal NH_2 groups,[157] and also as a result of reactions with unsaturated polyethers,[158] polybuta-1,2-diene with a molecular weight of 1000–200 000,[159] butadiene–acrylonitrile copolymers,[160] partly cyanomethylated polystyrene,[161] and polyethyleneimine.[162] Network polymers containing oxazolidine fragments are obtained by the reactions of cyanamides with various epoxides.[163–171]

Various cyanamide-based polymers have found applications as binders for filled plastics,[11,59,61,76,84–86,110,111,121,137,138,140,141,158–160,172,173] adhesives,[11,59,61,76,77,81,84–87,109–111] coatings,[11,26,59,61,76,77,81,84–86,109,113,154] films,[26,77,81,86,113,139] and fibres.[75,77,79,113] It has been suggested that polymers based on compounds containing cyanamide groups be used to prepare various thermostable materials—ion-exchange resins,[142,143] electrically insulating materials,[149,158–160,173] cast articles,[11,26,59,61,84,85,109,113,121] and materials for electronic engineering.[174]

Condensing agents in polycondensation

R D Katsarava
Institute of Molecular Biology and Biological Physics, Academy of Sciences of the Georgian SSR, Tbilisi

ABSTRACT. The advances have been examined and trends noted in the development of a new method of synthesis of heterochain polymers which has been called "direct polycondensation" and is based on the interaction of monomers under mild conditions in the presence of various condensing agents. The latter form reactive derivatives with one of the monomers, which then react *in situ* with the monomer of the opposite nature. It has also been shown that the condensing agents can be used successfully in the synthesis of activated dicarboxylic acid diesters and diamides, which are promising electrophilic monomers for the synthesis of a wide variety of heterochain polymers under the conditions of low-temperature polycondensation in solution. The possibilities of the synthesis of polymers by the "biochemical" activation of monomers, i.e. using enzymes as "condensing agents", are discussed.

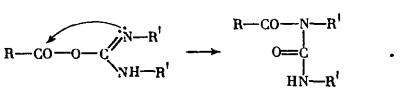
I. Introduction



The polycondensation of dicarboxylic acids with diamines, diols, and other difunctional and polyfunctional nucleophiles proceeds as a rule only at high temperatures (up to 250–300 °C) and at a low rate and is accompanied by numerous side reactions leading to the decomposition of the functional groups and the breakdown of heterounit structures.[1] In a number of instances, for example, when aromatic diamines are used in polycondensation, high-molecular-weight polymers are not formed even at the high temperatures stated above.[2]

One of the most effective and widely used methods of overcoming the above difficulties consists in the employment of the corresponding acid halides (mainly dichlorides), which are distinguished by a high reactivity and which permit the synthesis of high-molecular-weight heterochain polymers at low temperatures (–30 to + 50 °C).[3–5] However, each individual acid dichloride must be synthesised and brought to the required condition, which involves additional expense. The high hydrolytic instability of acid dichlorides, which, apart from the destruction of the functional groups, leads to the evolution of hydrogen chloride, causes corrosion of the apparatus. The synthesis of acid dichlorides therefore requires additional complex apparatus made of corrosion-resistant materials.

In the light of the foregoing, the idea of employing a wide variety of reagents the so called condensing agents (CA), leading to the activation of one of the monomers (more precisely either electrophilic or nucleophilic functional groups) with their subsequent polycondensation *in situ* under mild conditions in organic solvents, is extremely attractive.

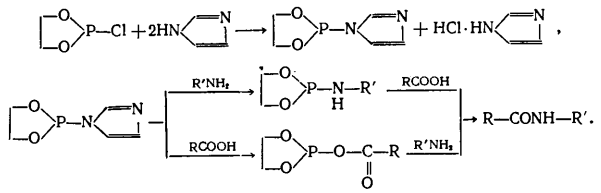
In synthetic organic chemistry, CA have been known for a fairly long time. A wide variety of halogen transferring agents ($SOCl_2$, PCl_3, $POCl_3$, etc.,[6] hexachlorocyclotriphosphazene,[7] cyanuric chloride,[8] picryl chloride,[9,10] picryl fluoride,[11] $SiCl_4$,[12–14] and $TiCl_4$[15]), carbonates,[16,17] sulphites,[18] carbodiimides,[19] a wide variety of phosphorus derivatives.[20–29] including derivatives immobilised on monomeric carriers,[30,31] polyphosphates,[32] as well as other compounds[33–35] have been used as highly effective CA. The employment of the above CA permits the successful solution of many complex synthetic problems, especially when water-soluble CA are used (see, for example, Woodward et al.[33] and Kemp and Chien[34]), which make it possible to form the amide bond or bonds of a similar nature in an aqueous medium. The employment of the above agents in peptide chemistry[12,14,18,20–22,25,26,33,34,36–40] and oligonucleotide chemistry[41] for the construction of peptide and phosphodiester bonds under mild conditions without the preliminary activation of the reactants has proved especially fruitful. This approach had hardly been used for polycondensation systems up to the beginning of the 1970's. A possible reason for this may be sought in the nature of the condensing agents commonly employed at the time in the peptide and nucleotide chemistry (dicyclohexylcarbodiimide, carbonyldiimidazole, etc.), which tended to undergo side reactions involving the destruction of the functional groups. This factor may not be so significant in the synthesis of individual low-molecular-weight substances (at worst it leads to a decrease in the yield) but is of primary importance in the synthesis of high-molecular-weight compounds, while the single-channel nature of the reaction (i.e. the absence of side processes involving chain termination) is a decisive factor for the attainment of high molecular weights.

The CA employed to construct the amide or ester bond form an activated intermediate with an electrophile (carboxylic acid, CO_2, or CS_2—see below) or a nucleophile; this then reacts further with a substrate of the opposite nature. The main requirement which must be met by such intermediate activated compounds is a sufficiently high stability (lifetime) and a low tendency to rearrange or undergo similar side reactions involving the destruction of the functional group. For example, the main disadvantage of carbodiimides as CA is the high tendency of the intermediate activated adduct to rearrange to an inactive acylurea:[19]

The introduction of various phosphorus compounds (both trivalent and pentavalent) as CA into the polymer chemistry made it possible to solve successfully the problem of the synthesis of high-molecular-weight polymers under the conditions of "direct polycondensation".

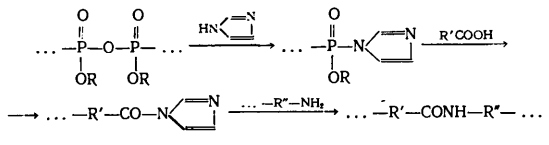
Subsequently other CA without phosphorus were also proposed. The prospects for the employment of various enzymes belonging to the class of hydrolases as CA are being discussed.

II. Phosphorus compounds as condensing agents



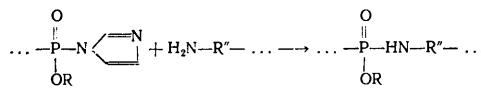
Phosphorus compounds, especially pyrophosphoric acid esters, were used as early as the 1950's–1960's in polycondensation (of the AB type) as CA for the synthesis of regularly alternating polypeptides. For example, polypeptides[20–22] with a molecular weight up to 25 000[22] were synthesised using tetraethyl pyrophosphate. However, up to the 1970's no systematic studies in the field of "direct polycondensation", involving also other "usual" monomers (among them those of the AA–BB type) were performed.

At the beginning of the 1970's, two groups of investigators (Ogata and co-workers and Yamazaki and Higashi) published almost simultaneously a series of communications on the successful use of phosphorus compounds as CA for the direct polycondensation of dicarboxylic acids with diamines and diols to form the corresponding polyamides and polyesters and initiated thereby systematic studies on a new promising field of synthesis of polymers.



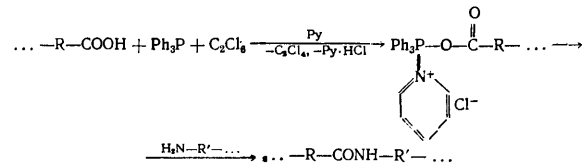
In their first publications, Ogata and co-workers[42,43] described the use of triphenyl phosphite $P(OPh)_3$ in the presence of imidazole as the CA and a somewhat modified version of the method proposed by Mitin and co-workers for the synthesis of peptides.[23] The authors suggest that the polycondensation proceeds with formation of an intermediate mixed anhydride, which reacts further with the diamine to form a polyamide:[43]

$$HOOC{-}R{-}COOH + 2P(OPh)_3 \xrightarrow{\text{imidazole}} (PhO)_2P{-}O{-}CO{-}R{-}CO{-}O{-}P(OPh)_2.$$



The mechanism and kinetics of the polycondensation reaction have been investigated in detail.[44] Apart from $P(OPh)_3$, its chloro-, methyl-, and methoxy-substituted analogues as well as 2-chloro-1,3,2-dioxaphosphorane (ethylene phosphorochlorodite) were used in the above reaction. The dioxaphosphorane reacts with imidazole to form 2-(1-imidazolyl)-1,3,2-dioxaphosphorane, which is capable, in its turn, of activating both an electrophile and a nucleophile:

In subsequent studies,[45] other phosphorus compounds were also used to synthesise polyamides, namely polyphosphoric acid esters (polyphosphates) in combination with imidazole. The mechanism of the activation put forward by the authors includes the formation of an acylimidazole, which has an exceptionally high acylating potential:



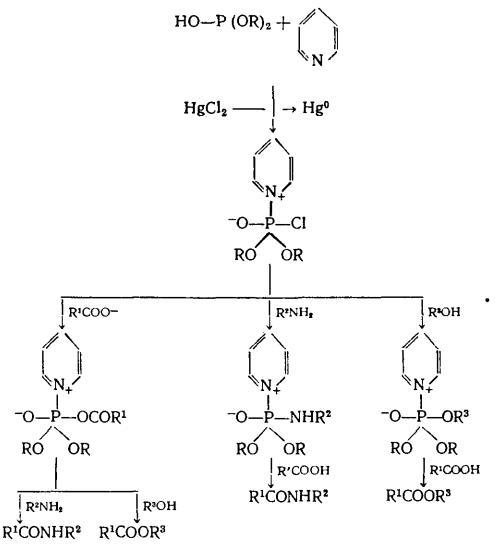
However, together with the reaction investigated, the formation of a relatively inactive phosphamide takes place at an appreciable rate, which is apparently in fact the main cause of the arrest of chain growth:

However, we cannot fully exclude chain termination due to the alkylation of amines, because it is known that phosphoric acid esters are fairly vigorous alkyl group transferring agents.[46]

The triphenylphosphine plus organic polyhalide condensing system[24,25] modified by pyridine[47–52] proved to be very successful. The proposed activation mechanism is as follows in this instance:

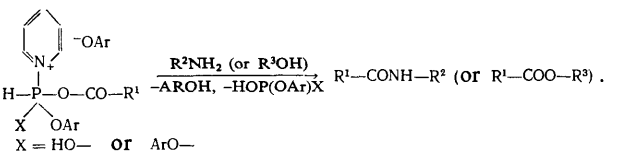
The above condensing system has been used to synthesise polyamides[46,48,52] and polyesters.[47,50]

Triphenylphosphine dichloride (plus a tertiary amine), which is in all probability actually an intermediate in the interaction of triphenyl phosphine with C_2Cl_6 when the reaction is carried out in accordance with the above scheme, has also been used successfully to synthesise polyesters.[53] A characteristic feature of this system is the possibility of regenerating the CA, which is important from the standpoint of the practical application of the method:



$$n\text{HOOCArCOOH} + n\text{HOAr'OH} \xrightarrow{2Ph_3PCl_2,\ B_N}$$
$$\longrightarrow {-}[{-}\text{COArCOOAr'O}{-}]_n{-} + Ph_3PO + B_N\cdot HCl,$$
$$Ph_3PO + COCl_2 \text{ (or ClCOCOCl)} \longrightarrow Ph_3PCl_2 + CO_2 + (CO);$$
$$B_N = \text{tertiary amine.}$$

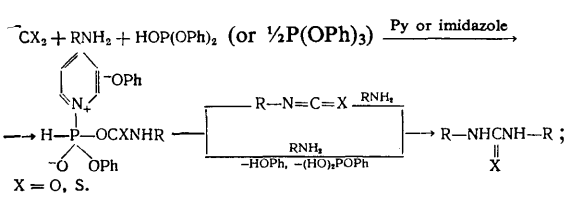
High-molecular-weight polyesters based on bisphenol A and isophthalic acid (η_{int} = 2.24 dl g^{-1}) and *m*-hydroxybenzoic acid (η_{int} = 2.33 dl g^{-1}) have been obtained using phosphorus compounds, the best results being achieved in the presence of polymeric matrices—poly-2-vinyl- and poly-4-vinyl-pyridines or polyepoxyethane.[51]



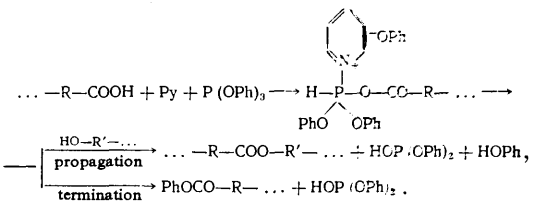
As regards the synthesis of polyamides, in the presence of the $P(OPh)_3$–imidazole system[42–44] low-molecular-weight polyamides with $\eta_{int} < 0.4$ dl g^{-1} were obtained from aliphatic monomers (salts of type AG). This is apparently due to the formation of appreciable amounts of comparatively inactive phenyl esters of carboxylic acids when imidazole is used as the tertiary amine in systems of this kind.[44] The polyphosphate–imidazole system also leads only to the synthesis of low-molecular-weight polyamides ($\eta_{int} < 0.3$ dl g^{-1}) for reasons discussed above.[45] The η_{int} for aliphatic polyamides was raised to 0.76 dl g^{-1} using the PPh_3–organic halide–pyridine system.[52] The system proved to be suitable for the synthesis of aromatic polyamides[47,49,50] especially of poly-*p*-benzamide, whose η_{int} was raised to 5.16 dl g^{-1}.[59] (For the halides employed, see Table 3 below.)

Since 1972, another group of investigators (Yamazaki, Higashi, and co-workers) also undertook systematic studies of a wide variety of phosphorus-containing condensing systems and of their employment both in the direct polycondensation and in peptide synthesis.[54–107] In their first publications, the authors established that the *N*-phosphonopyridinium derivative in the presence of an oxidant ($HgCl_2$) is

extremely reactive towards nucleophiles and activates carboxy- (interacting in the form of the carboxylate anion), amino-, and hydroxy-groups leading to the formation of the corresponding amides and esters on subsequent aminolysis, alcoholysis, or acidolysis:[54,56–58]

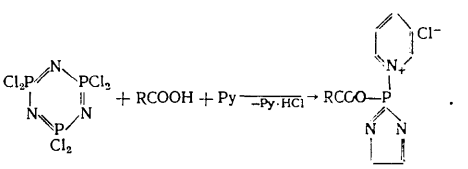


It was subsequently established that phosphates, in particular di- and tri-aryl phosphites, react with carboxylic acids, in the presence of pyridine but without an oxidant, to form the corresponding activated derivatives capable of further interaction with nucleophiles under mild conditions:[55]



Apart from phosphites, other phosphorus compounds can also be used in similar reactions—phosphinites (R_2P-OAr), phosphonites [$R-P(OAr)_2$], phosphonates [$R-P(O)(OAr)_2$], etc., which are presented in Table 1. Only the aryl esters are effective.[65] We may note that the promoting role of pyridine and imidazole (and also of other bases having properties similar to theirs—Table 2) is in all cases significant. Promoting functions are also performed by *N*-methylpyrrolidinone (*N*-MD) (which is in addition the most suitable solvent in the processes indicated) and tetramethylurea. Various organic halides (Table 3) as well as metal salts, particularly LiCl and $CaCl_2$ (Table 4), quaternary ammonium salts, and tertiary amine hydrochlorides (Table 5) are also effective promoting agents in the reactions of aryl phosphites described above.

The main advantages of the systems examined include the fact that the reaction is performed in one stage by adding the CA directly to the mixture of the electrophile and the nucleophile. It is essential to note that, apart from carboxylic acids, in the presence of pyridine or imidazole aryl phosphites form activated derivatives with CO_2 (or CS_2), which leads to the "direct" synthesis of the corresponding ureas:[64]



Various halogen-containing phosphorus compounds, namely $PhOPCl_2$,[69,70] $EtOPCl_2$, $PhPCl_2$, $(PhO)_2PCl$, $(EtO)_2PCl$, etc.,[70] have likewise been used as CA in order to synthesise ureas from CO_2. In the synthesis of polyureas, for example, from di(4-aminophenyl)-methane (t = 40 °C, P_{CO_2} = 20 atm), the systems $P(OPh)_3$ + imidazole in dimethylformamide (η_{ln} = 0.37 dl g^{-1}) and $HOP(OPh)_2$ in pyridine (η_{ln} = 2.24 dl g^{-1}) proved to be the most effective. The $PhOPCl_2$ system in pyridine made it possible to synthesise polyureas at atmospheric CO_2 pressure (η_{ln} = 0.4–0.5 dl g^{-1}).[69]

Aryl phosphites, which are excellent CA in the processes indicated above (in the synthesis of polyamides or their analogues), proved to be relatively ineffective in the synthesis of polyesters, which has been attributed to chain termination as a result of the competing intramolecular esterification reaction:[83]

The best CA in the synthesis of polyesters are pentavalent phosphorus compounds containing a phosphorus–chlorine bond. Thus polyesters (η_{ln} = 0.2–0.8 dl g^{-1}) have been synthesised successfully in the presence of hexachlorocyclotriphosphazene.[75,85,89] It is believed that the reaction proceeds via *N*-phosphinopyridinium derivatives:

Polyesters with higher molecular weights have been obtained by employing the $(PhO)_2P(O)Cl-LiCl$ system in pyridine,[98,101,103] best results being achieved in the presence of *NN*-disubstituted amides (forming Vilsmeier adducts with the CA),[101,103] especially dimethylformamide. The same system has been used successfully to synthesise

Yamazaki and co-workers[104] used a polymeric derivative of *N*-acylphosphoramidite (compound No. 50 in Table 1) as the CA for the synthesis of dipeptides. The use of similar compounds in polycondensation would be of interest, since this would greatly facilitate the removal of polycondensation side products from the reaction mixture and also the regeneration of the CA.

Using the above CA as well as a number of others, Yamazaki, Higashi, and co-workers achieved the syntheses of various high-molecular-weight film- and fibre-forming heterochain polymers: AA–BB and AB polyamides,[59,67,68,72,76–79,82,84,87,88,90–92,94,97,99,100,102,103,106] polyhydrazides,[78,84] polyaminoacids (α and β) and regularly alternating polypeptides,[55,60,62,63,71,80,92] AA–BB and AB polyesters,[75,81,83,86,89,92,97,98,100,101,103,105–107] and polyureas and polythioureas.[61,66,68,69,73,92,93] (Many CA proved to be effective also in the synthesis of peptides.[54,55,63,65,104]) The influence of various factors—the structure of the monomers, temperature, and the nature of the CA, promoting agents, and solvents—on the yield and the molecular weight characteristics of the target products has been investigated. These aspects of the process have been described in detail in the literature.[92,108] Here we shall mention only that high-molecular-weight polyamides can be obtained from aromatic diamines by the proposed direct polycondensation methods. Aliphatic diamines lead to the synthesis of low-molecular-weight polymers, which are relatively unpromising from the practical point of view. This has been attributed to the side interaction of the above diamines with the phosphorus compounds employed.

Subsequent communications by other investigators were devoted both to the solution of specific problems involving the application of condensing systems enumerated above and to the search for a series of new phosphorus-containing CA suitable for polycondensation designed to synthesise heterochain polymers of different classes.

Preston and co-workers[109–118] synthesised polyamides and polyhydrazides using the $P(OPh)_3-Py-LiCl$ system, having extended the Yamazaki–Higashi reaction to various aromatic diamines, dicarboxylic acids, and their hydrazides. It is of interest to note that they succeeded in synthesising poly-*p*-phenyleneterephthalamide with $\eta_{ln} = 6.2$ dl g^{-1} by means of direct polycondensation.

Azuma and co-workers[119–126] synthesised aromatic polyesters[119,120,124–126] and polyamides[121–123] using various diaryl phosphites, triaryl phosphites, chlorophosphines, hexachlorocyclotriphosphazene, chlorodiphenyl phosphate, etc.

A simplified method of synthesis of polyamides, where $P(OPh)_2$ was obtained from phenol and PCl_3 in solution in pyridine, has been described.[127] Without isolating $P(OPh)_3$, the reaction solution was used subsequently as the CA in the polycondensation of aromatic diamines with aromatic dicarboxylic acids. Polyamides with $\eta_{ln} \simeq 1.0$ dl g^{-1} were obtained.

Phosphorus compounds have been used to synthesise heterochain polymers by direct polycondensation,[130–132] including polyureas and polythioureas.[131,132] In the synthesis of the latter, ethylene phosphorochloridite was used as the CA.

Multiblock copolymers containing arylamide and polyoxyethylene fragments have been obtained in the presence of the $P(OPh)_3-Py-LiCl/CaCl_2$ system.[133]

The method of direct polycondensation in *N*-MP [the $P(OPh)_3-Py-LiCl$ system] has been used[134] to synthesise polyamides from *NN'*-terephthaloylbis-β-alanine (a diamidodicarboxylic acid whose dichloride is not obtainable) and hexamethylene diamine. However, despite the use of a wide variety of polymeric matrices [poly(ethylene oxide), poly-*N*-vinylpyrrolidinone, poly-4-vinylpyridine], only a low-molecular-weight polymer with $[\eta] = 0.14$ dl g^{-1} was obtained, which is typical for an aliphatic diamine.

P_2O_5 has been used as the CA for the synthesis of polyamides from aromatic diamines and dicarboxylic acids (both aromatic and aliphatic).[135] The reaction was performed in *N*-MP in two stages—initially a mixed anhydride of dicarboxylic acid and P_2O_5 was obtained (80 °C, 1 h), then the diamine was introduced into the solution and the polycondensation was carried out at 20 °C. Polyamides with $\eta_{int} = 0.18-0.85$ dl g^{-1} were obtained. However, it is essential to note that phosphorus pentoxide dehydrates aliphatic amides with formation of keten imines,[136] which can give rise to complications when aliphatic dicarboxyic acids are used. *NN*-Phenylene phosphonobis[2(3*H*)-benzothiazolone][137] and 1,2-benzoisoxazol-3-yl diphenyl phosphate[138] (Nos. 71 and 72 in Table 1) have also been used to synthesise polyamides.

A method of synthesis of various poly-α-aminoacids with a degree of polycondensation of approximately 50 using the $HOP(OC_2H_5)_2/I_2$ system in the presence of pyridine or imidazole as the CA has been described.[139]

The synthesis of polyamides, polyamidoimides, and polyamidohydrazides using the $P(OPh)_3-Py-LiCl$ system has also been described.[140–143] We may note that polyamides, distinguished by a satisfactory thermal stability, have been synthesised from cyclic aliphatic dicarboxylic acids.

Aharoni and co-workers[144–146] investigated thoroughly the mechanism of the polycondensation reaction with participation of phosphites and concluded that the formation of the *N*-phosphinopyridinium salt or of a mixed anhydride of the carboxylic and phosphorous acids, postulated in the studies examined above, does not occur. The diametrically opposite reaction mechanism, involving the formation of an intermediate aminodiphenoxyphosphine, was proposed:

$$P(OPh)_3 + H_2N{-}R{-}\ldots \xrightarrow[-PhOH]{} (PhO)_2P{-}NH{-}R{-}\ldots \xrightarrow{HOOC{-}R'{-}\ldots} \longrightarrow \ldots {-}R'{-}CONH{-}R{-}\ldots$$

In other words, according to the above workers,[144–146] the nucleophile and not the electrophile is activated, as would follow from the mechanism proposed by Yamazaki and Higashi. Their experimental data[144–146] are fairly convincing, but the role of pyridine solely as a promoting agent is not altogether clear. If pyridine functions only as a proton transferring agent, as suggested by the authors, then the same role could be played more successfully by other bases for example by hexamethylphosphoramide, which, however, is ineffective in the processes indicated (Table 2).

The polyamide extrusion process at 280–300 °C in the presence of small amounts (0.5–1.0%) of $P(OPh)_3$, accompanied by a sharp increase in the molecular weight of the polymer, proposed by Aharoni et al.,[145] is noteworthy.

Korshak and co-workers were the first to use the phosphorylation reaction in order to obtain high-molecular-weight polyamidophenylquinoxalines[147] and silicon-containing aromatic polyamides.[148] Polyamides with quinoxaline units have been synthesised by direct polycondensation using $P(OPh)_3$.[149,150]

A number of other studies have also been published in which a wide variety of heterochain polymers have been synthesised using phosphorus compounds as the CA: PPh_3 for the synthesis of polyesters,[151] PPh_3,[152] and $P(OPh)_3$[153] for the synthesis of polyamidoimides, and $(PhO)_2P(O)-N_3$[154] and $P(OPh)_3$[155–158] for the synthesis of regularly alternating polydipeptides and poly-α-aminoacids.

An interesting reaction involving the synthesis of polyamidines by the reaction of aromatic diamines with benzoic acids using poly(trimethylsilyl phosphate) as the CA, has been described.[159] An amide is formed in the first stage, reacting subsequently with the free amino-group to form the amidine bond:

$$\ldots {-}Ar{-}NH_2 + HOOCAr' \xrightarrow[-H_2O]{Me_3Si{-}\left(-O{-}\overset{\displaystyle O}{\overset{|}{P}}{-}\right)_{OSiMe_3}{-}OSiMe_3} \longrightarrow \ldots {-}Ar{-}NHCO{-}Ar'{-}\ldots \xrightarrow[-H_2O]{H_2N{-}Ar{-}\ldots} \ldots {-}Ar{-}NH{-}\overset{\displaystyle Ar'}{\overset{|}{C}}{=}N{-}Ar{-}\ldots$$

The $P_2O_5-CH_3SO_3H$ mixture has also been used in recent years as the CA in the reaction medium.[160,161] This system is particularly effective in the synthesis of polybenzazoles.

Thus it follows from the foregoing that the direct polycondensation reaction using phosphorus compounds has developed vigorously during the last 10–15 years. The phosphorus compounds proposed as the CA are listed in Table 1. Analysis of the available data shows that, bearing in mind their availability and the results achieved, diphenyl and triphenyl phosphites are the most common and promising substances among trivalent phosphorus compounds, while among pentavalent phosphorus compounds the most promising substance is diphenyl phosphorochloridate, which has the advantage that it can be regenerated after the reaction (see above).

When phosphorus compounds are used as the CA, promoting agents play a significant role, as already mentioned above (Tables 2–5). The exceptionally marked effect of a wide variety of polymers (Table 6), capable of forming hydrogen bonds with the monomers, must be especially emphasised. It was shown for the first time in a number of studies[51,76,77,80] that the introduction of polymers of the above type into the reaction solution increases significantly the rate of polycondensation and the molecular weight of the target polymers. The matrix effects of the added polymers consist in increasing the local concentration of the reactants and possibly in the attainment of their mutually convenient orientation in space. These considerations may be supported, for example, by the formation of high-molecular-weight polyaminoacids directly from free α-aminoacids (Val, Leu, Phe, Met) under direct polycondensation conditions $P(OPh)_3$ + LiCl] using poly-*N*-vinylpyrrolidinone (PDP) with molecular weights of 10^4, 4×10^4, and 3.6×10^5 as the matrix.[80] It has been established that the molecular weight of the final polyaminoacid increases with increasing molecular weight of the PDP and amounts to approximately 0.1 of the latter. In all probability, the matrix influences not only the molecular weight of the polyaminoacid synthesised but also the course of the reaction, directing it towards the formation of a linear polymer. The synthesis of poly-β-alanine from the free aminoacid has also been achieved under similar conditions.[80]

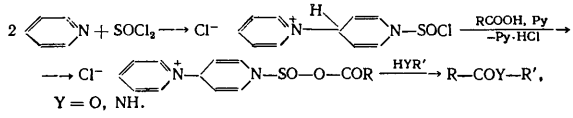
*Increases the rate of reaction or the molecular weight of the polymer synthesised.

It is essential to note that, in contrast to matrix polymerisation, the characteristic features of which have been thoroughly investigated,[162] matrix polycondensation is a new and little investigated field. The reasons for this should apparently be sought in the inapplicability of the traditional low-temperature polycondensation methods in matrix synthesis, mainly owing to the unduly high reactivity of the monomers employed (acid dichlorides, bischloroformates, diisocyanates, etc.), capable of interacting irreversibly with the polymers used as the

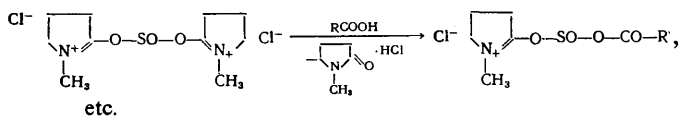
matrices. The development in recent years of "high order" polycondensation methods leads to interesting prospects for the investigation of the matrix polycondensation in which there are, from our point of view, considerable possibilities for polymer chemistry.



III. Phosphorus-free condensing agents

One of the first CA used successfully as early as the end of the 1950's[163,164] for the synthesis of polyhydroxyacids under the conditions of high-temperature polycondensation was thionyl chloride. The first communications about the applicability of $SOCl_2$ as the CA under the conditions of low-temperature polycondensation in the synthesis of polyamides were published by Ueda et al.[165] in 1978. Subsequently a series of studies devoted to this problem were published.[159,166–172] Regardless of the reaction conditions and the nature of the solvents and acceptors employed (tertiary amines) and also the method used to introduce the reactants, polyamides with $\eta_{int} \leqslant 0.6$ dl g^{-1} were obtained in the majority of cases.

A study devoted to the synthesis of polyesters (together with polyamides) under the conditions of low-temperature polycondensation using $SOCl_2$ as the CA was published in 1980.[166] Subsequently the synthesis of polyesters by the above method was achieved also by Maiti and co-workers,[170] who used dicarboxylic acid salts instead of the free acids themselves and also by Elias and co-workers.[173–175] Only low-molecular weight polyesters were obtained in most cases. Best results have been published by Elias and Warner,[173] who synthesised a polyester with $[\eta] = 0.96$ dl g^{-1} from 3-(*p*-hydroxyphenyl)propionic acid.



In the studies quoted, the polycondensation in the presence of $SOCl_2$ was carried out predominantly in two stages: the dicarboxylic acid was treated initially with a stoichiometric amount of $SOCl_2$ and then a nucleophile and a hydrogen chloride acceptor were added to the resulting solution. When the reactants are added in this order, the reaction proceeds via intermediate acid dichlorides and is apparently accompanied to a large extent by the side processes characteristic of the latter,[2–4] which is in fact the reason for the low molecular weights of the final polymers.

It has been established[176] that polyesters with much higher molecular weights (with η_{ln} up to 5.56 dl g^{-1}) are obtained when the mixture of dicarboxylic acid and the bisphenol (or an aromatic hydroxyacid) is treated with the complex $SOCl_2$.Py prepared beforehand at a low temperature. The authors suggest that the complex is converted on treatment with the carboxylic acid into the corresponding mixed anhydride, which then interacts with the nucleophile:

In other words, when the reactants are introduced in this sequence, the reaction proceeds via a different, non-acid dichloride pathway and is free from the disadvantages of the latter.

It has been found that the complex of $SOCl_2$ with *N*-MP is an effective CA.[177] In this case, the reaction proceeds via a mechanism involving the formation of a Vilsmeier adduct:

Various arenesulphonyl chlorides (Table 7), used in 1982–1983[178–180] for the direct polycondensation of aromatic dicarboxylic acids with bisphenols, proved to be excellent CA. It has been established that, in the presence of pyridine alone, arenetosylates, leading to chain termination, are formed as side products together with the ester. This undesirable process was suppressed by adding to the reaction system dimethylformamide[180] as well as other amides—diethylformamide, dimethylacetamide, and *N*-MP[181]—forming Vilsmeier adducts ($R_2\overset{+}{N}$ = $CR'-O-SO_2ArCl^-$) with arenesulphonyl chloride in the presence of pyridine. For example, the polycondensation of hydroxybenzoic acid using the tosyl chloride–dimethylformamide–pyridine system afforded polyesters with η_{ln} up to 2.52 dl g^{-1}.[180] The successes achieved can be attributed to the fact that the polycondensation in the presence of arenesulphonyl chloride proceeds with formation of electrophiles (mixed anhydrides) showing a small tendency to undergo side reactions:[178]

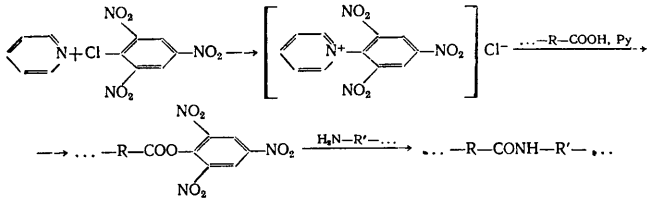
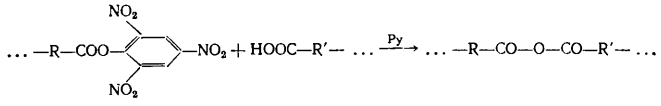
It has been shown[182] that *N*-methylimidazole is an effective base in the polycondensation reactions indicated. The authors suggest that the reaction proceeds via the following mechanism in its presence:



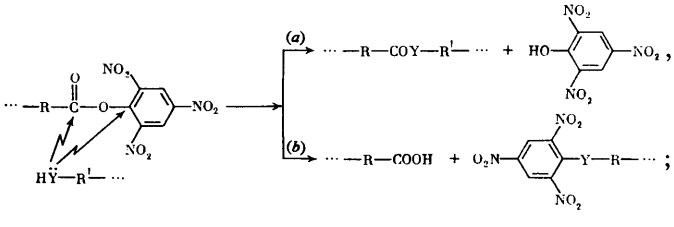
Subsequent studies[183] established that the formation of arenetosylates in the presence of pyridine can also be suppressed by the gradual introduction of phenol into a solution of the acid and tosyl chloride in pyridine. The rate at which the reagent is added has a corresponding significant influence on the molecular weight of the polyester synthesised. For example, when the duration of the addition of bisphenol A to the solution of isophthalic acid and tosyl chloride in pyridine at 120 °C is increased (from 20 to 60 min), the molecular weight of the polymer increases from 14 000 to 54 000.

A different version of polycondensation in the presence of tosyl chloride, also leading to the synthesis of high-molecular-weight polyesters, has been proposed. According to this procedure, a solution of tosyl chloride in pyridine is gradually added to a solution of the dicarboxylic acid and a bisphenol in a mixture of pyridine and dimethylformamide preheated to 120 °C over a period of 5 min.[184]



Arenesulphonyl chlorides have been used successfully to synthesise polyamides, polyesters, and polyamidoesters[185–187] and also polyesterimides.[188–191]

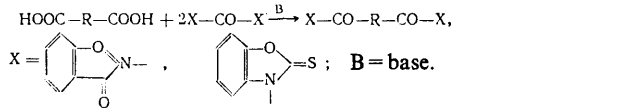
Picryl chloride has been used as the CA for the synthesis of polyamides[192,193] and polyesters.[192] The polymers obtained had comparatively low viscosity characteristics (η_{int} = 0.04–0.55 dl g^{-1}), although in a number of instances the viscosity of the polyamides could be raised to 0.87 dl g^{-1}.[193] On the basis of the data obtained in the study of a model reaction, the authors suggest that the reactions proceed with formation of an intermediate activated ester:



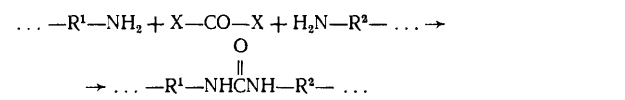
This mechanism is supported by the fact that the reaction does not occur when pyridine is replaced by triethylamine.

The formation of the carboxylic acid anhydride, in all probability as a result of the interaction of the intermediate ester with the carboxy-group, has also been observed in this process:[194]

However, the reaction could hardly be the case of the chain termination because, instead of one reactive group (activated ester group), another no less reactive (anhydride) group is produced. The aromatic nucleophilic substitution reaction (*b*), leading to the formation of relatively inactive trinitrophenyl derivatives and competing with the main reaction (*a*), constitutes a greater danger from this point of view:



Y = O, NH.



Such a reaction has been observed, for example, in the synthesis of polyamides by the polycondensation of activated nitrophenyl dicarboxylate esters with diamines, its probability increasing sharply with increase in the number of nitro-groups in the phenolic part of the ester.[195] Chain termination as a result of the formation of the trinitrophenyl derivative is also possible as a result of the interaction of the nucleophiles directly with picryl chloride or its pyridinium salt.

$SiCl_4$ proved to be an effective CA in the direct synthesis of aromatic polyamides.[196–198] Poly-*p*-benzamide with η_{ln} up to 1.97 dl g^{-1} has been obtained in its presence. $TiCl_4$ can also be used as the CA for the synthesis of polybenzamides (η_{ln} up to 0.14 dl g^{-1}).[199] The formation of SiO_2 and TiO_2 accompanies these reactions, which leads to interesting prospects for the "direct" synthesis of filled materials.

Varoius activated derivatives of carbonic acid and benzazoles (Nos. 10 and 11 in Table 7) have been used as CA in the synthesis of polyamides.[200,201] This resulted in the formation of polyamides with η_{ln} up to 0.5 dl g^{-1}. The polyamides were synthesised in two stages: the dicarboxylic acid was initially treated with the above reagent in an organic solvent in order to activate it:

The diamine was then added to the solution and the polycondensation was carried out. We may note that, if the first stage of the reaction is not quantitative, the residual CA interacts with the diamine to form urea, which leads both to a heterounit structure and to a deviation from equimolar proportions of the functional groups:

This apparently accounts for the low viscosity characteristics of the polyamides obtained. The synthesis of high-molecular-weight polyureas by the reaction of the closest analogues of compounds Nos. 11 and 12 (Table 7)—bis(*p*-nitrophenyl carbonate) and bis(2,4-dinitrophenyl carbonate) (Nos. 13 and 14)—with diamines can serve as evidence supporting the above explanation.[202,203] Incidentally, these processes can also be placed in the category of "direct polycondensation" because the reaction proceeds with formation of an intermediate activated compound (an isocyanate), reacting *in situ* with the free amine.

3-(2-Benzoxazolylthio)benzoisothiazole 1,1-dioxide and 3-(2-benzothiazolylthio)benzoisothiazole 1,1-dioxide (Nos. 15 and 16 in Table 7) have been used to synthesise polyamides by a single-stage method.[204,205] However, the above compounds have no special advantages over the appreciably more readily available CA listed above and in addition lead to the synthesis of low-molecular-weight polymers ($\eta_{int} \leqslant 0.3$ dl g^{-1} for the polyisophthalamides synthesised).

CA have been used successfully to obtain a wide variety of polymers with functional groups. For example, the synthesis of activated polyesters by treating chloro- and nitro-substituted hydroxyacids with dicyclohexylcarbodiimide in dimethylformamide has been described.[206] The polyesters obtained were used for a wide variety of purposes in peptide synthesis.[206–208] Polyesters and polyamides, suitable as polyazoradical initiators in the polymerisation of vinyl monomers, in particular, for the synthesis of block copolymers, have been synthesised by the polycondensation of azobiscyanopentanoic acid with diols and diamines using 2-chloro-2-methylpyridinium iodide as the CA.[209]

The applications of CA in polycondensation are not restricted to processes involving the direct synthesis of polymers. A wide variety of CA—dicyclohexylcarbodiimide,[210,211] $SOCl_2$,[212] trifluoroacetic acid anhydride,[211,212] triaryl phosphites,[211] and diaryl carbonates[211]—have been used successfully to obtain activated dicarboxylic acid diesters. The condensing agents Nos. 15 and 16 (Table 7) have also been used to synthesise *NN'*-bis(2-benzothiazolyl)benzene-1,3-dicarbothioate and 3,3'-isophthaloylbis(2,3-dihydro-2-thioxobenzoxazole)—an activated thioester and an activated amide of isophthalic acid respectively.[205] Activated diesters and diamides are promising polycondensation monomers for the synthesis of heterochain polymers of various classes—polyamides, polyhydrazides, polyesters, polybenzazoles, etc. Many of the CA listed in Tables 1 and 7 are suitable for the synthesis of the above monomers. The choice of a specific CA is determined by the problem formulated and also by its practical usefulness. We may note that this procedure is in many cases irreplaceable and makes it possible to synthesise activated diesters and the corresponding monomers from dicarboxylic acids to which the methods of the "direct" and traditional low-temperature polycondensation are inapplicable. For example, high-molecular-weight film- and fibre-forming polysuccinamides have been synthesised for the first time via activated diesters.[213] They are of interest from the practical point of view as self-annihilating polymers. Only low-molecular-weight polyamides have been obtained from succinic acid by direct polycondensation methods.[59] The use of activated diesters is more promising also for the synthesis of polyamides from highy basic aliphatic diamines.[212,213]

IV. Enzymes as condensing agents

It is known that under appropriate conditions the chemical equilibrium in reactions catalysed by enzymes can be displaced towards the desired product.[214] This applies also to enzymes of the class of hydrolases which under certain conditions, mainly in a non-aqueous organic medium, can be "compelled" to form heterobonds (amide and ester bonds) instead of cleaving (hydrolysing) them. This approach has acquired increasing importance in organic chemistry, for example, in the synthesis of esters,[215] peptides,[216] etc. Together with a high stereoselectivity, the advantage of enzymes is that they are used in catalytic amounts (in contrast to the chemical CA introduced in stoichiometric amounts) and are not consumed, i.e. they are virtually "eternal" CA, provided, of course, that conditions preventing their inactivation are created.[214]

In recent years studies devoted to the use of enzymes also for the solution of purely "polymeric" problems have appeared in the literature. For example, the use of chymotrypsin for the synthesis of high-molecular-weight multiblock copolymers with oligo(ethylene oxide) and oligopeptide segments[217] and the application of enzymes to the synthesis of polyaminoacids[218] have been described. The lipase-catalysed polycondensation of hydroxyacids has been achieved.[219] A short review discussing the possibilities and the prospects for the synthesis of polymers with the aid of enzymes has been published.[220]

— o0o —

Summarising the data described in the review, one may conclude that the employment of CA opens a new and extremely interesting and promising chapter in the field of polycondensation. The use of CA permits the successful solution of complex problems, which it is sometimes difficult to achieve with the aid of traditional methods of synthesis. Among the principal disadvantages of the proposed CA one should include mainly their extensive consumption and the formation of equally large amounts of fairly toxic low-molecular-weight polycondensation products which are difficult to recycle and which give rise to a series of problems, including environmental ones.

Taking into account the foregoing, those systems are promising which could be readily separated, after the completion of the process, from the reaction mixture and regenerated by an appropriate treatment or, what would be even more promising, those which could be used again without additional treatment. It may be that solutions of these problems can be achieved by creating "microreactors" in the form of CA (analogous to those employed in Refs. 30, 31, 104), for example polymeric arenesulphonyl chlorides, aryl phosphites and phosphorochloridates, etc., covalently attached to polymeric supports (soluble or insoluble). It would also be of interest to attach such reagents covalently to polymers playing the role of matrices in polycondensation. Enzymes as well as artificial enzyme-like systems immobilised on polymeric carriers or in inverted micelles (possibly covalently cross-linked for stability) can also be included among promising "microreactors". The application of the above constructions might open the way to a more universal variety of direct polycondensation, which would permit syntheses under milder conditions and independently of the nature of the monomers and would promote the practical realisation of this new and promising method of synthesis of polymers.

Chromonic mesophases

A S Vasilevskaya, E V Generalova, A S Sonin
Institute of Organic Intermediates and Dyes, Moscow

ABSTRACT. The chemical characteristics, structure, and physical properties of one of the most important types of lyotropic liquid crystals—chromonic mesophases—are examined. These liquid crystals are formed in solutions of large planar molecules and have a columnar structure. Chromonic mesophases are observed most often in solutions of dyes and medicinal drugs. The formation of mesophases is preceded by the aggregation of the molecules. The characteristics of this process are also examined in the review.

The bibliography includes 96 references.

V. Conclusion 914

I. Introduction

Liquid crystals have been known for more than 100 years but have entered the mainstream of the scientific and technical progress only during the last two decades—their optical properties proved to be convenient for the manufacture of simple and inexpensive indicating devices with a low power consumption. This led to a wide scale development of both chemical and physical and biological studies on liquid crystals.

By virtue of the unique combination of the properties of a liquid (the absence of translational order and hence fluidity and finite viscosity) and a crystal (the presence of orientational order and hence anisotropy of the physical properties), liquid crystals have become a favourite object in the study of the influence of structural order on the physicochemical properties of substances. It was found that liquid crystal (mesomorphic) properties are manifested by organic compounds in almost all classes. Furthermore, regardless of their chemical nature, a definite set of types of ordering proved to be typical for compounds of all classes, namely nematic with orientational order in only one direction, cholesteric with the same property but having in addition a helical superstructure in the direction at right angles to that of the orientational order, and smectic with the same properties as the nematic type of order but with layered order in a plane perpendicular to the direction of the orientational order. On the other hand, the chemical nature of the substance imparts detailed features to the canonical structural types. Thus the structural element for aromatic compounds is the molecule (sometimes the dimer), while for amphiphilic compounds it is a micelle consisting of tens of hundreds of molecules. A columnar order is characteristic of discotic molecules where a superstructure is produced as a result of the orientation of specific axes along a definite direction. Polymeric liquid crystals sometimes form a nematic mesophase with a hexagonal superstructure and twisted smectic mesophases.

The existence of dye and medicinal drug mesophases has been known for a long time but they have not attracted the attention of chemists or physicists. As early at 1916, Gaubert[1] found that a series of substances capable of forming thermotropic mesophases on fusion produced them when their solutions in ether, toluene, chloroform, carbon disulphide, etc. were evaporated. He later showed[2] that liquid crystals are formed also on evaporation of solutions of certain substances which do not give rise to mesophases on fusion. There is no doubt that all the liquid crystals obtained by this procedure are lyotropic, i.e. they were formed only when a highly concentrated solution was generated as a result of evaporation.

Among the substances investigated, there were also a number of dyes. Lyotropic liquid crystals were observed for anisylidene-*p*-aminoazotoluene,[1] tetrazine,[2] Brilliant Croceine,[3] Methylene Blue, and Neutral Red.[4] However, the structures of the mesophases of these compounds were not established and the above studies therefore remained unnoticed by specialists in the field of liquid crystals and had no influence on the further development of research into the physical chemistry of mesophases. Subsequently, in the 1940's–1950's, studies on the lyotropic mesomorphism of these compounds became of current interest for some time in connection with the vigorous investigation of the influence of the aggregation process in aqueous solutions of dyes on their absorption spectra, but, owing to the lack of interest in liquid crystals in general, they did not receive due development.

The study of the lyotropic mesomorphism of medicinal drugs began as early as the 1920's. The first drugs in which liquid crystal properties were discovered were apparently salvarsan and neosalvarsan.[5] However, these features were studied independently of the study of the liquid crystal properties of dyes and did not find an apparent practical application.

In recent years the situation has changed. The study of the structures of dye and drug mesophases showed that here there is a new type of mesormorphism. It was called chromonic mesomorphism, the name of the antiasthmatic drug sodium cromoglycate—a typical representative of this type of liquid crystal. It became clear in subsequent years that chromonic mesophases constitute one of the subgroups of lyotropic viscotic liquid crystals which are characterised by a column arrangement of planar molecules. Among them one can differentiate viscotic substances proper whose molecules have a symmetrical disc shape.[6–11] On the other hand, chromonic mesophases form planar molecules with a low symmetry having the form of a plank (sanidic). They can therefore be referred to also as sanidic mesophases. Incidentally, certain mesophases have been recently discovered among high-molecular-weight compounds.[12]

Chromonic mesophases have found a practical application. Thus it has been discovered that their lyotropic mesomorphism has a direct

bearing on the dyeing process[13,14] and the therapeutic effect of preparations.[15] Other technical applications of these mesophases have also been found.[16,17] All this has promoted the appearance of much interest in chromonic mesophases.

This review is devoted to the consideration of the present state of the problem of the lyotropic chromonic mesomorphism. Attention is concentrated on the conditions in the formation of mesophases, their structure, and its relation to the chemical structure of molecules and with physicochemical properties.

II. The aggregated state as the premesophase

The formation of the chromonic mesophase cannot be understood without considering its initial stage, the aggregation of molecules in aqueous solutions. This phenomenon is well known and has been studied mainly in relation to dyes.[18–21] It has been shown that the aggregation resembles to some extent micelle formation. There exists a critical concentration (we shall refer to it as the CCA—the critical concentration for aggregation), after the attainment of which a whole series of physical parameters, such as electrical conductivity,[19,22,23] the activity coefficient,[24] and the NMR spectra,[25] change sharply. Below the CCA, single molecules are present in solution, while above it they are aggregates. Typical CCA of certain dyes are listed in Table 1. Evidently the CCA depends not only on temperature but also on the nature of the electrolyte present. This indicates an appreciable role of electrostatic forces in the aggregation process. The CCA also depends on the length of the alkyl chain of the dye. Thus, in the case of 4-alkylamino-1-aminoanthraquinone-2-sulphonic acid, the increase in the length of the alkyl chain from 1 to 4 units (from methyl to butyl) diminishes the CCA at 40 °C in the presence of 0.05 M NaCl from 3.31×10^{-3} to 1.41×10^{-3} M, i.e. by a factor greater than 2. On the other hand, the introduction of 4 M urea into the same dyes increases the CCA almost by a factor of 4.[27] All this indicates that the aggregation process is influenced also by hydrophobic interaction.

Table 1. The values of the CCA for aqueous solutions of certain dyes.[26]

Dye	Electrolyte and its concentration, M	CCA, 10^{-4} M	
		30° C	40° C
Chlorazol Sky Blue FF	0.2 NaCl	2.8	4.0
	0.13 NaCl	5.0	6.2
	0.13 KCl	0.89	1.2
Congo Red	0.025 NaCl	3.0	5.2
	0.025 KCl	2.3	4.0
Benzopurpurine 4B	0.025 NaCl	2.6	4.9
	0.025 KCl	2.2	4.1

An important characteristic of the aggregation process is the aggregation number, i.e. the number of molecules in the aggregate. It is determined by many methods. The average aggregation number $\overline{N}_n$, defined as

$$\overline{N}_n = \sum_i (n_i M_i) \Big/ \sum_i n_i, \qquad (1)$$

where n_i is the number of molecules of type i having a molecular weight M_i, can be found from the rate of diffusion.

As a rule, aggregation begins with dimerisation. This process is accompanied by the absorption of heat. The thermodynamic data for certain typical dyes are presented in Table 2. They make it possible to regard dimerisation as a first-order phase transition which has become diffuse as a result of the finite size of the aggregates, as happens in micelle formation.[29] This can be readily seen from Fig. 1, which illustrates the dependence of the aggregation number of a dye, the sodium salt of 1-amino-4-butylaminoanthraquinone-2-sulphonic acid, on concentration. The aggregation number was calculated from the diffusion coefficient found by the polarographic method.[27] A large proportion of the data on the aggregation numbers of various dyes have been obtained by this procedure.[30–35] Table 3 lists the aggregation numbers for Direct Fast Orange SE in the presence of 2 g litre^{-1} NaCl at different concentrations and temperatures. Two typical tendencies are manifested here: $\overline{N}_n$ increases with increase in the dye concentration and diminishes with increase in temperature. At a given temperature, aggregation is intensified after a time. Thus the aggregation number of Benzo Light Red 8 BL at a concentration of 0.5 g litre^{-1} in the presence of 1.0 g litre^{-1} of NaCl increases by 30% in a week and by 100% in a month.[33] The origin of this behaviour can be understood from general considerations and needs no comment.

Table 2. Thermodynamic characteristics of the dimerisation reactions of certain dyes at 25 °C.[28]

Dye	ΔF, kcal mol^{-1}	ΔH, kcal mol^{-1}	ΔS, cal mol^{-1} K^{-1}
Orange P	−4.28	−10.48	−20.8
Thionine	−4.10	−6.82	−9.10
Methylene Blue	−5.17	−5.90	−0.77
Rhodamine 6G	−4.57	−8.6	−13.5

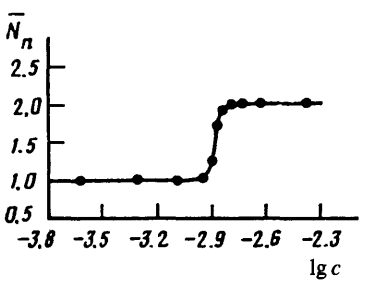

Figure 1. Dependence of the average aggregation number $\overline{N}_n$ on the concentration c of the sodium salt of 1-amino-4-butylaminoanthraquinone-2-sulphonic acid in the presence of 0.05 M NaCl at 30 °C.[20]

Table 3. The aggregation numbers for Direct Fast Orange SE.[33]

T, °C	c, g litre^{-1}	$\overline{N}_n$	T, °C	c, g litre^{-1}	$\overline{N}_n$
25	0.05	39	60	0.05	9
	0.1	43		0.1	10
	0.2	53		0.2	13
	0.5	64		0.5	17

As already mentioned, the presence of an electrolyte in the solution has a significant influence on the aggregation process. Fig. 2 presents the dependence of the aggregation numbers of certain dyes on the NaCl concentration.[36] It is readily seen that the electrolyte concentration has a greater effect on $\overline{N}_n$ than the concentration of the dye itself. Thus an increase in the concentration of benzopurpurine 4B from 0.005 to 0.01 wt.% does not lead to an increase in the aggregation number, which remains 6, but an increase in the NaCl concentration from 0.01 to 0.02 wt.% increases $\overline{N}_n$ from 6 to 400.[30]

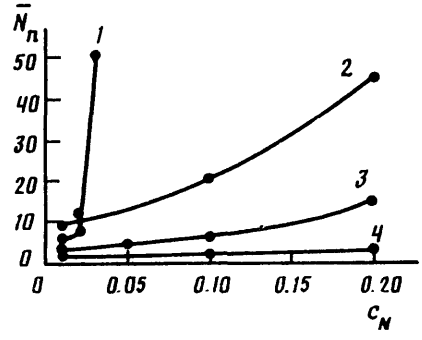

Figure 2. Dependence of the average aggregation number for dyes on the NaCl concentration: (*1*) benzopurpurine 4B; (*2*) Congo Red; (*3*) Chicago Blue; (*4*) Orang P.[36]

The weight-average aggregation number can be found by the classical light scattering method:

$$\overline{N}_w = \sum_i (n_i M_i^2) \Big/ \sum_i (n_i M_i), \qquad (2)$$

It is not identical with the $\overline{N}_n$ found by the diffusion method.[37,38] Thus $\overline{N}_n$ = 552 and $\overline{N}_W$ = 2621 for benzopurpurine 4B in the presence of 0.04 M KCl at 25 °C.[39] Whereas the average aggregation number yields the actual average number of aggregated molecules, the weight-average aggregation number reflects only the maximum degree of aggregation. The discrepancy between $\overline{N}_n$ and $\overline{N}_W$ therefore indicates the polydispersity of the aggregates in the given solution. The knowledge of both aggregation numbers makes it possible to plot a diagram illustrating the distribution of the micelles with respect to size.[40]

The aggregation process has a significant influence on the absorption spectra of dyes.[19–21] The presence of a long-wavelength absorption band *M* and a shorter-wavelength band D with a lower intensity is typical for the monomeric form of the dye. A still shorter-wavelength low intensity band *H* is sometimes also manifested. When aggregates are formed, the intensity of the band M falls but those of the bands H and D increase. An example of this kind is illustrated in Fig. 3, which presents the absorption spectra of a solution of pseudoisocyanine chloride.

A deviation from the Beer–Lambert law is also a sign of the appearance of aggregates in solution, although the degree of deviation is not linked directly to the aggregation number.[41]

Dye solutions at concentrations above the CCA exhibit flow birefringence. This effect has been observed for benzopurpurine 4B both in the absence of an electrolyte[42] and in the presence of 0.05 M NaCl.[43] Hence it was concluded that the aggregates are large highly anisometric particles. Under certain conditions, they can be observed under an ultramicroscope.[43] Similar conclusions were reached also in the interpretation of the absorption spectra.[44]

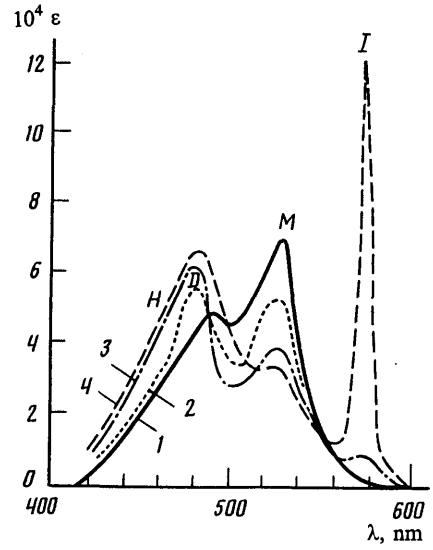

Figure 3. Absorption spectra of aqueous solutions of pseudoisocyanine chloride at 25 °C and different molar concentrations: (*1*) 1.3 × 10^{-5}; (*2*) 1.3 × 10^{-3}; (*3*) 7.1 × 10^{-3}; (*4*) 1.4 × 10^{-2}.[21]

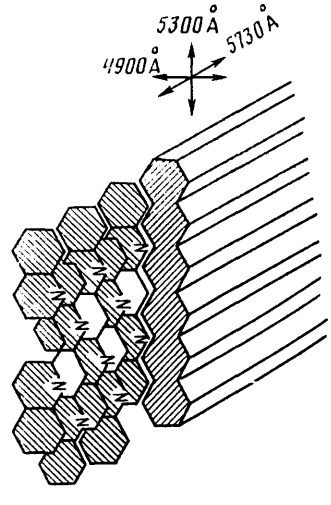

Figure 4. A model of the packing of pseudoisocyanine molecules in the aggregate; above—schematic illustration of optical trichroism.[46]

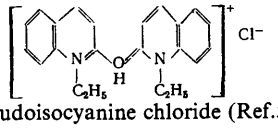
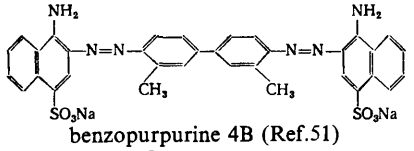
The question arises what these aggregates represent. In order to answer it, it is essential to say a few words about the structure of the molecules of the dyes considered. In the majority of cases, the molecules of ionogenic dyes have a planar form, although the oxygen and hydrogen atoms of terminal groups such as SO_3, OH, or NH_2 project upwards or downwards from the main plane of the dye. In aqueous solutions, these hydrophilic groups are in contact with water



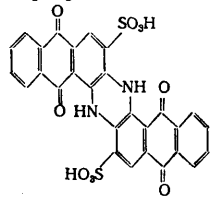
molecules, which inevitably leads to the mutual contact of the hydrophobic hydrocarbon skeletons of the molecules. As a result, the dye molecules are arranged like coins in a stack.[45,46] Specific details of such packing are naturally different for different dyes. Thus in the case of pseudoisocyanine dyes each successive molecule in the stack is displaced relative to the preceding one in such a way that the nitrogen atom in the quinoline ring lies above the carbon atom of the methylidyne group. This model[46] explains satisfactorily the trichroism of the absorption spectra (Fig. 4).

The question arises what retains the molecules in the aggregates. There exists the view[41] that these are van der Waals dispersion forces. However, according to other ideas,[47] hydrogen bonds play the main role here. The latter model presupposes the insertion of two water molecules between the dye molecules for each layer. These molecules form hydrogen bonds with the oxygen or nitrogen atoms of the dye. This view has found support in investigations[48,49] where it was shown that the aggregation of dyes in non-aqueous solutions is also accompanied by the formation of hydrogen bonds.

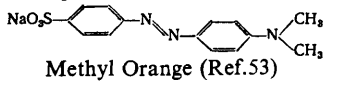


III. Dye mesophases

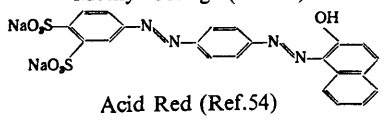
With increase in the dye (and also electrolyte) concentration, the degree of association also increases, leading ultimately to the precipitation of the solid phase. So long as the aggregates are small, their motion is uncorrelated, since they do not experience steric hindrance. The solution remains isotropic and birefringence arises only in flow. On the other hand, when the aggregates grow so much that they begin to "interfere" with one another, their motion acquires a correlated character. They can now move only together, since the orientation of one aggregate in one way or another specifies the orientation of all the others. Spontaneous birefringence arises. Such a phase is a lyotropic liquid crystal phase.



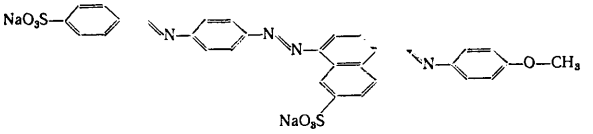
Fairly numerous dyes whose aqueous solutions have chromonic phases are now known. The chemical formulae and names of the most typical liquid crystals are presented below:



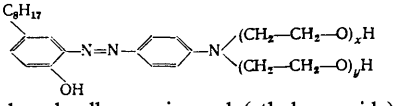
pseudoisocyanine chloride (Ref.50)



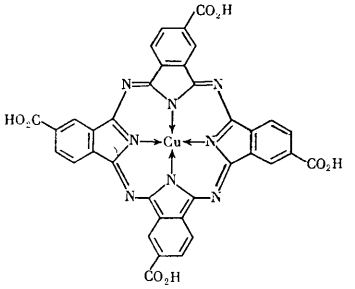
benzopurpurine 4B (Ref.51)



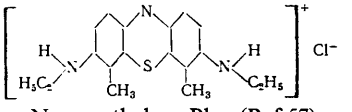
disulphoindanthrone (Ref.52)



Methyl Orange (Ref.53)



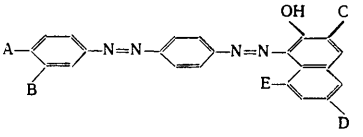
Acid Red (Ref.54)



Sirius Supra Brown (Ref.54)

p-t-Octylphenol yellow amine poly(ethylene oxide) (Ref.55)

Copper-tetracarboxyphthalocyanine (Ref.56)



Novomethylene Blue (Ref.57)

It is readily seen that the liquid crystal dyes belong to different groups. They include cyanine, anthraquinone, and azo-dyes. They are represented by different water-soluble forms—salts and acids. One of the compounds is a dye possessing surface-active properties. It is related to a long-chain hydroxyethylated alcohol,[55] which also forms liquid crystals. Finally, the penultimate dye—copper-tetracarboxyphthalocyanine[56]—represents the large class of metal-containing porphyrins.

All the dyes indicated above have large planar molecules. Thus the length of the benzopurpurine 4B molecule is 24 Å whilst that of disulphoindanthrone is 14 Å. The width of the latter is 8 Å, whilst its thickness, like that of all such planar molecules, is approximately equal to the diameter of the carbon atom (3.4 Å). As already stated, such molecules can be readily arranged in stacks.

The question of the influence of the chemical structure on the ability of the dye to form the liquid crystal phase has acquired considerable importance in this connection. Such influence has been investigated[54] in relation to diazo-dyes having the general formula

(I)

The combinations of the substituents A, B, C, D, and E in various compounds are indicated in Table 4.

Distinct mesophases are formed by the dyes (I) and (IV) over a fairly wide concentration range. The formula of the latter dye (Acid Red) was indicated above. The dye (V) affords a mesophase over a narrow concentration range. The remaining dyes do not form mesophases. Hence one may conclude that the addition of sulpho-groups to the benzene fragment favours the formation of a mesophase to a greater extent than their addition to the naphthalene fragment.

The following rules have been formulated as a result of detailed studies of the influence of chemical structure on the liquid crystal properties of dyes.[58] If the dye molecule consists of one or two planar fragments linked by a twofold axis and has a symmetry point group C_2 or higher and the planar fragments of the molecule have at the same time a single possible conformation, the inogenic hydrophilic groups are such that, at a pH greater or smaller than a certain value pH_0, the dye acquires an appreciable solubility ($\sim 10^{-2}$ M) due to the dissociation of these groups, all the hydrophilic groups are located only on the periphery of the molecular plane, i.e., the planar part from the molecule is hydrophobic, and on the plane and along the periphery of the molecules there are no groups capable of preventing the formation of dimers and multimers, i.e. the molecular planes are capable of sliding freely past one another without experiencing steric hindrance whose overcoming would require the expenditure of an energy greater than kT, then conditions exist (pH, ionic strength, temperature, and concentration ranges) such that the dye forms a lyotropic liquid crystal phase in an aqueous electrolyte solution. An obligatory requirement is also that the adsorption of electrolyte ions does not entail the breakdown of the above conditions.

Although these rules are in fact fairly general, they were found to be well justified in the search for new chromonic mesophases.[59]

Table 4. Substituents in diazo-dyes having the general formula (I).

Compound	A	B		D	E
(I)	SO_3Na	H	H	H	H
(II)	H	H	H	SO_3Na	H
(III)	H	H	H	H	SO_3Na
(IV)	SO_3Na	SO_3Na	H	H	H
(V)	H	H	SO_3Na	SO_3Na	H
(VI)	H	H	H	SO_3Na	SO_3Na
(VII)	H	H	SO_3Na	SO_3Na	SO_3Na
(VIII)	H	H	H	H	H

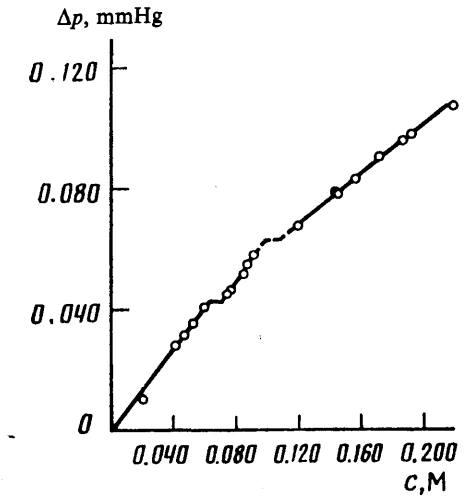


Figure 5. Dependence of the decrease in the vapour pressure of an aqueous solution of the dye Naphthol Yellow S on its concentration at 20 °C.[60]

Like the appearance of aggregates, the formation of the mesophase is a critical process and is accompanied by a sharp alteration of a number of physical properties when both the concentration and the temperatue are varied. In both cases a first-order phase transition take place. Fig. 5 shows how the vapour pressure of an aqueous solution of Naphthol Yellow S decreases as a function of its concentration at 20 °C.[60] Two anomalous sections can be readily seen at ~0.06 and 0.01 M. At low concentrations, an aggregated isotropic solution exists. With increase in concentration, a liquid crystal solution, separated into two phases, arises (see below).

A similar situation occurs also when the temperature is altered. Fig. 6 presents the temperature variation of the specific conductance of a 0.1 M aqueous solution of the disulphoindanthrone dye.[52] Above 32 °C, an isotropic solution exists in which two chromonic mesophases are formed in succession on cooling. The electrical conductivity undergoes pronounced changes at the phase transition points.

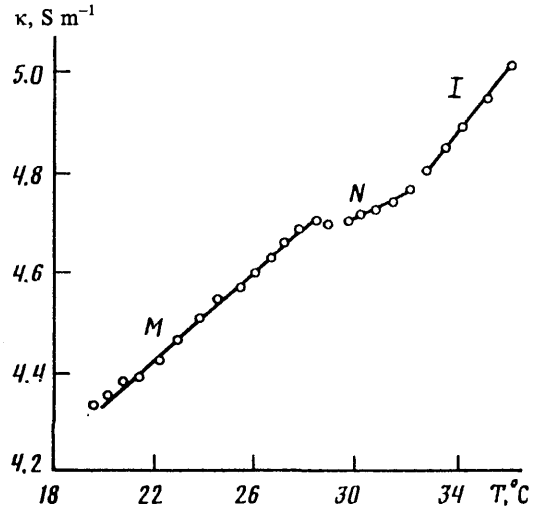

Figure 6. Temperature dependence of the specific conductance κ of a 0.1 M solution of disulphoindanthrone: *M*—hexagonal mesophase; *N*—nematic mesophase; *I*—isotropic phase.[52]

The positions of the points corresponding to transitions to mesophases on the concentration and temperature scales are naturally determined by the nature of the dye and the solvent. This can be represented most fully by phase diagrams (see below). However, in order to provide an idea about the order of magnitude of the quantities, Table 5 lists the critical concentrations at which typical dyes form mesophases at room temperature. On comparing the data in Table 5 with the values of the CCA listed in Table 1, it is readily seen that the transition to the mesophase is completed at concentrations which exceed on average the CCA by two orders of magnitude.

The formation of mesophases in dye solutions is characterised not only by the appearance of double refraction but also by a change in the transmission spectrum—a new narrow band (the so called *J*- or *Z*-band) appears in the long-wavelength region. It is readily seen in Fig. 3. Partial polarisation and fluorescence are observed in this part of the spectrum.[44–46,50]

The formation of a liquid crystal is accompanied by yet another interesting effect—the appearance of induced optical activity. It has been observed[61] in an aqueous solution of 1,1'-diethyl-2,2'-carbocyanine iodide after the addition of NaCl. The optical activity is due to the linear dichroism arising as a consequence of the ordering of the supermolecular structures. It appeared only after the cell had been rotated around its longitudinal axis.

Table 5. Critical concentrations for the formation of chromonic mesophases by typical dyes in aqueous solutions at room temperature.[52,60]

Dye	Critical concentration, 10^{-2} M
Amaranth	3.8—4.2
Naphthol Yellow S	6.2—7.0
Potassium Methyl Orange	2—10
Pseudoisocyanine chloride	1
Disulphoindanthrone	10
Benzopurpurine 4B	1—10

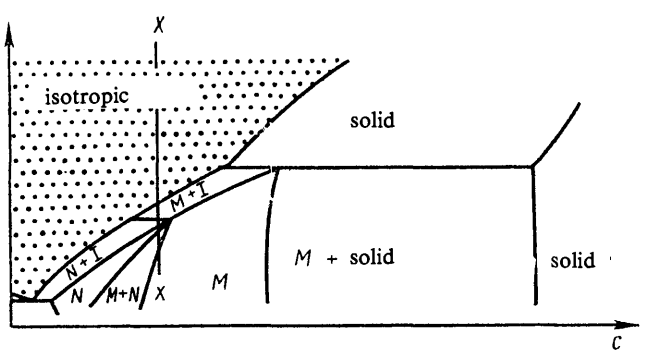

Figure 7. Typical phase diagram of chromonic mesophases.[54]

The appearance of the chromonic mesophase entails the appearance of spontaneous birefringence and of characteristic textures which differ little from the textures of the usual thermotropic liquid crystals (see below).

There are altogether still few complete phase diagrams for binary dye–water systems. A phase diagram which is to some extent typical is illustrated in Fig. 7.[54] Leaving aside the solid phases, we shall consider the sequence of mesophases arising on heating along the *X–X* line in the above diagram. For the typical dye Sirius Supra Brown, this line corresponds to a concentration of 16 wt.%. At room temperature, the dye forms the mesophase *M*. It follows from the analysis of the X-ray diffraction patterns for this phase that the thickness of the dye molecule is 3.4 Å and the parameters of the hexagonal cell are 40 and 23 Å, i.e. are in the ratio $1 : 1/\sqrt{3}$.

A model of such hexagonal structure is illustrated in Fig. 8. It was constructed taking into account the real rectangular structure of the dye molecule. Although the centres of the columns are arranged in accordance with the hexagonal law, in fact the structure should be more correctly regarded as being of the "chevron" orthorhombic type. This thickness of the layer of counterions and water between the columns of the dye molecules is then 10—20 Å.

In certain dyes, the hexagonal mesophase has a more complex nature. For example, four varieties of the mesophase *M* have been found in Acid Red. At room temperature and a dye concentration of 14 wt.%, the usual mesophase *M* is produced. However, when it is heated to 50 °C, lens-shaped regions, resembling the sodium caprylate "sticks" are formed.[62] This is the second hexagonal mesophase. On further heating, the lens-shaped regions merge, forming an island type texture, which belongs to the third hexagonal phase. Above 90 °C, the lens-shape regions reappear, giving rise to a network texture. This is the fourth mesophase *M*. However, presumably not all the formations described above are really mesophase *M*. Analysis of the textures described by Jones and Kent[63] suggests that at least the high-temperature phase is nematic (*N*).

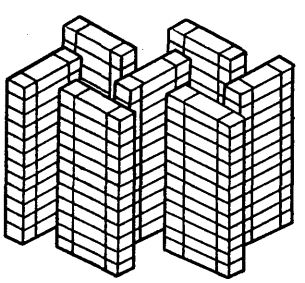

Figure 8. A model of a hexagonal chromonic mesophase *M*.[54]

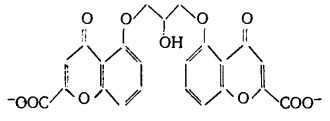
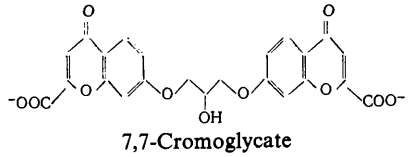
This mesophase *N*, is clearly manifested on the phase diagram presented in Fig. 7 only beyond the two-phase region (along the *X–X* line). It has a typical Shchlieren texture with appreciable planar regions (see below). In the nematic mesophase *N*, the columns of the dye molecules are fairly free. They are structural units like the anisometric micelles in micellar nematic phases.[64] On the X-ray diffraction patterns of the mesophases *N*, only one reflection, permitting the estimation of the thickness of the dye molecules, can be observed.[65,66] The number of such molecules in each column is $10^3 - 10^6$ depending on the concentration and temperature.[66]



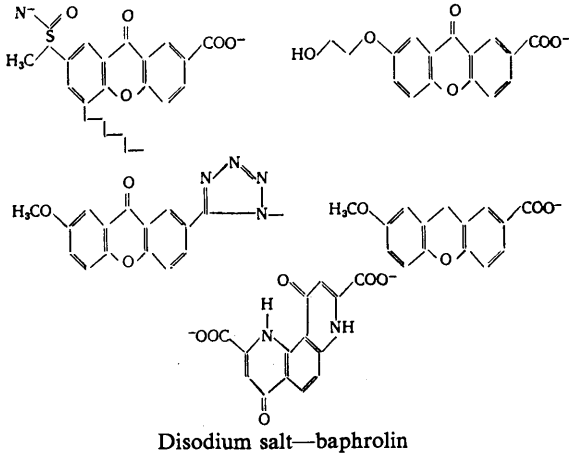
A few words have to be said about the chromonic phases of the porphyrins. Copper compounds are sparingly soluble in water but in the presence of NH_4OH (pH 10—12) both nematic and hexagonal phases are clearly manifested.[56,67,68] A nematic mesophase has been found[69] also in cobalt(II)-phthalocyanines.

In conclusion, we may mention the behaviour of the chromonic phases of dyes at high concentrations. At the critical concentration of the dye or the electrolyte, a solid phase is precipitated from the lyotropic mesophase. Structural and electron microscope studies have shown[17,65,66] that it has no crystal structure but exhibits double refraction. It is, as it were, a "frozen" chromonic phase in which the columns are oriented in parallel. Such a solid phase is characterised by a high dichroism and is used to manufacture polaroids.[16,17,70]



IV. Medicinal drug mesophases

We shall turn initially to mesophases of compounds whose properties are close to those examined in the previous Section. We shall deal with the derivatives of naphthylaminedisulphonic acids[71] related to the widely familiar dye Congo Red. Many of these derivatives are highly active agents against trypanosomes, the simplest parasites in human and animal blood and tissues. Many of them possess liquid crystal properties. The sodium salt of *N*-(*m*-aminobenzoyl)-2-naphthylamine-5,7-disulphonic acid, the tetrasodium salt of *N*-(*m*'-aminobenzoyl-*m*-aminobenzoyl)-2-naphthylamine-6,8-disulphonic acid, the disodium salt of *N*-(*m*'-nitrobenzoyl-*m*-aminobenzoyl)-2-naphthylamine-6,8-disulphonic acid, and also free *N*-(*m*'-nitrobenzoyl-*m*-aminobenzoyl)-2-naphthylamine-4,8-disulphonic acid may serve as examples. It is of interest to note that there exists a distinct correlation between the therapeutic effect and the affinity of these compounds for cotton in dyeing.[71] This shows that there is a single mechanism of their action: the medicinal drugs add equally readily to chemically similar groups in copper and trypanosomes, blocking the reproduction of the latter.



A large group of antiasthmatic drugs also form chromonic mesophases. These are mainly the sodium salts of non-steroid anions, whose structures are presented below:[15,72,73]

Cromoglycate. Disodium salt—cromolyn, intal, sodium cromoglycate (DSCG)

7,7-Cromoglycate

Disodium salt—baphrolin

Examination of the structures of these compounds makes it possible to differentiate the following general features:[15] (1) all the compounds have rigid planar aromatic nuclei containing benzopyrone or isoelectronic benzopyridone groups; (2) there are two hydrophilic groups at the opposite ends of the molecule in all these compounds, one of the groups representing an acid residue and the other either yet another acid residue or another group capable of forming a hydrogen bond. These groups do not have a permanent position: in some cases, they are linked directly to the pyrone ring, whereas in others they are linked to a neighbouring ring.

We may note that the benzopyrone and beonzopyridone structures can have an appreciable dipole moment if the molecule contains in the ring an oxygen atom which carries a large positive charge. For this reason, such an atom does not form hydrogen bonds.

The mesophases of these compounds are formed for the same reason as the mesophases of the dyes examined above. Here too water molecules play a major role (see above).

Like dyes, antiasthmatic drugs possess two main chromonic mesophases—nematic (*N*) and hexagonal (*M*). These phases have been investigated in greatest detail in relation to sodium cromoglycate (DSCG).

The phase diagram for the DSCG–H_2O system (Fig. 9) has been frequently investigated,[72,74–76] being gradually refined and amplified. On the whole, it resembles the phase diagrams for chromonic dyes (cf. Fig. 7), but there are also certain differences. A common feature is the existence of a premesophase region where aggregates, usually dimers, are formed. At room temperature, aggregation begins when the DSCG concentration reaches approximately 5 wt.%.[77] On the other hand, in the concentration range 5–25 wt.%, the aggregation of molecules is already manifested when the temperature of the system exceeds by 10–15 °C the temperature of the region of the mesophases.[78]

As for dyes, there are two chromonic mesophases—nematic (*N*) and hexagonal (*M*)—in the DSCG–H_2O system. The presence of extensive two-phase regions is also a common feature of these two diagrams.

Table 6. The enthalpies and temperatures of the $N + I \rightarrow I$ transitions in aqueous 13 wt.% DSCG solution.[79]

NaCl concentration, M	pH	ΔH, cal g^{-1}	Transition temperature, K
—	6.9	0.39	314.9
—	6.5	0.49	314.4
—	6.0	0.40	313.2
—	5.0	0.36	313.7
10^{-6}	—	0.40	310.2
10^{-5}	—	0.54	309.9
10^{-4}	—	0.58	310.0
10^{-3}	—	0.54	307.4
10^{-2}	—	0.40	309.9
10^{-1}	—	0.49	314.7
0.5	—	0.54	323.0
1.0	—	0.43	330.5
1.5	—	0.62	334.9

The positions of the mesophases on the phase diagram depend on the pH of the solution and on the concentration of the added salts.[79] This conclusion is well illustrated by Table 6, which lists the temperatures and enthalpies of the transition to the isotropic phase at different pH and NaCl concentrations. It is seen from the table that the pH has only a weak influence on the enthalpy and temperature of the transition. On the other hand, the influence of the salt concentration is very appreciable, the transition temperature falling initially and then increasing as the concentration rises. A similar effect was found also after the addition of KCl and LiCl. The minimum transition temperature corresponds to a different salt concentration: 10^{-3} M for NaCl, 10^{-4} M for KCl, and 10^{-5} M for LiCl. It is of interest to note that the crystal-nematic phase transition temperature also increases only slightly with increasing concentration of the salts investigated.[79]

The principal difference between dyes and the DSCG – H_2O system is the presence on the phase diagram of the latter of a new smectic mesophase, with a hitherto unknown structure, at low temperatures (–4 °C) before the transition to the solid phase.[80] It is designated as III in Fig. 9. Measurement of the enthalpy of the transition with the aid of a differential scanning calorimeter (DSC) permitted the hypothesis[75] that in fact two mesophases III exist. However, analysis of the NMR spectra and optical observations have not so far confirmed this hypothesis.

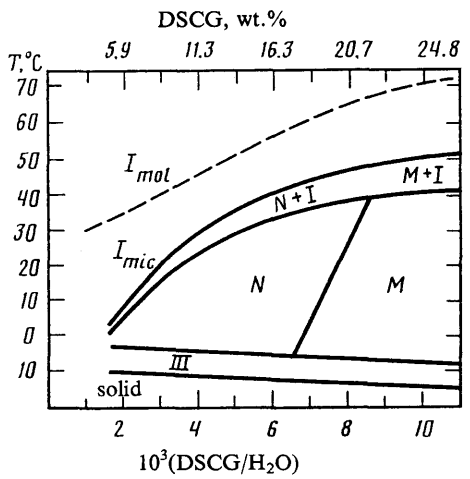


Figure 9. Phase diagram of the DSCG – H_2O system: *M*—hexagonal mesophase; *N*—nematic mesophase; *I*—isotropic phase; I_{mol}—isotropic molecular phase; I_{mic}—isotropic micellar phase.[72]

The mesophase III is satisfactorily manifested following the addition of ethylene glycol or glycerol to the system. The starting point of the solid phase to give the mesophase (III) then diminishes and the temperature of the transition to the nematic phase increases. Thus the region of the existence of the mesophase (III) expands. This made it possible to find the thermodynamic characteristics of the phase transitions in this system with the aid of the DSC. As for thermotropic liquid crystals, fusion to give the mesophase is a first-order phase transition accompanied by large heat and entropy changes. On the other hand, the transitions between the mesophases and between the mesophase and the isotropic liquid have all the features of weak first-order phase transitions. With increase in the glycerol content, the heat changes diminish and the transition temperatures increase.

New mesophases have also been found in the 7,7-cromoglycate (7,7-DSCG) – H_2O system.[73] At temperatures below the temperature of the existence of the mesophase *N* (in the 7,7-DSCG concentration range form 3 to 25 wt.%), an extensive region of a birefringent gel phase (the phase *R*), having a network structure, was discovered. The texture of this phase is illustrated in Fig. 10*a*. In the same temperature range as for the phase *N* but with a salt content above 15 wt.%, the more ordered and denser phase *S* was found (Fig. 10*b*).

The mesophases *N* and *M* give rise to readily identifiable optical textures (Figs. 10*c* and 10*d*), typical for chromonic mesophases.[15,72–75] Their structure was investigated by small angle X-ray diffraction analysis[74,76,81] and NMR.[76,78,80,82]

We shall consider primarily the shape of the DSCG molecule. Here there is no unanimous view as yet. In the first study concerned with the solid phase,[72,74] a planar molecular structure was postulated although it was also suggested[74] that at high water concentrations the planar configuration can hardly persist as a consequence of the possibility of the free rotation of one end of the cyclic system relative to the other about the –CH– bond. However, light scattering and magnetic double refraction data[77] have not confirmed this hypothesis even in the concentration range 0.3 – 3 wt.% (isotropic solution). The planar configuration is likewise supported by the formation of hydrogen

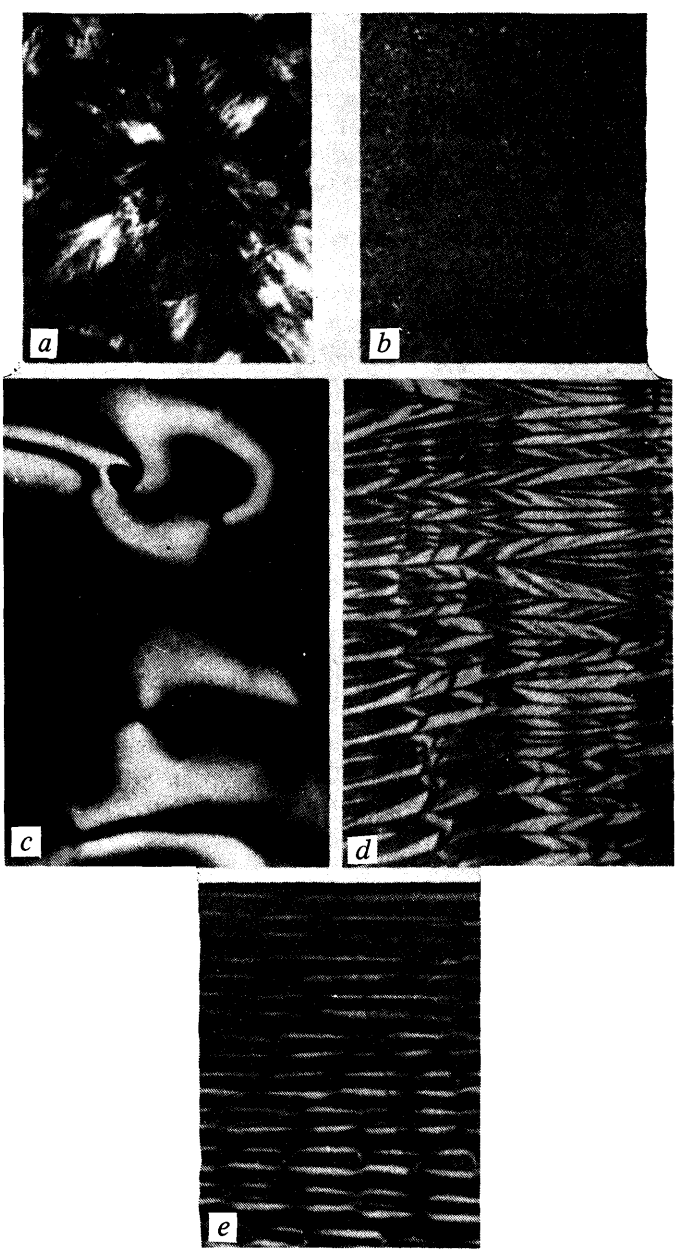

Figure 10. Textures of chromonic mesophases: (*a*) *R*; (*b*) *S*; (*c*) *N*; (*d*) *M*; (*e*) "bamboo".[15,73,79]

bonds between the water molecules and the hydroxy- and carbonyl groups of the DSCG molecules. This is indicated by the pronounced hygroscopicity of solid DSCG and the presence of an appreciable amount of bound water in the mesophases.[72,74] However, the non-coplanarity of the chromonium rings (the angle between them is 53°) was observed in a later study,[83] where the detailed structure of DSCG was found. It may be that such non-coplanarity is characteristic only of the solid phase.

Important information about the structure of DSCG was obtained by small angle X-ray diffraction.[74] Reflections with the ratios $1:1/\sqrt{3}:1/\sqrt{4}$ are clearly manifested in the phase *M*, which indicates hexagonal packing. In addition there is a reflection corresponding to a distance of 3.4 Å, which is interpreted at the identity parameter along the long axis of the column, i.e. as the thickness of the DSCG molecule. If it is assumed that the columns have a circular cross-section, then it is easy to calculate their diameter and the distance between them. Thus in solution at a DSCG concentration of 20 wt.% at room temperature the column diameter is 16 Å and the distance between the columns is 43.3 Å. The nematic mesophase gives rise to only one reflection corresponding to a distance of 3.4 Å, which indicates the breakdown of hexagonal packing.

Thus the structure of the mesophases in the DSCG–H_2O system corresponds to the chromonic type. However, bearing in mind the size of the DSCG molecules and the diameter of the columns, presumably[84] four molecules are accommodated in the cross-section of the chromonic columns, the polar ends of the molecules projecting to the outside (Fig. 11*a*).

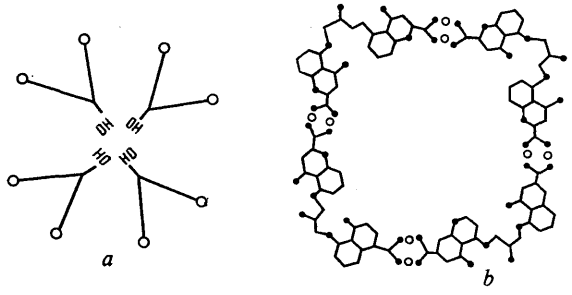

Figure 11. Models of the packing of DSCG molecules in chromonic columns: (*a*) cylindrical model;[84] (*b*) square model.[85]

However, this simple structure agrees poorly with the high moisture absorption capacity of the mesophases. Density measurements have shown[72] that in the mesophase *M* there are 9 water molecules for each DSCG molecule, while in the mesophase *N* there are 260 water molecules. Taking into account these data and other information about the structural features of the system, another hypothesis has been put forward concerning the structure of the columns,[85] according to which 4 DSCG molecules, linked to hydrated sodium ions, form hollow rings (Fig. 11*b*). These rings are superimposed on one another, as in the usual chromonic columns, forming square hollow columns filled with water. In the nematic phase, the columns are distributed freely, while in the mesophase *M* they are packed in accordance with the hexagonal law, as shown in Fig. 12.

The latter model was fully accepted by Hartshorne and Woodard,[86] although the square form of the chromonic columns was rejected.

The chromonic type of the structure of the DSCG mesophases was confirmed by X-ray diffraction.[76] The phase (III) was investigated in the same study. It was found that it too is made up of columns, but more detailed data were not obtained. The study of all the phases in the DSCG–H_2O system by ^2H, ^{17}O, and ^{23}Na NMR showed[76,78,80] that in all the mesophases the anisotropy of the diamagnetic susceptibility $\psi_a = \psi_{\parallel} - \psi_{\perp}$, where $\psi_{\parallel}$ and $\psi_{\perp}$ are diamagnetic susceptibilities along and at right angles to the director, is negative. This means that the planar DSCG molecules are arranged perpendicularly to the column axes, like the molecules in the chromonic phases of dyes.

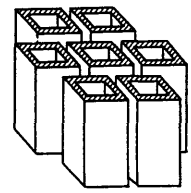

Figure 12. A model of the packing of columns in the mesophase *M* of the DSCG–H_2O system.[85]

A second important result is the fact that the quadrupolar splitting in the ^2H and ^{17}O spectra of the D_2O molecules and in the ^{23}Na spectrum changes sharply on transition from the phase (III) to the phases *N* or *M* and varies linearly on transition from *N* to *M*. The quadrupolar splitting on the ^2H and ^{17}O spectra on transition to the mesophase *N* or *M* diminishes under these conditions, while that in ^{23}Na spectra increases. A detailed study[78] of the NMR spectra of the ^{23}Na atoms showed that, following the addition of NaCl to the system, the quadrupolar splitting in all the phases initially falls to zero and then changes sign and increases again. This makes it necessary to postulate that the Na^+ ions occupy two different types of positions in the structure, to which splittings of different sign correspond. They can be found both in the columns (the binding of the DSCG molecules) and in the surrounding water. In the initial system, almost all the Na^+ ions are in the first positions. After the addition of NaCl, most of the Na^+ ions pass to the surrounding water, which in fact diminishes the quadrupolar splitting.

A study[82] of the influence of NaCl on the ^2H NMR spectra of D_2O led to the conclusion that there is only an increase in the stability of the mesophases and the associated impairment of the quadrupolar splitting. The increase in stability was explained by the weakening of the repulsion of the DSCG molecules as a result of the shielding effect of Na^+ ions. The absence of two different doublets in the NMR spectrum of D_2O, which should have been observed according to the model illustrated in Fig. 11*b*, was also noted. However, this finding can be readily accounted for also by the easy exchange between the free water molecules and the molecules incorporated in the columns.

NMR data yielded some information about the order parameters S_{ij} of the DSCG–H_2O system. The order parameter, which is a second rank tensor, describes quantitatively the ordering in the system and is defined as follows:

$$S_{ij} = S(n_i n_j - {}^1/_3\delta_{ij}), \qquad (3)$$

where *S* is the scalar order parameter, n_i and n_j are the components of the director, and δ_{ij} is the Kronecker symbol.

It proved possible to calculate from the ^{17}O spectra of D_2O the principal components of the order parameter tensor for these molecules and to determine their temperature dependence.[80] It was found that the water molecules are well ordered and that the average parameter is about 0.5.

A detailed study[76] of the order parameter of the C–D bond has been carried out using DSCG containing deuterium in the chromonium rings and in the central CH group of the hydrocarbon bridge. The scalar order parameter S was calculated from the concentration dependence of the quadrupolar splitting in the ^2H spectrum. It increases linearly with increase in concentration in the range 4–29 wt.% from 0.76 to 0.97. These unusually high values are surprising, since the order parameter determined from the NMR spectra is a product of the order parameter of the molecules in the column and of the effective order parameter of the columns themselves. Nevertheless the value of S obtained correspond to those predicted by the Onsager theory.[87] Using its formal treatment and assuming that the diameter of the DSCG molecule is 26 Å, it is possible to estimate the length of the columns. It is about 2000 Å in the phase M and about 800 Å in the phase N.[76]

The order parameter in the nematic phase of the DSCG–H_2O system has also been investigated[84,88] by polarisation absorption spectroscopy.† Dichroic dyes such as indigo, carmine, eosin, Methyl Red, Congo Red, etc. were dissolved in the mesophase and the absorption spectra were measured in polarised light parallel and at right angles to the direction of a 20 kG magnetic field. It was found that S for the "guest" dye molecules varies from −0.2 to −0.005. The order parameter of the DSCG molecule as a whole was determined at the wavelength corresponding to the intrinsic absorption band. It proved to be −0.20. With increase in temperature, the order parameter diminishes as usual. It also decreases with decrease in the ionic strength of the solution.

In an interesting study[89] the order parameters were calculated from the intensities of individual IR absorption bands corresponding to particular bonds (Table 7). As was to be expected, all the parameters S are negative, which confirmed the perpendicular orientation of the DSCG molecules relative to the magnetic field. The average order parameter is −0.14, which agrees with the results of independent measurements.[84]

Spectroscopic data[89] also suggest that the oxygen atoms of the chromonium rings are linked by hydrogen bonds to water molecules. In addition it was found that the overlapping of the DSCG molecules in the nematic mesophase is much more marked than in the isotropic phase.

The 7,7-DSCG mesophases have also been investigated by X-ray diffraction.[81] The high-temperature phase R gives rise to three diffraction peaks corresponding to distances of 51.2, 25.1, and 32.1 Å at 27 °C. They are in proportions of $1:1/2:1/\sqrt{2}$ and correspond to the indices 1.0 : 1.1 : 2.0 of a two-dimensional square lattice. With decrease in temperature, the distances increase but their ratios do not change. The nematic phase produces only one peak corresponding to an index of 1.0. This peak, which does not undergo sharp changes in the transition $R \rightarrow N$, corresponds to distances between the columns of 60–70 Å. The three diffraction peaks of the phase M are in the ratios $1:1/\sqrt{3}:1/2$, which correspond to the hexagonal lattice. Immediately below the temperature of the transition from the phase N to the phase R, the hexagonal lattice parameter is about 46 Å, but it reaches 80 Å as the temperature is reduced.

Table 7. Order parameters for individual bonds in the nematic phase of the DSCG–H_2O system.[89]

Bond	Wavenumber, cm^{-1}	S
C=C	1482	−0.132
=C–H	1412	−0.127
CO_2^-	1364	−0.136
CO_2	1311	−0.149
C–O (ether)	1267	−0.110
C–O (in =C–O–C)	1128	−0.071
OH	1047	−0.102

The ^2H and ^{17}O NMR spectra of D_2O and the ^{23}Na NMR spectra of the same systems have been investigated. In the spectrum of phase R, there is no quadrupolar splitting, which indicates a disordered disposition of the water molecules. The usual quadrupolar splitting is observed in the spectra of the other mesophases. The quadrupolar splitting in the ^{23}Na spectrum is of a similar character and does not undergo sharp changes in the transition from the phase N to the phase S or M. This is explained by the fact that the distribution of Na^+ ions between two possible positions (see above) is independent of concentration. The study of the NMR spectra of the compound deuteriated in the chromonium ring made it possible to determine the order parameter of the C–D bond. It is independent of concentration but varies linearly with increase in temperature. Estimates have shown that the order parameter in the mesophases N and S is approximately unity, which indicates the almost complete ordering of the columns, although it does not rule out the free rotation of the molecular planes.

Detailed structural studies have made it possible to put forward the hypothesis of a relation between the liquid crystal nature of the anti-asthmatic drugs and their therapeutic properties.[15] If this relation is not fortuitous, three mechanisms are possible.

The therapeutic effect is associated with the formation of a chromonic mesophase on the surface of the lung.

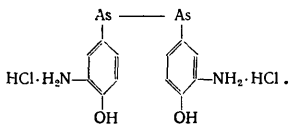
The mesophase is not formed but the therapeutic effect is associated with a biologically active complex (a cyclic structure or a hollow column), which promotes the formation of the mesophase.

The mesophase is not formed but the therapeutic effect is due to the structure of the molecule itself, which is at the same time mesogenic.

Available knowledge is so far insufficient to reject *a priori* any of the three mechanisms indicated. However, the first is supported by the presence on the surface of the lung of a mesophase with a high phospholipid content. The breakdown of the liquid-crystal state of this layer leads to the breakdown of the tiny alveoli at the end of exhalation. It is therefore quite likely that the mesophases of anti-asthmatic drugs compensate for the deficiency of liquid crystal phospholipids.

As we have already stated, chromonic mesophases have a negative diamagnetic anisotropy. The geometry of the column permits the ready spontaneous formation of a planar texture. Reorientation in a magnetic field (the Fredericks transition) is usually observed in fields of 10–20 kG. It is accompanied by the appearance of interesting defects.

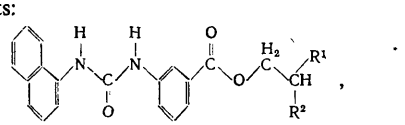
†The order parameter determined by this method is $S = (A_{||} - A_\perp)/(A_{||} + 2A_\perp)$, where $A_{||}$ and $A_\perp$ are the absorption intensities along and at right angles to the director respectively. Since $A_\perp > A_{||}$ for molecules with negative dichroism such as DSCG, it follows that $S < 0$ and amounts to −0.5 in the fully ordered state ($A_{||} = 0$).



Thus, when an 18 kG magnetic field is applied to a thick (80–200 μm) planar DSCG specimen in the plane of the specimen and along the axes of the columns, a "bamboo" type of texture is formed (Fig. 10*e*). In the course of time, the "bamboo" sections grow and are obliterated.[79]

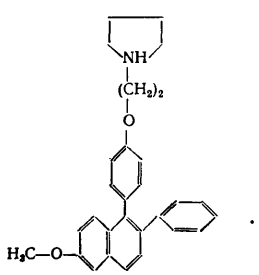
A periodic domain structure, the repeat step of which depends periodically on the magnetic strength, has been clearly observed on thin specimens (~20–40 μm).[90] This structure exhibits an interesting time variation.[91] The formation of a domain structure has a purely hydrodynamic cause—it arises as a result of the presence of a reverse flux accompanying the Fredericks transition.[79,90,91]

The addition of chiral admixtures converts the nematic DSCG mesophase to a cholesteric phase.[79] Various aminoacids, for example, alanine, proline, lysine, etc., at concentrations ranging from 1 to 36 wt.%, are used as the additives. Naturally the pitch of the helix of the cholesteric phase obtained depends on the concentration of the chiral additive. In all cases, the reciprocal of the pitch of the helix increases linearly with increasing concentration of the chiral additive.[79,92]



An interesting result was obtained in a study of the influence of the magnetic field on such induced cholesteric phases. After prolonged exposure to the field, the pitch of the helix diminishes, but not to zero. It falls to a finite value approximately equal to one-third of the initial pitch.[79]

Aqueous solutions of salvarsan and neosalvarsan—drugs active against syphilis, malaria, and recurrent fever—apparently form a chromonic mesophase.[5,93] Although direct structural studies have not been made, nevertheless the physical properties of these systems support indirectly this hypothesis. Firstly, the salvarsan molecule has a planar shape with polar hydrophilic groups at the end:



Secondly, the occurrence of polarisation in aqueous solutions indicates the formation of large aggregates. The third piece of evidence is provided by the presence of the nematic mesophase, which is optically monoaxial and negative, the negative side being in fact typical for chromonic mesophases.

Chromonic phases are formed in aqueous solutions and in heptane by *N*-1-naphthyl-*N'*-phenylenecarboxyalkylureas[94] which are used as antisunburn agents:

where R^1 and R^2 are various alkyl groups ranging from methyl to dodecyl. These compounds are chiral and form chromonic structures, which has been confirmed by the observation of the corresponding textures. Furthermore, more ordered mesophases, apparently hexagonal, have also been discovered:

Two mesophases are likewise formed by naphthoxidine hydrochloride,[95] eight molecules of which form a ring with the pyrrole groups on the periphery. The rings are in their turn packed in a chromonic column, which is an element of the superstructure.

Chromonic phases are apparently formed also by rivanol (6,9-diamino-2-ethoxyacridine lactate).[96] However, here further studies are necessary.

V. Conclusion

An independent branch of the field of study of lyotropic crystals, involving the investigation of the conditions governing the formation, structure, and properties of chromonic mesophases, has now been established. These phases differ from the classical lyotropic micellar liquid crystals but at the same time they have features in common with the latter. The amphiphilic nature of the molecules, their extended shape, and the presence of a long ($n > 8$) hydrocarbon "tail" are typical for micellar mesophases. Such construction ensures the formation, as a result of a balance between ionic and hydrophobic interactions, of anisotropic micelles, both normal (in water or in any polar solvent) and inverted (in non-polar solvents). The balance of forces is so fine that a change in the concentration of the amphiphilic substance alone is sufficient to entail a significant change in the form of the micelles, which change from spherical to discotic, biaxial, and cylindrical.

Molecules forming chromonic mesophases can be called amphiphilic only by way of a convention. They have the planar shape of a "plank" with small end groups which ensure its solubility in water. The principal cause of the formation of ordered structures is therefore in this instance the appearance of hydrogen bonds between the polar groups and water molecules. The hydrophobic interaction plays only a secondary role. However, micelles are formed, as in the classical lyotropic liquid crystals. Their role is assumed by columns—"coin stacks". The occurrence of a single leading interaction creates simpler structures—isotypical columns arise instead of a set of anisometric aggregates. Admittedly the packing of the molecules in the column depends on their chemical nature but this does not lead to a great variety. Structurally, chromonic mesophases are closer to columnar thermotropic liquid crystals than to micellar lyotropic mesophases. The principles of the molecular packing are identical although chromonic materials do not exhibit the wide variety of structures characteristic of columnar thermotropic mesophases.

The study of chromonic mesophases has continued at a high rate. Their practical importance is evident, because important substances such as dyes and medicinal drugs are the principal chromonic materials. However, much still remains to be done. In the first place, there are still very few data on the viscoelastic properties of these compounds. There is no information about their electrooptical and magnetooptical behaviour. There is no microscopic theory of the mesomorphic properties of these phases. Further studies will undoubtedly fill these gaps and will provide an answer to the principal question concerning the relation between the mesomorphic properties of chromonic phases and their structure.

The viscosity of nematic liquid crystals

V V Belyaev

ABSTRACT. A simultaneous examination of data on the dynamic, kinematic, and rotational viscosities of nematic liquid crystals (NLC) belonging to 320 chemical classes has been carried out for the first time. The methods for the measurement of the viscosities of the NLC have been subjected to a comparative analysis and the limits of applicability of different procedures for the description of their temperature variation are discussed. The tables present data permitting the calculation with satisfactory accuracy of the viscosities of the majority of mesogenic substances at any temperature in the nematic range. The influence of the molecular structure of the NLC on the viscosities and on their temperature variation has been analysed and information is presented about the viscosities of the Soviet and foreign liquid crystal materials used in practice.

The bibliography includes 158 references.

IV. Relation between the molecular structure of nematic liquid crystals and their viscosity 938

By virtue of their unique optical properties and low energy consumption, nematic liquid crystals (NLC) have now found wide scale applications in devices for the treatment and representation of information. One of the important characteristics of NLC, which determines the rapidity of their response in the working temperature range, is their viscosity. Both the dynamic viscosity η (or the kinematic viscosity ν), describing the flow of liquid in the nematic and isotropic phases, and the rotational viscosity γ_1, which has no analogue in isotropic liquids and is related to the dissipation of energy on reorientation of the NLC director (the director is a unit vector indicating the direction of the long axes of the NLC molecules), are measured for NLC. The communications by Benicewicz and Johnson[1] and de Gennes[2] are devoted to the viscosity of liquid crystals (LC) but the data presented there are too limited to permit a discussion not only of the relation between the viscosity and the molecular structure of NLC but also of the form of the temperature variation of the viscosity, the knowledge of which is essential for the development of LC materials with a satisfactory fast response at low temperature.

This review gives for the first time a systematic account of data concerning the relation between the chemical structure of NLC and their viscosity, the temperature variation of the viscosity of different NLC being considered from a single standpoint. The tabulated data are of interest for specialists dealing with liquids and may serve as a basis for specific investigations and the search for new nematic, smectic, polymeric, and lyotropic liquid crystals.

I. Methods for the measurement of the viscosities of nematic liquid crystals

Only the dynamic (η) or kinematic [$\nu = \eta/\rho$ (ρ is the density of the NLC)] viscosities are usually measured for many liquid crystals. However, in the present study attention is concentrated on the rotational viscosity γ_1, which determines the time of the electro-optical response. It has been shown[3,4] that there is a relation between the rotational viscosity γ_1 and the viscosity measured by capillary methods, described approximately by the relation

$$\gamma_1 \simeq a\eta + b, \tag{1}$$

$$\gamma_1 \simeq a(\eta_3 - \eta_2) + b, \tag{2}$$

where a and b are weakly temperature dependent coefficients and η_2 and η_3 are the Miesowicz viscosity coefficients.[2] These relations are confirmed by the simultaneous measurements of the viscosities γ_1 and η or η_2 and η_3 for a set of NLC belonging to different chemical classes.[4,5] For comparison, the tables indicate in a number of instances the values of γ_1 and η as well as the ratio γ_1/η.

Depending on the type of viscometer, the dynamic viscosity η (Ubbelohde viscometer) or the kinematic viscosity ν (Ostwald viscometer) is measured. Novel methods have been developed for the measurement of the rotational viscosity γ_1. They reduce to one of three types: the rotating magnetic field method, the dynamics of the Fredericks transition, and the spectrum of the light scattered by the thermal fluctuations of the director.

In the first method, the rotation of the magnetic field leads to the rotation of the NLC director, the second rotation occurring with a phase delay at sufficiently low angular velocities.[2,6] Having measured this delay, for example, with the aid of a torsional balance,[7] it is possible to determine the quantity γ_1/ρ or γ_1/χ_a (χ_a is the anisotropy of the diamagnetic permeability). The errors arising in this method of measurement have been studied in detail.[7] In order to measure γ_1 to within 0.1%, approximately 60 cm^3 specimens have been used,[4,7] which is by no means always possible especially in the study of new substances. The reduction of the volume of the specimen leads as a rule to an unduly low value of the measured quantity (compare, for example, the studies of Kneppe et al.[4] and Siedler et al.[8]).

An appreciably smaller amount of substances (less than 30 mg) is required in the measurement of γ_1 on the basis of the dynamics of the Fredericks transition. In this case the ratio γ_1/K_{22}[9] or η_S/K_{11}[10,11] is determined from the characteristic relaxation time (K_{11} and K_{22} are the elasticity coefficients of the NLC, $\eta_S = \gamma_1 - \alpha_3^2/\eta_2$ is the

viscosity describing the rate of relaxation of the transverse bending deformation, and α_3 is the Leslie viscosity coefficient). In the direct measurement of γ_1/K_{22}, one investigates the time variation of the location of the conoscopic figure formed when a convergent light beam is passed through a liquid crystal cell in a longitudinal magnetic field (the field is parallel to the supports but is at right angles to the director). Owing to the difficulty of determining the angle of rotation of the conoscopic figure and of K_{22}, this method has not come to be widely used. The method of measurement of η_S/K_{11} based on the optical[10] or capacitative[11] response of a planarly oriented cell after a transverse electric field has been switched off, has come to be more widely used. Since $|\alpha_3| \ll \gamma_1, \eta_1$,[12] the relation $\eta_S \simeq \gamma_1$ holds to within 1–2%, which is better than the accuracy of the measurement of η_S by this method (to within 7–10%). Simultaneously with γ_1, it is possible to measure in this cell the double refraction Δn and the elasticity coefficient K_{11} (when the dielectric anisotropy $\Delta\varepsilon$ is known). A method for the measurement of γ_1, based on the relaxation of the deformation of a specimen placed in a strong magnetic field (up to 0.8 T), has been described.[13] Its accuracy is to within 6%. It suffers from the disadvantage that the quantity χ_a has to be known.

The thermal fluctuations of the liquid crystal director lead to light scattering, which greatly exceeds that in isotropic liquids. The viscoelastic ratio γ_1/K_{22} or η_S/K_{11} can be determined from the half-width of the scattering spectrum and, knowing the intensity of the scattered light and of the refractive index of the NLC, the viscosity γ_1 or η_S itself can be determined.[2,14,15] Because of the need to view the light scattering at low angles where there is an appreciable contribution due to scattering by inhomogeneities in the orientation of the liquid crystal, the direct measurement of γ_1 is difficult or altogether impossible. The quantity η_S/K_{11} is therefore usually measured for the following geometry of the observation: the polarisation of the incident light is parallel to the director and perpendicular to the polarisation of the scattered light, while the scattering angle is 30–40°.[14] Although the corresponding method is fairly complex (the optical mixing spectroscopy and the correlation of single signals are needed), it has a significant advantage, namely the absence of are needed), it has a significant advantage, namely the absence of deformation of the specimen, which is important in the study of NLC with a strong transverse intermolecular interaction.

The tabulated γ_1 have been obtained using all the principal methods. It has been shown[16] that the results of the measurement of γ_1 by different methods agree well.

II. Temperature variation of the viscosities of nematic liquid crystals

The temperature variation of the viscosity of an isotropic liquid is usually described satisfactorily by the Arrhenius law:

$$\eta = a \exp(E/kT), \tag{3}$$

where a is a constant, E the activation energy, k the Boltzmann constant, and T the temperature. On the assumption that there is no intermolecular interaction, this relation is described by the Fulcher–Tammann formula:

$$\eta = b \exp[B/(T-T_0)], \tag{4}$$

where b and B are constants, $(T - T_0)/B$ is the fluctuation free volume, $T_0 \simeq T_g + 50$, and T_g is the glass point of the liquid. A dependence on the order parameter S is introduced into the preexponential factor in order to describe the variation of the viscosity γ_1 near the NLC–isotropic liquid transition temperature T_{NI}:

$$\gamma_1 = aS^x \exp(E/kT). \tag{5}$$

It has been shown[16] that $x = 1$ for liquid crystals with an elongated conjugation chain (biphenyls, phenylpyrimidines, phenyl benzoates, etc.), while $x = 2$ for liquid crystals whose molecules contain a fragment with saturated bonds (phenylcyclohexanes, phenylbicyclooctanes, etc.).

The limits of applicability of the activation and free volume models have been found.[17] The former is valid for all NLC with a small mesophase range (up to 40°) at temperatures $T > 20$ °C, while the latter is valid for NLC with a low activation energy ($E < 0.45$ eV = 4.95×10^3 Å) and also for NLC with an appreciable (above 60°) mesophase range extending to the region of reduced temperatures (as far as 0 °C and below). In the same study, it was shown that the viscosity γ_1 is determined by the molecular packing density, its temperature variation [the activation energy in Eqn. (5)] is determined by the intermolecular interaction energy, the order of magnitude of which is equal to that of the enthalpy of fusion of the NLC and is determined by the presence or absence of a fragment with saturated bonds (a cyclohexane or bicyclooctane fragment).

A theoretical description of the temperature variation of the rotational viscosity on the basis of a molecular-statistical approach, combining the characteristics of the activation and free volume models, has been proposed:[18]

$$\gamma_1(T, S) = gS^2 \exp[\varepsilon S/kT + \theta S^2/(T-T_0)], \tag{6}$$

where g is a weakly temperature dependent parameter, εS the height of the Maier–Saupe potential, θ a parameter determined by physical properties, and T_0 the temperature at which the motion of the director is frozen; in fitting the $\gamma_1(T, S)$ relation for any substance, the first or second term in the argument of the exponential function is neglected. The choice of the fitting procedure is determined by the width of the nematic range.

A comparative mathematical analysis of the suitability of different models for the description of the dependence of the rotational viscosity on temperature and the order parameter has been carried out.[16,17] The best agreement between the calculated curves and the experimental points and the highest correlation coefficients have been obtained for the majority of substances when the $\gamma_1(T)$ relation is described by an equation type (5). For certain cyclohexane and bicyclooctane derivatives, the smallest deviation was obtained when the results were fitted on the basis of the free volume model taking into account the order parameter S. Equations of type (6) as a rule give rise to a poorer agreement with experimental results although it has been noted[17] that the theory[18] makes it possible to explain the change in γ_1 in the homologous series of liquid crystal substances and the proportionality $E \propto T_{NI}$ for substances with a similar type of intermolecular interaction.

In most cases the experimental relations have therefore been fitted by curves of type (5) taking into account the specific molecular structure of the substance ($x = 1$ or 2). For a number of substances, the values of S were not available but the double refractions Δn were known, which made it possible to use analogous fitting procedures, because $\Delta n \propto S$.[2,16] In the absence of data making it possible to infer the temperature variation of the order parameter S, a simple equation of type (3) was fitted. For certain cyclohexane and bicyclooctane derivatives, a fitting procedure corresponding to the free volume model with allowance for the variation of S was employed.

Overall, in the tables an attempt has been made to analyse the temperature variations of the rotational viscosities of NLC belonging to different chemical classes using a single approach to their description. The relations were fitted on the basis of data presented in the tables or figures in the original publications. Only in certain cases (as a rule when the values of γ_1 or η were quoted at only one temperature) was an additional mathematical treatment of the original results not carried out.

III. Tables of the viscosities of nematic liquid crystals

The tables are constructed so that the values of γ_1 (or η and ν) can be obtained from the parameters listed in them at any temperature at which the given substance is nematic. Apart from specially stipulated cases, all the equations fitted were of the Arrhenius type:

$$\ln A = \ln A_0 + E/T. \qquad (a, b, c)$$

In equation (*a*) the letter A denotes the rotational viscosity γ_1 or its kinematic analogue γ_1/ρ (ρ is the density of the NLC) and also the dynamic viscosity η or the kinematic viscosity $\nu = \eta/\rho$. In the description of the temperature variation of the rotational viscosity by means of formula (*b*), the letter A denotes the ratio γ_1/S or $\gamma_1/\Delta n$ (account is taken of the proportionality $\Delta n \propto S$), whereas in the case where formula (*c*) is fitted A denotes the ratio γ_1/S^2 or $\gamma_1/(\Delta n)^2$. The viscosity is expressed in IS units: in 0.1 Pa s = 1 P (γ_1, η) or in 10^{-4} m^2 s^{-1} = 1 Stokes (γ_1/ρ, ν).

Table 1. The viscosities of nematic liquid crystals.

Remarks. The physical quantities (viscosity, temperature, activation energy, and double refraction), obtained by extrapolating the concentration variations of these quantities in the mixtures, are quoted in square brackets throughout the table.

*[1]The viscosities obtained by extrapolating their temperature variation are given in round brackets.

*[2]The temperatures of the "isotropic liquid—nematic liquid crystal" monotropic transition are given in round brackets.

*[3]The order parameter S or the double refraction Δn are quoted (also for reference), depending on the approximation formula used, taking into account the proportionality of the temperature variations of these physical quantities.

The order in which the liquid crystal substances have been arranged in terms of chemical classes approximately corresponds to the order adopted in the familiar Demus Tables for liquid crystals.[19] For substances belonging to one chemical class, for example, Schiff bases, the relative positions are determined by the polarity of the substituent (alkyl, alkoxy-, acyloxy-, cinnamate, CN, etc. groups). For representatives of a single chemical class which are members of a homologous series, the values of γ_1 or η are indicated at one or several temperatures at which these homologues exhibit mesogenic properties and also for the same temperature difference $\Delta T = T_{NI} - T$ or at the same reduced temperature, for example $T = 0.95T_{NI}$. The values of S or Δn are also listed for the same temperature difference. The temperature variation of the order parameter S is similar for different substances and can be described approximately by the formula

$$S \simeq S_0(1 - T/T^*)^{\beta}, \qquad (7)$$

where $T^* \simeq T_{NI} + (0.2-0.7)$, $\beta \simeq 0.18 \pm 0.02$, and $S_0 = 1.1-1.4$.[2,20,21]

Table 2. The viscosities of 4,4'-di-n-alkylazoxybenzenes C_nH_{2n+1}—⟨⟩—N=N(→O)—⟨⟩—C_nH_{2n+1}.

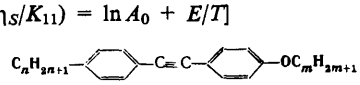
For homologous series of certain substances, more detailed information about the viscosity and other physicochemical properties is given in Tables 2–13. The values of γ_1 and/or η, taken from different literature sources and treated by different procedures, are presented for certain substances. The results of the treatment based on the activation and free volume models are presented simultaneously for some of the substances. In a number of instances, the glass point T_g is indicated, which makes it possible to infer the value of γ_1 at low temperatures. In some cases, a general (alkyl, alkoxy-groups) rather than specific substitution is indicated and the values



of γ_1 or η presented make it possible to infer only approximately the influence of molecular structure on the viscosity. Some of the results were obtained in studies of the properties not of individual substances but of mixtures of compounds referring to a single chemical class, which made it possible to extend greatly the range of existence of the mesophase while retaining a specific chemical structure. It has been shown[17] that, for the majority of NLC, the activation energy for rotational viscosity E is equal to or only 1.5–2 times greater than the enthalpy of fusion ΔH_m. The values of ΔH_m have therefore been listed for a number of substances making it possible to estimate the temperature variation of the viscosity.

The activation energy E and the enthalpy of fusion ΔH_m are quoted in Kelvin degrees to facilitate the use of the tables. All the temperatures are expressed in Kelvin degrees. The NLC clarification temperatures T_{NI}, listed in round brackets, indicate the monotropic isotropic liquid–nematic phase transition observed when the NLC is supercooled; the virtual isotropic liquid–nematic phase transition temperatures, calculated from the concentration variations of T_{NI} in NLC mixtures, are indicated in square brackets. In some cases, the anisotropies of the dielectric constant $\Delta\varepsilon$, the dipole moments μ expressed in Debyes (1 D = 10^{-18} CGSE units), the viscoelastic ratios γ_1/K_T, where $K_T = K_{11} + 1/4(K_{33} - 2K_{22})$ is the elasticity coefficient for the deformation in the twist-cell, as well as the times when the electrooptical response of the twist-effect t_{off} is switched off, which are of interest as regards practical applications, are indicated in the remarks. The cubes of the van der Waals radii r of the hydrogen, fluorine, chlorine, and bromine atoms are given in the 'remarks' for halogeno-derivatives. The relation between the parameters given in the 'remarks' and the viscosity of the NLC is discussed in Section IV.

IV. Relation between the molecular structure of nematic liquid crystals and their viscosity

We shall trace the variation of the viscosities of NLC (rotational or dynamic) and their activation energies as the geometrical structure of the molecule and the distribution of electron density within it are varied, namely with increase in the length of the alkyl chain in the homologous series, with increase in the dipole moment of the molecular skeleton or of the connecting bridge, and after the introduction of heteroatoms or lateral substituents. We shall also attempt to indicate the causes of these changes.

In a homologous series with alkyl substituents, an even-odd correlation is observed for the values of γ_1 and η—in the even homologues the viscosity is greater than in the odd ones. The viscosities at the same remove from the nematic liquid crystal–isotropic liquid transition temperature and not viscosities at the same absolute temperature are compared for different homologues. Such variation of the viscosity with increase in the number of the homologue has been observed for dialkylazoxybenzenes (Table 2), cyanobiphenyls (Table 9), cyanophenylcyclohexanes (Table 11),

cyanobicyclohexanes (compound 92),† and cyanophenylpyridines (109). For tricyclic compounds, the even–odd alternation of the viscosity is much less pronounced, which has been confirmed by alkylcyclohexyl esters of alkylcyclohexylbenzoic acids (225). In the series with alkoxy- and acyloxy-substituents [dialkoxyazoxybenzenes (Table 3), alkoxycyanobiphenyls (Table 10), phenyl acetate derivatives (Table 5), and alkoxybenzylidenebutylanilines (Table 4)], the opposite situation obtains—the viscosity is greater for the odd homologues. Such variation of the viscosity in the homologous series is associated with the characteristic features of the molecular packing, which has been confirmed by theoretical calculations[18] (Fig. 1). As the alkyl chain is lengthened, the viscosity generally speaking increases, which can be seen particularly clearly in relation to alkoxyphenyl esters of alkylbenzoic and alkylcyclohexanecarboxylic acids (Tables 7 and 8, Fig. 2). If the molecular skeleton contains two benzene rings, the viscosity increases linearly with increase in the length f of the molecule. For Demus esters, where one benzene ring has been replaced by a cyclohexane fragment, the viscosity increases exponentially with increase in the length of the molecule. This suggests that, with increase in the contribution by repulsion forces, the free volume necessary for the migration and reorientation of the NLC molecules diminishes appreciably. For this reason, in the development of liquid crystal materials for matrix screens, where a greater steepness of the voltage-contrast characteristic (VCC) is required, phenyl benzoates with a long alkyl chain are preferred. They are not only characterised by a lower elasticity coefficient ratio K_{33}/K_{11}, ensuring a greater steepness of the VCC, but they also have a lower viscosity compared with that of Demus esters. The examples quoted above permit the conclusion that the activation energy for viscosity depends only slightly on the number of the homologue.

The influence of the increase in the polarisability of the substituent will be examined in relation to the alkenyl derivatives of phenylcyclohexanes (Table 13). The increase in the distance of the group containing a double bond from the molecular skeleton increases the polarisability of the solvent, which can be seen from the increase in the values of Δn, and also increases the rotational viscosity compared with pentylphenylcyclohexane. Nevertheless, the practical value for alkenyl derivatives is high, since they have shorter twist-effect switch-over times owing to the smaller viscoelastic ratio. By comparing the viscosities of a series of substances (compounds 5–8), we also see that an increase in the polarisability of the substituents (alkyl, acetoxy-, cinnamoyloxy-, and cyano-groups) leads to an increase in viscosity (see also Figs. 3 and 4).

Table 9. The viscosities of 4-n-alkyl-4′-cyanobiphenyls [fitting formula *b*: $\ln(\gamma_1/\Delta n) = \ln A_0 + E/T$; *e*: $\ln(\gamma_1/S^2) = \ln A_0 + ES/T$]

n	3	4	5	6	7	8	9
ν (70 °C), S	0.15	0 085	0.18	0.12	0.10	0.155	0.12 (80° C)
T_{NI}	347.7	351.2	312.2	330.2	327.2	327.7	337.2

A quantitative relation between the viscosities η and the bulk and dipole moment of the substituent has been obtained for halogenoderivatives of propylcyclohexylbiphenylylethane (compounds 233 to 236). On successive replacement of the hydrogen atom by F, Cl, and Br atoms, $\ln\eta$ increases in proportion to the dipole moment of the bond between the carbon and halogen atoms or in proportion to the cube of the van der Waals radius of the substituent (Fig. 5). Bearing in mind that the halogen substituent is rigidly bound to the molecular skeleton, this result can be interpreted also from the standpoint of the influence of the dipole moment of the molecular skeleton on the viscosity (the dipole moments of molecules or their fragments were taken from the papers of Minkin and co-workers[151,152] or calculated in accordance with their procedures). The correlation between the dipole moments of substituents rigidly attached to the molecular skeleton and the dynamic or kinetic viscosity of the NLC can be seen also in relation to the bicyclic and tricyclic derivatives of phenylcyclohexane (compounds, 60, 61, 66, 69 and 135, 138, 140, 141). We may note that alkylphenylalkylcyclohexanes (compounds 60) have the smallest viscosities among the known NLC and also the smallest

†The numbers of the compounds in Table 1 are indicated in brackets.

glass points T_g = 159 K, as a result of which they are used as the main components in the development of liquid crystal materials with a fast response at low (down to −60 °C) temperatures.

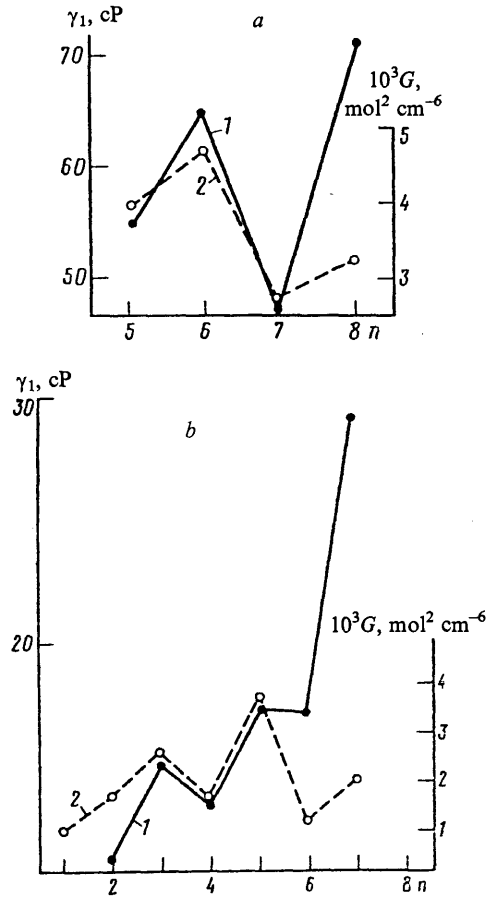

Figure 1. Correlation between the odd-even variation of the rotational viscosity γ_1 (line *1*) and the parameter G (line *2*) characterising molecular packing for alkylcyanobiphenyls (52) ($\Delta T = T_{NI} - T$ = 5 °C) (*a*) and dialkoxyazoxybenzenes (line *3*) (ΔT = 10 °C) (*b*). $G = [V_N(V^a - V_N)]^{-1}$, where V_N is the molar volume in the nematic phase and V^a is the molar volume in the nematic phase extrapolated from the isotropic phase.[18]

The influence of the dipole moment of the bridge connecting the benzene rings on the rotational viscosity and its activation energy can be examined with the aid of Table 14. The tabulated data not only confirm the correlation established between the dipole moment of the molecular skeleton and the viscosity of the NLC but also permit the claim that the distribution of electron density within the molecule influences significantly also the activation energy, which characterises the intermolecular interaction energy.

Table 15 presents the viscosity and dielectric characteristics of the NLC whose molecules contain a heterocyclic fragment. Although the dipole moments of the heterocycles themselves are almost the same, their introduction into the NLC molecule alters significantly the dipole moment of the latter, which has an appreciable effect on the anisotropy of the dielectric constant Δε; furthermore, a correlation is again observed between Δε and γ_1. The quantities γ_1 and E are influenced also by the positions of the heteroatoms (see the data for phenylpyridines—compounds 110, 111, 114, and 115 in Table 1). It can be seen in relation to dioxane, oxathiane, and dithiane derivatives (103–105) that the replacement of one and then the second oxygen atoms in the dioxan fragment by sulphur atoms increases the viscosity.

straight line is described by the equation $\eta = 0.105 + 0.02\,\Delta\varepsilon$ and virtually all the $\eta(\Delta\varepsilon)$ points fit between the two straight lines $\eta_{max} = 0.22 + 0.02\,\Delta\varepsilon$ and $\eta_{min} = 0.055 + 0.02\,\Delta\varepsilon$.

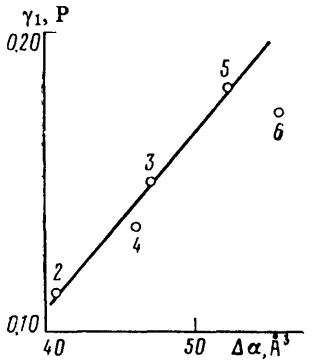

Figure 3. Dependence of the rotational viscosity γ_1 of dialkoxyazoxybenzenes ($C_nH_{2n+1}O$—⟨⟩—N=N(O)—⟨⟩—OC_nH_{2n+1}) on the anisotropy of the polarisability of the molecule. The numerals represent the numbers of the homologues.

Table 16 is a compilation of data for polar compounds without heterocyclic fragments. The replacement of the CN groups by NCS diminishes the viscosity of the liquid crystal, although the twist-effect switch-over times remain the same. The introduction of the ethane bridge instead of a single bond or the replacement of the alkyl group by an alkenyl group with the double bond remote from the cyclohexane fragment did not alter t_{off} either, although both these factors increase appreciably the viscosity of the NLC. On the other hand, the combination of two factors acting in opposite directions—the introduction of the thiocyanoto-group and of the ethane bridge—leads to an appreciable decrease in γ_1 and t_{off} (apparently as a consequence of the less dense molecular packing and the absence of a dipole moment in the bridge).

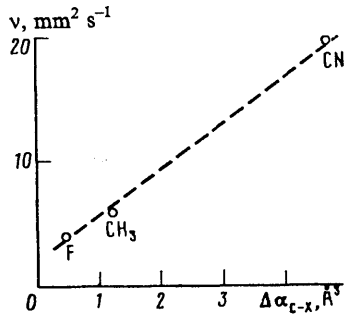

Figure 4. Dependence of the kinematic viscosity ν of phenylcyclohexane derivatives (C_3H_7—⟨⟩—⟨⟩—X) on the anisotropy of the polarisability of the C—X bond, where X = F, CH_3, or CN.

Although the substitution of a hydrogen atom by a fluorine atom is actually referred to as isogeometrical,[153] the increase in the electronegativity of the molecule occurring thereupon diminishes the thermal stability of the mesophase and increases the coefficient of internal friction, which can be seen in relation to the fluorinated derivatives of the alkylphenyl esters of alkylcyclohexanecarboxylic acids (compounds 34), tolanes (16), biphenyls (53, 54), and biphenylcyclohexanes (136, 137). However, the simultaneous introduction of fluorine in the *meta*- and *para*-positions promotes a significant decrease in viscosity. Thus the difluorophenyl derivatives of bicyclohexylethane (239 and 318) have almost the lowest viscosities among the tricyclic and tetracyclic substances respectively. It is also

Table 13. The viscosities of 1-alkenyl-4-(4-cyanophenyl)cyclohexanes[50,78] (fitting formula: $\ln\gamma_1 = \ln\gamma_0 + E/T$)

noteworthy that compounds containing the CN group in the *para*-position and fluorine in the *meta*-position have a higher positive value of $\Delta\varepsilon$ than the analogous compounds without fluorine. For example, $\Delta\varepsilon = +12$ for cyanophenyl heptylbenzoate, while $\Delta\varepsilon = +49.7$ (22, 23) for the analogous 4-cyano-3-fluorophenyl ester, which is associated with the fact that the fluorine atom prevents the dimerisation of the polar molecules leading to the partial cancelling of their dipole moments. This property makes it possible to reduce significantly the threshold potential of the electrooptical effect. Substances with fluorine or chlorine in the terminal position (compound 66 is an analogue) are frequently introduced into the liquid crystals in order to reduce their viscosity.[154]

Table 14. The influence of the dipole moment μ of the skeleton of a molecule having a bridging fragment on the rotational viscosity γ_1 and the activation energy E.

Compound	γ_1, P (25 °C)	E (10^3 K)	μ, D
C_4H_9—  —OC_5H_9	(0.9)	3.6	0—0.3
CH_3O—  —C_4H_9	1.09	5.82	1.57
CH_3O—  —C_4H_9	1.57	4.55	1.70
C_4H_9—  —OC_5H_9	2.20	5.11	1.90
CH_3O—  —C_4H_9	(6)	7.35	2.39

The sulphur atom is less electronegative than the oxygen atom and the substitution of oxygen by sulphur in the COO ester bridge therefore tends to increase the thermal stability of the mesophase and to increase slightly the viscosity, which can be seen from a comparison of the alkoxyphenyl and alkoxythiophenyl esters of alkylcyclohexanecarboxylic acids (35, 44) and methylphenyl and methylthiophenyl esters of propylbiphenylcarboxylic and propylcyclohexylbenzoic acids (compounds 206 and 230, 211 and 231).

Table 15. The influence of a heterocyclic fragment having a dipole moment μ on the anisotropy of the dielectric constant $\Delta\varepsilon$ and the rotational viscosity γ_1.

Compound	γ_1, P (25 °C)	μ, D	$\Delta\varepsilon$ ($\Delta T = 10$ K)
C_nH_{2n+1}—  —CN	1.02	~0	11.73
C_nH_{2n+1}—  —CN	1.34	2.14÷2.55	13.30
C_nH_{2n+1}—  —CN	1.84	2.11—2.20	16.60
C_nH_{2n+1}—  —CN	2.01	2.0÷2.42	19.72

When liquid crystals are selected for the observation of the dynamic scattering effect or in order to obtain a low frequency of the inversion of the sign of the anisotropy of the dielectric constant, substances with a large transverse dipole moment, usually with one or two lateral CN groups, are used. On comparing the viscosities of 4-methylphenyl 4'-propylbiphenyl-4-carboxylate and 3-cyano-4-methylphenyl 4'-propylbiphenyl-4-carboxylate (compounds 206 and 207), the analogous propylcyclohexyl derivatives (211, 214), as well as the 4-ethoxyphenyl 4'-alkylcyclohexylbenzoate and the analogous 2,3-dicyanophenyl benzoate (215, 216), we see that the increase in

viscosity (by a factor of 2.2–2.5 compared with the viscosities of substances without lateral groups) is independent of the number of CN groups. The less polar methyl group increases the viscosity to a lesser extent (compound 212). By increasing the length of the alkyl chains along the long molecular axis, it is in general possible to reduce to a minimum the increase in viscosity caused by the introduction of the CN group (see the data for compound 214, where the viscosities of two derivatives of 3-cyanophenyl benzoate with overall lengths of the alkyl chains equivalent respectively to 4 and 9 methyl groups are compared). Evidently the presence of lateral cyano-groups in bicyclic compounds affects the viscosity to a greater extent (35, 42).

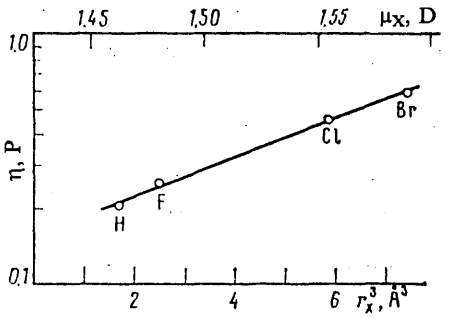

Figure 5. Dependence of the dynamic viscosity η of halogeno-derivatives on the van der Waals radius of the substituent (r_X) and the C–X bond dipole moment (μ_X).

The introduction of lateral alkyl and alkoxy-groups in the *meta*-position as in bisalkyl(or alkoxy)benzoyloxybenzenes (compounds 260–264) leads to an appreciable increase in the viscosity of the NLC for purely geometrical reasons, alkoxy- and acyloxy-groups giving rise to a greater increase in viscosity than alkyl groups. The viscosity of derivatives of bicyclooctane (compounds 96–99) is high mainly because of geometrical reasons—as a consequence of the denser molecular packing due to the presence of bulky fragment. We may note yet again that this does not affect the character of the intermolecular interaction and the activation energy for phenylbicyclooctanes is just as low as for phenylcyclohexanes. The influence of molecular packing on the rotational viscosity of bicyclic polar compounds is illustrated in Fig. 7.

In order to enhance the amplitude modulation of light using the dynamic light scattering effect or phase modulation in conjunction with *S*- and *B*-effects in image transformation problems in defectoscopy a high double refraction Δn is needed. Tolane derivatives (compounds 13–16, 243, 244, 272, 273) have a low viscosity combined with a high value of Δn. It is seen from Table 6 that tolane derivatives have a low activation energy for the viscoelastic ratio, which is the reason for the weak temperature dependence of the electrooptical response switch-over times.

The influence of the form of the skeletal fragment and also of the position of the substituent in the *cis*- and *trans*-position can be observed in relation to derivatives of spiro[3.3]heptane (compound 205), *cis*- and *trans*-cyclobutanes (203, 204), bicyclohexanes (88–94), and cyclohexylcyclohexenes (86, 87). In relation to derivatives of cyclohexene (134, cf. with 132, 141; 276, cf. with 282) and naphthalene (compounds 126–128), we see that the hydrogenation of the bonds in the molecular skeleton does not always reduce the

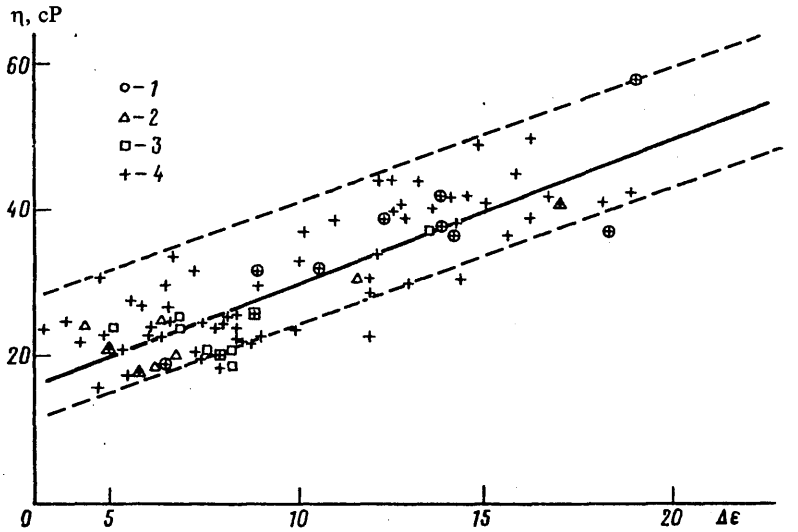

Figure 6. Dependence of the viscosity η of Hoffmann-La Roche liquid crystals on the anisotropy of the dielectric constant Δε: continuous line—averaging with respect to all the liquid crystals; dashed lines—η_{max} and η_{min} (see text); (*1*) liquid crystals with 1 : 4 multiplexity; (*2*) liquid crystals for TPT-matrices; (*3*) liquid crystals for the supertwist-effect; (*4*) remaining liquid crystals.

viscosity. Analysis of the data for this group of substances reveals a very small viscosity of the methyl ether of propylbicyclohexylmethanol (90) combined with a fairly high clarification temperature. The unusual structure of their side chain is responsible for this property.

Table 16. The rotational viscosities (γ_1), activation energies (E), and times at which the twist-effect is switched off (t_{off}) for bicyclic polar compounds.

Compound	γ_1, P	E (10^4 K)	t_{off}, ms
C_5H_{11}–⟨⟩–⟨⟩–CN	1.28	4.87	43
C_5H_{11}–⟨⟩–⟨⟩–NCS	0.83	4.30	41

C_5H_{11}/C_7H_{15}–⟨⟩–COO–⟨⟩–CN	2.69	4.43	29
C_5H_{11}–⟨⟩–⟨⟩–CN	1.01	6.27	55
C_4H_{11}/C_7H_{15}–⟨⟩–CH=N–⟨⟩–CN	3.60	5.36	39
C_5H_{11}/C_7H_{15}–⟨⟩–COO–⟨⟩–CN	4.10	6.48	70

The higher viscosity of the polar cyclohexylcyclohexane derivative (92) combined with a higher clarification temperature compared with the phenylcyclohexane analogue (69) suggests a denser packing of the bicyclohexane molecules, despite the fact that repulsion forces play the main role in the formation of the mesophase in these substances. A similar increase in viscosity and in activation energy can be seen also in the tricyclic derivatives of pyrimidine (183 and 185) having a cyclohexane fragment next to the CN group. At the same time, the lower values of T_{NI} for these compounds compared with the benzonitrile analogue (184) show that in such cases the molecule is apparently non-linear. Among substances consisting of tricyclic polar molecules, alkylcyclohexylpyrimidinylbenzonitrile (184) is optimal as regards viscosity and temperature for the preparation of liquid crystal materials.

The molecular shape and hence the viscosity and thermal stability of the test substance depend to a large extent on the atom of the –COO– bridge group to which the cyclohexane fragment is linked, which is clearly confirmed by many examples [compare the viscosities of the cyanophenyl esters of alkylcyclohexanecarboxylic acids and alkylcyclohexyl esters of cyanobenzoic acids (39 and 48, 40 and 49), alkylcyclohexyl alkylcyclohexylbenzoate and alkylcyclohexylphenyl alkylcyclohexanecarboxylate (200 and 225), the alkylphenyl and alkylcyclohexyl esters of alkylphenylbenzoic acids (206 and 221), and the analogous esters of alkylbicyclohexanecarboxylic acids (222 and 226)]. The comparison shows that substances with the C_nH_{2n+1}–⟨⟩–O– fragment have a lower viscosity and lower clarification temperature compared with substances having the C_nH_{2n+1}–⟨⟩–O– fragment. Among tricyclic non-polar compounds, methylphenyl propylbicyclohexanecarboxylate has the lowest viscosity and a fairly high clarification temperature, which makes it promising for practical application. A lower viscosity of alkoxy-compounds with –COO– bridges is achieved when the benzene ring is located between two oxygen atoms [compared with data for alkoxyphenyl akylbenzoates and alkylphenyl alkoxybenzoates (18 and 19) and also for alkoxyphenyl akylbiphenylcarboxylates and alkylphenyl alkoxybiphenylcarboxylates (208 and 209)].

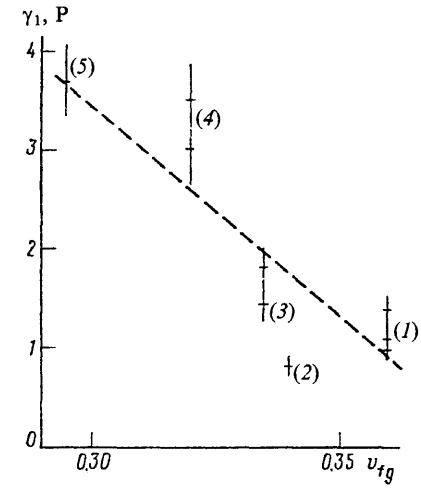

Figure 7. Relation between the rotational viscosity γ_1 of bicyclic polar compounds and the geometrical free volume $v_{fg} = 1 - k_p$, where k_p is the molecular packing coefficient determined from density measurements:

(*1*) – C_nH_{2n+1}–⟨⟩–⟨⟩–CN, (*2*) – C_nH_{2n+1}–⟨⟩–⟨⟩–CN,

(*3*) – C_nH_{2n+1}–⟨N⟩–⟨⟩–CN, (*4*) – C_nH_{2n+1}–⟨⟩–⟨⟩–CN,

(*5*) – $C_nH_{2n+1}O$–⟨⟩–⟨⟩–CN

By way of principal conclusion, we emphasise that the viscosity of NLC is determined by the following molecular characteristics: the size and shape of the molecule, the polarisability of the substituents, and the dipole moment of the molecular skeleton. The tables can serve as a guide for the specific synthesis of new substances and the selection of existing compounds for the creation of liquid crystal materials with a specified fast response. We may note that the viscosities of liquid crystals in mixtures are not always additive. The properties of mixtures of NLC and liquid crystal materials have been

described[133,155–158] and constitute the subject of a separate study. For reference purposes, Table 17 presents the kinematic viscosities of various Soviet and foreign materials.

Table 17. The kinematic viscosities of Soviet and foreign liquid crystal materials.[156–158]

Acetylenic ethers and their analogues

S I Radchenko, A A Petrov
Lensovet Leningrad Technological Institute

ABSTRACT. The latest data on the chemistry of acetylenic ethers, sulphides, selenides, and tellurides are considered: their methods of synthesis, physical properties, and reactivities in relation to various reagents. The principal applications of these compounds in fine organic synthesis are indicated.

The bibliography includes 455 references.

I. Introduction

The vigorous development of the chemistry of acetylenic ethers and their sulphur, selenium, and tellurium analogues is associated with the high reactivity of these compounds, which makes them irreplaceable synthons in the specific synthesis of many classes of organic compounds. The principles of the chemistry of acetylenic ethers and sulphides have been examined in an exhaustive review.[1] It has been established that the regioselectivity of the addition of electrophiles and nucleophiles to acetylenic ethers can be predicted with a high degree of probability on the basis of the concept of the existence of a strong +M effect of the alkoxy-group. The mode of addition of electrophiles to acetylenic sulphides is determined by the same effect. On the other hand, the modes of addition of nucleophiles to acetylenic ethers and sulphides are different:

$$RC{\equiv}COR \xrightarrow{\overline{Nu}} R\bar{C}{=}C(Nu)OR,$$
$$RC{\equiv}CSR \xrightarrow{\overline{Nu}} RC(Nu){=}\bar{C}SR.$$

Numerous studies of the regioselectivity of the addition of various reagents to acetylenic chalcogenides, studies undertaken to determine the characteristic features of their electronic structure, and studies involving attempts to predict the regioselectivities from the standpoint of the structure–reactivity concept were published subsequently. However, the fragmentary character of the existing new reviews[2–6] precludes the assessment of the state of the problem as a whole.

The aim of the present review is the analysis of the current state of the chemistry of acetylenic ethers and their analogues and also the principal directions of its development.

II. Methods of synthesis

During the last 20 years, the existing methods of synthesis of acetylenic ethers and their analogues have been significantly improved and new procedures have been developed. The following general methods have been developed further: dehydrohalogenation of halogen-containing ethers and their analogues, the substitution of the halogen in halogenoacetylenic compounds, the reactions involving the elimination of mercaptans and alcohols, isomerisation with migration of multiple bonds, and the reactions of metal acetylides and alkali metal ethynoxides.[1]

Acetylenic ethers, sulphides, and selenides as well as their halogeno-derivatives have been obtained by the dehydrohalogenation of various saturated and ethylenic αβ- and ββ-dihalogenoethers and their analogues.[7–16]

Ethoxyethyne can be obtained particularly conveniently by the dehydrobromination of 1-bromo-2-ethoxyethene with potassium hydroxide in diglyme[17] or petroleum ether.[18,19]

The dehydrohalogenation of saturated βββ-trifluoro-substituted ethers and sulphides with the aid of lithium alkyls lengthens the hydrocarbon chain.[20] Alkylthio(seleno)ynamines $R_2NC{\equiv}CXR$ (X = S, Se) have been obtained by dehydrohalogenation with lithium dialkylamides.[21–23] The dehydrohalogenation of ββ-dichlorovinylorganyl sulphides with the aid of potassium mercaptides results in the formation of di(organylthio)acetylenes.[24,25] The dialkoxyacetylenes with an analogous structure are unstable; dimethoxyacetylene has been detected only by NMR spectroscopy in pentane at −40 °C:[26]

$$Z\text{-}CH_3OCCl{=}CHOCH_3 \xrightarrow[NH_3(liq.)]{NaNH_2} CH_3OC{\equiv}COCH_3.$$

Di-t-butoxyacetylene is the most stable; it can be stored at room temperature for several days.[27]

A vinylethynyl sulphide has been synthesised in 60% yield by the opening of the ring in 1,1-dichloro-2,2-dimethyl-3-phenylthiocyclopropane with subsequent dehydrochlorination of the 1,3-dienyl sulphide:[28,29]

$$C_6H_5SCH\text{—}C(CH_3)_2 \xrightarrow{(CH_2)_3COK} C_6H_5SCH{=}CClC(CH_3){=}CH_2 \xrightarrow{-HCl}$$
$$\xrightarrow{-HCl} C_6H_5SC{\equiv}CC(CH_3){=}CH_2.$$

A series of diacetylenic sulphides have been synthesised by the dechlorination of chlorine-containing 1,3-dienyl or vinylethynyl sulphides:[30]

$$RSCCl{=}CClCCl{=}CCl_2 \xrightarrow[-70\ ^\circ C]{C_4H_9Li} RSC{\equiv}CC{\equiv}CLi \xrightarrow{R^1Hal} RSC{\equiv}CC{\equiv}CR^1,$$

R = cycloalkyl, Ph; R^1 = H, $(CH_3)_3Si$, $(C_6H_5)_3Sn$, organyl.

A method of synthesis of an ethynyl vinyl sulphide has been developed:[31]

$$(CH_3)_3SiC{\equiv}CSCH_2CH_2Cl \xrightarrow[NH_3(liq.)]{LiNH_2} LiC{\equiv}CSCH{=}CH_2 \xrightarrow{H_2O} HC{\equiv}CSCH{=}CH_2.$$

Phenylethynyl ethers have been obtained in a low yield from phenylethynyl halides on treatment with alkoxides:[32,33]

$$C_6H_5C{\equiv}CX \xrightarrow{RONa} C_6H_5C{\equiv}COR,$$
$$X = Cl, Br;\quad R = alkyl.$$

A reaction mechanism, including addition, β-elimination and sulphenium ion formation stages, has been proposed as a result of a study of the nucleophilic substitution of chlorine in t-butylchloroacetylene by the thiophenoxide ion.[34,35] The rate constants for the substitution of a halogen[36] are correlated with Charton's steric constants of the alkylthio-groups σ_{SR}.[37]

Substituted acetylenic ethers,[38,39] sulphides,[38,41] and selenides[40,41] as well as ethynyl vinyl sulphides[42,43] have been obtained from the corresponding acetylenic halides by a similar procedure.

A two-stage method of synthesis of terminal ethynyl sulphides has been developed. It is based on the reaction of chloroethynyldimethylcarbinol with alkali metal thiolates and subsequent cleavage of the resulting dimethyl(organylthioethynyl)carbinol by heating with potassium hydroxide.[3,44–46] Terminal acetylenic ethers have been obtained similarly but in low yields.[47,48]

Halogen-containing acetylenic ethers and sulphides enter into the reaction involving the nucleophilic substitution of the halogen on treatment with organometallic compounds:[3,24,49–51]

$$RZC{\equiv}CX + R^1M \rightarrow RZC{\equiv}CR^1 + MX,$$
$$Z{=}O: R{=}C_2H_5;\ X{=}I;\ R^1{=}Ar;\ M{=}Cu{\cdot}MgBr_2;$$
$$Z{=}S: R = alkyl,\ C_6H_5;\ X = Cl, Br;\ R^1 = organyl;$$
$$N(C_2H_5)_2;\ M{=}Li,\ Cu{\cdot}MgX_2.$$

Chloroethynyl organyl sulphides react with mercaptoethanol in the presence of potassium hydroxide to form di(organylthio)-acetylenes.[52] The reactions with secondary amines have afforded organylthioynamines,[14,53,54] while those with tertiary amines and phosphines gave rise to ammonium and phosphonium salts:[14,15,55]

$$RSC{=}CCl \xrightarrow{HNR^1_2} RSC{\equiv}CNR^1_2,$$
$$R = alkyl;\ R^1_2N = morpholinyl, piperidinyl, piperazinyl.$$

$$[RSC{\equiv}CP(C_2H_5)_3]^+Cl^- \xleftarrow{(C_6H_5)_3P} RSC{\equiv}CCl \xrightarrow{R^1_3N} [RSC{\equiv}CNR^1_3]^+Cl^-,$$
$$R, R^1 = alkyl.$$

Trialkyl phosphites react with chloroethynyl organyl sulphides in accordance with the mechanism of the Arbuzov rearrangement to form organylthioethynylphosphonates:[15,56]

$$RSC{\equiv}CCl + P(OR^1)_3 \rightarrow RSC{\equiv}CP(O)(OR^1)_2 + R^1Cl;\ R, R^1 = alkyl.$$

The 1,4-elimination of a mercaptan from 1,4-dialkyl- or 1,4-di(phenylthio)but-2-ynes on treatment with potassium alkoxide in liquid ammonia by a standard procedure[1] led to high yields of vinylethynyl sulphides.[57] When an attempt was made to synthesise a vinylethynyl ether from 1,4-dialkoxybut-2-yne, ethynyl vinyl ether or a butatrienyl ether were obtained.[58] Vinylethynyl ethers were synthesised by treating compound (I) with ethyllithium:[59]

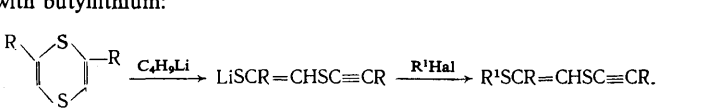
$$ROCH{=}C{=}CHCR^1R^2OR \xrightarrow{C_2H_5Li} ROC{\equiv}CCH{=}CR^1R^2,$$
(I)

$$R = alkyl;\ R^1, R^2 = H, alkyl, cyclopentyl.$$

A mixture of ethynyl and 1,3-dienyl sulphides was obtained by the isomerisation of 1-t-butylthiobuta-2,3-diene in the presence of sodium ethoxide in alcohol.[60] The study of the kinetics of the isomerisation of propargyl selenides to methylethynyl selenides established the carbanionic nature of the intermediate compound.[61]

The isomerisation of allenic sulphides to acetylenic sulphides can be induced by catalytic amounts of an amine or on heating.[62] During the formation of propargyl sulphides, their isomerisation to allenic and acetylenic sulphides is frequently observed.[63]

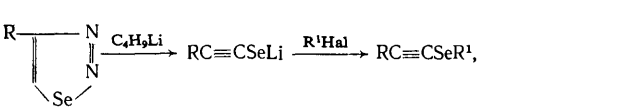
Metal acetylides have found extensive application as the starting materials for the synthesis of acetylenic sulphides and their analogues. An ethynyl sulphide has been obtained by refluxing copper phenylacetylide with 4,6,8-trimethyl-1-thiocyanato-azulene in dimethylformamide (DMF).[64] The Iotsich reagent reacts with arenesulphenyl chloride to form acetylenic sulphides.[65] Acetylenic selenides have been obtained by the reaction of silver[66] or lithium[67] acetylide with benzene selenyl bromide. Arylethynyl tellurides have been prepared by treating metal acetylides with arene-tellurenyl halides.[68,69]



The reaction of lithium acetylide with α-bromodithioisobutyric acid ester leads to the formation of an ethynyl sulphide:[70]

$$(CH_3)_3CC{\equiv}CLi + (CH_3)_2CBrC(S)SCH_3 \rightarrow$$
$$\rightarrow (CH_3)_3CC{\equiv}CSC(SCH_3){=}C(CH_3)_2 + LiBr.$$

The first[1] and a series of subsequent attempts at the synthesis of ethynyl ethers from lithium alkylethynoxide[71] or an acetylenic potassium dithiolate,[72,73] by treating them with alkyl halides were unsuccessful. However, the reaction of lithium alkylethynoxide with trialkylsilyl chloride[74] or diethyl phosphorochloridite[75] leads to the formation of the corresponding ethynyl ethers.



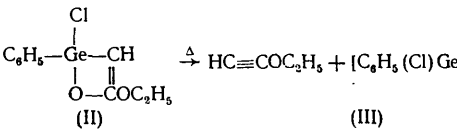
The simplest method of synthesis of ethynyl sulphides and their analogues became the reaction of a metal acetylide with the chalcogen and subsequent alkylation of the metal thiolate.[1] The methods of synthesis of acetylenic alkali metal thiolates have been published in reviews[76,77] and their use for the synthesis of ethynyl sulphides and their analogues has been described in a monograph.[78] A series of ethynyl sulphides,[3,79–84] selenides, and tellurides[41,69,85–87] have been obtained by this method. Dialkyl thiosulphonates have been used as alkylating agents for the synthesis of asymmetric di(alkylthio)acetylenes.[88] Acetylenic lithium thiolate has been used in an especially great variety of ways as the reagent for the synthesis of ethynyl sulphides.[89–98]

Ethynyl sulphides have also been obtained by treating 1,4-dithiines with butyllithium:[99]

$$R = H, alkyl;\ R^1 = alkyl.$$

Acetylenic lithium selenolates are obtained by treating substituted selenodiazoles with butyllithium:[100]

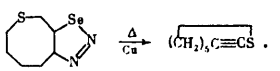
$$R = alkyl, aryl;\ R^1 = alkyl.$$



Acetylenic alkali metal thiolates (selenolates, tellurolates), which are ambient anions, enter into reactions involving the anionic 1,3-cycloaddition and nucleophilic addition to the triple bond, apart from the nucleophilic substitution of the metal.[100,101] Ethynyl selenides[100,102,103] and tellurides[100] are therefore frequently formed in a mixture with heterocyclic compounds.

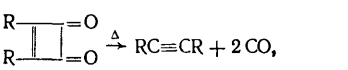
Acetylenic potassium selenolates react with epichlorohydrin to substitute the chlorine atom or to cleave the epoxide ring.[104]

An ethynyl telluride has been obtained by oxidising sodium phenylethynyltellurolate with iodine:[105]



$$2C_6H_5C{\equiv}CTeNa \xrightarrow[-NaI]{I_2} [C_6H_5C{\equiv}CTeTeC{\equiv}CC_6H_5] \xrightarrow{-Te} \rightarrow C_6H_5C{\equiv}CTeC{\equiv}CC_6H_5.$$

A new aspect of the methods of synthesis of acetylenic ethers and their analogues is thermosynthesis. Thus ethoxyacetylene and a germoxane (III) have been obtained in 25–30% yield by the decomposition of the unstable compound (II):[106]



(II) (III)

1-Thiacyclooct-2-yne (V) was synthesised for the first time in 15% yield by heating compound (IV) in the presence of copper:[107]

(IV) (V)

Acetylenes have been obtained by the thermal decomposition of 3,4-di(methylthio)- or 3,4-di(methylseleno)cyclobutene-1,2-diones:[108]

R = CH_3S, CH_3Se.

Di(ethylthio)acetylene has been synthesised in 53% yield by the thermolysis of the phosphorylide (VI):[109]

$$(C_6H_5)_3\overset{+}{P}-\overset{-}{C}=C(SC_2H_5)_2 \xrightarrow{\Delta} C_2H_5SC{\equiv}CSC_2H_5.$$

(VI)

The thermolysis of the phosphorylides (VII) afforded internal ethynyl selenides:[110]

$$(C_6H_5)_3\overset{+}{P}-\overset{-}{C}(SeAr)COR \xrightarrow{\Delta} RC{\equiv}CSeAr,$$

(VII)

R = alkyl, aryl.

Terminal ethynyl ethers and sulphides can be readily converted into the corresponding internal compounds by the substitution of the terminal hydrogen atom by metals. Thus various element-containing and functional derivatives of a metal-substituted ethoxyacetylene have been obtained from the latter:

$$C_2H_5OC{\equiv}CM \xrightarrow{RHal} C_2H_5OC{\equiv}CR,$$

M = Li, MgBr; R = CH_3CO (Ref.111), Alk_2P, Ar_2P (Refs.112, 113), $(CH_3)_3Si$ (Ref.2), $(CH_3)_2C_6H_5Si$ (Ref.114), Alk_3Ge, Alk_3Sn (Ref.6).

Lithium ethoxyethynylboranate has been synthesised by treating lithium ethoxyacetylide with a trialkylborane. Treatment of the boranate with iodine led to the synthesis of internal ethynyl ethers in 30–58% yields:[115,116]

$$R_3B + LiC{\equiv}COC_2H_5 \xrightarrow[THF]{0°C} Li^+R_3\overline{B}C{\equiv}COC_2H_5 \xrightarrow{I_2} RC{\equiv}COC_2H_5,$$

R = C_4H_9, $C_2H_5CHCH_3$.

The interaction of lithium ethoxyacetylide with epoxyethane or epoxypropane gave rise for the first time to vinylethynyl ethers.[117]

The reaction of dialkylamino(trialkyl)stannanes with ethoxyacetylene is a convenient method of synthesis of tin-containing ethynyl ethers.[6]

Phosphorus-containing ethynyl sulphides have been obtained from a methylthioacetylenic Iotsich reagent and phosphinic acid chlorides.[118]

The reaction of ethoxy- or phenylthio-ethynylmagnesium bromide with 4-benzenesulphonyl- or acetoxy-azetidine has been used to synthesise a heterocyclic ethynyl ether and sulphide:[119]

R = C_2H_5O, C_6H_5S; R^1 = $C_6H_5SO_2$, CH_3COO.

Alkynyl carboxylates and phosphates (X) have been obtained for the first time from the iodonium salts (VIII) by an ion-exchange reaction in the presence of an ion-exchange resin saturated with the anion A^-.[75] In contrast to compounds (IX, A = $OCOR^1$), compounds [IX, A = $OP(O)(OC_2H_5)_2$] are stable crystalline substances:

$$[RC{\equiv}ClPh]^+\,Ts^- \xrightarrow{A^-} [RC{\equiv}ClPh]^+\,A^- \rightarrow RC{\equiv}CA + PhI,$$

(VIII) (IX) (X)

A = $OCOR^1$, $OP(O)(OC_2H_5)_2$; R = alkyl, R^1 = aryl.

III. Physical properties

The electronic structure of ethynyl ethers and their analogues has been investigated by various physical methods. Previously published studies involving the analysis of the dipole moments (d.m.) of ethynyl sulphides and ethers did not provide unambiguous data about the direction of polarisation of the triple bond in the $-C{\equiv}C-S-$ system.[1]

As a result of the investigation of the dipole moments of phenylethynyl sulphides and their analogues p-$YC_6H_4XC{\equiv}CR$ (R = H, C_6H_5; X = S, Se, Te; Y = H, CH_3, Cl, Br, CH_3O, NO_2), new studies led to the discovery of the dependence of the direction of polarisation of the triple bond on the character of the substituents at the heteroatom and at the triple bond.[120–130] It was shown that, in the case of electron-donating substituents, the sulphur, selenium, and tellurium atoms behave as π-donors in relation to the triple bond, which increases the $X-C_{sp}$ bond order. The character of the polarisation of the triple bond is the same in this case: $-XC^{\delta+}=C^{\delta-}-$. An electron-accepting substituent (Y = NO_2) reverses the direction of polarisation of the triple bond. The occurrence of direct conjugation in the $-XC{\equiv}CC_6H_4Y$ group with the varied substituent (Y) via the benzene ring with inversion of the direction of the shift of electron density in the triple bond on passing from Y = CH_3O to Y = NO_2 was established.

The dependence of the dipole moments of ethynyl sulphides on the induction constants of the ethynyl[81] and alkyl groups at the heteroatoms[131] confirms the high sensitivity of the $-C{\equiv}CX$-system to the influence of substituents.

The influence of Group VIA heteroatoms at the triple bond on the degrees of shielding of the carbon atoms is clearly manifested in the ^{13}C NMR spectra. The inversion of the relative shielding of the α- and β-carbon atoms of the triple bond on passing from ethers to sulphides has been adopted as evidence for the manifestation of the $-M$ effect by the alkylthio-group in contrast to the alkoxy-group.[132,133] The shielding of the α-carbon atoms and the deshielding of the β-carbon atoms increase linearly with decrease in the electronic activity of the heteroatom in the series of ethynyl chalcogenides.[134,135]

Correlation analysis of the ^{13}C NMR spectra of acetylenic compounds established the additivity of the contribution of the substituents to the chemical shifts of the carbon atoms of the triple bond. The effects of the substituents constitute a linear combination of their induction, resonance, and steric constants.[136,137]

The study of the NMR spectra of ethoxyacetylene[138] and silicon-, germanium-, and tin-containing ethynyl ethers[139–141] and sulphides[142] showed that the alkoxy-group is an effective *p*-donor in relation to the triple bond, while the alkylthio-group is a weak *p*-acceptor.[143] However, the deshielding of the tellurium atom in 1-methyltellurobut-3-en-1-yne compared with dimethyl telluride, established from the ^{125}Te NMR spectra,[144] may be a consequence of a weak electron-donating effect of the methyltelluro-group in relation to the triple bond.

The $^{77}Se-^{13}C$ spin–spin coupling constants (SSCC) of ethynyl selenides have been measured and the influence of the medium on the shielding of the ^{77}Se atoms has been investigated.[145–147]

The carbon atoms of the triple bond in di(ethylthio)acetylene are deshielded compared with the terminal ethynyl sulphides.[148]

An equation which simplifies the assignment of the signals of the carbon atoms of the triple bond in ethynyl sulphides and their analogues has been proposed.[149]

The intensity of the band due to the triple bond in the Raman spectrum of t-butylthioacetylene is approximately twice as great as in the spectrum of butylacetylene, which is evidence of an effect of the conjugation of the triple bond with the alkylthio-group.[150,151] The stretching vibration frequencies of the triple bond in the Raman spectra of phenylethynyl sulphides and their analogues, $CH_3XC{\equiv}CC_6H_5$ and $p\text{-}YC_6H_4XC{\equiv}CC_6H_5$ (X = S, Se, Te; Y = H, CH_3, CH_3O, F, Cl, Br, NO_2), decrease in the sequence S > Se > Te, whilst their integral intensities increase. It has been concluded that the sulphur and selenium atoms participate in the transmission of conjugation via the triple bond. In relation to tellurides, a distinct manifestation of this effect has not been observed.[126,152]

The intensity of the absorption bands of the triple bond in the IR spectra of ethoxy- and ethylthio-acetylenes is determined by the resonance interaction with the substituent. It has been shown that the sulphur atom in the molecules of methylthiophenylacetylene and 1-ethylthio-3,3-dimethylbut-1-yne is involved in conjugation with both π-bonds of the acetylenic fragment.[153] The integral intensities of the triple bond in ethoxy- and phenoxy-acetylenes are not correlated with the induction constants of the substituents.[154]

The force constants of the bonds in the molecules of methoxyacetylene and trimethylsilylmethoxyacetylene have been calculated.[155,156] The absorption bands in the IR spectrum of methylthioacetylene have been assigned.[151]

A combined study of the IR, UV, and NMR spectra of silicon-, germanium-, and tin-containing ethynyl ethers and sulphides demonstrated the occurrence of interaction via the triple bond.[143,157] It has been established that the intensity of the absorption bands of the triple bond in the IR spectra of structurally similar germanium- and tin- containing compounds depends on the inductive effect of the substituents. In the case of silicon-containing compounds, there is in addition the influence of the specific interaction of the silicon atom with the triple bond.

The possibility of an approximate quantum-mechanical approach to the description of the behaviour of the stretching vibration frequencies of the $C_{sp}-H$ bond in methoxyacetylene has been examined.[158]

Apart from the absorption bands assigned to the $\pi \rightarrow \pi^*$ electronic transition, the UV spectra of vinyl- and phenyl-ethynyl sulphides and their analogues contain a band which has been assigned to the $n \rightarrow \pi^*$ transition, the band being most pronounced in the spectra of the tellurides.[126,159–161] Analysis of the UV spectra indicates an increase in the degree of interaction of the heteroatoms with the triple bond in the electronically excited state in the direction Te < Se < S, which is the opposite of the direction of variation in the ground state. This interaction can be attributed to the variation of the ionisation potentials, diminishing on passing to the tellurides, which promotes charge transfer to the triple bond in the excited state. The ionisation potentials of ethynyl sulphides have been obtained in the study of the mass spectra[162,163] and those of the sulphides and selenides have been determined by the method of photoelectron ionisation.[108,164] The ionisation potentials of di(methylthio)acetylene have been calculated by the MNDO method.[165]

The photoelectron spectra of 1-ethoxybut-3-en-1-yne[166] and ethynyl sulphides have been obtained.[167] Radicals have been detected in the laser photoionisation of the deuterium-containing di(methylthio)acetylene[168] and a radical-cation has been detected in the radiation-induced ionisation of methoxyacetylene.[169]

The decrease in the $C_{sp}-X$ bond length in methoxyacetylene,[170,171] ethoxyacetylene,[172] and methylthio-[173] and ethylthio-acetylenes,[174] established by microwave spectroscopy, may be a consequence of the effect of p,π conjugation. The potential energy of the internal rotation of the methylthio-group in methylthioacetylene is higher than that of the methoxy-group in methoxyacetylene,[175] which has not so far been satisfactorily explained. The microwave spectrum of ethoxyacetylene has been used in a computer program for the identification of the radiospectra of the molecular clouds in space.[176]

It has been established by gas electron diffraction that the di(methylthio)acetylene molecule exists preferentially as the conformer with a CSSC dihedral angle of 86°.[148]

The study of the X-ray fluorescence *K* spectra of sulphur in aryl and pentafluorophenylethynyl sulphides established that the *d* orbitals of sulphur are appreciably populated with retention of the p,π conjugation effects.[65]

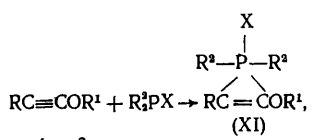
The formation energies of methoxy- and methylthio-acetylenes,[177] the geometrical parameters of methoxyacetylene,[178] the distribution of electron density,[179] and the stabilisation energy[180,181] have been calculated by quantum-chemical methods.

Thus the triple bond in ethynyl sulphides and their analogues differs from that in the ethynyl ethers by an increased sensitivity to the influence of substituents associated with the possibility of the manifestation of the effect of d,π interaction by the heteroatoms.

The differences between the electronic structures of ethynyl ethers and their analogues are manifested by the greater acidity of the terminal ethynyl sulphides compared with the ethers and acetylenic hydrocarbons.[150,182] A linear relation between the kinetic and thermodynamic CH acidities of ethynyl ethers or sulphides has been established.[183] The state of the exchange equilibrium in the ethoxyacetylene–*p*-fluorophenylethynylcyclohexylmercury has been investigated by ^{19}F and ^{1}H NMR.[184] The stabilisation energy of methoxyacetylene in the reaction involving the exchange of the methoxy-group has been calculated by the quantum-chemical method.[185]

The formation of hydrogen bonds in aryloxyacetylenes has been investigated by IR spectroscopy.[186] It has been shown that the basicity of ethoxyacetylene in the interaction with phenol depends on the inductive effect of the ethoxy-group.[187] The energy of the hydrogen bond between phenol and vinylethynyl sulphides, selenides, and tellurides increases on passing to the tellurides[188] in parallel with

the energy of the electronic excitation of the molecules. The oxygen or sulphur atom is the centre involved in the hydrogen bond with phenol in the molecules of silicon-, germanium-, and tin-containing ethynyl ethers and sulphides.[157]

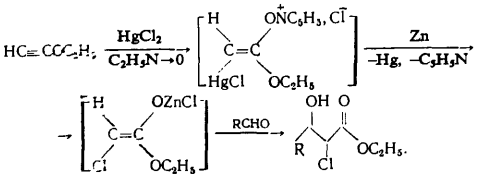


The antiparallel variation of the electronic structure of the molecules in the series of ethynyl ethers and their analogues with their susceptibility to the perturbing effect of reagents is manifested by the regioselectivity of the addition of the reagents to the triple bond in ethynyl sulphides.

IV. Chemical properties

1. The addition of electrophiles

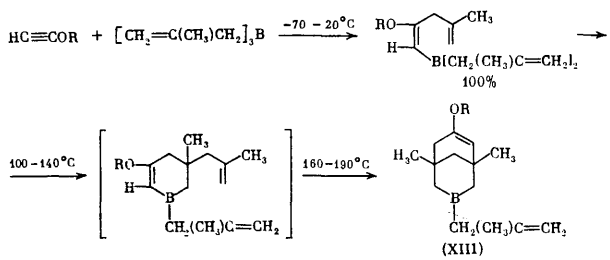
It was established previously that the addition of electrophiles to ethynyl ethers and sulphides takes place with the attachment of the electrophilic component of the reagent to the β-carbon atom of the triple bond.[1] The addition of phosphorus pentachloride, phosphorus trihalides, dialkylhalogenophosphines, dialkyl phosphorohalidites, mercury chloride, Group IV element tetrachlorides, and trialkylstannyl chloride to ethynyl ethers proceeds in accordance with this rule.[2,6,189–195] Asymmetric di(alkylthio)- and di(arylthio)-acetylenes react with phosphorus pentachloride to form equal amounts of regioisomers.[196,197] Ethynyl sulphides react with phosphorus tribromide similarly to the ethers.[198] The reaction of 3-t-butyl-1-ethoxy-3-methylprop-1-yn-3-ol with phosphorus trichloride in the presence of pyridine leads to the formation of ethyl 2-dichlorophosphino-3,4,4-trimethylpent-2-enoic acid.[199]



In the absence of a catalyst, new representatives of phosphirenes (XI) are formed in almost quantitative yields from dialkyl and diaryl-halogenophosphines by the reaction with internal ethynyl ethers:[200]

(XI)

R, R^1, R^2 = alkyl, aryl; X = Cl, Br.

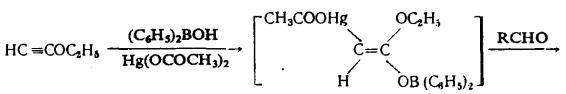


The successive treatment of ethoxyacetylene with mercury chloride, pyridine *N*-oxide, and zinc dust leads to the formation of the enolate (XII), which reacts with aldehydes to form α-chloro-β-hydroxyesters:[201]

(XII)

Triethylsilane reacts with phenoxyacetylene in the presence of a modified Speier catalyst predominantly with attachment of the triethylsilyl group to the β-carbon atom of the triple bond.[202] Triethylgermane reacts at the triple bond under similar conditions with 90% regioselectivity, forming a 1 : 1 mixture of the (*Z*)- and (*E*)-isomers.[203]

Boron-containing reagents, which we have formally classified as electrophilic, add to terminal ethynyl ethers with attachment of the boron atom to the β-carbon atom of the triple bond and the formation of ethylenic boranes. Thus the hydroboration of ethoxyacetylene[204,205] leads to the formation of tri(*trans*-2-ethoxyvinyl)-borane. The mode of addition of dialkyl- and triorganyl-boranes to ethoxyacetylene is similar.[204–209] The stereoselectivity of the addition of dialkylboranes to ethynyl selenides with subsequent acidolysis of the intermediate has been used to synthesise (*Z*)-vinyl selenide.[110,210,211] (*Z*)-β-Trimethylsilylvinyl ether has been obtained by the same method.[212] The allylboration of alkoxyacetylene proceeds stereoselectively as *cis*-addition.[213–215] Heating of the adduct leads to the allyl rearrangement with formation of the bicyclic borane (XIII):



(XIII)

R = alkyl.

The use of the products of the addition of allylboranes to ethynyl ethers as synthons has been the basis of a method of synthesis of other unsaturated compounds. Thus 2-alkoxypenta-1,4-dienes have been synthesised[217] by the alcoholysis of the products of the addition of dialkylallylboranes to ethynyl ethers.[216] The addition of triallylborane to ethoxyacetylene and subsequent treatment of the products with triethylaluminium led to the synthesis of pent-1-en-4-yne.[218] The regioselectivity of the addition of the dialkylborylmethylcyclobut-1-ene–dialkylboryl-2-methylene-cyclobutane system is similar to the regioselectivity of the addition of allylboranes.[207]

Ethoxyacetylene reacts with aldehydes in the presence of diphenylboronic acid and mercury acetate with formation of approximately equal amounts of β-hydroxy- and β-acetoxy-esters.[219] The coupled addition of diphenylboronic acid and mercury acetate to ethoxyacetylene apparently takes place initially:

R = alkyl, aryl.

The study of the mechanism[3] and regioselectivity of the hydration reactions of internal ethynyl ethers and their analogues has been continued. Thus the hydration of diethylaminophenylselenoacetylene leads to the formation of the diethylamide of 2-phenylselenoacetic acid:[23]

The mode of hydration of 4,4-dichloro-1-methoxybut-1-yn-3-one[220] and 1-alkylselenobut-3-en-1-ynones[85] is similar to the familiar hydration reaction of ethynyl ethers.[1]

The product of the addition of two alcohol molecules to ethoxyacetylene can be used as a plasticiser of solid polymers.[221] Phenols react with ethoxyacetylene regiospecifically with formation of α-aryloxyvinyl ethers.[222]

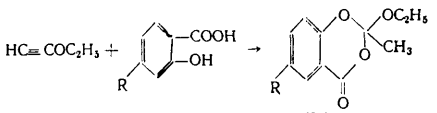
The bromination of ethoxyacetylene[223] and phenoxyacetylene[224] leads to the formation of di- and tetra-bromides. The halogenation of vinylethynyl sulphides and selenides involves predominantly the triple bond.[225,226] The tetrabromide has been obtained by the

bromination of 1-methyltellurobut-3-en-1-yne as a result of the addition of bromine to the double bond and to the tellurium atom.[227]

The joint chlorination of ethoxyacetylene and epoxyethane afforded a chlorine-containing orthoester:[228]

$$HC{\equiv}COC_2H_5 + 2\,Cl_2 + 2\,CH_2{-}CH_2 \rightarrow CHCl_2C(OCH_2CH_2Cl)_2(OC_2H_5).$$

The interaction of ethynyl ethers with sulphur monochloride pentafluoride proceeds with substitution of the alkoxy-group and the formation of 2,2-difluoro-1-pentafluorothioethylene.[229]



The hydrohalogenation of substituted ethynyl ethers[230] and sulphides[118] is regioselective[1] and proceeds in accordance with the *trans*-addition rule. The hydrochlorination of di(alkylthio)- and di(alkylseleno)-acetylenes proceeds predominantly as *trans*-addition with 80% regioselectivity for asymmetric di(alkylthio)acetylenes.[231] Vinylethynyl selenides combine with hydrogen chloride selectively via the triple bond:[232]

$$CH_2{=}CHC{\equiv}CSeR \xrightarrow{HCl} CH_2{=}CHCH{=}C(Cl)SeR,$$
$$R = \text{alkyl}.$$

The bond between the acetylenic carbon atom and tellurium in vinylethynyl tellurides is cleaved on treatment with hydrogen chloride.[232] The hydrochlorination of a diethynyl sulphide[233] and selenide[234] afforded only the 1,3-diene products of the addition of two molecules of hydrogen chloride: $C_2H_5CH{=}CClCH{=}CClXCH_3$ (X = S, Se). Calculation by the CINDO/2 method of the perturbation energy of the hydrochlorination reaction of vinylethynyl sulphides and selenides in an ionising solvent has led to the conclusion that the reaction is subject to orbital control.[234]

The mode of addition of carboxylic acids to ethynyl ethers[224,235–239] is of the usual type.[1] Acid anhydrides are formed from trimethylsilylethoxyacetylene by reaction with carboxylic acids.[240]

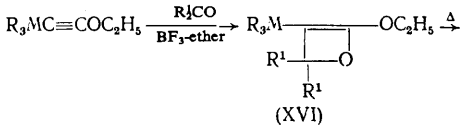
Ethoxyacetylene and 5-(4-fluorophenyl)salicylic acid react to form the benzodioxane (XIV), which has analgesic properties:[241]

(XIV)

$R = p\text{-}FC_6H_4.$

Certain products of the addition of carboxylic acids exhibit chemiluminescence[239,242] or can be recommended as UV-stabilisers of polymers.[238]

Alkanesulphonic acids in the form of pyridinium salts add to ethoxyacetylene with the usual mode of addition of the acid residue.[243]



Fluorosulphonic acid adds to the ethoxyacetylene regiospecifically with formation of compound (XV):[244]

$$HC{\equiv}COC_2H_5 \xrightarrow[SO_2ClF,\ -60\ ^\circ C]{FSO_3H} CH_2{=}C(OC_2H_5)OSO_2F.$$
(XV)

Like the analogous ethynyl ethers, ethynyl sulphides[3] and vinylethynyl sulphides,[245] selenides,[246] and tellurides[188] combine with carboxylic acids chemoselectively via the triple bond with the usual mode of addition of the acid residue. On being refluxed in acetic acid, 1-methyltellurobut-3-en-1-yne is protodemetallated with formation of vinylacetylene. Di(alkylthio)acetylenes react with carboxylic acids to form predominantly the (*E*)-isomers of vinyl sulphides.[247]

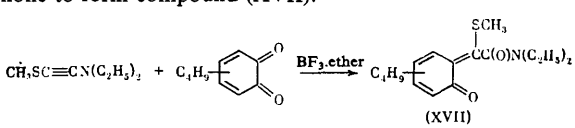
Methanesulphenyl chloride adds to vinylethynyl sulphides at the triple bond with formation of 1-chloro-2-methylthiobutadienyl sulphides.[248]

One of the methods of synthesis of αβ-unsaturated acid esters is the reaction of ethynyl ethers with carbonyl compounds in the presence of boron trifluoride etherate.[249–252] Substituted oxetenes (XVI) are sometimes formed, isomerising on heating:

(XVI)

$$\rightarrow (CX)_2C{=}C(MR_3)COOC_2H_5,$$
$$M = Si, Ge;\ R^1 = CF_3,\ CF_2Cl,\ \text{alkyl};\ R = \text{alkyl},$$
$$R_3M = H,\ R^1 = CF_3,\ CF_2NO_2.$$

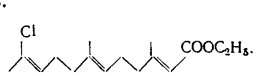
In the absence of the catalyst, trimethylstannylethoxyacetylene adds to ketones, the adduct isomerising to an α-stannylated acrylate after the addition of a catalyst:[250]



$$(CH_3)_3SnC{\equiv}COC_2H_5 \xrightarrow{(CF_2Cl)_2CO} (CF_2Cl)_2C[OSn(CH_3)_3]C{\equiv}$$
$$\equiv COC_2H_5 \xrightarrow{BF_3\text{.ether}} (CF_2Cl)_2C{=}CSn(CH_3)_3COOC_2H_5.$$

The reaction of diisopropylaminophenylselenoacetylene with perfluoroacetone leads to the formation of the amide of an αβ-unsaturated acid.[23]

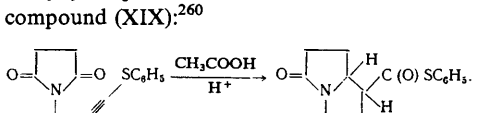
$$(\text{iso-}C_3H_7)_2NC{\equiv}CSeC_6H_5 \xrightarrow[BF_3\text{.ether}]{(CF_3)_2CO} (CF_3)_2C_2{=}C(SeC_6H_5)CON(\text{iso-}C_3H_7)_2.$$



Phosgene[253] and acetyl chloride[254] add to internal ethynyl ethers with formation of α-chlorovinyl ethers.

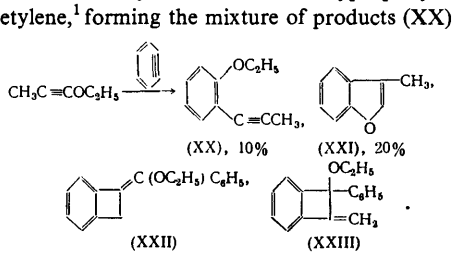
Diethylamino(methylthio)acetylene reacts with a substituted *o*-quinone to form compound (XVII):[51]

(XVII)



Ethoxyacetylene has been used in the synthesis of αβ-unsaturated esters,[255–257] among which compounds of type (XVIII) are juvenile-hormonal insecticides:[258]

(XVIII)



The reaction of terminal ethynyl sulphides with thiophenaldehydes afford esters of αβ-unsaturated thio-acids.[259]

The intramolecular addition of the carbonyl group to the triple bond of an ethynyl sulphide in an acid medium leads to the formation of compound (XIX):[260]

(XIX)

Dehydrobenzene readily reacts with 1-ethoxyprop-1-yne[261] as well as ethoxyacetylene,[1] forming the mixture of products (XX)–(XXIII):

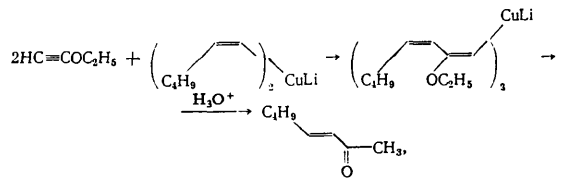
(XX), 10% (XXI), 20%

(XXII) (XXIII)

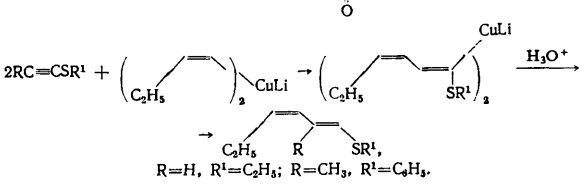
The main product of the reaction of dehydrobenzene with ethylthioacetylene is benzothiophen.[261]

2. The addition of nucleophiles

The previously established different modes of addition of nucleophiles to ethynyl ethers and sulphides are usually interpreted from the standpoint of the concept of the mesomeric stabilisation of cryptoanions by the sulphur atom.[1] A new aspect of the study of the electrophilic activity of the triple bond in ethynyl ethers and sulphides involves the investigation of the addition of organometallic and organophosphorus reagents. The high regio- and stereoselectivities of the addition of organometallic reagents to ethynyl ethers and sulphides make it possible to obtain vinyl ethers and sulphides with a specified structure. Thus mixed organic copper-magnesium (lithium) compounds and Grignard reagents add to ethynyl ethers and sulphides with the mode of addition of the organic group characteristic of nucleophiles.[3,262–264] The hydrolysis of the intermediate and treatment with carbon dioxide or iodine lead to the formation of the *cis*-isomers of substituted vinyl ethers and sulphides:



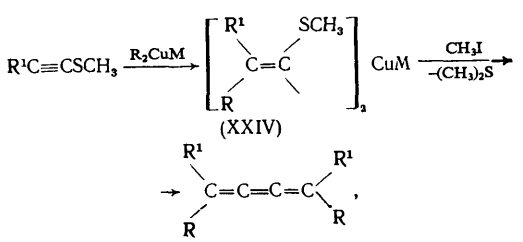
$$HC{\equiv}COC_2H_5 \xrightarrow{RCu.MgBr} [CH(Cu,\ MgBr){=}C(R)OC_2H_5] \xrightarrow[(CO_2,\ I_2)]{H_2O} \rightarrow XCH{=}C(R)OC_2H_5,$$



$$HC{\equiv}CSC_2H_5 \xrightarrow{RCU.MgBr} [RCH{=}C(Cu,\ MgBr)SC_2H_5] \xrightarrow[(CO_2,\ I_2)]{H_2O} \rightarrow RCH{=}C(X)SC_2H_5,$$

R = alkyl; X = H, COOH, I.

Phenylmagnesium bromide adds chemoselectively to 1-methylthiohexa-1,3-diyne in the presence of Ni^{2+} ions at the triple bond adjoining the sulphur atom with attachment of the phenyl group to the α-carbon atom and the predominant formation of (*E*)-ethynylvinyl sulphide.[265]



A vinylketone has been obtained by the reaction of an ethylenic lithium cuprate with ethoxyacetylene.[266] 1,3-Dienyl sulphides have been obtained from ethynyl sulphides under similar conditions:

R=H, $R^1=C_2H_5$; $R=CH_3$, $R^1=C_6H_5$.

The methylation of the intermediate (XXIV) by methyl iodide leads to the elimination of the methylthio-group and the formation of a vinylidene, which is converted into a cumulene hydrocarbon:[3,267]

R, R^1 = alkyl, M = MgHal, Li.

The copper-aluminium hydride complex adds to ethynyl sulphides regio- and stereo-selectively; (*Z*)-vinyl sulphides are formed after hydrolysis:[268]

$$RC{\equiv}CSR^1 \xrightarrow{\text{"CuH"}} [RCH{=}C(Cu)SR^1]^-Li^+ \xrightarrow{H_2O} RCH{=}CHSR^1,$$

R = alkyl, R^1 = alkyl, Ph; "CuH" = $LiCuHBr.Al(OCH_3)_3$.

In the absence of copper ions, the reaction with lithium trimethoxyhydroaluminate affords a mixture of regioisomers of (*E*)-vinyl sulphides.[269]

The 1,4-addition of alkylsilver to vinylethynyl sulphides leads to allenyl sulphides after hydrolysis:[270]

$$CH_2{=}CR^1C{\equiv}CSCH_3 \xrightarrow{RAg} RCH_2C(R^1){=}C{=}CHSCH_3,$$

R^1 = H, CH_3; R = alkyl.

Lithium alkyls add to ethynyl ethers with formation of allenyl and ethynyl ethers, whose ratio depends on the structure of the lithium alkyl, the ethynyl ether, and the solvent:[271]

$$R^2R^3C(OR^1)-C{\equiv}C-OR \xrightarrow{R^4Li} R^2R^3C{=}C{=}CR^4(OR) + R^2R^3C(OR^1)-C{\equiv}C-R^4,$$

R, R^1 = alkyl; R^2, R^3 = H, alkyl; R^4 = alkyl, Ph.

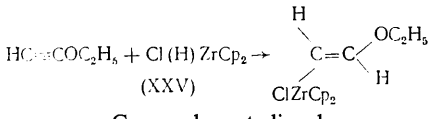
The chemoselective addition of lithium alkyls to the double bond in vinyl ethynyl sulphides is a convenient method of synthesis of allenyl sulphides.[272–274] The ambient nature of the intermediate in this reaction makes it possible to obtain alkylthioethynylcarbinols on oxidation of the intermediate by oxygen[275] or silicon-containing ethynyl sulphides on treatment with chlorotrimethylsilane.[276]

The acetylenic carbon atom–selenium bond in ethynyl selenides is readily cleaved on treatment with a lithium alkyl.[110] The reaction of phenyltelluroacetylene with butyllithium involves the simultaneous cleavage of the acetylenic carbon atom–tellurium bond and substitution at the acetylenic carbon atom.[68]

The synthetic possibilities of the reactions of organometallic compounds with vinylethynyl sulphides have been considered in a review.[277] On treatment with lithium alkyls of alkyl diacetylenic sulphides, the alkylthio-groups are substituted and diacetylenic hydrocarbons are formed.[233]

The reactions of vinylethynyl sulphides, selenides, and tellurides with lithium in liquid ammonia lead to the substitution of the alkyl group in the sulphides and of the alkylheteroatom group in the selenides and tellurides.[278] The alkyl group in the sulphides can be substituted by employing acetoxydiazomethane in the presence of copper salts.[3,279]

A method has been developed for the synthesis of tin- and lead-containing vinyl ethers and sulphides by the coupled hydrostannylation or hydroplumbylation of ethynyl ethers and sulphides.[280–284] The regioselectivities are different for ethers and sulphides:

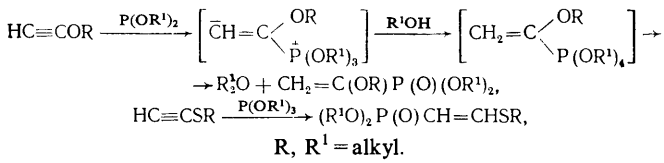


$$HC{\equiv}COR \xrightarrow{(C_2H_5)_3MNa} CH_2{=}C[M(C_2H_5)_3]OR,$$

$$HC{\equiv}CSR \xrightarrow{(C_2H_5)_3MNa} (C_2H_5)_3MCH{=}CHSR,$$

M = Sn, Pb; R = CH_3, C_2H_5.

In the stannylation reaction, tin-containing ethynyl ethers and sulphides are formed as side products. The metallation process predominates in the reaction of phenoxyacetylene with triethylgermyl-lithium.[203] The Schwartz reagent (XXV) adds regio- and

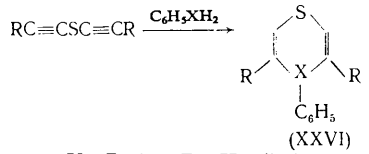


stereo-specifically to ethoxyacetylene with formation of an (*E*)-vinyl ether in which zirconium is readily substituted by electrophiles.[285,286]

(XXV)

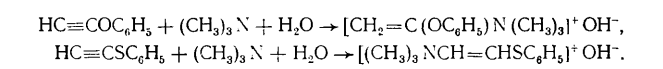
Cp = cyclopentadienyl.

Di- and tri-alkyl phosphites undergo the opposite type of addition to ethynyl ethers and sulphides:[287–294]



R, R^1 = alkyl.

According to the authors, the product of the addition of tributylphosphine to ethoxyacetylene has the structure of a dipolar ion:[295–298]

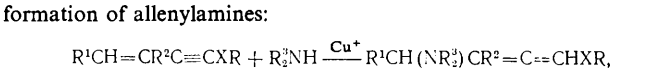


Phenylphosphine and phenylarsine react with di(alkylethynyl) sulphide in liquid ammonia in the presence of lithium amide to form the heterocyclic compounds (XXVI):[299]

(XXVI)

X = P, As; R = H, alkyl.

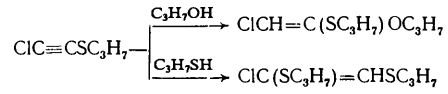
Tertiary amines readily add to terminal ethynyl ethers and sulphides in aqueous solution with the opposite mode of addition:[300]



Internal phenoxy- and phenylthio-acetylenes do not react with triethylamine.

The addition of secondary amines to ethynyl sulphides leads to thioamides.[79,80,84] In the presence of an electron-accepting group at the triple bond in the ethynyl sulphide molecule, the usual mode of addition of amines changes and the amino-group is attached to the α-carbon atom of the triple bond.[118] Di(alkylthio)acetylenes and their selenium and tellurium analogues combine with diethylamine non-stereoselectively with formation of vinylamines.[301]

2-Methyloxazoline has been obtained as a result of the double addition of monoethanolamine to phenoxyacetylene.[224]

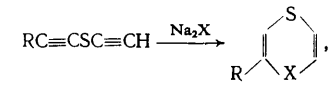


Secondary amines add to vinylethynyl sulphides,[302] selenides, and tellurides[303] in the presence of copper ions as the catalyst with formation of allenylamines:

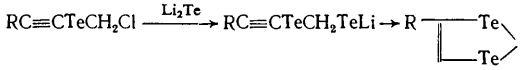
X = S, Se, Te; R^1, R^2 = H, alkyl; R = alkyl; R^3 = alkyl, organyl.

Ethynyl ethers[39] and sulphides[118] with an electron-accepting group at the triple bond combine with phenol and methanol with a similar mode of addition. The mode of addition of allyl alcohols to phenoxyacetylene[304] is the same as that in the addition of ethanol to ethoxyacetylene.[1] Intramolecular cyclisation occurs in the reactions of acylthioacetylenes with alcohols.[305,306]

The different modes of addition of alcohols and mercaptans to 1-chloro-2-propylthioacetylene[307] are a consequence of the charge and orbital control of the reactions:

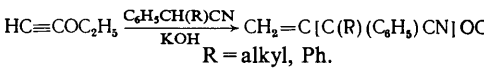


The addition of mercaptans to phenoxyacetylene[308] and ethynyl sulphides[9,88,309] takes place in conformity with the familiar rules.[1] Lithium methane-thiolate reacts with vinylethynyl sulphides chemoselectively via the triple bond with the attachment of the methylthio-group to the β-carbon atom and the formation of a (*Z*)-1,3-diene bis-sulphide:[310]



The attachment of the phenylthio-group to the α-carbon atom takes place in the addition of benzenethiol to ethynyl sulphides with electron-accepting substituents at the triple bond.[259]

The addition of sodium sulphide (selenide, telluride) to diethynyl sulphides leads to the formation of substituted 1,4-dithianes and their analogues:[5,311]



X = S, Se, Te; R = alkyl, isopropenyl.

Ethynyl tellurides react with lithium telluride, affording a substituted 1,3-ditellurole:[87]

R = H, alkyl, Ph.

The rule governing the addition of nucleophiles holds in the reaction of a carbanion to ethoxyacetylene:[312]

R = alkyl, Ph.

Ethynyl sulphides react non-regioselectively under similar conditions.

The mode of hydration of ethylthioethynylmorpholine in an alkaline medium is determined by the polarisation of the triple bond by the morpholino-group:[54]

Alkaline hydrolysis of 1-thiacyclooct-2-yne leads to the cleavage of the acetylenic carbon atom–sulphur bond.[107]

The reduction of methoxyacetylene with lithium tetradeuterio-aluminate constitutes a method of synthesis of deuteriated vinyl ethers:[313,314]

Ethynyl selenides can be hydrogenated by lithium tetrahydro-aluminate with formation of (*Z*)-ethynyl selenides.[110] The hydrogenation of vinylethynyl sulphides by lithium tetrahydro-aluminate in the presence of copper bromide leads to (*Z*)-1,3-dienyl sulphides, while in the absence of copper ions their (*E*)-isomers are formed.[315]

3. The radical addition reactions

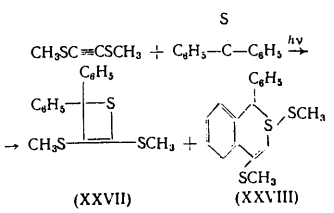
Radical reagents add to ethynyl ethers and sulphides as a rule with the attachment of the radical to the β-carbon atom of the triple bond.[1] However, exceptions are known. Thus the reactions involving the photochemical addition of phosphorus tribromide to terminal ethynyl ethers[316] and sulphides[198] take place in different ways:

$$ROC{\equiv}CH + PBr_3 \xrightarrow{h\nu} ROC(PBr_2){=}CHBr,$$
$$RSC{\equiv}CH + PBr_3 \xrightarrow{h\nu} RSC(Br){=}CHPBr_2,$$
$$R = \text{alkyl}.$$

The free-radical addition of mercaptans to ethoxy- or phenoxyacetylene[308,317,318] and to substituted ethynyl sulphides[9,39,118] takes place in accordance with the familiar rule.

In the case of vinyl ethynyl sulphides, mercaptans undergo radical addition to the double bond:[319]

$$CH_2{=}CHC{\equiv}CSCH_3 + C_2H_5SH \rightarrow C_2H_5SCH_2CH_2C{\equiv}CSCH_3.$$



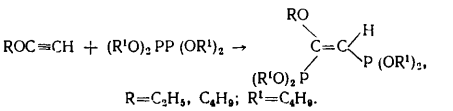
Under similar conditions, vinylethynyl selenide combines with ethanethiol via both multiple bonds with formation of a mixture of isomers.

Grignard reagents add chemoselectively and regioselectively to vinylethynyl sulphides at the double bond with formation, after hydrolysis, of a mixture of acetylenic (75%) and allenic isomers:[320,321]

$$CH_2{=}CHC{\equiv}CSR \xrightarrow{R^1MgHal} R^1CH_2CH_2C{\equiv}CSR + R^1CH_2CH{=}C{=}CHSR,$$
$$R,\ R^1 = \text{alkyl}.$$

Under similar conditions, 1-methylselenobut-3-en-1-yne forms an allenyl selenide in 38% yield. Vinylethynyl tellurides react with cleavage of the acetylenic carbon atom–tellurium bond.[322]

The mode of photochemical addition of ethynyl ethers[323,324] to ketones is of the usual type.[1] Thioketones add to di(methylthio)acetylene predominantly in accordance with the [2 + 2]cycloaddition mechanism with formation of compounds (XXVII). The [4 + 2]-cycloaddition product (XXVIII) is formed in 5–10% yield:[325–329]



(XXVII) (XXVIII)

The reaction of 1,2-diones with ethynyl sulphides leads to the formation of a mixture of (*Z*)- and (*E*)-alkylthiobut-2-ene-1,4-diones.[3] Products having a similar structure have been obtained as a result of the [2 + 2]cycloaddition of phenanthrenequinone to internal ethynyl sulphides.[330]

The free-radical addition of trialkylgermanes and trialkyl- or triphenylstannanes to terminal ethynyl ethers[331] is similar to the already known reaction of trialkylstannanes.[1] The mode of addition of trialkylstannanes is retained in relation to silicon-, germanium-, and tin-containing ethynyl ethers.[6,212]

A substituted triazole adds to methoxyacetylene at the triple bond with the attachment of the triazole ring at the α-position relative to the methoxy-group.[332]

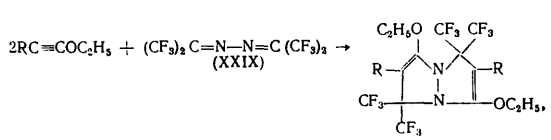
Tetraalkoxydiphosphines add stereospecifically to terminal ethynyl ethers:[333]

$R = C_2H_5,\ C_4H_9;\ R^1 = C_4H_9.$

The hydrogenation of ethoxyacetylene in the presence of a palladium catalyst has been investigated.[334] Vinylethynyl sulphides are slowly reduced at the palladium catalyst to the (*Z*)-1,3-dienyl sulphides.[335] The attempts to reduce ethynyl tellurides by various reductants led to the cleavage of the acetylenic carbon atom–tellurium bond.[69]

The energy of the interaction of singlet oxygen with dimethoxyacetylene has been calculated by the INDO method; a mechanism has been proposed for the oxidation reaction.[336]

The photochemical interaction of 1,4-dithiine and its homologues with di(ethylthio)acetylene leads to the formation of unstable coloured complexes as a result of [2 + 2]cycloaddition.[337]

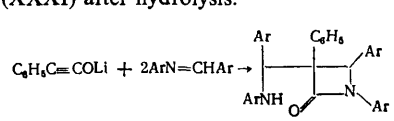


For the electrochemical reduction and oxidation of ethynyl sulphides, selenides, and tellurides, see Tomilov et al.[338]

4. Cycloaddition

The cycloaddition reactions of ethynyl ethers and sulphides with diazomethane, organyl azides, 1,3-dipolar reagents, ketens, cyclic ketones, and 1,3-dienes have been developed further.[1] Diazomethane adds to methoxyacetylene,[339] 4-bromo-1-methoxy-4-methyl-3-oxopent-1-yne,[220] and silicon-, germanium-, and tin-substituted ethynyl ethers[340] with formation of the corresponding 4-alkoxypyrazoles, similarly to the familiar reaction of ethoxyacetylene.[1] The reaction of dimethyldiazomethane with terminal ethynyl sulphides[341] leads to the predominant formation of the product of the opposite mode of addition, similarly to the familiar reaction of ethylthioacetylene.[1]

The reaction of organyl azides with ethoxyacetylene[1] has been used to obtain a series of substituted 1,2,3-triazoles,[342–344] one of which is a potential antibiotic.[345]

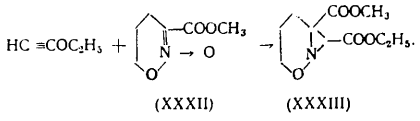


Hexafluoroacetone azene (XXIX) reacts with two molecules of ethynyl ether to form a mixture of compound (XXX) and its regioisomers:[346–348]

(XXIX) (XXX)

R=H, CH_3.

Aromatic imines add to lithium phenylethynoxide with formation of compound (XXXI) after hydrolysis:[349]

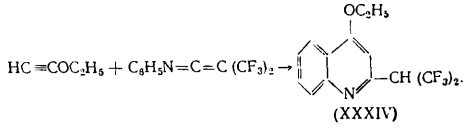


(XXXI)

The 1,3-dipolar cycloaddition of nitrile oxides to ethoxyacetylene has been used in the synthesis of isoxazole-containing *C*-nucleosides[350] and other isoxazole derivatives.[351]

The perturbation energy of the methoxyacetylene MO in the reaction with 1,3-dipoles has been calculated by quantum-chemical methods.[352,353]

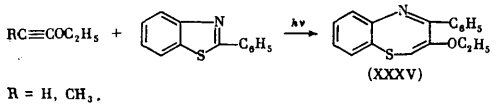
Oxazine *N*-oxide (XXXII) reacts with ethoxyacetylene to form the aziridine derivative (XXXIII):[354]



(XXXII) (XXXIII)

The nitro-derivative of the *N*-oxide reacts with elimination of the nitro-group and the formation of a substituted oxazine.[355,356]

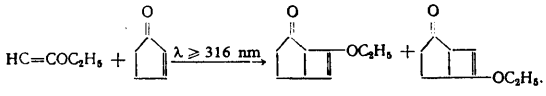
The [2 + 2]cycloaddition of dimethylketen,[357,358] dichloroketen,[359] ring-containing ketens,[360,361] and vinylketen[362] to ethoxyacetylene and of dichloroketen to silicon- and germanium-containing ethynyl ethers[363] leads to the formation of the corresponding cyclobutenones, similarly to the familiar reactions.[1] The reaction of bis(trifluoromethyl)keten with silicon- and germanium-containing ethynyl ethers affords products having a linear structure in addition to the substituted cyclobutenone.[363] Aromatic ketens react as a rule with ethoxyacetylene via the [2 + 2]- and [2 + 2 + 2]cycloaddition mechanisms.[362,364] The mode of reaction of diphenylketen with ethoxyacetylene has been calculated by the CNDO/2 method.[365] Diphenyl keten reacts with organylthioalkynes via the [2 + 2]cycloaddition mechanism.[92]



The [2 + 4]cycloaddition of *N*-phenylbis(trifluoromethyl)keten imine to ethoxyacetylene leads to the formation of the ethoxyquinoline (XXXIV):[366]

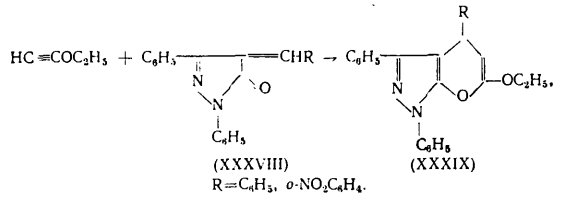
(XXXIV)

Isocyanates react with organylthioalkynylamines[92] and thioisocyanates react with 1-ethoxyprop-1-yne[367] in accordance with the [2 + 4]cycloaddition mechanism.



The photocyclisation reaction of 2-phenylbenzothiazole with ethynyl ethers, accompanied by linear expansion, leads to the formation of substituted 1,5-benzothiazepines (XXXV):[368,369]

(XXXV)

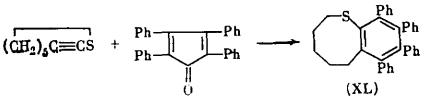


R = H, CH_3.

The photochemical [2 + 2]cycloaddition of 2-cyclopent-1-enone to ethoxyacetylene proceeds with a low regioselectivity—compounds (XXXVI) and (XXXVII) are formed:[370,371]

The photocycloaddition of 5,8,9,10-tetrahydro-*p*-naphthoquinone to ethoxyacetylene leads to the formation of 4-ethoxy-2,7-dioxotricyclo-[6.4.0.0^{3,6}]dodeca-4,10-diene.[372]

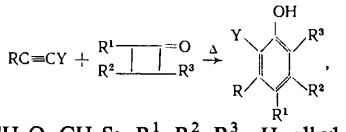
Cyclopentadiene enters into the Diels–Alder reaction with 1,3-dimethoxy-3-oxoprop-1-yne and 3-methoxy-1-phenylthio-3-oxoprop-1-yne.[373] Compounds (XXXIX) have been obtained by the [2 + 4]cycloaddition of arylidenepyrazolones (XXXVIII) to ethoxyethylene:[374]



(XXXVIII) (XXXIX)

R = C_6H_5, *o*-$NO_2C_6H_4$.

Substituted 3-methyleneoxindole reacts with ethoxyacetylene similarly.[375]



A tetrasubstituted cyclopentadienone reacts quantitatively with 1-thiacyclooct-2-yne, forming compound (XL):[107]

(XL)

The perturbation energy of the MO of 2-pyridone and ethoxyacetylene in the [2 + 4]cycloaddition reaction has been calculated by the CNDO/2 method.[376]

Substituted phenols have been obtained by heating ethynyl ethers and sulphides with cyclobutenone:[377]

R = alkyl, Y = CH_3O, CH_3S; R^1, R^2, R^3 = H, alkyl, C_2H_5O, Cl.

5. Substitution reactions

It was established previously that alkylheteroatom groups are substituted in the reactions of internal ethynyl ethers and sulphides with organolithium compounds.[1] The effect of organyl halides on element-containing ethynyl sulphides with heteroatoms at the sulphur atom has been studied. Thus treatment of ethoxy(trimethylsilyl)-acetylene with an excess of bromotrimethylsilane afforded bis-(trimethylsilyl)keten.[2]

The reaction of lithium dialkylamides with alkoxy(silyl)- and alkoxy(germyl)-acetylenes leads to the formation of silyl- and germyl-alkynylamines:[378]

$$R^1_3MC{\equiv}COR \xrightarrow{R_2NLi} R^1_3MC{\equiv}CNR_2,$$

M = Si, Ge; R, R^1 = alkyl.

Ethoxy(trimethylstannyl)acetylene reacts with lithium diethylamide with cleavage of the tin–carbon atom bond. Transmetallation of ethoxy(trimethylstannyl)acetylene yielded a germanium-containing ethynyl ether.[6]

Alkoxyethynyl ketones have been synthesised by treating tin-containing ethynyl ethers with carboxylic acid chlorides:[220,379]

$$(CH_3)_3SnC{\equiv}COR \xrightarrow{R^1COCl} R^1COC{\equiv}COR,$$

R = alkyl, R^1 = organyl.

Tin-containing alkynylamines have been obtained in 40% yield by the reaction of ethoxy(trimethylsilyl)acetylene with diethyl-(trimethylstannyl)amine:

$$(CH_3)_3SiC{\equiv}COC_2H_5 \xrightarrow{(CH_3)_3SnN(C_2H_5)_2} (CH_3)_3SnC{\equiv}CN(C_2H_5)_2.$$

Diethylamino(trimethylsilyl)acetylene is formed as an intermediate.

The methylseleno-group is readily substituted by the triethylstannyl group in reactions of di(methylseleno)acetylene with triethylstannylsodium in liquid ammonia.[380]

Trialkylstannylthioacetylenes have been obtained by substituting the acetyl group in acetylthioacetylenes by the trialkylstannyl group:[381,382]

$$RC{\equiv}CSCOCH_3 \xrightarrow{R_3SnOR} RC{\equiv}CSSnR_3,$$
$$R = \text{alkyl}.$$

The "transmetallation" reactions of compounds (XLI) have been described:[94,381,382]

$$RC{\equiv}CSMR_3 \xrightarrow{R^1_3M^1X} RC{\equiv}CSM^1R^1_3,$$
(XLI)
$$M{=}Sn,\ M^1{=}Si,\ Ge;\ M{=}Si,\ M^1{=}Ge,\ Sn,\ Pb.$$

The trialkylsilyl group at the sulphur atom is readily split off on treatment of compound (XLII) with methanol with formation of compound (XLIII):[94]

$$(CH_3)_3SiC{\equiv}CSSi(CH_3)_3 \xrightarrow{CH_3OH} [(CH_3)_3SiC{\equiv}CSH] \rightarrow$$
(XLII)
$$\rightarrow [(CH_3)_3SiCH{=}C{=}S] \xrightarrow{CH_3OH} (CH_3)_3SiCH_2C(S)OCH_3.$$
(XLIII)

The cyano-group in ethynyl thiocyanates is substituted on treatment with lithium acetylide[5,311] or lithium dialkylamide:[90]

$$RC{\equiv}CSCN \xrightarrow{LiC{\equiv}CR^1} RC{\equiv}CSC{\equiv}CR^1$$
$$RC{\equiv}CSCN \xrightarrow{R_2NLi} RC{\equiv}CSNR_2$$
$$R = \text{alkyl},\ R^1 = R_3Si.$$

Ethynyl disulphides react with secondary amines at 0 °C with cleavage of the sulphur–sulphur bond and the addition of an amine molecule to the thioketen formed.[89]

Ethynyl sulphides are oxidised by an equimolar amount of H_2O_2 in acetic anhydride with formation of ethynyl sulphoxides:[383,384]

$$HC{\equiv}CSR \xrightarrow{[O]} HC{\equiv}CS(O)R,$$
$$R = \text{alkyl}.$$

Terminal ethynyl sulphones have been obtained by oxidising ethynyl sulphides with acetyl hydroperoxide[385] or with hydrogen peroxide.[386]

Phenylethynyl selenides are oxidised by *m*-chloroperbenzoic acid with cleavage of the acetylenic carbon atom–selenium bond:[387]

$$RC{\equiv}CSeR^1 \xrightarrow{m\text{-}ClC_6H_4COOOH} RC{\equiv}CC{\equiv}CR,$$
$$\text{R-aryl, cyclohexenyl};\ R^1 = \text{alkyl, aryl}.$$

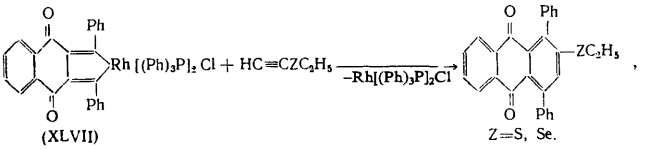
In the presence of water, only terminal acetylenic hydrocarbons are formed.[388]

In contrast to ethynyl sulphides and selenides, ethynyl tellurides give rise to telluronium compounds in the reaction with ethyl iodide.[231,389,390] The ammonium salt is formed in the reaction of ethylthiomorpholinoacetylene with methyl iodide.[54]

6. Complex formation

It was shown previously that methoxyacetylene readily forms a complex with iron carbonyl.[1]

The carbene complex of tungsten pentacarbonyl (XLIV) adds to the triple bond of ethoxyacetylene with formation of the unstable complex (XLV), which isomerises to the complex (XLVI):[391]



$$HC{\equiv}COC_2H_5 + (CO)_5W{=}CHC_6H_5 \rightarrow \left[\begin{array}{l} C_6H_5 \\ | \\ (CO)_5W{-}CH \\ | \\ C_2H_5O{-}C{=}CH \end{array}\right] \rightarrow$$
(XLIV) (XLV)
$$\rightarrow (CO)_5W{=}C(OC_2H_5)CH{=}CHC_6H_5.$$
(XLVI)

Ruthenium carbonyl hydrides react with ethoxyacetylene to form the allyltriruthenium cluster.[392] Aromatic compounds have been obtained by the reaction of cyclobutadiene-tricarbonyliron with ethoxyacetylene.[393] The reaction of internal ethynyl ethers with carbene pentacarbonylchromium also leads to the formation of aromatic compounds.[394,395]

Dimethoxyacetylene forms complexes with iron nonacarbonyl and cobalt octacarbonyl at –60 °C:[26]

$$CH_3OC{\equiv}COCH_3 \xrightarrow{Fe_2(CO)_9} (CH_3OC{\equiv}COCH_3)_2Fe(CO)_6.$$

Substituted anthraquinones have been obtained by the reaction of the rhodium complex (XLVII) with ethylthio- and ethylseleno-acetylenes:[396]

(XLVII)

Di(methylthio)acetylene forms complexes with cyclopentadienylmolybdenum and cyclopentadienyltungsten carbonyls and iron, cobalt, and ruthenium carbonyls.[397,398] In the complex with tungsten carbonyl, the di(methylthio)acetylene ligand is substituted in the reaction with bis(dimethylphosphino)ethane.[399]

In the reaction with 1-t-butylthioprop-1-yne, the dimeric tungsten t-butoxide gives rise to an unstable tungsten complex:[400]

$$CH_3C{\equiv}CSR \xrightarrow{W_2(OR)_6} (RO)_3W{\equiv}CSR,$$
$$R = t\text{-}C_4H_9.$$

Aryl ethynyl sulphides and their analogues $p\text{-}XC_6H_4EC{\equiv}CC_6H_4Y\text{-}p$ (E = S, Se, Te; X = H, CH_3OCH_3, F, Cl, Br; Y = H, Cl) form charge-transfer complexes with tetracyanoethylene, the tellurides being the strongest electron donors in this series.[401] The pentafluorophenyl derivatives of the sulphides do not form charge-transfer complexes with tetracyanoethylene as a consequence of the reduced electron-donating capacity of the $-C{\equiv}C-S-$ fragment.[65]

7. Rearrangements and isomerisation

It was established previously that allenyl ethynyl sulphides undergo the thio-Claisen rearrangement in the presence of secondary amines.[1] The study of this rearrangement was continued in the presence of secondary amines[83,93,402,403] and lithium amides[404] and on heating.[97] Allenyl ethynyl selenides undergo the same rearrangement.[98]

Methoxyethynylphosphine undergoes an unusual rearrangement in the course of its synthesis with formation of compound (XLVIII):[113]

$$R_2PC{\equiv}COCH_3 \rightarrow R_2(CH_3)P{=}C{=}C{=}O,$$
(XLVIII)
$$R = \text{alkyl, aryl}.$$

The sigmatropic rearrangement of ethynyl sulphides takes place in the presence of sodium amide and bromobenzene in liquid ammonia:[405]

$$RCH_2C{\equiv}CSCH_2R^1 \xrightarrow[NaNH_2]{C_6H_5Br} C_6H_5SCHR^1CHRC{\equiv}CH,$$
$$R,\ R^1{=}H,\ CH_3.$$

Internal ethynyl ethers and sulphides are known to isomerise readily to allenyl ethers and sulphides in the presence of bases.[1] 3-Methoxy-1-methylthioprop-1-yne isomerises to the methylthioallenyl ether in the presence of lithium diisopropylamide.[3] Allenyl sulphides have been obtained by the isomerisation of other ethynyl sulphides under similar conditions.[406,407]

8. Thermolysis and polymerisation

The thermal decomposition of ethynyl ethers and sulphides, leading to the formation of ketens and thioketens, has been examined in other reviews.[1,6] Pyrolysis of methoxyacetylene at 600 °C for 10 min leads to the formation of formaldehyde, acetylene, ethylene, and ethane.[408] The gas-phase pyrolysis of di(phenylthio)-acetylene at 560 °C afforded mainly diphenyl sulphide, thiophenol, and acetylene.[409]

The polymerisation of ethynyl ethers has been examined in a review.[1] The study of the polymerisation process was later extended to ethynyl sulphides.[410,411]

In the presence of boron trifluoride, diethylamino(phenylthio)-acetylene dimerises:[412]

$$2\,C_6H_5SC{\equiv}CN(C_2H_5)_2 \xrightarrow[THF]{BF_3} (C_2H_5)_2N{-}C{=}C{-}SC_6H_5$$
$$\qquad\qquad\qquad

Prospects for the chemistry of pyrrole

B A Trofimov
Institute of Organic Chemistry, Siberian Division of the USSR Academy of Sciences, Irkutsk

ABSTRACT. The principal advances and trends in the development of the chemistry of monopyrrole compounds in the last 15 years are analysed and new approaches to the construction of the pyrrole ring and the introduction of functional groups into the latter as well as the possibilities of pyrroles as building blocks in organic synthesis are discussed.

The bibliography includes 116 references.

V. Conclusion 974

I. Introduction

The modern chemistry of pyrrole is so extensive, is developing so rapidly, and covers so many different aspects that an adequate description of all its prospects and trends is hardly feasible in a single review.

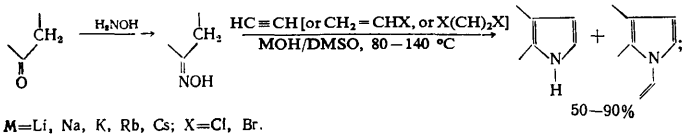
Nature has assigned to pyrrole structures a fundamental role in the molecular logic of the entire living world. The two most important and interrelated biological processes — the photosynthesis of plants and the respiration of animals — are controlled by pyrrole systems — chlorophyll and haemoglobin. The non-fortuitously linked pyrrole rings (tetrapyrroles) have been chosen by evolution to create a microreactor in a molecular cavity with a very high degree of perfection and operating on a principle which we are only now beginning to understand and assimilate in relation to macrocyclic polyethers and their analogues. Special Conferences have been devoted to the properties and structures of tetrapyrroles.[1] In the present review, one can only conclude in the introduction that the chemistry of tetrapyrroles — porphyrins, chlorophylls, and haems — is now at an accelerating stage in its development: methods for their synthesis are being improved,[2–4] their biosynthesis is being investigated,[5–7] preparations for oxygen transport in living organisms are being synthesised from them,[8,9] metal complex catalysis using tetrapyrrole ligands is developing rapidly,[10–12] etc. (The literature on all these problems is extensive and here only some of the latest studies are quoted as an illustration.)

To make the picture complete, it is necessary to note just as briefly that during the last several years the polymerisation of pyrroles, especially electrochemical polymerisation, has received a powerful stimulus.[13–15] It has opened up a pathway to electrically conducting materials[16–22] with extensive prospects for their employment in electrical engineering (light, flexible conductors, powerful accumulators,[16,20] antistatic materials, ribbon heaters, HF screens), in electronics[16–18] (semiconductor devices, solar batteries and photoconductors,[18] photoelectrochromic memory and display devices,[17,19] electrophotographic systems[16]), in lithography,[21] for the photoelectrolysis of water,[22] etc.

The subject of the present review is the principal advances and trends in the development of the modern chemistry of monopyrrole compounds.

II. New methods for the construction of the pyrrole ring

Together with the improvement and modification of the traditional pyrrole syntheses (the Knorr, Paal–Knorr, Hantzsch, Piloti, Chichibabin and Yur'ev synthesis), new effective methods have been discovered for the construction of the pyrrole ring (see the review of Trofimov et al.[23] and the references therein) frequently from more readily available starting materials and perhaps preparatively more attractive. These include the following:

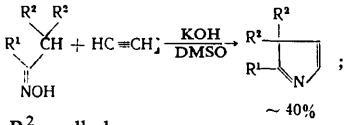


1. The reaction of ketoximes with acetylenes or their cryptoforms — vinyl halides and dihalogenoalkanes (see Refs. 23–25 and the references therein).
2. The condensation of βγ-dihalogenoketones with ammonia and primary amines.[26–34]
3. The decomposition of 1,3-oxazolidines in the presence of bases.[35–39]
4. The condensation of ketimines with 1-cyano-1-(*N*-methylanilino)alk-1-enes.[40,41]
5. The condensation of acetylenes with trimethylsilyl cyanide.[42,43]

1. The reaction of ketoximes with acetylenes (vinyl halides, dihalogenoalkanes)

The method based on the reaction of ketoximes with acetylenes, vinyl halides, or dihalogenoalkanes has developed to the greatest extent. More than 120 papers, more than 30 patents (see Refs. 23–25 and the references therein), a number of monographs[23,25,44] and reviews,[24,45] and a series of dissertations[46–50] have been devoted to this method. This reaction, its modifications, and its products are now being investigated by a series of research groups both in the USSR and abroad. An important place has been assigned to it in the new technical encyclopedia published in the USA (in the article "Acetylenes"[51]).

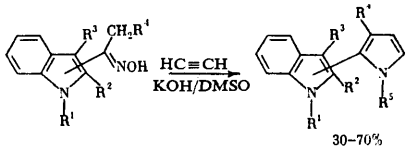
Here we shall consider mainly new results which have not been included in the existing monographs and reviews.



In a general form, the reaction can be represented schematically as follows:

M=Li, Na, K, Rb, Cs; X=Cl, Br.

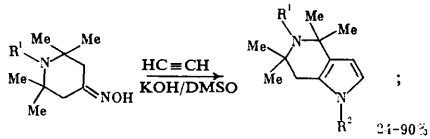
Pyrroles and *N*-vinylpyrroles (when acetylene is used in excess) are formed from ketoximes with α-methylene or α-methyl groups without substituents sensitive to strong bases. The reaction is catalysed specifically by a superbasic alkali metal hydroxide–dimethyl sulphoxide (DMSO) system, whose activity increases in the sequence LiOH < NaOH < KOH < CsOH, and also in the presence of additives—open-chain additive or macrocyclic polyethers, which weaken ionic association and increase basicity. The KOH–DMSO system, which is readily available, convenient to use, and ensures satisfactory yields of pyrrole, is usually employed in practice. In fact, the chemistry of heterocyclic compounds now has at its disposal a reliable two-stage process involving the conversion of ketones into pyrroles with a wide variety of structures and their *N*-vinyl derivatives.



3*H*-Pyrroles, stabilised by two substituents in the 3-position, are formed from the reaction of ketoximes with an aliphatic α-CH group:[25,50,52]

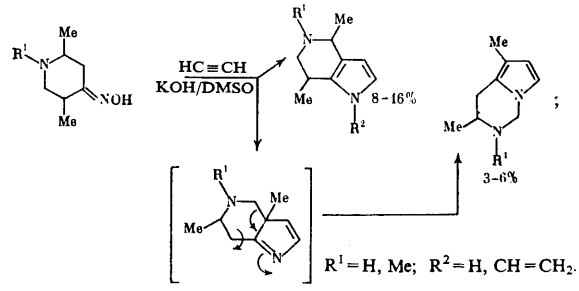
R^1=Ar, R^2= alkyl.

Thus the reaction of ketoximes with acetylene leads to highly reactive but nevertheless difficult to obtain and therefore little investigated pyrrole isomers with an impaired aromatic conjugation. This is one of the promising aspects of the study of the given reaction.



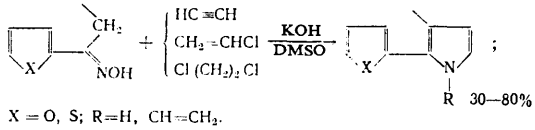
Studies[53,54] where this reaction was successfully extended to the oximes of 2- and 3-acylindoles and where a general approach to the synthesis of pyrrolylindoles—a whole class of previously unknown pyrrole compounds—was developed have made a definite contribution to the development of the process leading to the heterocyclisation of ketoximes by reaction with acetylene:

R^1, R^2, R^3=H, Me; R^4=H, Me, Pr^i, Ph; R^5=H, CH=CH$_2$.



At the same time unambiguous evidence has been obtained for the *O*-vinyloxime heterocyclisation pathway.

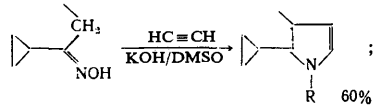
Two research teams have recently independently extended this reaction to yet another class of ketoximes—piperidinone oximes, including those with a nitroxy-radical centre.[50,55–59] The latter fact is particularly important, since it indicates the absence of a one-electron stage in the process involving the conversion of ketoximes into pyrroles on treatment with acetylene. Otherwise, the nitroxy-radical, being an effective radical trapping agent, would have prevented the reaction. The outcome of these studies was the development of a general method of synthesis of rare azaindoles—pyrrolo[3,2-*c*]piperidines:



R^1 = H, OH, O$^-$; R^2 = H, CH=CH$_2$.

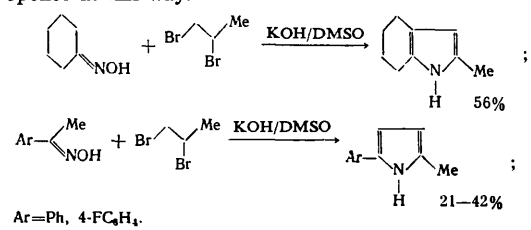
It is of interest that 1,2,3,4-tetrahydropyrrolo[1,2-*c*]pyrimidines have also been obtained from the oximes of 1,2,5-trimethyl- and 2,5-dimethyl-4-piperidinones apparently as a consequence of the rearrangement and aromatisation of the intermediate 3*H*-pyrroles formed via an alternative reaction involving the CH and not the CH_2 group:

R^1=H, Me; R^2=H, CH=CH$_2$.



Furyl- and thienyl-pyrroles, which are now readily obtained from the oximes of acylfurans and acylthiophens,[23,25,60–64] have lost their exotic nature:

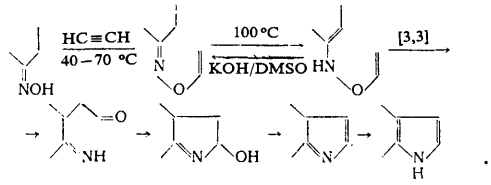
X = O, S; R=H, CH=CH$_2$.



Thus the problem of the synthesis of compounds in which the pyrrole ring is linked to other five-membered aromatic heterocycles has now been obviated. Until recently this problem was solved in more complex ways.[65]

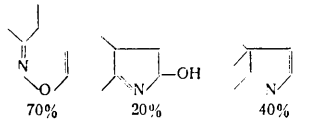
The first representatives of the class of cyclopropylpyrroles have been synthesised from the oximes of cyclopropyl ketones:[66]

R=H, CH=CH$_2$.



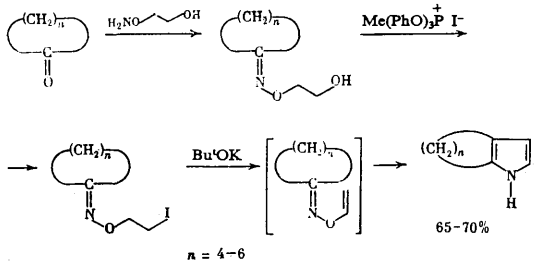
It has been shown recently that, together with dihalogenoethanes, 1,2-dihalogenopropanes can be used successfully in the synthesis of pyrroles from ketoximes.[67] The pathway to 2-R-5-methylpyrroles has been opened in this way:

Ar=Ph, 4-FC$_6$H$_4$.



Since 1,2-dihalogenopropanes split off hydrogen chloride under the reaction conditions and are converted into methylacetylene and allene, these results suggest the possibility of pyrrole syntheses based on the industrially available methylacetylene–allene mixture and also on other alkylacetylenes and allenes.

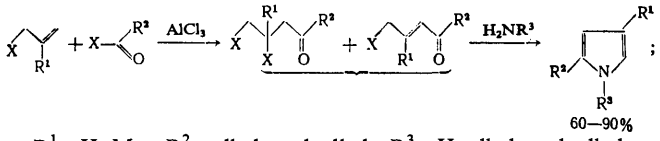
Additional evidence for the intermediate formation of *O*-vinyloximes and for their [3,3]sigmatropic rearrangment has been obtained in a study of the interaction of the oximes of acylindoles and acetylene[49,54] and also of acetophenone oxime and acetylene.[68] It was shown that, even if this is not the only reaction path, it is at any rate the main one:



A convenient two-step method has been proposed on the basis of this mechanism[49,54,68] for the selective synthesis of pyrroles free from admixtures of *N*-vinyl derivatives: the *O*-vinyloxime is obtained initially at 40–70 °C from a ketoxime and acetylene and then it is rearranged, without being isolated, into a pyrrole at a temperature of the order of 100 °C.

In a number of instances, the reaction can be arrested at stages involving the formation of 2-hydroxy-2,3-dihydropyrroles and 3*H*-pyrroles:[25,69]

The chemistry of these relatively unstable but undoubtedly very interesting classes of pyrrole compounds developed fairly sluggishly until recently because of the lack of reliable methods of their synthesis. Nowadays, when this limitation has apparently been removed, one may expect an acceleration of the research in this field.

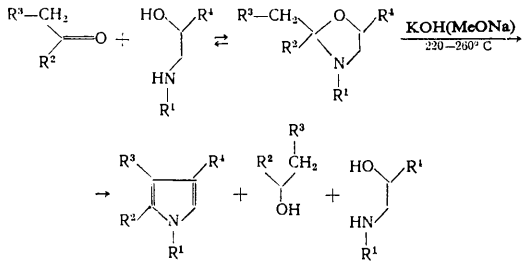


The method of synthesis of pyrroles from ketones via *O*-vinylketoximes has been used recently by English investigators[70] to obtain tetrahydroindole and pyrroles annelated to seven- and eight-membered saturated rings. For this purpose, *O*-(2-hydroxyethyl)ketoximes, prepared from the ketones and *O*-(2-hydroxyethyl)hydroxylamine, were treated with an excess of methyltriphenoxyphosphonium iodide and then the resulting iodide was converted by treatment with potassium t-butoxide into an *O*-vinyloxime, which was rearranged to the pyrrole:

Despite the high yield of pyrroles in the last stage, the advantages of this modification of the ketoxime method[24,25] do not appear unduly convincing in view of the large number of stages and the exotic nature of the reagents.

2. Condensation of βγ-dihalogenoketones with ammonia and primary amines

βγ-Dihalogenoketones or the αβ-ethylene-γ-halogeno-ketones, linked preparatively to them and readily obtainable by acylating allyl and methylallyl halides via the Kondakov reaction, afford 2,4-di- or 1,2,4-tri-substitute pyrroles in 60–90% yield on treatment with ammonia or primary amines:[26–34]



R^1 = H, Me; R^2 = alkyl, cycloalkyl; R^3 = H, alkyl, cycloalkyl, $CH_2=CHCH_2$ Ph.

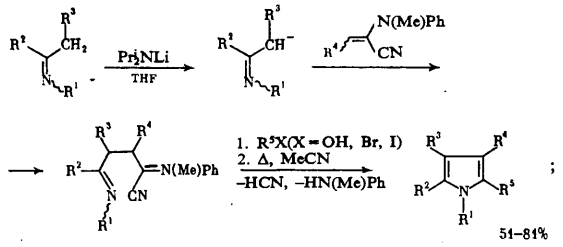
The attempts to extend this method to other allyl halides were unsuccessful.[29] Nevertheless the synthetic potential of the method is very considerable: by varying the groups in the initial acid chlorides and amines, it is apparently possible to obtain fairly representative series of substituted pyrroles. The most complete publication on this reaction dates back to 1976.[29] Unfortunately this promising method has not been developed further.

3. Alkaline pyrrolysis of *N*-substituted 1,3-oxazolidines

When *N*-substituted 1,3-oxazolidines are fused with potassium hydroxide or alkali metal alkoxides, *N*-substituted pyrroles, secondary alcohols corresponding to the carbonyl component of the molecule, and the corresponding hydroxyalkylamines are formed. It is believed[35–39] that the "disproportionation" of the 1,3-oxazilidines takes place:

R^1 = alkyl, cycloalkyl, Ph, CH_2Ph, $(CH_2)_2OH$, $CH_2CH_2CH(CH_3)OH$;
R^2 = Et, Pr^n;
R^3 = Me, Et, Pr^i;
R^4-H, Me;
$R^2-R^3 = (CH_2)_4$, $(CH_2)_3CH(CH_3)$, $(CH_2)_5$.

The yield of pyrroles is 15–40% relative to the oxazolidine or 30–80% on the basis of the disproportionation mechanism, as stated in the original communications.[35–39] A limitation of the method is the impossibility of obtaining *N*-unsubstituted pyrroles. The conversion of *N*-β-hydroxyethyl derivatives into *NH*-pyrroles[71] (*N*-β-hydroxyethyl → *N*-vinyl → NH) requires at least a further



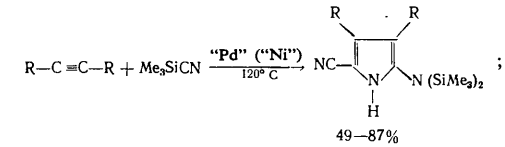
two–three preparative stages. *N*-Benzylpyrroles, which can be reduced to *NH*-pyrroles in one stage,[72] can be obtained by this method in a low yield (20% relative to oxazolidine).

The reaction mechanism has not been discussed.[35–39] It is however clear that this is a complex oxidation-reduction process occurring under the conditions of ultrahigh basicity (ultra-concentrated solutions of strong bases, chelation of alkali metal cations by 2-aminoalkanol molecules), where the dehydrogenating agent is the carbonyl component of the 1,3-oxazolidine. Although it had been established[38] that the addition of a ketone or an aldehyde to the reaction mixture promotes the reaction, subsequently this fact was ignored.[39]

Despite the low yield of products, severe reaction conditions, and the disadvantages and limitations associated with it, this method apparently merits attention and further improvement as a single-reactor synthesis of pyrrole from ketones and amiono-alkanols.

4. Condensation of ketimines with 1-cyano-1-(*N*-methylanilino) alk-1-enes

Yet another reaction permitting the conversion of ketones into pyrroles and based on the condensation of ketimines with 1-cyano-1-(*N*-methylanilino) alk-1-enes in the presence of the Pr^i_2NLi–tetrahydrofuran (THF) superbasic system, has been discovered recently:[40,41]



R^1 = Me, Pr^i, cyclo-C_6H_{11}, CH_2Ph;
R^2 = Me, Et, Bu^n;
R^3 = H, Me, Bu^n;
$R^2–R^3 = (CH_2)_3$;
R^4 = H, Et;
R^5 = H, Me, Et, Bu^n.

The key stage of this synthesis is the addition of the ketimine carbanion to the double bond. The carbanion adduct is subsequently protonated or alkylated and is then converted by heating in acetonitrile into the pyrrole with elimination of hydrogen cyanide and *N*-methylaniline, apparently via the [2,3]sigmatropic shift; the yield of the pyrrole is 50–80%. This is a one-pot method and in terms of its possibilities it is in essence similar to the syntheses of pyrroles from ketoximes and acetylene (1-anilino-1-cyanoalk-1-enes behave here as acetylenic synthons). However, in contrast to the ketoxime method, it does not permit the synthesis of *NH*- and *N*-vinyl pyrroles, is applied under dry conditions and in an inert atmosphere (argon), and requires reagents which are more expensive, more difficult to obtain, and less convenient to handle. It is also not clear whether other 1-amino-1-cyanoalk-1-enes can be used just as effectively in this synthesis.

5. Condensation of acetylenes with trimethylsilyl cyanide

Two groups of Japanese investigators[42,43] have recently discovered independently that the reaction of substituted acetylenes, catalysed by palladium or nickel compounds, with an excess of trimethylsilyl cyanide quite unexpectedly leads to 2-cyano-5-[*NN*-bis(trimethylsilyl)amino] pyrroles;

R = H, alkyl, aryl, 2-C_4H_3S, C≡CSiMe$_3$;
"Pd" = Pd(0), Pd/C, $PdCl_2$, $PdBr_2$, $Pd(OAc)_2$, $Pd(CN)_2$, $Pd(PhCN)_2$, $PdCl_2/C_5H_5N$, $PdCl_2(PPh_3)_2$, $Pd(PPh_3)_4$;
"Ni" = Ni(0), $NiCl_2/Bu^i_2AlH$, $NiCl_2/Et_3Al$.

There is such a profound redistribution of the atoms of trimethylsilyl cyanide during the reaction that so far it is difficult to put forward any reasonable mechanism for this process, particularly since in the case of disubstituted acetylenes it is necessary to assume the transfer of hydrogen from the methyl group to the nitrogen atom, since there are no other hydrogen donors in the system.

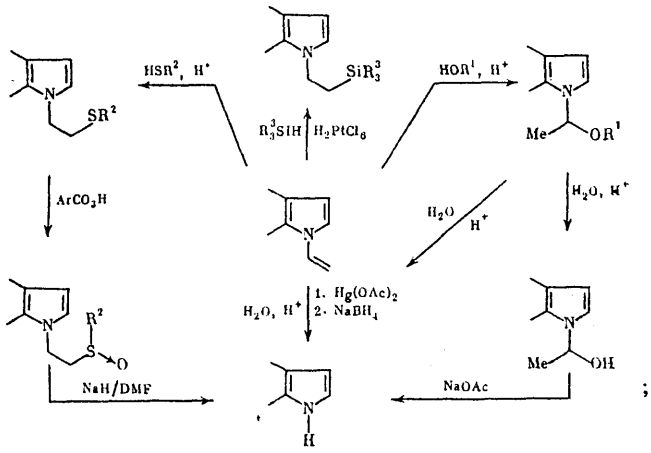
The single-stage nature and regioselectivity of the reaction, the availability of the initial compounds, and the high yields of pyrroles with reactive functional groups, which are difficult to introduce into the pyrrole ring by the usual methods, are all factors leading to good prospects for the new method.

6. General comments

In conclusion of this Section of the review, we may note that the majority of new methods for the construction of the pyrrole ring are based on ketones and acetylenes or their synthons and ultrastrong bases are used in many methods. These are the trends in modern pyrrole synthesis.

Unfortunately none of the methods examined permits the synthesis of pyrroles having both α-positions free (including, paradoxically, pyrrole itself), although such pyrroles are necessary, for example, for the construction of porphyrin structures. The search for reactions which might fill this gap remains urgently necessary.

III. Trends in the study of the reactivity of pyrrole compounds

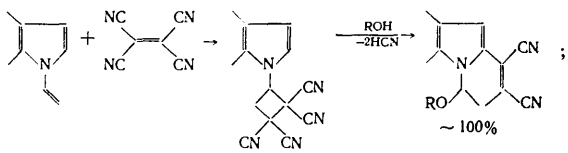


The following new trends have come to the fore in the field of the reactivity of pyrrole compounds: (a) systematic study of *N*-vinylpyrroles which have become available; (b) development of new methods for the introduction of functional groups into the pyrrole ring; (c) the growth of interest in 2*H*- and 3*H*-pyrroles as azadienes.

1. The reactions of *N*-vinylpyrroles

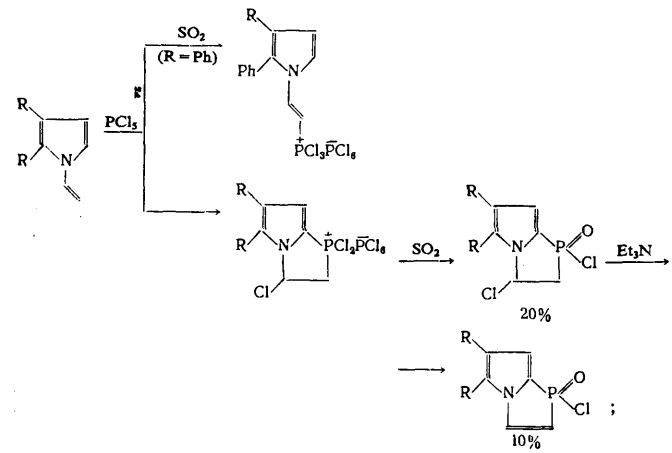
After it became possible to obtain *N*-vinylpyrroles in high yields in a single stage from ketoximes and acetylene (see Section I), they became the most readily available class of pyrrole compounds and, being completely uninvestigated, naturally attracted the attention of not only specialists in synthetic and polymer chemistry and biologists[25] but also of spectroscopists[25,44,46,73] and theoreticians.[75] The question arose how the reactivity and spectroscopic parameters of the pyrrole ring and of the double bonds are affected by the competition between the π-systems for conjugation with the unshared electron pair of the nitrogen atom. New prospects arose

for the synthesis of *N*-substituted pyrroles which are difficult to obtain, namely by the addition of various reagents to the double bond in *N*-vinylpyrroles (Scheme 1):[25] alcohols and water add to the double bonds under the conditions of electrophilic catalysis, thiols add under the conditions of radical catalysis, and hydrosilanes add under the conditions of metal complex catalysis.



Scheme 1

R^1 = H, alkyl, aryl, $CH_2C{\equiv}CH$; R^2 = alkyl, aryl; R^3 = alkyl.

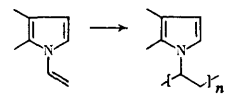


Since the *N*-vinyl and *N*-α-alkoxyethyl groups can be removed without difficulty by means of hydrolysis (for example, in the presence of mercury acetate followed by treatment with sodium tetrahydroborate[71]), *N*-vinylpyrroles are now regarded as protected *NH*-pyrroles and are used increasingly as such.[71] The *N*-β-alkylthioethyl group, into which the *N*-vinyl group can be readily converted and which can be subsequently removed if necessary after oxidation to the sulphoxide group (by treatment with peracids and then with sodium hydride in dimethylformamide[71]) can also serve successfully as a protecting group.

As expected,[25] *N*-vinylpyrroles have begun to be used for the synthesis of 1,2-fused condensed pyrrole systems. Thus they enter into [2 + 2] cycloaddition with tetracyanoethylene, forming *N*-(2,2,3,3-tetracyano-1-cyclobutyl) pyrroles, which are converted on heating with alcohols into 7,8-dicyano-5-organyloxy-5,6-dihydroindolizines in a virtually quantitative yield:[76,77]

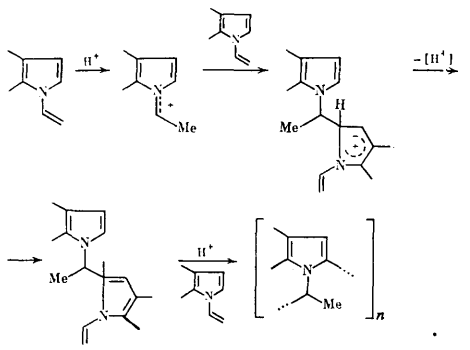
R-alkyl, $CH_2CH{=}CH_2$, $CH_2C{\equiv}CH$, etc.

The phosphorylation of *N*-vinylpyrroles with phosphorus pentachloride opens up a pathway to new condensed pyrrole systems — pyrrolo[1,2-*a*]-1,3-dichloro-1-oxo-4,1-azaphospholans and pyrrolo[1,2-*a*]-1-chloro-1-oxo-4,1-azaphosphol-2-enes:[78]



R = H, alkyl, Ph; R − R = $(CH_2)_4$.

A very pronounced competition for the electrophile between the α-position of the pyrrole ring and the double bond is observed in phosphorylation. In the case of electron-donating (alkyl) substituents, which increase the electron density in the ring, the heterocycle is phosphorylated initially and this is followed by annelation via the double bond, while phenyl substituents, which deactivate the ring, promote the attack by the electrophile on the vinyl group and the formation of a phosphorylated olefinic fragment with the (*E*)-configuration, which is incapable of further cyclisation.

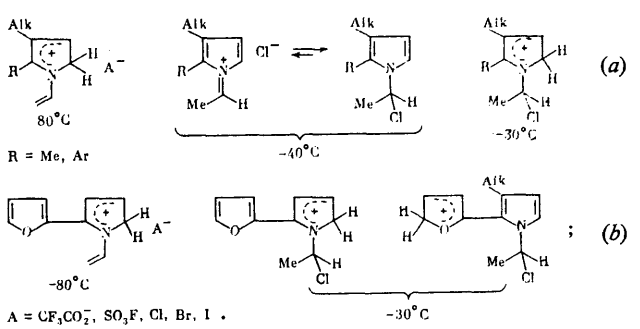


N-Vinylpyrroles are promising although little investigated systems for polymerisation. The interest in them as monomers has been growing rapidly. The principal results already achieved in this field have been surveyed in a review.[45]

N-Vinylpyrrole polymers and copolymers synthesised by the traditional radical polymerisation in the presence of azoisobutyrodinitrile have the properties of photoconductors:[79]

There are extensive possibilities for improving the properties of such polymers by altering the structural framework of the pyrrole ring and by its chemical modification. By means of the copolymerisation of *N*-vinypyrroles with other monomers, pyrrole fragments can be introduced into various polymers, imparting new properties to the latter.

The cationic oligomerisation of *N*-vinylpyrroles takes place in a non-traditional way — not as the usual vinyl polymerisation but as an alternative process — the carbonium ion, formed as a result of the addition of a proton to the *N*-vinyl group, attacks subsequently not the double bond but the heterocycle, converting it into the pyrrolium ion, which is stabilised by ejecting a proton:[80,81]



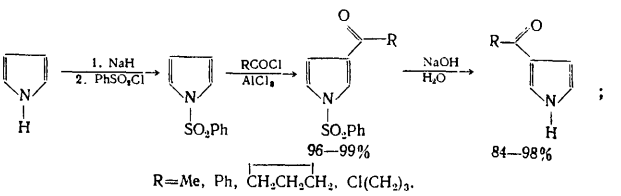
This process yet again illustrates clearly the competition between the double bond and the pyrrole ring in electrophilic reactions. The outcome of the reaction depends on the nature of the electron-deficient species: hard electrophiles (the proton) attack predominantly the double bond, while soft electrophiles (a delocalised carbonium ion) attack mainly the α-position in the pyrrole ring.

The protonated forms of *N*-vinylpyrroles — new types of stable carbonium ions and key intermediate species in the various electrophilic processes proceeding with participation of *N*-vinylpyrroles (polymerisation, addition, and substitution) — are being vigorously investigated.

The cations generated from *N*-vinylpyrroles in the presence of acids can find extensive applications in organic synthesis, in particular in the construction of new heterocyclic systems. Several examples of this kind were examined above.

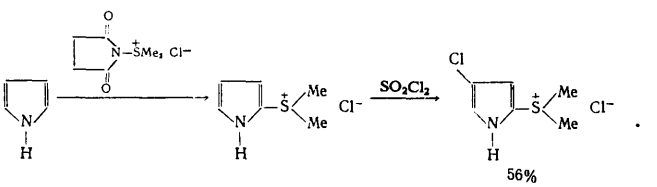
The products of the protonation of *N*-vinylpyrroles both at the heterocycle and at the double bond and also both these nucleophilic centres simultaneously (Scheme 2, *a*) have been detected and characterised by NMR spectroscopy:[82]

Scheme 2



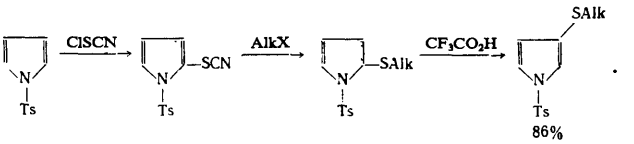
The mode of protonation and the ratio of the cations formed are determined by the strength and nature of the acid, the temperature, and the structure of the substituents in the pyrrole ring. Only the α-position of the pyrrole ring, regardless of the acid strength, is protonated at −80 °C. On raising the temperature to −30 °C in the presence of HCl taken in excess, the protonation of not only the ring but also of the double bond is observed. At −40 °C and in the presence of an equimolar amount of HCl, only *N*-α-chloroethyl derivatives are formed. It is of interest that 2-(2-furyl)-1-vinylpyrroles (Scheme 2, *b*) form selectively at −80 °C only the pyrrolium cations, whilst at a higher temperature (−30 °C) they form both pyrrolium and furanium cations at comparable concentrations. The products of the simultaneous protonation of the pyrrole and furan rings were not detected.[83]

Thus, in thermodynamically controlled electrophilic processes, the furan ring is not always significantly less reactive than the pyrrole ring, contrary to the established ideas.



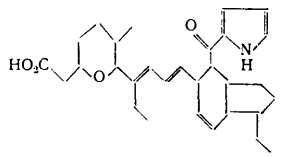
2. New methods for the introduction of functional groups into the pyrrole ring

Methods based on the alteration of the direction of attack by the reagent as a result of the introduction into the ring of polarising substituents (sulphonyl, sulphonium, etc.) have been developing to an increasing extent for the introduction of functional groups into pyrroles.[84]

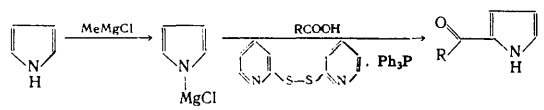


Reactions leading to electrophilic substitution in pyrroles take place predominantly in the α-position in the ring. However, in the case of *N*-sulphonylpyrroles, unprecedented regiospecific β-acylation takes place. The sulphonyl protecting and polarising group is removed just as readily as it is introduced. These preparatively simple operations constitute the basis of an effective method for the synthesis of β-acylpyrroles (in 84–98% yield):[85]

The α-dimethylsulphonium group, which can be readily introduced into the pyrrole ring with the aid of the adduct of dimethyl sulphide and *N*-chlorosuccinimide, similarly deactivates the heterocycle inductively and directs the electrophilic or radical substitution reaction (for example, chlorination[86]) to the 4-position:

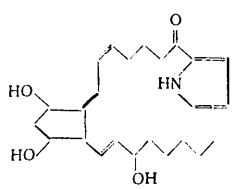


However, the redirecting effect of strong electron-accepting substituents is not always sufficient and is not sufficient for all electrophiles. For example, the direction of attack on the pyrrole ring by various sulphur chlorides cannot be altered in this way. In this case, the β-substitution products are obtained as a result of the acid-catalysed (CF_3COOH) migration of the alkylthio-group from the α- to the β-position:[87]



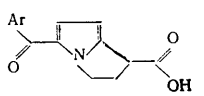
The HBr-catalysed migration of bromine from the α- to the β-position has been observed in the bromination of *N*-substituted pyrroles.[88]

In view of the important biological role of the 2-ketopyrrole structure and its role in the realisation of the programme designed for the complete synthesis of the antibiotic X-1457A, i.e.



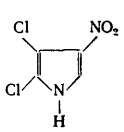
antibiotic X-1457A

a highly effective and highly selective method has been developed for the mild (−78 °C) acylation of pyrrolylmagnesium chloride by a 2-pyridyl thiolo-ester formed *in situ* from di(2-pyridyl) disulphide, triphenylphosphine, and a carboxylic acid:[89]



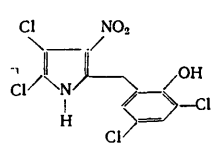
80—95%

The method is suitable even for complex polyfunctional and highly reactive compounds such as thromboxanes, prostaglandins, and monensin. For example, a ketopyrrole derivative has been obtained from prostaglandin $F_{2\alpha}$ in 95% yield:



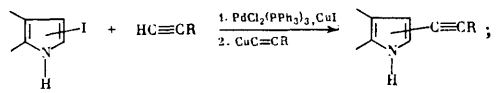
ketopyrrole derivative of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$).

Non-steroid anti-inflammatory and analgesic agents with the structure of 1,2-dihydro-3*H*-pyrrolo-1,2-*a*]pyrrole-1-carboxylic acid are being actively developed:

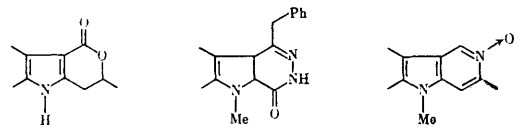


A series of novel methods for the cyclisation of pyrrole compounds have been developed for this purpose.[86,90]

The mode of halogenation and nitration of the pyrrole ring has now acquired special importance in connection with the isolation from natural substrates (*Streptomyces* SF-2080) of new chlorinated nitropyrrole antibiotics (pyrrolomycins A, B, etc.):[91,92]



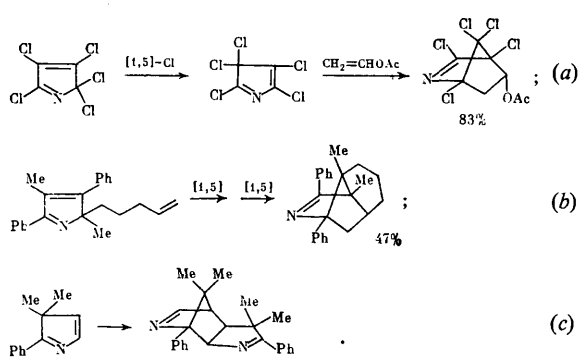
pyrrolomycin A (SF-2080 A)



pyrrolomycin B (SF-2080 B)

The problem of the introduction of acetylenic substituents into the pyrrole ring has been solved.[93—101] Two mutually complementing versions of the condensation of iodopyrroles with acetylenes have been used for this purpose: catalytic [in the presence of $PdCl_2(PPh_3)_2$ or CuI] and acetylide. The yields of ethynylpyrroles are 50—96%:

R = H, alkyl, Ph, $C(OH)Me_2$.

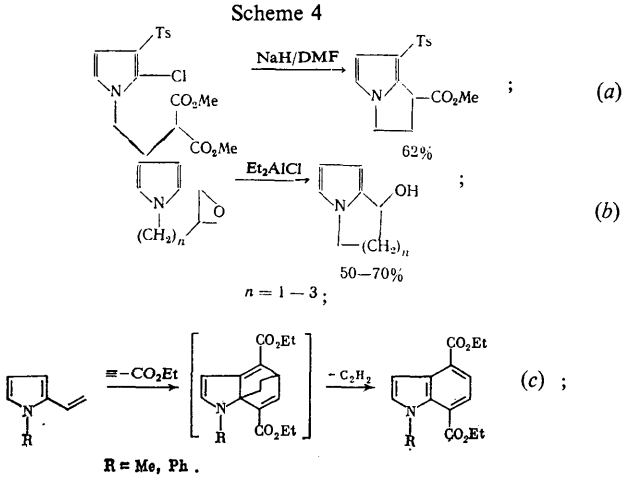


This reaction has important preparative consequences: the ethynyl substituent in the pyrrole ring provides new and unusually wide possibilities for the introduction of functional groups and the construction of complex heterocyclic systems, which has been demonstrated convincingly[102—105] in relation to the intramolecular cyclisation of functional pyrroles and indoles with ethynyl substituents, as a result of which pyran, pyridazine, and pyridine rings have been built onto the pyrrole ring:

3. 2*H*- and 3*H*-pyrroles as azadienes

The picture of the modern pyrrole chemistry would be incomplete if no mention were made of the enhanced interest in 2*H*- and 3*H*-pyrroles,[106] especially in the prospects for their employment in the Diels—Alder reaction as azadienes.[107] The first steps in this direction appear very promising. Examples of both intermolecular (Scheme 3, *a*) and intramolecular (Scheme 3, *b*) diene syntheses with participation of 3*H*-pyrroles, formed as a result of the rearrangement of 2*H*-pyrroles via a 1,5-shift, are known:[106—108]

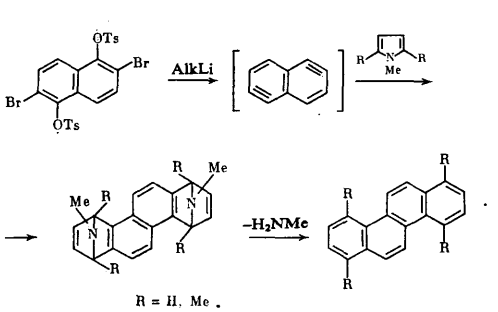
Scheme 3



An interesting approach to new skeletal and condensed tetrahydropyridine systems may be provided by the diene autocondensation of the available 3,3-dimethyl-2-phenyl-3*H*-pyrroles (Scheme 3, *c*).[52]

IV. Pyrroles as intermediates in organic synthesis

Pyrroles have been recently investigated with increasing frequency not as objects of synthesis but as a means for the construction of particular complex molecules with a specified structure.[109] The most evident employment of pyrroles on these lines involves the synthesis of condensed heterocyclic systems by various annelation reactions.

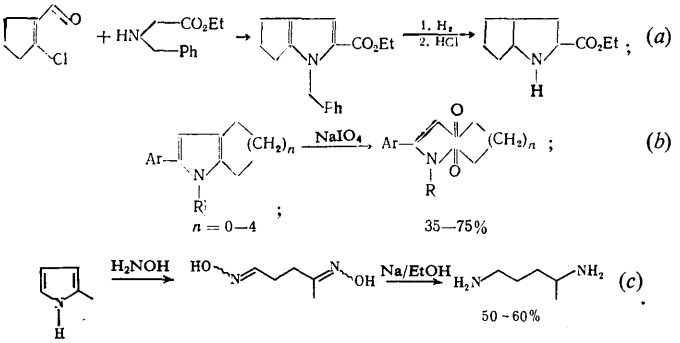


Intramolecular nucleophilic substitution of a halogen in the pyrrole ring, facilitated by the tosylate group (Scheme 4, *a*),[110] the electrophilic cyclisation of *N*-epoxyalkylpyrroles (Scheme 4, *b*),[111] and the diene condensation of 2-vinylpyrroles with electron-deficient acetylenes (Scheme 4, *c*)[109,112] are developing. *N*-Vinylpyrroles, which are now available, have led to new interesting prospects in this respect (see Section III, subsection 1).

Scheme 4

The use of the pyrrole ring itself as the 1,3-diene component in the Diels—Alder reaction for the construction of bicyclic structures with a bridging nitrogen atom is more traditional (Scheme 5).[109] Here pyrroles frequently play the role of butadiene synthons, because the adducts are capable of being deaminated. A typical example is provided by the synthesis of carcinogenic polycondensed aromatic hydrocarbons: pyrroles undergo the Diels—Alder condensation with 1,5-naphthodiyne generated *in situ* and subsequently give rise to chrysenes (in 33—49% yield) as a result of the splitting off of methylamine from the diadducts (Scheme 5):[113]

Scheme 5



In many multistage specific syntheses, pyrroles are converted into pyrrolidine structures, for example, in the synthesis of 2-azabicyclo[3.3.0]octane-3-carboxylic acid—a key precursor of a highly active enzyme inhibitor (Scheme 6, *a*).[109,114]

The opening of the pyrrole ring is used successfully in the solution of certain synthetic problems. Thus macrocyclic ketolactams are obtained by the regiospecific oxidation of pyrroles annelated to alicyclic systems (Scheme 6, *b*).[115]

Dioximes formed from pyrroles on treatment with hydroxylamine have been used recently to synthesise 1,4-diaminobutanes, which participate, together with putrescine, spermidine, and spermine, in protein synthesis and cell proliferation (Scheme 6, *c*).[116]

Scheme 6

V. Conclusion

The chemistry of pyrroles continues to develop vigorously at the present time. In particular, this development has been stimulated by advances in the chemistry of porphyrins and organic metals. New approaches to the construction of the pyrrole ring and the introduction of functional groups into the latter are being vigorously developed. Pyrroles are being used increasingly as building blocks in organic synthesis. A close interaction and interpenetration of studies designed to seek and develop general synthetic reactions and methods, whose aim is the specific synthesis of complex structures, are characteristic of modern pyrrole chemistry.

Syntheses of organic compounds in the presence of the fused iron catalyst and their mechanisms and kinetics

L S Glebov, G A Kliger
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences

ABSTRACT. New synthetic possibilities of the reduced promoted fused iron catalyst in intermolecular and intramolecular amination, cyanation, hydrogenation-dehydrogenation, and hydrodeoxygenation reactions and intermolecular and intramolecular dehydration, polymerisation, and isotope exchange are examined. The mechanisms and kinetics of the reactions leading to the synthesis of amines, alcohols, hydrocarbons, and other organic compunds are discussed. A laser Raman spectroscopic method is described for the investigation of heterogeneous organic catalysis *in situ*.

The bibliography includes 148 references.

I. Introduction

The problem of the development of new effective methods of synthesis of organic compounds remains, as before, of current interest in the field of organic synthesis and petrochemistry. The experimental data accumulated hitherto make it possible to differentiate the principal approaches which are most often used in the development of catalytic syntheses. By arranging the approaches in the order based on the decrease in the relative novelty of the reactions and catalysts, we obtain the following list:

(1) New reactions + new catalysts;
(2) Known reactions + new catalysts;
(3) New reactions + known catalysts;
(4) Known reactions + known catalysts.

The first approach is heuristic and the fourth involves the optimisation of known syntheses. In the present review, attention is concentrated on the second and third approaches, namely on the preparation of organic compounds of different classes using the reduced promoted fused iron catalyst (RPFIC), which is known primarily as the catalyst of the synthesis of ammonia from hydrogen and nitrogen and of organic compounds from CO and H_2. Since a large number of monographs and reviews (see, for example, Refs. 1–4) have been devoted to these two processes, they are not considered in this review.

Fused iron catalysts have a number of significant advantages, among which one should include in the first place the simplicity and ecological purity (lack of waste) in their preparation, low cost, high thermal stability permitting the use of catalysts of this type in highly exothermic processes (hydrogenation, hydrogenolysis, etc.), stability and mechanical strength which permit their use in reactors with a fluidised catalyst bed (fluid process), as well as the ease of varying their chemical composition (by employing as promoting agents various oxides or their mixtures), on which depend the activity and selectivity of the catalytic action. All the foregoing factors create, in our views, the necessary groundwork for a more comprehensive investigation of the RPFIC in order to synthesise organic compounds of different classes.

II. Fused iron catalysts: preparation, activation, and investigation

Several methods are used to prepare RPFIC. The following is most widely used under laboratory conditions. The initial mixture is made up from dry powders (60–120 mesh) comprising Fe_3O_4, whose fraction in the mixture is 90–95 wt. %, and promoting additives, which are usually Al_2O_3, SiO_2, K_2O, CaO, MgO, V_2O_5, BaO, Cr_2O_3, and MnO_2. By varying the composition of the initial mixture, it is possible to obtain catalysts with different activities, selectivities, and stabilities. The mixture of oxides is fused in a water-cooled steel crucible lined with asbestos and kaolin, fusing being effected with the aid of an electric arc generated by steel or copper electrodes, which are also water-cooled. The melting point of the mixture of oxides is 1500–1600 °C and the fusion time is 60–120 s. The ingots formed are comminuted and screened into fractions, from which the fraction with a grain size of approximately 1–3 mm is usually taken for preparative purposes in organic synthesis.

The catalyst is activated (reduced) at 400–480 °C and a hydrogen pressure of 1–50 atm, the reduction time being 4–50 h. Completion of the reduction of the catalyst is checked from the amount of water evolved, which is usually close to the stoichiometric amount. The catalyst activated in this way is pyrophoric and it is therefore stored and inserted into and removed from the reactor in a protecting gas atmosphere (CO_2, Ar, N_2). Depending on the composition and the preparation conditions, the reduced catalyst has a specific surface of 10 ± 5 m^2 g^{-1} (BET method, N_2).

The phase and elemental compositions of the RPFIC, both before and after reduction with hydrogen, have been the object of continuous study.[1,3,5–13] In the melting stage with promoting agents,

partial interaction of the components is already observed, leading to the formation of a multiphase multicomponent alloy.[5,12] When the latter is reduced with hydrogen, the iron oxides with different stoichiometries are almost quantitatively converted into α-Fe^0. At the same time, the displacement of the promoting agent and their compounds from the bulk of the catalyst onto the surface is observed. Certain other processes also occur, as a result of which the bulk phase and the surface of the RPFIC acquire different compositions.[1,5,6,13]

Thus the surface of the promoted fused iron catalyst for the synthesis of ammonia, containing (calculated relative to the non-reduced specimen) 2% Al_2O_3(Al/Fe = 0.16), 1% K_2O(K/Fe = 0.012), and 1.5% CaO(Ca/Fe = 0.015), the remainder being Fe_3O_4,† acquired, as shown by X-ray photoelectron spectroscopy, a composition‡ corresponding to the component ratios Al/Fe = 2.0, K/Fe = 0.78, and Ca/Fe = 1.2 after reduction with hydrogen.[13] Thus the fraction of Fe^0 on the surface of the given RPFIC was less than 50%.

Measurements of the fraction of Fe^0 on the surface of the RPFIC by the selective adsorption method agree with the results obtained by the X-ray photoelectron spectroscopic method.[1,5,14]

Information about the structure and properties of surface compounds directly in the course of the activation of heterogeneous catalysts and catalysis in their presence can be provided in principle by IR spectroscopy. Considerable advances have been achieved recently in the measurement of the IR spectra of adsorbed molecules.[15] However, the application of this method under real activation and catalytic conditions involves considerable experimental difficulties which become impossible to overcome for RPFIC owing to the strong absorption of IR radiation by the latter.

In this connection, the data on the activation of the RPFIC obtained by laser Raman spectroscopy *in situ* are of special interest. Despite the advantages of Raman spectroscopy over IR spectroscopy in the study of this catalyst (they have been described in detail[16]), there have so far been only two studies in which the method was applied to the RPFIC. In these studies, the interactions of H_2 and D_2 with the surfaces of RPFIC having the composition $5V_2O_5$ [17] and $3Al_2O_3 + 1K_2O$ [18] were investigated. Treatment of the RPFIC with H_2 is accompanied by the appearance of absorption bands in the region of $\sim$980 cm^{-1} [17] (Fig. 1) and $\sim$1950 cm^{-1},[18] which may indicate the presence on the surface of hydride-like forms of hydrogen having the structure

$$\overset{H^{\delta-}}{Fe^{(\delta+)}}\!\!\diagup\!\!\diagdown\!\!Fe \quad \text{and} \quad \overset{H^{\delta-}}{|}\;Fe^{\delta+}\,.$$

The surface of the RPFIC before the start of the catalytic reaction on the latter can be represented as shown[19] in Fig. 2. This scheme reproduces two significant features in the structure of the RPFIC surface. The first is associated with the presence of Fe^0 and hydride hydrogen on the surface. The second is due to the high concentration of oxide promoting agents on the surface, which suggests, in its turn, the existence on it of Brønsted and Lewis acid–base centres (pairs). Thus RPFIC can be classified as bifunctional heterogeneous catalysts which are capable of manifesting simultaneously both oxidation-reduction (hydrogenation-dehydrogenation) and acid–base properties.

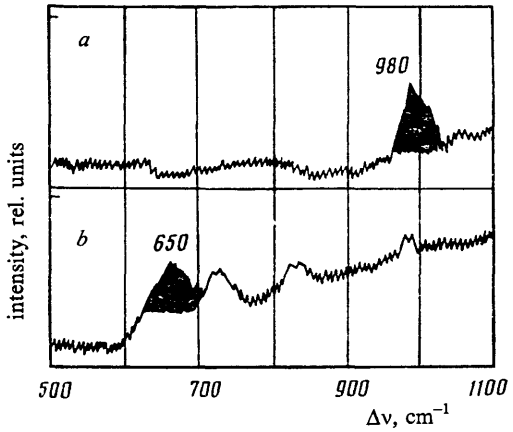

Figure 1. The Raman spectra *in situ* of the surface of an iron melted catalyst promoted with 5% V_2O_5 in the course of activation with protium or deuterium [187 °C, $p_{H_2(D_2)}$ = 0.2 MPa]:[17] *a*, H_2, $\nu_H \simeq 980$ cm^{-1}; *b*, D_2, $\nu_D \simeq 650$ cm^{-1}.

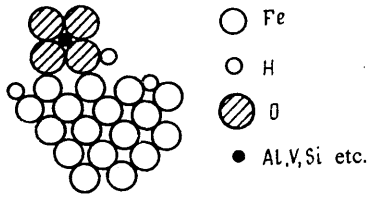

Figure 2. Schematic representation of the surface of a reduced promoted fused iron catalyst.[19]

Naturally, under the conditions of catalysis where there is direct interaction of the RPFIC with the reactants, the composition of the multiphase and multicomponent catalysts can undergo appreciable additional changes.[3,7,8,11,20–23] The effects of the reaction medium on the RPFIC have been studied in greatest detail in relation to syntheses from CO and H_2.[3,7,8,20,21,23] It has been established that, as a result of such interaction, the catalyst is enriched in iron carbides (ε-carbide, χ-carbide, etc.) and iron oxides of different composition ($Fe_{1-x}O$) both in the bulk phase and on the surface.

III. Modified Fischer–Tropsch syntheses

These include syntheses from CO and H_2 with the addition of a third component in which organic compounds belonging to different homologous series are formed. The use of a third component leads on the one hand, to new synthetic possibilities of the Fischer–

† An abbreviated formulation of the composition of the RPFIC will be used henceforth in the text, for example, $2Al_2O_3 + 1K_2O + 1.5CaO$.

‡ The composition of the RPFIC surface is understood as the composition of the surface layer 10–30 Å thick.

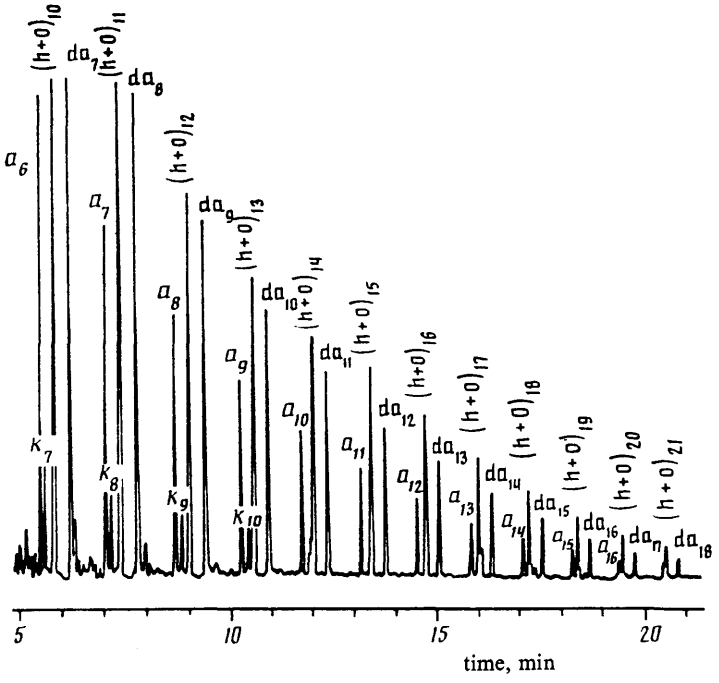

Figure 3. A fragment of the chromatogram of the products of synthesis from CO, H_2, and $(CH_3)_2NH$: h—alkanes; o—alkenes; a—alkanols; k—alkyl methyl ketones; da—dimethylalkylamines.

Tropsch reaction (FT-synthesis), associated primarily with the introduction of functional groups into individual components of the FT-product§ and, on the other hand, it makes it possible to discover and refine the mechanism of the interaction of CO and H_2. The third component, added directly to the synthesis gas, frequently plays simultaneously several functions, among which one should include, apart from those mentioned above, the functions of a chemical label, chemical trapping agent, synthesis initiating reagent, etc. As a rule, this component undergoes a wide variety of intrinsic reactions both with and without the participation of the components of the synthesis gas. Ammonia, primary and secondary amines, acetylenes and some of its derivatives, etc., are used as modifying substrates in FT-syntheses.

1. The Fischer–Tropsch synthesis modified by ammonia or alkylamines

The first example of such FT-synthesis is the preparation of alkylamines from CO, H_2, and ammonia.[24,25] In the presence of the RPFIC $5Al_2O_3 + 7BaO$ at 175–205 °C, a synthesis gas ($H_2:CO = 2$) pressure of 20 MPa, and an ammonia concentration of 8 vol. %, a product containing up to 30% of alkylamines was obtained. The alkylamines consisted of 88.5% of primary amines, 8.5% of secondary amines, and 3% of tertiary alkylamines.[26]

§ Here and henceforth the components of the FT-product are understood to be organic compounds of one class (hydrocarbons, alcohols, etc.).

In order to increase the yield of alkylamines in the FT-synthesis with participation of ammonia, catalysts of different composition have been used.[27–29] The best result (selectivity with respect to alkylamines of 50%) was achieved in the presence of a RPFIC prepared on the basis of natural magnetite.[29]

Methods have been developed for the synthesis of secondary alkylamines from CO, H_2 and n-butylamine [30] or methylamine,[31] and also for the synthesis of tertiary alkylamines from CO, H_2, and dimethylamine.[32] At 168–175 °C, a synthesis gas pressure of 10–14 MPa, and for $H_2:CO:$methylamine = 1:1:1.25 ratios, the yield of alkylamines reached 35–35 g m^{-3} in terms of the converted synthesis gas with a selectivity with respect to n-alkylmethylamines of 78%.[31]

It is noteworthy that, together with alkylamines, other components of the FT-products, especially alkanols, are formed in all cases when ammonia or alkylamines are used as modifying additives.[23–32]

Using high performance gas–liquid chromatography on quartz capillary columns and chromatograph-linked mass spectrometry, a detailed study has been made of the composition of the products of synthesis from CO, H_2, and ammonia[33] and dimethylamines[32,34,35] (Fig. 3 of Table 1).

The mechanisms of the formation of alkylamines in modified FT-syntheses have been examined[28,32–35] and it has been shown[32–35] that the mechanism proposed by Henrici-Olive,[28] which presupposes competition between CO and NH_2 for insertion in the metal–alkyl bond, does not operate when the reaction is carried out in the presence of the RPFIC. The probable pathways leading to the

formation of alkylamines in the presence of RPFIC can be represented schematically as follows:[32-35]

$$n\,CO + (2n+1)\,H_2 \xrightarrow[-(n-1)H_2O]{} [OI]_n \xrightarrow{+H_2} C_nH_{2n}O$$

$$[OI]_n \xrightarrow{-H_2O,\ +HNR^1R^2,\ H_2} C_nH_{2n+1}NR^1R^2,$$

where $[OI]_n$ is an oxygen-containing intermediate in which the number of carbon atoms is n and R^1, R^2 = H or Me.

One of the pathways in this scheme leads to the formation of amines as a result of the direct hydroamination of the surface oxygen-containing intermediate $[OI]_n$—the precursor of an aldehyde, ketone, or alcohol, while the other pathway leads to the hydroamination of the alkanals and alkyl methyl ketones $C_nH_{2n}O$—the primary components of FT-products. The scheme proposed above agrees with the data in Table 1 and with the fact that the alkanols formed under the conditions of the FT-synthesis with the addition of a third component are not aminated.[34,35]

Table 1. Composition of Fischer–Tropsch synthesis products (wt. %) with participation of ammonia and dimethylamine (RPFIC $1Al_2O_3 + 1.5BaO + 0.4SiO_2$, 176 °C, 12 MPa, $H_2 : CO = 4$).

Reaction	Alkanes	Alkenes	Alkanols	Alkyl-methyl ketones	Alkyl-amines	Unidentified components	Refs.
$CO + H_2$	26.5	9	50	3.5	—	11	[33]
$CO + H_2 + (CH_3)_2NH$ (5%)	29	8.5	18	3.5	26*	15	[32]
$CO + H_2 + NH_3$ (12%)	32	11.5	6.5	2	37**	11	[33]

* Alkylamines $C_nH_{2n+1}N(CH_3)_2$, where $1 \leqslant n \leqslant 17$.

** Alkylamines $C_nH_{2n+1}NH_3$ including 3.5% of di-n-alkylamines.

2. The Fischer–Tropsch synthesis modified by acetylene and its derivatives

The addition of acetylene or its derivatives makes it possible in the first place to increase the productivity of the FT-synthesis.

The productivity of the gas-phase synthesis from CO and H_2 with the addition of 1.5% of C_2H_2 at 170–190 °C, p_{CO} = 11 MPa, and p_{H_2} = 3.5 MPa in the presence of the RPFIC $2Al_2O_3 + 0.5V_2O_5 + (0.5-1)K_2O$, calculated relative to the product which is a liquid at 20 °C, amounted to 60–65 g h^{-1} (litre cat.)$^{-1}$ [36,37] against 40–45 g h^{-1} (litre cat.)$^{-1}$ in the usual FT-synthesis. The achievement of the acetylene-modified FT-synthesis in the liquid phase makes it possible to increase the productivity to 450 g h^{-1} (litre cat.)$^{-1}$.[38]

The study of the products of the FT-synthesis from CO, H_2, and $HC{\equiv}{}^{14}CH$ showed that the molar radioactivity of all the alkanols, starting with 1-propanol, is constant and close to the molar radioactivity of the added acetylene,[39] i.e. acetylene (or its radioactive fragment) is incorporated singly in the growing hydrocarbon chain. This fact suggests that the observed increase in productivity is caused by the initiating role of acetylene, which gives rise to a primary C_3 complex on interaction with the synthesis gas.[40,41]

The FT-syntheses modified by compounds having the general formula R–C≡CH, where R = Ph, CH_2OH, CH_2OCH_3, or $CH_2O(CH_3)_3$, have been investigated.[42-47] In the presence of the RPFIC $(3-4)(SiO_2 + Al_2O_3 + V_2O_5) + (0.5-1)K_2O$, the interaction of the synthesis gas with phenylacetylene yields mainly aromatic alkyl-substituted alcohols and hydrocarbons having the composition $Ph(CH_2)_nX$, where n = 3–8 and X = OH or H. Most of the added phenylacetylene is then hydrogenated to styrene and ethylbenzene and gives rise to oligomers. Apart from the components containing an aromatic ring, the product contains up to 25% of n-alkanes, alkanols, and alkanals. Certain characteristics of the phenylacetylene-modified FT-synthesis are presented in Table 2.

Table 2. Characteristics of the gas-phase and liquid-phase syntheses of aromatic alkyl-substituted alcohols from CO, H_2, and PhC≡CH (150 °C, 10 MPa, $CO : H_2 = 1$, $v = 10^3$ h^{-1}).[44]

Process	Productivity, g h^{-1} (litre cat)$^{-1}$			Selectivity, %			Losses, %	Conversion, %
	$\Sigma Ac_{ph} + Ad_{ph}$	H_{ph}	ΣAc, Ad, H	$\Sigma Ac_{ph} + Ad_{ph} + H_{ph}$	EB + ST	oligomers		
Liquid-phase (C_6H_6 soln)	48	21	1—1.5	21	43	1	6	29
Gas-phase	15	5	6—8	7	15	70	3	5

Notation. v is the space velocity of the synthesis gas, $\Sigma Ac_{ph} + Ad_{ph}$ the overall content of alcohols and aldehydes incorporating the $Ph(CH_2)_2$ fragment, H_{ph} hydrocarbons containing the $Ph(CH_2)_2$ fragment, ΣAc, Ad, H the overall content of alkanols, alkanals, and alkanes, EB + ST the overall content of ethylbenzene and styrene.

The synthesis of bifunctional compounds—αω-diols and alkoxyalcohols—from CO, H_2, and substituted acetylenes have also been achieved in the presence of RPFIC:[45-47]

$$CO + H_2 + HC{\equiv}CCH_2OH \rightarrow HO(CH_2)_nOH + H_2O,$$

$$CO + H_2 + HC{\equiv}CCH_2OR \rightarrow HO(CH_2)_nOR + H_2O,$$

where R = CH_3 or $C(CH_3)_3$ and n = 4–7.

In terms of their reactivity in the synthesis, the initiating reagents can be arranged in the sequence $HC{\equiv}CH > PhC{\equiv}CH > (CH_3)_3COCH_2C{\equiv}CH \simeq CH_3OCH_2C{\equiv}CH > HOCH_2{\equiv}CH$.

It has been shown[48] that oct-1-yne, hex-1-yne, and hex-3-yne participate, like acetylene, in the propagation of the hydrocarbon chain in their interaction with the synthesis gas. On the other hand, acetonitrile, butyne-1,4-diol, and the halogenoalkynes $HC{\equiv}CCH_2X$, where X = Cl or Br, do not possess the properties of initiating reagents in the FT-synthesis.

IV. Reactions of alcohols, aldehydes, and olefins under the conditions of the Fischer–Tropsch synthesis

In order to elucidate the possible involvement of oxygen-containing compounds in FT-synthesis in the presence of RPFIC of different composition, the reactions of the methanol $^{14}CH_3OH$,[49-51] the ethanols $CH_3{}^{14}CH_2OH$, $^{14}CH_3CH_2OH$, $CH_3{}^{14}CD_2OH$, and $CD_3{}^{14}CH_2OH$,[52-54] the propanols $CH_3CH_2CH_2OH$, CH_3CH_2.

.$^{14}CH_2OH$, $CH_3{}^{14}CH_2CH_2OH$, $^{14}CH_3CH(OH)CH_3$,[49,55,56] the butanols n-C_4H_9OH, $^{14}CH_3CH(CH_3)CH_2OH$, and $C_3H_7{}^{14}CH_2OH$,[49,51,55] benzyl alcohol,[57] the formaldehyde $H^{14}CHO$,[50] the ethanals $CD_3{}^{14}CHO$ [58] and $CD_2D^{14}CHO$,[59] and propanol[55,56] were investigated. It was established that the principal reactions of alkanals under the conditions of the FT-synthesis are their hydrogenation to the corresponding alcohol, decarbonylation to alkanes containing 1 carbon atom less, and oxidation to the corresponding acid.[55,58,59] On the other hand, acetaldehyde added to the synthesis gas is partly decomposed via the reaction[59]

$$2CH_3CHO+2H_2=C_4H_9OH+H_2O.$$

Under the conditions of FT-synthesis, alcohols undergo ester condensation:[55,59]

$$2C_4H_9OH=C_3H_7COOC_4H_9+2H_2$$

and enter into a homologisation reaction:[51]

$$C_4H_9OH+CO+2H_2=C_5H_{11}OH+H_2O.$$

Aromatic alkyl-substituted alcohols and hydrocarbons $Ph(CH_2)_nX$, where X = OH or H and n = 2–4, were first obtained in FT-synthesis with added benzyl alcohol. The conversion of $PhCH_2OH$ reaches 90% in the presence of the RPFIC $2Al_2O_3$ + $0.8V_2O_5$ + $0.5K_2O$. The main alcohol reaction product is then toluene, benzene and bibenzyl being formed in small amounts.[57]

Studies on syntheses from CO and H_2 with added alkenes CH_3CH_2CH = $^{14}CH_2$,[60] CH_2 = $^{14}CH_2$,[56,61,62] CH_2 = CH_2,[63] and CH_2 = $C(CH_3)CH$ = CH_2 [64] are important for the understanding of the mechanism of the FT-synthesis and ways of intensifying it. The principal reaction of olefins is their hydrogenation (to the extent of 80–90%) to the corresponding alkanes. On the other hand, but-1-ene is partly converted into n-pentane and pent-1-ene in the presence of RPFIC $2Al_2O_3$.[60]

However, under the conditions of FT-synthesis in the presence of RPFIC alkenes are capable of entering to a definite extent also into the oxo synthesis reaction,[60,62] the yield of alcohols increasing with increase in their concentration (Table 3).

Table 3. The influence of ethylene on the yield of alcohols in synthesis from CO and H_2 in the presence of the RPFIC $2Al_2O_3$ + $0.5V_2O_5$ + $0.5K_2O$ [62] (2–2.5 MPa, H_2 : CO = 3.8).

T, °C	C_2H_4 concentration, %	Relative yield of $C_nH_{2n+1}OH$ with different n				
		1	2	3	4	5
204	7	0.4	1.0	1.0	0.3	0.2
204	15	0.3	1.0	1.3	0.4	0.3
230	50	0.3	1.0	13.0	0.6	0.5
230	0	0.3	1.0	0.4	0.2	0.1

Studies on the reactions of aldehydes, alcohols, and olefins under the conditions of FT-synthesis[49–65] have shown that in the presence of the RPFIC the contribution of reactions with participation of these compounds with formation of the FT-product is as a rule low and amounts to only several per cent.

Apart from the synthesis from CO and H_2, the synthesis from CO and H_2O (the Kölbel–Engelhardt synthesis), which results in the formation of products close in composition to the FT-product, has also been achieved.[66]

The synthesis from CO and H_2O in the presence of RPFIC was first achieved in the presence of the catalyst for ammonia synthesis at a temperature of 300 °C, a pressure of 4 MPa, and for the ratio CO : H_2O = 2–2.5. Under these conditions, the conversion of CO reaches 84% and the main products are alkanes and alkenes.[67] The formation of alkanes in the Kölbel–Engelhardt synthesis (KE-synthesis) is formally regarded as a result of the combination of the water gas reaction[4] and the FT-synthesis:

$$(2n+1)CO+(2n+1)H_2O=(2n+1)CO_2+(2n+1)H_2 \quad \text{(water gas reaction)},$$
$$n\,CO+(2n+1)H_2=C_nH_{2n+2}+n\,H_2O \quad \text{(FT-synthesis)}$$
$$(3n+1)CO+(n+1)H_2O=C_nH_{2n+2}+(2n+1)CO_2 \quad \text{(KE-synthesis)}$$

Similar combinations of stoichiometric equations can be formulated also for the formation of other components of the KE-products—alkenes, alkanols, alkanals, etc.

The results obtained in the synthesis from CO_2 and H_2 in the presence of RPFIC, whose main product is ethanol, have been published.[68] At 335–370 °C and 20–40 MPa and for H_2 : CO_2 = 3 and a space velocity of the synthesis gas of $10^4(2-3)$ h^{-1}, the productivity of the process with respect to ethanol is 30–45 g h^{-1} (litre cat.)$^{-1}$. Together with ethanol, appreciable amounts of methanol, 1-propanol, and acetic acid are formed.

The products of the Fischer–Tropsch synthesis with participation of a third component, the Kölbel–Engelhardt synthesis, and the synthesis from CO_2 and H_2 are complex mixtures of organic products with a broad range of compositions in terms of different fractions. Alcohols and amines can be isolated from the products by familiar chemical methods (in the form of borates or hydrochlorides respectively). After their separation by fractionation into comparatively narrow fractions, they can find applications as raw materials for the preparation of plasticisers, surfactants, etc. The remainder of the products can be used as additives to hydrocarbon fuels or as a hydrocarbon raw materials suitable for further processing by traditional methods.

The processes examined are not at present competitive in relation to the familiar methods of synthesis of functional derivatives of hydrocarbons (alcohols, amines). However, in view of the possibility of their being carried out on the basis of virtually any hydrocarbon raw material, including a renewable raw material, the above synthesis will become increasingly more promising for practical use as the petroleum resources are exhausted.

This is why the interest in the study of syntheses from carbon oxides and hydrogen is at present growing continuously.

V. Syntheses of nitrogen-containing compounds

1. Hydroamination of oxygen-containing compounds

(a) Hydroxy-compounds. The deliberate search for effective catalysts of the reaction involving the amination of alcohols, which is prosecuted also at the present time, led at the beginning of the 1960's to development of an effective RPFIC for the synthesis of alkylamines from alkanols and ammonia in the presence of hydrogen.[69] The best yield of amines, stable in time, are attained in the presence of the RPFIC having the composition $5V_2O_5$.[70]

In the interaction of the RPFIC with a mixture of an alcohol, ammonia, and hydrogen, there is a possibility of the formation, during the amination reaction on the surface and in the bulk of the catalyst, of iron nitrides, carbonitrides, and oxides, which can influence the activity and selectivity of the catalyst. This problem has been partly considered in relation to the gas-phase reaction of 1-butanol with an ammonia–hydrogen mixture ($C_4H_9OH : NH_3 : H_2 = 1 : 8 : 24$) at 120–170 °C in the presence of three modified specimens of the RPFIC $5V_2O_5$.[22] The first specimen was enriched in iron ε-nitride, the second in iron carbonitride, and the first in iron oxides. In the presence of all three specimens, the yield of butylamines was significantly lower than in the presence of the initial RPFIC after prolonged use. This shows that, on contact between the RPFIC and the reaction mixture containing more than 70% of H_2, iron nitrides, carbonitrides, and oxides accumulate in the catalyst at least in amounts which can be detected from the change in the yield of amines.

A consequence important for the preparative gas-phase synthesis of amines, consisting in the fact that the stable activity and selectivity of the RPFIC can be maintained by retaining a high H_2 concentration in the initial gas mixture, follows from the data of the above study.[22]

In terms of their ability to enter into the amination reaction in the presence of the RPFIC $5V_2O_5$, alkanols can be arranged in the sequence[70,71] 1-octanol ≃ 2-octanol > 3-octanol > 4-octanol ≃ 2-methyl-4-heptanol ≃ 2-ethyl-1-hexanol.

On the other hand, in the amination of $C_nH_{2n+1}OH$, where $n = 5-10$, the conversion and overall selectivity with respect to alkylamines are independent of n, although the selectivity with respect to secondary alkylamines increases somewhat with increase in n.[72]

Table 4. Amination of 1-octanol in the presence of a RPFIC (210 °C, 5 MPa, space velocity of n-$C_8H_{17}OH$ 1.2 h^{-1}).[73]

State of aggregation of alcohol	$H_2:NH_3:ROH$	Conversion of ROH, %	Composition of amines, %		
			$C_8H_{17}NH_2$	$(C_8H_{17})_2NH$	$(C_8H_{17})_3N$
Gas*	15:12:1	88	75	21	4
Gas	34:3:1	45	38	50	12
Liquid	4:3:1	46	20	72	8

* 230 °C, space velocity of the alcohol 0.35 h^{-1}.

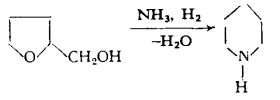
The amination of primary alcohols in the presence of RPFIC is a consecutive reaction leading to the formation of primary, secondary, and tertiary amines. In this reaction, it is always difficult to attain a high selectivity with respect to each amine separately. In order to increase the yield of secondary amines from alkanols and ammonia, a novel procedure has been proposed, consisting in carrying out the reaction in a film of the liquid alcohol.[73] In the amination of 1-octanol, this procedure makes it possible to increase the selectivity with respect to secondary amines from 21 to 72% (Table 4).

Optimum conditions have been found for the preferential synthesis of primary, secondary, or tertiary alkylamines from primary alcohol and ammonia under hydrogen pressure.[74–77] In the amination of 1-alkanols $C_{n+1}OH$, where $n = 6-12$, in the presence of the RPFIC $5V_2O_5$ at 260–295 °C, mixtures of alkylamines containing up to 96% of $C_nH_{2n+1}NH_2$, or up to 60% of $(C_nH_{2n+1})_2$, or up to 70% of $(C_nH_{2n+1})_3N$ were obtained. In all cases, amines containing the alkyl fragment of the initial alcohol are formed.[78]

Alkanols with a branched carbon skeleton (2-ethyl-1-hexanol and 2,2-dimethyl-1-propanol) are also aminated in the presence of RPFIC with high yields of the corresponding primary amines.[79,80]

Important results concerning the kinetics and mechanism of the amination of alkanols by ammonia in the presence of RPFIC have been obtained.[81–87] It has been established that the dependence of the rate of amination of the alcohol on its partial pressure at a constant rate of supply is characterised by a maximum in the region of $p_{ROH} = 0.02-0.03$ MPa.[83,85] This suggested that the kinetic equation for the reaction has a rational-fractional form, the power exponent of p_{ROH} in the denominator of the equation being greater than in the numerator.[83–85] The occurrence of the kinetic isotope effect in the amination of $CH_3(CH_2)_6CD_2OH$ and CH_3CD_2OH [82,84,85] permitted an inference about the character of the rate-limiting stage of the process. Within the framework of the Langmuir–Hinshelwood–Hogan–Watson kinetic model, a multistage amination mechanism has been proposed in which the rate-limiting stage is the dehydrogenation of the initial alcohol to the aldehyde.[84,85] The rate of amination of primary alkanols at moderate[84] and atmospheric[85] pressures is described by the equation

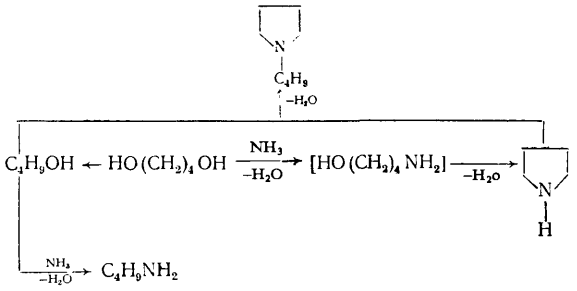
$$W = \frac{k \cdot b_{ROH} \cdot p_{ROH}}{(1 + b_{ROH} \cdot p_{ROH} + b_{H_2O} \cdot p_{H_2O})^2},$$



where k is the amination reaction rate constant, p_{ROH} and b_{ROH} are respectively the partial pressure and adsorption coefficient of the alcohol, and p_{H_2O} and b_{H_2O} are respectively the partial pressure and absorption coefficient of H_2O. The equation describes satisfactorily all the experimental data in the temperature range 180–270 °C and in the range of alcohol conversions 11–96%.

Fused iron catalysts exhibit an activity also in the *N*-alkylation of dimethyl- and methyl-amines.[86–88] Thus, in the reaction of 1-octanol with CH_3NH_2 in the presence of the RPFIC $1V_2O_5$ + 0.85BaO at temperatures in the range 230–240 °C, at a pressure of 2 MPa, for the ratios $H_2 : CH_3NH_2 : C_8H_{17}OH = 16 : 4 : 1$, and for a rate of supply of the alcohol at 350–400 g h^{-1} (litre cat.)$^{-1}$, the conversion of the alcohol reaches 93% and the overall selectivity with respect to amines is 93%, of which 70% corresponds to methyl-n-octylamine.[88] The kinetic equation proposed for the description of the interaction of alcohols with ammonia is also applicable to the reactions of alkanols with $(CH_3)_2NH$.[86,89]

Effective methods have been developed for the preparation of amines from alicyclic[90–92] and aromatic alkyl-substituted[93] alcohols and ammonia in the presence of RPFIC. Under conditions optimal for the synthesis of primary amines [315 °C, $p_{NH_3} = 3.2$ MPa, $p_{H_2} = 1.8$ MPa, rate of supply of cyclohexanol 36 mol h^{-1} (litre cat.)$^{-1}$] the conversion of the alcohol into amines is 88.5% for a selectivity with respect to cyclohexylamine of 95%.



It was shown above that reactions involving the amination of alcohols with different structures take place selectively in the presence of RPFIC with formation mainly of the corresponding primary amines. In contrast to this, in the hydroamination of

tetrahydrofurfuryl alcohol (THFA) the main reaction product is not tetrahydrofurfurylamine but piperidine, whose yield is 51%:[94-96]

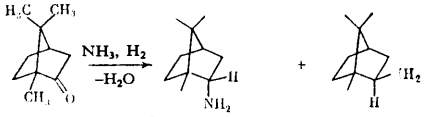
By virtue of the availability of the THFA, which is obtained from a renewable natural raw material, this synthesis of piperidine can be of interest for practical use.

Fused iron catalysts are used not only for intermolecular amination but also for intramolecular amination. Thus the interaction of butane-1,4-diol (BD) with an ammonia–hydrogen mixture in the presence of RPFIC results in the formation of pyrrolidine and its derivatives.[97] Under optimum conditions [260 °C, p_{NH_3} = 2, p_{H_2} = 2.8, and p_{BD} = 0.14 MPa; rate of supply of BD 560 g h^{-1} (litre cat.)$^{-1}$], the conversion of BD is 99% for a selectivity with respect to pyrrolidine above 70%.[97] The principal reactions of BD in the presence of RPFIC are illustrated schematically below:

The syntheses of piperazine from diethanolamine, of 1-alkyl- and 1,4-dialkyl-piperazines from *N*-alkyldiethanolamines, as well as morpholine from diethylene glycol have also been achieved.[97-99]

Table 5. Hydroamination of aldehydes and ketones [230 °C, p_{H_2} = 2.5 MPa, p_{NH_3} = 1.3 MPa, $p_{R^1COR^2}$ = 0.05 MPa,[102] $V_{R^1COR^2}$ = 20 mol h^{-1} (kg cat.)$^{-1}$]

Initial carbonyl compound	Amine formed	Conversion, %	Selectivity w.r.t. amine, %
2-Heptanone	2-Aminoheptane	93	95
4-Heptanone	4-Aminoheptane	92	92
2-Octanone	2-Amino-octane	92	95
2-Nonanone	2-Aminononane	90	96
Octanol	1-Amino-octane	87	90
Cyclohexanone	Cyclohexylamine	98	98
1-Phenyl-2-propanone	2-Amino-1-phenylpropane	85	93
Acetophenone*	1-Amino-1-phenyl ethane	96	70



* Temperature 210 °C, rate of supply of acetophenone 9 mol h^{-1} (kg cat.)$^{-1}$.

(b) Carbonyl compounds. Aliphatic aldehydes can be hydroaminated to amines in the presence of RPFIC.[69] The kinetics of the hydroamination of carbonyl compounds have been investigated in relation to 2-octanone.[100,101] The kinetic isotope effect has been noted in the hydroamination of butanone when H_2 in the initial reaction mixture was replaced by D_2 and a multistage process mechanism, corresponding to this observation, was proposed, in which the addition of hydrogen to the ketimine is regarded as the rate-limiting stage. The kinetic equation assumes the form

$$W = \frac{k\, p_{H_2}^{0.5}}{1 + b_{H_2O} p_{H_2O}},$$

where k is the apparent hydroamination rate constant, p_{H_2} and p_{H_2O} are the partial pressures of H_2 and H_2O respectively, and b_{H_2O} is the adsorption coefficient of H_2O. The optimum conditions for the synthesis of primary amines from certain aldehydes and ketones of different structure in the presence of RPFIC $5V_2O_5$ have been determined using this equation[102] (Table 5).

In certain cases, the RPFIC exhibits a stereoselectivity unusual for metallic heterogeneous catalysts. Thus in the hydroamination of *d,l*-camphor,[103-105] its overall conversion into *endo*- and *exo*-bornylamines reaches 92% for the *endo* : *exo* = (1.4–1.8) : 1 ratio.

endo-bornylamine *exo*-bornylamine

Such stereoselectivity has been examined in a study[105] where it was shown that its most probable cause is the "imine–enamine" tautomerism on the acid–base centres of the RPFIC. However, one cannot rule out also a relation between the unusual stereoselectivity and the characteristic features of the coordination of the sterically hindered camphor molecule on the active centres of the RPFIC.

(c) Esters and ethers. In the hydroamination of aliphatic symmetrical and asymmetric esters in the presence of the RPFIC $5V_2O_5$, both the alcoholic and acid components of the ester molecule participate in the replacement of the ester group by the amino-group:[106-108]

$$R^1CH_2OOCR^2 \xrightarrow[-H_2O]{NH_3} R^1CH_2NH_2 + R^2CH_2NH_2.$$

At 280–300 °C, p_{NH_3} = 1.5–2.3, p_{H_2} = 2.6–3.5, and $p_{R^1CH_2OOCR^2}$ = 0.06–0.01 MPa and for a specific rate of supply of the ester of 200–500 g h^{-1} (litre cat.)$^{-1}$, the conversion of the latter reaches 86% for a selectivity of 70–88% with respect to primary alkylamines and 12–30% with respect to secondary alkylamines. On the other hand, ethers (diethyl ether, t-butyl methyl ether, tetrahydrofuran, and 1,4-dioxane) are not aminated in the presence of RPFIC.[108]

2. The interaction of oxygen-containing compounds with ammonia

It was shown above that alkylamines are formed from a vapour–gas mixture of an alcohol, aldehyde, ketone or ester, ammonia, and hydrogen on contact with RPFIC. The interaction of alcohol with ammonia in the absence of hydrogen in the presence of RPFIC of different composition ($2Al_2O_3 + 5Cr_2O_3$; $2Al_2O_3 + 2.5MnO_2$; $2Al_2O_3 + 0.5V_2O_5$; $5Al_2O_3 + 2.5K_2O$) has been investigated.[109,111] At 300–320 °C and for an alkanol : ammonia = 1 : 1–3 ratio and a rate of supply of the alcohol of 4–4.5 mol h^{-1} (litre cat.)$^{-1}$, $C_3H_7C{\equiv}N$, $C_5H_{11}C{\equiv}N$, and $C_8H_{17}C{\equiv}N$ are formed from 1-butanol, 1-hexanol, and 1-nonanol respectively in 80–85% yields. The rate of cyanation of alkanols to nitriles is independent of the length of the carbon chain.[109,110] Data concerning the influence of the structure of the oxygen-containing

group on its conversion into nitriles are presented in Table 6.[111]
A general mechanism of the conversion of alcohols into amines and nitriles is presented below.

Scheme 1

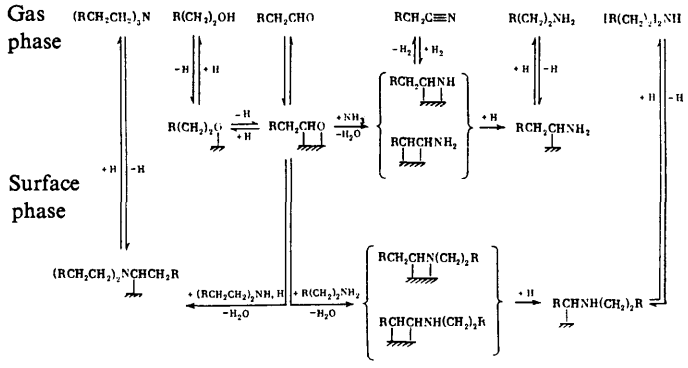


Table 6. Interaction of oxygen-containing compounds with NH_3 in the presence of the RPFIC $2Al_2O_3$ at 320 °C.[111]

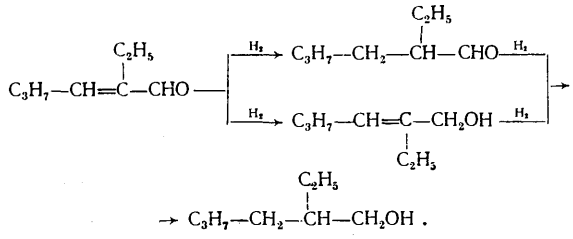
Initial compound	Content of nitriles in reaction mixture, %			Content of amines, %
	$C_3H_7C{\equiv}N$	$C_2H_4C{\equiv}N$	$CH_3C{\equiv}N$	
1-Butanol	80	—	—	1-Aminobutane, 4
2-Methyl-1-propanol	73.5	1.5	0.2	1-Amino-2-methylpropane, 3.6
2-Butanol	—	3.9	2.0	—
t-Butyl alcohol	—	—	—	—
Butanone	—	2.6	1.0	—
1-Butanal	69.7	0.4	0.2	1-Aminobutane, 4.9
Ethyl acetate	—	—	51	—

Overall, RPFIC are fairly effective in the syntheses of alkylamines, certain simple saturated heterocycles, and nitriles from oxygen-containing compounds. Analysis of the literature data shows that these processes make it possible to attain higher productivities and proceed more stably than the processes involving the synthesis of the above nitrogen-containing compounds by other known preparative methods in the presence of other heterogeneous catalysts (nickel, copper–chromium, etc.). The reaction mixtures obtained as a result of the amination of individual oxygen-containing compounds in the presence of RPFIC are fairly simple in composition and as a rule contain the target products at a high concentration, which makes it possible to isolate them by means of the usual fractionation.

VI. Hydrogenation and dehydrogenation, isotope exchange, and other reactions

1. The hydrogenation of aldehydes and ketones to alcohols

Alcohols, especially aliphatic alcohols, are the most important products of preparative and industrial organic synthesis. The preparation of high-quality alcohols is in most cases based on the use of the reaction involving the hydrogenation of aldehydes and ketones.



The possibility, in principle, of the formation of alcohols in the hydrogenation of aliphatic aldehydes in the presence of RPFIC has been demonstrated[112,113] but the RPFIC proposed for this purpose ($1MoO_3$ or $2Al_2O_3$) require a hydrogen pressure of 10 MPa and above.

The improvement of the method led to the development of the highly effective RPFIC $(2-5)V_2O_5$, in the presence of which carbonyl compounds were converted into the corresponding alcohols at p_{H_2} = 1–3.5 MPa [114–117] at a high rate and with a high selectivity (Table 7).

Table 7. Hydrogenation of aldehydes and ketones in the presence of a RPFIC (space velocity of H_2 2 × 10^4 h^{-1}).[114,117]

Initial carbonyl compound	Alcohol obtained	T, °C	p_{H_2}, MPa	Rate of supply, h^{-1}	Conversion, %	Selectivity w.r.t. alcohol, %
Butanol	1-Butanol	180	1.5	2	99.5	99.5
Nonanal	1-Nonanol	180	2.5	4.5	98	98.5
2-Octanal	2-Octanol	150	3.5	3	97.5	99.5
2-Ethylhex-2-en-1-al	2-Ethyl-1-hexanol	135	0.9	1.5	95	99
Cyclopentanone	Cyclopentanol	185	2.1	3.5	97	99
Cyclohexanone	Cyclohexanol	185	2.5	4.5	94	99.5

The hydrogenation of 2-ethylhex-2-en-1-al in the presence of water leads to an increase in the yield of an unsaturated alcohol 2-ethylhex-2-en-1-ol:[116]

Data on the kinetics of the hydrogenation of aliphatic and alicyclic ketones have been published.[117–121] The kinetics of the hydrogenation of 2-octanone and cyclohexanone have been investigated in the presence of the RPFIC $5V_2O_5$ under conditions where the reverse dehydrogenation reaction of the alcohols formed could be neglected. The rate of reaction increases with increase in the ketone and hydrogen concentrations and is independent of the alcohol concentration (the reaction product). A kinetic isotope effect (KIE) was observed following the replacement of H_2 by D_2 in the hydrogenation of 2-octanone.[121] A multistage reaction mechanism was proposed in which the rate-limiting stage is the addition of the first hydrogen atom to the adsorbed ketone molecule. For low conversions of ketones under isothermal conditions, the initial rate is described by a kinetic equation of the type[117,118]

$$W_0 = k \cdot p_{0(R^1COR^2)} \cdot p_{0(H_2)}^{0.5},$$

where k is the apparent reaction rate constant and $p_{0(R^1COR^2)}$ and $p_{0(H_2)}$ are the initial partial pressures of the ketone and hydrogen.

The equation holds satisfactorily over the entire experimental temperature range and the ranges of the ketone and hydrogen partial pressures.

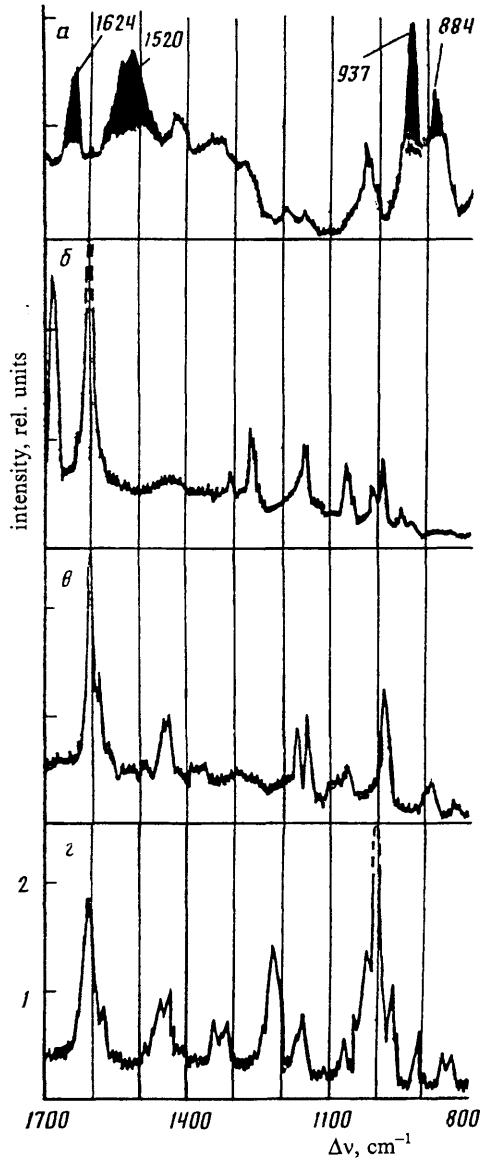


Figure 4. Raman spectra: *a*, the RPFIC surface in the hydrogenation of acetophenone *in situ* (177 °C, p_{H_2} = 0.2 MPa, p_{PhCOCH_3} = 4 kPa); *b*, acetophenone; *c*, methylphenylcarbinol; *d*, ethylbenzene.[16,122]

The kinetics of the non-isothermal hydrogenation of ketones in a tubular flow reactor up to a conversion of 0.8 are described by the equation[120]

$$1/V = (1/A \cdot p_{o(R^1COR^2)} \cdot p^{0,5}_{o(H_2)}) \int_0^x \{[1/(1-x)] \exp E/RT_0(1+\alpha x)\}\, dx,$$

where V is the specific rate supply of the ketone, T_0 the initial reaction temperature, E the apparent activation energy, A the pre-exponential factor, α a coefficient, and x the conversion of the ketone

The mechanism of the addition of hydrogen to ketones during their hydrogenation to alcohols in the presence of RPFIC has been investigated by a combined method involving laser Raman spectroscopy *in situ* and gas–liquid chromatography[16,17,122] and also by reaction chromatograph-linked mass spectrometry (RCMS).[123,124]

The Raman spectrum (Fig. 4*a*) of the surface of the RPFIC $5V_2O_5$ in the hydrogenation of acetophenone (ACP) by hydrogen (ACP conversion 6%, selectivity with respect to methylphenylcarbinol ~70%, selectivity with respect to ethylbenzene ~30%) differs significantly both from the spectrum of the initial ACP (Fig. 4*b*) and from the spectra of the reaction products (Figs. 4*c* and 4*d*). The intense lines in the region of ~1624, ~1520, ~937, ~884 cm^{-1} (Fig. 4*a*) can probably be attributed to intermediates in which there are C=O, C=C, C–C, and C–O bonds and the intermediates themselves can be interpreted as the "keto-" and "enol-forms" of the adsorbed ACP.

The question of the ratio of the "ketone" and "enolic" mechanisms in the hydrogenation of ketones in the presence of RPFIC was solved[123,124] by the RCMS method using a deuterium label and involving the analysis of the isotope composition of the trimethylsilyl ethers of the deuterioalcohols formed. The initial ketones can undergo the following reactions:

ketone mechanism

$$-CH_2-\overset{|}{C}=O \xrightarrow[RPFIC]{D_2} -CH_2-\overset{|}{C}D-OD \xrightarrow{BSTFA} -CH_2-\overset{|}{C}D-OSiMe_3 \quad (E_k)$$

"enolic" mechanism

$$-CH=\overset{|}{C}-OH \xrightarrow[RPFIC]{D_2} -CHD-\overset{|}{C}D-OH \xrightarrow{BSTFA} -CHD-\overset{|}{C}D-OSiMe_3 \quad (E_e)$$

BSTFA = *N,O*-bis(trimethylsilyl)trifluoroacetamide

It is seen from the scheme presented that, depending on the mechanism, trimethylsilyl ethers E_k and E_e with different numbers of D atoms are formed, which can be demonstrated mass-spectrometrically. A typical chromatogram, recorded in an experiment with cyclohexanone, is presented in Fig. 5, while the mass spectra of the cyclohexanone deuteriation products are illustrated in Fig. 6. Calculation of the isotope composition of the trimethylsilyl ethers E_k and E_e, taking into account the isotope composition of the unreacted cyclohexanone and its H/D exchange, established that the hydrogenation of alicyclic ketones to alcohols at 70–210 °C proceeds with equal probability via both the "enolic" and "ketone" mechanisms.

2. Dehydrogenation of alcohols and amines

It is known that the catalysts $1MoO_3$ or $2Al_2O_3 + 0.5V_2O_5 + 1K_2O$ for the hydrogenation of carbonyl compounds to alcohols can be used under appropriate conditions for the reverse alcohol dehydrogenation reaction. 1-Heptanol and ethanol have been hydrogenated in the presence of such catalysts to heptanal and acetaldehyde respectively in 30–40% yield.[113,125] The kinetics and mechanism of the dehydrogenation of alcohols in the presence of the RPFIC $5V_2O_5$ have also been investigated in other studies.[85,125] In the gas-phase dehydrogenation of CH_3CD_2OH, CD_3CH_2OH, and

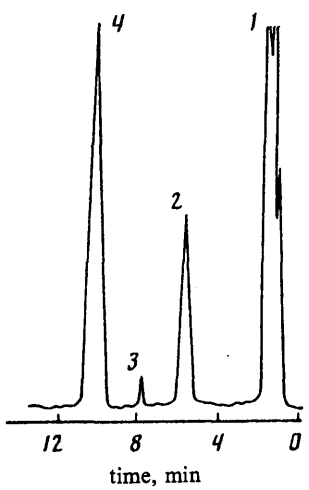
CH_3CH_2OH [125] in helium at 180 °C, the rates of reaction of these ethanols are in the following proportions:

$$W_{CH_3CH_2OH}/W_{CD_3CH_2OH} \simeq 1;$$
$$W_{CH_3CH_2OH}/W_{CH_3CD_2OH} \simeq 2.5 \pm 0.1.$$

Hence it follows that the slow stage of the reaction is the abstraction of a α-hydrogen atom from the alcohol molecule. The kinetics of the dehydrogenation of the ethanols in the presence of the RPFIC $5V_2O_5$ correspond to the equation

$$W = \frac{k \cdot b_{ROH} \cdot p_{ROH}}{(1 + b_{ROH} \cdot p_{ROH} + b_{ACH} \cdot p_{ACH})^2},$$

where k is the reaction rate constant, p_{ROH} and b_{ROH} are the partial pressure and the adsorption coefficient of the alcohol respectively, and p_{ACH} and b_{ACH} are the partial pressure and the adsorption coefficient of the aldehyde respectively.



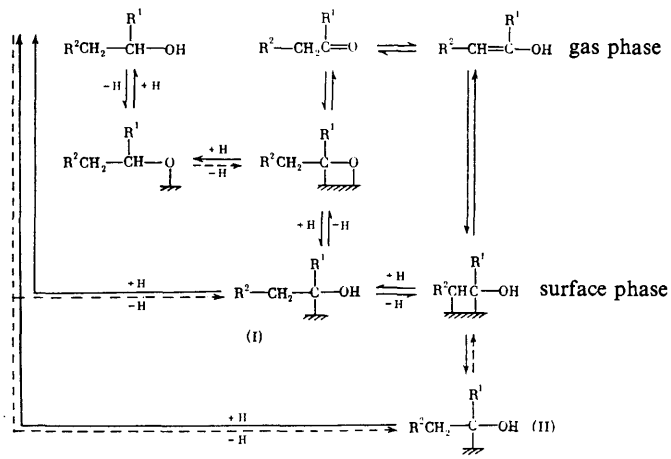


Figure 5. Chromatogram of the reaction mixture obtained in the deuteriation of cyclohexanone in the presence of a RPFIC:[124] *1*, BSTFA and its hydrolysis products; *2*, trimethylsilyl ether of deuteriated cyclohexanol; *3*, trimethylsilyl ether of deuteriated cyclohex-1-enol; *4*, deuteriated cyclohexanone.

The catalysts examined are capable of effecting the dehydrogenation of not only alcohols but also amines. Thus n-butylamine is dehydrogenated to butyronitrile in 78% yield in the presence of the RPFIC $2Al_2O_3$ at 280–320 °C.[111]

The mechanisms of the hydrogenation of carbonyl compounds to alcohols and of the dehydrogenation of the latter to aldehydes and ketones in the presence of RPFIC, based on data in Refs. 123–125, are presented below:

Scheme 2

After deuteriation, the isotope compositions of compounds (I) and (II) are different. The reactions designated by a dashed line occur only in the dehydrogenation of the alcohol.

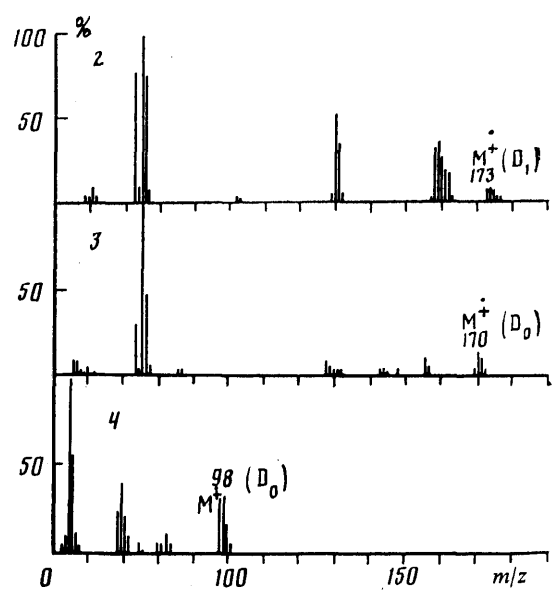

Figure 6. Mass spectra of the chromatographic bands presented in Fig. 5.[123]

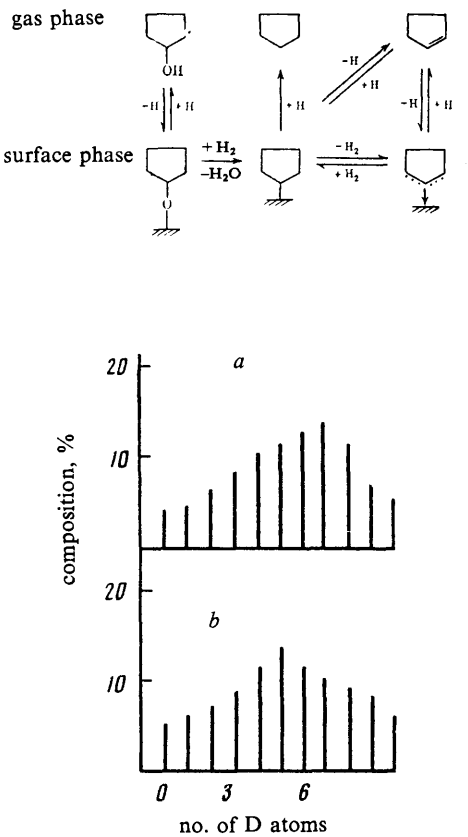
3. Hydrodeoxygenation of alcohols, aldehydes, and ketones

The hydrodeoxygenation (HDO) of oxygen-containing compounds to hydrocarbons is used widely in preparative and industrial organic chemistry. Alcohols, aldehydes, and ketones with different structures are hydrodeoxygenated quantitatively to saturated hydrocarbons at 250–350 °C and p_{H_2} = 0.1–0.3 MPa in the presence of the RPFIC

$5V_2O_5$ with retention of the carbon skeleton of the initial oxygen-containing substrate.[126,127] The distribution of deuterium in the saturated hydrocarbons formed on deuteriodeoxygenation of alcohols, aldehydes, and ketones has been investigated[127] by the RCMS method.[128]

Analysis shows that the isotope compositions of the deuteriocyclopentanes obtained in the reaction of cyclopentene and cyclopentanol with deuterium (Fig. 7) are similar,[127] which suggests that the products of the deuteriation of an olefin and of the deuteriodeoxygenation of an alcohol are formed via intermediates having similar structures:



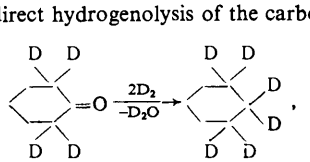


Figure 7. Isotope composition of the deuteriocyclopentanes obtained in the reactions of cyclopentene (*a*) and cyclopentanol (*b*) with D_2 (300 °C, p_{D_2} = 0.15 MPa).[127]

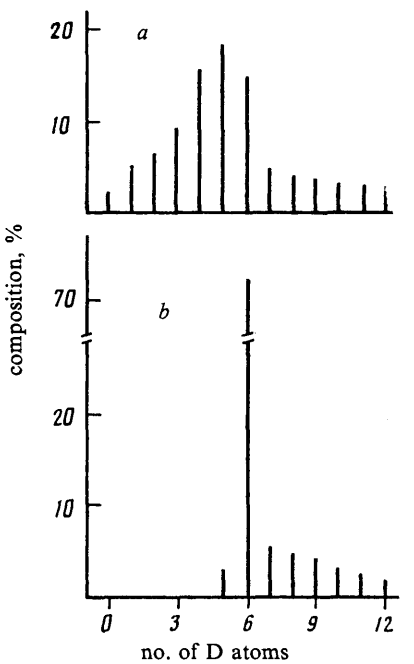
On the other hand, comparison of the isotope compositions of the deuteriocyclohexanes obtained as a result of the deuteriodeoxygenation of cyclohexanone and 2,2,6,6-tetradeuteriocyclohexanone (Fig. 8), according to which about 70% of all the $[D_n]$cyclohexanes is $[D_6]$cyclohexane, provides grounds for the assumption that this reaction proceeds via two pathways, the main one involving the direct hydrogenolysis of the carbonyl group:

while the other involves the hydrogenation initially of the ketone to the alcohol and then of the alcohol to the hydrocarbon.

When benzaldehyde was hydrodeoxygenated, it was observed unexpectedly that, together with toluene, up to 30% of bibenzyl and *trans*-stilbene is formed.[129] It has been suggested that one of the pathways leading to the formation of stilbene is the metathesis of benzaldehyde at the carbonyl group.



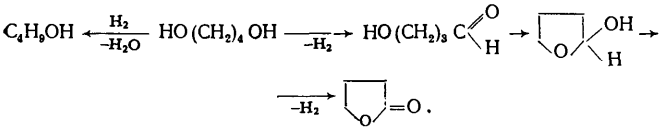


Figure 8. Isotope composition of the deuteriocyclohexanes obtained in the reaction of cyclohexanone (*a*) and 2,2,6,6-tetradeuteriocyclohexanone (*b*) with D_2.[127]

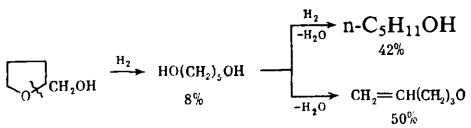


4. Hydrogenolysis of esters, diols, and other oxygen-containing compounds

The gas-phase hydrolygenolysis of esters and ethers in the presence of RPFIC has been examined.[106–108] At 200–250 °C, n-heptyl oenanthate gives rise to 1-heptanol and n-heptane in 50 and 25% yields respectively. Only heptane in 18% yield was obtained under the same conditions from di-n-heptyl ether.

On interaction with H_2 in the presence of the RPFIC (4–5)V_2O_5 + 1(Al_2O_3 + SiO_2) at 280–300 °C and p_{H_2} = 2–3 NPa, butane-1,4-diol is converted into γ-butyrolactone and 1-butanol in 20–30% and 10–20 yields respectively:[130]

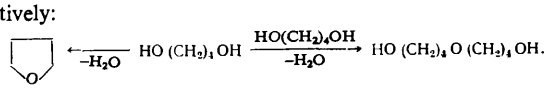
The reactions of THFA in the presence of RPFIC are illustrated in the following scheme:

The hydrogenolysis of THFA to pent-4-en-1-ol is an interesting case of the conversion of a heterocyclic alcohol into an unsaturated aliphatic alcohol.

5. Hydrogenation of C=C and C≡C bonds

Only a few studies have been specially devoted to questions concerning the hydrogenation of multiple carbon–carbon bonds in the presence of RPFIC. The possibility of the hydrogenation of hexene to hexane in the presence of the ammonia synthesis catalyst has been reported.[131]

Hept-1-ene and cyclopentene are hydrogenated quantitatively in a microreactor with a fluidised bed of RPFIC $5V_2O_5$ with pulsed supply of the olefin into a stream of H_2 or D_2 at 250 °C.[127]

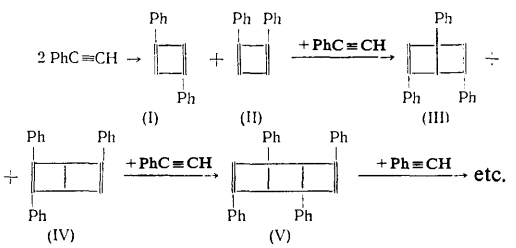


There are data for the hydrogenation of acetylene at 70 °C in the presence of the RPFIC $2Al_2O_3 + 0.5V_2O_5 + 1K_2O$. Isoprene is hydrogenated to a mixture of isopentane and isopentene in the presence of the same catalyst at 165–170 °C.[64]

Benzene is capable of being converted into cyclohexane in the presence of RPFIC, the catalyst having the composition $(5-8)Al_2O_3$ being the most active.[132,133] In its presence, the rate of hydrogenation of benzene is only several times smaller than in the presence of the nickel catalyst.[133]

6. Dehydration and polymerisation reactions

Until recently, the RPFIC was regarded exclusively as a metallic catalyst.[134] The role of stabilisers of the disperse metallic iron phase on the surface and of regulators of the particle size and of the overall surface area was attributed to the promoting agents. However, the RPFIC surface consists mainly of a non-metallic phase (see Section II). In other words, the surface layer of the RPFIC bears a formal similarity to that of traditional bifunctional catalysts, whose composition includes Group VIII metals (1–10%) on Al_2O_3, SiO_2, zeolite, etc. carriers.[135,136] The difference of the RPFIC consists primarily in the fact that, unlike the traditional catalysts, it incorporates 1–10% of promoting agents (Al_2O_3, SiO_2, V_2O_5, etc.) and 90–99% of α-Fe^0. Thus the RPFIC can be regarded as an inverted bifunctional catalyst. The manifestation of both oxidation-reduction (hydrogenation–dehydrogenation processes) and acid–base activities is characteristic of bifunctional catalysts. The efficiency of the RPFIC in oxidation–reduction reactions was demonstrated in previous Sections, but, as will be shown below, some of the results obtained in the presence of RPFIC can be treated from the standpoint of acid–base catalysis.



A typical acid–base catalytic reaction is the dehydration of alcohols or diols. The first such reaction carried out in the presence of the RIPMC $(4-5)V_2O_5 + 1(Al_2O_3 + SiO_2)$ was the dehydration of butane-1,4-diol.[130] It underwent both intermolecular and intramolecular dehydration in a H_2 atmosphere at 280–300 °C with formation of dibutylene glycol and tetrahydrofuran (THF) respectively:

Subsequently the intramolecular dehydration of ethylene glycol[137] and the intermolecular dehydration of t-butyl ether of propargyl alcohol[138] were achieved in the presence of RPFIC.

Compounds with the C=C and C≡C multiple bonds can enter into polymerisation reactions in the presence of RPFIC: at 220 to 230 °C, isoprene forms a solid rubber-like product, which consists of polyisoprene.[64]

The development of this approach led to the creation of a procedure for the oligomerisation of phenylacetylene (PA).[139,140] In the presence of the RPFIC $(0.5-1)K_2O + (3-4)(SiO_2 + Al_2O_3 + V_2O_5)$ at 150 °C in a nitrogen atmosphere, PA undergoes linear oligomerisation with formation of PA dimers, trimers, and tetramers and also cyclisation with formation of the diphenylcyclobutadienes (I) and (II), triphenyl-substituted Dewar benzenes (III) and (IV), and the ladder oligomer (V):

The authors[139,140] did not discuss the mechanism of the oligomerisation of PA, but, taking into account the acid–base properties of the RPFIC, presumably one of the possible pathways to the oligomerisation of PA involves a mechanism analogous to that of cationic polymerisation.

7. Isotope exchange reactions

Gaseous deuterium or a deuterium label in the molecule are frequently used in the study of the mechanisms of heterogeneous organic catalysis.[141–143] Certain examples of the employment of gaseous deuterium or a deuterium label, involving the measurement of kinetic isotope effects in syntheses of oxygen- and nitrogen-containing compounds in the presence of RPFIC, were presented above. We shall consider in greater detail a series of isotope exchange reactions occurring in the presence of RPFIC.

In the interaction of CH_3OH with D_2 in a stationary system in the presence of the RPFIC $2K_2O$ at 112 °C, p_{CH_3OH} = 4.5 GPa, and p_{D_2} = 20 GPa, methanol acquires, after 40 min, the following isotope composition (5): CH_3OH 80, CH_3OD 19, CH_2DOD 1, CHD_2OH < 0.1.[144] Hence, it is seen that in the presence of the RPFIC the most vigorous H/D exchange occurs in the hydroxy-group of the alcohol.

The exchange of n-hexane, cyclohexane, cyclohexanol, cyclopentanol, cyclohexanone, and cyclopentanone with D_2 has been investigated in the presence of the RPFIC $5V_2O_5$.[123,127] In alicyclic alcohol molecules (p_{D_2} = 0.1–0.3 MPa), as in CH_3OH molecules, only the H atom of the hydroxy-group is replaced by deuterium at 250 °C. Under these conditions, saturated hydrocarbons hardly undergo the H/D exchange. On the other hand, in ketone molecules protium is vigorously exchanged for deuterium at carbon atoms in the α-position to the carbonyl group.

In a study of deuterium distribution in the products of synthesis from CO and H_2 with added D_2O, it was established that there is no exchange between the hydrocarbons formed and D_2O.[145] On the other hand, the hydrocarbons contain a certain amount of deuterium

which was believed to pass from D_2O to gaseous hydrogen, reacting subsequently with CO. The deuterium content in the alcohols formed in the FT-synthesis is higher than in hydrocarbons.

When $^{14}C^{18}O_2$ is added to the synthesis gas in the presence of a RPFIC, the carbon label is transferred from carbon dioxide to the monoxide mainly via the reaction

$$^{14}CO_2 + H_2 \rightleftarrows {}^{14}CO + H_2O,$$

while the transfer of the oxygen label proceeds via the reaction[146]

$$C^{18}O_2 + C^{16}O \rightleftarrows C^{16}O^{18}O + C^{18}O.$$

A novel one-stage synthesis of aliphatic alcohols labelled with ^{18}O isotope consists in the vapour-phase interaction of alkanols with $H_2{}^{18}O$ in the presence of hydrogen at 150–250 °C over a RPFIC.[147,148] Thus, when a mixture of $H_2{}^{18}O$ methanol vapours is passed through the catalyst bed, $C_2H_5{}^{18}OH$ is formed in 92% yield relative to the equilibrium yield. The authors[147,148] explain the observed $^{16}OH/^{18}OH$ isotope exchange by the reversible dehydrogenation of the alkanols under the conditions indicated. Taking into account the acid-base properties of the RPFIC, such oxygen exchange can be described by the following multistage scheme in which RMC represents reduced FeH metallic centres and ABC represents POH acid–base centres (P = V, Al, Si):

$$C_2H_5OH \xrightarrow[-H_2]{RMC} CH_3CHO,$$
$$CH_3CHO + H_2^{18}O \xrightarrow{ABC} CH_3CH^{18}O + H_2O,$$
$$CH_3CH^{18}O + H_2 \xrightarrow{RMC} CH_3CH_2^{18}OH.$$

Thus reduced promoted fused iron catalysts exhibit a high (frequently unexpected) efficiency in a whole series of hydrogenation syntheses. In some cases they are superior to the familiar catalytic systems in terms of a series of most important technological parameters such as productivity, selectivity, and stability (Fischer–Tropsch syntheses modified by ammonia or lower amines, hydroamination and hydrogenation of certain oxygen-containing compounds, etc.). In other cases, they may prove preferable, despite their lower efficiency, because of their availability, low cost, and the simplicity of their preparation. Such an unusually broad spectrum of the catalytic activity of RPFIC is probably associated with its bifunctional nature, which is manifested in the syntheses of organic compounds of different classes via a combination of oxidation-reduction (hydrogenation-dehydrogenation) and acid–base catalytic properties. By varying easily within wide limits the chemical composition of the RPFIC and hence also the nature of the catalytically active surface on which a wide variety of reactions of the initial reactants take place, it is possible to achieve deliberately the necessary ratio of these properties. This is in fact why experimental search on a broad front makes it possible in most cases to select a RPFIC best corresponding to the purposes of the synthesis of the organic compounds. The latter factor makes it extremely likely that new examples of the successful employment of RPFIC in organic synthesis will appear in the future.

Finally, the wide-scale application of RPFIC and other universal catalysts may prove a useful alternative to the approach, dominant at present in chemical research, according to which a new catalyst is developed for each specific synthesis of an organic compound.

Self-diffusion in solutions and melts of flexible-chain polymers

V P Budtov
ONPO "Plastpolimer", Leningrad

ABSTRACT. The review deals with the characteristic features of the molecular motion of flexible chain macromolecules and oligomers associated with the multisegmental nature of the chain and topological limitations. The dependence of the self-diffusion coefficients of chain molecules in polymer melts and solutions, including a weakly cross-linked gel, is analysed. Attention is concentrated on data for self-diffusion where there is a change not only in the molecular weight (MW) of the diffusing molecule but also in the molecular weight of the macromolecules surrounding the specified molecule. Both model ideas and approaches based on the scaling theory, including the concept of the curvature of the trajectories of the "reptation tube", are used for the theoretical analysis. The "inhomogeneity" of the segmental mobility in the chain has made it possible to describe specific features of the behaviour of oligomers. The dependence of the self-diffusion coefficient on the MW of the chain and the matrix and on the concentration in the region of dilute, moderately concentrated, and concentrated solutions and melts has also been described quantitatively.

The bibliography includes 69 references.

I. Introduction

The problems of molecular mobility in polymeric materials have continually attracted the attention of both theoreticians and specialists in applied chemistry. Self-diffusion processes occupy a major place in this problem. Firstly, the principal features and characteristics of the mobility in polymeric materials are manifested most clearly in self-diffusion phenomena. Secondly, together with the chemical potential gradient, self-diffusion coefficients determine the rate of mass transfer in polymeric bodies. Thirdly, self-diffusion processes can affect significantly the rates of chemical reactions (diffusion-controlled chemical reactions). Despite the importance of the problem under discussion, these questions have not been solved appropriately because of the difficulty of experimental measurement of the self-diffusion coefficients (D) of chain molecules.

Together with further improvement of the "tracer" atom and NMR "spin echo" methods,[1,2] during the last ten years there has been a development of other methods for the investigation of self-diffusion processes based on the use of the laser technique.[3–5] The results of studies of self-diffusion processes up to 1983 have been surveyed in two books.[1,2] However, in recent years fundamentally new experimental data have been obtained for the mobility of polymers and theoretical equations describing satisfactorily the experimental behaviour have been proposed. Indeed, previously it was believed that the scaling theory is adequate for the understanding of the concentration dependence of D.[6] However, in the latest studies (see below) it was found that the predicted relations hold only over a limited concentration range. The predictions of the scaling theory concerning the dependence of D on the molecular weight M also failed to come true. Indeed, the scaling theory predicted a broken line (with a jump at a certain concentration) dependence of D on M. However, it has been shown in studies carried out in 1984–1986 that these results of the scaling theory are applicable only within a restricted concentration range. There are data which cannot be in any way reconciled with the previously proposed theoretical relations.

The aim of the present study is the analysis of both experimental and theoretical results for the self-diffusion coefficients of macromolecules, obtained mainly in recent years, and the establishment of a correlation of these results with one another.

II. Characteristic features of the molecular motion of flexible chain polymers

The characteristic features of the molecular motion of flexible chain macromolecules in polymer solutions and melts are determined by their structure.[6,7] Indeed a flexible chain macromolecule consists of a large number of segments N capable of being oriented independently of one another and of executing definite types of motion. Thus, in constructing a molecular picture of the motion of chain molecules, it is essential to take into account the "duality" of the thermal motion. The displacement of a flexible chain macromolecule takes place as a result of the displacement of its elements (kinetic segments). The set of such displacements of the chain sections leads to the displacement of the centre of gravity of the entire macromolecule. The mobility of the chain segments is determined in its turn by the mobility of the elements of the system (their interaction): the segments of other chains (for a melt) or solvent molecules and chain segments (for a solution).

For the simplest chain model, where the motion of the chain is regarded as the motion of N non-interacting chain segments with a coefficient of friction of the segments ζ, the following expression has been obtained † for the self-diffusion coefficients D_R (motion of the Rouse type):[8]

$$D_R = kT/N\zeta, \quad (1)$$

where k is the Boltzmann constant and T the temperature.

It was postulated previously (and is still postulated in certain studies) that the coefficient of friction of the segments ζ is proportional to the macroscopic viscosity of the medium η. This is true only for low-molecular-weight substances and dilute polymer solutions.

Analysis of numerous experimental data[11] for low-molecular-weight liquids has shown that the following relation holds for them:

$$D\eta = \frac{N_A kT}{4\sqrt{2}}\left(\frac{\rho}{MN_A}\right)^{1/3},$$

where ρ is the density of the liquid and N_A the Avogadro number. The dependence of $D\eta$ on $M^{-1/3}$ is characteristic of molecular models in the form of a sphere moving in a medium having a viscosity η.

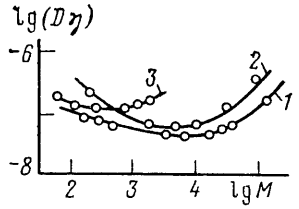

Figure 1. Dependence of $\lg(D_\eta)$ on $\lg M$ for polydimethylsiloxane (curve *1*), poly(ethylene oxide) (curve *2*), and polyethylene (curve *3*) according to the results of Budtov and Konsetov[16] and Tanner et al.[29]

However, with increase in the polymer concentration and in the molecular weight (M) of the chain (for solutions and for the melt), the quantity ζ is no longer determined by the macroscopic viscosity η. Fig. 1 illustrates the dependence of $D\eta$ on M for certain polymers.[12–14] Evidently, $D\eta$ varies with increasing M in a complex manner, although it follows from the simplest relation (1) that it should only decrease with increase in M (or N). Thus the classical ideas of the hydrodynamics of a continuous medium are inapplicable in the interpretation of the diffusion phenomena in flexible chain macromolecules.‡

† An analogous model has been proposed by Kargin and Slonimskii independently of Rouse.[9,10] The viscoelastic properties of polymeric materials have been calculated on the basis of this model.

‡ This apparently evident assertion was nevertheless not recognised for a long time, which led to a significant retardation of the development of ideas about the diffusional mobility of macromolecules.

We shall consider the displacement of an element X of a diffusing macromolecule.[15,16] Suppose that the medium surrounding the polymer chain consists of low-molecular-weight substances (a low-molecular-weight solvent) (Fig. 2*a*). Having received momentum from a certain section of the selected chain, the solvent molecule can move away from the initial position sufficiently "far" and "fast". The mean square of the displacement of the solvent molecule is $\langle X_S^2 \rangle = 2D_S t$, where D_S is the diffusion coefficient of the solvent molecule and t is the time. Nothing inhibits its motion apart from the natural viscous retardation determined by the viscosity of the solvent η_S.

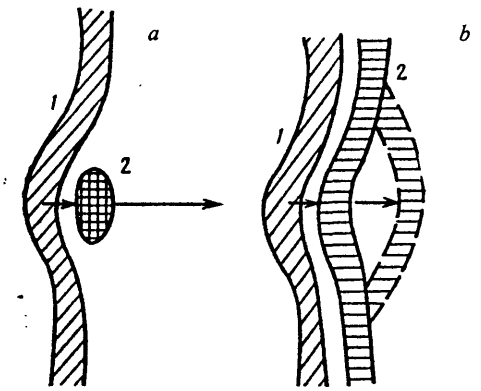

Figure 2. Schematic representation of the molecular picture of the motion of a chain molecule in a low-molecular-weight solvent (*a*) and in the melt (*b*).

Another situation arises if the medium consists of long flexible chain macromolecules (melts) (Fig. 2*b*). When a unit of a selected molecule is displaced, an elementary unit of the chain molecule surrounding the specified molecule is also displaced. However, this elementary unit cannot move away from the initial position sufficiently "far" and "fast", since it is bound to the macromolecule "at rest". The rate of displacement of this section is determined not only by its local characteristics (the size of the segment and the local viscosity of the medium) but also by its elastic linkage with the entire macromolecule and by its overall displacement. Fig. 3 presents the time variation of $\langle X_A^2 \rangle$ of an elementary unit of a chain macromolecule for the simplest Kargin–Slonimskii–Rouse model. It is seen that the longer the time of the observation, the smaller the contribution of the displacement of the element of the polymer chain compared with the displacement of the solvent molecule $\langle X_S^2 \rangle$. Fig. 3 illustrates this in a generalised form: $\langle X_A^2 \rangle / \langle X_S^2 \rangle = f(t/t_A)$.

Thus we cannot speak of the "constraint" of the transverse motion of a chain macromolecule, or about the anisotropy of the diffusional motion of a chain, or about topological limitations of the diffusional mobility, for which an attempt has been made to describe them in terms of the so called "quasi-network".

A molecular model for the diffusional motion in such systems has been proposed by de Gennes[17,18] (see also Gotlib et al.[6]). It has been shown that the square of the displacement of the elementary unit is

specified by the relation

$$\langle X_A^2 \rangle = 2A\sqrt{D_A t/\pi}, \quad t_A < t < \tau, \tag{2}$$

where D_A is the diffusion coefficient of the segment, $t_A = A^2/2DA$, τ is the relaxation time of the entire chain, and A is the size of the segment.

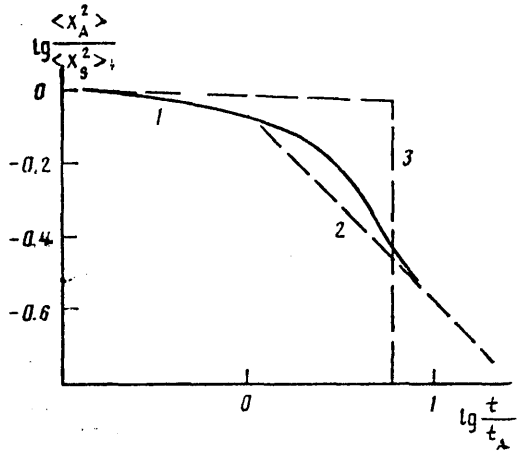

Figure 3. Dependence of $\lg(\langle X_A^2\rangle/\langle X_S^2\rangle)$ on $\lg(t/t_A)$ calculated for the Kargin–Slonimskii–Rouse model (curve *1*) and for the reptation model (curve *2*) [Eqn. (2)]; curve *3* represents the corresponding dependence of the transverse displacement for the "tube" model.

Thus a radical alteration of the mobility of the elements of the medium is characteristic of concentrated polymer solutions and melts. The displacement of the specified macromolecule by changing places with solvent molecules, observed previously for dilute solutions in a low-molecular-weight solvent, is no longer attainable for melts. The diffusional motion in a viscoelastic medium takes place in two ways. On the one hand, this is a specific motion of a section of a specified macromolecule, which involves only "local" changes in the conformation of the surrounding medium. On the other hand, this is the motion of the segment over long distances (owing to topological limitations, such motion occurs in only one direction) along the chain. The terminal chain element moves "ahead" and drags behind it the entire chain, i.e. a "snake-like" type of motion is observed—the reptation type of motion. The molecular theory of this type of motion, applied to the calculation of the viscoelastic properties of polymeric materials, has been developed in a number of studies.[17–19] In later studies, it has been used widely to develop a molecular theory of liquid-phase polymers.[6]

We shall consider below in greater detail the application of reptation motion to the description of the diffusion of chain molecules. Here one would wish to note that the reptation type of motion can be readily modelled by considering the motion of the chain in a "tube", whose configuration resembles the configuration of a flexible chain macromolecule[20,21] (Fig. 4).

Indeed in Fig. 3 we can replace the smooth decrease in $\langle X_A^2\rangle$ with increase in t by a stepwise decrease (curve *3*). This means that, for long times, one no longer observes a transverse displacement of the segment ($\langle X_A^2\rangle = 0$), i.e. an "impermeable" wall is thereby introduced. This limit in fact determines the "tube" diameter. It amounts to several segments (t/t_A at the boundary is ~ 5).

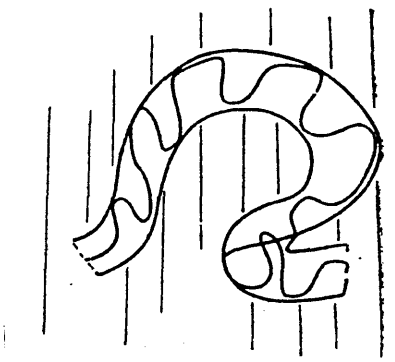

Figure 4. The "tube" model for the study of the reptation motion of the chain.

In order to characterise the configuration of the "tube", the parameter b, which is an analogue of the persistent length of a chain macromolecule, has been introduced.[22] The mean square of the distance between the ends of the "tube" is then given by

$$B^2 = Lb - \frac{b^2}{2}[1 - \exp(-2L/b)], \tag{3}$$

where L is the contour length of the "tube", i.e. the length of the fully straightened "tube". The quantity b characterises the degree of twist of the configuration of the "tube": the smaller the value of b, the more twisted is the "tube". For $L < b$, we have $B^2 = L^2$, i.e. the "tube" has the configuration of a rod, while for $L > b$, we obtain $B^2 = Lb$,[17–19]§ whereupon $b > A$. Whereas the size of the chain segment A is determined by the chemical structure of the chain, the quantity b depends on the structure of the molecules of the medium surrounding the specified macromolecule. For example, b may depend on the deformation, degree of cross-linking, and concentration of the polymer in the matrix through which the labelled macromolecule diffuses.

The introduction of the concept of curvature of the tube (or curvature of the reptation path of the diffusing macromolecule) is of fundamental importance, since it permits a molecular interpretation of concepts widely used in the physical chemistry of polymers such as the critical molecular weights M_c. For $M < M_c$ (or $L < b$), the chain behaves as a Rouse chain, whereas for $M > M_c$ (or $L > b$), the twisting of the chain and the topological limitations of the mobility of the macromolecule are fully manifested.

An attempt is usually made to interpret M_c as the distance between the nodes of a "quasi-network". For solutions, such a representation is possible. However, it is clearly inapplicable to melts, since in a melt it is impossible to specify the characteristic

§ The case $L \gg b$ was also considered in the above studies.[17–19]

point of the interaction between the specified chain and other chains, since this interaction is uniformly distributed along the chain. If a "node" with a definite lifetime τ_c is introduced into the model for the melt as a characteristic of the interaction,[22] then naturally the number of nodes N_c, hindering diffusion, will depend on the velocity of the motion v:

$$N_c = \frac{N_c(0)}{\exp(A/v\tau_c) - 1}.$$

Hence it follows that the translational friction coefficient $\Lambda = \Lambda_0(1 - N_c)$, where $N_c(0) = N_c(v \to 0)$ and $\Lambda_0 = \Lambda(v \to 0)$. Estimates have shown[22] that, for self-diffusion processes, the quantity $A/v\tau_c$ ranges from 10 to 10^6 and the influence of the nodes arising in the system can be disregarded.

We shall consider below the application of the above ideas to the analysis of experimental results obtained in recent years.

III. Self-diffusion coefficients of chain macromolecules in the melt

1. General relations

The dependence of the self-diffusion coefficient D on the molecular weight M has been investigated for a fairly large number of flexible chain polymers (PE, PDMS, PEO, PI, BSR)¶ (Fig. 5). These data have been analysed.[16] The data published subsequently[23–27] confirmed the earlier relations. The dependence of D on M can be described empirically by the relation

$$D = KM^{-\alpha}, \qquad (4)$$

where the numerical coefficient α is in the range from +1.3 to +2.0 and K is an empirical constant. These relations were confirmed in subsequent studies and the upper limit of α reached 2–2.4.[3–5]

However, the most interesting data were obtained when self-diffusion processes were investigated with variation of the molecular weight M_m of the surrounding medium.[28–30] The dependence of D on the molecular weight of the diffusing macromolecule (M) and on the length of the macromolecule in the surrounding medium (P) makes it possible to elucidate the characteristic features of the diffusional behaviour in such complex systems.

Fig. 6 illustrates the dependence of P for "labelled" PS macromolecules in a matrix comprising PS macromolecules on the molecular weight M_m of the matrix as far as weakly cross-linked gels ($M_m = \infty$).[28] Evidently, with increase in the molecular weight of the diffusing chain (M) and of the matrix (M_m), D diminishes. However, for sufficiently large values of M_m (up to weakly cross-linked gels—see also Zakharov[31]), the quantity D no longer depends on M_m. Similar data have been obtained also for PDMS,[29] PS,[30] and polyisoprenes.[31] An interesting result of Zakharov's study has been the establishment of the fact that the variation of D as a function of M depends on the method of preparation of the matrix (the method used for its deformation and annealing). The dependence of D on the deformation of the medium is clearly manifested: with increase in deformation, D fell.[31,32] However, for non-annealed elastomers, the coefficient D could actually increase on extension of the material.

¶ The following notation has been adopted: PE = polyethylene, PDMS = polydimethylsiloxane, PEO = poly(ethylene oxide), PI = polyisoprene, and BSR = butadiene–styrene rubber.

The dependence of D on M and M_m makes it possible to determine not only the values of α but also the differential indices α_N and α_P, i.e.

$$\alpha_N = d\lg D/d\lg M;$$
$$\alpha_P = d\lg D/d\lg M_m,$$

which will be analysed below.

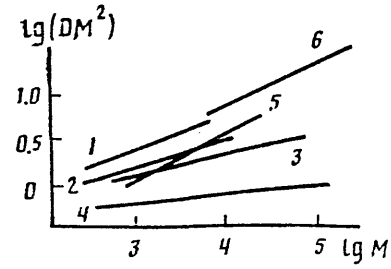

Figure 5. Dependence of $\lg(DM^2)$ on $\lg M$ for melts of certain polymers:[16] *1*, PE; *2* and *3*, PDMS; *4*, PEO; *5*, PI; *6*, BSR.

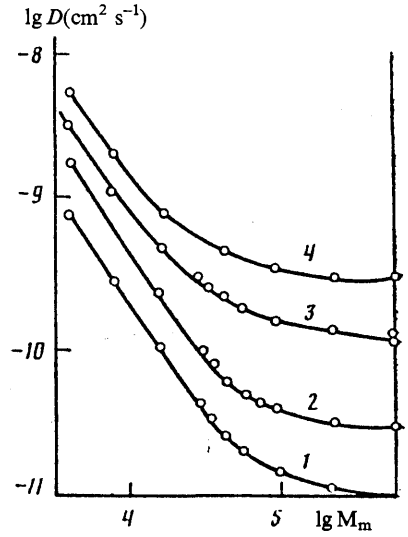

Figure 6. Dependence of $\lg D$ for a trial chain on $\lg M_m$ of the surrounding medium for PS molecules in a polystyrene matrix (T = 212 °C); 10^{-4} M: *1*, 10; *2*, 5.8; *3*, 3.0; *4*, 1.8. The points on the right-hand axis represent diffusion in a weakly cross-linked gel.

2. The motion of a chain through a weakly cross-linked gel

We shall consider the motion of a chain through a matrix with infinitely large molecules, i.e. a weakly cross-linked gel.[20] Suppose that the "local" molecular motion has developed fairly strongly and is characterised by a segment diffusion coefficient D_A. This is the

most direct instance of the manifestation of the reptation motion of a macromolecule: the chain can move only via the terminal element. Suppose that the length of the macromolecule is L ($L = NA$). Using the distance between the nodes of the quasi-network (N_c is the number of segments between quasi-cross-links), one can write the following formula for the overall length of the axial line of the tube:[17]

$$L_\tau = NA/N_c^{0.5} = L/N_c^{0.5}.$$

It follows from Eqn. (1) that the diffusion coefficient of the macromolecule within the tube is $D_T = D_A/N$. The time τ required for the chain to leave the initial tube is given by

$$\tau = \frac{l_\tau^2}{2D_\tau} = \tau_A \frac{N^3}{2N_c}, \quad (5)$$

where τ_A is the relaxation time of the segment. Although the chain migrates along the tube over a distance L during the time τ, nevertheless in space this migration is much smaller, since the tube is strongly bent [see Eqn. (3)]. The mean square of the displacement of the chain† during the time τ is $<X^2> = LA$. The following relation can then be obtained for the self-diffusion coefficient:[20]

$$D_{DG} = \frac{LA}{2\tau} = \frac{D_A N_c}{N^2} = D_R \frac{N_c}{N}. \quad (6)$$

Thus, for a very long chain, we have $D \propto N^{-2}$ in contrast to $D \propto N^{-1}$ for a short chain [see Eqn. (1)], i.e. Eqns. (1) and (6) yield the limiting laws governing the dependence of D on N.

Real macromolecules have a finite molecular weight. Calculations of the dependence of D on N for chains with a finite molecular weight have been performed.[22] The mean square of the displacement of the terminal chain element B^2 along the tube is specified by Eqn. (3). Since the relaxation time of the chain in this tube is $\alpha_T = L^2/2D_T$, we obtain finally

$$D_B = \frac{B^2 D_A}{L^2 N} = \frac{D_A}{N}\frac{B^2}{L^2}. \quad (7)$$

When $L < b$, we have $B^2 = L^2$ [see Eqn. (3)] and $D_B \propto D_A N$, i.e. the Rouse formula is obtained, whereas in the case where $L > b$ we obtain $B^2 = Lb$ and $D_B \propto D_A b/NL$, which corresponds to the de Gennes formula if it is assumed that $b = N_c A$. In the general case $D \propto N^{-1}$—N^{-2} [between N^{-1} and N^{-2}] and α is in the range from 1 to 2 [see Eqn. (4)].

We shall compare quantitatively the theoretical and experimental data. Here, we shall consider only the results of the study of the diffusion coefficients of a "trial" macromolecule diffusing in a matrix with an infinite molecular weight. We shall designate this value of D by D_∞. It is convenient to analyse the values of $D_\infty M$, whereupon Eqn. (7) is transformed into

$$D_\infty M = D_A M_A (B^2/L^2). \quad (8)$$

Fig. 7 illustrates the dependence of $\lg(D_\infty M)$ on $\lg M$ for PDMS [29] and PS [28,30] melts and also the dependence of $\lg(B^2/L^2)$ on $\lg(L/b)$ calculated by Eqn. (3). Evidently the theoretical curves reproduce correctly all the characteristic features of the experimental curves. A quantitative agreement can be obtained if the following values are selected: $D_A M_A = 4 \times 10^{-4}$ cm^2 s^{-1} and $M_b = 5 \times 10^3$ for PDMS and $D_A M_A = 6.3 \times 10^{-6}$ cm^2 s^{-1} and $M_b = 1.2 \times 10^4$ (D = 212 °C) for PS, M_b being the molecular weight of a chain section with a length b. The quantities M_b are close to the "critical" molecular weights obtained from rheological data. The quantities $D_A \simeq 10^{-6}$ cm^2 s^{-1} (PDMS) and $D_A \simeq 10^{-8}$ cm^2 s^{-1} (PS) have reasonable values. For example, for M = 746, the experimental D is 2.2 × 10^{-6} cm^2 s^{-1}. The data obtained permit the claim that a quantitative agreement is observed between the theoretical and experimental results for melts with $M_m = \infty$.

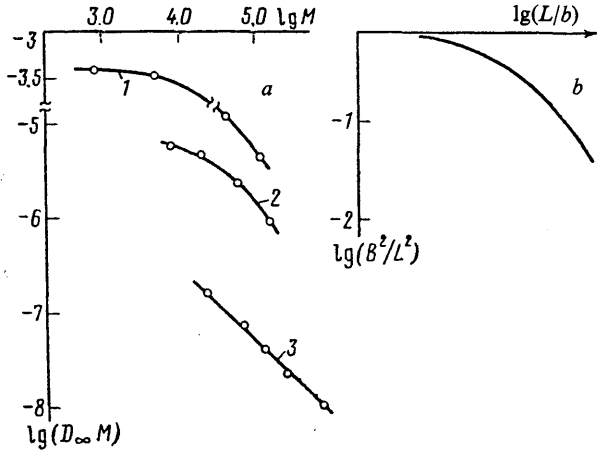

Figure 7. Dependence of $\lg(D_\infty M)$ on $\lg M$ (*a*) and of $\lg(B^2/L^2)$ on $\lg(L/b)$ (*b*) [the curve was calculated by Eqn. (3)]: *1*, PDMS;[29] *2* and *3*, PS.[28,30]

It is seen from the above analysis that, when $M < 10^3$ (PDMS) or $M < 10^4$ (PS), the diffusional motion of the macromolecule is of the Rouse type ($D \propto M^{-1}$). Only when $M > 10^4$ (PDMS) and $M > 10^5$ (PS) can one claim that the reptation type of motion is fully achieved. This means that, when $M > 10M_b$, the topological limitations by the surrounding medium on the mobility of the macromolecular chain are decisive. In view of such "diffuse" transition from one type of motion to another (a $10M_b$ range), the different literature values of "critical" molecular weights determined by different methods become understandable. Here it is essential to note that the study of the self-diffusion of "labelled" macromolecules provides a unique possibility for varying separately both the molecular weight of the diffusing chain and the molecular weight of the surrounding medium. In the usual rheological studies these two parameters are varied simultaneously, which hinders a quantitative interpretation (see the next Section).

3. Motion through a matrix with a finite molecular weight

Together with the diffusion of a chain along the tube, the process involving the renewal (relaxation) of the tube itself, as a result of the motion of other chains constituting the tube, take place.[17] The self-diffusion coefficient of the macromolecule in the melt (D_1) is then given by

$$D_1 = D_R + D_P, \quad (9)$$

where D_P is the component of D associated with the relaxation of

† The mean square of the distance between the ends of a chain with a length L is $NA^2 = LA$.

the tube and D_B is specified by Eqn. (7). The existing model theories have shown that D_P is proportional to N_c/P, N_c^2/P^2, and $N^{0.5}(N_c^2/P^3)$ [20,33,34] (here P is the number of segments in the matrix macromolecule surrounding the trial chain with a length N). Unfortunately the question of the selection of a particular dependence is so complex that fairly arbitrary hypotheses concerning the nature of the phenomenon are put forward in the studies mentioned above. One cannot therefore give preference at the present time to any one model and we therefore used the approach of the scaling theory for the description of the dependence of D_P on N.[35,36] We adopt the following functional relation for D_P (when $P > N_c$):

$$D_P = \frac{D_A}{N}(\gamma N_c/P)^n Z, \qquad (10)$$

where γ and n are empirical coefficients and Z is the probability that the molecule is located in the tube, i.e. is subjected to topological limitations by the surrounding medium as regards motion across the contour line:

$$Z = 1 - \exp[-(P - N_c)/N_c].$$

When $P < N_c$, we have $Z = 0$ and, when $P > N_c$, we have $Z = 1$.

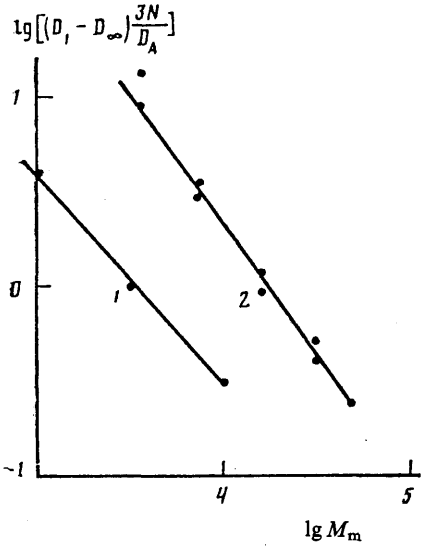

Figure 8. Dependence of $\lg[(D_1 - D_\infty)(3N/D_A)]$ on $\lg M_m$ for PDMS (curve *1*) and PS (curve *2*) according to different data.[28-30]

The coefficients γ and n can be found by analysing the experimental data. Suppose that $P > N_c$ ($Z = 1$). We then examine the variation of $(D_1 - D_\infty)(3N/D_A)$ as a function of M_m. Fig. 8 illustrates the dependence of $\lg[(D_1 - D_\infty)(3N/D_A)]$ on $\lg M_m$ for PDMS [29] and PS.[28] The quantities n (1.1 for PDMS and 1.4 for PS) and γ (0.28 for PDMS and 0.12 for PS) can be determined from the straight lines presented. The similarity of the empirical coefficients n and γ obtained for different objects shows that the hypotheses put forward are reasonable.

Thus we obtain finally for the self-diffusion coefficients of the melt[35,36]

$$D_1 = \frac{D_A}{N}\left[\frac{Lb - \frac{b^2}{2}[1 - \exp(-2L/b)]}{L^2} + Z\left(\gamma\frac{N_c}{P}\right)^n\right]. \qquad (11)$$

Fig. 9 presents the theoretical dependences of D_1M/D_AM_A on M_m/M_b for different values of M and n. Evidently the self-diffusion coefficients presented decrease with increase in M_m and tend to a limit which is independent of M_m (cf. Fig. 6). The observed relations are consistent with experimental data.

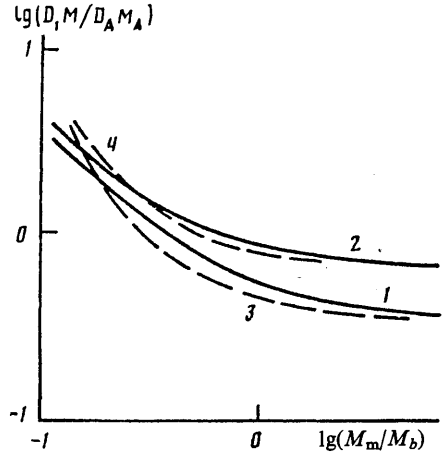

Figure 9. Dependence of $\lg(D_1M/D_AM_A)$ on $\lg(M_m/M_b)$ calculated by Eqn. (11) for $n = 1$ (curves *1* and *2*) and $n = 1.5$ (curves *3* and *4*) ($\gamma = 0.2$) with $N/N_c = 2.5$ (curves *1* and *3*) and $N/N_c = 0.5$ (curves *2* and *4*).

In the study of the dependence of D on M, the molecular weights of both the moving chain and of the surrounding medium are usually varied, i.e. $N = P$. Fig. 10 illustrates the dependence of D_1M/D_AM_A on M/M_b for $N = P$ calculated by Eqn. (11). In the range where $N > N_c$, the contribution of the second term in brackets is insignificant, i.e. the role of the "tube" renewal processes is the self-diffusion phenomenon is insignificant in this range of N. For $N \simeq N_c$, the "tube" renewal process can already play a definite role and when $N < N_c$ the very concept of the "tube" and reptation loses physical significance. Thus the second term in Eqn. (11) is significant only in the region where $N \simeq N_c$. Fig. 10 also illustrates the $D \propto N^{-2}$ relation, which gives rise to the $D(N)$ limiting law at $N \to \infty$. Evidently the straight line obtained in terms of logarithmic coordinates is close to the curve calculated from Eqn. (11). Allowance for the second term in Eqn. (11) then expands the region of applicability of the $D \propto N^{-2}$ law to cover also the region of low molecular weights. Fig. 10 also presents the dependence of D_∞ on M plotted in terms of the approximate formula

$$D_\infty = \frac{D_A}{N}\frac{1}{1 + L/b}. \qquad (12)$$

This relation is more convenient for analysis and actually agrees with the more accurate relation (7).

Thus it is seen that the relations obtained describe quantitatively the behaviour observed for self-diffusion coefficients in melts.

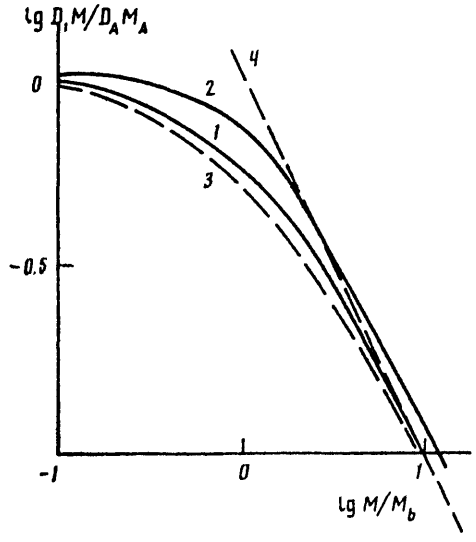

Figure 10. Dependence of $\lg(D_1M/D_AM_A)$ on $\lg(M/M_b)$ calculated by Eqns. (8) (curve *1*) and (11) (curve *2*) for $N = P$. Curve *3*, calculated from the approximate formula (12), and curve *4*, representing the limiting law governing the variation of D with M ($D \propto N^{-2}$), are presented for comparison.

IV. Self-diffusion in concentrated polymer solutions

1. General relations

In the region of dilute solutions, the theory of the translational mobility of macromolcules has been developed using Kirkwood's ideas about intermolecular hydrodynamic interactions between the elements of a chain macromolecule. The simplest relation for D when $c \to 0$ (D_0) is

$$D_0 = \frac{kT}{N\zeta}(1 + 1.843\sqrt{N}), \qquad (13)$$

where c is the concentration in g cm^{-3}. For more accurate and complex relations, see Rafikov et al.[7] All the available experimental data indicate a satisfactory agreement between the theoretical and experimental relations in the region of very dilute solutions.

The concentration dependence of D in the region of moderate concentrations has been investigated for certain systems in fair detail.[1,2] In the first studies, the authors concluded[37–39] that the scaling relations hold fairly well for the $D(c, M)$ function. It is essential to note tht the studies were performed in a restricted concentration and molecular weight range. However, in later investigations[40–45] a discrepancy between the predictions of the scaling theory and experimental relations was noted. The range of experimental concentrations of the solutions was greatly extended by Sundukov et al.[43] Fig. 11 [43] presents the dependence of D on c for solutions of poly(ethylene oxide) in dioxan.

Proceeding to the analysis of the dependence of D on c (or the volume concentration φ), it is necessary to take into account in the first place the variation of D_A (or ζ) as a function of φ. Failure to take into account the variation of the segmental mobility with increases in concentration has led in some of the early studies to incorrect conclusions. The variation of D_A (or ζ) with φ is usually described by a relation obtained on the basis of the free volume theory [see Eqn. (22) below]. The variation of D_A with φ can be taken into account more rigorously by an experimental procedure. The determination of the dependence of the self-diffusion coefficient of the solvent D_S on φ appears to be most correct.[16] In some investigations, it has been suggested that the spin–lattice relaxation times,[13,46] the monomeric friction coefficients determined from the viscoelastic properties of solutions,[44] etc. can be used to determine the dependence of D_S on φ. Below, we shall consider the reduced self-diffusion coefficient $\tilde{D} = D/D_A$. The quantity $\tilde{D}$ no longer depends on the variation of the local mobility with increasing concentration of the polymer solution.

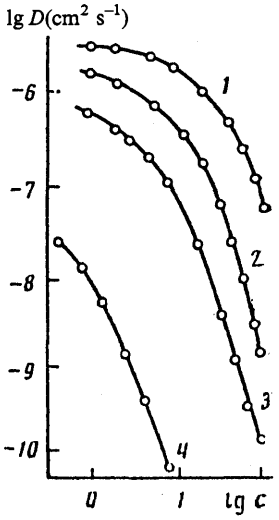

Figure 11. Dependence of $\lg D$ on $\lg c$ for PEO solutions in dioxane; 10^{-4} M: *1*, 0.2; *2*, 2; *3*, 4; *4*, 30.[43]

As in the analysis of the dependence of the viscosity of polymer solutions on concentration,[16] it has been suggested in some studies that generalised coordinates be employed for the representation of the dependence of D on c for solutions of different fractions. Thus the present author[15,47] proposed the generalised coordinates $\tilde{D}-c[\eta]$ (Fig. 12), while Sundukov et al.[43] proposed $D-(c/c_p)$, where c_p is an empirical quantity selected for each solution with a given molecular weight (Fig. 13).‡ In terms of these coordinates, it is possible to obtain a generalised dependence of D on c and M for solutions having different molecular weights in solvents of different kinds

‡ Here it is essential to note that the dependence of c_p on M is close to that of $[\eta]$ on M.

(differing in the interaction between the solvent and polymer molecules) and for polymers with different chemical structure of the chain.[47]

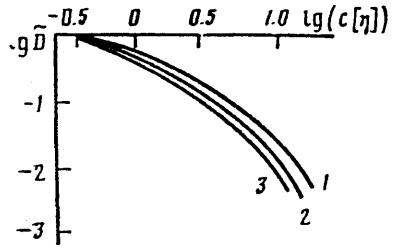

Figure 12. Dependence of $\lg \tilde{D}$ on $\lg\{c[\eta]\}$ for PS (curve *1*), PDMS (curve *2*), and PEO (curve *3*) solutions.

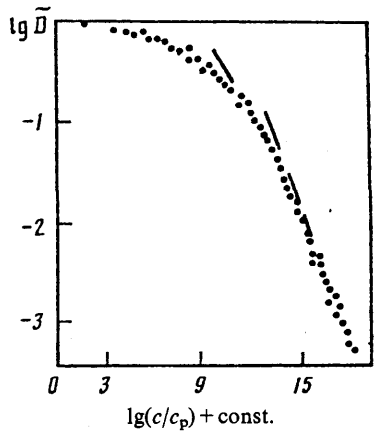

Figure 13. Dependence of $\lg \tilde{D}$ on $\lg(c/c_p)$ for PEO solutions in dioxane.[43] Data for different fractions are presented (see the caption to Fig. 11).

2. Theoretical relations for D in concentrated solutions

The main experimental relations between D and M have been explained by the present author.[36,47] Indeed, in the analysis of data for moderately concentrated solutions it is necessary to take into account the presence of the units of other macromolecules whose interaction with the units of the main chain diminishes the intramolecular hydrodynamic interactions of the selected macromolecule. There is no rigorous solution of this type of problem. However, the use of the "effective hydrodynamic field" model for the description of the hydrodynamic interactions of elements moving in a viscous liquid[48,49] proved successful. An equation for the dependence of D on M and φ was obtained:[47]

$$D(\varphi) = \frac{kT}{N\zeta}[1 + 1.843\sqrt{N}\exp(-1.27\sqrt{c[\eta]})]. \qquad (14)$$

Eqn. (14) is valid in the following concentration ranges: $1 < c[\eta] < c^*[\eta]$, where $c^*[\eta] = 0.64(\ln 2\sqrt{N})^2$. For the usual values of N, the upper limit is $c^*[\eta] \simeq 10-15$.

Fig. 14 illustrates the dependence of $\lg \tilde{D}$ on $\sqrt{c[\eta]}$ for PS, PDMS, and PEO. In terms of these coordinates, linear $D = f\{c[\eta]\}$ relations are observed and can be described by the following empirical equation:

$$\ln(\tilde{D}/\tilde{D}_0) = -(1.15-1.4)\sqrt{c[\eta]}. \qquad (15)$$

The slopes of these relations (1.15 – 1.4) are close to 1.27 [see Eqn. (14)].

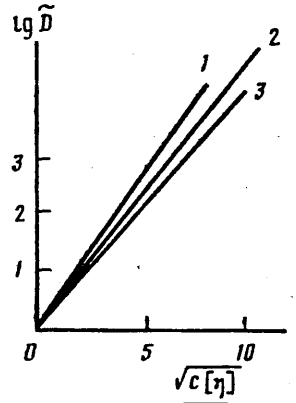

Figure 14. Dependence of $\lg D$ on $\sqrt{c[\eta]}$ for solutions of different polymers: *1*, PDMS; *2*, PS; *3*, PEO.

The values of α in Eqn. (4) vary continuously with c from +0.5 to 1 in contrast to the stepwise variation, predicted by the scaling theory, from $1(c < c^*)$ to $2(c > c^*)$. The dependence of α on $c[\eta]$ then differs somewhat for different values of N (Fig. 15*a*).

The influence of the molecular weights of the moving macromolecule and of the surrounding medium on the $D(c)$ relation have been considered separately.[35] In conformity with the notation adopted for the specified macromolecule and the macromolecules of the surrounding medium (N, P), the following equation can be written for the $D = f(c)$ relation:

$$D = \frac{D_A}{N^{0.5}}\left[\frac{1}{1.843N^{0.5}} + \exp(-1.27\sqrt{c[\eta]})\right].$$

Here $[\eta] = 0.6\bar{\nu}P^{0.5}$, where $\bar{\nu}$ is the specific partial volume. In these equations, the exponents of N and P are 0.5 (θ-conditions).

3. Self-diffusion in concentrated polymer solutions

In this concentration range, there are in fact no experimental data for the dependence of D on c and M. However, the existence of experimental and theoretical data for moderate concentrations and for polymer melts makes it possible to obtain reasonable relations also for high concentrations. The scaling theory can be used conveniently to describe the dependence of $\tilde{D}$ on φ.[35,36,47] The dependence of $\tilde{D}$ on φ is usually considered in the form

$$\tilde{D} = \tilde{D}_R(\varphi/\varphi_{th})^{\beta}(\varphi > \varphi_{th}), \qquad (16)$$

where φ_{th} is the threshold concentration proportional to $[\eta]^{-1}$ and β is a numerical coefficient. β is found from the condition $D(\varphi \to 1) \propto N^{-2}$.

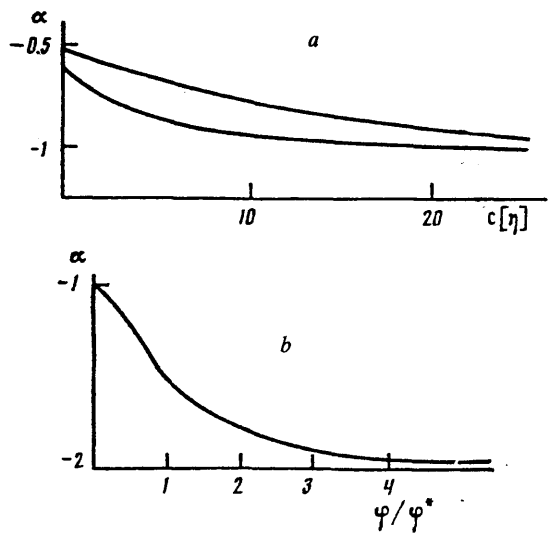

Figure 15. Dependence of α on $c[\eta]$ (*a*) and on φ/φ^* (*b*): *1*, $N = 10^3$; *2*, $N = 10^2$.

The scaling theory was first used to describe the $D(\varphi, M)$ function by Daoud and Jannink.[50] Since here we consider only the region of concentrated solutions (the θ-region), we have for the latter $\beta = -2$,[47] i. e.

$$\tilde{D} = \tilde{D}_R(1/\varphi^2 N). \tag{17}$$

However, the relations obtained in this way[47,50] suffer from one significant disadvantage. By analysing the $D \propto N^{-\alpha}$ relation [Eqns. (16) and (17)] we see that $\alpha = 1$ when $\varphi < \varphi_{th}$, $\alpha = 2$ when $\varphi > \varphi_{th}$ and α has no significance at the point φ_{th} when $\varphi = \varphi_{th}$. Naturally, there is in reality no such discontinuity in the dependence of α on φ.[37–45] This inaccuracy of the scaling theory has been removed[35] by invoking the concept of the reptation character of the motion of the macromolecule in the region of high concentrations.

We shall consider Eqn. (12). The quantity b (or N_c) is known to increase with decrease in concentration. Since the region of high concentrations is the region of the θ-solvent, it follows that, according to the scaling theory, we have

$$N_c(\varphi) = N_c/\varphi^2. \tag{18}$$

Substitution of Eqn. (18) in Eqn. (12) yields the following relation for the component D_∞ (when $\varphi > \varphi^*$):

$$D_\infty = \frac{D_A}{N} \frac{1}{1 + \varphi^2 N/N_c}. \tag{19}$$

The quantity φ^* is determined from the equation

$$\varphi^* = \sqrt{N_c/N}. \tag{20}$$

For the usual polymers, $N_c \simeq 100$, whereupon $\varphi^* = 0.2-0.3$.

Evidently Eqn. (19) gives rise to a continuous transition from $D \propto N^{-1}$ to $D \propto N^{-2}$. Omitting the intervening stages, we quote the final relation:

$$\tilde{D} = \tilde{D}_R\left[\frac{1}{1 + \varphi^2 N/N_c} + Z_\varphi\left(\gamma \frac{N_c}{\varphi^2 P}\right)^n\right], \tag{21}$$

where Z_φ is the probability that the macromolecule is in a tube at a specific concentration φ. For $\varphi < \sqrt{N_c/P}$, we then have $Z = 0$ [see also the explanation of Eqn. (10)]. The dependence of α on φ can be calculated from Eqn. (21) [see Eqn. (4)] (Fig. 15). Evidently, α varies continuously from 1 to 2. The $\alpha(\varphi)$ relation depends somewhat on the molecular weight of the surrounding medium.

The general dependence of D on φ (and not only the dependence of $\tilde{D}$ on φ) should take into account also the dependence of D_A (or D_S) on φ. The most generally accepted approach to the analysis of $D_S(\varphi)$ is associated with the "free volume" theory.[16] The simplest relation for the dependence of D_S on φ is

$$D_S = D_S(0) \exp\left\{-\frac{B_1\beta_1\varphi}{f_S(f_S - \beta_1\varphi)}\right\}, \tag{22}$$

where B_1, β_1, and f_S are parameters of the free volume theory.[12] For more complex relations governing $D_S(\varphi)$, see Budtov and Konsetov[16] and Budtov.[51] For a wide class of flexible chain polymers without specific interactions (hydrogen bonds, ionic bonds), the limits of the variation of the ratios B_1/f_S and β_1/f_S have been obtained: from 3 to 5 and from 0.25 to 0.4 respectively.[16] Interesting results concerning the influence of the size of the solvent molecules on these coefficients have been given.[52] For $d \lg D/d \lg \varphi$, we obtain

$$\frac{d \lg D}{d \lg \varphi} = \beta(\varphi) + \frac{B_1\beta_1^2\varphi}{f_S(f_S - \beta_1\varphi)^2}. \tag{23}$$

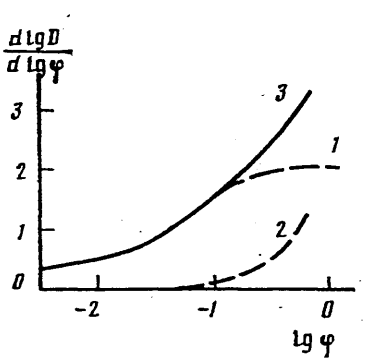

Figure 16. Dependence of $d \lg D/d \lg \varphi$ on $\lg \varphi$ calculated by Eqn. (23): *1*, the contribution of the first term in Eqn. (23); *2*, the contribution of the second term; *3*, the overall contribution.

Fig. 16 presents the dependence of $d \lg D/d \lg \varphi$ on the most typical representative of PS polymers (with toluene as the solvent). Evidently, when $\varphi \simeq 0.1$, the second term in Eqn. (23) constitutes an insignificant proportion of the first, while under conditions where $\varphi > 0.3$ it has to be taken into account.

Interesting studies have been initiated on self-diffusion processes during phase separation in polymer solutions.[53,54] Special methodological procedures have been proposed, which make it possible to estimate the self-diffusion coefficients in different phases from the non-exponential decay of the spin echo in NMR.

V. Characteristic features of the self-diffusion in oligomer melts and solutions

The relations discussed above are valid for fairly long chain molecules. When the self-diffusion of oligomers is investigated, other unusual dependences of D on M are observed.[55]§ The dependence of D on M for oligomers can be conveniently analysed in terms of the coordinates $(D_1/L_0)L - L$ (Fig. 17).¶ Evidently, in terms of these coordinates, D_1/D_0 for ethers and esters and also for n-alkanes initially diminishes with increase in L, but, when $L \simeq 30$ Å, the quantity D_1/D_0 no longer depends on L. If the end groups or other specific groups in the chain are in groups of atoms characterised by a strong interaction with the surrounding molecules, then the dependence of D_1/D_0 on L is different: the quantity increases with increase in L and subsequently attains a plateau. When the influence of the inhomogeneity of the chain structure can be disregarded ($L > 30$ Å), the ratio D_1/D_0 assumes the same value for all the systems investigated.

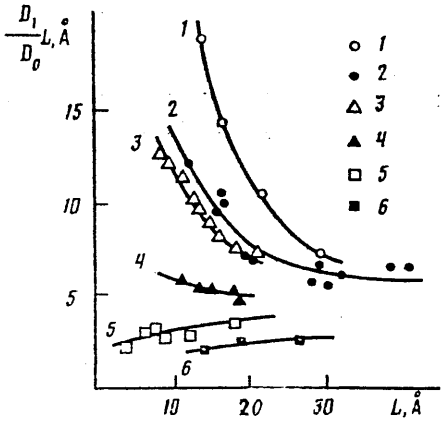

Figure 17. Dependence of $(D_1/D_0)L$ on L for different substances: *1*, ethers; *2*, esters; *3*, n-alkanes; *4*, phthalates; *5*, alcohols; *6*, acids.

The above effects can be accounted for using the free volume theory without resorting to the concept of aggregation. Indeed, it is well known that $f = f_0 + \Delta/N$, where f_0 is the fraction of the free volume for a homogeneous chain, N is the number of chain elements, and Δ is the increment in the ratio of the free volumes of the characteristic group and the repeating chain element. Then the diffusion coefficient of the oligomer D_{ol} depends on M in a complex manner:

$$D_{ol} = D_{hom}(M)\exp\left(\frac{\beta_L}{f_0}\frac{\Delta}{N}\right), \quad (24)$$

where D_{hom} is the diffusion coefficient for a homogeneous chain.

Indeed, in terms of the coordinates $\lg[(D_{hom}/D_0)L] - 1/L$, a set of curves, arranged fanwise, is observed and from their slopes it is possible to determine Δ for particular functional groups:

Group of atoms (or atom)	—O—	$-CH_3$	$-CH_2-$	C_6H_5-	>C=O	—OH	
Δ	5.4	1.7	0	—3.3	—3.5	—4.3	—11.5

The negative values of Δ indicate the retardation of the "local" motion of the corresponding group compared with the motion of the $-CH_2-$ group. These results make it necessary to treat with caution the interpretation of the dependence of D on M when low-molecular-weight polymers ($M < 10^4$) are considered. Unfortunately these effects are not taken into account in the majority of studies discussed.

VI. Numerical modelling of the translational mobility of macromolecules

The modelling of the mobility of macromolecules by means of direct computer simulation of molecular models by Monte Carlo (MC) and molecular dynamics (MD) methods has come to be widely used in recent years.[6] The first studies on the analysis of small scale movements of generalised polymer chains by the MD method were carried out Balabaev et al.[58] Subsequently this approach was widely employed for the solution of specific problems. However, the majority of calculations were limited to the consideration of lattice systems idealised to the maximum extent, while for a microscopic description of the system it is essential to take into account explicitly the interactions between all the species (atoms). This imposes significant limitations on the number of species and their dimensions (molecular weights) and also on the time of observation of the species.[59]

A significant achievement of the dynamic calculations in the study of condensed systems has been the demonstration of the fact that the widely held hypothesis that the diffusion of species in a simple monotonic liquid has a jump (activation) mechanism does not correspond to the real picture of molecular motion.[60] The molecular flux of species in such a liquid involve successive small displacements of the molecules. A negligibly small contribution of "large jumps" to the overall diffusional flux is observed. An appreciable influence by attraction forces on the relaxation of large chain fragments has also not been discovered.[61] This type of motion has in fact been taken into account by the "free volume" theory[16] [see Eqn. (22)].

It has been shown[62] that the mobility of the terminal chain elements differs from the mobility of the central elements, which is consistent with the observations made for oligomers (see Section V). The question of the anisotropy of the motion of the chain unit has been considered[63] for a liquid polymer. It was shown that for short observtion times, the tangential component of the mobility is smaller than the transverse component. However, for large observation

§ Similar effects have been observed also both for the viscosity η and for $[\eta]$ of oligomers.[56,57]

¶ Here D_1 and D_0 are the self-diffusion coefficients of oligomers for $\varphi = 1$ and $\varphi = 0$.

times, the units are able to diffuse over a distance close to the average distance between the nearest neighbouring macromolecules in the system. The surrounding chains hinder the motion of the chain considered and force the units to move preferentially along the chain contour, i.e. the anisotropy of the mobility is significant. For a dilute solution, the anisotropy of the mobility is manifested to the least extent. It is essential to note that attempts to observe reptation processes (the anisotropy of mobility) yielded a negative result in the studies of Baumgartner and Binder[64] and Evans and Edwards[65] due to the small chain length and the short observation time.[66]

Within the framework of the pseudostochastic Verdier–Stockmayer model, the dynamics of an assembly of particles has been investigated.[57,58] It was shown that $D \propto N^{-\alpha}$, increasing with increasing concentration (Fig. 15). The $<X^2> \simeq t^g$ relation also varies with increasing concentration: g diminishes to 0.2 (see above).

The diffusion of a chain macromolecule in a matrix with stationary elements which the diffusing chain cannot cross has been modelled on a computer.[69] The distance between such obstacles is d. It was found that[22] the dependence of $D(d)/D(\infty)$ on N^2/d is represented by a single curve regardless of the value of d. It coincides with the dependence of D on L/b specified by Eqn. (7) if it is assumed that $bA = 2d^2$. This relation ($bA = 2d^2$) resembles the familiar formula for the square of the length of a chain whose contour length is b.

Thus it is seen that the principal results of numerical modelling have been reflected in analytical models and have been observed experimentally. An important feature of computer modelling is that it is possible to obtain unique information about the local structure of the material.

---o0o---

The experimental and theoretical results presented in this study show that the dependences of the self-diffusion coefficient on concentration and on the molecular weights of the diffusing macromolecule and of the surrounding medium have been fairly thoroughly investigated and can be described quantitatively. The influence of the interaction of the chain with the solvent on the self-diffusion coefficient has been discovered. The characteristic features of the diffusion of oligomers have been examined.

The relations obtained can be used to solve a wide range of problems in the physical chemistry of polymers.

Isoprenoids as natural products with a wide variety of functions†

Vlastimil Herout
Institute of Organic Chemistry and Biochemistry, Czechoslovak Academy of Science, Prague

ABSTRACT. The available information about certain biological properties of isoprenoid is surveyed. Their role in the regulation of the vital activity of plants and insects as well as their ecological importance, consisting in ensuring the coexistence of organisms of different classes, are demonstrated. Certain structural elements essential for the manifestation of antifeedant activity are indicated.

The bibliography includes 47 references.

III. Conclusion 1008

I. Introduction

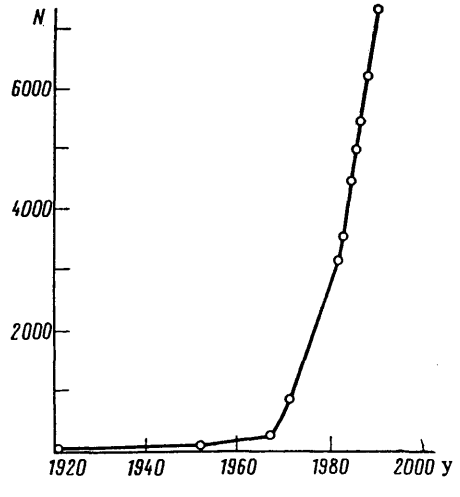
The enormous strides which isoprenoid chemistry and biology have made in the recent decades necessitate a survey of the present state of our knowledge of the importance of isoprenoids as biologically active compounds. The information explosion resulting from the current vigorous research into this topic can be illustrated by two examples: (1) the Glasby Encyclopaedia of Terpenoids (edited in 1982) which still contains not less than 10 000 compounds after the exclusion of all data on natural steroids. (2) The present author's illustration by a graph of the enormous rise of the number of natural sesquiterpenoids found hitherto (Fig. 1). Fig. 1 shows the number of compounds of this single class of terpenoids, which was more than 7500 by the end of 1987, over half being sesquiterpene lactones. The curve has a consistently exponential shape. During 1970 and 1971,[1] the author attempted to summarise the data available at the time on the biological activities of (1) all isoprenoids[1] (one chapter comprising 50 pages of concentrated information) and (2) all data concerning sesquiterpenoids[2] (a 37 page chapter). However, it was already evident that we obtain information about the structures of newly described natural products much faster than data on different types of their biological activity. The latter are often combined nowadays with data on their ecological importance.

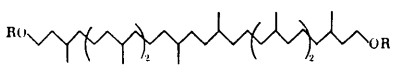
† Lecture delivered by Prof Herout at the Czechoslovak-Polish Meeting on Isoprenoids (1987), the relevant data being presented at the Zelinskii Institute of Organic Chemistry, Moscow, in 1988.

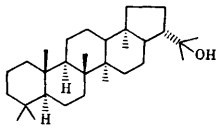
The version printed here is based largely on the English text kindly supplied by the author and partly on the Russian translation by N Ya Grigor'eva (edited by A M Moiseenkov) (Ed. of Translation).

II. Secondary isoprenoid metabolites as biologically important compounds

The question which the author put as early as 1970, namely "are secondary metabolites (in our case isoprenoids) present in plants only as waste products?", is being solved nowadays more or less unambiguously. Of course they are biosynthesised as "secondary" metabolites, but many (if not all) are essential for the life and/or survival of plants. It is now known that similar "secondary products" are not produced exclusively by the plant kingdom but are used in a wide variety of different ways also in other domains: insects and diverse marine organisms are producers of typical isoprenoids and steroids. They are not only important regulators of life functions but their presence in intracellular membranes is essential for the complex functions of living cells. This is typical, with some differences, for all classes of organisms, for example, the most primitive of the existing micro-organisms, the so called archeobacteria, have the membranes in their unicellular bodies "fixed" or "reinforced" with the aid of α,ω-bisphytanol ethers (I). The more advanced "true bacteria" contain in their membrane triterpene derivatives, for example, of the hopane type (II) (cf. Ourisson[3]). At present most advanced organisms, such as plants, fungi, and animals, make use exclusively of sterols. These are phytosterols, such as sito-, stigma-, or campe-sterols for plants and ergosterol, for example, in the case of fungi, and cholesterol (III) for animals.







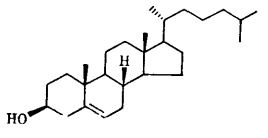


Figure 1. Growth as a function of time of the number of sesquiterpenoids (N) discovered in natural sources.

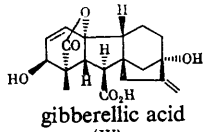
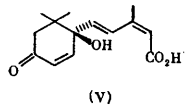
(I)

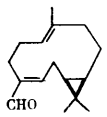


hopanol (II)



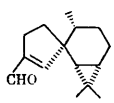
(III)

Djerassi's recent work[4] on the widely differing side chains in the sterols of marine organisms demonstrates that our knowlege of these facts remain far from perfect. The important place which hormones and vitamins as well as a number of other regulators and transferring agents occupy among secondary metabolites and which is closely related to the regulatory functions is noteworthy. Such substances have to be examined in greater detail. Certain vitamins are typical products derived from isoprenoids or steroids (A, D, E, K). Carotenoids, which are tetraterpene derivatives, have in addition important functions participating together with the chlorophylls in photosynthesis; phytol is an important component of the molecules of different chlorophylls. Steroid hormones are typical hormonal regulators in vertebrates, functioning as sexual hormones, corticoids, etc. We now have a deeper understanding of the function of ecdysteroids and juvenile hormones in the class of Arthropoda (insects, crustaceans) and probably worms (Annelida) as well. In the plant kingdom other isoprenoids function as hormones, for example, diterpenoids such as gibberellins (IV) (about 70 naturally occuring compounds of this type are known)[5] and the sesquiterpenoid abscisic acids (V) together with some of its metabolites.

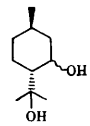


gibberellic acid

(IV)

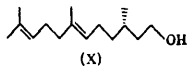


(V)

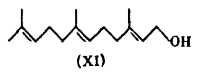


The function of the "prolongation factor" has been discovered, in addition to gibberellins, also in other compounds, especially brassinoids[6,7] during recent decades. The list of compounds of isoprenoid character able to influence the germination or growth of plants is also large. This influence, mostly in a negative sense, represents the known "allellopathic activity" of many plants in their fight against competing plants belonging to other species. Here mention will be made only of some components of liverworts discovered quite recently, for example, (–)-lepidozenal (VI) [8] and (+)-vitrenal (VII).[9] Monoterpene derivatives with the same mode of action are known in certain higher plants, such as the eucalyptus, for example *p*-menthane-3,8-diols (VIII) and (IX).[10]

(VI)



(VII)

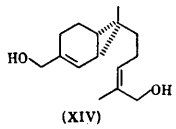


(VIII), (IX)

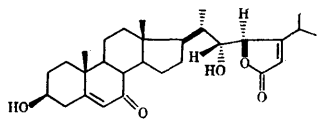
The important role of "secondary metabolites" in the coexistence with organisms belonging to different domains and hence their ecological importance have been traced during recent decades. In view of the manifold activity of isoprenoids, the above studies were concentrated on the latter. The activity of isoprenoids is frequently encountered in the interactions of different organisms belonging to all existing domains: Mabry and Gill[11] attempted to list the different types of activity of terpenoids in 1979 but today the list would have to be much larger. Only certain striking examples will be selected, since a detailed description would require several books. For example, the relatively recently discovered group of sesterpenoids (with 25 carbon atoms in their molecules)—not yet mentioned by Mabry and Gill—includes, according to a more recent review,[12] more than 160 compounds, mostly with functions of a defensive character. They are not restricted to plants but occur as metabolites of insects and especially of diverse marine organisms.

Isoprenoids do not by any means serve solely as deterrent substances. On the contrary, they frequently possess attractant properties. The scent of flowers has its value in attracting pollinators and many simple derivatives of the monoterpene series are generally known. Some of them have been adopted by insects as their own "pheromones", which is particularly interesting: a single example may be quoted: orchid (*Ophrys* sp.) pollinators are attracted from a distance to orchid flowers (and to flowers of similar, mainly tropical species) by scents of a sesquiterpene character (the name of the Swedish entomologist Kullenberg[13,14] may be mentioned in this connection), which are identical with the sexual pheromones of their females (such pollinators may be, for example, the solitary bees *Aculeate Hymenoptera*). The spectrum of the activity of simple aliphatic sesquiterpenoids is broad—for example, the dihydrofarnesol derivative terrestrol (X) [15] is a "territory marker" for the male bumble bee. Farnesol (XI) is a typical scent of certain flowers, while the basic hydrocarbon farnesene (XII) and its geometrical isomers are known "alarm"pheromones in certain Aphids.[16] Homo-derivatives of this series, for example homofarnesene (XIII) constitute[17] a "trail marker" for an ant (*Solenopsis invicta*).

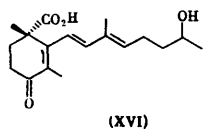
(X)



(XI)

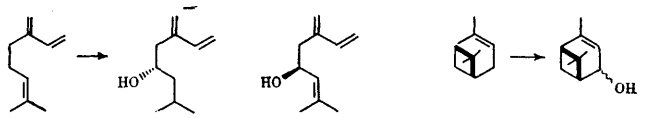


R = H (XII), R = CH_3 (XIII)



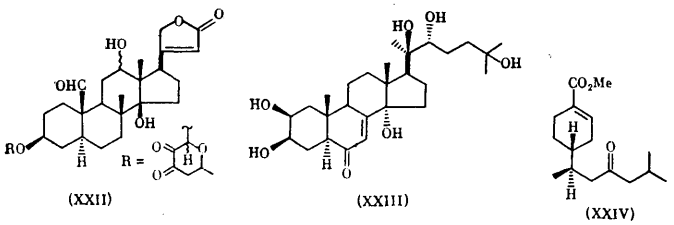
The sesquiterpenoid derivative sirenin (XIV) is known as a "sperm attractant" in the water-mould *Allomyces* sp., a fairly primitive organism on the evolutionary scale. Other examples where isoprenoids play a similar role in the sexual reproduction of fungi[18] are the steroid antheridiol (XV) and the nor-carotenoid derivative trisporic acid (XVI).

(XIV)



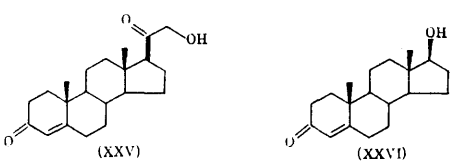
(XV)

(XVI)



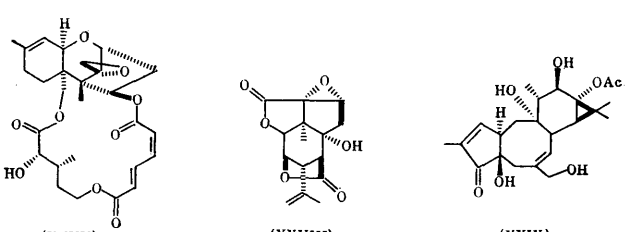
Certain compounds ingested with food and modified somewhat during their assimilation are frequently converted into derivatives with a new property, which is an entirely normal process. For example, the aggregation pheromones of certain bark beetles (*Ips* sp., *Dendroctonus*, etc.) convert some of the terpenoid derivatives in their food [for example, myrcene (XVII), α-pinene (XX)] into their own aggregation pheromone ipsenol (XVIII), ipsdienol (XIX), and/or *cis*- and *trans*-verbenols (XXI)—cf. Fergusson and Metcalf;[19] naturally, they usually contribute "another component", arising from their own biosynthetic capacity, to the mixtures of their pheromones.

(XVII) (XVIII) (XIX) (XX) (XXI)



Our "human" interest is concerned at present mainly with "deterrent" activities and we are therefore much more familiar with the latter. Individual monoterpene compounds, contained in most of the essential oils of the needles or barks of conifers, play, according to their quantity or concentrations, a decisive role in determining whether these plants will or will not be resistant to the attack of herbivores. The influence of myrcene, limonene, Δ^3-carene, α- and β-pinenes, and α-phellandrene has been frequently found to be a decisive factor in the animals' choice of food. They are probably not "toxic" in the narrow sense but are unpleasant and therefore deter. This is exemplified by the fact, discovered some years ago in our laboratories, that a mixture of this kind, resembling "turpentine oil", is used by the soldiers of certain *Nasutitermes* as a deterrent against their usual natural enemies—ants.[20] In this case the terpenoids do not originate from their food but are biosynthesised in their bodies.

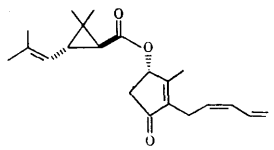
If we follow the activities of secondary metabolites, we can conclude that their function can often vary. The necessity to limit the active potential of any "secondary product" results in its being sequestered in some place in the body (for example, in the case of plants, in vacuoles, glandular trichomes, and resin- or milk-ducts) in such a way that it cannot disturb the vital functions of the organism producing it. It can of course be present in the form of a harmless precursor as well. By possessing such a "latent" active principle, organisms have secured a weapon against their enemies. Consider cardenolides as an example. The plants producing them are protected against many phytophages (as well as vertebrates, molluscs, and insects), since these compounds are toxic in the true sense—can be regarded as "antifeedants", since they deter most enemies. These compounds (or at least many of them), applied in appropriate doses, are used in human medicine as valuable stimulators of the heart's activity. Some insect species have discovered, during their coevolution with plants, how to "sequester" these noxious compounds in their own body, usually in the larval stage; however, cardenolides [for example, uzaridin (XXII)] are also maintained in pupae and later in adults. They thus gain a double advantage: firstly they secure a competitive advantage in being able to feed on plants with cardenolides in their tissues and, secondly, they are now toxic to their natural enemies such as lizards, birds, and others.[21] This is a rare but by no means a unique case, as we have recently discovered in a series of similar adaptations (not only for isoprenoids but also for alkaloids, cyanogens, etc.). A similar situation can be traced in other seemingly non-toxic compounds—hormones. Plants which were able to develop during their phylogeny the production of insect hormones [ecdysteroids, for example, ecdysterone (XXIII), or juvenile hormone simulators, for example, juvabione (XXI)], whose only importance according to present knowledge involves their ecological function, are protected from any insect phytophages, since the presence of their hormones in their food or in contact with their food can disturb the normal evolution of these organisms.



(XXII) (XXIII) (XXIV)

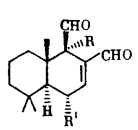
On the other hand, some insects produce relatively large quantities of vertebrate steroid hormones for their defense (for a series of these studies, we are indebted to Schildknecht[22]). Certain water beetles produce, for example, cortexone (XXV), testosterone (XXVI), etc. which protect them against vertebrates such as predatory frogs, fish, etc. The vertebrate hormones are probably useless against insects.

(XXV) (XXVI)



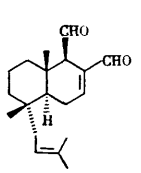
If we attempt to follow the complexity of compounds produced in nature as "secondary products", we encounter a distinct tendency—during the phylogeny of many taxa (especially in the plant kingdom), many complicated structures are biosynthesised successively and many "elaborate" molecules are also the most active. The author does not wish to develop a definition of the "toxic" principle in these terms, since very simple compounds such as HCN are toxic enough, but the isoprenoids which can be designated as "truly toxic" usually have a more complex structure. Trichothecenes are a good example[23] [see, for example, verrucarin A (XXVII)] of typically very active but very toxic antibiotics with a sesquiterpenoid moiety. Here one may include picrotoxinin (XXVIII), a compound isolated for its toxic properties, and phorbol (XXIX), a well known toxic component of plants belonging to the family *Euphorbiaceae* (cf. Evans and Taylor[24]).

(XXVII) (XXVIII) (XXIX)



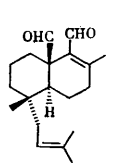
Other also relatively complex molecules, protecting their parent organisms, need not be toxic in the usual sense. We know of compounds which we simply designate as insecticidal, since they are relatively harmless to classes of organisms other than insects. It may be that they simply penetrate the special sort of chitin cuticle

which is important for arthropods. We shall mention as the only example pyrethrins (XXX) [25] with an isoprenoid component (chrysanthemic acid) in their molecules.



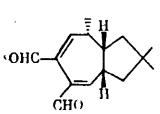
pyrethrin A (XXX)

We find that the physiological activity of secondary products is mostly not so specialised and their activity is then expressed in different ways—we speak of their bactericidal, fungistatic, and molluscicidal activities. As a result of the coevolution of plants (as the main source of food, directly or indirectly, of most other classes of organisms), their secondary metabolites represent a broad array of components with similar activities. Their phytophagous enemies have to develop sensory systems to protect themselves against feeding on noxious food. Such compounds are classified nowadays as deterrent compounds or antifeedants. These apparently include the vast majority of the known isoprenoids (naturally on the basis of the data published hitherto, although only a limited fraction of the compounds indicated have been investigated on these lines). However, certain rules concerning the structural prerequisites for "deterrents" can be derived from the limited number of examples available. The author's favourite examples are certain groups[26] which are found repeatedly in isoprenoid structures, in the first place a vicinal dialdehyde group, usually conjugated with a double bond, as in polygodial (XXXI) and in the related drimanes [warburganal (XXXII), ugadensidial (XXXIII)]. They are all very pungent to the human tongue and are deterrent to many insect herbivores. Polygodial was first encountered in *Polygonaceae* (*P. hydropiper*) and later in *Magnoliales* and independently in some liverworts (*Marchantiopsida*).

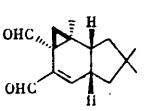


R = R' = H (XXXI)
R = OH, R' = H (XXXII)
R = R' = OH (XXXIII)

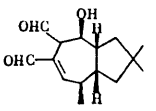
To complete the list, it also occurs in animals—molluscs (certain nudibranchs[27]). All these organisms are protected against their predators, although the latter are very different. For nudibranchs, it represents a unique weapon against fish. The same "model" is repeated in the diterpenoid series in liverworts, for example, in sacculatal (XXXIV) [28] and in perottetianal (XXXV).[29]



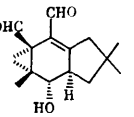
(XXXIV)



(XXXV)

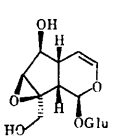


A similar pungent taste and protecting properties are known for the fruit bodies of many fungi which contain, for example, velleral (XXXVI), isovelleral (XXXVII), piperdial (XXXVIII), and merulidial (XXXIX).[30]

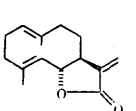


(XXXVI)

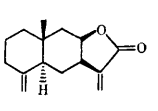
(XXXVII)



(XXXVIII)



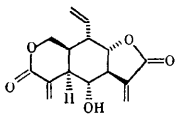
(XXXIX)

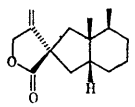


In the case of velleral, an interesting aspect of its deterrent activity was noted: in the fruit body, only a precursor (velutinol) is present. After mechanical damage to the fruit body's cells, it gives rise to the pungent velleral as a result of an enzyme reaction. Velleral, being unstable, later changes into another more stable compound. The idea of a parallel effect—the interaction with receptors on the human tongue and deterrent activity—was originally proposed by Kubo.[31] This is probably a much wider phenomenon and we believe that not only compounds giving rise to a "hot" or "pungent" perception but all bitter compounds act similarly. This concerns, for example, alkaloids, since the latter are mostly quite bitter, as well as other classes of compounds. Among isoprenoids, we know very many groups of bitter derivatives, for example, all iridoids[32] and especially their glycosides [for example, catalpol (XL)]. There is at present much evidence that they exhibit a common antifeedant activity. Furthermore, this concept agrees well with the properties of the large group of sesquiterpene lactones which have been investigated in the author's Prague laboratories for more than 40 years. In the author's research, the principal indication of their presence in a plant belonging to the family Compositae was a "sensory" one: the pungent taste indicated the presence of certain simple γ-lactones having a typical structure usually with an exocyclic methylene group and the lactone ring formed as a result of the oxidation of the methyl component of the isopropyl residue of the acyclic precursor and the subsequent ring closure at the hydroxyl in the α-position relative to this residue; typical examples are costunolide (XLI), isoalantolactone (XLII); for more information, see one of the latest reviews.[33]

(XL)

(XLI)

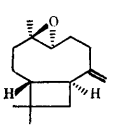




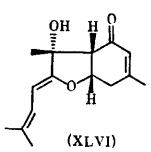
(XLII)

Compounds with a large number of oxygen-containing functional groups are usually bitter. The typical α,β-unsaturated γ-lactone group is believed to constitute the active principle, since it is capable of interacting with cysteine and of inducing cytotoxicity—a typical property in many kinds of biological activity.[34,35] This is the reason why many of these compounds were studied as possible anticancer agents. Vernolepin (XLIII) [36] was found to be the most active; its molecule contains two such lactone groups at once. More than 20 syntheses of this compound or its simplified derivatives have been described.

Dozens of the more than 3700 sesquiterpene lactones known at present have now been tested and found active in many respects (as antifeedants, not only for insects but also for mammals, bacteriostatic agents, fungicides, vermifuges, etc.). In many cases they induce human dermatitis. They are not in practical use and α-santonin is very obsolete today as a vermifuge. Nevertheless, in the plant kingdom they represent a good example of an antifeedant group which occurs repeatedly in classes which are distant on the evolutionary scale—mostly in *Compositae* (nearly 3500), *Umbeliferae* (more than 100), Magnoliales, and finally liverworts (more than 50



compounds). In our experiment, we demonstrated together with Dr Nawrot that the antifeeding effect for some insects **is not** necessarily combined with the α,β-unsaturation in the lactone ring [cf. the activity of bakkenolide (XLIV); cf. Harmatha and Nawrot[37]].

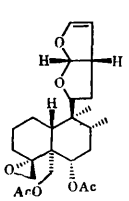


(XLIII)

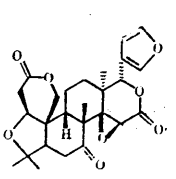
(XLIV)

The antifeeding activity is not limited to lactones, since many other active sesquiterpene compounds are known. An interesting compound is caryophyllene epoxide (XLV), which has been repeatedly identified as the antifeedant for leaf-cutting ants (*Atta* sp.); because of its fungistatic properties, caryophyllene epoxide stops the growth of a special fungus which is cultivated by these ants as food.[38]

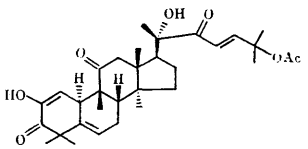
Compound (XLVI), a very potent antifeedant which is the main component of the seeds of *Angelica sylvestris*,[39] was discovered during our studies on bisabolangelone.



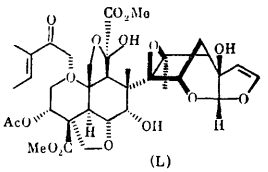
(XLV)



(XLVI)

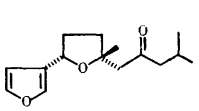


Diterpenoid derivatives are feeding deterrents as well. This concerns not only the many relatively simple diterpenic acids but especially two groups of bitter compounds—quassinoids[40] and clerodanes [as an example, see clerodin (XLVII)]. Clerodanes are the largest group of compounds tested hitherto for their antifeedant activities—more than 100 compounds (see the recent review of Van Beek and de Groot[41]).

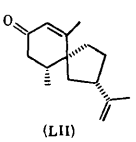


In the triterpene series, the same situation is repeated as in diterpenoids: apart from the relatively simple triterpenoids, certain groups of bitter compounds of this class are known, for example, cucurbitacins, limonoids, and/or meliacins. All their names are derived from the names of plant families [*Cucurbitaceae*; limonoids from the lemon; *Meliaceae*; for example, see limonin (XLVIII) and cucurbitacin E (XLIX)].

The most thoroughly studied compound until now, namely the tetranortriterpenoid azadirachtin, is a meliacin. It is the characteristic compound found in the neem tree (*Azadirachte indica*) and its very complex final structure (L) was established only recently by Kraus et al.[42] Three symposia and several books[43,44] have been devoted to this special antifeedant—still probably the only one in practical use in the form of alcoholic seed extracts. Rembold called it a "blessing for the developing countries", since in tropical areas it is readily available even to simple farmers.



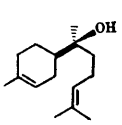
(XLVII)



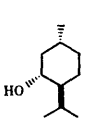
(XLVIII)

(XLIX)

(L)



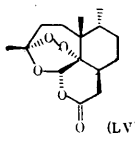
This is a brief resumé of the antifeedant history. It is incomplete since new groups with deterrent activity are being discovered, for example, saponins of triterpenoid and/or steroid origin. Whole books have been devoted to phytoalexins—compounds which are produced by plants only after they have been damanged, for example, by pathogenic fungi.[45] One fact must be emphasised as remarkable, namely plants of the family *Solanaceae*, which contain no sesquiterpenoids when in a healthy condition, produce exclusively the sesquiterpene derivatives ipomeamarone (LI) and solavetivone (LII) as phytoalexins for their protection.



(LI)

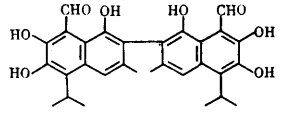
(LII)

III. Conclusion



An attempt has been made to comment very briefly on the broad spectrum of the biological activities of isoprenoids known at the present time. Owing to their important functions, they are used in many branches of human activity. Their importance in medicine is well known. They serve as medicaments in the form of natural products (hormones, vitamins, etc.) or as products of organic synthesis as well. They have retained their importance in perfumery and in the cosmetic industry at the time when synthetic materials have clearly come to the fore. However, as models, natural products remain irreplaceable. We shall consider two characteristic examples as an illustration. The author's studies of the common European medicinal plant camomile in the early 1950s led to the discovery of *l*-α-bisabolol (LIII)—its most important component with anti-inflammatory properties. At the present time, tonnes of synthetic dl-α-bisabolol are being produced by the BASF company, since it is one of the five most valued components of cosmetics. (–)-Menthol (LIV), an important product of the food industry (sweets, chewing gum, and, of course, cigarettes) is also made synthetically.

(LIII)



(LIV)

New compounds are being added to the contemporary medicinal preparations on the basis of recent studies on substances listed in the old "Materia Medica", i.e. traditional drugs of different nations. In China, where this is a very old tradition and recent research has been very active and fruitful, two preparations of isoprenoid origin have been discovered. Qinghaousu (LV) and its derivatives have been found[46] in *Artemisia annuua L.* They are also known as arteannuins or artemisimins. They are rare sesquiterpene lactones

with a cadinane carbon skeleton. These compounds constitute a very useful remedy against some forms of malaria—also in cases where the classical drug quinine is not successful. Furthermore, gossypol (LVI), a cadinane type of dimeric sesquiterpenoid, is now undergoing clinical experimental tests[47] as a chemosterilant for men (but not for women, since steroid derivatives are still normally employed for the latter).

(LV)

(LVI)

In agriculture and forestry novel means for the integrated fight against insect pests may be expected to be added to the hitherto most effective pyrethrin and the insecticides derived from this model substance, known as pyrethroids and constituting at the present time a major proportion of the agents used in practice. However, hitherto azadirachtin, mentioned above, is the only substance suitable for practical application; none of the others meet the rigorous criteria imposed on compounds of this kind. However, certain new (non-isoprenoid) natural products may prove to be more promising. I therefore end with a hopeful thesis: "Nature possesses much more potent means than we, humans, have been able to discover hitherto".

The use of $^{15}N-X$ (X = ^{29}Si, ^{73}Ge, $^{117/119}Sn$, ^{207}Pb) spin–spin coupling constants in structural studies on Group IV organoelement compounds

E Kupče, E Lukevics
Institute of Organic Synthesis, Academy of Sciences of the Latvian SSR, Riga

ABSTRACT. Data for the $^{15}N-X$ spin–spin coupling constants and their relation with the structure of Group IV organoelement compounds are surveyed. The ^{15}N and X chemical shifts are quoted. The experimental and theoretical aspects of the spin–spin coupling are briefly considered. It is shown that the possibility of measuring the given constants for the natural abundance of the isotopes and also of their sensitivity to the nature of the N–X chemical bond and various aspects of the electronic and steric structures of the molecules, which has arisen recently, has given rise to new prospects in strucural research on nitrogen-containing Group IV organoelement compounds.

The bibliography includes 80 references.

I. Introduction

The spin–spin coupling constants (SSCC) are a valuable source of information about the steric and electronic structures of molecules.[1–4] Almost all Group IV elements (with the exception of germanium) have natural isotopes with spin $I = 1/2$ (Table 1). This creates favourable conditions for the investigation of SSCC with participation of these nuclei X and provides a unique possibility for tracing the periodicity in the variation of SSCC for Group IV elements.

Until recently, the $^{15}N-X$ (X = ^{29}Si, $^{117/119}Sn$, ^{207}Pb) SSCC were measured only for individual compounds. One of the causes of this is the extremely low natural abundance of molecules with two magnetically active isotopes—^{15}N and X. Therefore all the data were obtained in the early stages of this research for isotopically enriched specimens, which required a considerable expenditure of time and resources for the synthesis of the labelled compounds. Nevertheless, the first investigations already showed that the $^{15}N-X$ SSCC (J_{NX}) can be used successfully in structural research.

Table 1. The NMR parameters of the nuclei of nitrogen and Group IVA elements.[16]

Nucleus	Natural abundance, %	Spin	$\gamma \cdot 10^{-7}$	$\lvert\psi_{ns}(0)\rvert^2$, a.u. (Ref.66)	Sensitivity* $\times 10^3$
^{13}C	1.10	$^1/_2$	6.7263	2.772	15.90
^{14}N	99.63	1	1.9331	4.775	1.01
^{15}N	0.37	$^1/_2$	−2.7116	4.775	1.04
^{29}Si	4.70	$^1/_2$	−5.3146	3.811	7.84
^{73}Ge	7.76	$^9/_2$	−0.9331	9.543	1.40
^{117}Sn	7.61	$^1/_2$	−9.5319	12.680	45.20
^{119}Sn	8.58	$^1/_2$	−9.9756	12.680	51.80
^{207}Pb	22.60	$^1/_2$	5.5797	20.53	9.13

* Relative to protons for the same number of nuclei and in a constant field B_0.

The $^{15}N-^{13}C$ spin–spin coupling constants were investigated in much greater detail than the constants involving other elements of this Group, which is undoubtedly due to the important role which the N–C bond plays in bioorganic chemistry. The $^{15}N-^{13}C$ spin–spin coupling constants have been examined in other reviews[5–7] and therefore will not be considered here. Furthermore, the chemistry of the remaining Group IV elements differs significantly from the chemistry of carbon. For example, such compounds are characterised by a greater tendency towards the formation of coordinate bonds and by a lower stability in the case of unsaturated compounds. The fields involving research into the SSCC differ correspondingly and their comparison is not always possible. Nevertheless, the principal conclusions and regularities observed in the study of the $^{15}N-^{13}C$ SSCC indicate the most promising aspects of such research. Thus the popularity and success of the empirical relations between the $^{15}N-^{13}C$ SSCC ($^1J_{NC}$) and different structural parameters, such as the hybridisation of the N and C atoms (the Binsch relation[8]), i.e.

$$80\,{}^1J(^{15}N—^{13}C) = \alpha_N^2\alpha_C^2 \qquad (1)$$

(where α is the amount of s character of the localised hybrid bond

expressed as a percentage), the pyramidality of the nitrogen atom,[7,9] the atomic charges, etc., demonstrates the usefulness of studies of this kind.

After superconducting magnets had been devised and a method had been developed for increasing the sensitivity of the NMR of heavy nuclei via polarisation transfer from protons, the measurement of the $^{15}N-X$ SSCC became possible for the natural abundance of isotopes. The amount of experimental data which have become available hitherto is so large that their systematic arrangement and survey are required. This communication is the first attempt on these lines. Together with the SSCC, we quote also the chemical shifts (CS) of the ^{15}N nuclei (relative to $MeNO_2$) and X (relative to XMe_4), since this usually makes it possible to achieve a more reliable interpretation of SSCC which have been little investigated hitherto. We hope that this review will promote the expansion of the field of research into $^{15}N-X$ SSCC and will facilitate the interpretation of new data.

II. Fundamentals of the theory

According to Ramsey's theory,[10] the spin–spin coupling in a liquid can be regarded as a result of the contribution of three components: spin–orbital (SO), spin–dipole (SD), and Fermi-contact (FC). The spin–orbital coupling can also be subdivided into two components—diamagnetic (OD) and paramagnetic (OP). The contributions of the SO and SD components are relatively small and tend to diminish with increase in the degree of π-bonding between the atoms of the interacting nuclei.[11] If the interacting nuclei are linked by a multiple chemical bond, then the SSCC is as a rule determined by the FC interaction. This simplifies significantly the interpretation of the experimental data within the framework of the analytical relations obtained from the quantum-chemical theory of spin–spin coupling.

The observed SSCC $^1J_{NX}$ depend significantly on the gyromagnetic ratio γ of the N and X nuclei. In order to exclude from consideration the individual properties of the nuclei, the concept of the reduced SSCC ^1K, which depends only on the electronic environment of the nuclei, has been introduced:

$$^1K_{NX} = 4\pi^2\, {}^1J_{NX}/h\gamma_N\gamma_X. \quad (2)$$

According to Pople and Santry,[12] in terms of the approximation of the LCAO-MO theory, the contribution of the FC interaction is described by the equation

$$^1K_{NX}^{FC} = -\frac{16e^2h^2}{9M_p^2c^2} |\psi_N(0)|^2 |\psi_X(0)|^2 \cdot \sum_i^{occ} \sum_j^{unocc} (^3\Delta E_{i\to j})^{-1} \cdot c_{is_N} c_{js_N} c_{is_X} c_{js_X}, \quad (3)$$

where $|\psi_N(0)|^2$ and $|\psi_X(0)|^2$ are the valence s electron densities at the N and X nuclei, $^3\Delta E_{i\to j}$ the energy of the excitation of the electronic transitions, and c_{is} and c_{js} are the LCAO coefficients of the s orbitals of the N and X atoms, while the remaining constants have the usual significance. In the extended Hückel method, $^3\Delta E_{i\to j} = e_j - e_i$ (e_i and e_j are the energies of the occupied and unoccupied orbitals respectively), which makes it possible to simplify Eqn. (3):

$$^1K_{NX}^{FC} = \frac{4e^2h^2}{9M_p^2c^2} |\psi_N(0)|^2 |\psi_X(0)|^2 \pi_{NX}, \quad (4)$$

$$\pi_{NX} = 4 \sum_i^{occ} \sum_j^{unocc} (e_i - e_j)^{-1} c_{is_N} c_{js_N} c_{is_X} c_{js_X}, \quad (5)$$

where π_{NX} is the mutual polarisability of the s orbitals of the N and X atoms.

In terms of the average excitation energy (ΔE) approximation, the contribution of the FC interaction can be represented by Eqn. (6), which reflects the relation between $^1K_{NX}$ and the s order of the N–X bond ($P_{s_Ns_X}$):

$$^1K_{NX}^{FC} = \frac{4e^2h^2}{9M_p^2c^2} |\psi_N(0)|^2 |\psi_X(0)|^2 P_{s_Ns_X}^2/\Delta E. \quad (6)$$

A modification of this equation within the framework of the valence bond theory [Eqn. (7)], using the concept of the s character of the localised hybrid bonds [see, for example, Eqn. (11)], is also frequently employed:

$$^1K_{NX}^{FC} = \frac{4e^2h^2}{9M_p^2c^2} \alpha_N^2\alpha_X^2 |\psi_N(0)|^2 |\psi_X(0)|^2/\Delta E. \quad (7)$$

In the interpretation of the SSCC, it is usually assumed that the quantities $|\psi_X(0)|^2$ and $|\psi_N(0)|^2$ are constant (in reality they depend on the atomic charge). This makes it possible to explain the observed changes in the SSCC by the differences in the nature of the chemical bond.

Eqns. (6) and (7), based on the ΔE approximation, presuppose that the FC interaction makes a positive contribution to the SSCC. In fact, negative contributions to the ^1K are frequently observed, especially for Group V–VII nuclei. This arises from the fact that the ΔE approximation is not always valid.

Jameson and Gutowsky[11] showed that the quantities ^1K obey periodicity laws and proposed a model for the prediction of the sign of ^1K for the nuclei of any elements in the Periodic System. According to this model, the nuclei involved in spin–spin coupling can be divided into three types.

A. Elements having an open s shell in the ground configuration. The s orbitals participate directly in the formation of the chemical bond (Group I in the Periodic System).

B. Elements having open s shells in an accessible configuration. The involvement of valence s orbitals in the formation of a chemical bond is possible as a result of the mixing of these configurations with the ground configurations (Groups II–VI).

C. Elements which do not have open s shells. In this case, the s electrons do not participate in the formation of a chemical bond (Groups VI and VII) and spin–spin coupling occurs mainly via the mechanism involving the polarisation of outer s shells, which leads to a negative sign of the FC interaction.

For Group IV elements, the valence s and p electrons have fairly close energies, so that, as a result of their mixing, the s electrons become available for the formation of a chemical bond. For this reason, the elements X should be assigned to type B. However, with increase in the radius of the atoms X their polarisability increases greatly. This can lead to an increase in the negative contribution of the polarisation of the inner s shells and hence to more negative values of $^1K_{NX}$.

For compounds of divalent X, mainly the p electrons participate in the formation of a chemical bond and the properties of the valence s electrons resemble those of closed s shells, which makes it possible to assign them to type C.

Jameson and Gutowsky assigned the Group V elements to a type intermediate between types B and C. The nitrogen(III) atom has a lone electron pair (LEP) and the difference between the energies of the valence $2s$ and $2p$ electrons is relatively large. For this reason, the use of the ΔE approximation is in general unreliable. Nevertheless, the observed correlation between $^1J_{NC}$ and the s character of the N–C bond in carbon compounds shows that in this instance the ΔE approximation is valid.

Equations describing the spin–spin coupling in liquids have been derived for a non-polar covalent bond. At the present time, there are no analogous equations describing the SSCC for coupling via a coordinate bond. Therefore in the interpretation of such SSCC, it is usually assumed that the equations obtained for the FC interactions are valid for the covalent component of the coordinate bond. Here we have in mind Eqn. (8), describing the nature of the coordinate bond within the framework of the valence bond theory:[13]

$$\psi_{N\to X} = \psi_{NX} + \lambda\psi_{N^+X^-}, \qquad (8)$$

where λ is a coefficient. However, the question how this interaction takes place and how to predict the sign of ^1K is not entirely clear. The coordinate bond has also been examined in Jameson and Gutowsky's model.[11] Certain considerations concerning this topic can be deduced from the study of the ionic bond by the above workers. In particular, it has been shown[11] that for ionic bonds there is a possibility of a small positive contribution to the FC coupling component. The overlap of the occupied *s* and *p* orbitals with the unoccupied *d* orbitals of the metal and also any kind of their mixing (covalence) give rise to a positive contribution to the spin density on the X nuclei. Consequently, in the case of a coordinate bond (at least in σ-bonding) the FC interaction should make a positive contribution to the SSCC.

III. Experimental aspects

1. The ^{14}N–X spin–spin coupling

The ^{14}N–X spin–spin coupling constants can be observed directly relatively rarely because of the effective relaxation of the ^{14}N nuclei via a quadrupolar mechanism. The merging of the components of the multiplet is then observed in the spectra of the X nuclei as a consequence of the scalar relaxation of the second kind.[14,15]

In principle, the ^{14}N–X SSCC can be determined by analysing the line form in the spectra of the X nuclei. Neglecting the natural width of the signal, the line form can be described analytically with the aid of the equation

$$I(x) = \frac{2\eta}{\pi J}\,\frac{45+\eta^2(5x^2+1)}{225x^2+\eta^2(34x^4-2x^2+4)+\eta^4(x^6-2x^4+x^2)}. \qquad (9)$$

Here $x = \Delta\nu/J$, where $\Delta\nu = \Delta\omega/2\pi$; $\eta = 10\pi T_{qN}J$, T_{qN} being the quadrupolar relaxation time. The description of the line form taking into account the natural width of the signal is more difficult. This problem has been described in detail.[15] It follows from Eqn. (9) that the line form in the spectra of the nuclei X is determined by the dimensionless parameter η. The quadrupolar relaxation time of the ^{14}N nuclei can be determined from the ^{14}N spectrum using the relations $T_2 \simeq 1/\pi\Delta\nu_{1/2}$ and $T_{qN} \simeq T_2$, where $\Delta\nu_{1/2}$ is the width of the signal at half its height.

The ^{14}N–X SSCC can be obtained directly in this case if $\eta \geqslant 10$. A clearer criterion is the relation $J \geqslant \Delta\nu_{1/2}(^{14}\mathrm{N})$, provided that the line half-width in the ^{14}N spectra does not exceed the ^{14}N–X SSCC. Consequently, the probability of finding directly these SSCC increases with increase in $^1J_{NX}$ (Fig. 1). For this reason, the ^{14}N–X SSCC for the heavy nuclei ^{117,119}Sn and ^{207}Pb are observed more frequently than for the ^{29}Si nuclei.

On the other hand, $\Delta\nu_{1/2}(^{14}\mathrm{N})$ diminishes (T_{qN} and ν increase) with increase in the symmetry of the charge distribution around the ^{14}N nuclei. Molecules with a tetrahedral or linear configuration of the nitrogen atom as well as quasi-linear molecules (isocyanates, isothiocyanates) usually have relatively long times T_{qN} because of the rapid (on the NMR time scale) exchange. In certain cases, this makes it possible to determine the ^{14}N–X SSCC from the satellites of the X nuclei in the ^{14}N spectra.

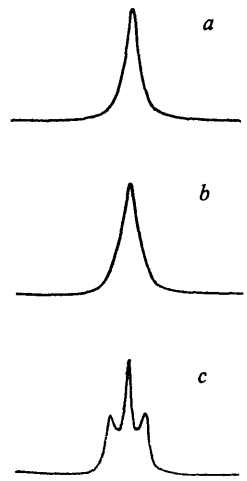

Figure 1. Dependence of the line form in the spectra of the X nuclei on the SSCC $^1J(^{14}\mathrm{N}-\mathrm{X})$ for a constant relaxation time of the ^{14}N nuclei (T_{qN} = 1.6 ms). The spectra were calculated by Eqn. (9): *a*, J = 50 Hz; *b*, J = 100 Hz; *c*, J = 200 Hz.

However, the ^{14}N–X SSCC can be found directly relatively rarely. Furthermore, the accuracy of the ^{14}N–X SSCC determined directly depends significantly on η, since the distance between the components of the multiplet in the spectra of the X nuclei (but not the ^{14}N nuclei) diminishes with decrease in η. For these reasons, preference is usually given to the study of the ^{15}N–X SSCC.

2. The ^{15}N–X spin–spin coupling

As a consequence of the extremely low natural abundance of the ^{15}N isotope, the ^{15}N–X spin–spin coupling constants were initially measured for enriched specimens. In this case, an accurate measurement of the ^{15}N–X SSCC presents no problems, provided that the ^{15}N and X nuclei form a first order spectrum. Furthermore, there is a possibility of determining the sign of ^1K.

The high sensitivity of modern NMR spectrometers makes it possible to measure ^{15}N–X SSCC for the natural abundance of the isotopes. This can be achieved in two ways: on the basis of the satellites of the X nuclei in the ^{15}N spectra and on the basis of the satellites of the ^{15}N nuclei in the spectra of X nuclei. In most studies, the ^{15}N–X SSCC have been determined from the ^{15}N spectra because the satellites are in this case more intense. It is noteworthy that the sensitivity of the measurements is in this case limited by the low natural abundances of both isotopes. However, from the standpoint of the limitations associated with the dynamic range of the spectrometer,[16] the use of ^{15}N NMR is preferable (see the reviews on ^{15}N NMR [5,7,17,18]).

The intensity of the useful signal in the measurement of the ^{15}N–X SSCC depends in the first place on the NMR sensitivity of

the observed nuclei (Table 1). A number of other factors are also significant—the Overhauser nuclear effect and the increase in signal intensity when methods involving the transfer of polarisation from protons are used (INEPT, DEPT, etc.[19,20]). Since the NMR sensitivity of the X nuclei is in all cases appreciably higher than that of the ^{15}N nculei, in principle the $^{15}N-X$ SSCC can be more conveniently determined from the spectra of the X nuclei.

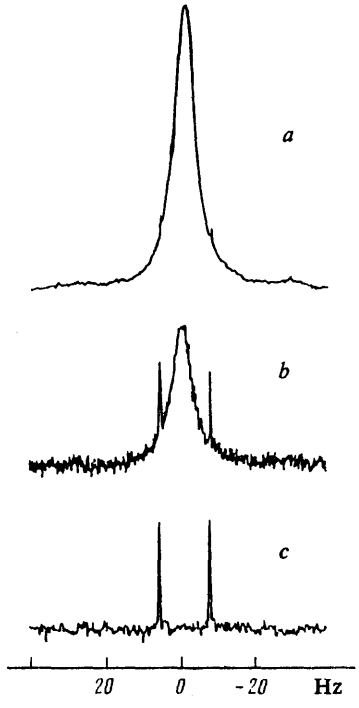

Figure 2. The ^{15}N satellites in the ^{29}Si NMR spectra of hexamethyldisilazane. The spectra were obtained by the INEPT (*a*), DEPT (*b*), and INEPT + Hahn's spin-echo (*c*) methods. Working frequency 71.55 MHz, temperature 303 K, number of accumulations 16 (*a* and *b*) and 64 (*c*).[22]

We have shown that[21] the detection of the ^{15}N satellites in the ^{29}Si NMR spectra facilitates significantly the broadening of the central line and of the ^{13}C satellites as a result of the $^{14}N-X$ spin–spin coupling and relaxation of the second kind (Fig. 2*a*). Using polarisation transfer from protons, it is usually possible to measure the $^{15}N-^{29}Si$ SSCC in the ^{29}Si NMR spectra after only a few accumulations. It has been shown[22] that the DEPT method is preferable to INEPT, since it decreases appreciably the intensity of the central line and of the ^{13}C satellites (Fig. 2*b*). The difference between the relaxation times of the central signal and of the ^{15}N satellites can be used to suppress completely the central line[22] (Fig. 2*c*). If several nitrogen atoms are attached to the silicon atom, then the ^{15}N satellites are also broadened as a result of the quadrupolar relaxation in the $^{14}N-^{29}Si-^{15}N$ fragments. In this case, the $^{15}N-^{29}Si$ SSCC can be more usefully determined from the ^{15}N spectra.

The observation of the ^{15}N satellites in the $^{117/119}Sn$ and ^{207}Pb NMR spectra is difficult.[23] This is apparently associated with the fact that the above nuclei have relatively short relaxation times.[24,25] For this reason, the difference between the widths of the central line and of the ^{15}N satellite is less pronounced, which leads to their merging as a consequence of the low intensity of the latter.

In the case of the protonated nitrogen atom, the satellites of the X nuclei in the ^{15}N NMR spectra can be observed after accumulation for 1–2 h [23,26] using the usual polarisation transfer methods (INEPT, DEPT, etc.),[19,20] provided that there is no rapid intramolecular or intermolecular exchange of NH protons. It has been shown[23,27] that, for a non-protonated nitrogen atom, it is also possible to employ the INEPT method, assuming that the long-range $^{15}N-^{1}H$ SSCC are 1–2.5 Hz. The best results have been achieved on the assumption that J_{NH} = 2.5 Hz for the NR (R = alkyl) group, 1.5 or 2 Hz for the Me_3SnN group, and 1 or 1.5 Hz for the Me_3SiN group.[23] In this case, the measurement of the $^{15}N-X$ (X = ^{29}Si, $^{117/119}Sn$) SSCC required accumulation for 6–12 h. It has been observed that[27] the main INEPT sequence (without the suppression of the spin–spin coupling with protons) is most suitable, since the use of refocussing (of the longer DEPT sequence) for such low values of the $^{15}N-^{1}H$ SSCC diminishes appreciably the signal intensity due to relaxation effects.

Table 2. The $^{15}N-^{29}Si$ SSCC for the silazanes (I)–(XVIII) (solvent—$CDCl_3$).[31]

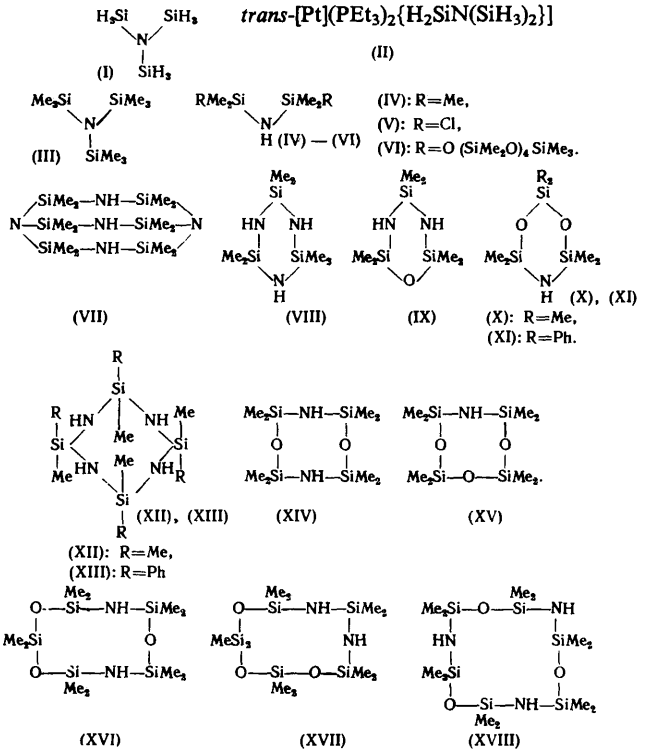
Note. Here and in other tables the numerals in square brackets denote references (Ed. of Translation).

IV. Silicon-29



1. Coupling across a covalent bond

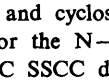
(a) Silazanes

Historically the $^{15}N-^{29}Si$ SSCC were first measured for compounds (I) and (II) enriched in the ^{15}N isotope.[28,29] It was established that $^1K_{NSi} > 0$. During the next 10 years, these SSCC

were scarcely measured. Systematic studies on the $^{15}N-^{29}Si$ SSCC began in 1983 [30] after polarisation transfer methods, permitting measurements for the natural abundance of the isotopes, became available.

It has been found that the $^{15}N-^{29}Si$ SSCC for the silazanes (I)–(XVIII) increase with increasing electronegativity (EO) of the substituents at the Si atom in the sequence H < Me < Cl < NR, OR (Table 2).[31] A similar trend has been observed also for substituents at the nitrogen atom. Thus, when the silyl group is replaced by the more electronegative hydrogen atom, the $^{15}N-^{29}Si$ SSCC increase. On this basis, it has been suggested that $^1K_{NSi} > 0$ for the silazanes (I)–(XVIII). However, in the presence of only electropositive substituents at the nitrogen atom (for example, Li), negative values of $^1K_{NSi}$ may be expected.[22]

The cyclosilazane and cyclosiloxazane $^{15}N-^{29}Si$ SSCC are virtually the same for the N–Si–N and N–Si–O fragments, whereas the $^{29}Si-^{13}C$ SSCC differ significantly (63 ± 1 Hz and 69 ± 1 Hz respectively). This was explained on the basis of Bent's rules[32] by the more significant change in the *s* character of the bonds involving the Si atom with the most electropositive substituents, i.e. Si–C.



The tendency towards a decrease in the $^1J_{NSi}$ on passing to smaller rings has been explained by the increased polarity of the N–Si bonds (decrease in $d_\pi-p_\pi$ conjugation), which agrees well with the conclusions reached for the ^{15}N and ^{29}Si chemical shifts. A decrease in the Si–N–Si valence angle in smaller rings reduces the *s* character of the N–Si bonds and hence reduces $^1J_{NSi}$.

(b) Silylamines

Higher values of $^{15}N-^{29}Si$ SSCC have been observed for silylamines (Table 3) compared with silazanes (Table 2). This is associated with the increase in the electronegativities of the substituents at the nitrogen atom in the sequence $SiMe_3$ < H < alkyl.

The $^{15}N-^{29}Si$ SSCC increase systematically with increase in the electronegativities of the substituents at the Si atom in the sequence Me < Ph < NR < OR.[22,26] Consequently $^1K_{NSi} > 0$ in the given sequence. A similar conclusion was reached from a comparison of the SSCC $^1J_{NSi}$ and $^1J_{PSi}$ for isostructural nitrogen(III) and phosphorus(III) compounds,[22] which revealed the opposite dependences of these SSCC on the electronegativities of the substituents. Since it is known that $^1K_{PSi} < 0$,[33,34] it follows from the foregoing that $^1K_{NSi} > 0$.

Table 3. The $^{15}N-^{29}Si$ SSCC for silylamines, silylamides, azasilatranes, and other compounds with a covalent N–Si bond (solvent—$CDCl_3$).[21,22,26,42,43]

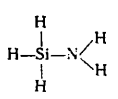
*1 Solvent—C_6D_{12}.

*2 Solvent—$(CD_3)_2SO$.

*3 $^1J_{NSi}$ is not observed because of the rapid intermolecular exchange of the $SiMe_3$ groups.

*4 $^1J(^{14}N-^{29}Si)$ = 8.4 Hz.

*5 Calculated from $^1J(^{14}N-^{29}Si)$ = 23.2 Hz by multiplying it by $\gamma(^{15}N)/\gamma(^{14}N)$.



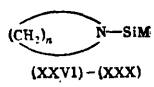
*6 The δ(^{14}N) chemical shift is quoted.

The parallel variation of the $^{15}N-^{29}Si$ and $^{29}Si-^{13}C$ (for the $Si-CH_3$ bond) SSCC has been observed in silylamines.[22] A linear correlation has been discovered for aniline derivatives:

$$^1J(^{15}N-^{29}Si) = 0.41\ ^1J(^{29}Si-^{13}C) - 7.3 \quad (r = 0.97,\ n = 7). \qquad (10)$$

Bearing in mind that $^1K_{SiC} > 0$ [35] and that this SSCC is determined by the contribution of the FC interaction,[36] it has been postulated that a similar equation is valid also for $^1K_{NSi}$.

The first calculation of the $^{15}N-^{29}Si$ SSCC for the silylamine (XIX) was carried out recently by the *ab initio* method:[37]



(XIX)

PC = 25.97 Hz
OD = 0.02 Hz
OP = −1.00 Hz
SD = 0.29 Hz
$^1J_{theor} = 25.26$ Hz.

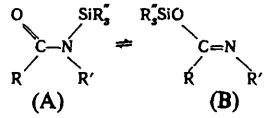
The theoretical quantity (25.26 Hz) reflects correctly the sign of $^1K_{NSi}$ and has a reasonable value. An important result of these calculations has been the conclusion that the $^{15}N-^{29}Si$ SSCC is determined by the sign of the FC interaction.

Bearing in mind that the $^{15}N-^{29}Si$ SSCC for silylamines have large and positive values, it has been suggested that they can be interpreted within the framework of the ΔE approximation, i.e. in conformity with Eqns. (6) and (7). Consequently the application of the $^{15}N-^{29}Si$ SSCC in structural studies in no less promising than the application of $^1J_{NC}$. The higher value of $^1J_{NSi}$ and the possibility of measuring them for the natural isotope abundances make them actually preferable.

An example in illustrating the sensitivity of $^1J_{NSi}$ to the hybridisation of the nitrogen atom is the significant decrease of the $^{15}N-^{29}Si$ SSCC on passing to smaller rings which has been observed for the trimethylsilyl (TMS) derivatives of the cyclic amines (XXVI)–(XXX) [21] and has been explained by the enhancement of the pyramidal configuration of the nitrogen atom.

(XXVI)–(XXX)

(XXVI): $n = 6$, (XXIX): $n = 3$,
(XXVII): $n = 5$, (XXX): $n = 2$.
(XXVIII): $n = 4$,



The similar phenomenon observed for silazanes is also associated with the decrease in the valence angle at the nitrogen atom in smaller rings.[31]

The anomalous decrease in $^1J_{NSi}$ on passing from the NBu^t derivatives to the NPh derivatives of silylamines has been explained by the weakening of the $d_\pi-p_\pi$ conjugation via the N–Si bond as a result of the stronger competing conjugation of the LEP of the nitrogen atom with the phenyl group.[26] It has been suggested that this leads to lengthening of the N–Si bond, as a result of which the degree of overlap of the valence *s* orbitals diminishes and $^1J_{NSi}$ also decreases.

(c) Silylamides

Fairly low $^{15}N-^{29}Si$ SSCC have been observed for trimethylsilylamides [compounds (LVII)–(LXII)]. It has been suggested that this is a consequence of the stronger competing conjugation of the LEP of the nitrogen atom with the carbonyl group.

The high polarity of the N–Si bond in trimethylsilylamide increases the rate of the intramolecular and intermolecular exchange of the Me_3Si groups. The question which of the structures (A) or (B) predominates in solution has been most frequently discussed for these compounds.[38–40]

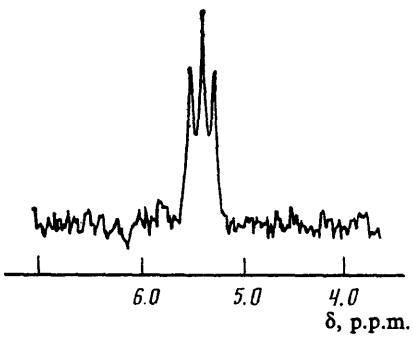
(A) (B)

The ^{29}Si chemical shifts do not always make it possible to solve unambiguously this problem, whereas the $^{15}N-^{29}Si$ SSCC can be used as significant evidence in support of structure (A).

The ^{15}N and ^{29}Si chemical shifts also failed to permit the observation of the intermolecular exchange of the $SiMe_3$ groups. On the other hand, using the $^{15}N-^{29}Si$ SSCC it is possible, in principle, not only to observe the process but also to determine the activation parameter by means of dynamic NMR methods.[41] For a detailed investigation of this process, specimens enriched in the ^{15}N isotope are apparently essential. However, it has been demonstrated by simulating the ^{29}Si line form that the observation of the ^{15}N satellites in the ^{29}Si NMR spectrum is difficult or impossible if the free energy of activation for the intermolecular exchange of $SiMe_3$ group ($\Delta G^{\neq}$) is smaller than 80 kJ mol^{-1}.[22]

(d) Silicon isocyanates

The relatively long relaxation times of the ^{14}N nuclei in these compounds frequently make it possible to find the $^{14}N-^{29}Si$ SSCC directly. Thus a relatively well resolved triplet with a splitting of 8.4 Hz has been observed in the ^{29}Si NMR spectrum of trimethylsilyl isothiocyanate (LXIV) (Fig. 3). The low solubility and long relaxation time of the ^{29}Si nuclei of the compound (LXV) precluded the measurement of the ^{29}Si NMR spectrum of this compound. However, it has been possible to observe the ^{29}Si satellites in the ^{14}N NMR spectrum and to measure the $^{14}N-^{29}Si$ SSCC.[22]



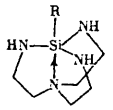


Figure 3. The splitting of the signal in the ^{29}Si NMR spectra of the compound $Me_3SiN=C=S$ as a result of the $^{14}N-^{29}Si$ spin–spin coupling. The spectrum was obtained using the INEPT pulse train for a 50% solution in $CDCl_3$ at a frequency of 71.55 MHz.[22]

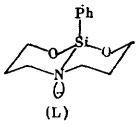
The constants $^1J_{NSi}$ for the isocyanates (LXIII)–(LXV) are relatively small, which has been explained tentatively by the increase in the length of the N–Si bond in trimethylsilyl isocyanate (1.76 Å) and trimethylsilyl isothiocyanate (1.78 Å) compared with trimethylsilyl-amine (cf. the value 1.72 Å).

The $^{15}N-^{29}Si$ SSCC could not be found for trimethylsilyl azide (LXVI) with the natural isotope abundances.[22] The ^{29}Si line width (0.4 Hz) shows that $^1J_{NSi}$ is apparently not high (< 10 Hz). The difficulties in the measurement of the $^{15}N-^{29}Si$ SSCC were in this case associated with the fact that the ^{15}N satellites in the ^{29}Si spectra are apparently broadened as a result of the long-range $^{14}N-^{29}Si$ coupling; the lines in the ^{15}N spectra are also broadened as a result of the $^{14}N-^{15}N$ coupling; furthermore, there is a possibility of the intermolecular exchange of the $SiMe_3$ groups.

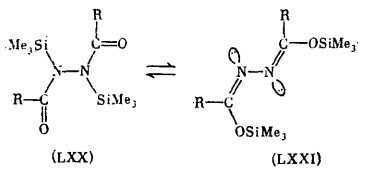
(e) Other compounds

The $^{15}N-^{29}Si$ SSCC can be used to investigate the influence of the transannular N → Si interaction on the properties of equatorial bonds in the triazasilatranes (LXVII)–(LXIX).[42]



(LXVII): R=Me,
(LXVIII): R=CH=CH$_2$,
(LXIX): R=CH$_2$Cl.

(LXVII)–(LXIX)

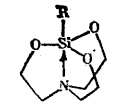


The decrease in the SSCC for these compounds relative to the corresponding aminosilanes [compounds (XLIII)–(XLV)] has been explained by the diminution of the $d_\pi-p_\pi$ interaction in the equatorial N–Si bond in compounds (LXVII)–(LXIX) with increase in the N → Si bond strength.

The $^{15}N-^{29}Si$ SSCC for compound (L) is much lower than the SSCC for compound (XLVIII) (Table 3),[43] indicating a pyramidal structure of the nitrogen atom in the given compound, which is fairly unusual, since in silylamines the nitrogen atom has a planar structure. The phenomenon is apparently caused by ring strain.

(L)

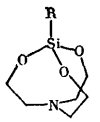
The study of compounds of type (LXX) and (LXXI) enriched in the ^{15}N isotope is an example of the use of the $^{15}N-^{29}Si$ SSCC for the investigation of tautomeric processes and for demonstrating the presence of the N–Si bond:[44]



(LXX) (LXXI)

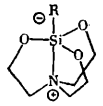
Although the quantity $^1J_{NSi}$ could not be measured accurately, since second order effects were observed in the ^{29}Si NMR spectra, nevertheless the very fact of this $^{15}N-^{29}Si$ spin–spin coupling is evidence in support of the structure (LXX).

2. Interaction across a coordinate bond



(a) Silatranes

The $^{15}N-^{29}Si$ SSCC for the silatranes (LXXII)–(LXXIX) have been measured using specimens enriched in the ^{15}N isotope (Table 4).[45–47] The structures of the silatranes (LXXII)–(LXXIX) have been studied in detail by X-ray diffraction of crystals (see the review of Voronkov et al.[49]), which made it possible to study in detail the dependence of the $^{15}N-^{29}Si$ SSCC on the N → Si bond length [l(N–Si)]. The structures of compounds (LXXII)–(LXXIX) in crystals depend significantly on the N → Si bond strength.



(LXXII)–(LXXIX)

(LXXII): R=Me,
(LXXIII): R=CH=CH$_2$,
(LXXIV): R=Ph,
(LXXV): R=OMe,
(LXXVI): R=H,
(LXXVII): R=CH$_2$Cl,
(LXXVIII): R=CHCl$_2$,
(LXXIX): R=Cl

(A)

(B)

If the N → Si bond is absent [structure (A)], the nitrogen atom is planar and the silicon atom is tetrahedral. With increase in the strength of the N → Si bond, the pyramidal configuration of the nitrogen atom is enhanced, whilst the configuration of the silicon atom approaches the trigonal-bipyramidal configuration [structure (B)]. The majority of silatranes have a structure intermediate between (A) and (B). In solutions, the $^{15}N-^{29}Si$ SSCC increase with decrease in the length of the N → Si bond found in crystals and also with increase in solvent polarity[45] and with decrease in temperature.[47] This indicates the corresponding increase in the mutual polarisability of the valence s orbitals of the N and Si atoms (π_{NSi}). The dependence of $^1J_{NSi}$ on l(N–Si) is non-linear and its character varies as a function of the nature of the solvent (Fig. 4). One of the causes of this behaviour of $^1J_{NSi}$ is the weakening of the N → Si bond on passing from crystals to solutions and also on passing to solvents with a lower polarity. Simultaneously with increase in $^1J_{NSi}$, the constant $^1J_{NC}$ diminishes, which clearly reflects the redistribution of the s character of the bond with increase in strength of the 1,5-transannular N → Si interaction in silatranes. A linear dependence of $^1J(^{15}N-^{13}C)$ on $^1J(^{15}N-^{29}Si)$ was then observed:

$$^1J(^{15}N-^{13}C) = 7.30-0.28\,^1J(^{15}N-^{29}Si) \quad (r = -0.96,\ n = 16). \tag{11}$$

The decrease in the $^{15}N-^{13}C$ SSCC with increase in strength of the N → Si bond was explained by the increasingly pyramidal configuration of the nitrogen atom. This shows that the relation between the structure and the N → Si bond strength, observed in crystals, persists also in solutions.

In the case of 1-hydrosilatrane, a linear correlation was observed between $^1J_{NSi}$ and the stretching vibration frequency, ν_{SiH}, of the Si–H bond in the IR spectra (for different solvents):

$$\nu_{SiH} = 2159-23.23\,^1J(^{15}N-^{29}Si) \quad (r = 0.99,\ n = 4). \tag{12}$$

Extrapolation of this relation to ν_{SiH} in nujol yielded the value of $^1J_{NSi}$ for solid 1-hydrosilatrane, which proved to be 2.97 Hz.

A similar reaction has also been observed for $^1J(^{15}N-^{29}Si)$ and $^1J(^{29}Si-^1H)$:

$$^1J(^{29}Si-^1H) = 290.0-10.63\,^1J(^{15}N-^{29}Si) \quad (r = 0.96,\ n = 4). \tag{13}$$

Relation (13) also indicates a redistribution of the s character of the bonds, i.e. the involvement of the valence s orbitals of the Si atom in the formation of the Si–H bond diminishes with increasing s character of the N → Si bond.

Since the $^{29}Si-^{1}H$ and $^{15}N-^{13}C$ SSCC reflect the *s* character of the corresponding bonds and the ΔE approximation is applicable to them [Eqns. (6) and (7)], the existence of the correlations between $^{1}J_{SiH}$ and $^{1}J_{NC}$, on the one hand, and $^{1}J_{NSi}$, on the other, indicates that the ΔE approximation is valid also for the quantitative interpretation of the constants for the $^{15}N-^{29}Si$ spin–spin coupling across a N → Si bond. Using the model of a S_N2 substitution reaction, this made it possible to obtain equations for the calculation of the length *l* and order *P* of the N → Si bond in solutions:[45]

$$l(\text{N—Si}) = 2.291 - 0.084\ ^{1}J(^{15}\text{N—}^{29}\text{Si}), \quad (14)$$

$$P(\text{N—Si}) = \sqrt{^{1}J(^{15}\text{N—}^{29}\text{Si})/25.1}. \quad (15)$$

We may note that Eqns. (14) and (15) are valid provided that the electronegativity of the substituent R at the Si atom is close to the electronegativity of the H atom. With increase in the electronegativity of the substituent (for example, in the case of R = OMe and Cl), the $^{15}N-^{29}Si$ SSCC acquire values smaller than expected. This has been explained by the tendency of ΔE to increase with increase in the electronegativity of the substituent.

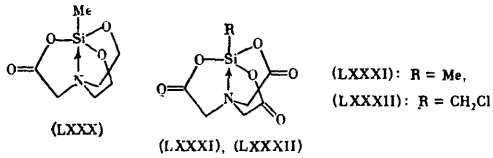


Table 4. The $^{15}N-^{29}Si$ SSCC for the silatranes (LXXII)–(LXXIX) and the silatranones (LXXX)–(LXXXII) at 303 K.[45,47,51]

	DMSO-d_6	2.57	−353.2	−83.1
	CD_3CN	2.4 [48]	—	—
(LXXVIII)	CD_3CN	3.3 [48]	—	—
(LXXIX)	$CDCl_3$	1.98	−348.8 [48]	−85.8
	DMSO-d_6	3.37	−347.8 [48]	−87.0
(LXXX)	DMSO-d_6	0.9	−344.3	−73.0
(LXXXI)	DMSO-d_6	8.2	−319.9	−135.8
(LXXXII)	DMSO-d_6	10.9	−320.6	−144.7

A non-linear dependence of the $^{15}N-^{29}Si$ SSCC on the ^{15}N chemical shift has been observed (Fig. 5). Here too low values of $^{15}N-^{29}Si$ SSCC are observed for R = OMe and Cl. The correlation between $\delta(^{15}N)$ and $^{1}J(^{15}N-^{29}Si)$ can be used to introduce a correction for the electronegativity of the substituent at the Si atom. In particular, this makes it possible to obtain a better agreement between the quantities *l*(N–Si) calculated from the chemical shifts of the ^{15}N atom[50] and $^{1}J_{NSi}$.[45]

(b) Silatronones

The $^{15}N-^{29}Si$ SSCC for the silatronones (LXXX)–(LXXXII)[45,47,51] increase with increase in the number of CO groups in the molecule (Table 4), which can be explained by the increase in strength of the N–Si bond as a consequence of the increase in the polarity of the equatorial Si–O(CO) bonds in silatronones. A pronounced temperature dependence of the $^{15}N-^{29}Si$ and $^{15}N-^{13}C$ SSCC for silatrane-3,7,10-triones has been observed.[47]

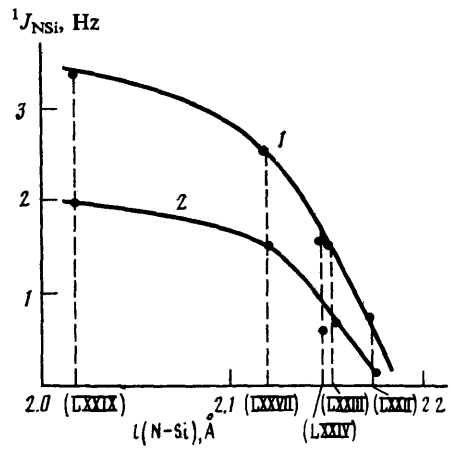

Figure 4. Dependence of the $^{15}N-^{29}Si$ SSCC on the N → Si bond length in the crystals of the silatranes (LXXII)–(LXXIV), (LXXVII), and (LXXIX) in DMSO-d_6 (*1*) and $CDCl_3$ (*2*).[45]

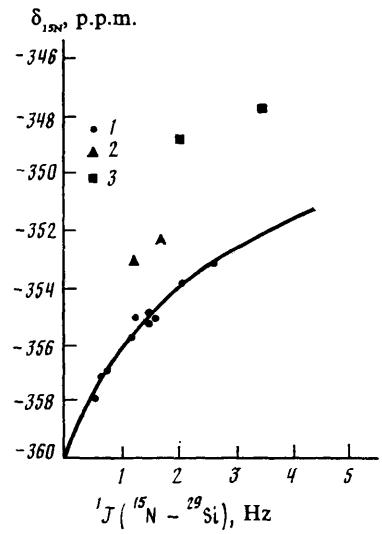

Figure 5. Relation between the ^{15}N chemical shifts and the $^{15}N-^{29}Si$ SSCC for the silatranes (LXXII)–(LXXIX): *1*, R = alkyl, Ph, or CH_2 = CH; *2*, R = OMe; *3*, R = Cl.

(c) Silocans

The $^{15}N-^{29}Si$ SSCC for the silocans (1,3-dioxa-6-aza-2-silacyclooctanes) (LXXXIII)–(XC) have been measured both for specimens enriched in the ^{15}N isotopes and for specimens with the natural abundances of the isotopes (Table 5). The range of variation of the constant $^1J_{NSi}$ for silocans is much greater than for silatranes, which can be explained by the smaller rigidity and greater variation of the substituents at the nitrogen and silicon atoms in silocans. The sign of $^1K_{NSi}$ for compound (LXXXVI) (Table 5) has been determined. Assuming that $^1J(^{29}Si-^1H) < 0$ and $^2J(^{15}N-Si-^1H) < 0$, it was noted that $^1J(^{15}N-^{29}Si)$ and $^1K_{NSi}$ are positive.

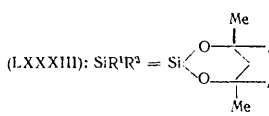

Table 5. The $^{15}N-^{29}Si$ SSCC for the silocans (LXXXIII)–(XC).

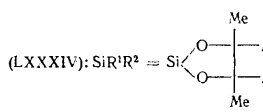
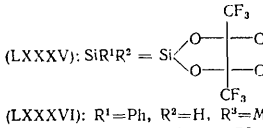
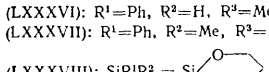


Compound	Solvent	*T*, K	$^1J_{NSi}$, Hz (Ref.45)	$\delta(^{15}N)$, p.p.m. (Ref.45)	$\delta(^{29}Si)$, p.p.m. (Ref.47)
(LXXXIII)	$CDCl_3$	238	<0.2	—	−81.1
(LXXXIV)	CCl_4÷C_6D_6	286	1.85	—	—
	$CDCl_3$	298	2.71	—	−91.5
	DMSO-d_6	314	3.18	—	−92.2
	DMSO-d_6	298	3.30	—	−92.5
(LXXXV)	DMSO-d_6	303	8.36	—	−95.1
(LXXXVI)	acetone-d_6	303	+3.5	—	−57.3
	DMSO-d_6	303	4.3	—	−61.5
(LXXXVII)	acetone-d_6	303	1.2	—	−28.0
Ph (*a*), Me (*e*)	acetone-d_6	193	3.96	—	−30.7
Me (*a*), Ph (*e*)	acetone-d_6	193	1.47	—	−30.2
(LXXXVIII)	DMSO-d_6	303	5.31	−347.0	−106.3
(LXXXIX)	DMSO-d_6	303	6.63	−348.2	−90.2
(XC)	DMSO-d_6	303	10.61	−347.2	−92.4

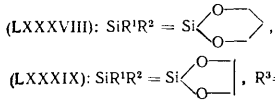


The characteristic features of the variation of the $^{15}N-^{29}Si$ SSCC for silocans and silatranes are similar. A tendency towards a decrease in $^1J_{NSi}$ with increase in the [strength?] of the N → Si bond in the crystals, with decrease in solvent polarity, and with increase in temperature has also been noted for silocans.[45]

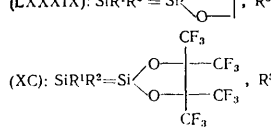
(LXXXIII)–(XC)



(LXXXIII): SiR^1R^2 =  , R^3=Me;

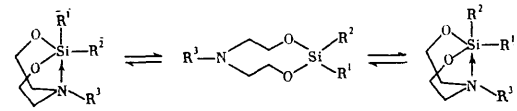


(LXXXIV): SiR^1R^2 =  , R^3=Me;



(LXXXV): SiR^1R^2 =  , R^3=Me;

(LXXXVI): R^1=Ph, R^2=H, R^3=Me;



(LXXXVII): R^1=Ph, R^2=Me, R^3=Me;

(LXXXVIII): SiR^1R^2 =  , R^3=H;

(LXXXIX): SiR^1R^2 =  , R^3=H;

(XC): SiR^1R^2=  , R^3=H.

By virtue of the smaller rigidity of silocans in solutions, the dissociation of the N → Si bond, accompanied by the inversion of the eight-membered ring and the positional exchange of substituents at the Si atom, has been observed in these compounds.

Using the dynamic NMR method, this fact makes it possible to determine the free energy of dissociation of the N → Si bond.[45,52] A linear relation between $^1J_{NSi}$ and $\Delta G^{\neq}$ has been observed for compounds (LXXXIII)–(LXXXV) (Table 5):

$$\Delta G^{\neq} = 51.4 + 51.11^1J(^{15}N-^{29}Si) \quad (r = 0.999,\ n = 5). \tag{16}$$

Using Eqn. (16) and assuming that $\Delta G^{\neq} \simeq \Delta H^{\neq}$, the dissociation energy of the N → Si bond in silatranes was determined. The measurement of this characteristic for silatranes by NMR is impossible.[45] A satisfactory agreement was noted between the energies calculated by Eqn. (16) and the values obtained by other methods.

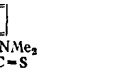
In the general case, the dependence of the $^{15}N-^{29}Si$ SSCC on the nature of the substituents at the N and Si atoms is complex. On the one hand, the strength and *s* character of the N → Si bond increase with increasing electronegativity of the substituents at the Si atom [52] and the $^{15}N-^{29}Si$ SSCC tends to increase. On the other hand, as a result of the increase under these conditions of the electron density on the Si atom and of its decrease on the nitrogen atom, the difference between the energies of the occupied and unoccupied MO rises (ΔE increases), which leads in its turn to some decrease in the $^{15}N-^{29}Si$ SSCC. Thus, one can explain, for example, the higher values of $^1J_{NSi}$ for compounds (LXXXVI) and (LXXXVII) compared with (LXXXIII) and (LXXXIV) (Table 5).

V. Germanium-73

The ^{73}Ge nucleus is exceptionally "unsuitable" for the observation of scalar spin–spin coupling. The presence of a relatively large quadrupole moment and the low frequency of the observation greatly complicate the recording of the ^{73}Ge NMR spectra. As a consequence of the effective relaxation via the quadrupolar mechanism, the direct observation of the SSCC is possible only for highly symmetrical compounds. As a result of the low value of $\delta(^{73}Ge)$ (Table 1) the observed SSCC involving the ^{73}Ge nuclei have low values.[53] The expected values of the $^{14}N-^{73}Ge$ and $^{15}N-^{73}Ge$ SSCC range from 0 to 11 and 15 Hz respectively.

VI. Tin-117 and tin-119

1. Coupling across a covalent bond



(a) Amines

The first studies on the $^{15}N-^{119}Sn$ SSCC showed[54–56] that the constants $^1K_{NSn}$ can be both positive and negative. This is associated with the relatively large atomic radius and polarisability of Sn, which leads to more negative values of π_{NSn} compared with π_{NSi}. The decrease in the degree of overlap of the valence *s* orbitals of the N and Sn atoms (β_{NSn}) compared with β_{NSi} leads to a more pronounced dependence of the sign and absolute value of $^1K_{NSn}$ on

the properties of the substituents at the N and Sn atom. For this reason, the ΔE approximation is inapplicable to the $^{15}N-^{119}Sn$ SSCC and they must be interpreted on the basis of Eqn. (4).

Subsequent systematic studies of the $^{15}N-^{119}Sn$ SSCC showed[57-60] that the quantity $^1K_{NSn}$ depends in a complex manner on the properties of the substituents at the N and Sn atoms. It has been suggested that β_{NSn} increases with the increasing electronegativity of the substituent. As a result, π_{NSn} becomes more positive and the observed values of $^1J_{NSn}$ become positive, having passed through zero. Thus Eqn. (4) makes it possible to describe at least qualitatively the trend in the variation of $^1K_{NSn}$, in particular the change in the sign of the $^1K_{NSn}$ when H or $SnMe_3$ is substituted by the more electronegative Me or PMe_2 group (Table 6).

Table 6. The $^{15}N-^{119}Sn$ SSCC for tin derivatives.[55-62,66-71]

*1 The postulated sign is indicated in brackets (if the sign is not indicated, this means that it is unkown; in other cases, the sign has been established experimentally).

*2 The literature data relative to $NMe_4^+I^-$ have been recalculated in terms of the $MeNO_2$ scale in accordance with the relation $\delta[^{15}N(MeNO_2)] = \delta[^{15}N(NMe_4^+I^-)] - 337.3$.

*3 The constants were calculated by multiplying $^1J(^{14}N-^{119}Sn)$ by $\gamma(^{15}N)/\gamma(^{14}N)$.

*4 Data for the three isomers (A), (B), and (C) are presented.

It has been suggested that, for low values of $^1K_{NSn}$, the latter may be influenced significantly by steric factors, which in the general case complicates the determination of quantitative relations. This explains the more negative value of $^1K_{NSn}$ for $Me_3SnN[P(S)Me_2]Ph$ compared with $Me_3SnN(PMe_2)Ph$,[57] although the first substituent has a higher electronegativity. However, one cannot rule out in this instance also the influence by the LEP of the P^{III} atom on the $^{15}N-^{119}Sn$ SSCC.

The $^{15}N-^{119}Sn$ and $^{31}P-^{119}Sn$ SSCC have been compared qualitatively.[57] It has been shown that, on the whole, the constants $^1K_{PSn}$ have more negative values than the constants $^1K_{NSn}$, since the LEP of the P^{III} atom has a greater amount of *s* character.

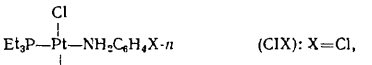
(b) Isothiocyanates

Direct observation of the $^{14}N-^{119}Sn$ SSCC is possible for the isothiocyanates (CVI) and (CVII) (Table 6)[61,62] because of the relatively slow relaxation of the ^{14}N nuclei as a result of the high symmetry of the charge distribution around the nitrogen atom.

A multiplet made up of 11 lines (13 have been predicted theoretically), with the relative intensities 6:14:36:67:90:100:90:67:36:14:6 and a splitting of 150 Hz as a result of the $^{14}N-^{119}Sn$ spin–spin coupling, has been observed[62] in the ^{119}Sn NMR spectrum of compound (CVII). The ratios of the line intensities of the multiplet, the high value of the $^{14}N-^{119}Sn$ SSCC, and the chemical shifts of the ^{14}N and ^{119}Sn nuclei confirm the hexacoordinate structure of the ion, demonstrating that the Sn atom is linked to the nitrogen and not the sulphur atom and showing that the intermolecular exchange of the NCS groups is slow (on the NMR time scale). All this demonstrates that the SSCC $^1J_{NSn}$ have a high information content.

$^{14}N-^{119}Sn$ spin–spin coupling has also been observed in the ^{119}Sn NMR spectrum of compound (CVI). In this case the ^{119}Sn signal was observed in the form of a well resolved triplet with a splitting of 136 Hz.

The $^{14}N-^{119}Sn$ SSCC cannot be observed directly for compound (CV),[62] which is extremely unexpected. It has been noted that this is associated with the rapid quadrupolar relaxation of the nitrogen atom in compound (CV) (T_{qN} = 0.15 ms) compared with compounds (CVI) and (CVII) (T_{qN} = 35 and 50 ms respectively). Only the $^{15}N-^{119}Sn$ SSCC has been measured for compound (CV).



It is noteworthy that the $^1K_{NSn}$ for the isothiocyanates investigated have comparable values. Since the sign of these SSCC has not been established, in order to account for this phenomenon it is reasonable to assume that $^1K_{NSn} > 0$ for compound (CVII) and $^1K_{NSn} < 0$ for compounds (CV) and (CVI) (Table 6).

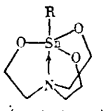
(c) Sn^{II} derivatives

Hitherto only one $^1J_{NSn}$ SSCC has been determined for Sn^{II} compounds. A signal in the form of a poorly resolved quintet as a consequence of the $^{14}N-^{119}Sn$ spin–spin coupling with $J = 245 \pm 10$ Hz has been observed[58] in the ^{119}Sn spectrum of compound (CVIII) at 80 °C. This SSCC represents at the present time the highest absolute value of $^1K_{NSn}$. It is reasonable to assume that $^1K_{NSn} < 0$ [$^1J(^{14}N-^{119}Sn) > 0$]. Such a negative value of $^1K_{NSn}$ can be accounted for by the high amount of *s* character of the LEP of the Sn(II) atom, which is indicated also by structural data.[63] In particular, the $N-Sn^{II}$ bonds are on average longer than the $N-Sn^{IV}$ bonds and the values of β_{NSn} are therefore smaller for Sn^{II}. This leads to more negative values of π_{NSn} and ultimately to negative values of $^1K_{NSn}$ for Sn^{II} derivatives. It is noteworthy that a similar phenomenon is known also for phosphorus derivatives, i.e. $^1K_{NP} > 0$ for P^V and $^1K_{NP} < 0$ for P^{III}.[64]

(d) Long range SSCC

Long range SSCC has so far been little studied. Using specimens enriched in the ^{15}N isotope, it has been observed[65] that the constants $^2J(^{15}N-^{119}Sn)$ are 9–10 Hz for the platinum complexes (CIX) and (CX).

(CIX), (CX)



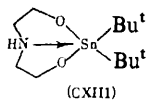
(CIX): X=Cl, (CX): X=Me.

Presumably these SSCC can be used to determine the *cis*- and *trans*-configurations of the ligands in similar complexes, by analogy with the widely known variation of the $^2J(^{31}P-^{119}Sn)$ SSCC.[66]

2. Coupling across the coordinate bond

(a) Sn^{IV} derivatives

The $^{15}N-^{117}Sn$ and $^{15}N-^{119}Sn$ SSCC have been measured for ^{15}N-enriched specimens and have been used mainly to demonstrate the existence of the N → Sn bond in solutions of the test compounds (Table 6). The first constants for the $^{15}N-^{117/119}Sn$ across a coordinate bond were measured for the stannatranes (CXI) and (CXII):

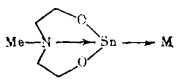


(CXI): R = Bu^t
(CXII): R = Me.

(CXI), (CXII)

Three sets of signals have been observed in the ^{15}N and ^{119}Sn NMR spectra of 1-methylstannatrane (CXII), which was explained by the formation of trimers in solution. The observed SSCC indicates the existence of the N → Sn bond in all the isomers and reflects quantitatively its strength. It has been noted that, in conformity with Bent's rules, the smallest $^{15}N-^{117/119}Sn$ SSCC are characteristic of the largest $^{119}Sn-^{13}C$ and $^{119}Sn-C-^1H$ SSCC [isomer (A)]. This indicates a redistribution of the *s* character of the bonds in the axial fragment of the molecule. A significant temperature dependence of the $^{15}N-^{117/119}Sn$ SSCC for the given compounds has not been observed.

Lower values of the $^{15}N-^{117/119}Sn$ SSCC have been noted for the stannocan (CXIII), which probably indicates a weaker N → Sn bond.[69]



(CXIII)

It has been noted that the $^{15}N-^{117/119}Sn$ SSCC decrease as the temperature is raised. This has been explained by the dissociation of the N → Sn bond at higher temperatures.

(b) Derivatives of Sn^{II}

The $^{15}N-^{117/119}Sn$ SSCC for the Sn^{II} stannocans (CXIV)–(CXVII) greatly exceed the values observed for the analogous Sn^{IV} derivative (CXIII).

(CXIV)–(CXVII)

M = LEP(CXIV), $Cr(CO_5)$(CXV), $Mo(CO)_5$(CXVI), $W(CO)_5$(CXVII).

This is partly associated with the greater strength of the N → Sn bond in Sn^{II} derivatives.[70,71] However, one should note that compounds (CXIII) and (CXIV) have comparable N → Sn bond dissociation energies, whereas the corresponding SSCC differ significantly.

It has been noted that the $^{15}N-^{117/119}Sn$ SSCC increase on passing to more polar solvents.[70]

VII. Lead-207

The $^{15/14}N-^{207}Pb$ SSCC have been investigated in less detail than the constants involving ^{29}Si and $^{117/119}Sn$. It is of interest to note that almost all compounds with the exception of compound (CXX) (Table 7) have been investigated for the natural abundances of the isotopes, which was facilitated by the high natural abundance of the ^{207}Pb isotope (22.6%). In certain cases the $^{14}N-^{207}Pb$ SSCC were measured directly in the ^{207}Pb spectra.[57,58]

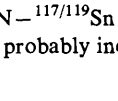


Table 7. The $^{14}N-^{207}Pb$ and $^{15}N-^{207}Pb$ SSCC.[57–59,72–75]

Compound	Chemical formula	Solvent	$^1J(^{14}N-^{207}Pb)/$ $^1J(^{15}N-^{207}Pb)$, Hz	δ(^{15}N), p.p.m.	δ(^{207}Pb) p.p.m.
(CXVIII)	$Me_3PbN(SnMe_3)_2$	C_6D_6	(—) 170/238*1	—	242.0

*2 The literature data relative to $NMe_4^+I^-$ have been recalculated in terms of the $MeNO_2$ scale in accordance with the relation $\delta[^{15}N(MeNO_2)] = \delta[^{15}N(NMe_4^+I^-)] - 337.3$.[7]

*3 Cydta = *trans*-1,2-diaminocyclohexane-*NNNN'*-tetraacetate.

*4 L = 

It has been established[72] that the SSCC $^1K_{NPb}$ have high negative values. This is associated with the high polarisability of the Pb atom and the weak overlap of the valence *s* orbitals of the N and Pb atoms. The values of $^1K_{NPb}$ for Pb^{IV} derivatives are comparable in magnitude despite the significant variation of the nature of the substituents at the nitrogen atom. This has been explained by the fact that the high and negative values of π_{NPB} are less sensitive to the variation of the character of the chemical bond than the quantity π_{NSn}.

The highest absolute value of $^1K_{NPb}$, which is probably negative, has been observed for a Pb^{II} derivative [compound (CXXII) in Table 7]. As for the Sn analogue, this can be explained by the low value of β_{NPb} and the large amount of *s* character of the LEP of the Pb^{II} atom.

The $^{15}N-^{207}Pb$ SSCC have been measured for two Pb coordination compounds, namely (CXXIII) and (CXXIV). The marked difference between the $^{15}N-^{207}Pb$ SSCC for the equatorial and axial bonds in compound (CXXIV) led to some misunderstanding,[73-75] since in crystals the lengths of these bonds differ little (2.43 and 2.47 Å for the equatorial bonds and 2.47 and 2.48 Å for the axial bonds[73,74]). It has been suggested that the frequency 207.5 Hz corresponds to the normal equatorial bonds and 19.8 Hz corresponds to bonds in the highly distorted axial fragment.

In our view, the SSCC data reflect the real bonding situation in the given compound in solution, i.e. the nature of the equatorial and axial bonds (length and strength) in solutions is significantly different in contrast to their apparent equivalence in crystals. In particular, this is indicated by the valence isomerisation process observed in solutions of compound (CXXIV),[73-75] which has an extremely high activation energy ($\Delta H^{\neq} = 100 \pm 10$ kJ mol^{-1}, $\Delta S^{\neq} = 105 \pm 20$ J mol^{-1} K^{-1}) at 298 K, probably leading to the averaging of the ^{15}N chemical shifts and SSCC. Some increase in the $^{15}N-^{207}Pb$ SSCC in the case of equatorial bonds in compound (CXXIV) compared with the analogous SSCC observed for the complex (CXXIII) agrees well with the shorter $Pb-N_e$ distance in the crystals of compound (CXXIV) compared with (CXXIII) (Table 7).

VIII. Conclusion

The $^{15}N-X$ (X = ^{29}Si, $^{117/119}Sn$, ^{207}Pb) SSCC make it possible to obtain information about the electronic and steric structures of nitrogen-containing Group IV organoelement compounds. A dependence of the $^{15}N-X$ SSCC on the hybridisation of the N and X atoms, their geometry, the *s* character of the N–X bond, its polarity and length, and the degree of $d_\pi-p_\pi$ conjugation between the N and X atoms has been observed for compounds with a covalent N–X bond. At the same time, these constants must be interpreted taking into account the position of the element X in the Periodic System. With increase in the atomic number of X, the constant $^1K_{NX}$ becomes more negative, which is associated with the increasing polarisability of the X atom. Thus all the $^1K(^{15}N-^{29}Si)$ SSCC known hitherto are positive, the constants $^1K(^{15}N-^{117/119}Sn)$ have both positive and negative values, while the constants $^1K(^{15}N-^{207}Pb)$ have only negative values. The highest absolute values of $^1J(^{15}N-X)$ increase in the same sequence: 47.6 Hz (X = ^{29}Si, 344 Hz for ^{119}Sn, and 421 Hz for ^{207}Pb. The constants $^1K(^{15}N-X)$ for the X(II) derivatives are as a rule more negative than the constant ^1K for X(IV). This is associated with the fact that the valence *s* shells in X(II) are less accessible compared with the *s* shells in X(IV), i.e. are less involved in the formation of chemical bonds with the nitrogen atom. With increase in the number of electro-negative substituents at the X atom, the constants $^1K(^{15}N-X)$ become more positive, since the polarisability of the X atom then diminishes and the amount of *s* character of the N–X bond increases. Hitherto the long-range $^{15}N-X$ SSCC have been hardly investigated.

The $^{15}N-X$ SSCC for the coordinate N → X bond make it possible to obtain very valuable information about the nature of the bond in solutions. In many instances, these SSCC have been used as direct evidence for the existence of the N → X bond in solutions. Quantitative relations have been obtained between the $^{15}N-^{29}Si$ SSCC and the length, dissociation energy, and the order of the N → Si bond. However these relations are valid only for related compounds. A correspondence between the change in $^1J(^{15}N-X)$ and the properties of the N → X bond have been observed also for X = $^{117/119}Sn$ and ^{207}Pb. The $^{15}N-X$ SSCC then as a rule increase with increase in the strength of the N → X bond. This is one of the reasons why we have suggested in the present review that all the constants $^1K(^{15}N-X)$ for spin–spin coupling across a N → X coordinate bond are positive. However, in order to justify this hypothesis, it is essential to carry out additional studies (in the first place theoretical studies), since the mechanism of the spin–spin coupling across a coordinate bond remains obscure.

At the present time the measurement of the $^1J(^{15}N-X)$ SSCC for the natural abundances of isotopes presents no difficulties in most cases. The recently developed ultrahigh resolution NMR method[76-78] has led to the possibility of measuring the long-range $^{15}N-X$ SSCC for the natural abundances of the isotopes.[79,80] Hence one may expect that the study of these constants and their employment in structural research will expand.

Adiabatic compression in studies on the kinetics and mechanism of reactions involving fluorine-containing carbenes

Yu A Kolbanovskii
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

ABSTRACT. The physicochemical principles of adiabatic compression and its characteristics and potentialities in studies on the kinetics and mechanism of thermal gas-phase reactions are examined. The results of studying reactions involving fluorine-containing carbenes are presented. Information is given on the high-temperature tautomerism of tetrafluoroethylene–trifluoromethylfluorocarbene, which has been detected and studied using kinetic spectroscopy during adiabatic compression. The set of experimental data on the pyrolysis and gas-phase isomerisation of perfluoroolefins has been interpreted using the concept of tautomeric changes involving the 1,2-shift of a fluorine atom in olefins.

The bibliography includes 53 references.

I. Introduction

The method of adiabatic compression is not very widely known to chemists. Therefore, we considered one of the aims of the present review to be a demonstration of the characteristics and potentialities of this method for studying the kinetics and mechanism of thermal gas-phase reactions. All the examples that we will use to illustrate the potentialities of adiabatic compression relate to reactions of organofluorine compounds and primarily to reactions involving the formation and conversion of fluoroolefins.

This choice can be substantiated from different viewpoints. Firstly, reactions involving carbenes are highly characteristic for this region of chemistry; secondly, it was in this direction that a number of basic results were obtained using adiabatic compression; and thirdly, we took into account the considerable significance of thermal (pyrolytic) processes in the present-day technology for obtaining monomers for fluorinated rubbers and fluoroplastics. The latter circumstance makes the task of establishing a detailed mechanism of pyrolysis that is directed at the preparation of fluorinated monomers an urgent one for the development of scientific principles in optimising their production.

II. Adiabatic compression in physicochemical studies

The term "adiabatic" in thermodynamics relates to processes for which $dQ = 0$ in the equation of the First Law of Thermodynamics. For this condition to be maintained, the compression of gas must be sufficiently rapid that heat exchange between the gas and the wall of the vessel can be neglected. There are two possible ways of bringing about such a compression: one—with specific times less than the characteristic time for transmitting a sound distances of the order of the linear dimensions of the compressed volume of gas; the second is a slower compression, when the ratio of these times is given by a number greater than unity. In the first of these cases, shock waves develop in the gas and the process is represented by the Hugoniot adiabatic equation, in the second case shock waves do not develop and the process is given by Poisson's adiabatic equation. In units for the adiabatic compression of gases using a piston, its rate of movement is several times less than the speed of sound and, in accordance with Poisson's adiabatic equation, the pressure and temperature of an ideal gas on compression change according to the principle $p = p_0\varepsilon^\gamma$ and $T = T_0\varepsilon^{\gamma-1}$, where $\gamma = C_p/C_V$, the adiabatic factor; C_p and C_V are the specific heats at constant pressure and constant volume respectively; ε is the geometric compression ratio ($\varepsilon = V_0/V$, where V_0 and V are the initial and current values of the volume of gas). With such a compression the entropy of the system does not change and therefore it is sometimes called isentropic compression, taking into account the adiabatic process represented by Poisson's adiabatic equation. In order that the reader can form some idea about the values of the parameters reached in isentropic compression, we shall give one example that illustrates the potentialities of this method. If a monoatomic inert gas is at a temperature $T = 500$ K and pressure $p_0 = 2$ atm. before compression, with a compression ratio $\varepsilon = 50$ the parameters $T_{max} = 6700$ K and $p_{max} = 1320$ atm will be reached in it (the index "max" indicates that the value of the parameter relates to the moment of attaining the maximum compression ratio). No single apparatus could withstand such a combination of pressure and temperature if their duration was not about 10^{-4} s. Heat losses to the wall can hardly take place during this time, and so the compression proves to be adiabatic, the walls of the reactor are not heated up, and the apparatus is not destroyed. Thus, a new region of combinations of high values of p and T parameters is opened up for chemical studies. There are virtually no kinetic data (and sometimes also no thermodynamic data) for this region, and it is extremely important from both a purely scientific and a practical viewpoint to obtain these data.

When chemical reactions are studied using this method, attempts are made in all cases to maintain conditions in which

heat exchange between the gas and the wall can be neglected. However, in far from every case is it possible to ignore the evolution (or absorption) of heat produced by the chemical reaction itself. This does not result in a change in fundamental approach of the method but it must be taken into account in calculations. This will be discussed below.

Two principal features of the method should be apparent from what has been stated: the possibility of studying a gas-phase reaction with a previously known elimination of the effect from the vessel walls and the fact that all of the gas parameters vary with time. Since the temperature is included in these parameters, the adiabatic compression method can be classed as anisothermal. We shall consider these questions in more detail.

In studying the kinetics and mechanism of homogeneous gaseous reactions, problems relating to the effect of the surface of the reaction vessel and in particular its quantitative determination are among the most complex.[1] We consider this point because at the present time the role of the surface has been established in a whole range of processes when they are carried out both under steady-state conditions and in flow reactors of different types.[2-11]

Adiabatic compression can essentially reduce the effect of heterogeneous factors to a negligible level. The lack of isothermal conditions in adiabatic compression led, particularly at the beginning, to difficulties in processing the results. Therefore, in the first stage of studies on reaction kinetics using this method, so-called overall single-stage reactions were mainly studied and approximation methods were used to determine kinetic parameters.[12-17] At the present time reliable computer methods have been developed to calculate kinetic parameters from the experimental data obtained from adiabatic compression. We should note that, in principle, anisothermal methods are more informative than isothermal ones and their advantage can be effectively realised using computers.

We shall consider below approaches to the calculations of kinetic parameters from experimental data obtained on adiabatic compression units. First of all we can demonstrate that adiabatic compression actually ensures that gas reactions take place homogeneously. An obvious condition for homogeneity in the diffusion transfer of a substance[19-21] is that the marked inequality $L_{dif} \ll L_{reac}$, where L_{dif} is the diffusion length and L_{reac} is the characteristic dimension of the reaction volume, should be fulfilled. Let us choose Xe as the gas diluent, a temperature of 1600 K, and an adiabatic factor for the mixture of $\gamma = 1.6$. Such parameters are attained in a gas with standard properties when the compression ratio is 17, which corresponds to a density of the medium 17 times higher and a coefficient of diffusion 17 times lower than at atmospheric pressure. Taking into account the fact that the coefficient of self-diffusion of xenon at a pressure p_{atm} and 1600 K is 1 $cm^2\ s^{-1}$,[18] and the characteristic duration of these parameters during adiabatic compression is about 10^{-3} s, we deduce that the diffusion length will be of the order of 10^{-2} cm, whereas the characteristic dimension of the reaction volume for a compression ratio of 17 in units for studying the kinetics of chemical reactions by this method is usually of the order of 1 cm. Thus, the marked inequality referred to above is fulfilled.[19-21]

Figure 1 depicts the basic diagram of a unit for studying chemical reactions by means of adiabatic compression. The details of the experimental procedure and techniques are reported in detail in a book.[22]

We should say a few words about the treatment of experimental results. All experiments can provisionally be divided into two large groups. In one of them "normal" data—the composition of the products before and after the compression pulse—will occur; in the other group are data from experiments in which (optical) measurements are taken directly during the compression–expansion cycle. We shall only refer here to experiments of the first group. For greater clarity the simplest example can be considered without losing a common approach.

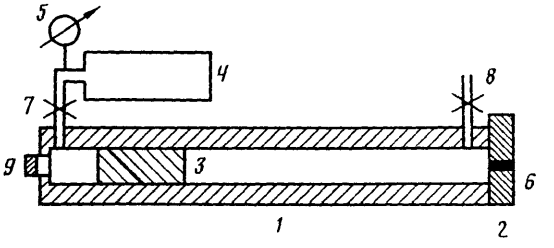

Figure 1. Basic diagram of the adiabatic compression unit:[22] *1*, cylinder; *2*, flange; *3*, piston; *4*, driving gas receiver; *5*, manometer; *6*, pressure gauge; *7*, valve for driving gas; *8*, valve for admission of operating mixture and withdrawal of samples for analysis; *9*, inertial valve.

Let the reaction under study be written in the form:

$$A + Xe \rightarrow \sum_{i=1}^{n} b_i B_i + Xe,$$
$$i = 1, 2 \ldots n,$$

where b_i are stoichiometric coefficients; n is the number of products, including unreacted substance A; B_i are reaction products. The kinetic equation may be written in the form:

$$\dot{N}_A = -kN_A (N_{Xe}/Sx),$$

where N_A and N_{Xe} are the numbers of moles of A and Xe respectively, k is the rate constant, S is the square of the cross section of the (cylinder) piston, x is the piston coordinate. It is assumed that the Arrhenius equation is satisfied, namely:

$$k = k_0 \exp(-E/RT).$$

Thus, in the kinetic equation, not only N_A proves to be a function of time as is usually the case but also the rate constant (since $T = T(t)$, where t is the time) and in addition the volume of the system $V = Sx$, since x also depends on time. Therefore, it is necessary to introduce equations which determine the dependences on time of both the piston coordinate and the temperature.

The piston coordinate can be found by interpreting the equation of its movement:

$$m\ddot{x} = S(p - p_d),$$

where m is the mass of the piston, p is the pressure of compressible gas, p_d is the pressure of driving gas. In this equation the frictional forces acting on the piston when it is moving in the cylinder are not taken into account since the experimental data show that the movement of the piston is wholly determined

by the pressure, and the frictional forces have virtually no effect on the movement of the piston. As is well-known, the relationship between pressure and temperature of a gas is given by the equation of state. In relatively simple cases (up to a compression ratio of about 17 for xenon) the equation of state of an ideal gas can be used. When a high compression is used in kinetic experiments, a virial equation of state must be used. Since the details of the calculation are naturally not covered here, we shall turn our attention to the dependence of temperature on time—the third value necessary to calculate the kinetic parameters. The calculation of temperature can be made in accordance with the equation of the conservation of energy:

$$N_\Sigma C_V^{mx}\dot{T} = q_V\dot{N}_A - Sp\dot{x},$$

where C_V^{mx} is the specific heat of the mixture at constant volume, q_V is the heat effect of the reaction at constant volume, and N_Σ is the total number of moles of the components of the gas mixture.

Thus we obtained a system of three differential equations for all three quantities that are dependent on time: the number of moles of reacting substance, the volume, and the temperature of the working mixture.

Such a simple situation is naturally exceptional. In practice it is necessary to deal with complex reactions, when there are more kinetic equations (according to the number of components) and the dependence of the specific heat of the mixture and the heat effect of the reaction on temperature must be taken into account. With high compression it is also necessary to include the dependences of the virial coefficients on temperature. However, an experiment to resolve these systems of differential equations in a study of the kinetics and mechanism of chemical reactions by means of adiabatic compression showed that the majority of the difficulties in this case were of a technical nature, the operating time expended was comparatively short, and the results were completely reliable. It is difficult now to point to another method used to study homogeneous gas reactions at high temperatures and pressures which is as effective as adiabatic compression.

Studies on high adiabatic compression of gases using a piston were started in the USSR Academy of Sciences on the initiative and under the direction of Khariton in the 1930's in Leningrad. Reinov and Klyazer participated in the studies. After the Second World War research was resumed by Ryabinin, Markevich, and their co-workers at the Institute of Chemical Physics of the USSR Academy of Sciences. Further details about this and references to the literature of those years are given by Kolbanovskii and Markevich.[23]

III. High-temperature carbene reactions involving fluorine-containing molecules

1. Early ideas about the mechanism of formation of lower perfluoroolefins during pyrolysis

Attempts to construct a consistent scheme for the mechanism of formation of C_2F_4, C_3F_6, and C_4F_8 during pyrolysis were undertaken right from the beginning when this area of chemistry was being developed.

The question concerning the formation of tetrafluoroethylene (TFE) by pyrolysis of CHF_2Cl (Cl-22) was perhaps one of the first to be elucidated. It was shown that the decomposition of Cl-22 leads to the formation of difluorocarbene (DFC), and the subsequent recombination of two molecules of the latter gives tetrafluoroethylene:

$$CHF_2Cl \rightarrow CF_2 + HCl, \quad (1)$$

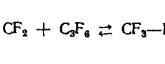
$$2\,CF_2 \rightarrow C_2F_4. \quad (2)$$

However, even for the next member of the perfluoroolefin series—hexafluoropropylene (HFP)—elucidation of the kinetics and mechanism of formation proved to be a complex task. The usual method for obtaining HFP is the pyrolysis of TFE. In the opinion of different authors[24,25] two reactions were responsible for the formation of HFP by pyrolysis of TFE:

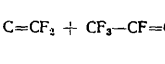
$$\rightarrow C_3F_6, \quad (3)$$

$$\rightarrow C_3F_6 + CF_2. \quad (4)$$

In this case both of the small rings are actually formed during pyrolysis according to the reactions:[26–36]



$$, \quad (5)$$



$$. \quad (6)$$

Traditional ideas concerning the formation of the different isomers of C_4F_8 are also based on a similar approach:

$$, \quad (7)$$

$$\rightarrow (CF_3)_2C{=}CF_2 + CF_3{-}CF{=}CF{-}CF_3 + CF_2{=}CF{-}CF_2{-}CF_3. \quad (8)$$

Let us analyse the basis of these conclusions. Cycloaddition reactions (5) and (7) are well-known for dihalocarbenes as is the cyclodimerisation of TFE. But these reactions do not give fluoroolefins directly, and therefore the conclusion about the mechanism of formation of perfluoroolefins was based on the results of the pyrolysis of perfluorocyclopropane and perfluorocyclobutane—in both the first and second cases HFP was found in the products. However, no real kinetic analysis of these experiments was carried out at that time. As regards reaction (8), there were no reliable data on the pyrolysis of perfluoromethylcyclopropane in the literature.

Let us now consider how the problem of determining the kinetics and mechanism of formation and the reactions of fluoroolefins at high temperatures was resolved.

2. Evidence for the incorrect nature of the early ideas about the mechanism of formation of perfluoroolefins by pyrolysis

We obtained the first evidence of this type without any special experiments at all. It was sufficient to analyse the results of one study[37] by means of comparative selectivities; it transpired that HFP is not a primary product of the pyrolysis of perfluorocyclopropane and hence reaction (3) does not take place. It follows from the same analysis that the only reaction in which this three-membered ring participates is reaction (5) in reverse. Only in this case TFE will be the sole primary stable product of the pyrolysis of perfluorocyclopropane.

Following this, doubts arose as to the possibility of the analogous reaction (8), about which there were no reliable experimental data, taking place. Therefore, an experimental study of the pyrolysis of perfluoromethylcyclopropane was undertaken using adiabatic compression. We shall only report here the qualitative results of this study carried out by Grigor'ev, German, Chepik, and the present author;† only TFE and HFP are found amongst the primary stable decomposition products and there are no compounds with the formula C_4F_8. This means that only reaction (7) in reverse takes place while reaction (8) does not occur at all.

Thus, only reaction (4) remained from the originally proposed mechanism for the formation of perfluoroolefins with composition C_3 and C_4. In order to determine the possible role of reaction (4) in the formation of HFP by pyrolysis of TFE, we undertook a study of the kinetics of the decomposition of octafluorocyclobutane by means of adiabatic compression. We shall report here only the principal results of this study.[38] It was established that the decomposition of perfluorocyclobutane is a first-order kinetic reaction with a rate constant of $10^{15.9\pm1.0}\exp(-322 \pm 19 \text{ kJ mol}^{-1}/RT)$. It was shown by the method of comparative selectivities that the sole primary stable product is TFE. It was found that the order of reaction for formation of HFP with respect to the initial compound was equal to 3/2, which is also not consistent with a scheme involving reaction (4)‡—formation of HFP is evidently first order with respect to the initial compound for this reaction.

Thus, it was shown during the initial studies that not a single one of the previously proposed reactions for formation of HFP and C_4F_8 occurs during pyrolysis and the mechanism of pyrolytic reactions involving lower perfluoroolefins had to be completely re-examined. It was established in this case in particular that perfluorocyclopropane and its derivatives do not undergo isomerisation reactions with ring-opening and decomposition to an olefin and CF_2 is the only route of their thermal reactions.

Thus, it was necessary not only to develop new, more thorough methods for the experimental study of the mechanism of high-temperature reactions involving carbenes but also to formulate a new hypothesis about such processes, since it was clear that a model for the mechanism which was based on any combination of previously proposed stages was not consistent with experiment.

3. Experimental detection of the high-temperature tautomerism $C_2F_4 \rightleftarrows CF_3 \simeq CF$:

We should mention initially that only for the convenience of presentation we will not start this section with an analysis of the literature data relating to the present subject and also with data on the "traditional" study of the kinetics of the pyrolysis of perfluoroolefins using adiabatic compression. These findings will be presented below.

Since it had transpired that not all of the data from studying the mechanism of pyrolysis that were solely based on an analysis of the final stable products could be successfully used, a spectroscopic method of studying the mechanism of pyrolysis was incorporated within the adiabatic compression technique. This method and the main results obtained from it are reported in a study[40] which we will mainly rely on in our review.

The following elements were incorporated into the adiabatic compression unit described in Section II. Windows made of optical quartz for spectroscopic probing of the compressed gas directly during a pulse were positioned at a distance of 9 mm from the closed end (see Fig. 1). The unit was provided with all the necessary equipment for evacuation of the working volume. The whole unit was rigidly fixed in a horizontal position on a main wall. Parallel to a line joining the centres of the quartz windows was positioned an optical bench. A light source (DRSh-500 lamp) and the necessary quartz optical equipment were fixed on it. A wide-aperture SDL-1 spectrometer with an FEU-39 and a double-beam storage S1-13 oscilloscope with a screen on which was recorded the optical signal and the signal from a piezoelectric pressure gauge were used. The data given below were obtained using a mixture of 5 vol. % C_2F_4 + 95 vol. % Ar.

It was necessary first of all to obtain spectroscopic purity in the adiabatic compression unit. There were certain misgivings about the possibility of aerosols being formed when the piston moved in the cylinder. It was therefore necessary to ensure that absorption of light by scattering on aerosol particles was excluded. This was tested in different regions of the ultraviolet and visible spectrum. It can be seen in Fig. 2 that the compression of specially purified argon does not alter the amplitude of the optical signal.

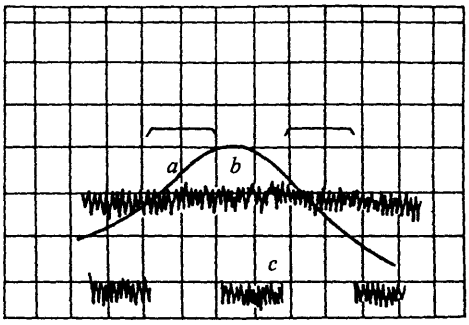


Figure 2. Oscillogram of the compression–expansion cycle of specially purified argon:[40] *a*, signal from piezoelectric pressure gauge; *b*, optical signal at λ = 248.3 nm.

After this it was necessary to ensure that the traces of triethylamine added to TFE in order to prevent it polymerising spontaneously did not contribute to the absorption of light. In order to do this, a comparison of the optical signal was made in two parallel experiments, in one of which TFE was not specially purified and in the other triethylamine was removed by careful freezing out at −60 °C. Within the limits of experimental error no difference was found between the oscillograms of these two experiments.

At high temperatures TFE is known to undergo reversible dissociation to two difluorocarbenes:

$$C_2F_4 \rightleftarrows 2CF_2. \quad (9)$$

†Presented at the anniversary session of the Scientific Council of the Institute of Petrochemical Synthesis, USSR Academy of Sciences, in November 1987.

‡A similar conclusion was reached by Preses et al.,[39] who studied the laser-initiated decomposition of cyclo-C_4F_8.

Amongst the studies investigating reaction (9) we should mention that of Schug and Wagner,[41] in which the values of the equilibrium constant and rate constant of the forward and reverse reaction of (9) were verified again using kinetic spectroscopy in shock waves at 1200–1600 K. The values of the kinetic constants found in this study[41] were used in our study.[40] However, when the first set of data from adiabatic compression was obtained it was found that with the values of the extinction coefficient of CF_2 given in the literature, the optical absorption at the maximum (Fig. 3), being attributed to CF_2, corresponded to concentrations of it that were much higher than that at equilibrium. Since there could be no notions of an excess equilibrium at the moment of maximum absorption during these experiments (on the contrary, it could be shown that the concentration of CF_2 at this point must be the equilibrium concentration) the conviction grew that during compression another component in addition to CF_2 appeared in the system, absorbing light in this region of wavelength. It could also be proved that this component was unstable and that its appearance was the result of a reversible process, since at the end of the compression–expansion pulse the absorption of light disappeared and the original transmission was restored. The result of resolving a direct kinetic problem was used as an addition argument. In this case a calculated curve of optical absorption during a pulse was obtained on the basis of literature data on the kinetics of reaction (9) with known values of the extinction coefficient. This curve was considerably different from the experimental one not only in amplitude, which has already been discussed, but also the characteristic time of the process: 1.8–1.9 ms instead of ~ 3 ms.

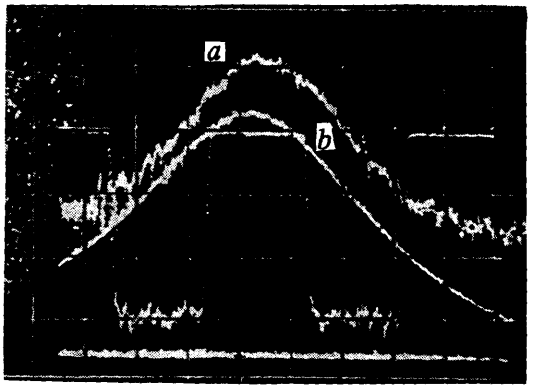

Figure 3. Oscillogram of the adiabatic compression–expansion cycle of a mixture of 5 vol. % C_2F_4 + 95 vol. % specially purified argon:[40] *a*, signal from piezoelectric pressure gauge; *b*, optical signal at λ = 248.3 nm; timescale: 1 square = 5×10^{-4} s.

Two experiments[40] provided definite clarification of the situation. Firstly, absorption of light was detected at a wavelength of 250 nm, where CF_2 does not absorb (taking into account the possible broadening of the lines and slit width). This experiment was based on the data of another study,[42] in which the electronic absorption spectrum of CF_2 was given. Secondly, there is an absorption at a wavelength of 271 nm, where it transpired that only CF_2 absorbs (Fig. 4). It can be clearly seen in Fig. 4 that the characteristic time of the signal actually constitutes about 2 ms, in exact agreement with the kinetic calculations for CF_2.

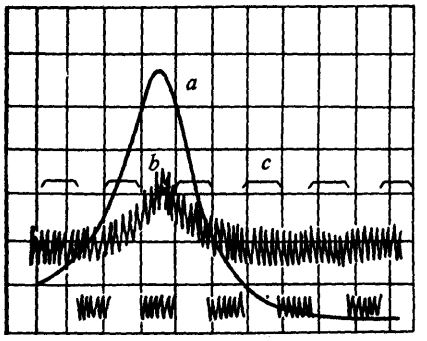

Figure 4. Oscillogram of the compression–expansion cycle of the same mixture (see Fig. 3); λ = 271.37 nm, 1 square = 10^{-3} s.

We should also mention that in all our experiments[40] absorption occurred starting at a temperature of about 820–850 K, although the absorption due to CF_2 at that point was far beyond the sensitivity limits of the spectrometer. Thus, the absorption of light by the carbene $CF_3–CF$:, not recorded previously by any direct methods, was detected in a region of light absorption typical for carbenes at a wavelength of 240–270 nm during the pulsed heating of C_2F_4 in argon. We should emphasise that the process is completely reversible and that the chemical conversion of C_2F_4 to other stable products under the conditions of our study[40] is at a level of about 2% (octafluorocyclobutane, which does not absorb at all in this region of the spectrum, is mainly formed).

It was not difficult to establish from the kinetic absorption curve that the process studied is kinetically first order. This means that trifluoromethylfluorocarbene is formed through a unimolecular reaction involving the 1,2-shift of a fluorine atom. In our opinion, this phenomenon is of basic significance for this area of chemistry and we are attempting to show here not only what conclusions folllow from it for an understanding of a whole series of experimental data but also the predictive power of the concept of olefin–carbene tautomerism in fluoroolefins.

Before going to the next section, it should be mentioned that Kushina et al.[43] had previously interpreted the formation of benzotrifluoride together with fluorobenzene in the combined pyrolysis of tetrafluoroethylene and cyclopentadiene as the result of the formation of $CF_3–CF$: from C_2F_4 and had proposed that this carbene must play an important role in the formation of HFP in the pyrolysis of TFE. Lipkind et al.,[44] by examining the data on the combined pyrolysis of C_2F_4 and C_3F_6 with cyclopentadiene and indene, also suggested that the carbenes CF_3CF and $(CF_3)_2C$ might possibly participate in these processes.

4. Kinetics and mechanism of the pyrolysis of TFE and HFP

In Sections III.1 and III.2 it was shown that the previously held ideas about the mechanism of the high-temperature reactions of TFE and HFP could not be consistent with experiment and it was

necessary to develop a new theory concerning the mechanism of these processes. In this connection let us consider the experimental data obtained using adiabatic compression and a kinetic analysis of the mechanism for pyrolysis of TFE and HFP. In interpreting the experimental results it is assumed that all changes in the number of carbon atoms in perfluoroolefins result from carbene reactions, with the carbenes formed either by decomposition of the olefin at the double bond or by tautomeric changes, namely, through a 1,2-shift of a fluorine atom.

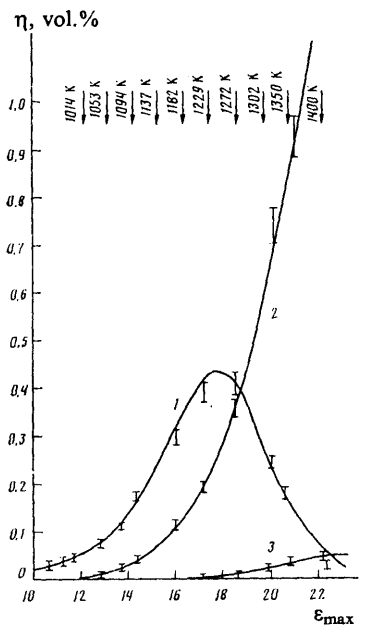

Figure 5. Pyrolysis of 5 vol. % C_2F_4 in specially purified argon by adiabatic compression;[22] T (deg K)—maximum temperature in one compression–expansion cycle; ε_{max}—maximum compression ratio; η—content in mixture after experiment in vol. % of: *1*, cyclo-C_4F_8; *2*, C_3F_6; *3*, C_4 fraction; points—experiment; lines—calculation.

The experimental data of Buravtsev et al.[45] on the pyrolysis of TFE and HFP using adiabatic compression are displayed in Figures 5 and 6. The experimental conditions are indicated in the captions. In Table 1, which is derived from the data collected and obtained by Grigor'ev,[46] are represented the fundamental stages which constitute in totality the mechanism for formation of HFP by pyrolysis of TFE. The values of the rate constants, some of which it was possible to determine for the first time using adiabatic compression, are also given.

An interesting detail was discovered in a computer calculation of the current concentration values of all components of the mixture during a single compression–expansion cycle. It transpired that the concentration of perfluorocyclopropane during pyrolysis was several orders less than the concentration of carbenes in all the systems of practical interest.

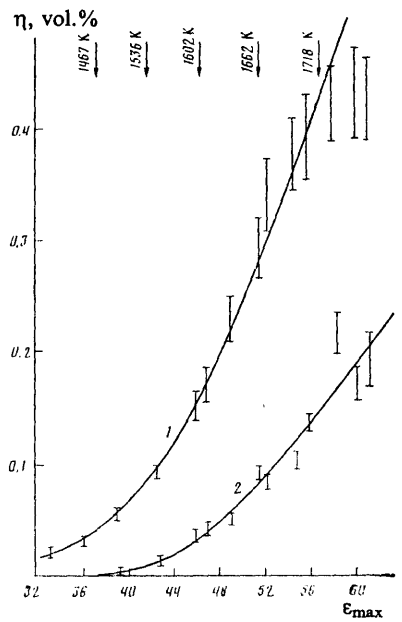

Figure 6. Pyrolysis of 4.65 vol. % C_3F_6 in specially purified argon by adiabatic compression[46] (see Fig. 5 for notation); *1*, C_2F_4; *2*, C_4 fraction.

Table 1. Arrhenius parameters of the fundamental reactions in the initial stages of the pyrolysis of $k = AT^n \exp(-E/RT)$ of TFE.[46]

Sample No.	Reaction	log A	E, kcal mol^{-1}	n
1	$2C_2F_4 \rightarrow$ cyclo-C_4F_8	12.1	30.3	0
2	cyclo-$C_4F_8 \rightarrow 2C_2F_4$	16.1	75.6	0
3	$C_2F_4 \rightarrow 2CF_2$	15.5	68.1	0
4	$2CF_2 \rightarrow C_2F_4$	8.7	1.2	1
5	$C_2F_4+CF_2 \rightarrow$ cyclo-C_3F_6	9.8	7.5	0

*Provisional value.

It is clear that only the stages of initial pyrolysis are given in Table 1, where secondary products, in particular perfluorobutenes of different structures, have not yet been formed. The processes relating to the formation and decomposition of C_4 perfluoroolefins require a separate treatment. As regards the pyrolysis of HFP, it is clear from the data given in Fig. 6 that the only stable primary product in this case is TFE. The reaction in which TFE is formed

by the pyrolysis of HFP is also given in Table 1 [reaction (9)] together with the calculated values of the pre-exponential factor and the energy of activation of the rate constant. The comment made above regarding the kinetics and mechanism of the formation and decomposition of C_4 perfluoroolefins is also valid with respect to the pyrolysis of HFP.

5. Pyrolysis and isomerisation of perfluorobutenes in the gas phase

In all of the data discussed in this review there is specific information on the formation of C_4F_8 compounds, but with two exceptions we will refrain from interpreting it. Let us recall these two cases. Firstly, from the data on the pyrolysis of perfluoromethylcyclopropane, amongst whose primary products there were no C_4 compounds, we could not regard it as an unstable intermediate during the formation of perfluoroolefins $C_2 \rightarrow C_3 \rightarrow C_4$. Secondly, there could be no doubt that the cyclic compound C_4F_8 — octafluorocyclobutane — is readily formed by cyclodimerisation of TFE but does not undergo isomerisation with ring-opening. Thus, it remained unclear how the principal minor products — C_4 perfluorocarbons with an open ring — are formed and how they behave during high-temperature pyrolysis. It should be mentioned that before studies using adiabatic compression were started, there was no information on this question in the literature familiar to us.

Let us consider first the data of German et al.[47] on the pyrolysis and isomerisation of perfluorobutenes of normal structure, obtained by means of adiabatic compression. In the pyrolysis of a mixture of 1.3 vol. % perfluorobut-2-ene (PFB-2) and argon the following was established. Even before the start of other reactions at a maximum temperature during the pulse of about 1100 K *cis-trans*-isomerisation becomes appreciable. When the temperature is increased further to 1200 K the *cis*/*trans* ratio remains almost constant at 0.35. Only TFE and HFP in the molar ratio 1 : 2 are recorded as stable primary products for low degrees of conversion of PFB-2. It must be admitted that for German et al.[47] this result was unexpected. In fact, after studying the pyrolysis of TFE and HFP, where it was found that their decomposition occurs by a carbene mechanism, it was natural to expect similar behaviour for the next members of the homologous series of perfluoroolefins, especially for PFB-2. In such a case only TFE should be amongst the stable primary pyrolysis products. In order for TFE and HFP to be in the stable primary pyrolysis product in the ratio 1 : 2, it was necessary in some way to eliminate from PBF-2 one CF_2 group, which does not exist in this molecule. The experimental data would readily demonstrate if decomposition were preceded by the isomerisation of PFB-2 to PFB-1. The decomposition of PFB-1 at its double bond must result in the formation of two carbenes:

$$CF_2=CF-CF_2-CF_3 \rightarrow CF_2 + CF-CF_2-CF_3.$$

The subsequent recombination of difluorocarbene and 1,2-shift of a fluorine atom in perfluoroethylfluorocarbene would give TFE and HFP in the observed ratio. However, PFB-1 was not found amongst the pyrolysis products of PFB-2. It was therefore necessary to make a second assumption: the isomerisation of PFB-2 to PFB-1 occurs more slowly than the decomposition of PFB-1. In other words, PFB-1 is considerably less stable at high temperatures than its isomer.

The data on the pyrolysis of PFB-1 that were obtained in the same study[47] confirmed both of these assumptions. In fact, when PFB-1 is pyrolysed, the stable primary products are TFE and HFP in the ratio 1 : 2 and the thermal stability of PFB-1 is markedly lower than for PFB-2. At 1174 K, when PFB-2 is completely stable, the degree of conversion of PFB-1 reaches 6%. It is important to mention that small quantities of PFB-2 are also found in this instance. This suggests that there is isomerisation on the double bond under the strictly homogeneous conditions of adiabatic compression. Previously there had been no information about this reaction. In addition, we should mention one further interesting feature of the pyrolysis of PFB-2. At high temperatures (about 1500 K) decomposition on the double bond proceeds more rapidly than isomerisation — TFE starts to predominate in the reaction products. In the pyrolysis of PFB-2 formation of its structural isomer — perfluoroisobutylene (PFI) — was only recorded at very high degrees of conversion and only in trace amounts, while in the pyrolysis of PFB-1 it was not detected at all. It must be concluded that the structural isomerisation of butenes does not occur during homogeneous pyrolysis.

Let us now consider the mechanism for the isomerisation of perfluorobutenes on the double bond. We shall also take into account here the strictly homogeneous reaction conditions and its kinetic first order. Using the concept of tautomeric changes in perfluoroolefins through the 1,2-shift of a fluorine atom, the following scheme can be proposed:

$$CF_3=CF-CF_2-CF_3 \rightleftarrows CF_3-C-CF_2-CF_3 \rightleftarrows CF_3-CF=CF-CF_3.$$

However, it is necessary here to make a reservation which in our opinion is very important. According to quantum-chemical calculations,[48] bis(trifluoromethyl)carbene $(CF_3)_2C$: has a triplet ground state which is separated from an excited singlet by 17.8 kcal mol^{-1}. It may be assumed that other carbenes which do not have fluorine atoms on the carbene carbon atom will also have a triplet ground state. But in that case the type of isomerisation depicted above is spin-forbidden unless we are dealing with the formation of a carbene in an electronically excited (singlet) state by a 1,2-shift. An alternative approach is isomerisation via a 1,3-shift. At the present time it appears to us premature to make a definite choice. For simple molecules, for example triatomic ones, spin-forbidden reactions are in fact known to occur via the formation of species in electronically excited states, as takes place, in particular, in the decomposition of nitrous oxide. There are up to now no data on reactions involving complex molecules of this type.

Let us now turn to the question of the mechanism for formation of PFI in the pyrolysis of perfluoroolefins. We recall (this has already been mentioned above) that in the decomposition of perfluoromethylcyclopropane no compounds with the formula C_4F_8 are formed. The simplest assumption of all is that PFI is formed by recombination of two carbenes:

$$CF_2 + (CF_3)_2C: \rightarrow CF_2=C(CF_3)_2.$$

However, the formation of bis(trifluoromethyl)carbene in the ground state by a 1,2-shift of a fluorine atom in HFP is spin-forbidden, according to Dixon.[48] Moreover, recombination of triplet $(CF_3)_2C$ with difluorocarbene, which has a singlet ground state, is also forbidden. Consequently, only a singlet electronically excited carbene must be obtained for the formation of PFI by this means through a 1,2-shift. In our opinion, this problem merits an additional special study. At the same time there is no prohibition for the formation of PFB-1, for example, in a recombination reaction

$$CF_2 + CF-CF_2-CF_3 \rightarrow CF_2=CF-CF_2-CF_3$$

since the carbene $CF-CF_2-CF_3$ which is formed by another 1,2-shift of a fluorine atom in HFP has a singlet ground state and such a shift is not spin-forbidden. It cannot be excluded that the formation of large quantities of PFI, which often occurs on pyrolysis in tubular reactors, is due to reactions on the wall of the tube, especially if there are deposits of carbon on it. Coking of the walls in metal tubes during pyrolysis is a familiar phenomenon and even in an earlier study[49] it was noted that reactions for the formation of bis(trifluoromethyl)carbene from HFP occur on activated carbon. Formation of the corresponding thioketone was accounted for exactly in this way:

$$CF_3-CF=CF_2 \rightarrow (CF_3)_2C:$$
$$S + (CF_3)_2C: \rightarrow (CF_3)_2C=S.$$

IV. Conclusion

It is evident from what has been stated above that high-temperature reactions of perfluoroolefins, having extensive practical application, have also proved interesting from the point of view of theoretical organic chemistry. We attempt here to arrive at some results. Since this article is both about "carbenes" and "method", our conclusion will touch upon both topics.

Let us start with method. The concentration of the tautomeric form of TFE in the temperature range 800–1000 K as found by Kolbanovskii et al.[40] reaches an equilibrium value after about 10^{-3} s. In adiabatic expansion such temperatures are reached at a compression ratio of 10, and hence the concentration of TFE increases relative to its initial value (under normal conditions) by a factor of 10. The equilibrium concentration of trifluoromethylfluorocarbene correspondingly increases by a factor of 10. With normal procedures for conducting the reaction, heating the gas to 1000 K leads a reduction in its density by approximately a factor of 3. Thus, the concentration of the tautomeric form of TFE using adiabatic compression when other conditions are the same is as a result one and a half decimal orders higher than it would be in conventional experiments at atmospheric pressure§ (in which it could hardly be detected and in fact has not been). It should be noted that in this respect the shock tube method is also considerably inferior to adiabatic compression. As regards the other advantages of adiabatic compression, they are described in sufficient detail in Section II.

Let us now turn to the "carbene" aspect of this review. We shall start with one important qualitative rule. The known processes for pyrolysis of hydrocarbons are usually aimed at obtaining products with a lower molecular weight than the initial starting material. A classic example of this type of process is the pyrolysis of gasoline to obtain ethylene. With perfluoroolefins everything is reversed; in the pyrolysis of C_1 (Cl-22), C_2F_4 is obtained, and in the pyrolysis of the latter, C_3F_6 is obtained. The mechanism of the pyrolysis of hydrocarbons consists of a set of radical chain reactions, as was established earlier by Rice. At the same time the synthetic processes for perfluoroolefins have a non-chain carbene mechanism. It is interesting to note that when it is necessary to account for certain high-temperature processes involving an increase in carbon chain in the chemistry of hydrocarbons, ideas about a carbene reaction mechanism also have to be included. Judging by recent studies, the formation of carbon black from acetylene occurs in precisely this manner.[50] It cannot be stated that high-temperature radical processes are untypical for perfluoroolefins. At high temperatures (usually above 1500 K) even after short pulses ($\sim 10^{-3}$ s), products such as C_2F_6 or C_4F_6 which result from radical reactions are formed from perfluoroolefins. However, even under these conditions, when free-radical reactions take place, chains do not develop.

Some comments should now be made regarding the tautomeric changes of perfluoroolefins. As was mentioned above, if the conversion of C_2F_4 to its tautomeric form is postulated, it is on the basis of indirect data (the final stable reaction products). As regards the reverse conversion of carbene to olefin, we cannot ignore two other studies,[51,52] in which not only was the IR spectrum of $(CF_3)_2C$: obtained for the first time (the carbene was obtained by photolysis of bis(trifluoromethyl)diazirine in an argon matrix at 12 K) but also some of its chemical reactions were studied. We only want to mention here the fact that at a temperature above 40 K this carbene disappeared and C_3F_6 appeared. This was the first direct observation of a reverse (carbene–olefin) change involving the 1,2-shift of a fluorine atom. The occurrence of this reaction at 40 K indicates that the reverse fluorine shift is a reaction which has virtually no energy barrier. There is no reason to suppose that for the other perfluorocarbene—CF_3CF:—there would be a different situation (or, at least, substantially different). At the same time, according to quantum-chemical calculations,[53] for fluoroethylene $CFH=CH_2$ the 1,2-shift of a fluorine atom requires an energy of activation both in the olefin and in the carbene.

In concluding our review of the reactions involving a 1,2-shift of a fluorine atom, we should like to draw the attention of the reader to a study that has been familiar for quite some time.[53] In this study the pyrolysis of trifluoroethylene gave the butene $CF_3-CH=CH-CF_3$ as the main product. When the concept of a 1,2-shift of a fluorine atom is applied, this result has a natural and perhaps the only reasonable explanation, if the following scheme is assumed:

$$CF_2=CHF \rightleftarrows CF_3-CH:,$$
$$2CF_3-CH: \rightarrow CF_3-CH=CH-CF_3.$$

There is no doubt that at the present time by no means everything has yet been clarified with regard to carbene reactions in the high-temperature conversions of organofluorine compounds. It is possible to identify such problems as the reasons for the low values of the recombination coefficients of C_2 and C_3 perfluorocarbenes (it is unclear whether they reduce solely to steric factors or whether there are other more fundamental causes), the possibility of forming electronically excited carbenes when the transition reactions to the ground state are spin-forbidden (this question is closely related to the mechanism for formation of PFI), and certain others. However, on the whole, it can be stated that by using adiabatic compression in studying high-temperature carbene reactions it was possible to obtain a series of new experimental results which did not simply supply facts but also served as a basis for developing the concept of tautomeric changes in fluorinated olefins.

§Dilution of C_2F_4 with an inert gas is necessary in any method for studying its tautomeric changes— otherwise the concentration of TFE will decrease sharply because of its cyclodimerisation.

Azaadamantanes with nitrogen atoms in the bridgehead positions

A I Kuznetsov, N S Zefirov
Lomonosov Moscow Institute of Fine Chemical Engineering

ABSTRACT. The methods of synthesis and properties of 1-aza-, 1,3-diaza-, and 1,3,5-triaza-adamantanes and their derivatives are discussed and treated systematically. The prospects for the employment of azaadamantanes in the solution of certain theoretical problems in the chemistry of nitrogen-containing compounds and for practical purposes—in catalysis, polymer technology and pharmacology—are demonstrated.

The bibliography includes 152 references.

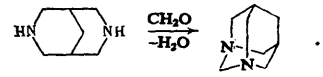
I. Introduction

Skeletal heterocyclic compounds with the adamantane structure (heteroadamantanes) constitute a large but so far only slightly investigated class of saturated heterocyclic compounds. They merit the continuous attention of chemists not only because of their structural relation to the unique hydrocarbon adamantane (I) but also because they have a set of specific properties resulting from the presence of heteroatoms in the adamantane nucleus. The published data on heteroadamantanes have been surveyed in a number of reviews[1–6] and in a separate chapter of a monograph on adamantanes.[7]

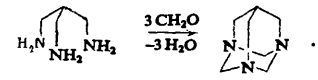
Azaadamantanes with nitrogen atoms in the bridgehead positions constitute a special branch of the chemistry of heteroadamantanes.



(I) (II) (III) (IV) (V)

They include 1-azaadamantane (II), 1,3-diazaadamantane (III), and 1,3,5-triazaadamantane (IV). Hexamethylenetetramine or 1,3,5,7-tetraazaadamantane (V) is also an azaadamantane. Together with this compound, azaadamantanes constitute an unusual series of compounds with identical molecular skeletons and common properties determined by the specific structure of their molecules (high melting point, volatility, thermodynamic stability, etc.) and by the presence of nitrogen atoms (basicity, high solubility in water, capacity for complex formation, etc.).[8]

Azaadamantane	(I)	(II)	(III)	(IV)	(V)
M.p., °C	269—272	250—252	260—264	260—262	287—288
p*K* (in DMSO)		9.70	8.80	7.60	6.40
p*K* (in water)		10.92	8.80	6.63	4.86



[8]

Together with common properties, there are also significant chemical differences between azaadamantanes. Whereas azaadamantanes (II) is a typical tertiary amine with a skeletal structure, in diazaadamantane (III) one of the methylene groups, located between the two nitrogen atoms, is an animal methylene group and the compound is the product of the condensation of 3,7-diazabicyclo[3.3.1]nonane (bispidine) (VI) with formaldehyde.

(VI) (III)

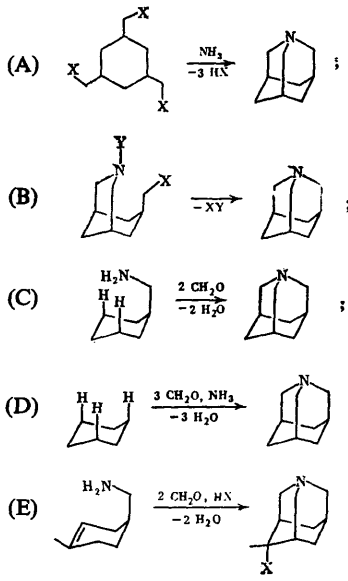
In triazaadamantane (IV), there are three aminal methylene groups and it is the product of the condensation of 2-aminomethyl-1,3-diaminopropane [tris(aminomethyl)methane] (VII) with formaldehyde.

(VII) (IV)

Azaadamantanes were first synthesised at the beginning of the 1950s and immediately aroused interest among investigators in different fields because of the possibility of using them in the solution of important theoretical problems in the chemistry of nitrogen-containing compounds and because of the prospect for their practical application in the synthesis of new biologically active preparations, rocket fuel components, and additives to fuel-lubricating materials, in photography, and in other fields.

The growth of the number of publications in the development of new novel methods of synthesis and the study of the properties of azaadamantanes and also the fields of their practical application which have arisen have given rise to the necessity for a survey and a separate examination of data which have accumulated on this new aspect of synthetic organic chemistry.

The review discusses literature data published up to 1987 inclusive.



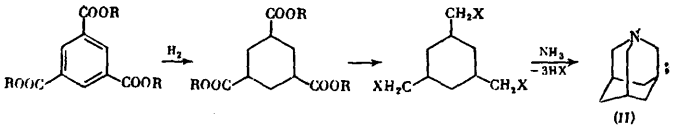
II. Methods of synthesis

Despite the existing general approaches to the synthesis of azaadamantanes, the ways leading to the formation of the structures of different azaadamantanes are extremely specific and require separate consideration. Whereas in the initial period of the development of the chemistry of azaadamantanes they were synthesised mainly by the gradual construction of rings, methods based on the condensation of acyclic or monocyclic compounds with the single-stage closure of all three rings of the adamantane nucleus

at once have been developed in recent years. Nevertheless, the multistage methods developed previously remain of practical value for the synthesis of individual representatives.

1. Synthesis of 1-azaadamantane and its derivatives

The methods of synthesis of azaadamantanes (II) and its derivatives are extremely varied but most of them can be reduced to the following several formal schemes:[4]

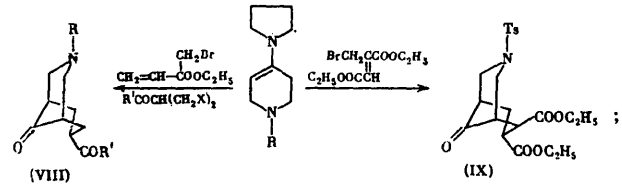


Pathway (A) represents the alkylation of ammonia, while pathway (B) represents the intramolecular alkylation of 3-azabicyclo-[3.3.1]nonane systems frequently with the simultaneous, preliminary, or subsequent elimination of the substituent at the nitrogen atom. Pathways (C) and (D) are based on the aminomethylation reaction of the type of the Mannich reaction and presuppose the presence of activating groups next to the designated hydrogen atoms. Pathway (E) is based on the condensation of alkenes with formaldehyde and amines.

The formal schemes present only the final stages of the formation of the azaadamantanes structure from the intermediates, whose synthesis is frequently a multistage process and requires special consideration.

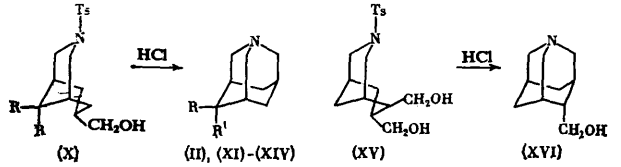
(a) The synthesis of 1-azaadamantane from trimesic acid

Azaadamantane (II) was first obtained in several stages from trimesic acid.[9−11] Subsequently individual stages of this synthesis were improved.[8,12] In the first stage, the methyl or ethyl ester of trimesic acid is hydrogenated in the presence of a platinum catalyst to esters of cyclohexanetricarboxylic acid and the latter are reduced with lithium tetrahydroaluminate to 1,3,5-tri(hydroxymethyl)cyclo-hexane.



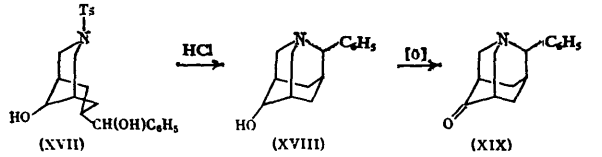
R=CH3, C2H5; X=OH, Br.

The latter is converted into azaadamantane (II) via 1,3,5-tribromo-methylcyclohexane or directly by interaction with ammonia over alumina at 375 °C.[12] Despite the low (not exceeding 10%) overall yield, this method still remains virtually the only one available for the synthesis of the unsubstituted azaadamantane (II).[8]



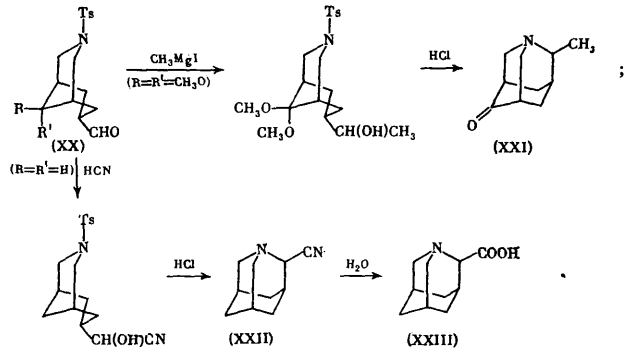
(b) Intramolecular alkylation of 3-azabicyclo[3.3.1]nonane derivatives

The intramolecular alkylation method is based on the αα′-annelation of enamines derived from 4-piperidinones with esters of β-bromomethacrylic,[13,14] ββ′-dibromoisobutyric,[13−16] and bromomethylfumaric[17] acids or with 2-benzoyl-1,3-dichloropropane,[18] which leads to the formation of 3-azabicyclo[3.3.1]nonanes (VIII) and (IX). The initial piperidinones were obtained in several stages from available initial compounds.



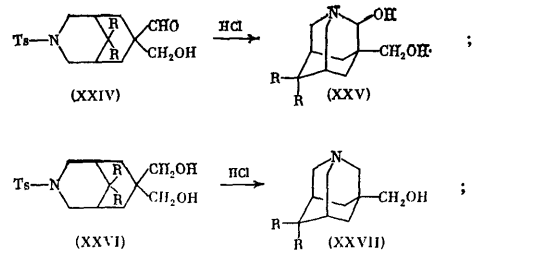
R=Ts, C6H5CO, C6H5CH2OCO; R′=C2H5O, C6H5;
X=Cl, Br.

After the modification of the keto-group in compounds (VIII) and (IX), the ester groups are reduced with lithium tetrahydroaluminate to the hydroxymethyl group. It has been observed that, when 7-hydroxymethyl-*N*-tosyl-3-azabicyclo[3.3.1]nonanes (X) and (XV), formed as a result of the reactions described above, are heated in acetic acid saturated with dry hydrogen chloride, simultaneous dissociation of the bond between the nitrogen atom and the tosyl group and intramolecular alkylation with formation of azaadamantane (II) and its derivatives (XI)−(XIV) and (XVI) take place.[14,15,17,18]



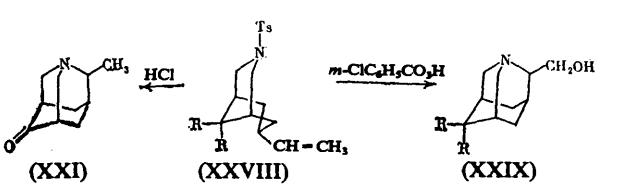
RR′ = O (XI); R = H, R′ = OH (XII);
R = OH, R′ = H (XIII); R = H, R′ = NH2 (XIV).

The diol (XVII)—the product of the reduction of the diketone (VIII, R = Ts, R′ = C6H5) (Ts = tosyl) with lithium tetrahydro-aluminate, cyclises in exactly the same way. Oxidation of 2-phenyl-1-azaadamantan-6-ol (XVIII), formed as a result of the cyclisation, with silver carbonate yields 2-phenyl-1-azaadamantan-6-one (XIX):[18]



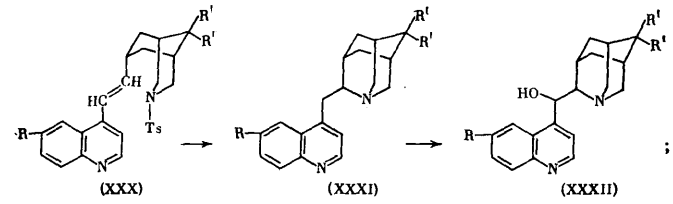
Oxidation of the 7-hydroxymethyl group in compounds (X) with R = R′ = H or CH_3O or with RR′ = SCH_2CH_2S affords the corresponding azabicyclononane derivatives (XX), from which azaadamantane derivatives with substituents at the C(2) atom can be obtained.[14,19] Thus treatment of the dimethoxy-derivative (XX, R = CH_3O) with a Grignard reagent or of the derivative (XX, R′ = H) with hydrocyanic acid, followed by treatment of the

resulting hydroxy-derivatives with hydrogen chloride in acetic acid, yielded respectively 2-methyl-1-azaadamantan-6-one (XXI) and 2-cyano-1-azaadamantane (XXII). 1-Azaadamantane-2-carboxylic acid (XXIII) was obtained from the latter by hydrolysis:[20]



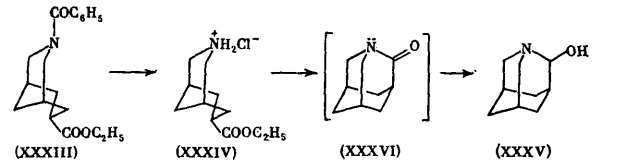
Condensation of formylazabicyclononanes (XX) with formaldehyde afforded the hydroxymethylformyl derivatives (XXIV), which cyclise on treatment with hydrogen chloride in acetic acid to 3-hydroxymethyl-1-azaadamantan-2-ol derivatives (XXV).[19] 2-Hydroxy-3-hydroxymethyl-1-azaadamantan-6-one (XXV, RR = O) obtained in this way is a rare example of a stable hemiaminal, whose stability can be explained by the incorporation of the hemiaminal nitrogen atom in the adamantane nucleus.

R=H, CH_3O; RR=O, SCH_2CH_2S.



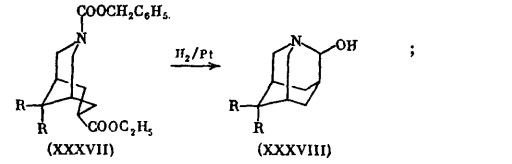
The 7,7-dihydroxymethyl derivatives of azabicyclononane (XXVI), obtained by reducing the aldols (XXIV), cyclise on treatment with hydrogen chloride in acetic acid to derivatives of 3-hydroxymethyl-1-azaadamantane (XXVII), but 3-hydroxymethyl-1-azaadamantane (XXVII, R = H) itself is not formed in this case. It is obtained[19] by eliminating sulphur from the thiolan derivative (XXVII, RR = SCH_2CH_2S) with Raney nickel.

The vinylazabicyclononanes (XXVIII) have been obtained from the corresponding formyl derivatives of azabicyclononane (XX) by the Wittig reaction. They are converted into azaadamantane derivatives (XXI) and (XXIX) by heating in acetic acid saturated with hydrogen chloride or by treatment with *m*-chloroperbenzoic acid.[19]



(XXVIII): R=H, CH_3O; (XXIX): R=H, RR=O.

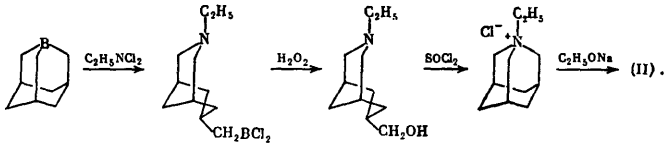
Condensation of the aldehydes (XX) with the lithium derivatives of quinolinylmethylphosphonic acid esters afforded quinolinylvinylazabicyclononane derivatives (XXX), which cyclise on treatment with hydrogen chloride to azaadamantane derivatives (XXXI). These were later used to obtain analogues of the quinuclidine alkaloids (XXXII) which contain the 1-azaadamantane nucleus instead of the quinuclidine nucleus.[21]



R=H, CH_3O; R′=H, CH_3O; R′R′=O, CH_2.

When an attempt was made to synthesise 1-azaadamantane (II) from *N*-benzoyl-7-ethoxycarbonyl-3-azabicyclo[3.3.1]nonane (XXXIII) the product of the annelation of compound (VIII, R = C_6H_5CO, R′ = C_2H_5O), i.e.

via the ester (XXXIV) (which was hydrogenated over a platinum catalyst in the form of the hydrochloride), 1-azaadamantan-2-ol (XXXV) was obtained unexpectedly instead of 1-azaadamantane (II).[16] It has been suggested that the readily reducible 2-oxo-1-azaadamantane (XXXVI) is formed as an intermediate. It is an unusual lactam, since the lone electron pair at its nitrogen atom is not conjugated with a carbonyl group but is disposed at a right angle to the C=O π-system.[16]

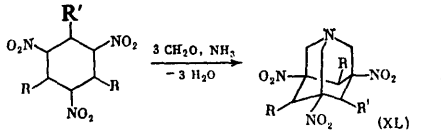


The *N*-benzyloxycarbonyl derivatives of azabicyclononane (XXXVII), obtained from the annelation product (VIII, R = $COOCH_2C_6H_5$, R′ = C_2H_5O), do in fact afford the corresponding derivatives of 2-hydroxy-1-adamantane (XXXVIII) on hydrogenation over a palladium catalyst.[16]

R=H; RR=OCH_2CH_2O.

Yet another method of synthesis of azaadamantane (II) via azabicyclononane derivatives has been developed by Soviet workers.[22] By treating 1-boraadamantane with ethyldichloroamine and subsequent oxidation of the resulting 7-dichloroboryl-methyl-*N*-ethyl-3-azabicyclo[3.3.1]nonane by hydrogen peroxide, they obtained *N*-ethyl-7-hydroxymethyl-3-azabicyclo[3.3.1]nonane (XXXIX). Its treatment with thionyl chloride in moist benzene leads

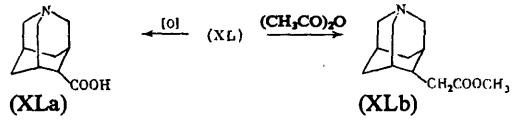
to 1-azaadamantane ethochloride. The ethyl group bound to the nitrogen atom is then removed by treatment with sodium ethoxide in alcohol.



(XXXIX)

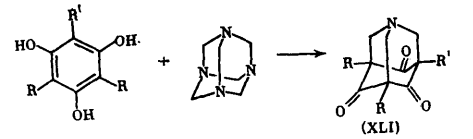
Improvement of the last two stages of the synthesis of azaadamantane (II) makes it possible to replan the synthesis of azaadamantane derivatives via azabicyclononanes.

(c) Aminomethylation of cyclohexane derivatives



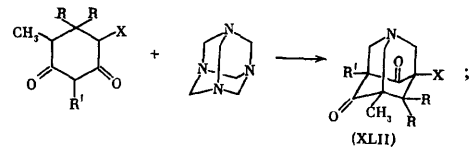
The possibility of synthesising the azaadamantane structure by condensing cyclohexane derivatives with formaldehyde and ammonia was first demonstrated in the synthesis of 3,5,7-trinitro-1-azaadamantane (XL, R = R′ = H) from trinitrocyclohexane, obtained by reducing trinitrobenzene [23] or picric acid [23–25] with sodium tetrahydroborate. Methyl- and dimethyl-trinitrocyclohexanes are obtained similarly from trinitrotoluene and trinitroxylene.[26] Trialkyltrinitrocyclohexanes are obtained by treating trinitrobenzene with Grignard reagents.[27] Hydroxymethyltrinitrocyclohexane has been obtained by reducing trinitrobenzaldehyde.[28] Treatment of trinitrobenzene with ketones in an alkaline medium followed by reduction with sodium tetrahydroborate afforded trinitrocyclohexane derivatives with a hydroxy-group in the side chain.[29,30]

The aminomethylation of trinitrocyclohexane and its derivatives is carried out in an aqueous medium using formaldehyde and ammonia or ammonium nitrate.[26,31,32] The yield of trinitroazaadamantane and its derivatives is between 10 and 50%. Instead of trinitrocyclohexanes, one can also use the hydroborate complexes, formed in the reduction of trinitroarenes, without isolating them in a pure form.[31–34] There are also other modifications of this reaction.[26,32]



R = H, CH_3, C_2H_5, C_3H_7; R′ = H, CH_3, C_2H_5, C_3H_7, CHO, CH_2OH, $CH_3CH(OH)CH_2$, $(CH_2)_3CH(OH)CH$, $(CH_2)_4CH(OH)CH$.

Oxidation of hydroxymethyltrinitroazaadamantane (XL, R = H, R′ = CH_2OH) afforded the acid (XLa) and its acylation gave rise to the acetate (XLb).[28]

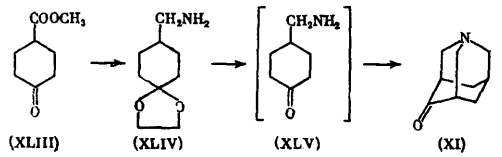


(XLa) (XLb)

Active hydrogen atoms, which are essential for aminomethylation, are also present in phloroglucinols, but phloroglucinol itself gives rise to only tarry products of the type of phenolformaldehyde resins in its reaction with formaldehyde and ammonia. On the other hand, it has been observed [35–37] that trialkylphloroglucinols are capable of condensing with hexamethylenetetramine to form 3,5,7-trialkyl-1-azaadamantane-4,6,10-triones (XLI) in high yields.

R = CH_3, C_2H_5, iso-C_3H_7; R′ = CH_3, C_2H_5.

1-Azaadamantane-4,6-dione derivatives (XLII) are obtained by condensing cyclohexane-1,3-diones with hexamethylenetetramine.[38–40]

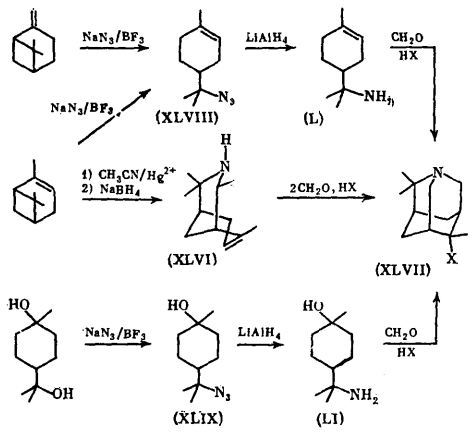


R = H, CH_3; R′ = CH_3, C_2H_5, n-C_8H_{17}, $C_6H_5CH_2$; X = $COOCH_3$, CN.

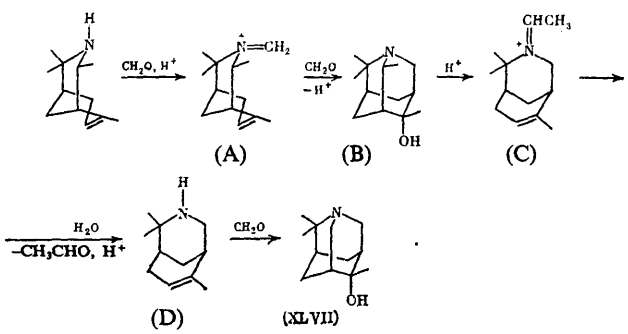
The initial cyclohexanediols are obtained by condensing α-vinylketones with malonic or cyanoacetic ester.

(d) Condensation of 4-(aminomethyl)cyclohexanone with formaldehyde

The possibility, in principle, of synthesising azaadamantane derivatives from 4-(aminomethyl)cyclohexanone derivatives has been demonstrated in relation to the synthesis of 1-azaadamantan-4-one (XI).[41]

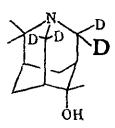


4-Methoxycarbonylcyclohexanone (XLIII), obtained from malonic and acrylic acid esters[41–43] or from 4-hydroxybenzoic acid,[44] was used as the starting material in this synthesis. After protecting the keto-group, the ketoester (XLIII) is converted into the amine (XLIV) (via the amide). When the latter is condensed with paraformaldehyde or trioxane in dilute sulphuric acid, the ketone protecting group is removed and the aminoketone (XLV) condenses with formaldehyde to azaadamantan-4-one (XI).[41] The value of the method is reduced by the low yield of the product (XI) in the condensation of the aminoketone (XLV) with formaldehyde.



(e) Synthesis of 1-azaadamantane derivatives from terpenes

An unusual approach to the building of the azaadamantane structure has been developed by French investigators.[44–48] They observed that, when α-pinene is treated with acetonitrile in the presence of mercury nitrate and the resulting adduct is reduced with sodium tetrahydroborate, 2,2,4,6-tetramethyl-3-azabicyclo[3.3.1]non-6-ene (XLVI) is obtained; the latter reacts in an acid medium with formaldehyde, whereupon the process involves formally the elimination of the methyl substituents from the C(6) atom and the formation of 4,8,8-trimethyl-1-azaadamantan-4-ol (XLVII, X = OH). By carrying out the reaction in the presence of azide or acetate ions, it is possible to obtain 4-azido- and 4-acetoxy-4,8,8-trimethyl-1-azaadamantanes (XLVII, X = N_3, CH_3COO). 4-Amino-4,8,8-trimethyl-1-azaadamantane (XLVII, X = NH_2) has

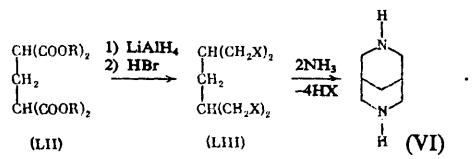


been obtained by reducing the azide with lithium tetrahydroaluminate.

The unusual elimination of the methyl group in the condensation of compound (XLVI) with formaldehyde is explained by the fact that, in the cyclisation of the methyleneimmonium cation (A) to the azaadamantane derivative (B), the methyl group at the C(4) and C(9) atoms are subjected to strong diaxial repulsion, which induces the dissociation of the C(2)–C(3)σ-bond of the type of Grob fragmentation. In the hydrolysis of the ethylideneimmonium cation (C), formed as a result of such fragmentation, a molecule of acetaldehyde is split off and the bicyclic product (D) condenses subsequently with formaldehyde, affording azaadamantanol (XLVII, X = OH).

In order to confirm the mechanism described, the deuteriated analogue of formaldehyde was employed instead of the usual formaldehyde, as a result of which deuteriated azaadamantanol was obtained.

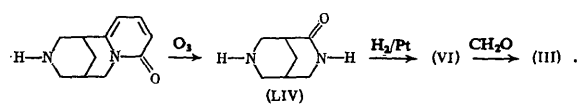
The use of the toxic mercury nitrate in the synthesis described above creates disadvantages which can be avoided by employing a somewhat different scheme for the synthesis of azaadamantane derivatives (XLVII). Thus treatment of α-pinene with sodium azide in ether in the presence of boron trifluoride leads to the opening of the four-membered ring and the formation of the azide (XLVIII). The same product is formed under analogous conditions also from β-pinene. The azidoalcohol (XLIX) is formed from terpyne hydrate under the same conditions. Both azides, (XLVIII) and (XLIX), were reduced with lithium tetrahydroaluminate to the amines (L) and (LI), which were then condensed with formaldehyde in an acid medium to azaadamantanol (XLVII, X = OH).



The development of methods of synthesis of azaadamantane derivatives from terpenes leads to their availability, which permits their practical employment.

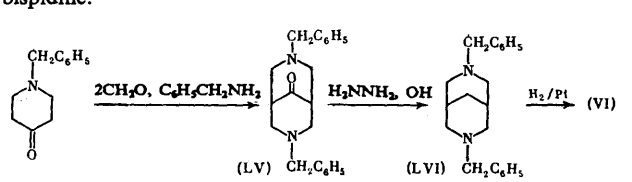
2. Synthesis of 1,3-diazaadamantane and its derivatives

The methods of synthesis of 1,3-diazaadamantane (III) and its derivatives frequently reduce to the synthesis of bispidine (VI) and its derivatives followed by their condensation with aldehydes, in some cases without isolating the bispidines.



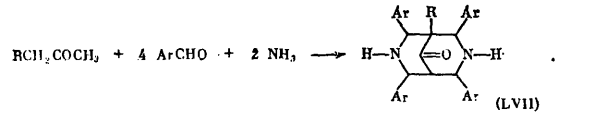
(a) Synthesis of 1,3-diazaadamantane and its derivatives via bispidine and its derivatives

The methods of synthesis of 3,7-diazabicyclo[3.3.1]nonane (bispidine) (VI) and its derivatives have been examined in detail in other reviews.[49,50] They included data published up to 1972. The synthesis of bispidine (VI) and diazaadamantane (III) from the products of the condensation of malonic ester with formaldehyde (LII), which is subsequently reduced with lithium tetrahydroaluminate to 2,4-di(hydroxymethyl)pentane-1,5-diol (LIII, X = OH), was reported later.[51] Treatment of the last compound with hydrogen bromide in acetic acid yields 1,5-dibromo-2,4-di(bromomethyl)-pentane (LIII, X = Br). When this tetrabromo-derivative is heated in a methanol solution of ammonia, bispidine (VI) is formed.

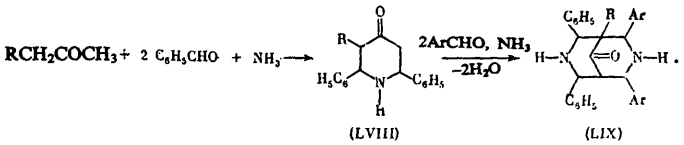


The method requires further improvement, especially in the stage involving reduction and the conversion of the tetrabromo-derivative (LIII, X = Br) into bispidine (VI), since in these stages the products are formed in a low yield, which reduces the overall yield (<7%).

The synthesis of diazaadamantane from the alkaloid cytisine has been reported.[52] In the first stage, 2-oxobispidine (LIV) is obtained by the ozonolysis of cytisine. Its hydrogenation in the presence of a platinum catalyst leads to bispidine (VI) from which diazaadamantane (III) is synthesised in its turn.

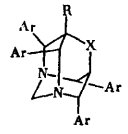


Perhaps the most effective method of synthesis of bispidine (VI) is based on the condensation of the readily available *N*-benzyl-4-piperidinone with paraformaldehyde and benzylamine, which leads to the formation of the unstable *NN'*-dibenzylbispidinol (LV). It is reduced, without isolation, by the Huang-Minlon method to *NN'*-dibenzylbispidine (LVI). Hydrogenation of the latter in acetic acid under pressure in the presence of a palladium catalyst leads to bispidine.[53]



The overall yield of bispidine (VI) recalculated in terms of *N*-benzylpiperidinone is about 60%.

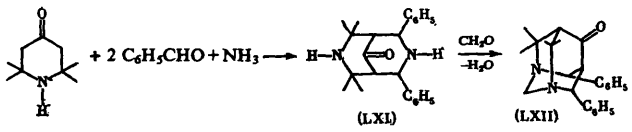
Condensation of acetone or ethyl methyl ketone (but not other ketones) with various aromatic aldehydes and ammonia or their reaction products affords exceptionally readily tetraarylbispidinones (LVII, R = H, CH_3) with aryl substituents at the bridging carbon atoms. In order to obtain bispidinones with various aryl substituents, the reaction is carried out in two stages: the first stage yields diphenylpiperidinones (LVIII, R = H, CH_3), while the second stage gives rise to the bispidinones (LIX):[54-58]



(LVII)

(LVIII) (LIX)

The keto-group in tetraarylbispidinones (LVII) and (LIX) is then reduced to the methylene or hydroxy-group. The condensation of tetraarylbispidines with paraformaldehyde in carbon tetrachloride, dichloroethane, dimethylformamide, or dioxane gives rise to the corresponding tetraaryldiazaadamantanes (LX).



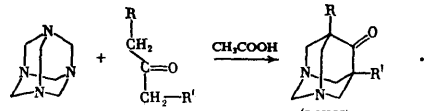
(LX)

R = H, CH_3; X = CH_2, CHOH, CO; Ar = C_6H_5, 4-$CH_3OC_6H_4$, 4-ClC_6H_4, 2-ClC_6H_4, 3,4-$(CH_3O)_2C_6H_3$, 4-$CH_3C_6H_4$, α-C_5H_4N.

Tetraaryldiazaadamantanols (LX, X = CHOH) and tetraaryldiazaadamantanes (LX, X = CH_2) are also obtained by reducing diazaadamantanones (LX, X = CO) with lithium tetrahydroaluminate or by the Wolff–Kishner method.

It has long been assumed,[59,60] that only formaldehyde can condense with diarylbispidine, but it has been found that aromatic aldehydes also react similarly;[56,58] however, the reaction is very slow (45 days) and the yield does not exceed 10%.

By a procedure similar to that used for tetraaryldiazaadamantanes (LX), tetramethyldiphenyldiazaadamantanone (LXII) can be obtained from triacetoneamine via a substituted bispidinone (LXI).[61,62]



(LXI) (LXII)

Despite the ease of their synthesis, tetraaryldiazaadamantanes (LX) are apparently not very promising because of the cumbersome nature of their molecules, only a small proportion of which corresponds to the diazaadamantane nucleus.

(b) Synthesis of 1,3-diazaadamantan-6-ones

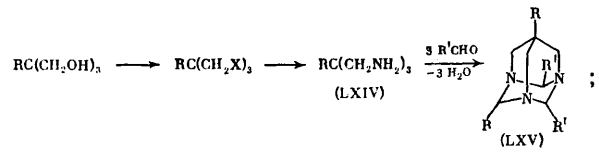
The most convenient and readily available intermediates for the synthesis of various diazaadamantane derivatives are at present 1,3-diazaadamantan-6-ones (LXIII). Until recently, they were obtained by condensing the corresponding ketones with formaldehyde and ammonia. Mainly ketones with activated α- and α′-hydrogen atoms were used in the reaction. 5,7-Diphenyl-,[63-65] 5,7-dimethoxy- and 5,7-diethoxy-,[65,66] 5,7-di(phenylthio)-,[63] 5-phenyl-7-phenylthio- and 5-phenyl-7-*p*-tolylthio-,[67,68] 7-ethoxycarbonyl-5-phenyl-,[69] and 7-methoxycarbonyl-5-phenylthio-1,3-diazaadamantan-6-ones[70] have been obtained in this way. It was shown later that 5,7-dimethyl-1,3-diazaadamantan-6-one can also be obtained by the same method but in a low yield.[71]

A more effective and a more general method of synthesis of diazaadamantanones (LXIII) is based on the condensation of ketones with hexamethylenetetramine.[72-74]

(LXIII)

The replacement of formaldehyde and ammonia by hexamethylenetetramine makes it possible to increase the yield of dimethyldiazaadamantanone (LXIII, R = R′ = CH_3) from 20 to 74% and that of diphenyldiazaadamantanone (LXIII, R = R′ = C_6H_5) from 59 to 90%; however, the most significant feature is that the new method makes it possible to obtain diazaadamantanones not only with two hydrocarbon substituents virtually of any kind but also with one substituent.

The increase in the yield of diazaadamantanones (LXIII) when hexamethylenetetramine is used can be explained by a change in the chemistry of the process. When ketones are condensed with formaldehyde and ammonia, the diazaadamantane structure is formed as a result of a large number of intermolecular reactions,[75] each of which may be accompanied by the formation of side products. On the other hand, in the condensation with hexamethylenetetramine, diazaadamantanones can be formed as a result of a single intermolecular interaction of the protonated form of hexamethylenetetramine with a ketone and subsequent intramolecular rearrangements with elimination of the methylenediamine fragment in one of the concluding stages and the formation of diazaadamantone.

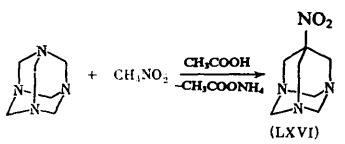


3. Synthesis of 1,3,5-triazaadamantane and its derivatives

1,3,5-Triazaadamantane (IV), which represents, as already mentioned, the products of the condensation of tris(aminomethyl)-methane (VII) with formaldehyde, was first obtained by this reaction in 1952.[76] The initial tris(aminomethyl)methane (VII) is difficult to obtain; it is synthesised by a complex multistage method from malonic and acetonedicarboxylic acid esters via methanetriacetic acid and its amide:[76]

$$HC(CH_2COOH)_3 \rightarrow HC(CH_2CONH_2)_3 \rightarrow HC(CH_2NH_2)_3.$$
(VII)

The homologues of tris(aminomethyl)methane (LXIV) can be obtained much more readily. They are obtained from the available



tris(hydroxymethyl)ethane and its homologues via the tribromo-derivatives by the phthalimide method[71] or via the tritosylate and the triazide:[78]

$R = CH_3$, $C_{12}H_{25}$; X = Br, N_3; $R' = H$, C_6H_5, α-C_5H_4N.

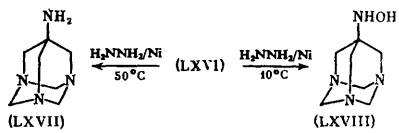
Condensation of the triamines (LXIV) with formaldehyde affords triazaadamantane (LXV, R′ = H) derivatives with substituents at the bridgehead carbon atom,[77,79] while condensation with benzaldehyde and 2-formylpyridine gives rise to tribenzyl- and tri-α-pyridyl-triazaadamantanes (LXV, R = CH_3, R′ = H, C_6H_5, α-C_5H_4N) containing substituents also at the aminal carbon atoms.[80,81]

Triazaadamantane derivatives with functional groups at the bridgehead carbon atom are obtained from 7-nitro-1,3,5-triazaadamantane (LXVI), which was first synthesised[82] by condensing nitromethane with formaldehyde and ammonia. A number of modifications of this process were proposed later.[83–92] The best method involves the condensation of hexamethylenetetramine with nitromethane in the presence of acetic acid[83,88,90] first proposed by Kuznetsov et al.[83]

By optimising the process, it was found[93] that the highest yield of the target product (LXVI) is obtained for the molar ratios hexamethylenetetramine : nitromethane : acetic acid = 1 : 1.1 : 2.3. The proposed mechanism of the formation of nitrotriazaadamantane (LXVI) has been described.[94]

The simple and convenient methods of synthesis of azaadamantane derivatives developed in recent years, especially those based on the condensation of hexamethylenetetramine with nitro-compounds and carbonyl compounds, make them extremely readily available for study and for use in the synthesis of other azaadamantane derivatives.

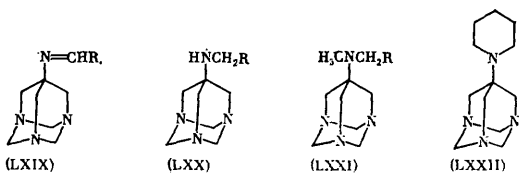
III. Chemical properties



The chemical properties of azaadamantanes are determined primarily by the presence and mutual influence of the nitrogen atoms in the bridgehead positions in the adamantane nucleus. The presence of aminal methylene groups in di- and tri-azaadamantanes is responsible for the tendency of these compounds to react with certain electrophiles. The similarity to adamantane (I), which increases as the number of nitrogen atoms is reduced, suggests that such derivatives, especially azaadamantane (II), have properties characteristic of adamantane, in particular those associated with the increased reactivity of hydrogen atoms at the bridgehead positions.

The mutual influence of nitrogen atoms affects primarily the basicity of azaadamantanes, which decreases with increase in the number of nitrogen atoms in the molecule.[8] Protonation of one of the nitrogen atoms leads to the distribution of the charge between the remaining nitrogen atoms of the molecule. Polyazaadamantanes usually behave as monoacidic bases in their reactions with acids. The aminal character of the methylene groups linking the nitrogen atoms in di- and tri-azaadamantanes is manifested to a much lesser extent than for the usual aminals or hexamethylenetetramine. Thus, whereas the latter readily breaks down on heating with inorganic acids, di- and tri-azaadamantanes do not decompose even on prolonged heating with concentrated hydrochloric acid.

1. Reactions of functional groups

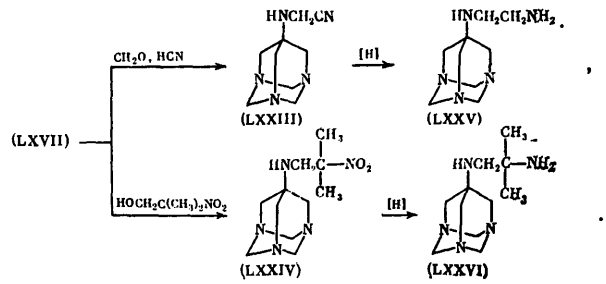


The method of synthesis of azaadamantane described in the previous Section lead as a rule to the formation of derivatives with functional groups which serve as intermediates in the synthesis of other azaadamantane derivatives.

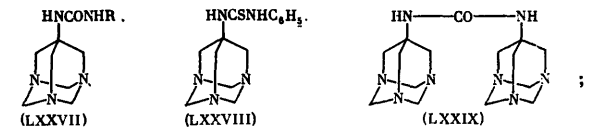
One of such available intermediates is nitrotriazaadamantane (LXVI). It is reduced to 7-amino-1,3,5-triazaadamantane (LXVII) with lithium tetrahydroaluminate,[82] with hydrogen in the presence of nickel,[82,84,85,91] cobalt,[91] rhodium[86,92] or platinum[89,92] catalysts, with zinc in an alkaline medium,[87,92] and with iron or tin in an acid medium.[87,92] The most convenient method involves reduction with hydrazine hydrate at atmospheric pressure in the presence of a nickel catalyst at 50 °C.[94]

At a lower temperature (+10 °C), 7-hydroxyamino-1,3,5-triazaadamantane (LXVIII) is obtained in 67% yield.[94]

Aminotriazaadamantane (LXVII) has also been used as an intermediate in the synthesis of a large number of derivatives. Its reactions with aromatic and aliphatic aldehydes afford the azomethines (LXIX).[95–97] Their hydrogenation in the presence of a platinum catalyst yielded alkyl- and aryl-methylaminotriazaadamantanes (LXX). The reductive methylation of the latter leads to methylalkylaminotriazaadamantanes (LXXI).[86,92]



R = C_6H_5, 4-$CH_3C_6H_4$, 4-ClC_6H_4, 2-HOC_6H_4, 4-$CH_3OC_6H_4$, 4-$(CH_3)_2NC_6H_4$, α-C_5H_4N, α-C_4H_3O, CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, iso-C_4H_9, n-C_5H_{11}, H.



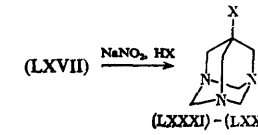
Methylaminotriazaadamantane (LXX, R = H) cannot be obtained by the reductive methylation of aminotriazaadamantane (LXVII), since dimethylaminotriazaadamantane (LXXI, R = H) is formed immediately.[84,86] Treatment of the amine (LXVII) with glutaraldehyde under reductive conditions yields 7-(1-piperidinyl)-1,3,5-triazaadamantane (LXXII).[86]

When aminotriazaadamantane (LXVII) is used as the amine component in aminomethylation reactions, only one hydrogen atom of the amino-group in compound (LXVII) participates in the reaction. The products of the condensation of compound (LXXVII) with formaldehyde and hydrocyanic acid [compound (LXXIII)] or

with 2-nitropropane [compound (LXXIV)] were reduced to the corresponding aminoethyl derivatives (LXXV) and (LXXVI).[84,89,98]

Triazaadamantanylureas (LXXVII) have been obtained by the reaction of the amine (LXVII) with isocyanates,[84,87,99,100] while the reaction with phenyl isothiocyanate afforded thiourea (LXXVIII). Heating of aminotriazaadamantane (LXVII) with urea gives rise to 1,3-bis(triazaadamantyl)urea (LXXIX).[99,101]

R = C_6H_5, 3-ClC_6H_4, 4-ClC_6H_4, C_6H_{11}.

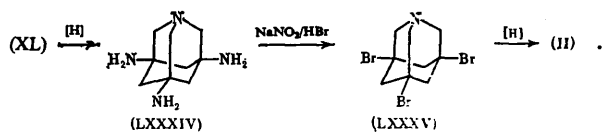


The synthesis of the amides (LXXX) from aminotriazaadamantane (LXVII) involves certain difficulties because acylating agents such as carboxylic acid anhydrides and chlorides can decompose the triazaadamantane skeleton. Therefore, in order to obtain 7-acetamido-1,3,5-triazaadamantane (LXXX, R = CH_3), the amine (LXVII) was heated with isopropyl acetate,[86] while the benzamido-derivative (LXXX, R = C_6H_5) and the nitrobenzamido-derivatives (LXXX, R = 3-$O_2NC_6H_4$, 4-$O_2NC_6H_4$) were obtained by heating the methyl benzoate and nitrobenzoate.[99] The nitrobenzamido-derivatives were reduced to the aminobenzamido-derivatives (LXXX, R = 3-$H_2NC_6H_4$, 4-$H_2NC_6H_4$).[99]

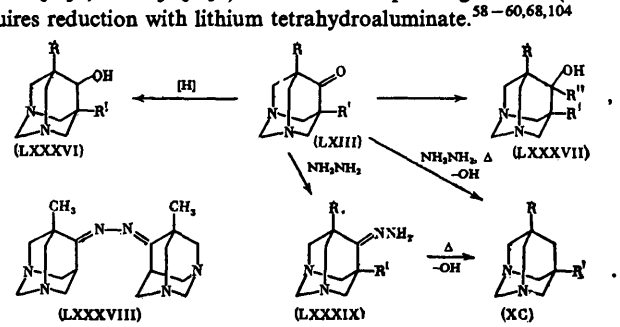
R = CH_3, C_6H_5, 3-$O_2NC_6H_4$, 4-$O_2NC_6H_4$, 3-$H_2NC_6H_4$, 4-$H_2NC_6H_4$, $C_6H_5CONHCH_2$, $C_2H_5OCONHCH_2$, $CH_3OCONHCH_2$, H_2NCH_2.

The benzamido-derivative (LXXX, R = C_6H_5) has also been synthesised by the carbodiimide method and the mixed anhydride method.[102] The acylglycinamido-derivatives (LXXX, R = $C_6H_5CONHCH_2$, $C_2H_5OCONHCH_2$, $CH_3OCONHCH_2$) have been obtained by the mixed anhydride method.[102] Their hydrolysis led to the glycinamido-derivative (LXXX, R = H_2NCH_2).[102]

In order to convert the readily available aminotriazaadamantane (LXVII) into other triazaadamantane derivatives, its diazotisation with sodium nitrite was investigated in different acids.[83,87,94] Triazaadamantanol could not be synthesised by this procedure, but, when the reaction was carried out in concentrated hydrochloric and hydrobromic acids, 7-chloro- and 7-bromo-1,3,5-triazaadamantanes (LXXXI) and (LXXXII) were obtained in preparative yields.



X=Cl (LXXXI), Br (LXXXII), SCN (LXXXIII).

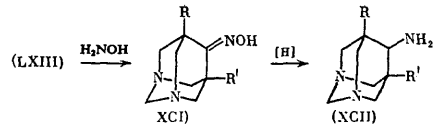


The diazotisation of compound (LXVII) in sulphuric acid in the presence of potassium thiocyanate leads to 7-thiocyanato-1,3,5-triazaadamantane (LXXXIII).[94] Heating of the latter with Raney nickel affords the unsubstituted triazaadamantane (IV).

Triazaadamantane (IV) has been synthesised in a virtually quantitative yield by reducing bromotriazaadamantane (LXXXII) with hydrazine hydrate in the presence of a nickel catalyst.[94] This is the last stage in what is nowadays the most convenient three-stage scheme for the synthesis of 1,3,5-triazaadamantane (IV) from the available nitrotriazaadamantane (LXVI).[94]

The unsubstituted 1-azaadamantane (II) can be obtained via a similar scheme from 3,5,7-trinitro-1-azaadamantane (XL), since it has been shown[103] that the diazotisation of 3,5,7-triamino-1-azaadamantane (LXXXIV), obtained by reducing compound (XL) [27] with sodium nitrite in concentrated hydrobromic acid, results in the substitution of the amino-group by a bromine atom, as in the diazotisation of aminotriazaadamantane (LXVII), and in the formation of 3,5,7-tribromo-1-azaadamantane (LXXXV). Thus deamination accompanied by substitution of aminoazaadamantane with preferential formation of halogenoazaadamantanes is a common reaction for compounds of this class; however, it does not extend to 1-aminoadamantane, which is converted into adamantan-1-ol under similar conditions.

The diazaadamantanones (LXIII) are intermediates for the synthesis of various derivatives of diazaadamantane, particularly those with functional groups at the C(6) atom. The reactivity of the carbonyl group in these compounds is determined to a large extent by the number and character of the substituents at the bridgehead positions.[104] In the presence of only one substituent or two substituents such as the methyl group, diazaadamantanones (LXIII) are reduced to 1,3-diazaadamantan-6-ols (LXXXVI, R = H, R′ = CH_3 or R = R′ = CH_3) even on treatment with sodium tetrahydroborate,[104] whereas the synthesis of the diazaadamantanols (LXXXVI, R = R′ = C_6H_5, $C_6H_5CH_2$, C_6H_5S or R = C_6H_5, R′ = C_6H_5S, 4-$CH_3C_6H_5S$) from the corresponding ketones (LXIII) requires reduction with lithium tetrahydroaluminate.[58-60,68,104]

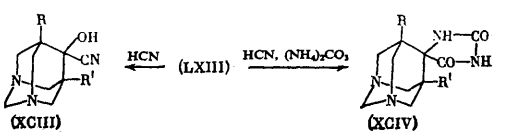


Various arylthiodiazaadamantanones (LXIII, R and/or R′ = C_6H_5S) have been obtained with the aim of their subsequent conversion into diazaadamantane derivatives without substituents at the bridgehead positions by eliminating sulphur, but the study of this reaction demonstrated their interesting and important feature: on heating with Raney nickel in alcohol, monoarylthioadamantanones (LXIII, R = C_6H_5S, R′ = C_6H_5, $COOCH_3$) smoothly eliminate sulphur with simultaneous reduction of the keto-group to an alcoholic group and are converted into monosubstituted diazaadamantanols (LXXXVI, R = H, R′ = C_6H_5, $COOCH_3$), whereas di(phenylthio)diazaadamantanone (LXIII, R = R′ = C_6H_5S) does not eliminate sulphur under these conditions and is merely reduced to di(phenylthio-diazaadamantanol (LXXXVI, R = R′ = C_6H_5S).[63]

Diazaadamantanones (LXIII) react with methylmagnesium iodide and organolithium compounds affording the corresponding tertiary alcohols (LXXXVII).[104,105]

Depending on the structure of the substituents R and R′, diazaadamantanones (LXIII) react in different ways with hydrazine: on heating with hydrazine hydrate, methyldiazaadamantanone (LXIII, R = CH_3, R′ = H) affords only the azine (LXXXVIII) as the stable product, while phenyl- and dimethyl-diazaadamantanones (LXIII, R = H, R′ = C_6H_5, CH_3 or R = R′ = CH_3) readily form the corresponding hydrazones (LXXXIX) whose fusion with alkali gives rise to the diazaadamantanes (XC).[104] Diazaadamantanones with two substituents such as the phenyl, phenylthio-, or *p*-tolylthio-group are reduced to the diazaadamantanes (XC, R = R′ = C_6H_5, C_6H_5S or R = C_6H_5, R′ = C_6H_5S, $CH_3C_6H_4S$) by the Huang-Minlon method.[59,60,63,68,104]

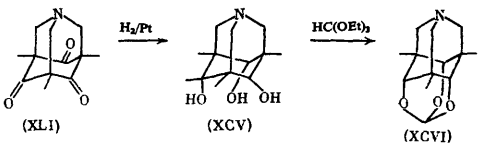
Monosubstituted diazaadamantanones and dimethyldiazaadamantanone react with hydroxylamine to form the oximes (XCI, R = H, R′ = CH_3, C_6H_5 or R = R′ = CH_3) in an aqueous medium,[104] whereas the oxime of diphenyldiazaadamantanone (XCI, R = R′ = C_6H_5) is formed only after prolonged heating with hydroxylamine in a pyridine-ethanol mixture in a yield of only 48%.[106]



XCI) (XCII)

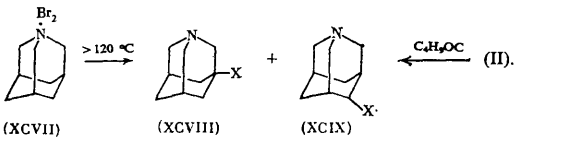
R=H, R′=CH_3, C_6H_5; R=R′=CH_3, C_6H_5.

The oximes (XCI) are reduced to 6-amino-1,3-diazaadamantanes (XCII) by a nickel-aluminium alloy in an aqueous alkaline medium.[104]



The diazaadamantanones (LXIII) with two bulky substituents, such as the phenyl and phenylthio-groups, do not form cyanohydrins, whereas methyl- and dimethyl-diazaadamantanones are readily converted into the corresponding cyanohydrins (XCIII) on heating with acetone cyanohydrin. 1,3-Diazaadamantane-6-spiro-5′-hydantoins (XCIV) were obtained from the cyanohydrins by the Bucherer method.[107]

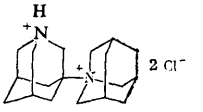
(XCIII) (XCIV)



R=H, R′=CH_3; R=R′=CH_3.

The reactivity of the monoazaadamantanones (XLI) and (XLII) is still to be investigated, but so far it has been shown that the hydrogenation of trimethylazaadamantanetrione (XLI, R = R′ = CH_3) in the presence of a platinum catalyst results in the formation of trimethylazaadamantanetriol (XCV) with the axial disposition of all three hydroxy-groups relative to the cyclohexane ring, which has been confirmed by its conversion into the heterodiamantane (XCVI).[36]

(XLI) (XCV) (XCVI)

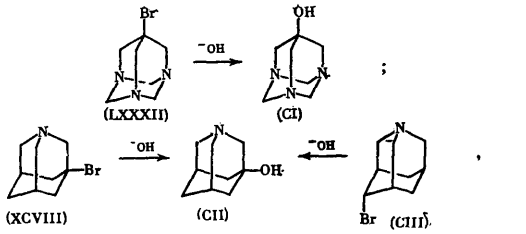


The most important intermediates in the synthesis of derivatives of adamantane (I) itself are halogenoadamantanes obtained by its halogenation.[7] The halogenation of 1-azaadamantane (II) has been investigated.[108,109] When bromine is added to a solution of azaadamantane (II) in carbon tetrachloride, complex (XCVII) is formed. When an attempt is made to obtain from it 3-bromo-1-azaadamantane (XCVIII, X = Br) via an ionic mechanism by adding aluminium chloride or bromide and bromine, it is possible to isolate only the complexes of azaadamantane with these salts. On the other hand, on heating complex (XCVII) to 120 °C, a mixture of 3- and 4-bromo-1-azaadamantanes (XCVIII, X = Br) and (XCIX, X = Br) is formed.

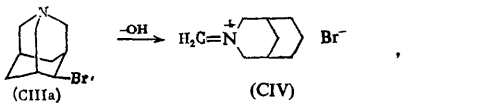
(XCVII) (XCVIII) (XCIX)

The absence of 2-bromo-1-azaadamantane from the radical bromination products probably indicates its instability.[108] 3-Chloro- and 4-chloro-1-azaadamantanes (XCVIII) and (XCIX) with X = Cl have been obtained by irradiating with UV light a mixture of azaadamantane and t-butyl hypochlorite.[108] Comparison of the ratios of the products of the radical halogenation of adamantane (I) and 1-azaadamantane (II) shows that the introduction of a nitrogen atom into the adamantane nucleus does not have a significant influence on the radical halogenation reaction.

When a solution of azaadamantane (II) in carbon tetrachloride is irradiated with UV light or when it is treated with hydrogen peroxide, the salt (C) is formed and can be regarded formally as the product of the alkylation of azaadamantane with 3-chloro-1-azaadamantane.



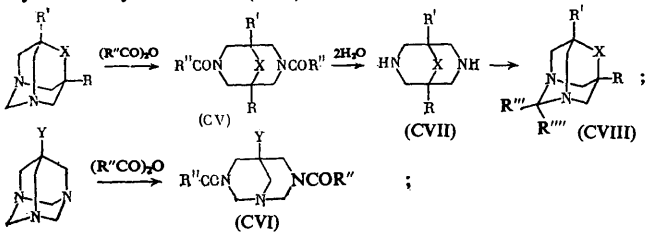
(C)



The same product is also formed in the photochemical chlorination of azaadamantane with trichloromethanesulphonyl chloride.[108] Here it was shown that 3-chloro-1-azaadamantane (XCVIII, X = Cl) does not participate in the formation of the salt (C), since irradiation of a mixture of compound (XCVIII, X = Cl) and azaadamantane (II) does not lead to the formation of the salt (C). On this basis, it has been suggested that the alkylating agent in the formation of compound (C) is the 1-azaadamantane radical-cation.[109]

The halogen atoms in 1-halogenoadamantanes, which are key intermediates in the chemistry of adamantane (I), are comparatively

readily substituted by nucleophiles. Kinetic studies have shown that the rate of hydrolysis of 3-bromo-1-aza- and 7-bromo-1,3,5-triaza-adamantanes (XCVIII, X = Br) and (LXXXII) is lower by several orders of magnitude than the rate of hydrolysis of their analogue—1-bromoadamantane.[108,110] The passivating influence of nitrogen atoms can be explained by their electron-accepting inductive effect and the impossibility, for geometrical reasons, of their anchimeric involvement, as in other β-halogenoamines. Hydrolysis of the halogenoazaadamantanes indicated leads to 1,3,5-adamantan-7-ol (CI) and 1-azaadamantan-3-ol (CII), which could not be obtained by other methods hitherto.[110]



Hydrolysis of the isomeric 4-bromo-1-azaadamantanes (CIII) proceeds in different ways: the isomer (CIIIa) with the bromine atom in the axial position relative to the piperidine ring is unstable under hydrolysis conditions and is converted into the methylene-immonium cation (CIV), i.e.

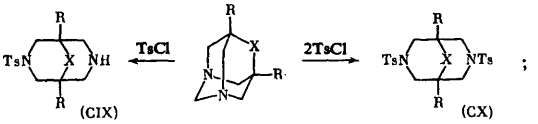
where the isomer (CIIIb) with the equatorial orientation, obtained by treating 1-azaadamantan-4-ol (XII) with phosphorus pentabromide, hydrolyses to 3-hydroxy-1-azaadamantan (CII) and not to the 4-hydroxy-derivative.[16]

2. Reactions with elimination of aminal methylene groups

The di- and tri-azaadamantanes containing aminal methylene group split them off on treatment with various reagents. Diazaadamantanes react with carboxylic acid anhydrides and chlorides to form diacylbispidines (CV), while triazaadamantanes afford diacyltriazabicyclononanes (CVI).[63,64,67,68,71,112–116]

X = CO, CHOH, CH_2; Y = NO_2, NHOH, NH_2, NHCOR;
R, R′ = H, C_6H_5S, 4-$CH_3C_6H_4S$;
R″ = H, CH_3, C_6H_5, C_2H_5O, $ClCH_2$;
R‴ = H, R′′′′ = CH_3, C_2H_5, C_3H_7, C_6H_5, 4-$O_2NC_6H_4$, 4-$CH_3OC_6H_4$, α-C_4H_3O, 4-($ClCH_2CH_2$), NC_6H_4, $H(CHOH)_4$, $H(CHOH)_5$ or R‴R′′′′ = $(CH_2)_4$, $CH_2)_5$.

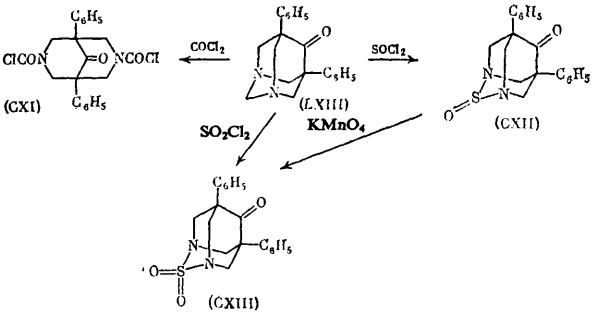
NN-Diformylbispidines (CV, R″ = H) can be obtained by the reaction of diazaadamantanes with chloroform in an alkaline medium.[65,114]



Arylthio- and diarylthio-diacetylbispidines (CV, R and/or R′ = C_6H_5S, 4-$CH_3C_6H_4S$) readily eliminate sulphur on treatment with Raney nickel, being converted into diacetylbispidines (CV, R and/or R′ = H) with one or two bridgehead positions free from substituents.[12,63,67,68]

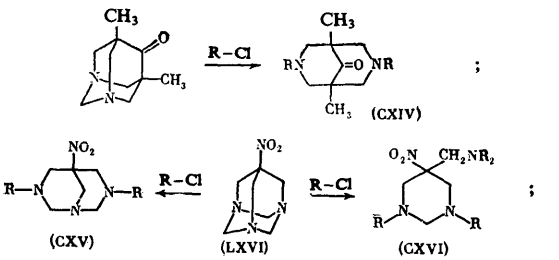
The bispidines (CVII) without substituents at the nitrogen atoms can be obtained by the hydrolysis of diacetylbispidines (CV). They condense with various aldehydes and ketones to diazaadamantane derivatives (CVIII) with substituents at the aminal carbon atom.[63,64,68,71,115]

Under hydrolysis conditions, the bispidinones (CVII, X = CO) can be converted into the corresponding diazaadamantanones (LXIII).[63]



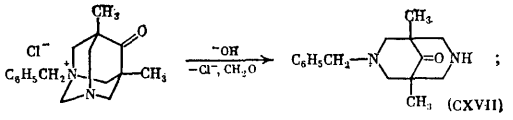
The hydroxyamino- and amino-derivatives (CVI, Y = NHOH, NH_2) can be obtained by hydrogenating nitrodiacetyltriazabicyclononane (CVI, Y = NO_2).[84,85]

Treatment of diazaadamantanes with toluene-*p*-sulphonyl chloride can yield *N*-tosylbispidines (CIX) or *NN*′-ditosylbispidines (CX).[63,109]

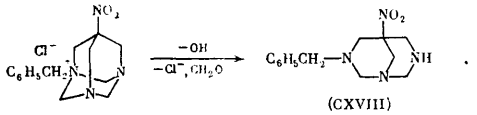


X = CO, CH_2; R = H, C_6H_5.

The attempt to replace the aminal methylene group in diphenyldiazaadamantane (LXIII, R = R′ = C_6H_5) by treating it with phosgene led to the formation of only the bispidine derivative (CXI), whereas treatment with thionyl or sulphuryl chloride in pyridine affords the 2-oxide (CXII) of the 2,2-dioxide (CXIII) of 5,7-diphenyl-1,3-diaza-2-thiaadamantan-6-one; the former can be oxidised to the latter with potassium permanganate.

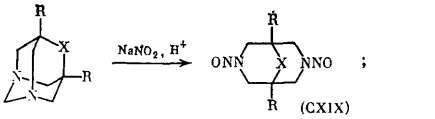


The interaction of di- and tri-azaadamantanes with benzyl, allyl, and propargyl chlorides, α-chloroketones, and chloroacetic acid esters can also be accompanied by the elimination of the aminal methylene groups; triazaadamantanes can then split off both one and two methylene groups, affording the corresponding derivatives of bispidine (CXIV), triazabicyclononane (CXV), and hexahydropyrimidine (CXVI).[118,119]

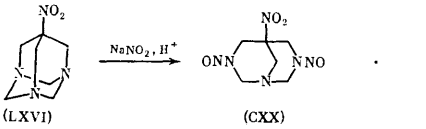


R = $C_6H_5CH_2$, CH_2=$CHCH_2$, HC≡CCH_2, $C_6H_5COCH_2$, $C_2H_5OOCCH_2$.

These reactions can be explained by the fact that, in the quaternary salts formed from di- and tri-azaadamantanes, the bond between the aminal methylene group and the quaternary nitrogen atom is weakened, which has been demonstrated by the X-ray diffraction analysis of the methiodide of diphenyldiazaadamantanone (LXIII, R = R′ = C_6H_5).[120] On treatment with bases, the aminal methylene group therefore splits off, affording the bispidine and triazabicyclononane derivatives (CXVII) and (CXVIII).[118,119]

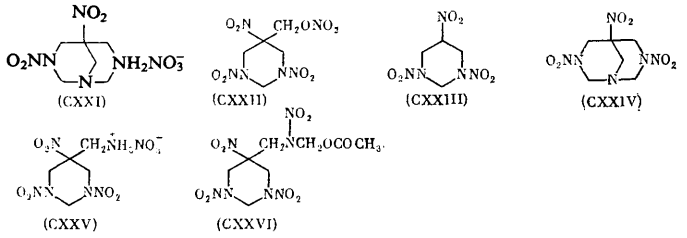


(CXVII)



(CXVIII)

Treatment of di- and tri-azaadamantanes with nitrous acid leads to the formation of the dinitroso-derivatives of bispidine (CXIX) and triazabicyclononane (CXX).[63,121,122]

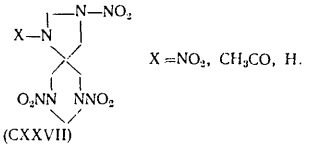


(CXIX)

R=H, C_6H_5; X=CO, CH_2.

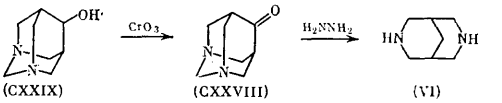
(LXVI) (CXX)

Nitration of nitrotriazaadamantane (LXVI) [123] resembles the nitration of hexamethylenetetramine[124,125] and leads to the following products (depending on the conditions):



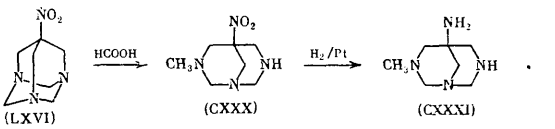
(CXXI) (CXXII) (CXXIII) (CXXIV)

(CXXV) (CXXVI)



The bicyclic product (CXXI) is formed in the nitration of compound (LXVI) with fuming nitric acid at −40 °C, whereas on raising the temperature to −10 °C more far-reaching decomposition of the triazaadamantane skeleton takes place with formation of the monocyclic product (CXXII). This product is stable on heating in alcohols, but, on boiling in water, it is converted into 1,3,5-trinitrohexahydropyrimidine (CXXIII). Nitration with a mixture of concentrated nitric and sulphuric acids results in the formation of 3,5,7-trinitro-1,3,7-triazabicyclo[3.3.1]nonane (CXXIV). Nitration of compound (LXVI) with a mixture of concentrated nitric acid and ammonium nitrate gives rise to the product (CXXV), while nitration with a mixture of fuming nitric acid, acetic anhydride, and acetic acid at the usual temperature affords the product (CXXVI).

When aminotriazaadamantane (LXVII) is nitrated with fuming nitric acid, the tetraazabicyclic products (CXXVII) are formed.

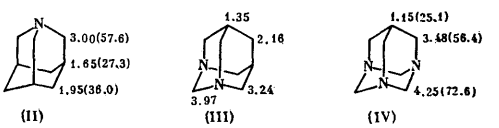


(CXXVII)

Under severe conditions, the aminal methylene groups can be split off also on treatment with hydrazine. Thus when an attempt was made to reduce 1,3-diazaadamantan-6-one (CXXVIII), [obtained by oxidising diazaadamantanol (CXXIX) with chromium trioxide[126]] by the Huang–Minlon method, bispidine (VI) was synthesised instead of diazaadamantane (III).[127]

(CXXIX) (CXXVIII) (VI)

The opening of one of the rings of nitrotriazaadamantane (LXVI) with the simultaneous reduction of the methylene group to the methyl group occurs when it is heated with formic acid under the conditions of the Leuckart reaction. The 3-methyl-5-nitro-1,3,7-triazabicyclo[3.3.1]nonane (CXXX) was hydrogenated to the amine (CXXXI) in the presence of a platinum catalyst.[23]



(LXVI) (CXXX) (CXXXI)

IV. Physical and spectroscopic properties

The nitrogen atoms hardly affect the spherical shape (sphere diameter 6.71 Å) [7] of the adamantane nucleus, which represents the unit cell of the crystal lattice of diamond. Such molecular geometry determines many physical and spectroscopic characteristics of azaadamantanes.

By virtue of the high molecular symmetry, the NMR spectra of azaadamantanes are exceptionally simple and characteristic. The chemical shifts δ (in p.p.m.) of the protons measured in CCl_4 are listed below[8] (the ^{13}C chemical shifts are indicated in brackets[128]):

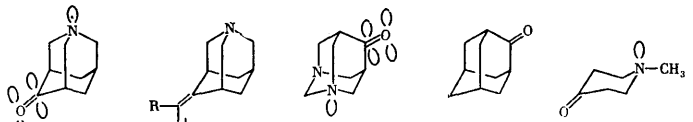
(II) (III) (IV)

The spectra of various azaadamantane derivatives have been published in a number of communications including Refs. 73, 74, 80, 112, and 129–131.

The protons at the bridgehead positions are manifested in all cases by broadened singlets in a higher field the greater the number of nitrogen atoms in the molecule.

The spectra of mono- and tri-azaadamantanes (II) and (IV) having the same molecular symmetry are similar and consist of singlets, due to the protons of the NCH_2C groups, and of the AB-systems due to the remaining protons. On the basis of the splitting into doublets of the AB-systems, induced by the interaction

with the protons of the NCH_2C groups, a definite orientation relative to the symmetry axes of the molecules can be assigned to the corresponding protons.



In the spectrum of diazaadamantane (III) the protons at the C(6) atoms and of the aminal methylene group are manifested by singlets, while the protons of the NCH_2C groups are manifested by an AB-system.

It is noteworthy that, whereas the nitrogen atoms shield the protons at the bridgehead positions [δ = 1.87 p.p.m. for the methylidyne proton of adamantane (I)], the protons of the methylene groups in the β-positions are strongly deshielded [δ = 1.74 p.p.m. for the methylene protons of adamantane (I)].

The mass spectra of triazaadamantane (IV) and its derivatives contain intense peaks due to molecular ions, which decompose subsequently via two independent pathways depending on the character of the substituents. If the substituents of the C(7) atom are H, Cl, Br, and NO_2, then they are readily abstracted and the spectra of different derivatives differ little from one another. On the other hand, if the substituents are electron-donating groups such as the amino-group, they are not split off and persist in all the main ions of the mass spectrum. The molecular ions of halogenotriazaadamantanes can split off, apart from halogen atoms, also hydrogen halide molecules, although with a lower probability. The most intense ion in the mass spectra of triazaadamantanes is, as for hexamethylenetetramine, the $[C_2H_4N^+]$ ion.[132]

The mass spectra of diazaadamantanones (LXII) have been considered.[74] The decomposition of the molecular ions is accompanied by the breakdown of the adamantane nucleus with formation of the ions $[C_2H_4N]^+$, $[M-C_2H_4N]^+$, $[C_3H_2RCO]^+$, and $[M-C_2H_5N]^+$, the last one being as a rule the most intense.

The UV spectra of azaadamantanone (XI), diazaadamantanone (CXXVIII),[80,127,129] and substituted 6-methyleneazaadamantanes (CXXXII, R = R′ = H, CN; R = $COOC_2H_5$, R′ = H, CN) are of special interest.[131] The last compounds were obtained from the ketone (XI) via Wittig, Horner, or Knoevenagel reactions.[17]

(XI) (CXXXII) (CXXVIII) (CXXXIII) (CXXXIV)

The point is that conditions under which the *n* electrons of the nitrogen atom can interact with the π-systems of the multiple bonds are largely maintained in these compounds: the orbitals of these electrons are almost parallel to one another and to the central bond along the σ-bonds separating them.[133–138] Such interaction, which has been called "σ-bonding interaction" or "σ-conjugation",[133] leads to the appearance in the near UV absorption spectrum of these compounds of intense bands which are not characteristic of the corresponding chromophores considered separately. Thus, whereas the spectrum of the adamantanone (CXXXIII) shows only a weak absorption with λ_{max} = 290 nm ($\varepsilon \simeq 19$), due to the $n \rightarrow \pi^*$ transition in the keto-group, in the case of azaadamantanones (XI) and (CXXVIII), a strong absorption is observed with λ_{max} = 243 nm (ε = 1366) (in hexane) and 255 nm ($\varepsilon \simeq 1700$) (in dioxane) respectively. *N*-Methylpiperidinone (CXXXIV), which is related to compound (CXXXIII) as regards the distribution of the chromophores and whose lone electron pair occupies an axial position, does not absorb at all in the near UV.

The basicity of the azaadamantanes (II)–(IV) in water (see above) and in dimethyl sulphoxide has been determined by potentiometric titration.[8] The p*K* values in water at 22 °C for 1-azaadamantane (IV) (2.96) 4-methylene-1-azaadamantane (CXXXII, R = R′ = H) (4.16), and 1-azaadamantan-4-one (XI) (5.43) have been published.[13] On the other hand, the basicity of azaadamantane derivatives in the gas phase has been determined[135] by cyclotron magnetic resonance.

The lower basicity of methyleneazaadamantane and azaadamantanone compared with azaadamantane is not caused solely by the "σ-bonding interaction", since 1-methyl-4-piperidinone (CXXXIV) (p*K* = 6.01), in which σ-conjugation is impossible, is also less basic than *N*-methylpiperidine (p*K* = 3.92).[131]

V. Conclusion

The development, especially in recent years, of simple and convenient methods of synthesis of azaadamantanes has made them entirely available for wide-scale research and practical applications.

There are as yet only a few published data concerning the practically useful properties and the possible applications of azaadamantanes. There are patent data[139] showing that the alkylaminotriazaadamantanes (LXX) and (LXXI) can be used as a solid rocket fuel, while their solutions in hydrocarbons can be used as a liquid rocket fuel. It has been suggested that the aminotriazaadamantane (LXVII) as well as the azomethines (LXIX) and ureas (LXXVII) obtained from it be used as stabilisers of various polymers against thermal light-induced ageing.[91,95,98,100,140] Diacetyltriazabicyclononanes (CVI) catalyse the formation of polyurethane resins and prevent the phase separation of liquid epoxy-resins in alcohol.[115] It has been suggested that certain triazaadamantane derivatives be used as modifying agents for rubbers.[141–145]

The thermal stability of azaadamantanes and their capacity for complex formation with various metal salts permit their application as additives to fuel-lubricating materials, as corrosion inhibitors, as high-temperature oil thickening agents, and as emulsifying agents and also for the regeneration of ion-exchange resins.[82]

Azaadamantanes can be used as catalysts in various processes,[8] for example, in the additional purification of a gas to remove sulphur.[146,147]

The use of azaadamantanes for the preparation of therapeutic drugs in medicine and veterinary science is particularly promising. It has been reported that diphenyldiazaadamantanol (LXXXVI, R = R′ = C_6H_5) and other diazaadamantanols exhibit a strychnine-like activity,[148] while diphenyldiazaadamantane (XC, R = R′ = C_6H_5) and some of its derivatives have a convulsant activity (Ref. 8, pp 348, 349). Derivatives of the trimethylazaadamantane (XLVII, X = COR) (R = alkyl, aryl, pyridyl, naphthyl, coumaryl, etc.) possess cardiovascular and antiarrhythmic activities.[149,150]

Experiments on mice have shown that the antiviral activity of 7-amino-1,3,5-triazaadamantane (LXVII) is close to that of the familiar preparation midantane.[151,152]

The available data concerning the practically useful properties of azaadamantanes and the specific chemical and physicochemical properties discovered in them lead to their differentiation as a separate new class of organic compounds of interest not only to chemists but also to representatives of other branches of science and engineering.

Reactions involving the addition of *N*-halogenoamides to unsaturated compounds

N N Labeish, A A Petrov

ABSTRACT. The literature data on the reactions involving the addition of *N*-halogeno- and *NN*-dihalogeno-amides of carboxylic sulphonic, sulphuric, and phosphoric acids as well as the esters of *N*-halogeno- and *NN*-dihalogeno-carbamic acids to various types of unsaturated compounds are surveyed. In many cases, the addition takes place with a different regiospecificity than for other compounds with *N*-halogen bonds, which has been explained by differences between the reaction mechanisms. The adducts of halogeno-amides with unsaturated compounds can be used in organic synthesis, especially in the synthesis of amides, aziridines, and other heterocyclic compounds.

The bibliography includes 113 references.

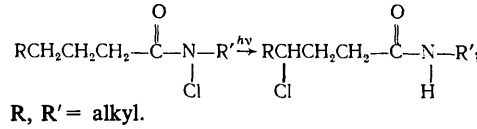
I. Introduction

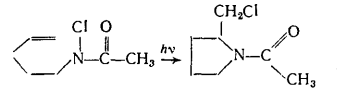
Highly reactive and readily available *N*-halogenoamides have long attracted the attention of investigators as effective halogenating agents. The chemistry of *N*-halogen-containing compounds, many representatives of which were already synthesised in the past century, began to develop vigorously during the last 30 years. The chemistry of *N*-chloroamines and *NN*-dichloroamines with various alkyl substituents, of *N*-halogeno- and *NN*-dihalogeno-amides of sulphonic, carboxylic, phosphonic, and sulphuric acids, as well as *N*-halogeno- and *NN*-dihalogeno-carbamic acid esters was investigated during this period. Reactions involving unsaturated compounds, which have now been investigated in relation to many examples, are of special interest because they lead to new possibilities for the introduction of functional groups into unsaturated organic compounds.



In the present review, which is devoted to the reactions involving the addition of *N*-halogenoamides to unsaturated compounds of different classes, we attempted to survey the available experimental data and to analyse the problems arising in their interpretation.

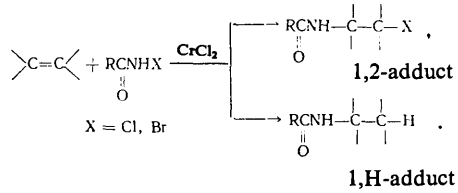
It is noteworthy that the previously published monographs and reviews by non-Soviet authors, in which this problem was dealt with in one way or another, inadequately reflect the modern advances in this field and hardly take into account the work of Soviet chemists.

II. Aliphatic alkenes



The reactions of alkenes with *N*-halogeno-substituted amides, carbamates, isocyanates, sulphonamides, and phosphoramides have been described in the literature.

The addition of *N*-halogenoamides to alkenes is usually carried out in neutral media under irradiation. Photolysis in the presence of alkenes proceeds via two pathways: with formation of adducts of the products of the substitution of the allyl hydrogen atom by the halogen. The reduction of temperature promotes an increase in the relative yield of the adducts.[1,2] It is noteworthy that, on irradiation, *N*-halogenoamides can rearrange (the Hoffmann–Loeffler reaction). For example, in the case of amides with three and more methylene groups, the following reaction occurs:[3]



R, R′ = alkyl.

Unsaturated *N*-chloroamides can also react intramolecularly:[4]

A number of studies have been devoted to reactions of this type.[5–8]

The study of the one-electron reduction of *N*-halogenoamides by low-valence transition metal salts led to the conclusion that amidyl radicals can be generated without the accompanying formation of halogen atoms.[9–12] For example, a fairly effective method has been developed for the addition of *N*-halogenoamides to alkenes with participation of chromium(II) chloride. Two types of products are obtained: *N*-(2-halogenoalkyl)amides (1,2-adducts) and *N*-alkylamides (1,H-adducts).

X = Cl, Br

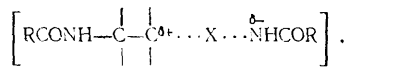
1,2-adduct

1,H-adduct

The overall yield of the adducts, the ratios of the yields of the 1,2- and 1,H-adducts, as well as the ratio of the *cis*- and *trans*-isomers depend on the nature of the alkene, the halogen, and the structure of the group R.

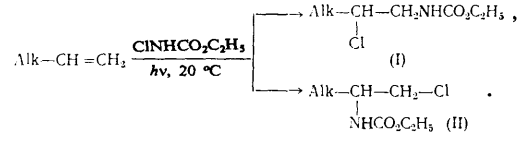
In the case of trisubstituted alkenes, 1,H-adducts have not been detected, whereas conjugated dienes afford exclusively 1,H-adducts. The following features have been observed for *N*-chloroamides:

(1) an increase in the overall capacity for 1,2-addition when R is varied in the sequence $CCl_3 < CH_3 < CF_3 < CH_2Cl < OAlk$;



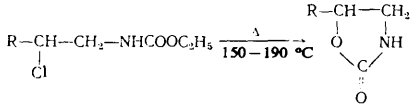
(2) an increase in the ratio of the 1,2- and 1,H-adducts in the sequence $CH_3 < CH_2Cl < OAlk < CCl_3 \leqslant CF_2$;

(3) an increase in the ratio of the *cis*- and *trans*-products in the sequence $CF_3 \simeq CCl_3 \leqslant CH_3 \simeq CH_2Cl < OAlk$.

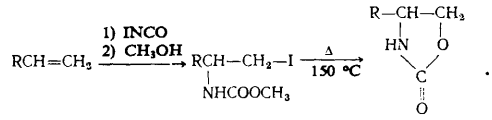


Thus both the best yields of the adducts and high selectivity of the reaction are obtained when *N*-chlorocarbamates are used.[11]

The influence of the structure of R on the yield of the adducts, on the ratio of the 1,2- and 1,H-adducts, and on the ratio of the *cis*- and *trans*-isomers is less significant when *N*-bromoamides are used. It is noteworthy that the competing electrophilic bromination (20–35%) in experiments with *N*-bromocarbamates lowers the yield of the adducts and thereby reduces the synthetic value of these reagents.



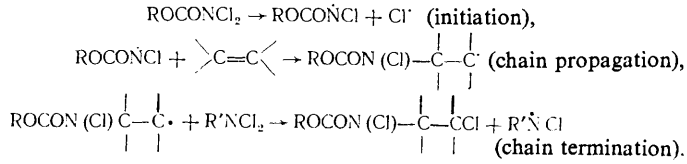
A radical mechanism has been proposed for the reactions described above.[12,13] The best chain transfer agent gives rise to the highest ratio of the 1,2- and 1,H-adducts for the given alkenes. Indeed, the *N*-bromoamide (the bromine atom is the actual chain transfer agent) is a better chain transfer agent than the *N*-chloroamide (where the chlorine atom is the actual chain transfer agent). On the other hand, the activity of the *N*-halogenoamide as a chain transfer agent increases as the electron-accepting capacity of the acyl residue (RCO) is enhanced as a result of the stabilisation of the polar transition state:



In the first studies on the addition of *NN*-dichlorocarbamate to a double bond,[14] it was already shown that the reaction proceeds with formation mainly of the adduct (contrary to the Markovnikov rule), i.e. with fixation of the nitrogen atom at the terminal carbon atom of the terminal double bond.[15,16] The UV-induced addition of *N*-chlorourethane proceeds with formation of a mixture of products (I) and (II) in proportions of 33 : 1:[17]

The position of the carbamate group was demonstrated both spectroscopically by ^1H NMR and chemically by pyrolysing the adduct with formation of 5-alkyl-2-oxazolidones:

The alternative formation of 4-alkyl-2-oxazolidinones has been observed in the pyrolysis of α-iodocarbamates obtained from iodine isocyanate and alkenes of a type similar to that described above:[18,19]



It is noteworthy that iodine isocyanate is a pseudohalogen and adds heterolytically. As a result of the electrophilic character of iodine isocyanate,[20] the iodine atom attacks the least substituted carbon atom, i.e. the adduct is formed "in conformity with the Markovnikov rule" (in contrast to the homolytic addition of *NN*-dichlorocarbamate).[21,22] The electrophilic addition of iodine isocyanate to a *cis*-alkene takes place *trans*-stereospecifically with formation of the *threo*-iodine isocyanate, which is converted into a carbamate without change of configuration. Treatment of this carbamate with base leads to a *cis*-aziridine, i.e. an intramolecular nucleophilic substitution takes place with inversion of configuration. A *trans*-aziridine is obtained similarly, albeit with lower yields than in the case of the *cis*-aziridine, from a *trans*-alkene via the *erythro*-iodine isocyanate.[19]

Homolytic addition of *NN*-dichlorocarbamates to alkyl-substituted alkenes proceeds non-stereospecifically with formation of a mixture of *erythro*- and *threo*-isomers[15] regardless of the geometrical configuration of the alkene. The lack of stereo-specificity in the UV-initiated addition of *N*-chlorourethane to but-2-ene is associated with the impossibility of the formation of a bridged structure.[23]

The most thorough information concerning the effect of steric factors on the rate of addition of *NN*-dichlorocarbamates to alkenes has been obtained in a study of its reactions with isomeric hexenes. Hex-1-ene reacts in less than 1 h quantitatively with formation of only the adduct. 2-Methylpent-2-ene is even more reactive, i.e. the electron-donating effect of the methyl group at the double bond overcomes its steric effect. 2,3-Dimethylbut-1-ene reacts much more slowly. 3,3-Dimethylbut-1-ene reacts on being refluxed for 4–5 h, while in the case of 2,3-dimethylbut-2-ene the addition to the double bond is not observed at all. Furthermore, the number of hydrogen atoms subjected to allylic attack changes simultaneously with the change in the steric parameters. Whereas hex-1-ene forms predominantly the 1,2-adduct with *NN*-dichlorourethane, 2,3-dimethylbut-1-ene and 2,3-dimethylbut-2-ene afford the allylic monochlorination products in 25 and 45% yields respectively.[24] Thus the yields of the main products diminish and those of side products increase with increase in the number of allyl hydrogen atoms.[25] As stated above, at low temperatures 1,2-addition predominates over the abstraction of an allyl hydrogen atom.[19]

The interaction of unsaturated compounds with *N*-halogeno-carbamates, which proceeds without the use of initiators (transition metal salts) or UV irradiation has all the features of a spontaneously initiated free-radical chain reaction, the sequence of the stages of which can be represented as folllows:

An inducation period is observed in this reaction and is followed by a rapid exothermic process; light accelerates the latter while free-radical reaction inhibitors retard it; the addition takes place also non-stereospecifically and contrary to the Markovnikov rule, the yields of the adducts diminish, and the yields of the side products (urethane, monochlorourethane) increase with increase in the number and activity of allyl hydrogen atoms. It is noteworthy that the radicals formed in the initiation stage are capable of abstracting an allyl hydrogen atom. This results in the appearance of a stable allyl radical, which subsequently participates in chain propagation.[15,19] The addition reactions are not then accompanied by vinyl polymerisation. Consequently in the formation of the primary radical, the monoadduct is produced at a rate much higher than the rate at which the polymerisation chain can be propagated. A concerted but non-synchronous molecularly induced homolysis (four-centre attack), in which the transition state is of a free-radical type, has therefore been proposed for the reaction considered. However, the impossibility of achieving the stereospecific addition to *trans*-hex-3-ene and stilbene constitutes evidence against the fully concerted homolysis.[24]

The reactions of alkenes with *NN*-dihalogenoarenesulphonamides are of considerable interest. Likhosherstov and co-workers[26–29] were the first to describe the interaction of *NN*-dichloroarene-sulphonamides with but-2-ene and isobutene in the presence of alcohols, phenols, or lower carboxylic acids in order to obtain β-chloroesters. In the reaction with but-2-ene, two racemic diastereoisomeric forms of *N*-(β-chlorobutyl)benzenesulphonamide and the corresponding aziridines were isolated as side products. The mode and mechanism of the addition reaction were not determined. The authors assumed that the reactions which they investigated are heterolytic.

There have been several communications containing contradictory data concerning the mode and mechanism of the addition of *N*-mono- and *NN*-di-halogenoarenesulphonamides to alkenes. In one of these communications,[30] it has been stated that *N*-bromo-*N*-methylarenesulphonamides add to alkenes and give rise to products in which the bromine atom occupies the same position as in the normal addition, i.e. in accordance with the Markovnikov rule, of HBr to these alkenes:

$$CH_3—CH=CH_2 + BrN(CH_3)SO_2Ar \rightarrow CH_3—CH(Br)CH_2—N(CH_3)SO_2Ar.$$

On the other hand, *NN*-dibromoarenesulphonamides add in the reverse order. However, here no account was taken of the different polarisations of the bromine atom in HBr and *N*-bromoamides. The structure of the product was demonstrated by a series of chemical conversions into known compounds.

In their reaction with propene, *NN*-dichloroarenesulphonamides give rise to two isomers, (III) and (IV), in proportions of 85 : 15.[31]

$$CH_3—CH=CH_2 + Cl_2NSO_2R \rightarrow \begin{cases} CH_3—CH(Cl)CH_2—N(Cl)SO_2R, & (III) \\ ClCH_2—CH(CH_3)N(Cl)SO_2R, & (IV) \end{cases}$$

It has been suggested that compound (III) is formed by a radical mechanism, similarly to the addition of *NN*-dichlorocarbamate,[31] while compound (IV) adds via the competing ionic mechanism. On the other hand, the product (IV) can be obtained, according to the authors, also via a radical mechanism, since the difference between the stabilities of the two possible radicals in the first chain propagation stage is not very great.

The reaction with isobutene proceeds quite differently. Mainly the allylic chlorination product (V) was isolated, its amount being equivalent to that of the benzenesulphonamide isolated. The formation of compound (VI) (in a low yield) takes place, according to the authors, via the cyclic chloronium intermediate (VII), i.e. via an ionic mechanism:

$$(CH_3)_2C=CH_2 + Cl_2NSO_2C_6H_5 \rightarrow (CH_3)_2C(\overset{+}{Cl})CH_2 + C_6H_5SO_2\bar{N}Cl \rightarrow$$
(VII)

$$\rightarrow ClCH_2—C(CH_3)=CH_2 + C_6H_5SO_2NHCl,$$
(V)

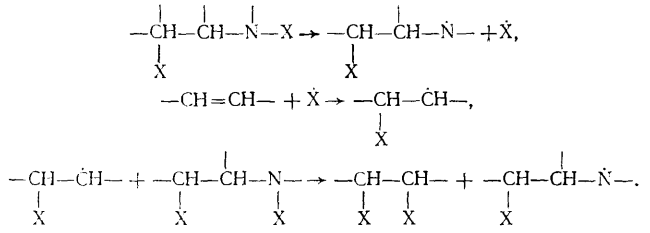
$$2\,C_6H_5SO_2NHCl \rightleftharpoons C_6H_5SO_2NCl_2 + C_6H_5SO_2NH_2,$$

$$(CH_3)_2C(\overset{+}{Cl})CH_2\cdot + C_6H_5SO_2NH_2 \rightarrow C_6H_5SO_2NHC(CH_3)_2CH_2Cl + H^{+}.$$
(VII) (VI)

Another communication describes the oxygen-inhibited radical addition of *NN*-dichloroarenesulphonamide to ethylene and hex-1-ene. In contrast to the example described above, the amide radical attacks the less substituted, i.e. the terminal, carbon atom.[32] However, an ionic reaction pathway involving atmospheric oxygen, in which a mixture of products with the opposite orientation is formed, is also possible.

The attack on the more substituted carbon atom by the amide radical in the reaction of *NN*-dibromoarenesulphonamide with 2,3-dimethylbut-1-ene and 2-methylpent-2-ene shows that *NN*-dibromoarenesulphonamide is less sensitive to steric factors than *NN*-dichlorocarbamate.[33] However, the structure of the adducts was not rigorously demonstrated.

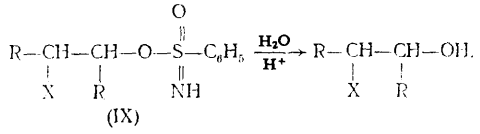
The reaction of *NN*-dichloroarenesulphonamide with *cis*- and *trans*-but-2-enes is not sensitive to radical process inhibitors and proceeds equally well both in the dark in an oxygen atmosphere and in nitrogen under the usual illumination. The *trans*-stereospecific addition via the ionic mechanism leads, according to the authors, to the formation of a new type of β-chloroalkyliminosulphonate derivative (VIII) together with the β-chloroalkanesulphonamide adduct:[34]



$$CH_3CH=CHCH_3 \xrightarrow[2)\ Na_2SO_3]{1)\ Cl_2NSO_2C_6H_5} \begin{cases} CH_3CH(Cl)CH(NHSO_2C_6H_5)CH_3, \\ CH_3CH(Cl)CH(CH_3)O—S(=O)(=NH)—C_6H_5 \quad (VIII) \end{cases}$$

The intermediate bridged chloronium ion is attacked either by the nitrogen atom or the oxygen atom of the *N*-chlorobenzene-sulphonamide anion. The high nucleophilicity of the oxygen atom is in this case completely unusual and conflicts with the available literature data on this problem.[34]

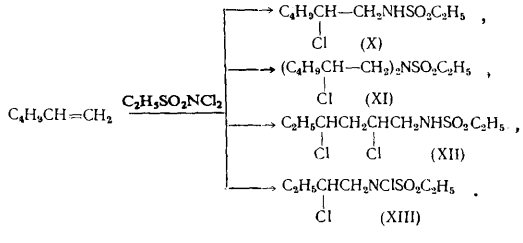
The *trans*-stereoselectivity of the addition of *NN*-dibromoarene-sulphonamide has been demonstrated in reactions with *cis*- and *trans*-hex-3-enes, *cis*-hept-2-ene, etc.[35] The formation of dibromo-derivatives and bromohydrins together with monoadducts has been observed:



$$C_2H_5CH(Br)CH(NHSO_2C_6H_5)C_2H_5, \quad C_2H_5CH(Br)CH(Br)C_2H_5, \quad C_2H_5CH(Br)CH(OH)C_2H_5.$$

Judging from the observed stereoselectivity, the reaction proceeds via an ionic mechanism. The formation of dibromo-derivatives is a result of the radical reaction of *N*-bromo-*N*(β-bromoalkyl)-arenesulphonamide with a second substrate molecule:

It is striking that, as in the case of cyclohexene, allylic bromination products were not detected in the reaction.



The elucidation of the pathways leading to the formation of bromohydrins was difficult. One of the possible pathways, namely the attack by water on the intermediate bromonium ion, is unlikely since the reaction is carried out under anhydrous conditions and the decomposition with bisulphite is performed in the complete absence of the alkene. An alternative possibility involves the hydrolysis of the iminosulphonate derivative (IX) which might have been formed in a reaction similar to that examined above:[34]

(IX)

However, all attempts to isolate compound (IX) were unsuccessful and a final conclusion about the mechanism of the formation of bromohydrins was not reached.

In the photoinitiated addition of *N*-chloro-*N*-methyl- and *NN*-dichloro-ethanesulphonamide to hex-1-ene, the nitrogen atom is attached to the terminal carbon atom of the alkene.[36] The formation of the products (X)–(XII) is described by the usual free-radical addition mechanism. Under these conditions, competition is observed between the abstraction of the allyl hydrogen atom from hex-1-ene and the rearrangement of the adduct (XIII) formed initially to (XII):

In a somewhat later study by the same workers,[37] it was observed that the mode of addition depends on the reaction conditions, while the yields vary with the alkene/*N*-chlorosulphonamide molar ratio. The data in Table 1 indicate a high regioselectivity of the addition only in photoinitiation. Under the usual illumination, the process competes with the radical reaction. The latter is slightly inhibited by oxygen and benzoquinone. It is of interest that virtually equal amounts of products with opposite orientations are obtained in a nitrogen atmosphere.

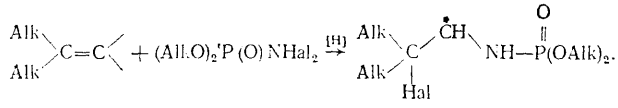


Table 1. The yields of the isomeric adducts in the reaction of *NN*-dichloroethanesulphonamide with hex-1-ene.[36,37]

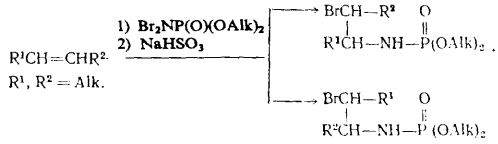
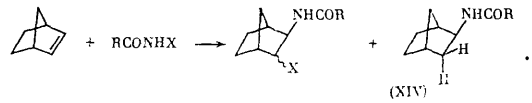
Reaction conditions	1:1 adduct, %	
	C_4H_9–CH–CH_2Cl | $HNSO_2C_2H_5$	C_4H_9CH–CH_2 | | Cl $HNSO_2C_2H_5$
Photoinitiation, N_2	traces	100
Normal illumination	60	40
O_2 atmosphere, in the dark	67	33
In the presenceof $AlCl_3$	69	31
In the presenceof *p*-benzoquinone	68	32
Normal illumination, N_2	55	45

Rearrangements resembling the Hoffmann–Loeffler reaction for *N*-halogenoamides have been investigated in relation to *N*-alkyl-*N*-chloroarenesulphonamides[38] and *N*-chloroalkane sulphonamides[39] on photoinitiation or heat treatment.



Thus there is no unanimity among investigators concerning the mechanism and order of the addition of *NN*-dihalogeno-sulphonamides to alkenes, which apparently depend both on the experimental conditions and on the nature of the halogen and the structure of the alkene. The wide variety of conditions under which the reactions were carried out and hence the wide range of products, which are in addition obtained via different mechanisms, preclude the comparison of the results of experiments of different workers.

The addition of *NN*-dichloro- and *NN*-dibromophosphoramidates to a series of alkenes with a terminal double bond has been studied recently.[40–45] The reactions take place in boiling benzene or methylene chloride or on photochemical initiation, depending on the reactivities of the reagents:



As in the example described above, the reaction of *NN*-dichloro-phosphoramidates is regiospecific and takes place with formation of a product in which the addition has taken place contrary to the Markovnikov rule. A radical mechanism has been proposed.

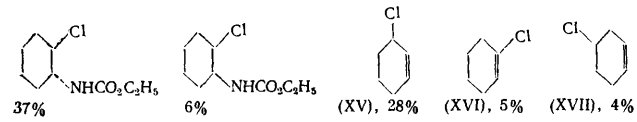
The heterolytic addition of *NN*-dibromophosphoramidate takes place in the presence of stoichiometric amounts of boron trifluoride etherate with formation of a mixture of products with opposite orientations:

III. Alicyclic alkenes

The regiospecificity of *N*-halogenoamides in the presence of chromium(II) chloride can be illustrated in relation to 1-methylcyclohexene and norbornene.[11] As might have been expected, the amido-group attacks the less substituted carbon atom. A small amount (up to 7%) of the 1,2-adduct with the opposite mode of addition was detected in the case of *N*-chlorocarbamate and *N*-bromoacetamide. The amide radical attacks norbornene exclusively in the *exo*-position in conformity with the generally accepted mechanism of the free-radical addition to norbornene:

An appreciable amount of the 1-*H*-adduct (XIV) was isolated in the above reaction, in contrast to the reaction involving 1-methylcyclohexene, which does not afford the 1,*H*-adduct even if the other reactant is *N*-chloroacetamide, producing the greatest amount of this adduct in its reactions with other alkenes. The ratio of the 1,2- and 1,*H*-adducts increases for cyclohexene and norbornene when R is varied in the sequence $CH_3 < CH_2Cl < OC_2H_5$.

The reaction involving ionic bromination by *N*-bromocarbamate, competing with the 1,2-addition, has been noted only for cyclohexene. According to the authors, in this instance the brominating agent is *NN*-dibromocarbamate arising as a result of the disproportionation of the initial reagent:



$$2ROCONHBr \rightleftharpoons ROCONBr_2 + ROCONH_2.$$

For *N*-bromoamides, this equilibrium is displaced to the left and the yields of the adducts are comparable to those for *N*-chlorocarbamates. Norbornene is unique in the series of monoolefins: in its reactions with *N*-chloroamides, it gives rise predominantly to the 1,*H*-adducts. On the other hand, in the reactions with *N*-bromo-amides, norbornene and cyclohexene afford comparable amounts of the 1,*H*-adducts. In the reactions involving the addition of *N*-halogenoamides to 1-methylcyclohexene and norbornene, the ratio of the *cis*- and *trans*-isomers increases in the sequence $CH_3 < CH_2Cl < OC_2H_5$. It is greater for *N*-chloroamides than for *N*-bromoamides and differs from the sequence observed for the reaction with cyclohexene. The addition to 1-methylcyclohexene is more stereoselective and that to norbornene is less stereoselective than the addition to cyclohexene. *N*-Alkyl-*N*-halogenocarbamates do not form 1,2- or 1,*H*-adducts in their reactions with cyclohexene. Small amounts of bicyclohexenyl (5%) and the corresponding alkyl carbamates have been isolated in such reactions. Table 2, compiled on the basis of the results of Driguez et al.,[11] summarises the relations examined above.

The UV-initiated addition of *N*-chlorocarbamates to cyclic alkenes proceeds with formation of a mixture of *cis*- and *trans*-products in proportions of 7 : 1. The predominance of the *cis*-configuration is a fairly rare phenomenon in radical addition reactions.[17]

The interaction of *NN*-dichlorocarbamate with cyclopentene can serve as an example of a *cis*-stereospecific radical reaction. In contrast to cyclohexenes, for five-membered cyclic alkenes there is a possibility of an intramolecular 1,3-transfer of a chlorine atom in the radical formed initially. On heating, the *cis*-isomer is converted into the *trans*-isomer.[46]

In contrast to the reaction examined above,[11] the *trans*-isomer predominates in the UV-initiated addition of *N*-chlorourethane to norbornene. It is noteworthy that the *cis*- and *trans*-isomers were isolated in this instance and the demonstration of the structure was based on the chemical conversion of the adducts into known compounds and also of the analysis of the ^1H NMR spectra of the isomers and their reaction products.[47] The overall yield of the adducts was high (93%) and the *trans*/*cis* ratio was 1.95, rising to 2.45 when a radical addition initiator was used. The reaction of *NN*-dichlorocarbamate with cyclohexene produces a complex mixture of products:[15]

In addition to the above set of products, monochlorourethane was detected in another study (4–5%).[48] It is of interest to compare this reaction with the chlorination of cyclohexene, where the products (XVIII), (XV), and (XVII) are obtained in proportions of 2 : 1 : 0.6, the formation of compounds (XV) and (XVIII) being the result of both radical reactions and the competing ionic reactions:

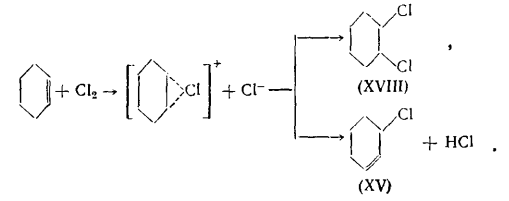


Table 2. The yields (%) of the products of the addition of *N*-halogenoamides to cyclohexene, 1-methylcyclohexene, and norbornene.[11]

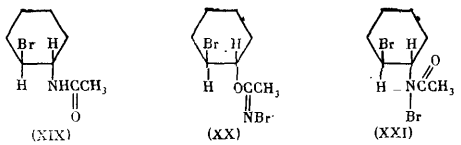


N-Halogenoamide	1-Methylcyclohexene		Norbornene			Cyclohexene		
	cis + *trans*	*cis*/*trans*	*cis* + *trans*	*cis*/*trans*	(XIV)	*cis* + *trans*	*cis*/*trans*	1,*H*
$CH_3CH_2OCONHCl$	80	25	41	5.8	54	87	6.7	6
$CH_3CONHCl$	74	6.4	1.6	*cis* only	93	34	2.1	36
$ClCH_2CONHCl$	77	5.5	33	2.8	55	75	2.0	13
$CH_3CH_2OCONHBr$	75	2.0	76	1.9	2	71	1.5	10.5
$CH_3CONHBr$	60	2.0	91	1.0	4	67	1.1	9
$ClCH_2CONHBr$	77	2.5	88	1.8	2.5	74	1.3	4

The mechanism of the formation of the product (XVII) in the reaction with *NN*-dichlorocarbamate is therefore not very clear. It could have been obtained as a result of the elimination of a hydrogen chloride molecule from the dihalogeno-derivative (XVIII), which, however, was not detected in the reaction with *NN*-dichlorocarbamate. The mechanism of the formation of

compound (XVI) as well as other chlorocyclohexenes was not discussed by Foglia and Swern[15] and Bal'on and Moskaleva.[48] On the other hand, it has been suggested that the 1,2-adduct is formed via free-radical mechanism.

In contrast to the addition of *N*-chloroamides to olefins, including alicyclic olefins, *N*-bromo- and *NN*-dibromo-carbamates add to cyclohexene stereospecifically (mainly by *trans*-addition). The structure of the product obtained was demonstrated by analysing the ^{1}H NMR spectra and by converting it into 8,9-*cis*-perhydrobenzoxazol-2-one. It had been established earlier that only the corresponding *trans*-compounds are capable of entering into similar reactions.[49] The lack of any side products whatever, in contrast to other reactions of *N*-bromocarbamate with alkenes, is striking.[11,15] The products of allylic bromination were not observed either on treating cyclohexene with *N*-bromo-acetamide.[50] Nevertheless, it is well known that bromoamides show a greater tendency than chloroamides to undergo allylic halogenation reactions and are used as specific brominating agents.[51,52] One of these widely used reagents is, for example, *N*-bromosuccinimide.[53] However, for *N*-bromosuccinimide also, experimental conditions have been found under which it (and *N*-chlorosuccinimide) add to cyclohexenes, producing adducts in yields up to 20%.[12]

The photoinitiated reaction of cyclohexene with *N*-bromo-acetamide, already mentioned above, is completely unexpected. Together with the formation of only 1% of the 1,2-*trans*-adduct (XIX), 36% of the *trans*-adduct (XX) and the isomeric product (XXI) were obtained:[50]

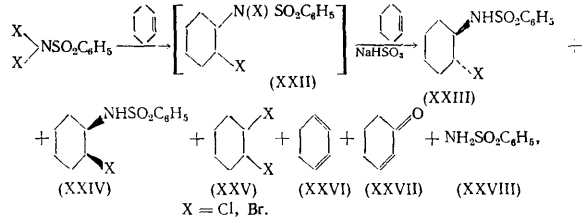
The *N*-bromoamidyl radical is generated via reactions (2) and (3), which are followed by the rapid reactions (4) and (5). The last of these explains, according to the authors, the absence of dibromo-derivatives and unsaturated bromo-derivatives as well as the formation of the products of the reaction of *NN*-dibromoacetamide with cyclohexene:

$$CH_3CONHBr \rightarrow CH_3CO\dot{N}H + \dot{B}r, \quad (1)$$

$$CH_3CO\dot{N}H + CH_3CONHBr \rightarrow CH_3CONH_2 + CH_3CO\dot{N}Br, \quad (2)$$

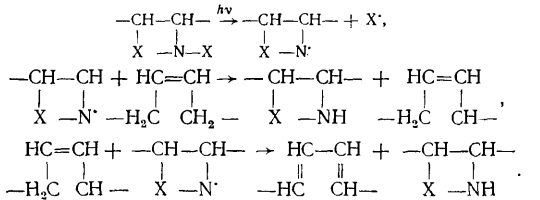
$$\dot{B}r + CH_3CONHBr \rightarrow CH_3CO\dot{N}Br + HBr, \quad (3)$$

$$HBr + CH_3CONHBr \rightarrow Br_2 + CH_3CONH_2, \quad (4)$$



$$Br_2 + CH_3CO\dot{N}Br \rightarrow \dot{B}r + CH_3CONBr_2, \quad (5)$$

$$CH_3CO\dot{N}Br + CH_3CONHBr \rightarrow CH_3CONBr_2 + CH_3CO\dot{N}H. \quad (6)$$

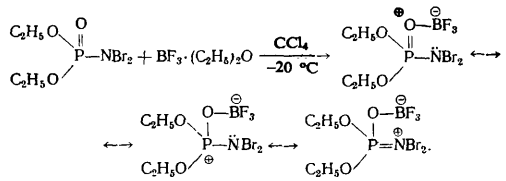


We may note that *N*-chloroiminosulphonates similar to compound (XX) are formed in the reaction of but-2-ene with chloramine B via an ionic pathway. The set of equations (1)–(6) quoted by the authors do not explain, in our view, the observed distribution of the yields of the products and leave open the question of both the reaction mechanism and of the "brominating" properties of mono- and dibromo-acetamides.

Asymmetrically substituted cyclohexenes have been investigated in the reaction involving the addition of iodine isocyanates.[54] It has been established that 1-ethyl-, 1-isopropyl-, and 1-phenyl-1-(α-naphthyl)cyclohex-1-enes react smoothly with formation of α-iodo-β-isocyanato-derivatives "in accordance with the Markovnikov rule". On acid hydrolysis, the adducts give rise to the corresponding salts of β-iodoamines in 30–40% yield. Among similar reactions, we may note the addition of iodine isocyanate to Δ^1-dihydronaphthalene.[55] Urea derivatives, aziridines, iodine carbamates, as well as amine hydrochlorides have been obtained from products of similar reactions (β-iodoisocyanates).

As already stated above, the addition of *NN*-dihalogeno-sulphonamides to alkenes proceeds via a free-radical or ionic mechanism depending on the experimental conditions. The reactions of cyclohexene with *NN*-dihalogenoarenesulphonamides afford similar sets of products for *NN*-dichloro- and *NN*-dibromo-benzenesulphonamides:[56–58]

Two reaction steps have been proposed: the intermediate (XXII) is formed in the first step and subsequently interacts with new cyclohexene molecules, giving rise to the reaction products indicated above. This hypothesis is confirmed by the results of the study of the reaction of compound (XXII) [obtained by brominating the adduct (XXIII) in the presence of alkali] with cyclohexene: the products (XXIV)–(XXVIII) are formed. On this basis, the authors postulated the absence of adducts in the reaction of *N*-alkyl-*N*-halogenobenzenesulphonamides with cyclohexene, which was in fact the case. The authors explain the formation of the dihalogeno-derivative (XXV) by invoking the well known mechanism of the bromination by *N*-bromosuccinimide.[59] However, the formation of cyclohexadiene via the free-radical abstraction of a hydrogen atom from the cyclohexenyl radical appears unlikely:

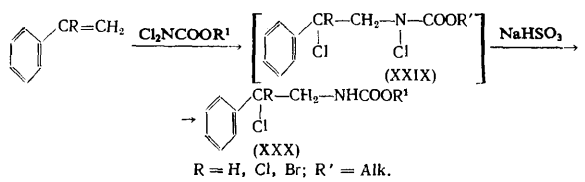


Thus the mechanism of the formation of cyclohexadiene and especially of cyclohexenone (XXVII) as well as the absence of products of allylic bromination from the reaction mixtures remain unexplained. On the other hand, competition between the halogen atom and the sulphonamide radical, which depends on their relative reactivities, can lead to the preferential formation of allylic bromination products and not products resulting from the addition of the halogen molecule. In confirmation of this, one may quote the results of a study of the reaction of *NN*-dichlorobenzene-sulphonamide with cyclohexene at 20 °C. A product of type (XXII)

was obtained (the reaction is non-stereospecific). It reacts with boiling carbon tetrachloride with a mixed cyclohexene molecule, affording the product of the allylic chlorination of cyclohexene together with compounds (XXIII) and (XXIV).[60] This course of the process is the opposite of the reactions described above.[56]

Two studies[61,62] were devoted to the reactions involving the addition of *NN*-dibromobenzenesulphonamides to norbornene and a series of bicyclic olefins, which occur, according to the authors, via an ionic mechanism. The principal pathway involved the formation of a nortricyclene bromo-derivative together with adducts, among which dibromo-derivatives and bromohydrins were detected. This was also observed in the reaction, discussed previously, of aliphatic alkenes, with *NN*-dibromobenzenesulphonamide and also in the reaction of *NN*-dichlorocarbamate with norbornene, which results in the formation of 3-chloronortricyclene in 45% yield.[15]

The reactions in which alkenes are subjected to *cis*-stereospecific hydroxyamination by chloramine T in the presence of catalytic amounts of osmium tetrachloride have been investigated vigorously in recent years.[63] In the above study, certain synthetic possibilities of this reaction and the practical applications of the product were investigated.

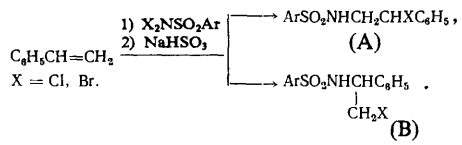


The ionic addition of *NN*-dibromophosphoramidate to cycloalkenes has been studied in relation to indene, cyclopentene, etc. The process has a *trans*-stereospecific character and proceeds rapidly at low temperatures without an induction period, in contrast to the radical reactions described above. Boron trifluoride etherate plays the role of an ionising agent for the dibromophosphoramidate molecule.[45] The electrophilic character of the bromine atom in the complex form leads to the heterolytic cleavage of the N—Br bond and ionic addition to the double bond.

IV. Arylalkenes

The reactions involving the addition of *N*-halogenoamides to aromatic alkenes exhibit the same features as the reactions with aliphatic and alicyclic alkenes.

As was to be expected, the addition of *NN*-dichlorocarbamate to styrene leads to the formation of the monoadduct (XXX) in which the carbamate group is attached to the less substituted carbon atom:[15]

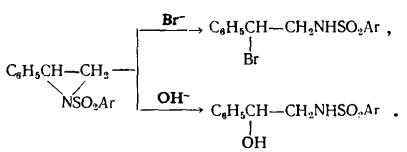


In this reaction it was possible to isolate the intermediate (XXIX).[48,64] Interesting series of reactions have been carried out in order to obtain various styrenes with functional group substituents.[65,66] These reactions as well as the synthesis of 5-alkyl-2-oxazolidinones from the adducts undoubtedly indicate that the carbamate group occupies the terminal position.[15,64] The addition of *NN*-dichlorourethane to bromostyrene proceeds similarly. The use of catalytic amounts of copper powder increases the yield of the adduct from 30 to 90%.[67]

In its reaction with *trans*-stilbene, dichlorocarbamate gives rise to an 11:9 mixture of the *erythro*- and *threo*-forms. The substances synthesised have been used to obtain 2-chloro-1,2-diphenylethyl isocyanate, 2-chloro-1,2-diphenylethylamine, 2,3-diphenylaziridine, and *NN*-disubstituted amides.[68]

The high regio- and stereo-specificities of the addition of *N*-bromocarbamates to styrene (a nitrogen-containing radical attacks the carbon atom, forming *trans*-adducts) has been demonstrated.[48]

The reactions of aromatic alkenes with *NN*-dihalogenoarenesulphonamides are of greatest interest, as for the olefins described above. The mechanism and mode of addition have been the subject of studies.

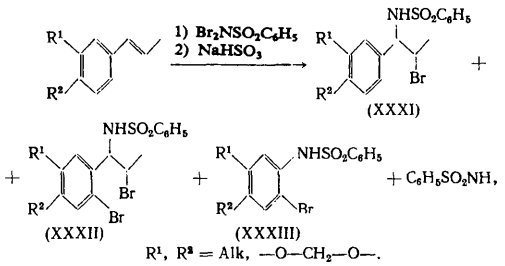


In the reaction with styrene, there is a possibility, in principle, of the formation of two isomers (A) and (B), which was already noted in one of the first studies on the addition of *N*-bromo-*N*-methylbenzenesulphonamide:[69]

The addition of dichloroarenesulphonamide to styrene in an inert gas atmosphere without an initiator leads to compound (A), while in the presence of equimolar amounts of aluminium chloride the product is compound (B). The authors believe that compound (A) is formed by a free-radical mechanism, while compound (B) is produced by an ionic mechanism via the complex $Cl^+[AlCl_3(NClSO_2Ar)]^-$ formed initially.[70]

A group of Soviet chemists have also shown that compound (A) is formed by a radical mechanism in a nitrogen atmosphere. However, in the presence of atmospheric oxygen, the reaction proceeds via an ionic pathway and the higher-melting adduct (B) is obtained.[71,72]

Japanese workers state that the reaction with styrene yields larger amounts of the product (A) formed "contrary to the Markovnikov rule" than in reactions with alkenes, where approximately equal amounts of adducts involving the opposite modes of addition were found in the case of *NN*-dichloroarenesulphonamides.[73] At the same time, it has been discovered that the reaction of *NN*-dibromoarenesulphonamide with styrene in the absence of catalysts gives rise to the product (B),[74] in contrast to *N*-bromo-*N*-methylarenesulphonamides, which, as for aliphatic alkenes, afford adducts formed contrary to the Markovnikov rule.[30] This can be illustrated by the formation of a bisadduct as a result of the addition of the brominated product (B) to a new styrene molecule. It is of interest to note that the opening of the ring of the aziridine obtained from compound (B) leads to the formation of a product in which the disposition of the substituents is the opposite to that in the initial compound.[68] This has also been noted in other studies:[75,76]



The adducts obtained were reduced to the corresponding amines, demonstrating rigorously thereby that the sulphonamide group occupies the initial position.

The ionic telomerisation of styrene by *NN*-dichloro-*p*-chlorobenzenesulphonamide leads to telomers of the following type:[77]

$$n\text{-}ClC_6H_4SO_2NH(C_8H_8)_nCl,\quad n=1,2,3;$$
$$n\text{-}ClC_6H_4SO_2N\begin{matrix}(C_8H_8)_mCl\\(C_8H_8)_{n-m}Cl\end{matrix}\quad n=2,5,6,14;\ m=1\ .$$

The addition of *NN*-dibromoarenesulphonamide to propenylbenzene derivatives proceeds *trans*-stereospecifically with formation of a mixture of products (XXXI)–(XXXIII):

R^1, R^2 = Alk, —O—CH_2—O—.

The formation of the product (XXIII) as a result of the elimination of the C_3 fragment from the adduct (XXXI), which occurs for 3,4-dialkoxypropenylbenzene, is of greatest interest according to the authors.[76,78] The fate of the C_3 fragment was not investigated. In the similar reaction with safrole (R^1, R^2 = —O—CH_2—O—) the products of the rearrangement predominate over the normal adducts for any reactant ratios.[79] The rearrangement proceeds via the phenonium ion (migration of the methylenedioxyphenyl group to the electron-deficient β-carbon atom of the safrole chain). Safrole and the rearranged products are brominated by an excess of *NN*-dibromoarenesulphonamide or the molecular bromine formed from it.

Thus *NN*-dibromoarenesulphonamides as a rule differ from their chloro-substituted analogues or *NN*-dichlorocarbamate in the mode of addition, which in the case of non-aromatic olefins depends on the experimental conditions.

NN-Dichlorophosphoramidates add to styrene and its analogues contrary to the Markovnikov rule, non-stereospecifically, and by the radical mechanism.[44,80] A vinyl chlorination product is also formed in the reaction of 1,1-di(*p*-methoxyphenyl)ethylene. *trans*-Stilbene reacts in the course of several hours, affording a low yield of adducts (33.5%). The products of allylic chlorination or vinyl polymerisation were not detected in the reactions with styrene, (*E*)- and (*Z*)-1-phenylpropenes and α-methyl styrene. In the presence of equimolar amounts of boron trifluoride etherate, adducts are formed in accordance with the Markovnikov rule (by an ionic mechanism).[45]

V. Substituted alkenes

1. Halogenoalkenes

The addition of *N*-chlorocarbamate to 1-chlorocyclohexene in the presence of chromium(II) chloride leads to smaller amounts of the 1,2- and 1,*H*-adducts than in the case of cyclohexene.[11]

Vinylidene chloride combines with *NN*-dichlorocarbamate fairly rapidly, giving good yields of the adducts,[24,81] which can be explained, according to the authors, by the stabilisation of the $CCl_2CH_2N(Cl)CCOR$ group as a result of the possibility of the delocalisation of the unpaired electron over the two chlorine atoms, which compensates to a large extent for their electron-accepting effect. Treatment of the adduct with alcoholic alkali leads to the formation of *N*-(1-alkoxy-2,2-dichloroethyl)-carbamic acid esters:

$$\dot{C}Cl_3CH_2NHCOR \xrightarrow[CH_3OH]{KOH} [CCl_2{=}CHNHCOR \rightleftarrows CHCl_2CH{=}NCOR] \rightarrow$$
$$\rightarrow CHCl_2CH(OCH_3)NHCOOR.$$

The increased reactivity of dichlorovinylamides is attributed to the possible enamide–*N*-acylimine tautomerism and the high reactivity of the *N*-acylimine form in nucleophilic addition reactions.[81]

When *NN*-dichlorourethanes are heated with trichloroethylene,[82] the adduct formed initially with the carbamate group at the less substituted carbon atom is readily dechlorinated, being converted into the *N*-acylimine:

$$CCl_2{=}CHCl + Cl_2NCOOR \rightarrow [CCl_3CHClN(Cl)COOR] \xrightarrow[-Cl_2]{30\ ^\circ C}$$
(XXXIV)
$$\rightarrow CCl_3CH{=}NCOOR.$$
(XXXV)

Together with the liberation of chlorine, the formation of pentachloroethane was detected in the given reaction[83] and the bisadduct $(C_2H_5OCONH)_2CHCCl_3$ was isolated. It is suggested, in contrast to the data of Mirskova et al.,[83] that the adduct (XXXIV) is not formed under the reaction conditions, while the azomethine (XXXV), isolated in the form of compound (XXXVI), is obtained as a result of the elimination of a chlorine atom from the radical (C) generated in the first stage of chain propagation:

$$C_2H_5OCONCl_2 \rightarrow C_2H_5OCO\dot{N}Cl + \dot{C}l,$$
$$C_2H_5OCO\dot{N}Cl + CHCl{=}CCl_2 \rightarrow C_2H_5OCON(Cl)CHCl{-}\dot{C}Cl_2,$$
(C)
$$(C) \rightarrow C_2H_5OCO\dot{N}CHClCCl_3 \xrightarrow{-\dot{C}l} C_2H_5OCON{=}CHCCl_3,$$
(XXXV)
$$(C) \xrightarrow{-\dot{C}l} C_2H_5OCONClCH{=}CCl_2 \rightarrow C_2H_5OCON{=}CHCCl_3,$$
(D) (XXXV)
$$(D) \rightarrow C_2H_5OCONCl_2 \rightarrow (C_2H_5OCONCl)_2CHCCl_3 \xrightarrow{H_2O} \rightarrow$$
(XXXV)
$$\rightarrow (C_2H_5OCONH)_2CHCCl_3 \xrightarrow{H_2O} C_2H_5O\overset{O}{\overset{\|}{C}}NH\overset{OH}{\overset{|}{C}}HCCl_3.$$
(XXXVI)

Chloral imines are obtained from trichloroethylene and *NN*-dichloroacetamide or *NN*-dichlorobenzamide, also with the intermediate formation of a type (C) radical-adduct, its rearrangement, the 1,3-migration of a chlorine atom, and the elimination of chlorine from the α-position.[84] Trichloroethylene reacts in the same way with *NN*-dichloroarenesulphonamides.[85–88] The saturated adducts $CCl_3CHClNClSO_2Ar$ are not formed under any reaction conditions. The reaction is accompanied by the liberation of chlorine and leads to trichloroethylidenearenesulphonamides.

The influence of Lewis acids on the mode of reaction of *NN*-dichloroarenesulphonamides with trichloroethylene and on the yield of its products[88] has also been studied. It has been shown that, in the presence of $SnCl_4$ or $AlCl_3$ under conditions ruling out to the maximum extent the free-radical reaction, the interaction of the above reactants proceeds in the same way as under the conditions of thermal and photochemical initiation.

The mechanism has been studied by CINP and EPR and the presence of radical stages in the photochemical reaction of *NN*-dichlorobenzenesulphonamide and *NN*-dichlorourethane with trichloroethylene was demonstrated.[89] The possible pathways leading to the formation of the final products were suggested.

1,1,2-Tribromo-1,2-dichloroethane has been detected, together with the liberation of gaseous chlorine and bromine, in the reaction of dichloroarenesulphonamide with tribromoethylene.[90] The rearrangement of the intermediate radical-adduct $C_6H_5SO_2NClCHBr\dot{C}Br_2$ (if it occurs) is achieved via the 1,3- and not the 1,2-migration of a chlorine atom. The elimination of a bromine atom with formation of the enamide $CBr_2=CHNClSO_2C_6H_5$ and its subsequent isomerisation appear to the authors to be less probable because of the greater ease of the homolytic dissociation of the N–Cl bond compared with C–Br.

In contrast to trichloro- and tribromo-ethylenes, vinylidene chloride[91] as well as other compounds containing the dichlorovinyl group[92] afford a 1 : 1 adduct with *NN*-dichloroarenesulphonamide, and in the last case the adducts obtained under ionic and radical conditions have the same structure (in contrast to the reaction of styrene).

The addition to ethylene, styrene, and allyl chloride of the product of the reaction of dichloroarenesulphonamide with vinylidene chloride has been investigated. Ionic reactions do not occur in this case and in the radical process the nitrogen atom adds to the styrene fragment contrary to the Markovnikov rule:

$$p\text{-}ClC_6H_4SO_2\overset{Cl}{\underset{|}{N}}CH_2CCl_3 + CH_2=CHR \rightarrow R\overset{Cl}{\underset{|}{C}}H-CH_2-\overset{SO_2C_6H_4Cl\text{-}p}{\underset{|}{N}}-CH_2CCl_3;$$
$$R = H,\ C_6H_5,\ CH_2Cl.$$

Such reactions proceed with much more difficulty than the analogous reactions with *NN*-dichloroarenesulphonamides.[94]

2. Alkenes with functional group substituents

The interactions of monochlorourethanes [in the presence of chromium(II) chloride] with methyl acrylate and methyl vinyl ketone do not afford 1,2-adducts.[11] A two fold excess of the reagent leads to the formation of small amounts of 1,*H*-adducts.

The yields of the products of the addition of *NN*-dichlorocarbamates to alkenes with functional group substituents are high regardless of whether electron-donating or electron-accepting groups adjoin the double bond. The polar effects of the substituents do, however, affect the rate of addition. The reaction of diethyl maleate with *NN*-dichlorocarbamate is slow (more than 30 h), while ethyl vinyl sulphone does not react even on refluxing in benzene for 72 h. Methyl acrylate reacts with dichlorocarbamate more slowly than does methyl vinyl ketone, while acrylonitrile reacts still more slowly.[24] In all these reactions, the carbamate group attacks the less substituted carbon atom; a free-radical mechanism of the addition reaction has been proposed. When they combine with *NN*-dichlorourethane on heating in benzene, vinyl ethers give rise to adducts with the opposite mode of addition (in accordance with the Markovnikov rule),[95] in contrast to vinyl acetate, which produces an adduct with the carbamate group in the terminal position regardless of the method of initiation.[24,96]

The use of a univalent copper salt or copper powder as the catalyst in the addition of *NN*-dichlorocarbamate to acrylic acid derivatives shortens the reaction from 4–5 h to 30–40 min and increases the yield and purity of the adducts.[97] It has been suggested that the reaction has a radical character:

$$AlkOCONCl_2 \xrightarrow[-CuCl]{Cu} AlkOCO\dot{N}Cl,$$
$$AlkOCONCl_2 \xrightarrow[-CuCl_2]{CuCl} AlkOCONCl \xrightarrow{CH_2=CHR}$$
$$\rightarrow AlkOCON(Cl)CH_2\dot{C}HR \xrightarrow[-CuCl]{CuCl_2} AlkOCON(Cl)CH_2CH(R)Cl\ .$$

It follows from the scheme presented that the copper(II) chloride formed in the initiation stage terminates the chain, which promotes, according to the authors,[98] an increase in the yield of the main reaction products. The formation of 5-alkyloxazolidinone, as in the case of aliphatic alkenes,[24] demonstrates the terminal position of the carbamate group.

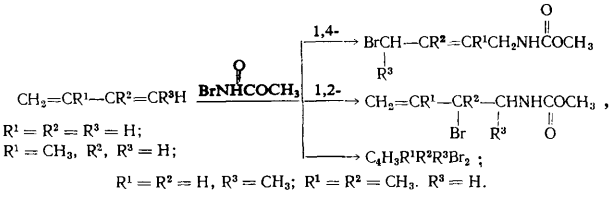
NN-Dichloroarenesulphonamides add to the double bond in alkenes containing electron-accepting groups in the presence of peroxide catalysts or under UV irradiation.[71] The proposed initiation system (univalent copper salt and tetraethylammonium bromide) promotes an increase in the yield of adducts in these reactions and a decrease in the reaction time.[98] The role of the second additive (tetraethylammonium bromide) consists, in the authors' view, in generating the bromine atoms which initiate the addition reaction.

The reaction of *NN*-dichlorobenzenesulphonamide with alkyl 2,2-dichlorovinyl ketone results in the formation of 1,1-adducts $C_6H_5SO_2N(Cl)-CH(COAlk)CCl_3$, which are converted into *N*-(1-acyl-2,2,2-trichloroethyl)benzenesulphonamides on exposure to atmospheric moisture. On treatment with alkali the sulphonamides eliminate HCl and afford *N*-(1-acyl-2,2-dichlorovinyl)benzenesulphonamides:[99]

$$C_6H_5SO_2NHCH(COAlk)CCl_3 \xrightarrow{OH^-} C_6H_5SO_2\underset{H}{\underset{|}{N}}-\underset{CCl_2}{\underset{\|}{C}}-COAlk.$$

In conclusion, it is of interest to note that *NN*-dibromoarenesulphonamides, which add to asymmetric alkenes in accordance with the Markovnikov rule, in contrast to *NN*-dichlorourethane, react with αβ-unsaturated carboxylic acid esters similarly to *NN*-dichlorourethanes, in such a way that the bromine atom enters a position adjoining the carbonyl group ("contrary to the Markovnikov rule").

VI. Alkadienes



The order of the addition of various reagents to alkadienes depends greatly on their structure and its determination therefore permits additional conclusions concerning the reaction mechanism. On the other hand, the possibility of the formation in this case of a mixture of 1,2- and 1,4-isomers hinders the isolation and identification of the adducts.

The addition of various *N*-halogenoamides to buta-1,3-diene, isoprene, piperylene, cyclohexadiene, chloroprene, etc. has been investigated.

The photochemical decomposition of *N*-halogeneamides (including urethanes) is inhibited by cyclohexa-1,3-diene. After irradiation for 45 h, the reaction mixture still contains 94% of the active halogen.[25] On the other hand, the addition to norbornadiene proceeds readily and affords three isomeric 3,5-disubstituted nortricyclenes in 66% yield and 7% of the 1,2-adduct. Only linear adducts are formed in the photoinitiated addition of *N*-halogenoamides to non-conjugated dienes. In the reaction of cycloocta-1,5-diene, bicyclic derivatives — the products of the "transannular cycloaddition" of the primary radical — were not detected.[25]

NN-Dichlorocarbamates add to butadiene with formation of a mixture of the 1,4-*trans*-adduct (86%) and the 1,2-adduct (14%).[100] The reactions with chloroprene and 2,3-dimethylbuta-1,3-diene result in the exclusive formation of 1,4-adducts. In the case of isoprene, the 1,4-adduct $ClH_2C-C(CH_3)=CHCH_2NHCOOR$ was isolated (selectivity 85%). The formation of the products of the reverse 4,1-addition has also been postulated from ^1H NMR data. A mixture of three isomeric adducts, the 1,2-adduct (26%), the 1,4-adduct (44%), and the 4,1-adduct (30%), is formed in the reaction of *NN*-dichlorocarbamate with piperylene.[100]

The *trans*-1,4-adducts are formed predominantly in all cases in the interaction of *N*-bromocarbamates with conjugated alkadienes under the same conditions as for *NN*-dichlorocarbamates[100] (Table 3):

Dibromo-derivatives, whose formation may be induced by the disproportionation of the reagent with formation of carbamate and *NN*-dibromocarbamate, were identified as side products. The *NN*-dibromocarbamate functions as a brominating agent (as in the formation of dibromo-derivatives in the reactions of *N*-bromocarbamates with alkenes).[11]

Table 3. The isomeric composition of the products of the addition of *N*-halogenocarbamates to alkadienes.[100,101]

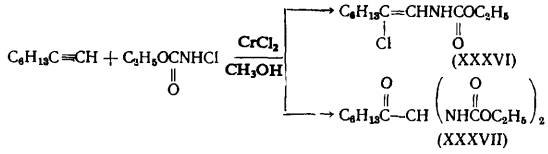
Hydrocarbon	$Cl_3NCOOCH_3$*			$BrHNCOOCH_3$		
	1,4-	4,1-	1,2-	1,4-	1,2-	dibromo-derivatives
$H_2C=CH-CH=CH_2$	90	—	10	70	20	10
$H_2C=C(CH_3)C(CH_3)=CH_2$	100	—	—	68	—	32
$H_2C=C(CH_3)CH=CH_2$	85	15		71	—	24
$H_2C=CH-CH=CH-CH_3$	44	30	26	66**	8	24

* According to the results of Daniher and Butler.[100]
** 1,4- and 4,1-isomers in proportions of ~1 : 1.

Thus the regio- and stereo-specificity of the addition of *N*-bromocarbamate hardly differs from that for *NN*-dichlorocarbamate. The reaction is not inhibited by oxygen (in contrast to the addition of dichlorocarbamate), while the ratio of the isomers depends little on the experimental conditions. A decrease in temperature promotes the formation of small amounts of dibromo-derivatives. The low selectivity of the addition reaction in the case of piperylene can be explained by the approximately equal stabilities of the two allyl radicals formed. The complete absence from the reaction mixtures of products resulting from chlorination and substitution of hydrogen atoms is noteworthy.[101]

The reactions of iodine isocyanate with alkadienes have also been investigated.[102] Aliphatic alkadienes with isolated double bonds combine with two moles of iodine isocyanate per mole of the substrate, in contrast to conjugated alkadienes which afford 1,4-mono-adducts; when the adducts are treated with methanol, the corresponding iodine carbamates are produced. Methylallene also combines slowly with one mole of iodine isocyanate; the structure of the adduct has not been demonstrated. With the exception of cycloocta-1,3-diene, alicyclic alkadienes react extremely rapidly, similarly to alkadienes with isolated multiple bonds. Contrary to expectation, cyclohexa-1,4-diene combines with only one mole of iodine isocyanate. Analysis of the ^1H NMR and IR spectra led to a tricyclic structure being attributed to the products of the addition of one mole of iodine isocyanate to norbornadiene.

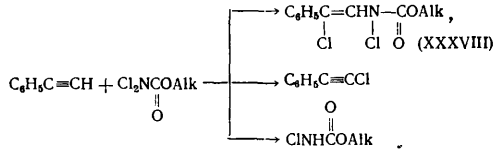
NN-Dichloroarenesulphonamides add readily and exothermically to buta-1,3-diene and chloroprene. 1,4-Adducts are then formed in high yields.[31] The oxygen-inhibited reaction proceeds via a free-radical mechanism, like the addition of *NN*-dichlorocarbamate.



In their reactions with *NN*-dihalogenoarenesulphonamides (but not with dichlorocarbamate), alka-1,4-dienes afford, together with open-chain products, small amounts of cyclic adducts, mainly pyrrolidine derivatives. However, cyclohexa-1,4-diene does not form an azabicyclic compound, in contrast to *cis,cis*-cycloocta-1,5-diene, which produces such a compound in its reaction with *NN*-dibromotoluene-*p*-sulphonamide.[103] 1,4-Diphenylbuta-1,3-diene reacts with *NN*-dibromobenzenesulphonamide to form a pyrrolidine derivative and 1,2,3,4-tetrabromo-1,4-diphenylbutane in low yields. The authors attributed a symmetrical structure to the cyclic products of the addition of *NN*-dibromobenzenesulphonamide to hexa-1,5-diene, which does not agree with the firmly established mode of addition of halogenoamides to alkenes.[104]

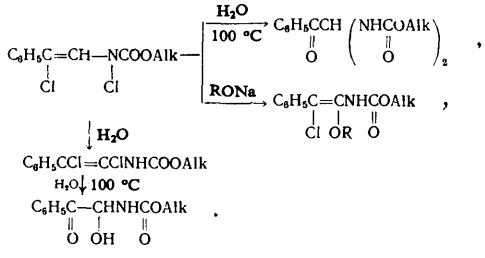
The addition of diethyl *NN*-dichlorophosphoramidate to conjugated alka-1,3-dienes (butadiene, isoprene, 2,3-dimethylbutadiene) proceeds regiospecifically with formation of an (*E*)-1,4-adduct. The addition to cyclohexa-1,3-diene takes place in the same way. *trans*-Piperylene, 4-methylpenta-1,3-diene, 2,5-dimethylhexa-2,4-diene, and 1,4-diphenylbuta-1,3-diene usually give rise to a mixture of products. As in the case of other *NN*-dichloroamides, the reaction proceeds via a free-radical mechanism.[105]

VII. Acetylenes

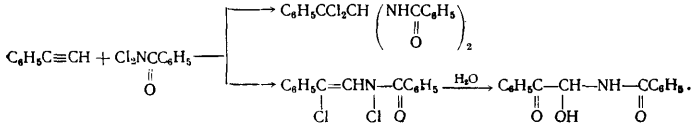


The reactions of acetylenes with *N*-halogenoamides have been least investigated. As a result of the high lability of enamines or enamides, obtained as a result of the addition reaction, the authors of the few studies which have been carried out succeeded in isolating either the products of further reactions or the true adducts in low yields. Only oct-1-yne and phenylacetylene were introduced into the reaction.

The addition of *N*-chlorocarbamate to oct-1-yne gives rise to a complex mixture of products, from which the adduct (XXXVI) and the *NN*-di(ethoxycarbonylamino)ketone (XXXVII), formed evidently as a result of the hydrolysis of the 2:1 adduct, were isolated. However, completely different proportions of the products (XXXVI) and (XXXVII) were obtained in two experiments (respectively 28 and 9% in one and traces and 13% in the other):

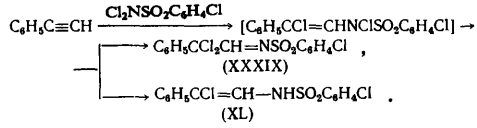


Unfortunately, the physicochemical constants and the methods used to isolate the above compounds are not quoted, which gives rise to some doubt as to the reliability of the results.[11]



The addition of *NN*-dichloroamides to phenylacetylene has been studied:[106,107]

The *N*-chloro-*N*-(β-chlorostyryl)urethanes (XXXVIII) obtained are a mixture of geometrical isomers in proportions of 7:3; after storage for 24 h they rearrange to $C_6H_5CCl=CClNHCOOAlk$, which in our view is not an entirely usual behaviour. A number of chemical reactions of the compounds isolated demonstrate, according to the authors, the structure of the adducts formed initially:



NN-Dichlorobenzamide adds in the same way to phenylacetylene:[108]

However, in both cases the hydrolysis and interaction of compound (XXXVIII) with sodium alkoxide are open to doubt. The lack of spectroscopic data for the NCl-adducts isolated and also the very high, in our view, chemical shift of the proton at the nitrogen atom in compound (XXXVIII) (9.05, 9.25 p.p.m.) suggest the possibility that the interaction of *NN*-dichloroamides with phenylacetylene proceeds differently than has been suggested.[106] *N*-Bromoamides have not been introduced into similar reactions.

The reaction of *NN*-dichloro-4-chlorobenzenesulphonamide with phenylacetylene afforded a high yield of the azomethine (XXXIX):[109]

Thus the previously uninvestigated "halogenotropism", i.e. the 1,3-migration of chlorine (most probably intramolecular) in the molecule of the NCl-adduct formed initially, occurs in this instance. Treatment of the reaction mixture with a solution of sodium bisulphite leads to a complex mixture of products, from which the adduct (XL) was isolated in a low yield (5%).

The addition of iodine isocyanate to acetylenes is complicated by the formation of diiodo-derivatives as side products. The pure reaction product cannot be obtained.[102] Ony the product derived from oct-4-yne by the addition of iodine isocyanate followed by treatment with methanol was isolated (yield 20%).

VIII. Alkenynes

The reactions involving the addition of *NN*-dihalogenoamides to conjugated alkenynes have been investigated in relation to vinylacetylene and its homologues.[101,109] The reactions of *NN*-dichlorocarbamates were performed in an argon atmosphere at a reduced temperature:

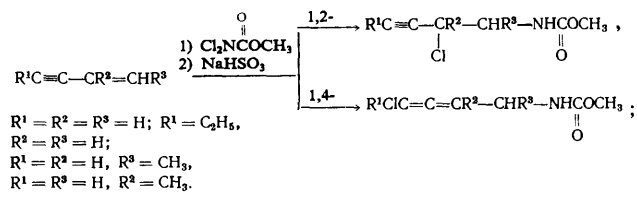


Table 4. The isomeric composition of the products of the addition of *N*-halogenocarbamates to alk-1-en-3-ynes.[101,112]

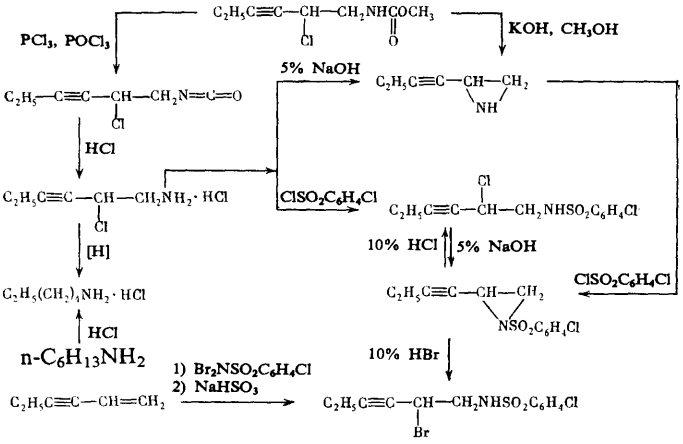
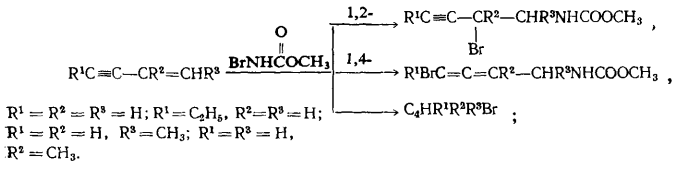


Hydrocarbon	$Cl_2NCOOCH_3$		$BrNHCOOCH_3$	
	1,2-	1,4-	1,2-	1,4-
$HC\equiv C-CH=CH_2$	30	70	70	30
$C_2H_5-C\equiv C-CH=CH_2$	100	—	95	5
$HC\equiv C-C(CH_3)=CH_2$	15	85	—	100
$HC\equiv C-CH=CH-CH_3$	60	40	20	80

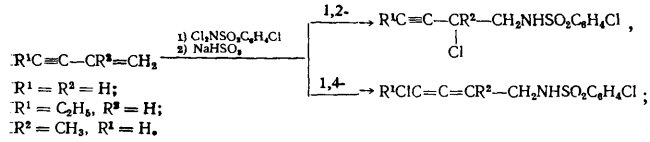
It has been established that vinylacetylene and its closest homologues are attacked by *NN*-dichlorocarbamate only at the terminal atom of the ethylene bond and in the case of monosubstituted acetylenes the 1,4-adduct is formed preferentially. The amount of the 1,2-isomer in the case of propenylacetylene is

much greater than for isopropenyl- and vinyl-acetylenes. In the reaction of vinylethylacetylene, only the 1,2-adduct is formed (Table 4).



Attack by the carbamate group on the extreme ethylenic atom of the 1,3-enyne system was demonstrated in the last case not only from a study of the NMR spectra but also by means of chemical reactions (Scheme 1). The allenic (acetylenic) carbamates obtained do not isomerise to 1,3-dienes or acetylenes (allenes) either in the presence of copper(I) chloride or on treatment with alkali.

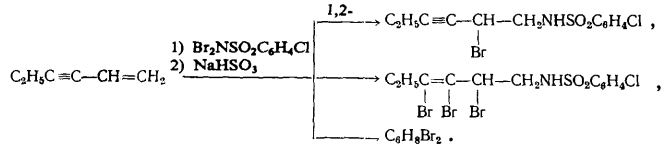
Scheme 1



The inability of the compounds indicated to isomerise supports the view that the 1,2- and 1,4-isomers are obtained independently via a single mechanism, i.e. their addition reaction begins with attack by the carbamate group on the terminal ethylenic atom and not with attack by the chlorine atom on the extreme carbon atom of the triple bond with a subsequent allene–acetylene rearrangement.

In the reactions of *N*-bromocarbamate with alk-1-en-3-ynes, the amide moiety added to the ethylenic end of the molecule with rigorous selectivity, as in the reaction described above:[101]

However, the amount of 1,2-adducts in these reactions is smaller than in the reactions with *NN*-dichlorocarbamates. Vinylacetylene, for which the ratio of the isomers is reversed on replacement of *NN*-dichlorocarbamate by *N*-bromocarbamate, is an exception (Table 4). The reaction of *N*-bromocarbamate with alk-1-en-3-ynes results in the formation, as in the reaction with 1,3-dienes, of a considerable amount of dibromo-derivatives as side products (up to 25%) (the mechanism of this reaction was examined in detail above).



It has also been established that the regioselectivity of the addition of *NN*,4-trichlorobenzenesulphonamide to conjugated vinylacetylenes is similar to that for halogenocarbamates regardless of the experimental conditions:[109,110]

The terminal position of the sulphonamide group has been confirmed, apart from spectroscopic evidence, by a series of chemical reactions (presented in Scheme 1) in relation to 2-chloro-1-(4-chlorobenzenesulphonamido)hex-3-yne.

Trialkylsilyl-substituted vinylacetylenes combine with aromatic *NN*-dichlorosulphonamides at the double bond in the 1,4-position. The chlorine-containing adducts formed are unstable and are converted, already under the conditions of the addition reaction, into the corresponding alkadienyl(chloroalkynyl)sulphonamides. The addition is accompanied by the chlorination of the initial unsaturated compounds.[111]

The addition of *NN*-dibromo-4-chlorobenzenesulphonamide has been studied only in relation to vinylethylacetylene. The reaction mixture contained up to 40–45% of dibromo-derivatives, which were determined chromatographically. A tribromo-derivative was isolated from the reaction mixure as the main product. It was converted into the corresponding aziridine, which was also obtained by unambiguous synthesis. The monoadduct was identified by comparison with the authentic *N*-bromosulphonamide obtained as a result of the opening of the aziridine ring (Scheme 1):

Thus the view expressed in the literature that the order of the addition of *NN*-dihalogenoarenesulphonamides to unsaturated compounds depends on the experimental conditions and also that *NN*-dibromoarenesulphonamides add preferentially in accordance with the Markovnikov rule in reactions involving the addition of 4-chloro-*NN*-dibromobenzenesulphonamide to alk-1-ene-3-ynes has not been confirmed.[112] The structures of all the products obtained (the amide part of the reagent is attached exclusively or mainly to the extreme ethylenic atom) is convincing evidence in support of a radical reaction mechanism. This is also indicted by the absence of an appreciable influence of the solvent polarity on the mode of addition (the reaction with vinyl-acetylene was carried out in hexane, chloroform, and ether) and by the spontaneity and exothermicity of the process.[113] The amidyl radical formed as a result of the homolytic dissociation of the N–halogen bond attacks mainly the terminal atom of the double bond with formation of a more stable resonance-stabilised secondary propargyl radical. The attack on the terminal acetylenic atom with formation of a vinyl radical is less likely, since the electrophilic amidyl radical tends to attack the more nucleophilic double bond. Thus the preferential or exclusive formation of allenic or acetylenic isomers depends on the structure of the initial hydrocarbon and on the nature of the halogen in the reagent.

—o0o—

Summarising the analysis of the literature data for the addition of *N*-halogenoamides to unsaturated compounds, one may conclude that, despite some conflict between the results of the studies described, *N*-halogenamides can add to multiple bonds via both radical and ionic mechanisms depending on the conditions. In the former case, adducts are formed contrary to the Markovnikov rule, while in the latter the reaction proceeds in conformity with the Markovnikov rule. The most promising application of the reaction involving the addition of halogenoamides is the synthesis of aziridines.

Phosphorus-containing alkyl, alkenyl, aryl, acyl, and sulphonyl isocyanates

B N Kozhushko, A V Lomakina, V A Shokol
Institute of Organic Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. In this review the information in the literature on the methods of synthesis, physicochemical properties, and application of phosphorus-containing alkyl, alkenyl, aryl, acyl, and sulphonyl isocyanates has been classified and correlated.

The bibliography includes 143 references.

I. Introduction

Alkyl and aryl isocyanates have been known for over a hundred years. The first examples of phosphorus-containing organic isocyanates were not synthesised until 1956.[1] In recent years a considerable number of new types of alkyl and aryl isocyanates containing one or more phosphorus atoms in the molecule have been obtained and some of their properties have been studied. In 1973 a short review was published on phosphorus-containing alkyl, aryl, acyl, and sulphonyl isocyanates, including studies carried out before 1971;[2] it is now out of date. It is therefore of interest to correlate both the old and new information on the methods of synthesis and properties of phosphorus-containing organic isocyanates.

II. Methods of synthesis

1. Phosphorus-containing alkyl, alkenyl, and aryl isocyanates

(a) Reactions of chloroalkyl phosphates and chlorophosphoramidates with silver cyanate

On heating tris(trichloromethyl)phosphate with silver cyanate in benzene, tris(isocyanatomethyl)phosphate is formed:[3]

$$OP(OCH_2Cl)_3 + 3AgOCN \rightarrow 3AgCl + OP(OCH_2NCO)_3.$$

Diethyl 1,2,2,2-tetrachloroethylphosphoramidate reacts with silver cyanate by a similar route, but it is not possible to obtain the resulting diethyl 1-isocyanato-2,2,2-trichloroethylphosphoramidate in a pure form.[4]

(b) Phosgenation of phosphorus-containing amines and *N*-phosphorylated amidines

Diesters of α-aminoalkylphosphonic and α-aminoalkylphosphonothioic acids react fairly readily with phosgene, and depending on the concentration of the reactants they form either diesters of α-isocyanato-substituted alkylphosponic and alkylphosphonothioic acids or *N*,*N*′-bis[α-(dialkoxyphosphoryl)alkyl]ureas:[1,5]

$$(C_2H_5O)_2P(X)CRR^1NH_2 \xrightarrow{COCl_2} \begin{cases} \xrightarrow[X=O,\,S]{3:1} (C_2H_5O)_2P(X)CRR^1NCO \\ \xrightarrow[X=O]{4:1} [(C_2H_5O)_2P(X)CRR^1NH]_2CO \end{cases}$$

X = O: R = R^1 = CH_3 or R = H, R^1 = C_6H_5; X = S: R = R^1 = CH_3.

The aminophosphonate and aminophosphonothioate diesters required for these syntheses are obtained from dialkyl phosphites (or dialkyl phosphorothioites), aldehydes (or ketones), and ammonia:[5–7]

$$(C_2H_5O)_2P(X)H + RC(O)R^1 + NH_3 \rightarrow (C_2H_5O)_2P(X)CRR^1NH_2.$$

Esters of α-(dialkoxyphosphoryl)aminoacetic acid react with phosgene in a similar manner[8] to form the corresponding isocyanates.[9]

Treatment of (*S*)-(−)-α-(diethoxyphosphoryl)benzylamine with phosgene[10–12] in the presence of pyridine resulted in the synthesis of the first example of optically active α-phosphorylated organic isocyanates—(*S*)-(+)-α-(diethoxyphosphoryl)benzyl isocyanate ($[\alpha]_D^{20}$ + 35.5°, *c* = 2, CCl_4).[12–14]

When aminoaryl esters of phosphoric, phosphorothioic, phosphonic, phosphonothioic, and phosphinothioic acids are reacted with phosgene in inert organic solvents at 50–120 °C, isocyanatoaryl esters of the corresponding phosphorus acids are obtained:[15–23]

$$XP(OC_6H_4NCO\text{-}4)_3,\quad (C_2H_5O)_2P(X)OC_6H_4NCO\text{-}4 \quad (\text{where } X = O, S),$$

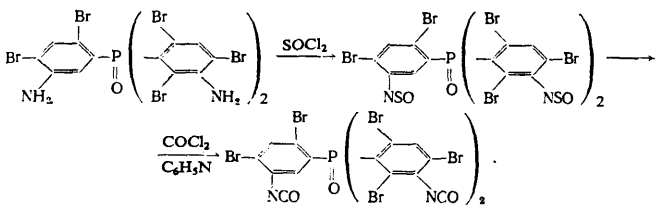
$$C_6H_5N(CH_3)P(O)(OC_6H_4NCO\text{-}4)_2,\quad C\left[\begin{array}{c}CH_2O\\ \diagdown\\ \diagup\\ CH_2O\end{array}\!\!>P(O)OC_6H_4NCO\text{-}4\right]_2,$$

$$C_6H_5CH{=}CHP(O)(OC_6H_3CH_3\text{-}4\text{-}NCO\text{-}3)_2,$$

$$(CH_3)_nP(S)(OC_6H_3CH_3\text{-}4\text{-}NCO\text{-}3)_{3-n}.$$

When *O*,*O*′-bis(4-aminophenyl)-*N*,*N*-dimethylphosphoramidate is treated with phosgene, cleavage of the P–N bond occurs together with phosgenation of the amino group and *O*,*O*′-bis(4-isocyanatophenyl)phosphorochloridate is formed:[20]

$$(CH_3)_2NP(O)(OC_6H_4NH_2\text{-}4)_2 \xrightarrow[-4HCl]{COCl_2} ClP(O)(OC_6H_4NCO\text{-}4)_2 + (CH_3)_2NCOCl.$$



When phosgene reacts with aminoaryl phosphites the P—O bond is cleaved and isocyanatoaryl phosphites are not formed.[20]

Aminoaryl esters of phosphorus acids are obtained by reduction of the corresponding nitroaryl esters, by reaction of phosphorus acid chlorides with aminophenol, or by oxidation of aminoaryl phosphites.[16–18,20,24,25] Tris(*p*-nitrophenyl) phosphate is obtained by nitration of triphenyl phosphate. Nitrophenyl esters of other phosphorus acids are obtained by reaction of phosphorus acid chlorides with nitrophenols.[17,18,20,24]

Hexa(4-isocyanatophenoxy)triphosphonitrile is synthesised by phosgenation of hexa(4-aminophenoxy)triphosphonitrile:[26]

$$(P_3N_3)(OC_6H_4NH_2\text{-}4)_6 \xrightarrow{COCl_2} (P_3N_3)(OC_6H_4NCO\text{-}4)_6.$$

The conversion of aminoarylphosphine oxides to isocyanatoarylphosphine oxides by phosgenation of the intermediate $-N=S=O$ compounds has been reported:[27]

When *N*-(diphenoxyphosphoryl)benzamidine is boiled with phosgene, *N*-(diphenoxyphosphoryl)iminobenzoyl isocyanate $C_6H_5C[=NP(O)(OC_5H_5)_2]NCO$ is obtained.[28]

(c) Reaction of haloalkyl isocyanates with alkyl esters of trivalent phosphorus acids

Trialkyl phosphites and alkyl phosphinites undergo an Arbuzov rearrangement with chloromethyl isocyanate at –20 °C to form dialkoxy-, dialkyl-, or diaryl-phosphorylmethyl isocyanates.[29–32] When chloromethyl isocyanate reacts with alkyl phosphoro-dichloridites, alkyl phosphorodifluoridites, dialkyl phosphorochloridites, and dialkyl phosphorofluoridites, dihalophosphoryl- and alkoxy-halophosphoryl-methyl isocyanates are obtained. Reactions with dialkyl phosphorohalidites occur both in the presence of catalytic quantities of $FeCl_3$ and without it, while alkyl phosphorodihalidites react only in the presence of a catalyst.[30,32–35] Bromomethyl isocyanate also reacts in a similar manner with trialkyl phosphites, dialkyl phosphorohalidites, and alkyl phosphorodihalidites, but the reaction takes place under milder conditions:[14,35,36]

$$R_2POR^1 + XCH_2NCO \longrightarrow [R_2(R^1O)PCH_2NCO]^+X^- \xrightarrow{-R^1X} R_2P(O)CH_2NCO,$$
$$R = AlkO,\ Alk,\ Ar;\quad X = Cl,\ Br;$$
$$ROPX_2 + YCH_2NCO \xrightarrow[-RY]{FeCl_3} X_2P(O)CH_2NCO;$$
$$(RO)_2PX + YCH_2NCO \xrightarrow{-RY} X(RO)P(O)CH_2NCO,$$
$$R = Alk;\quad X = Cl,\ F;\quad Y = Cl,\ Br.$$

α,β-Dichloro- and α,β-dibromo-methyl isocyanates react with trialkyl phosphites, dialkyl phosphorohalidites, and alkyl phosphorodihalidites to form only α-phosphorylated β-chloro- or β-bromo-ethyl isocyanates. The reaction with alkyl phosphoro-dihalidites only takes place in the presence of catalysts. The halogen atoms at the β-position of these isocyanates are much less active and do not undergo reaction.[14,35,37–40]

α-Chlorobenzyl isocyanate undergoes a reaction with trialkyl phosphites, dialkyl phosphorohalidites, and alkyl phosphoro-dihalidites in a similar manner to chloromethyl isocyanate but under slightly more severe conditions.[14,35,41]

Diphenylchloromethyl isocyanate exists as a tautomeric mixture with *N*-chlorocarbonyldiphenylketimine and on reacting with ethyl diaryl phosphites gives two isomeric products in approximately equal quantities—α-(diaryloxyphosphoryl)diphenylmethyl isocyanate and the *N*-benzhydrylidenamide of phosphonoformic acid:[14,42,43]

$$\begin{array}{l}(C_6H_5)_2C(Cl)NCO \\ \quad\uparrow\downarrow \\ (C_6H_5)_2C=NCOCl\end{array} \xrightarrow{C_2H_5OP(OAr)_2} (ArO)_2P(O)C(C_6H_5)_2NCO + \\ + (C_6H_5)_2C=NCOP(O)(OAr)_2.$$

In contrast to diphenylchloromethyl isocyanate, 1-chloro-1-phenyl-2,2,2-trifluoroethyl isocyanate exists only in the isocyanate form and when it reacts with triphenyl phosphite gives only the isocyanate:[44]

$$(C_2H_5O)_3P + C_6H_5CCl(CF_3)NCO \xrightarrow[-C_2H_5Cl]{} (C_2H_5O)_2P(O)C(C_6H_5)(CF_3)NCO.$$

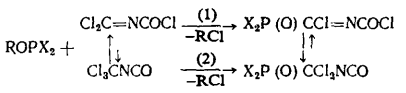
It was reported[45] that when 1,2,2,2-tetrachloroethyl isocyanate is reacted with triethyl phosphite in carbon tetrachloride, 1-(diethoxy-phosphoryl)-2,2,2-trichloroethyl isocyanate is obtained in good yield. It was later established that when this isocyanate is reacted with trialkyl phosphites and dialkyl phosphorohalidites, a mixture of 1-(dialkoxyphosphoryl)- or 1-(alkoxyhalophosphoryl)-substituted 2,2,2-trichloroethyl and 2,2-dichlorovinyl isocyanates is formed:[46]

$$(RO)_2PX + CCl_3CHClNCO \rightarrow X(RO)P(O)CH(CCl_3)NCO + \\ + X(RO)P(O)C(=CCl_2)NCO,$$
$$X = RO,\ Cl,\ F;\quad R = Alk.$$

Unsaturated α-chlorovinyl isocyanate undergoes an Arbuzov reaction with triethyl phosphite in the same way as α-chloroalkyl isocyanates but the reaction takes place under more severe conditions:[47]

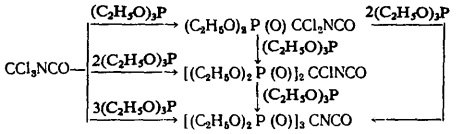
$$(C_2H_5O)_3P + CH_2=CClNCO \longrightarrow (C_2H_5O)_2P(O)C(=CH_2)NCO.$$

Dichloro- and trichloro-methyl isocyanates also readily undergo an Arbuzov rearrangement with phosphites, dialkyl phosphoro-halidites, and alkyl phosphorodihalidites. Under normal conditions dichloromethyl isocyanate exists as a tautomeric mixture with *N*-chloromethylenecarbamoyl chloride; this has been confirmed from its IR spectra. In the reaction with trialkyl phosphite nucleophilic attack by the phosphorus atom is directed on to both the carbon atom of the dichloromethyl group and the carbon atom of the chlorocarbonyl group so that a mixture of at least two products is formed. Only the isocyanate was isolated by vacuum fractionation:



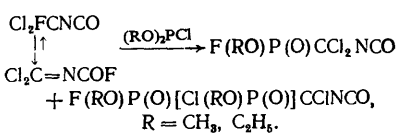
$$\begin{array}{l}Cl_2CHNCO \\ \quad\uparrow\downarrow \\ ClCH=NCOCl\end{array} \xrightarrow{(C_2H_5O)_3P} (C_2H_5O)_2P(O)CHClNCO + \\ + ClCH=NC(O)P(O)(OC_2H_5)_2.$$

Reaction of dichloromethyl isocyanate with 2 moles of triethyl phosphite results in the formation of the bis-phosphorylated methyl isocyanate $[(C_2H_5O)_2P(O)]_2CHNCO$.[32,48]



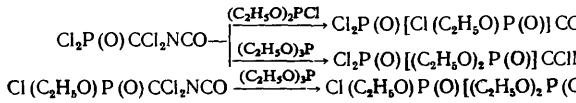
Diethyl phosphorofluoridite reacts with dichloromethyl isocyanate without a catalyst and depending on the ratio of the reactants (1 : 1 or 2 : 1) either ethoxyfluorophosphorylchloromethyl isocyanate or bis(ethoxyfluorophosphoryl)methyl isocyanate are formed.[32,35,49,50]

When dichloromethyl isocyanate reacts with diethyl phosphoro-chloridite, ethoxychlorophosphorylchloromethyl isocyanate is formed; in this case the second chlorine atom cannot be replaced by a phosphoryl group.[32,35,50] Dichloromethyl isocyanate reacts with alkyl phosphorodichloridites and phosphorodifluoridites in a similar manner to chloromethyl isocyanate, forming dihalophosphoryl-chloromethyl isocyanates.[32,35,50,51]

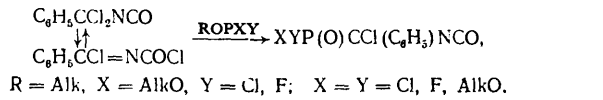


Under normal conditions trichloromethyl isocyanate exists in its tautomeric form—*N*-(dichloromethylene)carbamoyl chloride. On heating, the equilibrium is displaced towards the isocyanate form. When the tautomeric mixture reacts with alkyl phosphorodihalidites in the presence of catalytic quantities of $FeCl_3$, dihalophosphoryl-dichloromethyl isocyanates are obtained, and their formation can be represented by two routes.[32,52,53]

Depending on the ratio of the reactants (1 : 1 or 2 : 1), trichloromethyl isocyanate reacts with diethyl phosphorochloridite to form a mixture of mono- and bis-phosphorylated chloromethyl isocyanates or only bis-phosphorylated chloromethyl isocyanate. When diethyl phosphorofluoridite reacts with trichloromethyl isocyanate, only bis(ethoxyfluorophosphoryl)chloromethyl isocyanate can be isolated, whatever the ratio of the reactants (1 : 1, 2 : 1, or 3 : 1).[32,35,53] Trichloromethyl isocyanate reacts with one, two, and three moles of triethyl phosphite to form diethoxyphosphoryl-dichloromethyl, bis(diethoxyphosphoryl)chloromethyl, and tris(diethoxyphosphoryl)methyl isocyanates respectively. Bis- and tris-phosphorylated alkyl isocyanates are also obtained by reaction of mono- and bis-phosphorylated haloalkyl isocyanates with a suitable quantity of triethyl phosphite:[32,35,54]

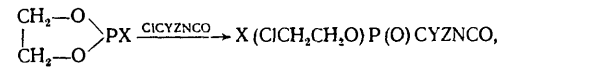


Dichlorofluoromethyl isocyanate, which exists mainly in the form of *N*-(dichloromethylene)carbamoyl fluoride (1 : 14), reacts with dialkyl phosphorochloridites in an interesting manner. In addition to formation of the expected alkoxychlorophosphorylchlorofluoro-methyl isocyanate and bis(alkoxychlorophosphoryl)fluoromethyl isocyanate, as in the case of the reaction with trichloromethyl isocyanate, a mixture of alkoxyfluorophosphoryldichloromethyl isocyanate and alkoxyfluorophosphoryl(alkoxychlorophosphoryl)chloromethyl isocyanate is formed with the latter predominating:[55]



Tribromomethyl isocyanate reacts with trialkyl phosphites, dialkyl phosphorohalidites, and alkyl phosphorodihalidites in a similar manner to trichloromethyl isocyanate. However, it was only possible to isolate dichlorophosphoryldibromomethyl isocyanate $Cl_2P(O)CBr_2NCO$, tris(diethoxyphosphoryl)methyl isocyanate $[(C_2H_5O)_2P(O)]_3CNCO$, and difluorophosphoryldibromomethyl isocyanate $F_2P(O)CBr_2NCO$, in a pure form, with a small quantity of initial Br_3CNCO present.[40]

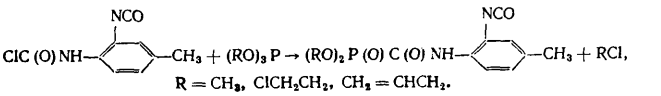
Dichlorophosphoryl- and ethoxychlorophosphoryl-dichloromethyl isocyanates also react with 1 mole of diethyl phosphorochloridite or triethyl phosphite to form mixed bis-phosphorylated chloromethyl isocyanates.[32,53]



Ethoxyfluorophosphoryldichloromethyl isocyanate reacts with diethyl phosphorochloridite in a similar manner:[55]

α,α-Dichlorobenzyl isocyanate reacts with esters and halide esters of trivalent phosphorus acids in a similar manner to α-chlorobenzyl isocyanate to form α-phosphorylated α-chlorobenzyl isocyanates. The reaction of α,α-dichlorobenzyl isocyanate with two (or more) moles of alkyl phosphorodichloridite or phosphorodifluoridite occurs with replacement of only a single chlorine atom by a dihalophosphoryl group, while when it is reacted with two moles of dialkyl phosphorohalidite or trialkyl phosphite a complex mixture is formed, from which pure compounds could not be isolated:[56]

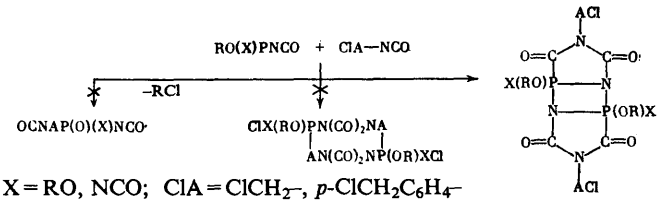
The cyclic phosphites—2-chloro- and 2-fluoro-phospholanes—undergo an Arbuzov reaction with chloro-, dichloro-, and trichloro-methyl isocyanates with ring-opening:[32,35,57]



In contrast to α-chloroalkyl isocyanates, *p*-chloromethylphenyl isocyanate reacts with triethyl phosphite under more severe conditions (150–160 °C) without a solvent and *p*-(diethoxy-phosphorylmethyl)phenyl isocyanate is obtained in low yield:[30,31]

1-Chloromethyl- and 1-bromomethyl-2,4-diisocyanatobenzenes and bis(4-isocyanatophenyl)chloromethane also undergo an Arbuzov reaction with trialkyl phosphites but the corresponding isocyanates cannot be isolated as they probably polymerise in the presence of trialkyl phosphites.[20,58,59]

It should be mentioned that *N*-(isocyanatoaryl)carbamoyl chlorides also undergo a reaction with trialkyl phosphites, forming the corresponding phosphorus-containing aryl isocyanates:[20,60,61]



When *N*-(1-chloro-2,2,2-trifluoroethylidene)carbamoyl isocyanate reacts with triethyl phosphite, an isocyanate group rather than a chlorine atom is eliminated and 1-(diethoxyphosphoryl)-1-chloro-2,2,2-trifluoroethyl isocyanate is formed:[62,63]

N-(1-Methoxy-2,2,2-trifluoroethylidene)carbamoyl isocyanate reacts with triethyl phosphite in a similar manner.[62,63]

Chloromethyl isocyanate and *p*-chloromethylphenyl isocyanate also undergo a reaction with dialkyl phosphoroisocyanates and alkyl phosphorodiisocyanates but the products of Arbuzov rearrangement are not obtained. It was earlier suggested that quasiphosphonium compounds of dimeric structure are formed.[29,30,64] It was subsequently

established that tricyclic 1,3,2λ⁵4λ⁵-diazadiphosphetidine derivatives are obtained as a result of this reaction:[14,65–67]

X = RO, NCO; ClA = $ClCH_2$–, *p*-$ClCH_2C_6H_4$–

(d) Reaction of diaryl phosphites with α-chloroalkyl isocyanates

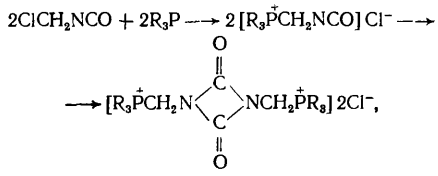
Diaryl phosphites readily react with a tautomeric mixture of diarylchloromethyl isocyanate with *N*-chlorocarbonyldiarylketimine in the presence of triethylamine to form diaryloxyphosphoryldiarylmethyl isocyanates:[42,43,68]

$$\begin{matrix} Ar_2C{=}NCOCl \\ \downarrow\uparrow \\ Ar_2C(Cl)NCO \end{matrix} + (Ar^1O)_2P(O)H \xrightarrow[-(C_2H_5)_3N{\cdot}HCl]{(C_2H_5)_3N} (Ar^1O)_2P(O)C(Ar)_2NCO.$$

(e) Reaction of chloroalkyl isocyanates with phosphorothioic acids

Chloromethyl isocyanate reacts with the potassium salts of *O,O'*-dialkylphosphorothioic and *O,O'*-dialkylphosphorodithioic acids to form the corresponding phosphorylated isocyanates:[29,69]

$$ClCH_2NCO + (RO)_2P(X)SK \rightarrow (RO)_2P(X)SCH_2NCO + KCl,$$
$$X = O, S.$$



1-Chloro-1-phenyl-2,2,2-trifluoroethyl isocyanate reacts with *O,O'*-diisopropylphosphorodithioic acid in a similar manner.[44]

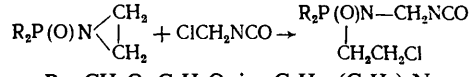
In contrast to chloromethyl and 1-chloro-1-phenyl-2,2,2-trifluoroethyl isocyanates, a tautomeric mixture of diphenylchloromethyl isocyanate and *N*-chlorocarbonyldiphenylketimine when reacted with *O,O'*-dialkylphosphorodithioic acids or their salts gives *O,O'*-dialkyl-*S*-(*N*-diphenylmethylenecarbamoyl)phosphorodithioates, which only in solution occur in tautomeric equilibrium with the corresponding isocyanates.[43,70]

$$\begin{matrix} (C_6H_5)_2C{=}NCOCl \\ \downarrow\uparrow \\ (C_6H_5)_2CClNCO \end{matrix} \xrightarrow{(RO)_2P(S)SH} \begin{matrix} (C_6H_5)_2C{=}N{-}C(O)SP(S)(OR)_2 \\ \downarrow\uparrow \\ (RO)_2P(S)SC(C_6H_5)_2NCO \end{matrix}$$

(f) Reaction of α-haloalkyl isocyanates with trialkyl- and triaryl-phosphines

Trialkyl- and triaryl-phosphines react very readily with chloromethyl isocyanate in inert solvents to form trialkyl- or triaryl-(isocyanatomethyl)phosphonium chlorides. Depending on the structure of the initial tertiary phosphines and also the reaction conditions and conditions for isolating the reaction products, either substituted isocyanatomethylphosphonium chlorides or their dimers can be obtained. In the case of triarylphosphines, both monomeric and dimeric products were obtained in a pure state, while in the case of trialkylphosphines only pure dimers were obtained:[29,71]

R = C_3H_7, C_8H_{17}, $C_{10}H_{21}$, C_6H_5, *p*-$CH_3OC_6H_4$, *p*-$CH_3C_6H_4$.



Bromomethyl isocyanate[36] and α-chlorobenzyl isocyanate[41,72] react in a similar manner with triphenylphosphine to form triphenyl(isocyanatomethyl)phosphonium bromide and triphenyl-(α-isocyanatobenzyl)phosphonium chloride.

It has not been possible to synthesise triaryl(isocyanatomethyl)-phosphonium iodides by this method since iodomethyl isocyanate, which is required for their synthesis, has not been prepared up to the present time. Attempts to obtain iodomethyl isocyanate demonstrated that it is very unstable and decomposes as it is being formed with considerable elimination of free iodine. Another method was used to synthesise triaryl(isocyanatomethyl)phosphonium iodides. On heating triaryl(isocyanatomethyl)phosphonium chlorides with methyl iodide in methylene chloride (45–60 °C, 1–2 h), chlorine is exchanged for iodine and triaryl(isocyanatomethyl)phosphonium iodides are obtained. For the purpose of preparative synthesis there is no need to obtain and isolate triaryl(isocyanatomethyl)phosphonium chlorides in a pure form. It is sufficient to add triarylphosphine to a mixture of chloromethyl isocyanate and methyl iodide and heat the reaction mixture:[73]

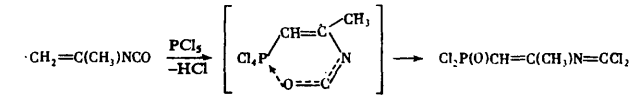
$$\left.\begin{matrix} [Ar_3\overset{+}{P}CH_2NCO]Cl^- + CH_3I \\ Ar_3P + ClCH_2NCO + CH_3I \end{matrix}\right\rbrace \rightarrow [Ar_3\overset{+}{P}CH_2NCO]I^- + CH_3Cl.$$

(g) Reaction of *N*-phosphorylated aziridines with chloromethyl isocyanate

When *N*-(dialkoxyphosphoryl)- and *N*-(tetraethyldiamino-phosphoryl)aziridines are reacted with chloromethyl isocyanate, the aziridine ring readily opens and *N*-phosphorylated aminomethyl isocyanates are formed:[74–76]

R = CH_3O, C_2H_5O, iso-C_3H_7, $(C_2H_5)_2N$.

(h) Reaction of phosphorus pentachloride with vinyl isocyanates



Vinyl isocyanate reacts with phosphorus pentachloride in the ratio 1 : 2 to form 2-(*N*-chlorocarbonylamino)vinyltrichloro-phosphonium hexachlorophosphorate, treatment of which with sulphur dioxide gives 2-(dichlorophosphoryl)vinylcarbamoyl chloride. The latter on heating under vacuum or by treatment with tertiary amines eliminates hydrogen chloride and is converted to 2-(dichlorophosphoryl)vinyl isocyanate:[77–80]

$$CH_2{=}CHNCO + PCl_4^+Cl^- \rightarrow [Cl_4PCH_2\overset{+}{C}HNCO]Cl^- \xrightarrow{-HCl}$$
$$\rightarrow [Cl_4PCH{=}CHNCO] \xrightarrow{PCl_5} [Cl_6\bar{P}Cl_3\overset{+}{P}CH{=}CHNCO] \xrightarrow{HCl}$$
$$\rightarrow [Cl_3PCH{=}CHNHCOCl]^+PCl_6^- \xrightarrow[-POCl_3,\ -SOCl_2]{SO_2}$$
$$\rightarrow Cl_2P(O)CH{=}CHNHCOCl \xrightarrow[-HCl]{} Cl_2P(O)CH{=}CHNCO.$$

When 2-(*N*-chlorocarbonylamino)vinyltrichlorophosphonium hexachlorophosphorate is treated with excess hydrogen sulphide or the calculated quantity of potassium xanthate, 2-(dichlorophosphoro-thioyl)vinyl isocyanate is obtained:[78,79]

$$[Cl_3PCH{=}CHNHCOCl]^+PCl_6^- \xrightarrow{H_2S \text{ or } CH_3OCSSK} Cl_2P(S)CH{=}CHNCO.$$

In contrast to vinyl isocyanate, 1-methylvinyl isocyanate reacts with phosphorus pentachloride in a 1 : 1 ratio of reactants to form *N*-[2-(dichlorophosphoryl)-1-methylvinyl]iminocarbonyl dichloride:[80,81]

It should be mentioned that the analogous dichloride is obtained on boiling 2-(*N*-chlorocarbonylamino)vinyltrichlorophosphonium hexachlorophosphorate in benzene or by treatment of it with methyl phosphorodichloridite at 60 °C:[80–82]

$$[Cl_3PCH{=}CHNHCOCl]^+PCl_6^- \xrightarrow{\Delta \text{ or } CH_3OPCl_2,\ 60\ ^\circ C} Cl_2P(O)CH{=}CHN{=}CCl_2.$$

When *N*-[2-(difluorophosphoryl)-1-methylvinyl]iminocarbonyl dichloride is treated with hexamethyldisiloxane, difluorophosphoryl-methylvinyl isocyanate is obtained:[83]

$$Cl_2P(O)CH{=}C(R)N{=}CCl_2 \xrightarrow{2C_2H_5OH} \rightarrow [Cl(C_2H_5O)P(O)CH{=}C(R)N{=}C(OC_2H_5)Cl] \rightarrow \rightarrow Cl(C_2H_5O)P(O)CH{=}C(R)NCO,$$
$$R = H,\ CH_3.$$

When *N*-[2-(difluorophosphoryl-1-methylvinyl]iminocarbonyl dichloride is treated with hexamethyldisiloxane, difluorophosphoryl-methylvinyl isocyanate is obtained:[83]

$$F_2P(O)CH{=}C(CH_3)N{=}CCl_2 \xrightarrow{[(CH_3)_3Si]_2O} F_2P(O)CH{=}C(CH_3)NCO.$$

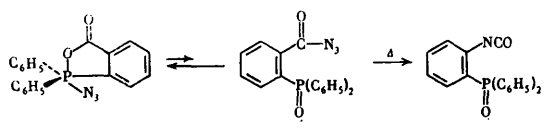
(i) Reaction of dialkoxyphosphorylsulphenyl chlorides with vinyl and allyl isocyanates

Vinyl isocyanate undergoes a reaction with diethoxyphosphoryl-sulphenyl chloride to form *S*-(diethoxyphosphoryl)thiovinyl isocyanate:[77]

$$(C_2H_5O)_2P(O)SCl + CH_2{=}CHNCO \xrightarrow{-HCl} (C_2H_5O)_2P(O)SCH{=}CHNCO.$$

Dialkoxyphosphorylsulphenyl chloride readily adds on to the C=C double bond of allyl isocyanate in two directions to form a mixture of two isocyanates in the ratio 3 : 1:[84]

$$(RO)_2P(O)SCl + CH_2{=}CHCH_2NCO \rightarrow \rightarrow (RO)_2P(O)SCH_2CHClCH_2NCO + (RO)_2P(O)SCH(CH_2Cl)CH_2NCO.$$



(j) Thermal decomposition of phosphorus-containing carboxylic acid azides

Thermal decomposition via the Curtius rearrangement of azides of phosphorus-containing fatty and aromatic carboxylic acids in toluene or without a solvent gives the corresponding phosphorus-containing alkyl and aryl isocyanates:[32,85–90]

$$R_2P(O)CH_2CH_2COCl \xrightarrow{NaN_3 \text{ or } (CH_3)_3SiN_3} \rightarrow [R_2P(O)CH_2CH_2CON_3] \xrightarrow[\text{toluene}]{\Delta} R_2P(O)CH_2CH_2NCO,$$
$$R = Cl,\ C_2H_5O,\ C_3H_7O,\ \text{iso-}C_3H_7O;$$
$$(RO)_2P(S)SCH_2CH_2COCl \xrightarrow{NaN_3 \text{ or } (CH_3)_3SiN_3} \rightarrow [(RO)_2P(S)SCH_2CH_2CON_3] \xrightarrow{\Delta} (RO)_2P(S)SCH_2CH_2NCO;$$

$$C_6H_5P(O)(C_6H_4COCl\text{-}p)_2 \xrightarrow{2NaN_3} [C_6H_5P(O)(C_6H_4CON_3\text{-}p)_2] \xrightarrow{\Delta} \rightarrow C_6H_5P(O)(C_6H_4NCO\text{-}p)_2;$$

$$(C_2H_5O)_2P(O)C(C_6H_5){=}C{=}O \xrightarrow{HN_3} (C_2H_5O)_2P(O)CH(C_6H_5)CON_3 \xrightarrow{\Delta} \rightarrow (C_2H_5O)_2P(O)CH(C_6H_5)NCO.$$

On boiling phosphorus-containing azides of aliphatic or aromatic carboxylic acids in absolute alcohol, nitrogen is eliminated and isocyanates are formed, immediately adding on alcohols and being converted to the corresponding urethanes $CH_3P(O)(C_6H_4NHCOOC_2H_5)_2$, $(C_6H_5)_2P(O)CH_2CH.(NHCOOC_2H_5)_2$, and $(C_6H_5)_2P(O)CH(NHCOOC_2H_5)(CH_2)_n.NHCOOC_2H_5$ (n = 1, 2).[63,92,93]

(k) Rearrangement of dialkyl- and diaryl-phosphinyl-acetohydroxamic acids and their *O*-benzoyl derivatives

On heating dialkyl- and diaryl-phosphinylhydroxamic acids with an excess of triethyl orthoformate, they rearrange to phosphorylated alkyl isocyanates, which are converted during reaction to *N,N'*-bis(diarylphosphinylmethyl)ureas and ethyl *N*-[dialkyl(diaryl)-phosphinylmethyl]carbamates:[92,94]

$$R_2P(O)CH_2CONHOH \xrightarrow[-2R'OH,\ -R'OC(O)H]{(R'O)_3CH} [R_2P(O)CH_2NCO] \rightarrow$$
$$\rightarrow \begin{cases} \xrightarrow{R'OH} R_2P(O)CH_2NHCOOR' \\ \xrightarrow{H_2O} R_2P(O)CH_2NH_2 \xrightarrow{R_2P(O)CH_2NCO} [R_2P(O)CH_2NH]_2CO, \end{cases}$$
$$R = C_2H_5,\ C_6H_5,\ p\text{-}CH_3C_6H_4,\ p\text{-}ClC_6H_4;\ R' = C_2H_5.$$

O-Benzoyl derivatives of diarylphosphinylacetohydroxamic acids when heated in aqueous alkaline solution also undergo the Lossen rearrangement to form phosphorylated methyl isocyanates, which are converted to symmetric *N,N'*-bis(diarylphosphinylmethyl)-ureas:[92,94]

$$R_2P(O)CH_2C(O)NHOC(O)C_6H_5 \xrightarrow[-H_2O]{KOH} \left[R_2P(O)CH_2C(=O)NOC(O)C_6H_5\right]^- K^+ \xrightarrow{-C_6H_5COOH}$$
$$\rightarrow \left[R_2P(O)CH_2C(=O)\ddot{N}:\right] \rightarrow R_2P(O)CH_2NCO \xrightarrow[-CO_2]{H_2O}$$
$$\rightarrow R_2P(O)CH_2NH_2 \xrightarrow{R_2P(O)CH_2NCO} [R_2P(O)CH_2NH]_2CO;$$
$$R = C_6H_5,\ p\text{-}CH_3C_6H_4,\ p\text{-}ClC_6H_4.$$

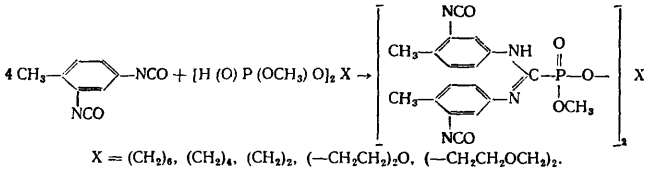
(l) Isomerisation of *O,O'*-dialkyl *S*-(ethyleniminocarbonyl)phosphoro-dithioate

When *O,O'*-dialkyl *S*-(chlorocarbonyl)phosphorodithioates are treated with ethylenimine in the presence of triethylamine, *O,O'*-dialkyl *S*-(ethyleniminocarbonyl)phosphorodithioates are formed, which on boiling in toluene undergo complete isomerisation to phosphorus-containing alkyl isocyanates:[87,95]

$$(RO)_2P(S)SC(O)Cl \xrightarrow{HN\langle CH_2\text{–}CH_2,\ (C_2H_5)_3N} (RO)_2P(S)SC(O)N\langle CH_2\text{–}CH_2 \xrightarrow[\text{toluene}]{\Delta} \rightarrow (RO)_2P(S)SCH_2CH_2NCO.$$

(m) Reaction of *N,N'*-bis(alkylidene)ureas with dialkyl phosphites and dialkylphosphorodithioic acids

When *N,N'*-bis(1-phenyl-2,2,2-trifluoroethylidene)urea is boiled with diethyl phosphite or *O,O'*-diisopropyl phosphorodithioate in benzene, the corresponding phosphorus-containing isocyanates are obtained:[96]



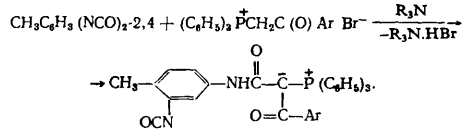
$$[C_6H_5(CF_3)C{=}N]_2CO \rightarrow$$
$$\rightarrow \begin{cases} \xrightarrow{(C_2H_5O)_2P(O)H} (C_2H_5O)_2P(O)C(C_6H_5)(CF_3)NCO \\ \xrightarrow{(\text{iso-}C_3H_7O)_2P(S)SH} (\text{iso-}C_3H_7O)_2P(S)SC(C_6H_5)(CF_3)NCO. \end{cases}$$

(n) Addition to 2,4-diisocyanatotoluene of phosphorus compounds containing active hydrogen atoms

2,4-Diisocyanatotoluene readily adds on 1 mole of dialkyl phosphite:[97–99]

$$(RO)_2P(O)H + CH_3C_6H_3(NCO)_2\text{-}2,4 \xrightarrow[\text{hexane}]{Na} \rightarrow (RO)_2P(O)C(O)NHC_6H_3NCO\text{-}3\text{-}CH_3\text{-}4.$$

Bis-phosphites react with excess 2,4-diisocyanatotoluene in the absence of catalysts to form phosphorus-containing aromatic isocyanates of complex structure:[100]



$X = (CH_2)_6,\ (CH_2)_4,\ (CH_2)_2,\ (-CH_2CH_2)_2O,\ (-CH_2CH_2OCH_2)_2.$

When 3 moles of 2,4-diisocyanatotoluene are reacted with tris(hydroxymethyl)phosphine or its oxide, aromatic isocyanates containing phosphorus are also obtained:[101]

$$XP(CH_2OH)_3 + CH_3C_6H_3(NCO)_2\text{-}2,4 \rightarrow XP[CH_2OC(O)NHC_6H_3NCO\text{-}3\text{-}.\ .CH_3\text{-}4]_3,$$

X = O or unshared electron pair.

2,4-Diisocyanatotoluene reacts with triphenylphenacylphosphonium bromides in the presence of ethyldiisopropylamine to form a phosphorus ylide containing a free isocyanate group:[102]

(o) Treatment of phosphorus-containing urethanes with phosphorus pentachloride

When methyl *N*-[1-(diethoxyphosphoryl)]-, *N*-([1-ethoxyphenylphosphonyl)]- and *N*-[1-diphenylphosphinyl)]-2,2-dichlorovinylcarbamates are heated with phosphorus pentachloride, the corresponding 1-phosphorylated 2,2-dichlorovinyl isocyanates are obtained:[103,104]

$$C_2H_5O(X)P(O)C(=CCl_2)NHCOOCH_3 \xrightarrow{n PCl_5} Cl(Y)P(O)C(=CCl_2)NCO,$$
$$X = C_2H_5O,\ Y = Cl,\ n = 3;\quad X = Y = C_6H_5,\ n = 2;$$
$$(C_6H_5)_2P(O)C(=CCl_2)NHCOOCH_3 \xrightarrow{PCl_5} (C_6H_5)_2P(O)C(=CCl_2)NCO.$$

(p) Reaction of trichlorophosphazotrichloromethane with *N,N',N''*-trichloroisocyanuric acid

Trichlorophosphazotrichloromethane readily reacts with *N,N',N''*-trichloroisocyanuric acid, whereupon a chlorine molecule is eliminated and 1-trichlorophosphazo-1,1-dichloromethyl isocyanate is formed, which exists in equilibrium with its acid chloride form:[105,106]

$$Cl_3P{=}NCCl_3 \xrightarrow[-Cl_2]{1/3(ClNCO)_3} Cl_3P{=}NCCl_2NCO \rightleftarrows Cl_3P{=}NCCl{=}NCOCl.$$

(q) Reaction of isocyanates of trivalent phosphorus acids with alkylene oxides

When ethylene oxide is reacted with triisocyanatophosphine in the presence of catalytic quantities of a tertiary amine, *O,O'*-bis(2-isocyanatoethyl) phosphorus isocyanate is obtained:[107]

$$P(NCO)_3 + 2CH_2{-}CH_2 \rightarrow OCNP(OCH_2CH_2NCO)_2.$$
$$\qquad\qquad\quad \backslash O /$$

(r) Halogenation of phosphorus-containing alkyl and vinyl isocyanates

When dichlorophosphorylmethyl isocyanate is chlorinated with the calculated quantity of chlorine in carbon tetrachloride in the presence of UV light, *N*-(dichlorophosphorylchloromethyl)carbamoyl chloride is formed, treatment of which with triethylamine gives dichlorophosphorylchloromethyl isocyanate:[51]

$$Cl_2P(O)CH_2NCO \xrightarrow[CCl_4,UV]{Cl_2} Cl_2P(O)CHClNHCOCl \xrightarrow[-(C_2H_5)_3N.HCl]{(C_2H_5)_3N} \rightarrow Cl_2P(O)CHClNCO.$$

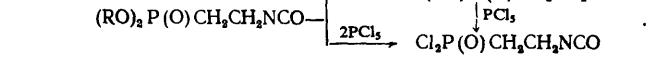
2-[*S*-(Diethoxyphosphoryl)thio]vinyl isocyanate reacts with an equimolar quantity of chlorine in carbon tetrachloride (20 °C, 20 h) to form 2-[*S*-diethoxyphosphoryl)thio]-2-chlorovinyl isocyanate:[77]

$$(RO)_2P(O)SCH{=}CHNCO \xrightarrow{Cl_2} (RO)_2P(O)SC(Cl){=}CHNCO.$$

1-(Dihalophosphoryl)- and 1-(alkoxyhalophosphoryl)-vinyl isocyanates readily add on bromine to the double bond:[14,40]

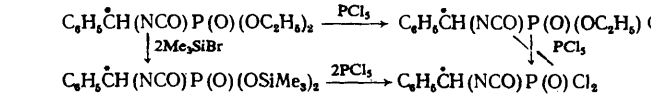
$$XYP(O)C(=CH_2)NCO \xrightarrow{Br_2} XYP(O)CBr(CH_2Br)NCO,$$
$$X = Y = Cl,\ F;\quad X = Cl,\ F,\ Y = C_2H_5O.$$

When 2-(dichlorophosphoryl)- and 2-(difluorophosphoryl)-alkenyl isocyanates react with an equimolar quantity of chlorine or bromine at 0 °C, *N*-[2-dichloro(difluoro)phosphoryl-2-haloalkenyl]carbamoyl halides are obtained, which on heating under vacuum readily eliminate hydrogen halide, being converted to 2-(dichlorophosphoryl)- or 2-(difluorophosphoryl)-2-haloalkenyl isocyanates:[108]



$$Y_2P(O)CH{=}C(R)NCO + X_2 \rightarrow [Y_2P(O)CHXCX(R)NCO] \xrightarrow{-HX} \rightarrow [Y_2P(O)CX{=}C(R)NCO] \xrightarrow{HX} Y_2P(O)CX{=}C(R)NHCOX \xrightarrow{-HX} \rightarrow Y_2P(O)CX{=}C(R)NCO,$$
$$R = H,\ CH_3;\quad Y = Cl,\ F;\quad X = Cl,\ Br.$$

2-(Dihalophosphoryl)alkenyl isocyanates react with excess chlorine according to the following scheme:[108]



$$X_2P(O)CH{=}C(R)NCO \xrightarrow[25-50\ ^\circ C]{Cl_2} X_2P(O)CCl_2CCl(R)NCO \xrightarrow[100-120\ ^\circ C,\ UV]{Cl_2} \rightarrow X_2P(O)CCl_2CCl(R')NCO,$$
$$X = Cl,\ F;\quad R = H,\ CH_3;\quad R' = Cl,\ CCl_3.$$

(s) Treatment of β-(dialkoxyphosphoryl)- and β-(alkoxychlorophosphoryl)-alkyl isocyanates with phosphorus pentachloride

β-(Dialkoxyphosphoryl)ethyl isocyanates react with an equimolar quantity of phosphorus pentachloride at room temperature in carbon tetrachloride to form β-(alkoxychlorophosphoryl)ethyl isocyanates. When β-(dialkoxyphosphoryl)ethyl isocyanates are treated with 2 moles of phosphorus pentachloride or β-(alkoxychlorophosphoryl)-ethyl isocyanate is treated with 1 mole of phosphorus pentachloride, β-(dichlorophosphoryl)ether isocyanates are obtained:[86]

On treatment with 1 mole of phosphorus pentachloride, (*S*)-(+)-α(diethoxyphosphoryl)benzyl isocyanate is converted to (*S*)-(+)-α-(ethoxychlorophosphoryl)benzyl isocyanate. It is not possible to obtain optically active α-(dichlorophosphoryl)benzyl isocyanate by treating the above isocyanates with phosphorus pentachloride. Another method has been proposed for the synthesis of this compound:[12-14]

(t) Fluorination of dihalophosphorylalkyl, dihalophosphorylalkenyl, and alkoxychlorophosphorylalkyl isocyanates

Dichlorophosphorylalkyl, dichlorophosphorylalkenyl, and alkoxychlorophosphorylalkyl isocyanates are fluorinated with arsenic trifluoride[12–14,57,86] or antimony trifluoride:[37,38,53,83]

$$Cl_2P(O)—A—NCO \xrightarrow{AsF_3 \text{ or } SbF_3} F_2P(O)—A—NCO,$$
$$A=CH_2CH_2,\ CCl_2,\ C(=CH_2),\ CH=CH,\ CH(C_6H_5);$$
$$Cl(RO)P(O)CR^1R^2NCO \xrightarrow{AsF_3} F(RO)P(O)CR^1R^2NCO,$$
$$R^1=R^2=H,\ Cl;\ R^1=H,\ R^2=Cl,\ C_6H_5.$$

Reaction of difluorophosphorylalkenyl isocyanates with sulphur tetrafluoride gives 2-isocyanatoalkenyltetrafluorophosphoranes,[80,83] which are also formed when *N*-[dichloro(difluoro)phosphorylalkenyl]-iminocarbonyl dichloride is treated with sulphur tetrafluoride:[83]

$$F_2P(O)CH=C(R)NCO \xrightarrow{SF_4} F_4PCH=C(R)NCO$$
$$X_2P(O)CH=C(R)N=CCl_2 \xrightarrow{SF_4} [F_2P(O)CH=C(R)N=CF_2]$$
$$X=Cl,\ F;\ R=H,\ CH_3.$$

It should be mentioned that it is not possible to obtain 2-isocyanatoperchloroethyltetrafluorophosphorane by reaction of 2-dichlorophosphorylperchloroethyl isocyanate with sulphur tetrafluoride as cleavage of the P–C bond occurs:[108]

$$Cl_2P(O)CCl_2CCl_2NCO \xrightarrow{SF_4} Cl_3\overset{+}{S}\ P\overline{F}_6 + [F_3SCCl_2CClFNCO + S_2Cl_2].$$

(u) Elimination of chlorine, hydrogen chloride, or hydrogen bromide from phosphorylated haloalkyl isocyanates

When 1-(dihalophosphoryl)-, 1-(alkoxyhalophosphoryl)- and 1-(dialkoxyphosphoryl)-substituted 2-chloro- or 2-bromo-methyl isocyanates are treated with triethylamine, hydrogen chloride or bromide is readily eliminated and the corresponding phosphorylvinyl isocyanates are obtained.[14,38–40]

$$XYP(O)CH(CH_2Z)NCO \xrightarrow[-(C_2H_5)_3N.HZ]{(C_2H_5)_3N} XYP(O)C(=CH_2)NCO,$$
$$X=Y=Cl,\ F,\ OAlk,\ Z=Cl,\ Br;\ X=Cl,\ F,\ Y=C_2H_5O,\ Z=Br.$$

When 1-(dichlorophosphoryl)-1,2-dibromoethyl isocyanate is treated with triethylamine, (*E*)-1-(dichlorophosphoryl)-2-bromovinyl isocyanate is obtained.[14,40] When 2-(dichlorophosphoryl)tetrachloroethyl isocyanate is heated with methyl phosphorodichloridite, 2-(dichlorophosphoryl)-1,2-dichlorovinyl isocyanate is formed:[108]

$$Cl_2P(O)CCl_2CCl_2NCO \xrightarrow[-CH_3Cl,\ -POCl_3]{CH_3OPCl_2} Cl_2P(O)CCl=CClNCO.$$

(v) Reaction of 2-isocyanatoalkenyltetrafluorophosphoranes with hexamethyldisiloxane

On heating 2-isocyanatoalkenyltetrafluorophosphoranes with hexamethyldisiloxane, 2-(difluorophosphoryl)alkenyl isocyanates are obtained:[83]

$$F_4PCH=C(R)NCO \xrightarrow[-2(CH_3)_3SiF]{[(CH_3)_3Si]_2O} F_2P(O)CH=C(R)NCO,$$
$$R=H,\ CH_3.$$

(x) Cyclopolymerisation of diisocyanates in the presence of trialkyl phosphites

It has been shown[109] that when 2,4-toluylene diisocyanate, 1,6-hexamethylene diisocyanate, and 1,4-tetramethylene diisocyanate undergo cyclopolymerisation in the presence of trialkyl phosphites, phosphorylated isocyanates that contain isocyanurate rings are formed.

2. Phosphorus-containing acyl isocyanates

(a) Reaction of *N*-(diethoxyphosphoryl)-*N*-(2-chloroethyl)carbamoyl chloride with trimethylsilyl isocyanate

N-(Diethoxyphosphoryl)-*N*-(2-chloroethyl)carbamoyl chloride reacts with trimethylsilyl isocyanate on boiling for 30 h in the presence of the catalyst $(C_4H_9)_4NI$ to form *N*-(diethoxyphosphoryl)-*N*-(2-chloroethyl)carbamoyl isocyanate:[110]

$$(C_2H_5O)_2P(O)NC(O)Cl + (CH_3)_3SiNCO \xrightarrow{\text{Cat. } (C_4H_9)_4NI}$$
$$\rightarrow (C_2H_5O)_2P(O)NC(O)NCO + (CH_3)_3SiCl.$$
$$CH_2CH_2Cl \qquad\qquad CH_2CH_2Cl$$

(b) Reaction of dialkoxyphosphorylcarboxamides and *N*-phosphorylated ureas with oxalyl chloride

Dialkoxyphosphorylcarboxamides react in carbon tetrachloride or chloroform at a temperature of 60–70 °C with oxalyl chloride to form dialkoxyphosphorylacyl isocyanates:[111–113]

$$(AlkO)_2P(O)CRR^1CONH_2 + (COCl)_2 \rightarrow (AlkO)_2P(O)CRR^1CONCO + 2HCl + CO,$$
$$R=R^1=H,\ Cl,\ CH_3;\ R=H,\ R^1=CH_3.$$

N-(Diethoxyphosphoryl)-*N*-(2-chloroethyl)urea reacts in a similar manner:[110]

$$(C_2H_5O)_2P(O)NC(O)NH_2 + (COCl)_2 \rightarrow (C_2H_5O)_2P(O)NC(O)NCO.$$
$$CH_2CH_2Cl \qquad\qquad CH_2CH_2Cl$$

(c) Treatment of *O,O'*-dialkyl *N*-alkylphosphoramidates with chlorocarbonyl isocyanate

When *O,O'*-dialkyl *N*-alkylphosphoramidates are boiled with chlorocarbonyl isocyanate in carbon tetrachloride, *N*-alkyl-*N*-(dialkoxyphosphoryl)carbamoyl isocyanates are obtained:[114]

$$(RO)_2P(O)NHR^1 + ClC(O)NCO \rightarrow (RO)_2P(O)N(R^1)C(O)NCO + HCl,$$
$$R=C_2H_5,\ R^1=CH_3,\ C_2H_5;\ R=\text{iso-}C_3H_7,\ R^1=C_2H_5.$$

(d) Reaction of *N*-phosphorylated ethylenimines with chlorocarbonyl isocyanate and dichloromethylenecarbamoyl chloride

When *O,O'*-dialkyl phosphoroethylenamidates are treated with chlorocarbonyl isocyanate, opening of the ethylenimine ring occurs with formation of *N*-(dialkoxyphosphoryl)-*N*-(2-chloroethyl)-carbamoyl isocyanates,[76,110] which are also obtained by the action of dichloromethylenecarbamoyl chloride followed by treatment of the intermediate with methanesulphonic acid:[75]

$$(RO)_2P(O)N\begin{array}{l}CH_2\\|\\CH_2\end{array}\begin{array}{l}\xrightarrow{ClC(O)NCO}\ (RO)_2P(O)N(CH_2CH_2Cl)C(O)NCO\\ \qquad\qquad\qquad\qquad\qquad\uparrow CH_3SO_2OH\\ \xrightarrow{ClC(O)-CCl_2}\ (RO)_2P(O)N(CH_2CH_2Cl)C(O)N=CCl_2\end{array}.$$

3. Phosphorus-containing sulphonyl isocyanates

(a) Addition of dialkyl phosphites to sulphuryl diisocyanate

One mole of dialkyl phosphite in ether solution at 0 °C adds on to one isocyanate group of sulphuryl diisocyanate to form the corresponding sulphonyl isocyanate.[115] With excess dialkyl phosphite products from the addition to both isocyanate groups are formed:[115,116]

$$SO_2(NCO)_2\begin{array}{l}\xrightarrow{(RO)_2P(O)H}\ (RO)_2P(O)C(O)NHSO_2NCO\\ \xrightarrow{2(RO)_2P(O)H}\ [(RO)_2P(O)C(O)NH]_2SO_2\end{array}.$$

(b) Treatment of *N*-isopropyl-*N'*-(triphenylphosphazosulphonyl)urea with phosgene

When *N*-isopropyl-*N'*-(triphenylphosphazosulphonyl)urea is boiled with phosgene in chlorobenzene, triphenylphosphazosulphonyl isocyanate is obtained:[117]

$$(C_6H_5)_3P{=}NSO_2NHCONHC_3H_7\text{-iso} \xrightarrow{COCl_2} (C_6H_5)_3P{=}NSO_2NCO.$$

III. Chemical properties

Phosphorylated organic isocyanates which contain no other reactive groups apart from the isocyanate are similar in their chemical properties to normal organic isocyanates. They readily react with alcohols, phenols, amines, and other compounds with an active hydrogen atom, forming the corresponding derivatives in good yield. Phosphorus-containing organic isocyanates which have other reactive sites in addition to the isocyanate group can undergo a reaction with nucleophilic reagents on one or more reaction sites. Some reactions of phosphorus-containing organic isocyanates which do not affect the isocyanate group and which give other phosphorus-containing organic isocyanates have been described above.

1. Reaction with water

The majority of phosphorus-containing alkyl and aryl isocyanates are very readily hydrolysed by atmospheric moisture and react with water; but only in certain cases have the reaction products—the corresponding phosphorus-containing symmetrical ureas—been isolated:[9,46,91,94,98]

$$\{(C_2H_5O)_2P(O)C(=CCl_2)NH\}_2CO,$$
$$\{2\text{-}CH_3\text{-}4\text{-}[(C_2H_5O)_2P(O)C(O)NH]C_6H_3NH\}_2CO,$$
$$\{(C_6H_5)_2P(O)CH_2NH\}_2CO,\ \{(RO)_2P(O)CH(COOR^1)NH\}_2CO,$$
$$\{2\text{-}[(C_6H_5)_2P(O)]C_6H_4NH\}_2CO.$$

When α-(diethoxyphosphoryl)benzyl isocyanate [racemate or (*S*)-(+)-enantiomer] is exposed to atmospheric moisture or a stoichiometric quantity of water in ether, racemic or (*SS*)-(−)-*N*,*N'*-bis[α-(diethoxyphosphoryl)benzyl]urea is obtained.[12]

When (*S*)-(+)-α-[bis-(trimethylsiloxy)phosphoryl]benzyl isocyanate is treated with excess water, (*S*)-(−)-α-aminobenzylphosphonic acid is obtained:[12,56]

$$C_6H_5\dot{C}H(NCO)P(O)[OSi(CH_3)_3]_2 \xrightarrow{H_2O} C_6H_5\dot{C}H(NH_2)P(O)(OH)_2.$$

Diethoxyphosphorylcarbonylamidosulphonyl isocyanate is hydrolysed with water to diethoxyphosphorylcarbonylamidosulphonamide:[115]

$$(C_2H_5O)_2P(O)C(O)NHSO_2NCO \xrightarrow{H_2O} (C_2H_5O)_2P(O)C(O)NHSO_2NH_2.$$

When bis(diethoxyphosphoryl)chloromethyl isocyanate is reacted with 2 moles of water in acetone, a compound containing a carbonyl group is formed:[118]

$$\{(C_2H_5O)_2P(O)\}_2CClNCO \xrightarrow{H_2O} [(C_2H_5O)_2P(O)]_2CClNHCOOH \xrightarrow{-CO_2}$$
$$\rightarrow [(C_2H_5O)_2P(O)]_2CClNH_2 \rightarrow [(C_2H_5O)_2P(O)]_2C{=}NH\cdot HCl \xrightarrow{H_2O}$$
$$\rightarrow \{(C_2H_5O)_2P(O)\}_2C{=}O.$$

In contrast to mono- and bis-phosphorylated alkyl isocyanates, tris(diethoxyphosphoryl)methyl isocyanate reacts with water only with great difficulty. It remains unchanged on boiling for 2 hours with a stoichiometric quantity of water in acetone. Only on boiling with a tenfold excess of water in dioxan for 3 h does the molecule decompose to form products with an undetermined structure.[118]

2. Reaction with alcohols and phenols

Phosphorus-containing alkyl, alkenyl, and aryl isocyanates that do not contain other groups can react with alcohols and phenols; they have the properties of normal organic isocyanates and readily add on alcohols,[1,4,5,12,26,27,30–32,36–38,40–42, 45–47, 54,68,69,74,75,88,89,91–95,107,119] glycols,[3,20,26,58,59,88,101,119,120] cresol,[20,58,59] and cellulose and cellulose acetate[99] to the isocyanate group. The reactions are usually carried out in inert solvents without a catalyst or in the presence of catalytic quantities of a tertiary amine.

$$R_{3-n}P(X)(ANCO)_n + nR^1OH \rightarrow R_{3-n}P(X)(ANHCOOR^1)_n,$$

$n = 1-3$; X = O, S; A—different bridging groups (see Methods of Synthesis)

It should be mentioned that tris(diethoxyphosphoryl)methyl isocyanate does not react at 20 °C even with a large excess of alcohol over a period of 10–15 days. Even in the presence of a base the reaction is only complete after 15 days under these conditions:[40,54]

$$[(C_2H_5O)_2P(O)]_3CNCO \xrightarrow[\text{Cat. } (C_2H_5)_3N]{ROH} [(C_2H_5O)_2P(O)]_3CNHCOOR.$$

Trialkyl- and triaryl-(isocyanatomethyl)phosphonium halides readily add on alcohols to the isocyanate group. Phenols add on only in the presence of catalytic quantities of a tertiary amine.[36,71,73]

$$[R_3PCH_2NCO]^+X^- + R^1OH \rightarrow [R_3PCH_2NHCOOR^1]^+X^-,$$
R, R^1=Alk, Ar; X=Cl, Br, I.

Phosphorus-containing acyl isocyanates[110–112] and sulphonyl isocyanates[115,117] also readily add alcohols to the isocyanate group to form the corresponding urethanes:

$$(RO)_3P(O)CCl_2CONHCOOR^1,\ (C_2H_5O)_2P(O)N(CH_3CH_2Cl)C(O)NHCOOC_2H_5,$$
$$(C_6H_5)_3P{=}NSO_2NHCOOR^2,\ (C_2H_5O)_2P(O)C(O)NHSO_2NHCOOC_2H_5$$

(where R = C_2H_5, C_4H_9; R^1 = CH_3, C_2H_5, iso-C_3H_7; R^2 = CH_3, iso-C_3H_7, tert-C_4H_9, cyclo-C_6H_{11}).

Dihalo- and alkoxyhalo-phosphoryl-substituted alkyl and alkenyl isocyanates have two reaction sites—the carbon atom of the isocyanate group and the phosphorus atom. Depending on the structure of the phosphorylated isocyanate, the alcohol reacting with it, the solubility of the product formed, the reaction conditions, etc., either only the isocyanate group reacts with an equimolar quantity of alcohol or replacement of a halogen atom on phosphorus by an alkoxy group takes place at the same time as addition. Thus, addition products of alcohols only on the isocyanate group have been obtained for the following types of isocyanates:[30,32,34,40,41,64,78,81,83,86,108,121–123]

$$XYP(O)CH_2NCO\ (X{=}Y{=}Cl;\ X{=}F,\ Y{=}RO);\ Cl_2P(O)CH(CH_2Br)NCO;$$
$$Cl_2P(O)CH(C_6H_5)NCO;\ F(C_2H_5O)P(O)CH(C_6H_5)NCO;\ F_2P(O)CH_2CH_2NCO;$$
$$Cl(RO)P(O)CH{=}CHNCO;\ X_2P(Y)CH{=}C(R)NCO$$
$$(X = Cl, F;\ Y = O, S;\ R = H, CH_3);$$
$$Cl_2P(O)CX{=}CHNCO\ (X = Cl, Br).$$

It is not possible to obtain products from the addition of 1 mole of a primary alcohol only to the isocyanate group of difluorophosphorylmethyl, alkoxychlorophosphorylmethyl, 2-(dichlorophosphoryl)ethyl, 1-(dichlorophosphoryl)vinyl, α-(difluorophosphoryl)benzyl, and α-(alkoxychlorophosphoryl)benzyl isocyanates.[30,34,38,40,41,64,86] However, when tertiary butyl alcohol is reacted with 1-(dichlorophosphoryl)vinyl isocyanate, the urethane $Cl_2P(O)C(=CH_2)NHCOOC(CH_3)_3$ is obtained.[38]

When difluorophosphorylmethyl isocyanate is treated with 2 moles of alcohol, alkyl *N*-(alkoxyfluorophosphorylmethyl)carbamate is

obtained in good yield.[30,34,64] With excess alcohol in the presence of tertiary amines, all dihalophosphoryl- and alkoxyhalophosphoryl-substituted alkyl and alkenyl isocyanates give alkyl *N*-[dialkoxyphosphorylalkyl(alkenyl)]carbamates.[30,34,38,40,41,46,64,86,108]

When 1-dichlorophosphoryl-2-chloro(bromo)ethyl isocyanates react with excess alcohol in the presence of triethylamine, as well as addition of the alcohol to the isocyanate group and replacement of the chlorine atom on phosphorus there is elimination of hydrogen chloride or bromide to give alkyl *N*-(1-dialkoxyphosphorylvinyl)-carbamate;[38,40] the same esters are obtained when 1-(dialkoxyphosphoryl)-2-bromoethyl isocyanate is treated with 1 mole of alcohol in the presence of triethylamine:[40]

$$\left.\begin{array}{l} Cl_2P(O)CH(CH_2X)NCO \xrightarrow[3(C_2H_5)_3N]{3ROH} \\ X=Cl,\ Br \\ (RO)_2P(O)CH(CH_2Br)NCO \xrightarrow[(C_2H_5)_3N]{ROH} \end{array}\right| \rightarrow (RO)_2P(O)C(=CH_2)NHCOOR.$$

α-(Dialkoxyphosphoryl)-α-chlorobenzyl isocyanate has two reaction sites—the carbon atoms of the isocyanate group and the substituted methylene group. When α-(diethoxyphosphoryl)-α-chlorobenzyl isocyanate in ether solution is treated with an equimolar quantity of methanol it appears that addition of methanol to the isocyanate group mainly occurs, and methyl *N*-[α-(diethoxyphosphoryll)-α-chlorobenzyl]carbamate, which is soluble with difficulty in ether, can be isolated in 50% yield. In the presence of triethylamine, methyl *N*-[α-(diethoxyphosphoryl)-benzylidene]carbamate is obtained in high yield.[56]

$$C_6H_5CCl(NCO)P(O)(OC_2H_5)_2 \longrightarrow \left|\begin{array}{l} \xrightarrow{CH_3OH} C_6H_5CCl(NHCOOCH_3)P(O)(OC_2H_5)_2 \\ \xrightarrow[CH_3OH,\ (C_2H_5)_3N]{} C_6H_5C(=NCOOCH_3)P(O)(OC_2H_5)_2. \end{array}\right.$$

Diethoxy phosphoryldichloromethyl and bis(diethoxyphosphoryl)-chloromethyl isocyanates react in a similar manner:[32,54]

$$(RO)_2P(O)C(X)ClNCO \xrightarrow{R'OH} [(RO)_2P(O)C(X)ClNHCOOR'] \xrightarrow{[(C_2H_5)_3N]} \rightarrow (RO)_2P(O)C(X)=NCOOR',$$
$$X=Cl,\ (RO)_2P(O).$$

In the case of the halophosphoryl compounds $Hal(X)P(O)C(Hal)_2.NCO$ and $Hal(X)P(O)CH(Hal)NCO$ (X = Hal or OR) there is a third reaction site—the phosphorus atom.

Depending on the structure of the isocyanate and the nucleophilic reagent reacting with it as well as their stoichiometric ratio, initially only the isocyanate group participates, then the phosphorus atom and the halogen on the α-carbon atom, or all reaction sites simultaneously.

Dichloro- and difluoro-phosphorylchloromethyl isocyanates add 1 mole of alcohol to form crystalline alkyl *N*-(dihalophosphoryl-chloromethyl)carbamates:[50]

$$X_2P(O)CHClNCO \xrightarrow{ROH} X_2P(O)CHClNHCOOR,$$
$$X=Cl,\ F.$$

Dichlorophosphoryldichloromethyl isocyanate, and alkoxychloro-, alkoxyfluoro-phosphorylchloromethyl isocyanates also react with 1 mole of alcohol mainly on the isocyanate group alone. However, the urethanes formed are very unstable and on evaporating the solutions, vacuum distillation, or treatment with tertiary amines they readily eliminate a hydrogen chloride molecule and are converted to the corresponding compounds with a C=N bond. It was only possible to isolate the stable alkyl *N*-(dichlorophosphorylchloro-methylene)carbamates in a pure form.[50,52-54] Dichlorophosphoryl-dibromomethyl isocyanate reacts with alcohols in a similar manner:[40]

$$Cl_2P(O)CX_2NCO \xrightarrow{ROH} [Cl_2P(O)CX_2NHCOOR] \xrightarrow{(C_2H_5)_3N} \rightarrow Cl_2P(O)CX=NCOOR,$$
$$X=Cl,\ Br.$$

It should be mentioned that it is not possible to add 1 mole of alcohol to the isocyanate group of difluorophosphoryl- or alkoxyfluorophosphoryl-dichloromethyl isocyanate. Reaction takes place simultaneously on two reaction sites—the carbon atom of the NCO group and the phosphorus atom—and a mixture of products is formed, from which pure compounds could not be isolated.[53,118] However, in the case of 2-chloroethoxychlorophosphoryldichloro-methyl isocyanate, *N*-(2-chloroethoxychlorophosphorylchloro-methylene)carbamate was obtained.[57]

When dichloro- or alkoxychloro-phosphoryldichloromethyl isocyanate reacts with excess alcohol in the presence of a tertiary amine, alkyl *N*-(dialkoxyphosphorylchloromethylene)carbamates are obtained,[32,52,53] while dichloro- and alkoxychloro-phosphorylchloro-methyl isocyanates under the same conditions give alkyl *N*-[alkoxy-(dialkoxyphosphoryl)methyl]carbamates:[50]

$$Cl(X)P(O)CCl_2NCO \xrightarrow[(C_2H_5)_3N]{ROH} (RO)_2P(O)C(Cl)=NCOOR,$$
$$Cl(X)P(O)CHClNCO \xrightarrow[(C_2H_5)_3N]{ROH} (RO)_2P(O)CH(OR)NHCOOR,$$
$$X=Cl,\ RO.$$

α-(Dichlorophosphoryl)-α-chlorobenzyl isocyanate reacts with excess methanol in a similar manner to dichlorophosphoryldichloro-methyl isocyanate, forming the urethane $C_6H_5C(=NCOOCH_3)P(O).(OCH_3)_2$.[56]

When dichlorophosphoryldibromomethyl isocyanate is treated with 4 moles of sodium ethoxide in ethanol, ethyl *N*-[diethoxy-phosphoryl(ethoxy)methylene]carbamate is obtained:[40]

$$Cl_2P(O)CBr_2NCO \xrightarrow{4C_2H_5ONa} (C_2H_5O)_2P(O)C(OC_2H_5)=NCOOC_2H_5.$$

2-(Dichlorophosphoryl)perchloroethyl isocyanate reacts with alcohols in a similar manner to dichlorophosphoryldichloromethyl isocyanate, forming urethanes $(RO)_2P(O)CCl_2CCl=NCOOR$.[108]

When difluorophosphorylchloromethyl isocyanate is treated with 3 moles of alcohol or alkoxyfluorophosphorylchloromethyl isocyanate is treated with 2 moles of alcohol in the presence of triethylamine, alkyl *N*-[alkoxy(alkoxyfluorophosphoryl)methyl carbamates are obtained:[50]

$$\left.\begin{array}{l} F_2P(O)CHClNCO \xrightarrow[2(C_2H_5)_3N]{3\ ROH} \\ F(RO)P(O)CHClNCO \xrightarrow[(C_2H_5)_3N]{2ROH} \end{array}\right| \rightarrow F(RO)P(O)CH(OR)NHCOOR.$$

It is not possible to add 1 mole of alcohol just to the isocyanate group of bis(alkoxyfluorophosphoryl)chloromethyl isocyanate, and when the latter is treated with 3 moles of alcohol in the presence of triethylamine the reaction proceeds thus:[53]

$$[F(RO)P(O)]_2CClNCO \xrightarrow[3(C_2H_5)_3N]{3\ ROH} [(RO)_2P(O)]_2C=NCOOR.$$

Bis(alkoxyfluorophosphoryl)methyl isocyanate and its corresponding α-chloro-substituted compound when reacted with alcohols give urethanes.[50,53]

$$[F(RO)P(O)]_2CHNCO \xrightarrow{ROH} [F(RO)P(O)]_2CHNHCOOR,$$
$$[F(RO)P(O)]_2CClNCO \xrightarrow[(C_2H_5)_3N]{ROH} [F(RO)P(O)]_2C=NCOOR.$$

The addition of phenols and glucose tetraacetate to dichloro-phosphorylvinyl isocyanate has been reported.[121-123]

3. Reaction with thiols

Thiols add to phosphorylated alkyl isocyanates with much greater difficulty than alcohols. Thioethanol reacts with 1-diethoxyphosphoryl- and 1-diethoxyphosphorothioyl-1-methylethyl isocyanates only in the presence of triethylamine on heating in a sealed tube on a boiling water bath:[1,5]

$$(C_2H_5O)_2P(X)C(CH_3)_2NCO \xrightarrow[(C_2H_5)_3N]{C_2H_5SH} (C_2H_5O)_2P(X)C(CH_3)_2NHC(O)SC_2H_5$$
X=O, S.

4. Reactions with ammonia and amines

Dialkoxyphosphorylalkyl isocyanates, in the same way as alkyl and aryl isocyanates, readily react with ammonia to form *N*-(dialkoxyphosphorylalkyl)ureas:[1,5,31,75,90]

$$(RO)_2P(X)—A—NCO + NH_3 \rightarrow (RO)_2P(X)—A—NHCONH_2,$$
X=O: A=CH_2, $C(CH_3)_2$, $CH(C_6H_5)$, —N$(CH_2CH_2Cl)CH_2$—;
X=S: A=$C(CH_3)_2$.

N-(Diethoxyphosphoryl)-*N*-(2-chloroethyl)aminocarbonyl isocyanate[110] and triphenylphosphazosulphonyl isocyanate[117] add ammonia in a similar manner.

Phosphorus-containing alkyl,[1,4,5,9,12,30–32,36,37,41,42,45–48,54,68,74,75,85,88,92,94,95,124] alkenyl,[46,47] and aryl[30,31,89,98] isocyanates as well as isocyanates of *N*-phosphorylated iminocarboxylic acids[28] which apart from the isocyanate group have no other reaction sites very readily add primary[1,5,46] and secondary[30–32,54,72,75] aliphatic amines, phosphorylated alkylamines,[12,92,94] primary aromatic amines,[1,4,5,9,12,28,30–32,36,37,41,42,45–48,54,68,74,75,85,88,89,95,98,124] and morpholine[41,124] to form the respective ureas.

$$[R_2P(X)]_nANCO + R^1R^2NH \rightarrow [R_2P(X)]_nANHCONHR^1R^2,$$
n=1: R=Alk, Ar, AlkO, ArO; A=CH_2, $(CH_2)_2$, $\dot{C}H(C_6H_5)$, $\dot{C}H(C_6H_5)$, $CH(CH_2Cl)CH(CCl_3)$, $CHCOOR^3$, $C(CH_3)_2$, $C(C_6H_5)_2$, $C(C_{10}H_7\text{-}\alpha)_2$, $S(CH_2)_2$, —$CH_2C_6H_4$—, $C(=CH_2)$, $C(=CCl_2)$, N=$C(C_6H_5)$ etc.;
n = 2: R=AlkO, A=CH; n = 3, R=AlkO, A=C;

$$C_6H_5P(O)(C_6H_4NCO\text{-}p)_2 + 2C_6H_5NH_2 \rightarrow C_6H_5P(O)(C_6H_4NHCONHC_6H_5\text{-}p)_2.$$

Triaryl(isocyanatomethyl)phosphonium halides add 1 mole of an aromatic amine to the isocyanate group, forming compounds of the type $[Ar_3PCH_2NHCONHAr^1]^+X^-$ (X = Cl, Br, I).[36,73]

Phosphorus-containing acyl isocyanates[110–113] and sulphonyl isocyanates[115,117] also add primary aromatic amines,[110–113,115] and diethyl- and cyclohexyl-amine[117] to the isocyanate group, forming ureas

$$(AlkO)_2P(O)C(R)(R')CONHCONHAr,\ (C_6H_5)_3P{=}NSO_2NHCONRR',$$
$$(C_2H_5O)_2P(O)N(CH_2CH_2Cl)CONHCONHAr,$$
$$(C_2H_5O)_2P(O)C(O)NHSO_2NHCONHC_6H_5.$$

When dialkoxyphosphoryldichloro- or bis(dialkoxyphosphoryl)-chloro-methyl isocyanate is treated with 2 moles of an aromatic amine or 1 mole of an aromatic amine in the presence of triethylamine, hydrogen chloride is eliminated at the same time as addition of the amine to the isocyanate group:[48,54]

$$(RO)_2P(O)CXClNCO \xrightarrow[(C_2H_5)_3N]{ArNH_2} (RO)_2P(O)CX{=}NCONHAr,$$
X=Cl, $(RO)_2P(O)$.

One mole of a primary aromatic amine reacts with difluorophosphorylated alkyl and alkenyl isocyanates,[30,34,36,40,41,83,86] fluoroalkoxyphosphorylalkyl isocyanates,[30,34,36,41,57] and bis(ethoxyfluorophosphoryl)methyl isocyanate[50] only on the isocyanate group.

$$F_2P(O)ANCO + ArNH_2 \rightarrow F_2P(O)ANHCONHAr,$$
A=CH_2, $CHCH_2Br$, CHC_6H_5, $C(=CH_2)$, CH_2CH_2, CH=CH, $CH{=}C(CH_3)$;

$$F(AlkO)P(O)ANCO + ArNH_2 \rightarrow F(AlkO)P(O)ANHCONHAr,$$
A=CH_2, CHC_6H_5;

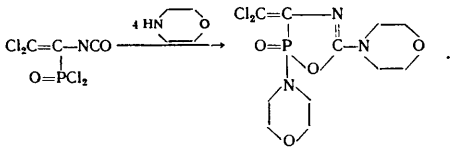
$$[F(C_2H_5O)P(O)_2CHNCO + p\text{-}ClC_6H_4NH_2 \rightarrow$$
$$\rightarrow [F(C_2H_5O)P(O)]_2CHNHCONHC_6H_4Cl\text{-}p.$$

2-(Dichlorophosphoryl)- and 2-(alkoxychlorophosphoryl)-vinyl isocyanates[78,79,81,108] as well as 2-(chlorazidophosphoryl)ethyl isocyanate[86] react in a similar manner.

It is not possible to add 1 mole of amine just to the isocyanate group of dichlorophosphorylalkyl, alkoxychlorophosphorylalkyl, 1-(dichlorophosphoryl)vinyl, 1-(dichlorophosphoryl)-2,2-dichlorovinyl and 1-(phenylchlorophosphonyl)-2,2-dichlorovinyl isocyanates or to isolate pure compounds. Reaction occurs simultaneously on the carbon atom of the isocyanate group and the phosphorus atom. With excess amine, as well as addition to the isocyanate group the chlorine atoms are completely replaced by amino groups[30,34,36,38,41,86,103,124] and the following ureas are formed: $(RR^1N)_2P(O)—A—NHCONRR^1$, $ArNH(R^2)P(O)—A—NHCONHAr$ [A = CH_2, CHC_6H_5, $(CH_2)_2$, $C(=CH_2)$, $C(=CCl_2)$, R^2 = AlkO, C_6H_5].

In the case of 1-(dichlorophosphoryl)- and 1-(phenylchlorophosphonyl)-2,2-dichlorovinyl isocyanates, treatment of the reaction mixture with water or alcohol gives products in which one chlorine atom on phosphorus has been replaced by a hydroxyl or alkoxyl group $R^2O(X)P(O)C(=CCl_2)NHCONRR^1$ (X = C_6H_5, RR^1N; R_2 = H, Alk).[103,124]

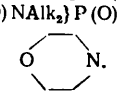
Depending on the structure of the isocyanate, α-halogen atoms are also replaced by an amino group or eliminated as hydrogen halides,[38,40,50,53,56] for example:



$$Cl_2P(O)CHClNCO \xrightarrow[3(C_2H_5)_3N]{4RR^1NH} (RR^1N)_2P(O)CH(NRR^1)NHCONRR^1,$$

$$[Cl(RO)P(O)]_2CClNCO \xrightarrow[3(C_2H_5)_3N]{3R^1R^2NH} [R^1R^2N(RO)P(O)]_2C{=}NCONR^1R^2.$$

In the case of bis(ethoxyfluorophosphoryl)chloromethyl isocyanate the fluorine atoms are not exchanged for amino groups under similar conditions:[53]



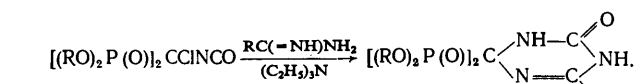
$$[F(C_2H_5O)P(O)]_2CClNCO \xrightarrow[(C_2H_5)_3N]{ArNH_2} [F(C_2H_5O)P(O)]_2C{=}NHCONHAr.$$

When 1-(dichlorophosphoryl)-2,2-dichlorovinyl isocyanate is reacted with 4 moles of morpholine, a cyclic compound—2,5-dimorpholino-4-dichloromethylene-5-oxo-5-phospha-2-oxazoline—is obtained:[103]

The addition of dialkyltrimethylsilylamines to α-(diethoxyphosphoryl)benzyl isocyanate and to triphenyl(α-isocyanatobenzyl)-phosphonium chloride has been reported:

$$C_6H_5CH(NCO)P(O)(OC_2H_5)_2 + Alk_2NSi(CH_3)_3 \rightarrow$$
$$\rightarrow C_6H_5CH\{N[Si(CH_3)_3]C(O)NAlk_2\}P(O)(OC_2H_5)_2,$$

$Alk_2N{=}(C_2H_5)_2N$,  .



In the latter case the addition product decomposes immediately it is formed at 15–20 °C, so that azomethine, triphenylphosphine, and trimethylchlorosilane are obtained.[72]

Diphenylketimines react similarly to amines with $(RO)_2P(S)SCH_2.CH_2NCO$ [95] and triphenylphosphazohydride reacts similarly with $Cl(X)P(O)CH_2NCO$ (X = Cl, RO) and $Cl_2P(O)CH=CHNCO$.[125,126]

α-Isocyanatophosphonoacetates add on hydrazine and 2,4-dinitrophenylhydrazine to form the corresponding semicarbazides:[9]

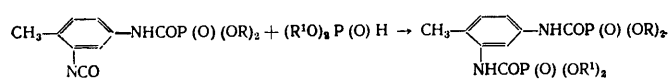
$$(RO)_2P(O)CH(COOR^1)NCO + R^2NHNH_2 \rightarrow \rightarrow (RO)_2P(O)CH(COOR^1)NHCONHNHR^2.$$

When bis(dialkoxyphosphoryl)chloromethyl isocyanate is reacted with amidines in the presence of triethylamine, phosphorylated 1,3,5-triazine derivatives are obtained.[127]

5. Addition of hydrogen chloride and hydrazoic acid

When hydrogen chloride is passed through an ether solution of 2-(dichlorophosphoryl)ethyl isocyanate, *N*-[2-dichlorophosphoryl)-ethyl]carbamoyl chloride is obtained:[86]

$$Cl_2P(O)CH_2CH_2NCO \xrightarrow{HCl} Cl_2P(O)CH_2CH_2NHCOCl.$$



2-(Dichlorophosphoryl)vinyl isocyanate adds on hydrogen chloride when exposed to UV radiation, while 2-(dichlorophosphorothioyl)vinyl isocyanate does not react with hydrogen chloride under similar conditions.[78]

The addition of hydrazoic acid to diethoxyphosphoryldichloroacetyl isocyanate has been reported:[128]

$$(C_2H_5O)_2P(O)CCl_2C(O)NCO + HN_3 \rightarrow (C_2H_5O)_2P(O)CCl_2C(O)NHC(O)N_3.$$

6. Addition of dialkyl phosphites

2-Methyl-5-(dialkoxyphosphorylcarbonylamino)phenyl isocyanate in dioxan adds dialkyl phosphites:[98]

Diethoxyphosphorylcarbonylaminosulphonyl isocyanate adds diethyl phosphite to form *N*,*N*^{1}-bis(diethoxyphosphorylcarbonyl)-diamides of sulphuric acid:[115,116]

$$(C_2H_5O)_2P(O)C(O)NHSO_2NCO + (C_2H_5O)_2P(O)H \rightarrow \rightarrow [(C_2H_5O)_2P(O)C(O)NH]_2SO_2.$$

Similar compounds are obtained when sulphuryl diisocyanate is treated with 2 moles of dialkyl phosphite. The reaction evidently occurs in two stages.[115,116]

7. Reaction with phosphazo compounds

Phosphorylated alkyl isocyanates undergo the Staudinger reaction with triphenylphosphazo hydrocarbons to form phosphorylated carbodiimides.[62,129–131]

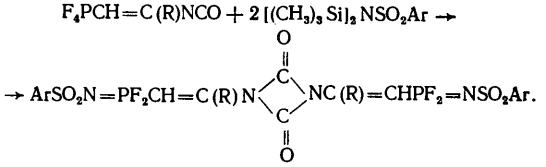
$$(RO)_2P(X)YC(CF_3)(C_6H_5)NCO + (C_6H_5)_3P=NR^1 \rightarrow \rightarrow (RO)_2P(X)YC(CF_3)(C_6H_5)N=C=NR^1 + (C_6H_5)_3PO,$$

X=O, Y–bond; X=Y=S.

8. Elimination of carbon dioxide from phosphorylated alkyl isocyanates

On heating the racemate of (*S*)-(+)-enantiomer of α-diethoxyphosphoryl)benzyl isocyanate for 1–2 h at 100–110 °C in the presence of a catalytic quantity of 1,3-dimethylphosphol-3-ene in anhydrous toluene, the corresponding racemic and optically active *N*,*N*′-bis[α-(diethoxyphosphoryl)benzyl]carbodiimides are obtained:[12]

$$2C_6H_5CH(NCO)P(O)(OC_2H_5)_2 \xrightarrow{\Delta} [(C_2H_5O)_2P(O)(C_6H_5)CHN=]_2C + CO_2.$$



9. Reaction with chlorine

When dimethoxyphosphorothioylthiomethyl isocyanate is chlorinated, dimethyl phosphorochloridothioate and (probably) isocyanatomethylsulphenyl chloride are obtained:[69]

$$(RO)_2P(S)SCH_2NCO \xrightarrow{Cl_2} (RO)_2P(S)Cl + [ClSCH_2NCO].$$

10. Reaction with *N*,*N*-bis(trimethylsilyl)arenesulphonamides

2-Isocyanatoalkenyltetrafluorophosphoranes, when treated with *N*,*N*-bis(trimethylsilyl)arenesulphonamides, form phosphazo isocyanate dimers:[83]

IV. IR and NMR spectra

The IR spectra of phosphorus-containing alkyl, alkenyl, aryl, acyl, and sulphonyl isocyanates contain absorption bands that are characteristic of vibrations of the –N=C=O group. They are very intense in the region 2250–2280 cm^{-1} (asymmetric stretching vibrations),[4,9,12,28,31,34,36–38,40–50,52–57,62,69–71,75,78,81,83–85,86,88,90,91,93,95,96,102,103,106,108,110,112,114,115,117,120,132] weak in the region 1415 to 1470 cm^{-1} (symmetric stretching vibrations),[12,34,40,41,56,85,86,88] and strong in the region of about 600 cm^{-1} (bending vibrations).[12,41,56] The absorption bands from the asymmetric stretching vibrations of the isocyanate group in phosphorylated alkyl and alkenyl isocyanates are displaced to lower frequency by 10–25 cm^{-1} relative to the isocyanates of phosphorus acids and they occur in approximately the same region as for organic isocyanates not containing phosphorus substituents.[132,133] It was established by IR spectroscopy that the majority of α-chloro-substituted phosphorylated alkyl isocyanates occur solely in the isocyanate form, but some phosphorylated α,α-dichloroalkyl isocyanates exist in equilibrium with their chlorocarbonyl form:[54,106,108]

$$(C_2H_5O)_2P(O)CCl_2NCO \rightleftarrows (C_2H_5O)_2P(O)CCl=NCOCl,$$
$$Cl_2P(O)CCl_2CCl_2NCO \rightleftarrows Cl_2P(O)CCl_2CCl=NCOCl,$$
$$Cl_3P=NCCl_2NCO \rightleftarrows Cl_3P=NCCl=NCOCl.$$

In order to confirm the structure of phosphorus-containing alkyl, alkenyl, and aryl isocyanates, the ^1H NMR spectra of the following isocyanates were studied: $(RO)_2P(O)CH(NCO)COOR'$ (R = C_2H_5, iso-C_3H_7; R′ = CH_3, C_2H_5, iso-C_3H_7),[9] $Cl_2P(O)C(=CH_2)NCO$,[38] and $(C_2H_5O)_2P(S)SCH_2CH_2NCO$.[95]

The following isocyanates were studied using ^1H NMR and ^{31}P NMR: $Cl(X)P(O)CY(CH_2Br)NCO$ (X = Cl, C_2H_5O; Y = H, Br)

and $Cl_2P(O)C(=CHX)NCO$ (X = H, Br),[40] $C_6H_5CH(NCO)P(O)(OR)_2$ (R = CH_3, C_2H_5),[41,90] $C_6H_5CH(NCO)P(O)(X)Cl$ (X = Cl, C_2H_5O),[41] $(RO)_2P(O)CH(CCl_3)NCO$ and $(RO)_2P(O)C(=CCl_2)NCO$ (R = CH_3, C_2H_5),[46] $C_6H_5CCl(NCO)P(O)(OR)_2$ (R = CH_3, C_2H_5), $C_6H_5CCl(NCO)P(O)(X)Cl$ (X = Cl, C_2H_5O),[56] and $(C_2H_5O)_2P(S).SCH_2CH_2NCO$.[88]

The following isocyanates were studied using ^{31}P NMR: (*S*)-(+)-$C_6H_5CH(NCO)P(O)(OR)_2$ [R = C_2H_5, $Si(CH_3)_3$],[12] a mixture of $(RO)_2P(O)SCH_2CHClCH_2NCO$ and $(RO)_2P(O)SCH.(CH_2Cl)CH_2NCO$ (R = CH_3, iso-C_3H_7),[84] $X(C_2H_5O)P(O)CH_2CH_2.NCO$ (X = Cl, C_2H_5O),[86] and *o*-$(C_6H_5)_2P(O)C_6H_4NCO$.[91]

The following isocyanates were studied using ^{31}P and ^{19}F NMR: $F(X)P(O)C(=CH_2)NCO$ (X = F, C_2H_5O),[40] $F(RO)P(O)CCl_2NCO$ (R = CH_3, C_2H_5),[55] and $(C_2H_5O)_2P(O)C(CF_3)(R)NCO$ (R = Cl, CH_3O).[62]

^1H NMR was used to study the diastereotopicity of the hydrogen atoms of the CH_2Br group in the isocyanates $X_2P(O)CH(CH_2Br)NCO$ (X = Cl, F) [40] and also the methoxyl groups in the isocyanates $C_6H_5CH(NCO)P(O)(OCH_3)_2$ [41] and $C_6H_5CCl(NCO)P(O)(OCH_3)_2$.[56]

^{31}P, $^{31}P-\{^1H\}$, ^{19}F, and ^1H NMR were used to confirm the structure and study the diastereotopicity of the fluorine atoms on phosphorus in isocyanates with a chiral carbon atom: (*S*)-(−)-$C_6H_5\dot{C}H(NCO)P(O)F_2$,[12] $C_6H_5\dot{C}H(NCO)P(O)F_2$,[12,41] $F_2P(O)\dot{C}H(CH_2Br)NCO$,[39,40] $F_2P(O)\dot{C}Br(CH_2Br)NCO$,[40] $C_6H_5\dot{C}Cl(NCO)P(O)F_2$ [56] and the diastereomeric anisochronism of isocyanates with chiral phosphorus and carbon atoms:

$(S)(+)\text{-}C_6H_5\dot{C}H(NCO)\dot{P}(O)(OC_2H_5)F$ (Ref.12),

$C_6H_5\dot{C}H(NCO)\dot{P}(O)(OC_2H_5)F$ (Refs.12, 41),

$F(C_2H_5O)\dot{P}(O)\dot{C}H(CH_2Br)NCO$ (Refs.39, 40),

$F(C_2H_5O)\dot{P}(O)\dot{C}Br(CH_2Br)NCO$ (Ref.40),

$C_6H_5\dot{C}Cl(NCO)\dot{P}(O)(OC_2H_5)F$ (Ref.56).

In addition, $^{19}F-\{^1H\}$ and $^{31}P-\{^1H\}$ NMR were used to study the structure and diastereomeric anisochromism of bis-phosphorylated chloromethyl isocyanates with chiral phosphorus atoms:[55]

$F(RO)\dot{P}(O)[Cl(RO)\dot{P}(O)]\dot{C}ClNCO$ (R = CH_3, C_2H_5),

$[F(C_2H_5O)\dot{P}(O)]_2CClNCO$ и $[Cl(C_2H_5O)\dot{P}(O)]_2CClNCO$.

A quantum-chemical calculation using the Hofmann method was carried out on the isocyanates $F_4PCH=CHNCO$ and $Cl_4PCH=CHNCO$ and also their isomers $F_2P(O)CH=CHNCF_2$ and $Cl_2P(O)CH=CHNCCl_2$, and it was established that the phosphorane form is stable for fluorine-containing compounds while for chlorine-containing compounds the dichloride form is stable.[80]

V. Use of phosphorus-containing isocyanates for obtaining polymers

Phosphorylated organic isocyanates that contain several isocyanate groups in the molecule when reacted with polyfunctional compounds containing an active hydrogen atom (hydroxyl and amino groups, etc.) form fire-resistant, thermally stable polymers—polyurethanes, polyureas, polyurethanoureas, etc. These polymers are used for the production of rubbers, glues, varnish coatings, films, foamed plastics, moulded products, finishing materials for fabrics, etc. Phosphorus-containing organic isocyanates are used as additives for plastics and cellulose in order to impart fire-resistant properties or as vulcanising agents. Tris(*p*-isocyanatophenyl) phosphorothioate (Desmodur RF) has been used in West Germany as a cross-linking agent in adhesive rubber solutions.[3,15,18,20,26,58,61,89,99–101,107,109,119,120,134–139]

VI. Physiological activity of compounds obtained from phosphorus-containing isocyanates

Esters and amides of phosphorylated *N*-alkyl- and *N*-alkenylcarbamic acids possess high insecticidal, acaricidal, and fungicidal activity.[56,64,118,140,141] *N*-[2-Diethylenediamidophosphoryl)vinyl]-substituted urethanes and *N'*-arylureas exhibit antitumorigenic activity.[76,79,121,123] The phosphonium salt $[(C_6H_5)_3PCH_2NH.COOC_{10}H_{21}]^+Cl^-$ has antimicrobial properties.[142] The compounds $SO_2[NHC(O)P(O)(OR)_2]_2$, obtained from sulphuryl diisocyanate, have fungicidical, nematocidal, and herbicidal activity.[116]

- - - o 0 o - - -

It is evident from the above that there has been an extensive development of the chemistry of phosphorus-containing alkyl, alkenyl, aryl, acyl, and sulphonyl isocyanates which are derivatives of synthetic and natural aminophosphonic acids[143] (the two hydrogen atoms on nitrogen replaced by a =C=O group), playing a definite role in biology. Phosphorus-containing organic isocyanates are starting to be used as raw materials for the synthesis of various types of aminophosphonic acids—analogues of aminocarboxylic acids. Moreover, phosphorus-containing organic isocyanates are very convenient and highly reactive compounds for introducing phosphorus into different organic products. They have already been used for the synthesis of phosphorus-containing polymers and biologically active compounds. From the theoretical point of view phosphorus-containing alkyl isocyanates have proved convenient subjects for studying the phenomena of diastereomeric anisochronism and diastereotopicity of atoms and groups in molecules with chiral carbon and phosphorus atoms.

Genetic engineering and modern enzymology

G D Kutuzova, E I Dement'eva, N N Ugarova
Moscow State University

ABSTRACT. The role of genetic engineering in the solution of problems involving enzymology is demonstrated. The method for the cloning and mutagenesis of protein and enzyme genes and the possibilities of genetic engineering for the study of the structure and functions of enzymes and their active centres and for the determination of the relation between the structure and stability of protein molecules are examined. The role of directed site-specific mutagenesis in the study of the structure and mechanism of the action of enzymes as well as their stability is indicated. The investigation of the mechanism and factors determining the stability of enzymes with the aid of aminoacid substitutions has led to prospects for protein design — the creation of proteins with new specified properties and improved stability.

The bibliography includes 301 references.

I. Introduction

The extensive development of the recombinant DNA technique has led to its penetration into the protein chemistry and enzymology and to the appearance of a new discipline – protein engineering. The 1980s have been called the "era of the second coming" of protein chemistry and have been associated with a new boom in biotechnology — protein engineering. Protein engineering is a "marriage" between the fundamental science of the structure and functions of protein macromolecules, providing a basis for the deliberate alteration of their properties, and genetic engineering methods which make it possible to achieve this. The complete cycle of protein engineering is described by the following scheme:[1]

Scheme 1

Genetic engineering provides modern enzymology with unlimited possibilities for the investigation of the properties of enzymes: (1) the possibility of the rapid determination of the primary structure of protein molecules and their genes; (2) the discovery of the principles governing the coiling of the polypeptide chain and prospects for the prediction of the secondary and tertiary structures of the protein or the protein domain; (3) the study of the structure and of the mechanism of the functioning of enzymes *in vitro* and *in vivo*; the solution of fundamental problems in enzyme catalysis: the structure of the active centres of enzymes, the mechanism of enzyme–substrate interactions, the types and strengths of the interactions, process energetics, etc.; (4) the determination of the relation between the structure and stability of protein molecules. The solution of these problems leads to splendid prospects for protein design (the synthesis of enzymes with specified properties). The following features can be altered deliberately by genetic engineering methods: catalytic parameters (k_{cat} and K_M); thermal stability and the optimum temperature for activity; stability in organic solvents; substrate specificity; the need for cofactors; the pH optima for activity and stability; resistance to proteolysis; allosteric regulation; molecular weight and subunit composition.

Finally, it has become possible to create completely new proteins by means of the *de novo* synthesis of genes and their subsequent expression.

All these possibilities in genetic engineering for the solution of problems in modern enzymology are in fact considered in the present review.

II. General principles of the biosynthesis and structural organisation of protein and its gene

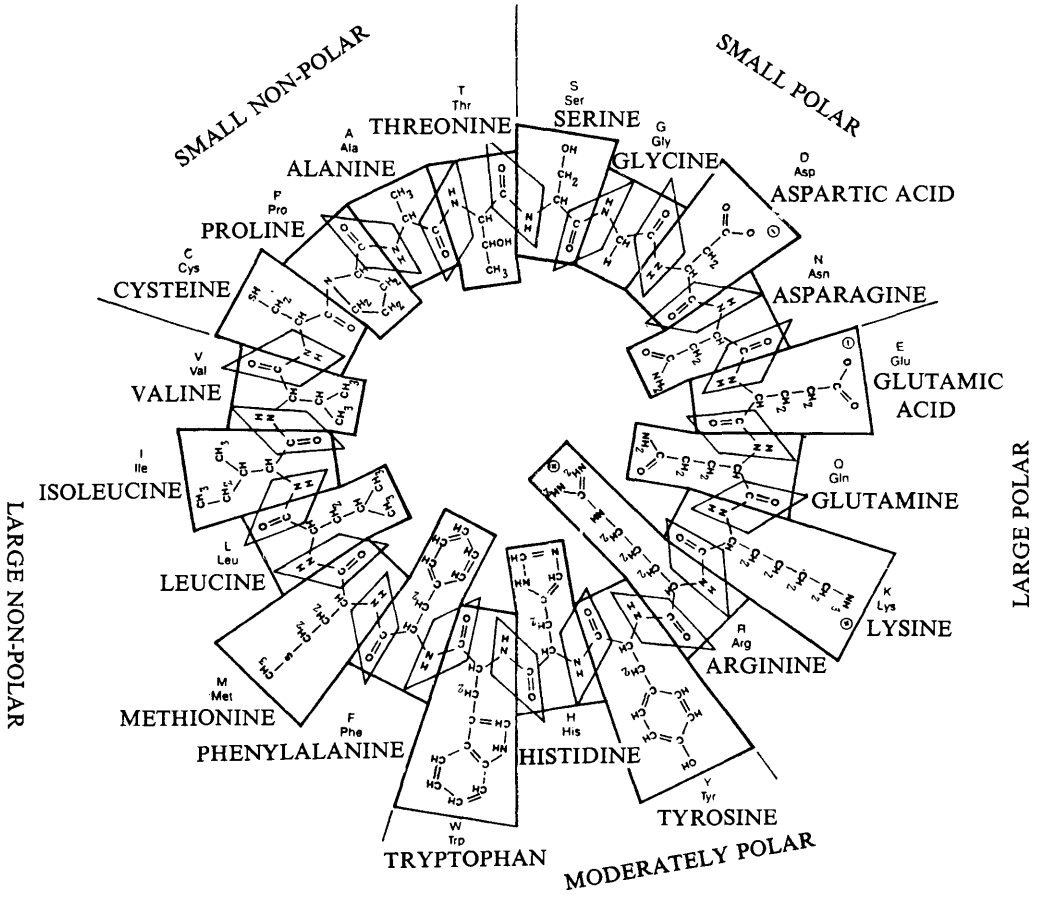
Protein is a polypeptide sequence made up of 20 aminoacid residues. A definite gene in DNA is responsible for the synthesis of each polypeptide chain.[2,3] The theoretical aspects and mathematical models of protein synthesis have been examined, for example, by Heijne et al.[4] A newly synthesised polypeptide chain in the cell undergoes post-translational modification and compartmentalisation.

The modification of various aminoacid residues (phosphorylation, methylation, hydroxylation, iodination, carboxylation, glycosylation, and substitution of lipids) in the protein chain can occur both during the period when the chain synthesised is linked to a ribosome and after the end of the synthesis.[5] The specific residues undergoing modification are determined in some proteins by the aminoacid sequence and in others by the conformation. For example, the carbohydrate binding sites in proteins are Asn in the Asn–X–Ser/Thr sequence, where X is any residue other than Pro. At this stage, there is a possibility of the binding of the protein synthesised to cofactors and M^{n+} ions, of the covalent and non-covalent assembly of subunits, and of the formation of disulphide linkages between polypeptide chains and within them. In certain cases, these processes take place cotranslationally. Intramolecular disulphide linkages are not encountered in molecules of intracellular cytoplasmic proteins. They are characteristic of extracellular proteins, for which the physiological environment and physicochemical conditions can be varied greatly and can induce the uncoiling of the protein.[6]

For proteins and enzymes functioning outside the cell, a signal sequence (presequence) is split off during passage through the cytoplasmic membrane by membrane signal proteases and the protein is simultaneously glycosylated.

The properties of the side groups in the aminoacid residues constituting the protein, which interact both with one another and with the molecules of the surrounding medium, exert the main influence on the steric structure of the protein molecule. All the aminoacid residues are divided into hydrophobic, hydrophilic, and neutral (Fig. 1). The assignment of a residue to a particular group as a function of criteria varies somewhat (cf. Kutuzova et al.[7] and Dolittle[8]). The hydrophobic residues (Gly), Ala, Cys, Val, Ile, Leu, Met, Phe, and Trp are fully immersed after the coiling of the protein, while the moderately polar residues (Gly), Ser, Thr, His, and Tyr and the highly polar residues (Gly), Pro, Asp, Asn, Glu, Gln, Arg, and Lys are immersed to a lesser extent: 76 and 63% respectively.[9] The structural organisation of the protein and the mechanism of the coiling and assembly of the polypeptide chain have been described in detail in a review.[10]

In the three-dimensional steric structure of a typical globular protein, the inner region is made up mainly of β-layers, while the surface consists of α-helices. Each third or fourth position in these outer α-helices is occupied by aminoacids with non-polar side groups directed into the interior of the globule, while the side groups of the remaining aminoacids are as a rule polar and are directed towards the aqueous medium.



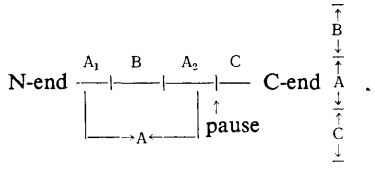


Figure 1. Classes of aminoacids based on the size and degree of polarisation of their side groups.[8]

The native protein molecule consists of several cooperative domains, each of which breaks down on denaturation as a single whole.[11] The protein consists as a rule of combinations of α- and β-structural elements, includes between 50 and 200 aminoacid residues, and is characterised by a minimal surface to volume ratio (S/V). Small proteins can contain only one domain, while larger ones contain up to tens of domains. Subdivision into domains, which is a general principle of the construction of protein molecules, ensures the necessary rigidity and relative mobility of specific groups in the protein and apparently reflects its evolution, which took place via the combination of previously independent small preproteins.[12] The existence of an independent unit of protein structure even smaller than the domain, namely the module,[13] has been postulated at the present time. The module consists of a polypeptide segment whose size is 2–5 kD (30–50 aminoacid residues) and which has a stable coiled conformation and performs a definite function in the highly specific binding of the ligand (substrate, allosteric effector, and cell components: lipids, carbohydrates, nucleic acids, etc.).[14] Thus the size of the protein may be determined by the number of different ligand-binding sections necessary for functioning *in vivo*. Knowing the size of the enzyme subunit, it is possible to estimate the number of ligand-binding sections: the size of the subunit, given by the ratio of the molecular weight to the average size of the module, is ~5.2 kD. The moduli and domains can also be visualised with the aid of crystallographic studies and microcalorimetric investigation of denaturation processes. Proteolysis usually occurs in the interdomain region and makes it possible to divide domains with partial retention of their function, as in the subdivision of DNA-polymerase into a large and a small domain, each of which is functionally active.[15]

Many proteins consist of several polypeptide chains—subunits, having both identical and different compositions and combined into a single entity via non-covalent interactions or disulphide linkages. The size of the subunit of a eukaryotic protein varies from 10 to 480 kD (the average size is 32 kD, while that of a prokaryotic protein is 24 kD).[16] For 90% of proteins, the size of the subunit is less than 60 kD. Thus the protein consists of subunits, each of which contains domains made up of moduli.

The problem of the coiling of the polypeptide chain synthesised with formation of the three-dimensional steric structure of the protein is one of the most complex and intriguing in protein chemistry. According to modern ideas about the mechanism of the coiling of the protein, the conformational information is distributed along the polypeptide sequence non-uniformly, certain aminoacids being of fundamental importance for the correct conformation. At the beginning of the coiling process, local reversible structures (nucleation centres) are produced. These are short sections of the secondary structure of the type of α-helices or β-layers. The structure is subsequently stabilised as a result of the interaction of neighbouring sections. Coiling begins independently and more or less simultaneously in several regions of the polypeptide chain (autonomous coiling domains).[17] The problem of coiling has now acquired especially great importance in connection with the preparation of hybrid proteins in the cloning of eukaryotic genes in bacteria, where the *N*-terminal section of the required protein has been fused with part of the prokaryotic protein, which can influence the coiling process, destabilising the kinetically important intermediate states of the eukaryotic protein. Furthermore, its *N*- or *C*-terminal component can be within the globule, while the fused hybrid protein will not have the required native conformation, giving rise to insoluble derivatives.[17]

The fact that the aminoacid residues in the polypeptide chain are separated not only in space but also in time during synthesis is very important for the protein coiling process. The importance of the separation in space and time of the aminoacid residues for the structure of the whole depends on the relative rates of synthesis of the protein and of its coiling. At the beginning of the synthesis, the coiling of the segment of the polypeptide chain synthesised takes place in microseconds, since it involves the interaction of only the nearest aminoacid residues. On average, the time required for the complete translation of a protein of average size is 2 min. The coiling of the polypeptide chain to a three-dimensional structure takes place before the completion of its total synthesis and there is a possibility of the formation of disulphide linkages, which did not exist in the completed protein. The subsequent isomerisation of disulphide linkages leads to the correct conformation, which has been demonstrated for the pancreatic trypsin inhibitor.[18] Direct evidence has been obtained for the existence of breaks during the synthesis of the protein, which results in the accumulation of specific polypeptides.[19,20] In terms of the mechanism of the coiling of the polypeptide chain *in vivo*, proteins can be divided into two groups:[21] (1) proteins the correct coiling of which is unaffected by the rate of translation; in such proteins the aminoacid sequence does indeed contain all the information necessary for the correct coiling of the chain (even *in vitro* after denaturation); (2) proteins incapable of coiling effectively into the native conformation *in vitro*. These are polypeptides with alternative kinetically easy coiling pathways, which can form distorted but stable conformations. The coiling of such proteins *in vivo* is greatly influenced by the translation process itself, which takes place at different rates and with translational pauses. The presence of the pauses is determined by the accumulation in the DNA chain of rarely used codons and hence by the presence of small amounts of the corresponding tRNA, which retards significantly the supply of the corresponding aminoacids. The presence of a secondary structure in mRNA also reduces the rate of translation.[21] The above features have been discovered, for example, for yeast pyruvate kinase.[22] Each of the four subunits of pyruvate kinase consists of a short N-terminal segment and three different domains: A, B, and C:

The translational pause before the start of the synthesis of the domain C enables the two sections A_1 and A_2 to form the central domain A, containing the catalytic centre, before the synthesis of the domain C containing the allosteric centre of pyruvate kinase. This prevents anomalous interactions between the still uncoiled regions of the domains A and C. Translational pauses, which enable functionally important domains to be formed, have also been observed for the Arom-protein catalysing the biosynthesis of aromatic acids.[23] The inability of certain proteins to return to the native conformation after denaturation *in vitro* may indicate the importance of the separation in time of the processes involving the synthesis and coiling of different sections of the polypeptide chain *in vivo*.

As a result of the employment of genetic engineering methods, it has now been possible to investigate in detail the mechanism of the coiling of proteins. The construction of mutant polypeptide

segments elucidates the role of individual aminoacid residues in the coiling and assembly of enzyme subunits.[24,25] It has been shown for the heterodimer (αβ) of *bacterial luciferase* that the scission of 10–15 residues from the C-terminal section of the β-subunit does not alter the activity and stability of the enzyme, but the mutant enzyme is incapable of recoiling after treatment with urea. The αβ complex of the subunits is formed initially between incompletely coiled α and β subunits and their final coiling takes place in the heterodimeric form. If the α and β subunits have been coiled *in vivo* separately, then the formation of the complex αβ is impossible without a preliminary treatment with urea. The coiling process is unaffected by the nature of the residues in the C-terminal section, but deletions in this region reduce the ability of the β-subunit to form a dimeric structure *in vitro* and *in vivo*.[26] Even one aminoacid residue can play a key role in the formation of the structure of the active enzyme. The introduction of an additional Met group at the N-end reduced significantly the rate of coiling of chick lysozyme, while the replacement of Ala-31 even by the structurally similar Val prevented the correct coiling of the protein.[27] In the pancreatic trypsin inhibitor, the Cys residues forming one of the three S–S bonds were replaced by Ala or Thr, whereupon the rate of coiling diminished by a factor of 3 but the correctly coiled protein was obtained.[28] Thus the formation of S–S bonds reduces the activation barrier to the polypeptide chain coiling process.

For enzymes with a known three-dimensional steric structure and gene structure, important conclusions have been reached by comparing these structures.[29] It is known that the genes of eukaryotic proteins are not continuous but are made up of coding sections (exons) and non-coding sections (introns). It has been suggested that the position of the introns in the gene corresponds to the boundary of the domain in the protein. For example, the subunits of NAD-dependent dehydrogenases contain two structurally and functionally different domains. One of them binds the coenzyme, while on the other there are substrate-binding and catalytic sections. The NAD^+-binding domains of alcohol dehydrogenase (ADH), glyceraldehyde-3-phosphate dehydrogenase (GAPD), and lactate dehydrogenase (LDH) have similar structures and bind the coenzyme in a similar way, while there is no homology as regards the catalytic domains and the latter have completely different structures.[30] The structure of the domain-containing subunits and the positions of the introns for these enzymes are presented in Fig. 2. The introns 6 and 9 for ADH, 5 and 6 for GAPD, and 3 and 7 for pyruvate kinase (PK) divide the catalytic and nucleotide-binding domains. Each nucleotide-binding domain can be roughly divided into two identical units, which refer to the mononucleotide-binding region and are separated by introns. This confirms the hypothesis that[31] the mononucleotide-binding domain is the principal unit for the generation of enzymes whose function is determined by the ability to bind nucleotides.

However, it has been shown for haemoglobin,[32] carboxypeptidase,[33] and antitrypsin[34] that the positions of the introns in the genes of eukaryotic proteins do not always correspond to the boundaries between the known domains. Furthermore, introns have not been observed in the genes of prokaryotes. It has been suggested that they have been eliminated in order to economise the genetic material.[8] On the other hand, several introns can be encountered within one domain (Fig. 2). Analysis of the genes of 80 proteins[35] has shown that for 70% of them the size of the exons

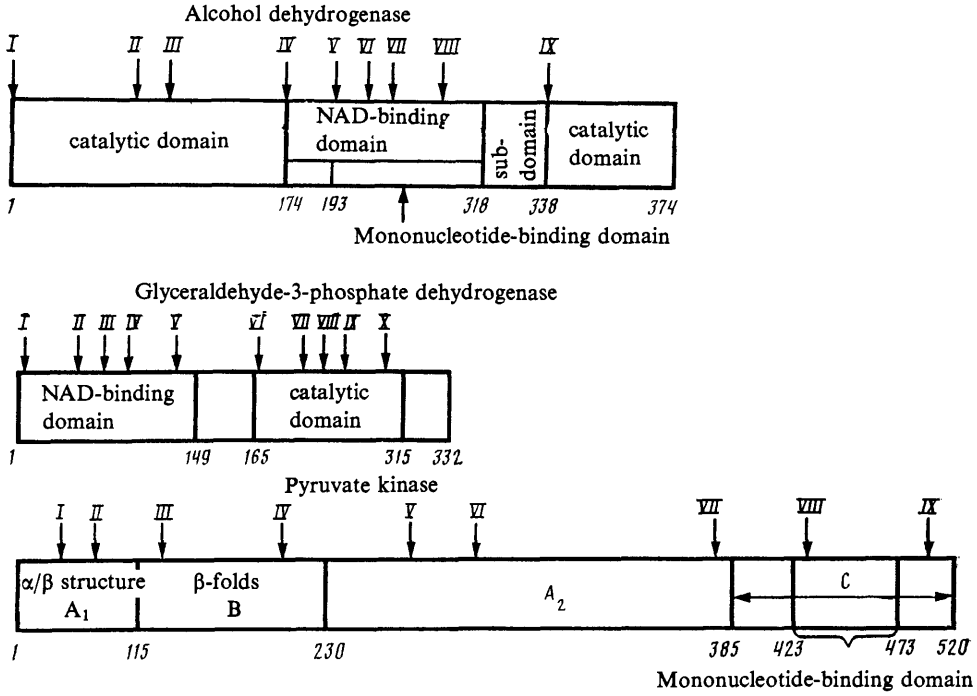

Figure 2. Diagram illustrating the positions of introns (roman numerals) and the limits of the domains along the polypeptide chains of enzyme subunits;[29] the arabic numerals indicate the positions of the residues in the aminoacid sequence.

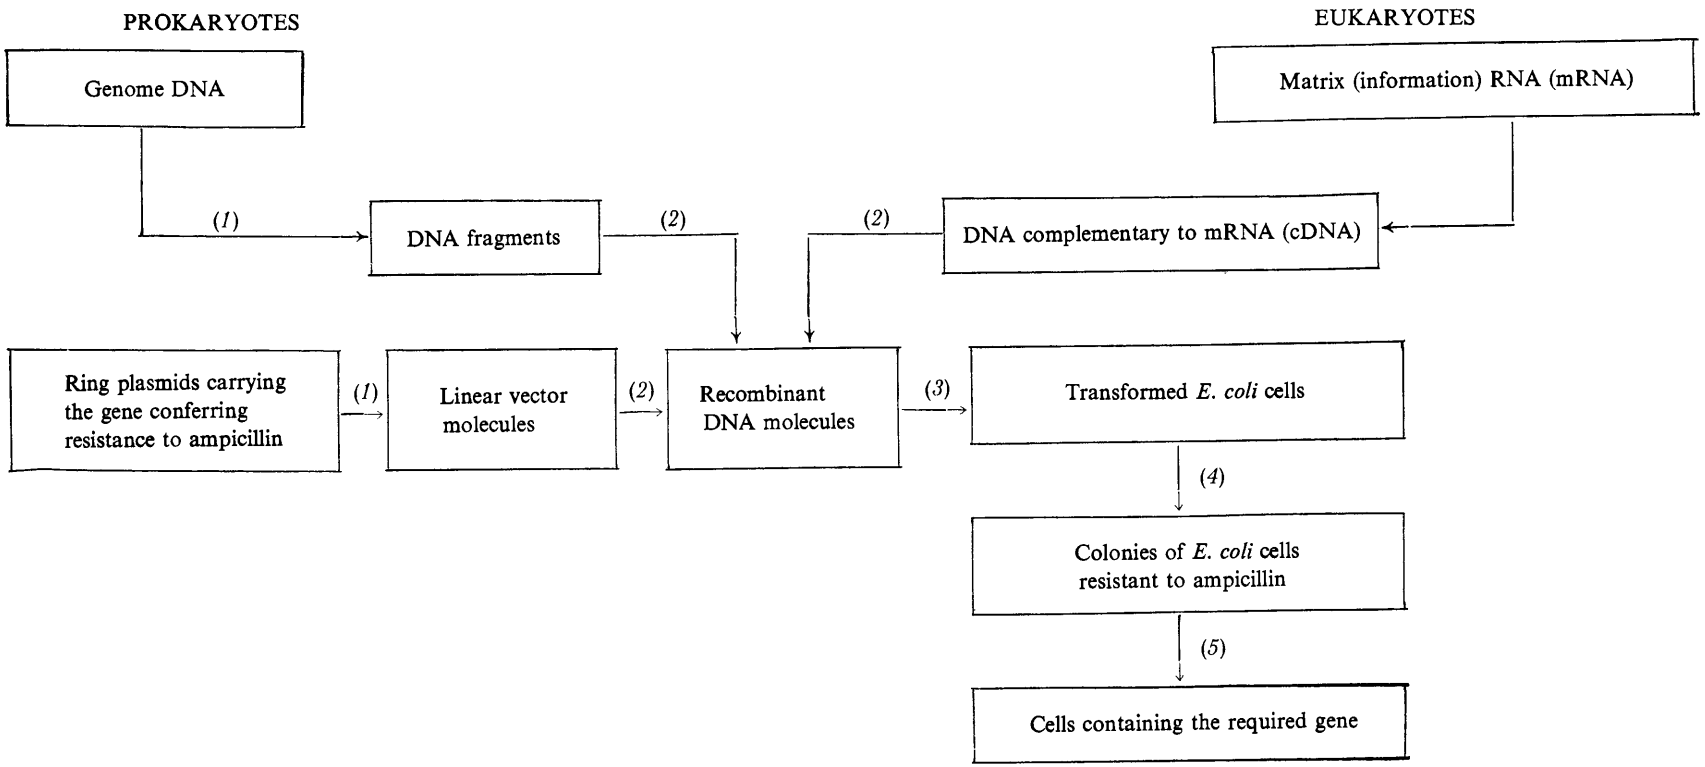

Figure 3. The principal stages in the cloning of the prokaryotic and eukaryotic DNA in the cells of *E. coli*:[3,37,38] (1) cleavage of DNA with the aid of restrictase; (2) cross-linking of DNA molecules with the aid of DNA ligase; (3) transformation of the cells of *E. coli* by the recombinant plasmids; (4) selection of *E. coli* colonies containing the recombinant plasmids on the basis of resistance to ampicillin; (5) screening of the library of clones with the aid of a radioactive probe.

varies from 52 to 223 pairs of nucleotides, which corresponds to the sizes of the moduli in the protein.[13] Introns apparently divide not only domains but also the protein moduli with definite ligand-binding functions. An algorithm has been proposed for the determination of the boundaries of the moduli and domains.[36] Many experimental facts confirm this hypothesis.

III. Methods for the cloning and mutagenesis of the genes of prokaryotic and eukaryotic proteins and enzymes

The methods for the cloning of the genes of proteins and enzymes from different sources, for the expression of genes in different host systems, have been described in detail in many textbooks and manuals.[3,37–39] The cloning of the DNA of the genes of prokaryotic proteins differs fundamentally from the cloning of the genes of the proteins from eukaryotic organisms. The DNA of the simplest organism consists of a set of genes coding for proteins and enzymes and arranged in a sequence. The first stage in its cloning is the isolation of the genome DNA, its splitting into fragments, and their incorporation into DNA vectors. The overall stages in the cloning of DNA in the plasmid vector of *E. coli* are presented in Fig. 3. The cells of *E. coli* are transformed by annular recombinant DNA molecules. The cells are then sewn in such a way that one colony, containing a population of identical daughter molecules (clones), grows from each cell. Among several thousand clones (the library), it is possible to find one or several clones containing the required incorporated DNA fragment. The colonies are screened by means of a specific radioactive probe, which makes it possible to inspect the library of clones. The probe can be pure or partly purified mRNA or a chemically synthesised oligonucleotide, which are hybridised with the corresponding gene sequence in the genome library. Antibodies to proteins, whose genes have to be detected, are also used frequently to identify the colonies.

Since the genes of the proteins of eukaryotes include non-coding sections (introns), one uses for the cloning of eukaryotic proteins cDNA — a DNA complementary to the matrix (information) RNA — or a chemically synthesised gene without introns. The first stage in the cloning of the proteins of eukaryotes is the isolation of mRNA on the basis of which the double-stranded cDNA is synthesised. Next it is incorporated in the cloning vector and is used to transform the host cells (Fig. 3).

The genetic engineering methods used for mutagenesis can be divided into two large classes. The first class includes the formation of random point mutations in the required gene. The classical method of mutagenesis with selection of mutant forms on the basis of a preselected property has been widely used hitherto for the formation of mutant enzymes differing from the wild enzymes in their catalytic activity, substrate specificity, or stability. A mutant gene is also obtained when the DNA in the form of an isolated fragment or as a component of a single-stranded or double-stranded DNA-vector is modified with the aid of chemical reagents or enzymes. In the second stage, the modified DNA is used to transform bacterial cells and individual clones are isolated. Next the mutant recombinant DNA is isolated from the set of clones and the nucleotide sequence in the mutant gene is determined. The characterised mutant gene is used to transform the host cells (bacteria, yeasts, and more rarely animal or plant cells), in which it is transcribed and translated, giving rise to the mutant protein.[40,41] The second class includes all the methods which make it possible to achieve specific preselected mutations. The modern methods for mutagenesis are classified in Table 1.

The most accurate and convenient method for the introduction of mutations into cloned DNA fragments is site-specific mutagenesis using synthetic oligonucleotides. A large number of studies have been devoted to the improvement of this method,[50–58] in particular to the increase of the yield of the mutant forms.[55,59–63] Site-specific mutagenesis has been used widely in the study of the relation between the structure and functions of proteins and their enzymes and for the creation of proteins with new properties.

Table 1. Classification of the methods for mutagenesis.

Name	Essential features of method	Remarks	Refs.
	Random mutations		
Chemical methods	Treatment of the gene by chemical mutagenic reagents (sodium bisulphite, hydrazine, nitrous acid, etc.)		[40–46]
Enzymic methods	Preparation of single-stranded DNA, construction of the second DNA chain with the aid of DNA polymerase in the presence of 4 deoxynucleotides, one of which has been replaced by its analogue	The bases of the nucleotides are modified, which leads to mutation	
	Specific preselected mutations		
Gene synthesis. Total synthesis of the gene	Construction of the gene from a set of segments of chemically synthesised oligonucleotides	The frequency of mutations approaches 100%, but the method is laborious and is nowadays rarely used	[42, 47, 48]
Partial (cassette) gene synthesis	Isolation of the gene, excision of a DNA segment at the restriction sites, and its replacement by the synthetic oligonucleotide containing the mutation	—	[40, 42, 49]
Deletion and insertion on cleavage of double-stranded DNA	Preparation of a linear DNA molecule, the removal of fragments located between restriction sites (deletions), the construction of an additional nucleotide chain (insertions)	—	[38, 42]
Site-specific oligonucleotide-directed mutagenesis	The synthetic oligonucleotide (10–20 bases) containing the mutation is hybridised with single-stranded DNA and is used as a primer for the synthesis of the second DNA chain. The additional chain is closed with the aid of DNA ligase and the resulting DNA is used to transform the *E. coli* cells, where DNA replicates with formation of two forms of the cloned gene: the wild and mutant types (Fig. 4)	The mutant form can be readily identified using the same nucleotide labelled with ^{32}P	[40–42, 47, 50–55]

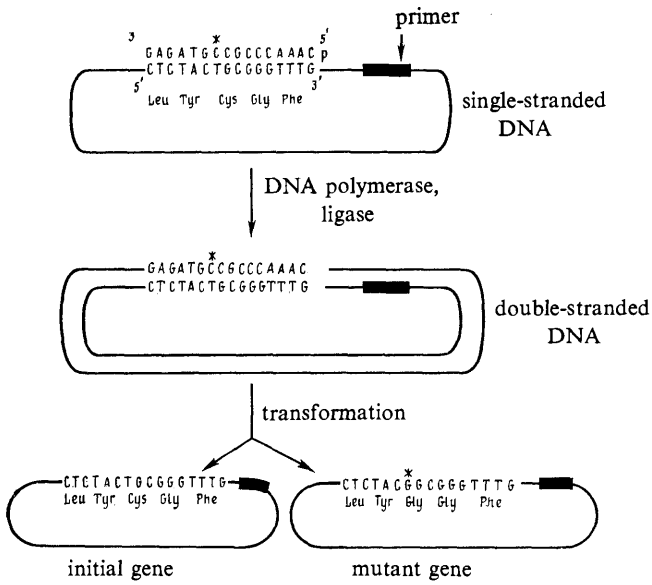

Figure 4. Schematic representation of the nucleotide-directed mutagenesis;[55] the asterisk designates the mutant nucleotide.

IV. The study of the structures and functions of proteins by genetic engineering methods

1. The primary protein structure and its evolution

The primary protein structure was determined previously solely by the sequence determination method with the aid of automatic aminoacid analysers. It was then necessary to have at ones disposal a large amount of the very pure protein, which was not always possible. With the aid of genetic engineering methods, it has become possible to isolate DNA and to determine the total nucleotide sequence in the gene coding for the given protein. The methods for the determination of the DNA sequence (the Maxan–Gilbert and Sanger methods)[3,37,38,64,65] made it possible to determine relatively simply and rapidly the sequence of nucleotide bases in the gene. With the aid of the genetic code, it is easy to establish subsequently the aminoacid sequence in the protein. The difficulty is the necessity for the error-free identification of a sequence of an enormous number of bases (a protein consisting of a thousand aminoacids is coded by 3000 bases) and also for a correct determination of the starting point of the reading of the code. The deletion of one base can lead to a shift of the reading framework and hence to an incorrect determination of the entire aminoacid sequence. In order to avoid such errors, one can, for example, determine the aminoacid sequences in short sections at the N- and C-ends of the protein by another method and to compare them with the sequence obtained from the nucleotide sequence of the gene. In order to check the correctness of the reading of the DNA base sequence, the molecular weights, measured mass-spectrometrically, of the tryptic peptides obtained from the test protein were also compared with the structures of these peptides derived from the DNA sequence.[66]

At the present time, the primary structures of more than 3700 proteins determined by different methods are known.[67] As genetic engineering methods have developed, the number of proteins and enzymes whose primary structures have been established has increased greatly (Fig. 5). In relation to certain enzymes, we shall consider what information about the structure of the enzyme itself and its active centre can be obtained solely from the analysis of the nucleotide sequence in the gene and by comparing it with the aminoacid sequence of the test protein.

The cloning and sequence determination for genes have made it possible to establish the presence of signal peptides in the proteins secreted: cytochrome c_3 from *Desulfovibrio vulgaris*,[68] protease III[69] and penicillin G-acylase[70] from *E. coli*, and chloroperoxidase.[71] The signal peptides promote the transmembrane protein transfer from the periplasm of bacteria and yeast and they split off immediately after secretion, so that the determination of nucleotide sequence in genes is a good method for the detection of signal peptides and for the investigation of their structure. Comparison of the aminoacid sequence of the protein and the nucleotide sequence of the gene shows whether the given protein undergoes post-translation modification. For example, aquarin is synthesised in the form of a precursor. During translation, seven *N*-terminal residues are split off.[72] The *N*-terminal residue in human creatine kinase M is lysine and the methionine residue is split off after translation.[73]

The determination of the aminoacid sequence makes it possible to reach certain conclusions concerning the presence of domains and the structure of the substrate-binding sections. Analysis of the structure of the penicillin acylase gene revealed the presence of four structural domains on the basis of the positions of introns: nucleotides 1–78 code for the signal peptide, nucleotides 79–705 code for the α-subunit, nucleotides 708–867 code for the peptide binding covalently two subunits, and nucleotides 868–2538 code for the β-subunit.[70] A multidomain structure has also been established for the heavy chain of calpactin (the substrate of viral protein-tyrosine kinase)[74] and calpastatin (inhibitor of the Ca^{2+}-dependent calpain).[75] The study of the structures of the genes of diglyceride synthetase and diglyceride hydrolase from *E. coli* showed that the former enzyme is an extremely hydrophobic membrane protein.[76] The latter enzyme is less hydrophobic, but

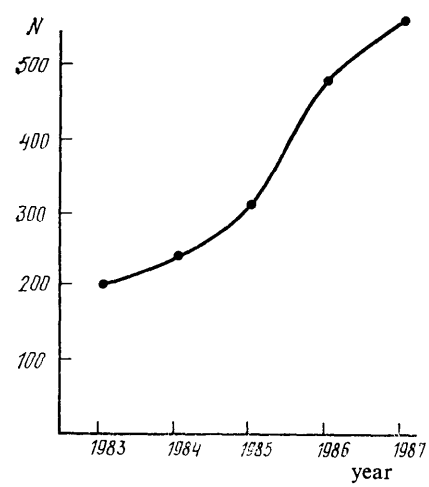

Figure 5. Number of publications (annually) on the determination of the aminoacid sequences of enzymes by genetic engineering methods (counted by the authors).

there is a very hydrophobic domain at its *N*-end, which binds the hydrolase to the membrane.[77] The composition of the bioluminescent Ca^{2+}-dependent protein aequorin incorporates three hydrophobic sections, which may be responsible for the binding of its functional chromophore, i.e. coelenterazine (luciferin), and three sections responsible for the binding of Ca^{2+} ions.[72] Analysis of the primary structure of Na^+, K^+-ATPase led to a hypothesis about the character of the disposition of this enzyme on the membrane.[78]

Comparison of the primary structure of the test enzyme with that of proteins having similar functions makes it possible to discover common structural sections. Analysis of the aminoacid sequences of aequorin and other Ca^{2+}-binding proteins (calmodulin, parvalbumin, and troponin C) revealed three Ca^{2+}-binding sections in the polypeptide chain of aequorin.[72] Important information about the structure of the active centre of bacterial luciferase has been obtained by comparing the primary structures of luciferases from different sources: *Vibrio fischeri*, *Vibrio harveyi*, *Photobacterium leiognathi*, and *P. phosphoreum*.[79] Data for the modification of the SH group of cysteine-106 in the luciferase from *V. harveyi* led to the hypothesis that this group participates in catalysis. However, the luciferases from other sources contain valine in the position 106. Thus the SH group of Cys-106 is not important for the manifestation of the activity of bacterial luciferase. The sections 115–117 and 280–282 of the α-subunit, which are the same in all the bacterial luciferases examined and are located close to one another in three-dimensional space, apparently constitute an appreciable proportion of the active centre.[39] Comparison of the primary structures of lipases from various sources (bacteria and pig pancreas) showed that Ser-83 is incorporated in the active centre.[80]

Similar aminoacid sequences have been noted for glutathione S-transferases from human and rat livers (50% homology),[81] catalase T from the yeast *S. cerevisiae*, the bacterium *Penicillinum vitale*, and ox liver (52.2% homology),[82] aromatic aminoacid hydroxylases — tryptophan, phenyl, and tyrosine hydroxylases (60% homology),[83] valyl-tRNA synthetase from *B. stearothermophilus* and isoleucyl tRNA synthetase from *E. coli*,[84] and for five adenylate kinases from various sources.[85] This means that the data for the steric structure and mechanism of action of one enzyme can be used in the study of an enzyme with a homologous sequence. The structure of the biopterin-dependent aromatic acid hydroxylases is homologous for approximately 2/3 of the molecule, starting from the C-end whereas at the N-end no homology has been observed. This confirms the hypothesis that the C-terminal domains in hydroxylases determine their catalytic properties (similar mechanism of catalysis), while 1/3 of the molecule, starting from the N-end, is made up of domains determining the substrate specificity.[83] The relation between the structure and function of human M creatine kinase,[73] Na^+, K^+-ATPase,[86] the heavy chain of calpactin,[74] glycogen phosphorylase,[87] glutathione S-transferase,[81] yeast catalase T,[82] and tryptophan hydroxylase[88] has been discussed on the basis of the homology established with other proteins.

It has become possible in recent years to investigate the evolution of protein in connection with the development of the recombinant DNA technique, the establishment of the primary structures of an enormous number of proteins, and advances in crystallography. Common domains have been discovered for a series of proteins with known crystal structures. Consequently, if any one structural element proves useful for the performance of a particular function, it is invariably used in different proteins. For example, Rossman[30] observed in a series of enzymes an invariant domain consisting of approximately 70 aminoacid residues. These enzymes had markedly different functions but had a property in common: they bound coenzymes of the type of NAD, FMN, or AMP, which had a common component — a mononucleotide. This domain is apparently a proprotein for a large number of nucleotide-binding enzymes, because its function proved to be vitally important. The first proteins capable of performing functions of any kind were small in size and had the property of being able to bind specifically other molecules. When two such proteins were combined, a primitive catalytic system might have arisen improving and developing in the course of evolution. From Gilbert's point of view,[89] exons are genome equivalents of protein domains which have been used to assemble the first proteins and which have been maintained throughout evolution in a genetically isolated state in the course of several billion years. The non-intersecting processes involving the transposition and reorganisation of domains into new combinations generated new proteins which included also useful constructions. The essential feature of the hypothesis is that the evolution of proteins was based on the sorting of exons coding for the domains.[8]

The principal mechanism of the evolution of proteins is the duplication of genes, which consists in the fact that two or more copies of the same gene arise in the cell genome. One of the copies retains the previous function, so that no changes take place in the organism, while the other copy can undergo mutations. The duplication of genes has been demonstrated by the existence of subunit enzymes with non-identical but homologous subunits (homologous proteins), containing one polypeptide chain, as in proteases of the serine–histidine–asparagine type with different substrate specificities.

Another example of gene duplication is provided by trypsin, chymotrypsin A, and elastase. Their sequences are approximately 40% homologous. They have a similar function, namely the hydrolysis of proteins, but there are differences in the type of bond hydrolysed. The residues in the active centre were different: Asp in trypsin and Ser in chymotrypsin. Analysis of the three-dimensional structures of these enzymes showed that serine proteases consist of two similarly coiled domains arranged symmetrically around a twofold axis.[90] In each case introns separate the codons of the catalytic triads (Asp, Ser, and His), but the main part of the exons is the same within this class of enzymes.

In the cAMP-, cGMP-, and Ca^{2+}-calmodulin-dependent protein kinases and phosphoryl azokinase, the domains fulfilling a similar function are homologous: for example, the cAMP- and cGMP-binding regions in the regulatory subunits are in homologous domains. The catalytic (ATP-binding) regions in all protein kinases are also encountered in homologous domains.[91] These proteins arose as a result of the duplication and fusion of the genetic elements of two related families, which determined the allosteric nature of these enzymes.[92] It may be that allosteric regulation arose initially from the random interaction of the active centre with inhibitor and the association was weakened by the covalent modification of the complex, for example, by phosphorylation, adenylation, etc.[88]

A model involving triple duplication of a precursor gene with formation of the gene of the prototype of modern calmodulin and the addition of non-coding segments to both ends of the gene has been proposed for the evolution of the calmodulin gene.[93] The last stage occurred relatively recently, since the size and nucleotide sequences of the segments of the 3′- and 5′-ends differ greatly for genes of different calmodulins.

Apart from the duplication of the genes, the latter can also fuse, as a result of which the protein becomes twice as long. The immunoglobulins, which arose from a common precursor—a polypeptide consisting of 110 aminoacid residues—may serve as an example. After duplication and merging, the different sections of the immunoglobulin chains acquired different biological functions.[2]

The evolution of proteins can be studied in terms of two aspects.

(1) Analysis of the changes in the structure of the same protein in different organisms during evolution. For example, comparison of the structures of cytochrome *c* derived from organisms ranging from yeast to man (more than 80 species) shows that closely related cytochromes hardly differ or differ in a small number of residues. The greatest differences in the aminoacid composition are characteristic of cytochromes *c* from the lowest and highest organisms. Conservative substitutions in which an aminoacid in the sequence is replaced by another aminoacid with similar properties and structure, so that the steric structure of the protein is not affected and there is no substitution in the region of the active centre and no substitution inducing pronounced conformational changes in the protein which can lead to the loss of activity, are characteristic of proteins from closely related species. There is an appreciable tolerance as regards substitutions, deletions, and insertions of aminoacids in many sections of the polypeptide chain in different proteins.[2] A homology has been observed near Cys residues among tryptophan, phenyl, and tyrosine hydroxylases from different sources. It has been suggested that they have arisen from a single gene as a result of the accumulation of point mutations.[83] On passing from the lowest to the highest organisms, the protein becomes more complex. Bacterial phosphofructokinase has a single regulatory section, while the human enzyme is larger and contains three regulatory sections and can bind in addition three different types of regulatory proteins.[13] In the limiting case, it may turn out that the aminoacid sequences of two proteins having similar steric structures differ so much that it is difficult to establish their evolutionary relation.

(2) Comparison of different proteins within the framework of a single species. A homology of the primary structure is frequently characteristic of enzymes catalysing similar reactions. For example, the homology reaches 40% for glutathione reductase and lipoamide reductase. On comparing the aminoacid sequences of any proteins, one may expect the coincidence to the extent of at least 5% on statistical grounds.

In comparing primary structures, it is essential to take into account the possibility of deletion and insertion. Cases where between 15 and 25% of coincidences are observed when account is taken of such deletions and insertions are of greatest interest. The roots of the family tree of proteins should be sought in this "intermediate" zone. For example, five proteins with different biological functions have been found to be related: antithrombin III (a protein present in blood plasma and neutralising the effect of thrombin), α_1-antitrypsin (a proteinase inhibitor), ovalbumin (a component of egg protein), angiotensin—(a precursor of the peptide hormone involved in the regulation of arterial pressure), and a barley grain protein with an unknown function.[8]

Structural similarity in the absence of homology in the sequence is exhibited by the chicken protein lysozyme and the bacteriophage T4 lysozyme, which suggests the presence of a common precursor.[94]

Studies of the evolution of proteins have given a powerful stimulus to the development of protein engineering at the level of DNA, because rearrangements, deletions, or insertions of exons can give rise to new combinations of domains and moduli, i.e. to proteins with completely new properties.

2. Prediction of the steric structure and functions of protein molecules

Comparison of the aminoacid sequences constitutes the basis for the modelling of protein at all the levels of the protein structure—the secondary structure, the structure of domains, the quaternary structure, the interaction with ligands, and the prediction of biological functions of the protein.[95–110] The approaches used to predict the protein structure on the basis of data for its primary structure can be represented schematically (Table 2).

The methods and criteria for the comparison of different proteins and for the modelling of the protein structure have been examined in a number of studies.[96,98–106]

The sequences in proteins are compared in order to discover homologous sections by means of standard programs for the analysis of aminoacid sequences and computer graphics. Special data banks of primary aminoacid sequences, for example, the data bank of The National Biomedical Research Foundation (NBRF) in the USA, have been created.

Table 2. Prediction of the structure of the protein on the basis of data for its primary structure.

Protein structure	Set of prediction methods
Aminoacid sequence	Prediction of the structures of individual section of proteins, determination of "structural motifs" (α- or β-helices, random coil, etc.)
↓ Secondary structure	The search for "structural" matrices, modelling of the disposition of structural motifs in space
↓ "Supersecondary" structure	Simplified energy calculations, minimisation of the energy, and molecular dynamics
↓ Domain	More detailed energy calculations, modelling of the disposition of the domains and subunits in space with the aid of computer graphics
↓ Set of domains, set of subunits	

There are several ways of predicting the secondary and tertiary protein structures. The first, simplest and most widely used method involves the finding of homologous proteins with a known steric structure. In order to construct a three-dimensional model of the test protein on the basis of structural homology with known proteins, special programs have been developed, for example the Frodo program[107] created by Jones as early as 1978 and the Composer program.[103] The latter is based on the simultaneous superposition of the structures of different proteins homologous with the modelled protein and on the derivation of an average structure or templet.

The following criteria serve as a basis for the comparison of the aminoacid sequences and the discovery of analogies between them: the identity of the aminoacid sequences, the identity of the nucleotide sequences, a minimal difference between the bases in the codon, the ratio of the number of modified aminoacids to the total number, and certain characteristics of the aminoacid residues, for example, their polarity, hydrophobicity, etc. Argos[100] developed a method for discovering weak analogies in protein sequences and established two sensitive criteria for their comparison: (1) the

relative molecular weight of the aminoacids replaced (the Dayhoff criterion); (2) comparison of five physical characteristics of aminoacid residues such as hydrophobicity, volume, refractive index, the location of the residue on sections corresponding to the rotation of the chain or sections anti-parallel to the chain. The author examined 30 classes of proteins, including haemoglobins, chymotrypsins, lysozymes, cytochromes *b* and *c*, triosephosphate isomerase, lactate dehydrogenase, the domains of different proteins fulfilling the same function — Ca-binding, arabinose-binding, etc. All these proteins have similar tertiary structures. If homologies with other proteins are not observed for the protein investigated, then some information about its secondary and tertiary structure can be obtained by analysing the structure of proteins close to it on the evolutionary scale. In the absence of a homology, a series of other methods are also used to establish secondary and tertiary structures. For example, the construction of a hydrophobicity profile and its comparison with the hydrophobicity profiles of other proteins permit the identification of sections forming the secondary structure. The structural profiles have been investigated for a series of proteins with different degrees of homology of the primary structures and it has been shown that identical structural profiles can imply identical three-dimensional structures even in the absence of a homology in the aminoacid sequences.[108,109] In the absence of homology, there are also other methods for predicting the tertiary structure of proteins, for example, calculations of the energy states of the protein molecule and the search for the conformation having the minimum free energy in the protein–solvent system, and also with the aid of templets: in proteins with different primary structures there is a possibility of the existence of regions which are structurally similar; thus the nucleotide-binding domain in certain proteins consists of parallel β-folds bounded by α-helices.[106]

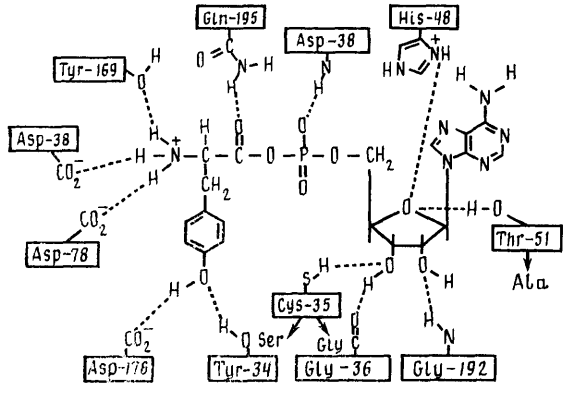

Figure 6. Schematic illustration of the active centre of tyrosyl-tRNA synthetase.[55]

Finally the primary structure permits the assignment of the protein to a particular functional class.[110] Klein analysed 2145 aminoacid sequences in the NBRF data bank and divided them into 26 functional classes. Physicochemical characteristics of the protein such as average hydrophobicity, maximum hydrophobicity, variation of the hydrophobicity of individual segments, charge, the probability of the formation of the α- or β-helix, and the periodicity in the appearance of glycine, phenylalanine, and the pentapeptide Phe-His-Phe-His-Trp were used in the analysis. It was found that 3–5 characteristics of this kind are sufficient to assign the protein with a high degree of probability to one of the 26 classes. These classes include collagen, nitrogenases, cytochromes (*b*, c_3, c^1, and *c* separately), carboanhydrases, ribonucleases, ATPases, ceratins, phospholipases, hormones, dehydrogenases, the class of prolactin and somatotropin, ferredoxins, toxins, histones, globins, the variable sections of antibodies, and the permanent sections of antibodies. A periodicity in the appearance of glycine in the primary structure is characteristic of the class of collagens, a periodicity in the hydrophobic regions is characteristic of globins, while the characteristic feature of ATPases is a low tendency towards the formation of β-folds. A characteristic feature of the variable sections of antibodies is a marked difference between the hydrophobicities of individual segments of the polypeptide chain. The knowledge of the primary and steric structures of the protein or its modelling by comparison with previously investigated proteins and data for the chemical modification of proteins and enzymes and for the activity of the enzyme centres, obtained by different methods, make it possible to proceed to a new level in the study of the active centres of enzymes with the aid of genetic engineering methods — site-specific mutagenesis.

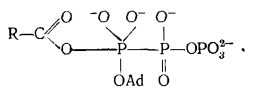
3. The study of the active centres of enzymes with the aid of site-specific mutagenesis

Studies on proteins by the method of site-specific mutagenesis can be divided arbitrarily into two groups: the site-specific mutagenesis of enzymes with a known crystal structure and the site-specific mutagenesis of enzymes whose steric structure has not been determined. In the first case, the steric model of the enzyme serves as a basis for the specific alteration of the structure of the protein molecule and for the prediction of the results of mutation-induced changes with the aid of computer graphics. If the crystal structure of the protein is unknown, chemical modification data and comparison of the structures and properties of homologous species and species close on the evolutionary scale are used as a basis for the assessment of the mutation. In this case, the results of mutations are usually random and it is much more difficult to achieve the required alteration of the catalytic properties or stability of the test protein.

(a) Site-specific mutagenesis of enzymes with a known steric structure

Tyrosyl-tRNA synthetase[55,111–128] (from *Bacillus stearothermophilus*) catalyses the two-stage $tRNA^{Tyr}$ aminoacylation reaction:

Scheme 2



$$E + Tyr + ATP = E \cdot Tyr—AMP + PP_i \ (a),$$

$$E.Tyr - AMP = tPHK^{Tyr} = Tyr - tPHK + AMP + E \ (b)$$

Analysis of the steric structure of the complex E.Tyr–AMP showed that a hydrogen bond may exist between the SH group of Cys-35 and the 3′-OH group of the ribose ring of Tyr-AMP (Fig. 6). The replacement of Cys-35 by Ser and Gly by the method of site-specific mutagenesis led to the impairment of the binding to the ATP and a decrease in k_{cat}. This shows that the strengthening of the hydrogen bond impairs the affinity of the enzyme for the substrate and that its elimination can improve the binding of ATP.[55,111,112] The Thr-51 residue is capable of forming a weak hydrogen bond with adenylate. The removal of the hydrogen bond by means of

the replacement Thr-51 → Ala and the change in the structure of the side chain (the replacement Thr-51 → Pro) increased k_{cat} and reduced $K_{M,ATP}$ for the tyrosine activation reaction [stage (*a*), Scheme 2], while in the aminoacylation reaction the binding to ATP improved but k_{cat} fell somewhat. Overall, a single-point mutation led to an appreciable improvement in catalytic activity: in the mutation Thr-51 → Pro, the ratio $k_{cat}/K_{M,ATP}$ increased from 8400 to 208 000 litre mol^{-1} s^{-1} for stage (*a*) and from 1860 to 95 800 litre mol^{-1} s^{-1} for stage (*b*).[55,112]

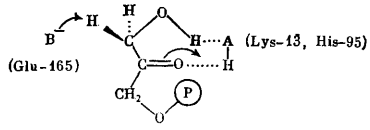
Catalysis by tyrosyl-tRNA synthethase leads to the formation of a pentacoordinate intermediate compound when ATP is subjected to nucleophilic attack by tyrosine:

The γ-phosphate group of the intermediate compound can interact with Thr-40 and His-45 side chains. The site-specific mutagenesis (the replacement Thr-40 → Ala, His-45 → Gly) provided an answer to the question concerning the mechanism of the catalysis. The mutations of the γ-phosphate-binding region of the enzyme increase the energy of the complex in the transition state, while the energy levels of the enzyme–substrate complexes do not change.[113,114] The main groups participating in catalysis are Thr-40 and His-45, but certain other groups, not included in the active centre, are also important for catalysis: Tyr-34, Cys-35, His-48, Thr-51, and Tyr-169.[114–118] Comparison of the free energy profiles for the mutant and initial enzymes has shown that the change in binding energy influences the rate constant and equilibrium constants. The principal conclusion derived from the study of the kinetic properties of the mutant and from the comparison of the free energy profiles is as follows: tyrosyl-tRNA synthetase uses in catalysis the mechanisms involving the stabilisation of the transition complex (in contrast to covalent, nucleophilic, and acid–base catalysis), stabilisation occurring via hydrogen bonds and electrostatic interactions.[114–122] By substituting the Lys and Arg residues located on either side of the substrate-binding pocket, it has been shown that the structure of the enzyme changes during catalysis: the positively charged side chains neutralise the negative environment of the pyrophosphate in the transition state on formation of tyrosyladenylate.[123,124]

The method of site-specific mutagenesis has also been applied to the study of the subunit interactions in this enzyme.[125–128] It has been shown that tRNA interacts with the N-terminal (catalytic) domain of one subunit and with the C-terminal section of another. The mutation of the residue located on the subunit interaction section (Phe-164 → Asp) led to the appearance of a negative charge on the binding section and induced a pH-dependent dissociation of the dimer, while the replacement Phe-164 → Lys led to the appearance of a positive charge. The introduction of mutations into the subunit interaction zone made it possible to control the subunit interactions in tyrosyl-tRNA synthethase by controlling the subunit interactions.

Cytochromes[129–138] and cytochrome *c* peroxidase.[139,140] The cytochromes are series of structurally similar haem-containing proteins involved in electron transport over large distances (10–20 Å). The role of residues which are present in all the cytochromes in electron transport has been elucidated with the aid of site-specific mutagenesis. According to X-ray diffraction data, the Phe-87 residue is located on the surface of the globule at a distance of 5 Å from haem. This residue in yeast iso-1-cytochrome *c* has been replaced by Ser, Gly, and Tyr[129–131] and also by Leu.[132] The mutants retained 20–70% of the activity compared with the native protein but the reduction potential fell by 50 mV. Thus Phe-87 does not participate directly in electron transport but ensures a hydrophobic environment for haem and determines the high reduction potential of cytochrome *c*. The mutations of Phe-87 induced conformational changes in the protein globule or cytochrome *c*, which is indicated by changes in the CD spectra in the region of the Soret band (385–445 nm). The mutations of the conservative Glu-66 in horse mitochondrial cytochrome *c* led to the conclusion that (1) it contributes to the stabilisation of the active conformation of the protein, possibly via the formation of a salt bridge, and (2) it participates in the binding of ATP.[133] Substitutions of the Cys-102 residue on the surface of iso-1-cytochrome *c*, which is rarely encountered in other cytochromes, did not alter the properties of the protein.[135,136] The sections retained in the course of evolution are not always involved in the mechanism of electron transfer. For example, the replacement of the conservative Lys-77 by Arg in iso-1-cytochrome *c* from yeast did not influence its interaction with cytochrome b_2, cytochrome *c* peroxidase, and cytochrome *c* oxidase.[134]

In order to elucidate the role of the sections of the polypeptide chain in the functioning of cytochrome P450, chimeral proteins were obtained from cytochrome P450c by replacing the central section, or the C-terminal section, or both sections by the corresponding sections of cytochrome P450d.[137] Cytochrome P450ccd had a higher monoxygenase activity than the initial cytochrome P450c, while the P450cdd mutant had a lower activity. The substrate specificity of the mutants did not change. Hence it was concluded that the central section in cytochromes P450c and P450d participate in the binding of substrates, while the C-terminal sections play an important role in electron transport.[137] However, other workers,[138] who obtained 13 mutants with substitutions at the C-terminal section of cytochrome P450d, discovered aminoacid residues on the C-end important for the binding of the apoprotein.



The method of site-specific mutagenesis helped to elucidate the role of Met-172 and Trp-51 in the catalytic function of **cytochrome c peroxidase**.[139,140] The interaction of the enzyme with hydroperoxide results in the formation of the intermediate (I), which contains [Fe^{IV}=O] and a free radical located on a certain hitherto unidentified group of the enzyme. It has been suggested that this group is either the indole ring of Trp-51, located 3.3 Å above and almost parallel to the plane of haem, or Met-172. However, the replacement of the indole ring by the phenylalanine ring, which is much more difficult to oxidise, did not entail a loss of activity. The Met-172 → Ser mutations also did not prevent the formation of compound (I). Thus the Trp-51 and Met-172 residues are not obligatory for the formation of compound (I) and the question of the location of the free radical remains open.

The serine proteases (trypsin[141–143] and subtilisin[144–151]) have been a satisfactory model for the construction of proteins by genetic engineering methods, since detailed information is available about their structure and kinetic and spectroscopic properties. Data on the structure of a protease from one source can be used to investigate the enzyme from another source. Although, for example, the crystal structure of trypsin from rat liver is unknown, the known structure of bovine trypsin was employed for experiments on site-specific mutagenesis having made sure that the aminoacid compositions of these enzymes are 74% identical. When Gly-166

in the substrate-binding region of the enzyme was replaced by the negatively charged Asp and Glu residues, the catalytic effectiveness (k_{cat}/K_M) of native subtilisin increased in relation to poor substrates and diminished in relation to good substrates. On replacement of Gly-166 by non-ionic residues (Ala, Leu), the catalytic activity increased for substrates containing hydrophobic groups. The change in specificity is associated mainly with the change in K_M and not in k_{cat}.[144-147]

Analysis of the crystal structures of the complexes of subtisilin with inhibitors demonstrated the presence of a hydrogen bond between the amide group of Asn-155 and the oxygen of the tetrahedral anion. Point changes in the position 155, leading to a change in the steric configuration (Asn-155 → Thr, Gln) or charge (Asn-155 → His, Asp) and in the hydrogen bond donor, diminished k_{cat} by a factor of 200–4000 and K_M by a factor of 7, which can be explained by a decrease in the stabilisation energy of the transition state by 9.2–20 kJ mol^{-1}.[148,149]

Triosephosphate isomerase.[152-155] The basic group (carboxylate ion) of Glu-165 is involved in the mechanism of catalysis by this enzyme:

Following the substitution Glu-165 → Asp, i.e. after the removal of one methylene group which shifts the basic group by 1 Å, k_{cat} diminished by a factor of 10^3 (from 4300 to 2.8 s^{-1}) with a slight alteration of K_M. Free energy calculations demonstrated that the mutation influences the free energy of the transition state in the enolisation stage.

Aspartate carbamoyltransferase[156-162] contains 12 polypeptide chains of two types: six catalytic and six regulatory. With the aid of point substitution in these chains and also on sections between them, the regions of the enzymes responsible for the regulatory properties were discovered: the loops formed by the residues 230–245 of the catalytic chains;[157] the Trp-209 residue on the section corresponding to the interaction of subunits.[156,158] The substitution Lys-83 → Gln in the catalytic chain diminishes the capacity of the enzyme for cooperation, while the substitution Gln-138 → Ala increases it, i.e. the aminoacid residues apparently determine many interchain and intrachain interactions.[159-162] Crystallographic studies on the complexes of the enzyme with substrate analogues showed that the active centre of aspartate carbamoyltransferase consists of several sections located on different catalytic subunits. A method has been proposed for the detection of the catalytic sites on oligomeric enzymes involving the construction of hybrids containing mutant monomers, for example, hybrids made up of monomers containing the Lys-84 → Glu, His-134 → Ala, and Ser-52 → His mutations or hybrids made up of trimers of the wild type and the Glu-84, Ala-134 binary mutant. The results of the mutation showed that the active species are formed only after the association of the chains with formation of an oligomer.

Staphylococcal nuclease.[163-167] Although the structure of staphylococcal nuclease has been determined by X-ray diffraction with a high resolution (1.5 Å), the detailed mechanism of the action of this enzyme has not been established. In order to elucidate the mechanism of the binding of Ca^{2+} ions, one of the residues surrounding Ca^{2+} in the protein was mutated (Asp-40 → Glu). The removal of one of the three *cis*-ligands diminished the affinity for Ca^{2+} by a factor of five and the maximum rate by a factor of 31. The mutation did not affect the binding of DNA, which agrees with the structural X-ray diffraction data, according to which Asp-40 interacts with the metal and not with the nucleotide chain.[163,164] The replacement of various Tyr residues in the substrate-binding cavity of the enzyme showed that the OH group in the Tyr residues does not play an appreciable role in catalysis. However, the mutations weakened the binding to the substrate (single-stranded DNA and RNA).[165] The mutations of Glu-43 in the active centre induce conformational changes in the protein at a distance of 15–30 Å from the residue 43.[166,167]

α-Antitrypsin[168-171]—an inhibitor of serine proteases. It has been shown by the method of site-specific mutagenesis that its inactivation is associated with the modification of Met-358 by oxidants. The Ile-356 and Pro-357 residues play an important role in the functioning of the inhibitor. The Met-358 residue in the active centre determines the specificity of the binding of antitrypsin to proteins. Native α-antitrypsin containing Met-358 recognises the Pro-Met sequence of elastase. The Ala-358, Ile-358, and Val-358 mutants proved to be effective inhibitors of neutrophilic and pancreatic elastases but not of cathepsin G; the Leu-358 and Phe-358 mutants inhibited cathepsin G preferentially.

Yeast 3-phosphoglycerate kinase[172-174] consists of two globular domains separated by a polypeptide chain loop. It has been suggested that the conformational change leading to the "merging" of the domains takes place during catalysis under the influence of the substrate. The Glu-190 and His-388 residues may interact with one another in the region between the domains (the formation of a hydrogen bond or of a salt bridge) and regulate the transition from the closed to the open form of the enzyme. The Glu-190 → Gln, Asp and His-388 → Glu mutations led to some decrease in catalytic activity and resulted in a change in the K_M with respect to both substrates. Thus the results of mutagenesis have shown that the model of the transition from the closed to the open form in catalysis requires further study.[172,173] The construction of a chimeral protein, one of the domains of which was isolated from human 3-phosphoglycerate kinase and the other from the corresponding yeast enzyme, was an interesting experiment. The hybrid retained the properties of the native proteins.[174]

Carboxypeptidases.[175-178] The three-dimensional structure of carboxypeptidase A has already been known for about 20 years, but certain details of the mechanism of its action are still not understood, for example, the role of Tyr-248 located at a distance of 3 Å from the substrate peptide bond undergoing cleavage. The results of site-specific mutagenesis have shown that this group participates in the binding of substrates and not in hydrolysis.[175,176] The OH group of Tyr-198 participates in the catalysis, stabilising the complex in the transition state.[177] The substitution Met-398 → Leu for yeast carboxypeptidase *y* altered the enzyme specificity. The mutation made the substrate-binding section more hydrophobic and the mutant therefore had an increased affinity, compared with the initial enzyme, for substrates with bulky and hydrophobic substituents.[178]

Other enzymes. The method of site-specific mutagenesis has also been used to investigate the influence of structure on the activity of dihydrofolate reductase from *E. coli* (DHFR).[179,180] The mutations of the Asp-27 residue in the enzyme active centre showed that it participates in the protonation of the substrate but not in the stabilisation of the transition state as had been postulated earlier. The dihydrofolate may be protonated directly by the asparagine group or with participation of water molecules. It has been shown for human DHFR that the Cys-6 residue partipates in the binding to NADPH and *p*-hydroxymercuriobenzoate.[181] Mutants with substitutions of aminoacids in the active centre have been obtained for human *lysozyme*.[182,183] Their analysis showed that the Asp-53 residue participates in the electrostatic stabilisation of the intermediate state in the hydrolysis of the glycosidic linkage. The existence of an aromatic residue in the position 63 and of Trp-64 is essential for the effective hydrolysis of chitin substrates but not for the lysis of bacterial substrates. The influence of insertions and deletions on the activity of ribonuclease P has been studied in detail[184] and it has been shown that, for the normal functioning of the RNA subunit of ribonuclease P from *E. coli*, a section of the secondary structure coded by the nucleotides 275–295 is essential.

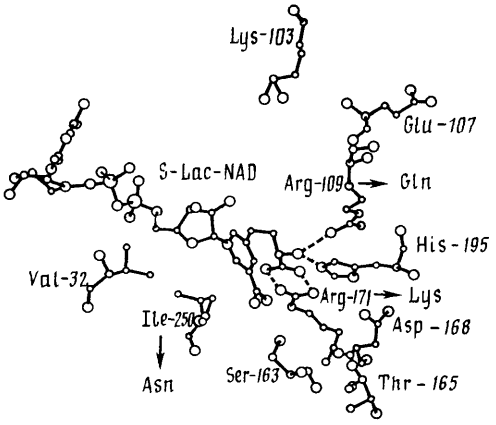


Figure 7. The active centre of native lactate dehydrogenase bound to the substrate.[188]

The sections at which the enzyme is bound to DNA have been discovered with the aid of mutagenesis for the **restriction endonuclease (restrictase)** EcoRI. The initial information about these sections was obtained from the X-ray diffraction structure of the complex EcoRI with a synthetic oligonucleotide. Point mutants (the Glu-111, Glu-144, and Arg-145 residues) hardly differed in their specificity from the initial enzyme, but their specific activity was reduced by a factor greater than 100 mainly as a result of the decrease in V.[185] Analysis of the crystal structures, especially of the geometry of the active centres, made it possible to alter with the aid of mutations the substrate specificity of *aspartate aminotransferase*,[186] *lactate dehydrogenase*,[187,188] and *alcohol dehydrogenase* [189] (see Section VI). The mutations of the Arg-109 residue in *lactate dehydrogenase* from *B. stearothermophilus*—a component of the mobile polypeptide group exposed to the solution—showed that it increases the polarisation of the carbonyl group of pyruvate and thus stabilises the transition state. The Ile-250 → Asn mutation impairs the catalytic properties of the enzyme (Fig. 7). The substitution of the catalytically important Ser-102 residue in *alkaline phosphatase*[190] by Cys altered the rate-limiting stage in the hydrolysis of esters: in contrast to the native alkaline phosphatase, the kinetics of the action of the mutant with the SH group instead of the OH group depend on the leaving group of the ester, a high catalytic constant being retained. Studies on *ATP synthetase* by the method of site-specific mutagenesis have been initiated.[191] Four residues capable of ionisation and important for the manifestation of activity have been found on the α- and β-subunits of the enzyme: Lys-175 and Asp-261 on the α-subunit and Lys-164 and Asp-252 on the β–subunit of the enzyme.

(b) The site-specific mutagenesis of enzymes with an unknown crystal structure

β-Lactamase[192–198] catalyses the opening of the β-lactam ring in penicillins and cephalosporins, ensuring the resistance of the cells to antibiotics. The class A β-lactamases contain the conservative catalytic triad (Ser-70) – (Thr-71) – (...) – (Lys-73). Point substitutions of Ser-70 permitted the conclusion that only mutants containing a nucleophilic group, for example, Cys, in the position 70 are catalytically active, although their activity is appreciably lower than that of the native β-lactamase.[192–196] Analysis of 19 mutants containing all the possible variants of the aminoacid residues in the position 71 showed that the Thr-71 residue does not participate in the binding of substrates and in catalysis but is important for the stabilisation of the protein and influences in some ways the specificity of the catalysis, determining the configuration of the β-lactam ring binding section.[197] The mutation Lys-73 → Arg led to an appreciable loss of activity. The role of the Lys-73 residue in catalysis has been discussed: the orientation of the proton moving away from the carboxy-group of the Ser-70 residue; the presence of a salt bridge with the Glu-166 residue participating in the hydrolysis of the acylenzyme.[198]

Ribulose diphosphate carboxylase.[199–202] Mutants with substitutions in the sections for the binding of CO_2, Mg^{2+} ions, and ribulose diphosphate have been obtained for the enzyme from *Rhodospirillum rubrum*. The ε-NH_2 group of the Lys-201 residue participates in the formation of the carbamate ion in the interaction with CO_2 and Mg^{2+}. The Asp-198 → Glu mutation showed that the carboxy-group of the Asp-198 residues also plays a role in the binding of the divalent metal.[199] It has been suggested that two residues (Lys-166 and His-291) participate in the enolisation of ribulose diphosphate, but the mutant in which the His-291 → Ala substitution has taken place showed a high catalytic activity. Thus the His-291 residue does not play a central role in catalysis.[200] The replacement of Lys-166 by seven different residues led to an appreciable loss of activity, but the mechanism of the participation of this group in catalysis has not been finally elucidated. The lack of crystallographic data precludes an answer to the question of the involvement of this group also in the binding of substrates.[201] The role of the small non-catalytic subunit S, point substitutions in which affected the catalytic activity but not the specificity, has been investigated by the method of site-specific mutagenesis in the enzyme from *Anacystis nidulans*. Hence it was concluded that the subunit participates in the activation of substrates but not in regulation.[202]

Lactose permease[203–212] is a hydrophobic enzyme controlling the transport of β-galactoside and of protons across a membrane. In order to investigate the role of the SH group of the active centre in catalysis, the Cys-148 → Gly[203,204] and Cys-148 → Ser mutants were obtained.[205,206] The results showed that Cys-148 is important for protecting the enzyme against inactivation (with the aid of the substrate) but is not obligatory for the transport of lactose. The mutations of other cysteine residues showed that, out of the eight residues, only Cys-154 is essential for the manifestation of activity.[207–209] According to preliminary data, the histidine residue also participates in the transport of the substrate. Each of the four histidine residues was replaced by Arg,[210] Gln, or Asp.[211] It was found that the His-322 residue is involved in the H^+ transport across the membrane via the protonation of the imidazole ring. The His-205 residue forms a hydrogen bond either with the substrate or within the protein. The Glu-325 and His-322 residues are located on the α-helix intersecting the membrane, form an ion pair, and act as components of the charge transfer system. The polarity of the residues and the distance between the imidazole and carboxy-groups therefore play an important role. The Glu-325 → Ala, Val mutations and the double mutation Glu-325 → His, His-322 → Glu lead to a partial or complete loss of activity.[212] Preliminary experiments with another membrane enzyme, melibiose permease, also demonstrated the presence of the His/Glu pair, which is important for catalysis.[212]

Other proteins and enzymes. The mutation-induced substitution of the Cys and His residues on three Ca^{2+} binding sections in the postulated active centre of the bioluminescent Ca^{2+}-dependent protein aequorin[213] showed that the binding of molecular oxygen does not proceed solely via the SH group. The His-58 residue and at least two of the four SH groups are necessary for the manifestation of activity. For another Ca^{2+}-binding protein, namely *calmodulin*,[214] a study has been made with the aid of mutagenesis of the influence of structure on the interaction with related proteins—myosin kinase, phosphodiesterase, and NAD kinase. The removal of the anionic α-helical section, which is complementary to the positively charged region of the binding protein, altered the binding specificity.

An unexpected result was obtained on substitution of the Thr–190 residue by Ile on the section close to the active centre of *malate dehydrogenase*: the catalytic activity increased mainly as a result of the increase in k_{cat}. It had been postulated earlier that the residues surrounding Asp-152, His-180, and His-187 in the active centre play a role in the binding of substrates and cofactors, but it has been found that the Thr-190 residue influences significantly also the activity.[215] The site-mutagenesis of the viral *neuraminidase*[216,217] suggested a model of the catalytic action of the enzyme involving the Glu-276 residue as a proton donor. Mainly conservative residues were used for the mutagenesis (12 residues identical for different types of viruses in 14 mutations). A series of mutants of the *RNA ligase* of the phage T4 have also been obtained.[218–220] The removal of 20% of the polypeptide chain from the C-end does not affect the RNA ligase activity. Mutations on the ATP-binding sections showed that the Lys-99 residue participates in the formation of the enzyme–adenylate complex, while the residues 100–101 do not affect this reaction. In order to elucidate the structure of the active centre of the *thiolopenicillin-binding protein* from *E. coli*, the Ser-307 and Ser-445 residues were substituted. It was found that the Ser-445 residue does not form part of the active centre, while the Ser-307 residue is responsible for the binding of penicillin in the penicillin-binding Ser–X–X–Lys section discovered in functionally similar proteins.[221] The Glu-49 residue, which is important for the manifestation of the activation of the α-subunit of *tryptophan synthetase*,[222] and the SH group important for the manifestation of the activity of *anthranylate synthetase*[223] have been identified. It has been shown for *isopenicillin N-synthetase* that the Cys-106 residue participates in the binding of the substrate but is not obligatory for catalysis.[224] The His-228 residue has been found next to the functionally important Lys-229 residue in the active centre of serine *hydroxymethyl transferase*.[225] The His-228 residue in enzymes of this type from various sources forms a hydrogen bond or a salt bridge with an aminoacid or pyridoxal phosphate. The results of mutation-induced substitutions in (or near) the phosphorylation centre of the *cAMP-dependent protein kinase* showed that the phosphorylation of the regulator subunit does not play a significant role in the regulation of the activity,[226] while the Tyr-371 residue makes a significant contribution to the manifestation of the positive cooperation between the two cAMP-binding centres of this subunit.[227]

V. Determination of the relation between the structure and stability of protein macromolecules (by genetic engineering methods)

1. Factors determining the structural stability of the protein

The difference between the Gibbs free energies of the native (N) and denatured (D) states of the cooperative domain or of a single-domain protein is a measure of the stability of its structure.[11,228]

Scheme 3

$$H \rightleftarrows D$$

$$\Delta G_{den} = G_{den} - G_{nat}.$$

For the majority of single-domain proteins, the temperature dependence of ΔG_{den} is described by a curve (Fig. 8) passing through a maximum at the temperature of the maximum stability of the protein (T_{max}) and having upper ($T_{den\,1} = T_m$) and lower ($T_{den\,2}$) temperature limits of the stability of the protein (for $\Delta G_{den} = 0$), i.e. proteins are inactivated in the cold as well as at an elevated temperature.[229] [T_m = melting point]. The temperatures T_{max} for many globular proteins are in the range from −3 to +15 °C and their ΔG_{den} in the physiological temperature range vary from 20 to 60 J mol^{-1}.[230]

The stability of the protein is characterised by the average temperature of the transition to the denatured state T_{den} (or T_m) at which 50% of the protein is denatured and $\Delta G_{den} = 0$, or by the temperature of the maximum stability of the protein T_{max} at which ΔG_{den} is a maximum (Fig. 8), or by the average concentration of the denaturing agent, etc. In the case of irreversible denaturation, the kinetic stability of proteins ($\Delta G^{\neq}_{den}$) is usually characterised by the rate constant k_{in} for the change in some kind of property of the protein (the CD or UV spectra, fluorescence, and, in the case of enzymes, their activity). The kinetic and thermodynamic parameters of the denaturation of proteins frequently vary in parallel with the variation of the denaturation conditions, i.e. the intramolecular interaction conditions, which govern the thermodynamic stability (ΔG_{den}), apparently determine their kinetic stability ($\Delta G^{\neq}_{den}$). In the general case, thermal denaturation is described by the scheme

Scheme 4

$$H \rightleftarrows D \rightarrow I,$$

where I is the irreversibly denaturing agent. When $K_{den} \geqslant 1$, the greater the stability of the enzyme in relation to reversible thermal denaturation, the greater its stability also in relation to the irreversible denaturation, but it has been assumed (without proof) that there is no such correlation for $K_{den} \ll 1$.[231] In the general case, the retention of the activity of enzymes may not in fact be identical with the stability of the entire protein globule.[232] The stability of enzymes is as a rule determined by the stability of the domains (or domain) forming the active centre and is in fact determined by the stability of the most labile domain.

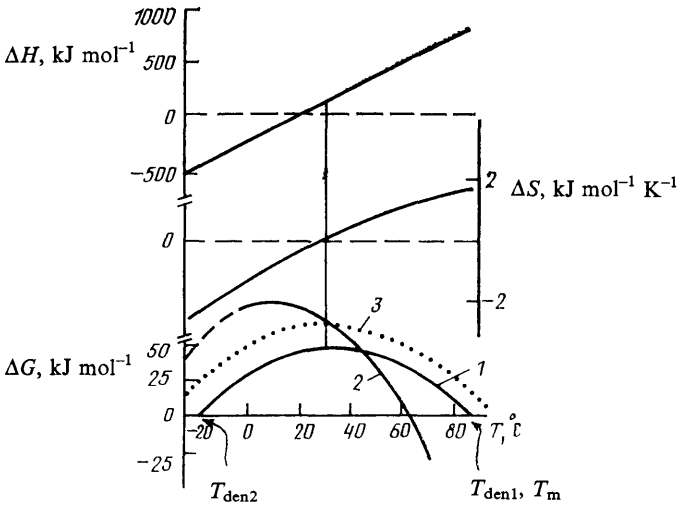

Figure 8. Temperature dependences of the enthalpy (ΔH), entropy (ΔS), and Gibbs free energy (ΔG) of the transition of proteins from the native to the denatured state: (1) myoglobin;[11] (2) α-chymotrypsin;[229] (3) hypothetical curve for the stabilised protein.

The factors responsible for the stability of the native conformation of the protein have been examined in detail in a review.[232] The main ones are as follows: (1) hydrogen bonds. (2) Increase in conformational entropy when the protein structure is uncoiled. (3) Long-range electrostatic interactions. If the charge distribution on the surface of the macromolecule is asymmetric in relation to composition and geometry, then the surface electrostatic potential in the absence of steric hindrance generates specific ion-binding regions whose saturation by the corresponding ions entails an increase in the stability of the protein.[233] (4) Hydrophobic interactions of the non-polar aminoacid residues resulting mainly from the van der Waals interactions between the molecules. The contributions of the hydrophobic interactions and hydrogen bonds to the stability of the protein structure are comparable.[228] (5) Intramolecular salt bonds (the energy of one bond is 1–3 kcal mol^{-1}) forming either single salt bridges or clusters. (6) Intramolecular –S–S– cross-links (1.8 kcal mol^{-1} per disulphide bond). (7) Formation of complexes by the protein with prosthetic groups and M^{n+} ions. The overall stability of the protein molecule is determined by the balance between the stabilising and destabilising contributions of the above interactions. The effective concentration of the interacting groups in the coiled and uncoiled states of the molecule makes a decisive contribution to the stability of the protein.[234]

The thermal stability of the protein is described by a complex relation between ΔG_{den} and temperature (Fig. 8).[11,229] The thermal stabilities of different enzymes must therefore be investigated and compared over a wide range of temperatures and not at a single temperature (cf. Lale and Klibanov[231] and Torchilin et al.[235]). The ratio of the ΔG_{den} for enzymes at a fixed temperature cannot be extrapolated to other temperatures. The formula for the calculation of small changes in ΔG_{den} from changes in T_{den} has been found for the case where the structure of one protein is altered, for example, by means of mutations.[229]

2. General relations for the specific alteration of the stability of proteins and enzymes *in vitro* and *in vivo*

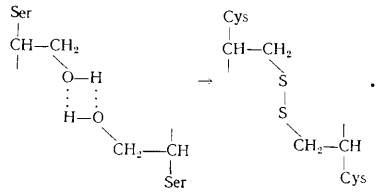
(a) **Stability** *in vitro*. In order to elucidate the causes of the different stabilities of proteins, the first attempts have been made to find a correlation between the aminoacid composition of the proteins and their stability (T_{den}) and to compare the primary structures of proteins with identical functions and aminoacid sequences but having different stabilities (isolated from thermophilic and mesophilic microorganisms). These questions have been described in detail.[236] Correlations have been proposed between T_{den} and the hydrophobicity index of the residues and their average volume,[237] between T_{den} and the ratio of the areas of the surface of the protein accessible to the solvent in the native and denatured states,[238] between T_{den} and the percentage content of the stabilising and destabilising residues in the protein,[239] and between T_{den} and the aliphatic index of the protein.[240] These correlations suffer from the following disadvantages: (1) they are valid only within a limited group of proteins of a definite class; (2) T_{den}, which, as already stated above, does not characterise the stability of the protein as a whole, was adopted as a measure of stability. It is most likely that, in view of the large variety of factors responsible for the stability of the native conformation of the protein, the existence of a simple correlation is hardly possible and interest in studies of this kind has therefore diminished. When thermophilic (*t*-) and mesophilic (*m*-) proteins with known primary and three-dimensional crystal structures were compared, the structural factors responsible for the increased thermal stability of *t*-enzymes were discovered:[7,236,241,242] (1) the thermodynamically more favourable disposition of a large number of polar and charged residues on the surface and of hydrophobic residues on the inside, which is characteristic of *t*-enzymes;[241] (2) additional one–two salt and hydrogen as well as hydrophobic linkages in *t*-enzymes; (3) the most frequent occurrence of the Ser → Gly, Thr, Ala, Gly → Ala, Lys → Arg, Ala, Val → Ala, Ile, and Asp → Asn, Glu substitutions on transitions from *m*- to *t*-enzymes; an increased content of the Arg residues and a reduced content of Lys residues are characteristic of *t*-enzymes;[243] (4) *t*-enzymes have a larger number of S–S bonds, α-helices, and β-structures.[7]

Knowledge of the principal factors determining the stability of the native conformation of the protein in solution and of the characteristic features of the structures of *t*-proteins makes it possible to formulate the general principles enabling one to obtain proteins and enzymes with an increased stability: (1) the introduction of additional intramolecular and intersubunit bonds (salt and hydrogen bonds) and the enhancement of hydrophobic interactions increase ΔG_{den} for the protein, as shown in Fig. 8 (the upward shift of curve *1*). Calculation shows that a decrease in k_{in} by a factor of

10 at 70 °C requires an increase in ΔG_{den} by only 1.56 kcal mol^{-1}, while an increase in T_{den} from 35 to 45 °C for a polypeptide chain with M = 35 kD requires an increase in the number of hydrogen bonds by only 3%.[244] Therefore even one additional bond with an energy of 1–3 kcal mol^{-1}, achieved as a result of the replacement of 1–2 aminoacid residues, can increase significantly the stability of the protein. (2) The decrease in the conformational mobility of the fragments of the polypeptide chain as a result of the formation of additional intermolecular covalent or non-covalent "cross-links" in the globule; substitutions by residues with a lower conformational flexibility diminish the conformational entropy ΔS_{conf} and hence increase ΔG_{den} (and T_{den}).

The practical application of these principles to a specific protein makes it necessary to establish the position in the three-dimensional structure where the aminoacid residues are to be substituted (or modified), which particular aminoacid residues are to be replaced, what aminoacids are to replace them, and what method must be used to achieve these aims.

Up to the beginning of the 1980s, the only method for the specific alteration of the structure of aminoacid residues was the chemical modification of functional side groups in the protein. However, this method suffers from important disadvantages and limitations: it is possible to modify only residues having functional groups and accessible to the solvent under the given conditions, the volume of the residues increases after modification, and the number of modifying agents is small.[245] Site-specific mutagenesis makes it possible to replace one aminoacid residue at any position in the polypeptide chain by another, even one with a smaller bulk. It is possible to substitute only one aminoacid residue.



The general characteristics of the changes in the stability of proteins and enzymes as a result of chemical modification have been formulated.[236] In a coiled protein globule, there are three types of functional groups accessible to modification. *The functional residues of type I* are distributed on the surface of the globule. These are effectively hydrated, polar, or charged groups, which do not interact with one another under the given conditions, interacting only with the solvent or ions in solution; their modification does not affect the structure and stability of the protein. *The functional residues of type II* are distributed on or near the surface of the protein. In the native enzyme, they have an unfavourable environment (charged groups in a hydrophobic environment or in an environment comprising groups bearing like charges) and destabilise the protein globule. The number of groups of this type in the protein is usually small. Their modification accompanied by a change in the destabilising factor increases the stability of the protein as a function of the degree of modification and the nature of the modifying agent. *The functional residues of type III* are remote from the surface of the globule and form intramolecular salt and hydrogen bonds stabilising the enzyme. These groups are inaccessible to modification under the usual conditions and are modified for a loosened protein conformation (at an elevated temperature, at extreme pH values, or in the presence of organic solvents). The modification of type III groups diminishes the thermal stability as a result of the rupture of intramolecular bonds stabilising the native conformation of the protein. The structure of the enzyme approaches the denatured structure after such modification.

If the three-dimensional steric structure of the protein is known, it is easy to determine the aminoacid residues located on the surface of the molecule (type I groups) and within it (type III groups). The type II groups can be identified by studying the immediate environment of the given aminoacid residue. Comparison of the crystal structures of proteins of different classes (homologous proteins and their evolutionary precursors and *t*- and *m*-proteins) and data for the influence of site-specific mutagenesis on the stability of the enzymes suggest that the rules governing the influence of the chemical modification of different functional groups of the protein on its stability are on the whole valid also in cases where the stability is changed by site-specific mutagenesis. The aminoacid substitutions in homologous proteins are encountered most often on the surface of the molecule, so that the conformation of the molecule hardly changes. More radical insertions and deletions tend to be encountered in surface loops between units of the surface structure. For proteins which are more than 50% homologous, their inner region contains more than 90% common aminoacid residues.[101]

The mechanism and strategy used in altering the stability of proteins and enzymes with the aid of aminoacid substitutions. In selecting the residues in the proteins to be replaced, it is essential to take into account the following factors: (1) the replacement of type I residues by any others will hardly alter the stability of the protein, since their average environments in the coiled and uncoiled states differ little. (2) The replacement of type II residues (non-polar Leu, Ile, Val, Phe, Tyr, Trp, Met, and Pro residues), which are in contact with water, and of residues in an unfavourable electrostatic environment by small polar and charged residues can increase the stability of the protein.[246] So far, this has been confirmed only in nature. Cytochrome *c* from ox heart is more stable than the protein from horse heart by 1.1 kcal mol^{-1}, which is due, according to the authors, to the fact that the first protein contains the Gly residue, while the second contains the Lys residue exposed to water (the energy of the destabilisation of the Lys residue on contact with water is 1.5 kcal mol^{-1}). In principle, the presence of unfavourably solvated Lys, Tyr, Met, and Trp residues can be established by chemical modification under non-denaturing conditions. The replacement of exposed Lys residues by the His residues (or Arg as in *t*-enzymes) on the whole takes place with retention of the overall charge of the molecule, but the protein destabilisation energy is diminished.[246] (3) The internal region of the proteins is packed to the optimum extent and all the polar atoms form hydrogen bonds.[247] An arbitrary alteration of the size, shape, or polarity of the inner residues (type III residues) destabilises the molecule. Experiments designed to investigate proteins from temperature-sensitive strains (and their chemical modification) showed that mutations in the inner nucleus of the molecule are critical for stability, while any mutations on the surface of the globule do not alter the stability of the protein. However, it is possible to increase the thermal stability of the protein by accurate substitutions of these residues in order to form additional S–S, hydrogen, and salt bonds and by improving the hydrophobic packing, as happens in nature. The aminoacid residues to be replaced are selected with the aid of computer modelling in such a way that the steric disposition of neighbouring residues is not altered and the shortest-range intramolecular interactions are unaffected.[248]

One of the energetic approaches to the stabilisation of the globular structure of the protein involves the decrease in its *conformational entropy* ΔS_{conf} in the uncoiled state. This can be achieved, for example, by forming *intramolecular disulphide bonds* by replacing type III residues. Disulphide bonds have been formed in proteins during evolution in order to increase their stability

during functioning under altered extracellular conditions (the intracellular proteins do not have S–S bonds). The S–S bonds increase the thermodynamic stability of the protein and its resistance to irreversible thermal inactivation, diminishing its capacity for aggregation or adsorption and restricting the exposure of the inner hydrophobic regions to the solution.[249] The strategy used in introducing additional S–S bonds into proteins is as follows.
(a) The Ser or Thr residues, resembling most closely the Cys residue, are selected. For example, the Ser–Ser pair, forming hydrogen bonds, can be replaced by Cys–Cys:

If the Ser–Thr pair is replaced by Cys–Cys, then an empty space is inserted in place of the methyl group, which can be compensated by the replacement of the nearest Val residue by a Leu or Ile residue.[250] (b) For proteins with a known crystal structure, residues are selected by computer analysis in which the carbon atoms are in the same geometrical position as in the residues between which a disulphide bond exists. There are steric limitations to the introduction of an additional disulphide bond. The distance between the carbon atoms of the residues forming a S–S bond should be 4.5–6.5 Å, while the angles formed by the S–S bond should fit within the range of values established.[251] (c) The energy of the strain in the S–S bonds in native proteins varies from 0.5 to 4.7 kcal mol^{-1}. If the S–S bond produced has a strain energy >4.7 kcal mol^{-1}, then the stabilising effect of this cross-link in proteins will be abolished.[249] For this purpose, hypothetical S atoms are introduced into the model structure and candidates with unsuitable steric interactions are rejected. The selected model structures must meet yet another requirement. The cysteine mutations must be in the positions for which certain changes are observed in the course of evolution.[252]

A decrease in ΔS_{conf} is achieved also by replacing aminoacid residues having a conformational flexibility, for example, Gly, by residues containing a β-carbon atom and therefore having a smaller flexibility (Ala, Pro),[250] since

$$\Delta S_{conf/residue} = R \ln Z,$$

where Z is the number of conformations accessible to the residue in the uncoiled protein. The residues to be replaced are chosen so that steric hindrance should not arise after the substitution and the functional properties of the protein should not be altered.

The contribution of the Ala residue to ΔS_{conf} relative to the Gly residue is 2.4 e.u., while that of the Pro residue relative to Ala is 4 e.u. For example, the substitution Ala → Pro for the phage T4 lysozyme at pH 6.5 corresponds to an increase in ΔG_{den} by 1.4 kcal and to an increase in T_m by 3.5 °C.

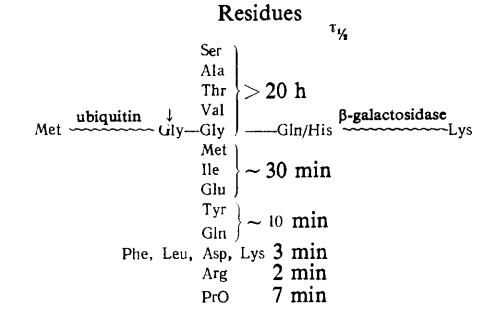
There exist also several special approaches to increasing the stability of proteins. A higher structural stability of the α-helix in proteins can be attained following the substitution Val → Ala, while the substitution Ala → Val stabilises the β-layered protein structure. Overall, it is essential to use for the substitutions not unduly hydrophobic and bulky residues in order to preserve their structure.[253] The Ala residue is an interesting candidate for the substitution of other residues and proteins. On the one hand, its introduction frequently increases the thermal stability of proteins (see above) and its increased content is characteristic of *t*-enzymes. On the other hand, the "antifreeze" proteins (proteins preventing the freezing of cells in organisms living at temperatures below 0 °C) contain up to 60 mol. % Ala.[254] The site-specific enrichment of the proteins in Ala residues apparently increases their resistance to denaturation by the cold. The site-specific substitutions of charged residues at the ends of the α-helix (a change in the charge on the N-terminal component from +2 to –1, as in the *S*-peptide of ribonuclease) can increase the stability of the protein.[255] Somewhat different approaches to the stabilisation of proteins have been proposed in relation to tyrosinase: (1) the replacements should involve exposed residues or residues in β-coils, while the residues in the α-helix or in β-layers should not be altered; (2) the hydrophobicity of the molecule must not change; (3) the Asp → Glu, Lys → Gly, Val → Thr, Ser → Asn, Ile → Thr, Asn → Asp, and Lys → Arg substitutions are preferable (on the basis of a comparison of the structures of *t*- and *m*-enzymes).[256]

The stability of proteins in relation to oxidation and heavy metal ions can be increased by the following substitutions: Cys → Ala or Ser; Met → Glu, Val, Ile, Leu; Trp → Phe or Tyr. The bulk of the residues after the substitution hardly changes and steric hindrance does not arise, but groups sensitive to oxidation and complex formation with metal ions are substituted.[257] An increase in stability can be achieved by increasing the number of metal-binding sections in proteins by introducing additional negative charges.[1]

It has been suggested in certain studies that mutations stabilising the protein act additively, i.e. the stability of the protein can be increased significantly by accumulating a large number of stabilising mutations. An increase in the stability of the protein can also be achieved by removing (or saturating) certain uncompensated groups capable of forming hydrogen bonds and also by filling the inner cavities in the three-dimensional structure.[258] On the other hand, the substitutions of many residues can hardly act additively.[259]

Thus, although the overall theory of the prediction of the stability of a protein on the basis of its primary structure is far from completion, with the aid of graphical modelling in the presence of a three-dimensional structure it is possible to reveal the presence in the protein of residues of types I, II, and III, to select *a priori* the residues to be replaced and the substituting aminoacid residues, and to obtain the expected result.

(b) **The stability of proteins** *in vivo* in the cell is determined primarily by their resistance to intracellular proteolysis. The degradation of intramembrane proteins and long-lived cytoplasmic proteins takes place in lysosomes and in cytosol (the latter is the most selective). The rates of turnover of different proteins in the cell differ by factors up to 1000 (from 2 min to more than 200 h). The question arises what determines the half-life of the intercellular proteins ($\tau_{1/2}$). When 35 proteins with unknown crystal structure were introduced into a culture of Hela cells, it was found that their $\tau_{1/2}$ varied from 16 to 220 h and was not correlated with the size, charge, and content of hydrophobic aminoacids, the acylation of the N-terminal aminoacid, or the ratio of the α-helical and β-layered conformations.[260] Calorimetric data obtained for 22 of these proteins showed that their thermal stability *in vitro* is also not correlated with $\tau_{1/2}$. The hypothesis that intracellular proteases "recognise" more readily the inner part of proteins rather than the outer part (i.e. proteins with a greater mobility and flexibility should



be degraded faster) has also not been confirmed, although it is known that proteins with a conformation distorted as a result of mutations are rapidly degraded.[261]

After denaturation, proteins become more accessible to proteolysis *in vitro*. However, comparison of the values of $\tau_{1/2}$ for native and denatured bovine serum albumin in cytosol and of β-lactoglobulin and cytochrome *c* in a culture of rat haepatoma cells showed that the denatured proteins are sometimes degraded several times more slowly than the native proteins (or at the same rate).[262]

Thus none of the global structural properties of the protein macromolecule which were examined above can serve as a criterion of its stability in the cell. Nevertheless, the latest data on protein sequences indicate the existence of definite signals in the sequence responsible for the degradation of the molecule. Thus proteins with $\tau_{1/2} < 2$ h contain one or more regions enriched in Pro, Glu, Ser, and Thr.[263] These regions have between 12 and 60 residues and are protected by clusters of positively charged aminoacids, which has been confirmed for a large number of intracellular proteins. There exists yet another type of signal for increased proteolysis: the S-peptide of ribonuclease — 20 N-terminal aminoacids in which (Lys-7)-Phe-Glu-Arg(Gln-11) are critical. The S-peptide "grafted" to lysozyme and insulin increased by a factor of 2 the rate of their degradation in fibroblasts.[264]

In the case of the ubiquitin-dependent non-lysosomal selective proteolysis, the state of the α-NH_2 group in the protein plays a fundamental role. The ubiquitinisation of the N-end of the protein is critical. The "N-end rule", establishing the dependence of the stability of the protein *in vivo* ($\tau_{1/2}$) on the nature of the N-terminal aminoacid, has been established.[265] With the aid of site-specific mutagenesis involving the cross-linking of β-galactosidase to the ubiquitin proteins, proteins with different aminoacids at the N-end of the molecule were obtained after the removal of the ubiquitin protein (Scheme 5). Depending on the aminoacid, $\tau_{1/2}$ varied as follows:

Scheme 5

If a Met group is placed at the ubiquitin binding site ahead of the residues destabilising β-galactosidase, then the $\tau_{1/2}$ for the enzyme increases (> 20 h). The authors suggest that, after the N-terminal peptidases have split off the N-end of the polypeptide chain synthesised, the "N-end reading" enzymes recognise specific residues at the N-end, which in fact determines their $\tau_{1/2}$. Long-lived proteins in the cell do indeed have Met, Ser, Ala, Gly, Thr, and Val residues at the end. On the other hand, eukaryotic toxins contain the destabilising Arg, Lys, Leu, Phe, and Asp residues at the N-end. Thus the rule established not only explains the metabolic stability of the protein but also suggests possible ways of regulating it. However, other workers[260] believe that this is a contranslation rule and holds immediately after translation for proteins which have still not coiled up, since $\tau_{1/2} = 1-3$ min is comparable to the protein translation time.

The oxidation of the His, Cys, and Met residues in the protein as well as the deamidation of Asn lead to its rapid degradation. The oxidised proteins are apparently recognised by special enzymes.[266] The stability of the intracellular proteins depends also on the site where they are located. The proteins forming part of multienzyme complexes and bound to membrane structures are more stable.

Thus the stability of proteins *in vitro* in solution is determined by specific intramolecular interactions. The stability of proteins *in vivo* is a more complex quantity and depends not only on the structure of the protein but also on its function — on the interaction of the protein with other proteins and cell components. The presence of specific signals in the aminoacid sequence, recognised by specific proteinases, and not the stability of the inner structure and the capacity for uncoiling when acted upon by various factors is of fundamental importance for the stability of the protein *in vivo* (in contrast to its stability *in vitro*).

3. The study of the stability of proteins with the aid of aminoacid replacements

The first studies of the influence of random aminoacid replacements on the stability of proteins were published at the end of the 1970s and concern the lysozyme of the T4 phage and the α-subunits of tryptophan synthetase (for a review of the first investigations, see Kutuzova et al.[236]). Since the proteins were isolated from mutant strains obtained in different ways, the influence of random aminoacid replacements on the stability of the proteins was also unpredictable. As the crystallographic technique and genetic engineering methods developed, it became possible to carry out specific replacements with prediction of a definite result. Examples of the study of the stability of different proteins with the aid of mutations (random and directed), which in many respects confirm and illustrate the features described above, are described below.

The presence of the type I, II, and III residues in proteins has been clearly demonstrated in a study of the lysozyme from the temperature-sensitive strains of the T4 phage, a convenient model monodomain protein, which has no S—S bond and prosthetic groups. Comparison of the crystal structures of the mutant lysozymes showed that the majority of the mutations destabilising lysozyme and encountered among residues which are inaccessible to the solvent have a rigid conformation, and are most static in the molecule. These aminoacid residues, located in the "hard" part of the molecule, form stabilising intermolecular bonds (type III residues). Mutant lysozymes, in which the inner Thr-157 residue, forming hydrogen bonds, has been replaced by the Ile, Ala, Ser, Leu, Asp, etc. residues, had T_{den} smaller than T_{den} for the native lysozyme by 9 — 13 °C (pH 2.0). This is caused by a dissociated and uncompensated hydrogen bond.[267—269]

Temperature-sensitive mutations are scarcely encountered among aminoacid residues which are exposed to the solvent and are mobile. For example, the replacement of the Cys-54, Glu-128, and Pro-86 residues by any others does not affect the stability of lysozyme.[270] Similar results were obtained for the staphylococcal nuclease[271] and kanamycin-nucleotidyl transferase.[272] Six mutants with one aminoacid substitution in the C-terminal region by the method of segment-directed mutagenesis were obtained for the last enzyme. The stability of all the Gly-242 → Arg, Gly-242 → Glu, Gly-204 → Asp, Phe-230 → Ser, and Pro-252 → Leu (except only Glu-210 → His) mutants diminishes in the above sequence and is smaller than the stability of the native enzyme. According to the authors, this can be explained by replacements among the residues

immersed into the hydrophobic nucleus of the molecule and depends on the nature of the substituted residue.[272] For the *protein* of the λ-phage repressor, which consists of an N-terminal DNA-binding domain (92 residues) and a C-terminal domain (144 residues), 11 single-point mutants were obtained in the region of the N-terminal domain. Analysis of the CD spectra showed that the mutations of the aminoacid residues exposed to the solvent do not alter the stability of the λ-repressor, while the mutations of the inner aminoacid residues diminish it. Just one surface mutation Gln-33 → Tyr increases the thermal stability of the λ-repressor (type II residue). It has been suggested that the Tyr-33 residue introduced interacts with the Tyr-22 residue over a distance of 25 Å, which stabilises the structure.[273]

A rare proved example of mutations of type II residues is of interest. All the mutations in subtilisin (Met-50 → Phe/Ile-107 → Val/Lys-113 → Arg), which increase its stability in the region of alkaline pH, are located near the surface of the molecule, which has been demonstrated for the three-dimensionai structure of the protein. The modelling of the Met-50 substitutions showed that the introduction of the Phe residue makes the hydrophobic interaction with the Trp-113 residue more favourable, which has in fact been observed in the crystal structure of the protein.[274]

Examples involving the introduction of additional S—S bonds. A patent has been recently obtained for the preparation of stable proteins with additional S—S bonds.[275] For this purpose, X-ray diffraction data for a specific protein are read into a computer and the sites for the introduction of Cys residues are found taking into account the necessary conditions indicated above.[39] The gene coding for the given protein with nucleotide replacements giving rise to the Cys residue is modified by the method of site-specific mutagenesis and is incorporated into the plasmid and expressed in the required culture.

A stable mutant of the T4 phage lysozyme was obtained in this way. The native enzyme has two Cys residues (54 and 97), but contains no S—S bonds. Analysis of the X-ray diffraction structure of lysozyme led to the selection of positions 3 and 97 for the formation of the disulphide bond and the Ile-3 → Cys mutant was constructed (with retention of 77% of activity) (Fig. 9). Oxidation of lysozyme *in vitro* leads to the formation of the (Cys-3)—(Cys-97) S—S bond. The stability then increases approximately by a factor of 30 (at 67 °C). Thermal inactivation in the presence of dithiothreitol (DTT) showed that the stabilisation is caused precisely by the formation of the S—S bond and not by the Ile → Cys substitution. At the same time, at an elevated temperature the Cys-54 residue is involved in the thiol—disulphide exchange, which inactivates the lysozyme as a result of the formation of intermolecular S—S bonds. Mutants were therefore obtained in which the Cys-54 residue was replaced by other residues with retention of the S—S bond in positions 3 and 97, which increased the stability several times more (the replacements of only the Cys-54 residue by Thr and Val do not alter the stability of lysozyme).[276] For a detailed study of the role of the Cys-54 and Cys-97 residues in the oxidative inactivation of the T4 phage lysozyme, the Cys-54/Cys-97 → Val/Ser double mutant was constructed. Its stability proved to be higher than that of native lysozyme. The use of such mutations made it possible to discover the mechanism of the thermal inactivation of lysozyme. The reversible uncoiling of the molecule at elevated temperatures is complicated by secondary processes, the main ones of which are oxidative inactivation with

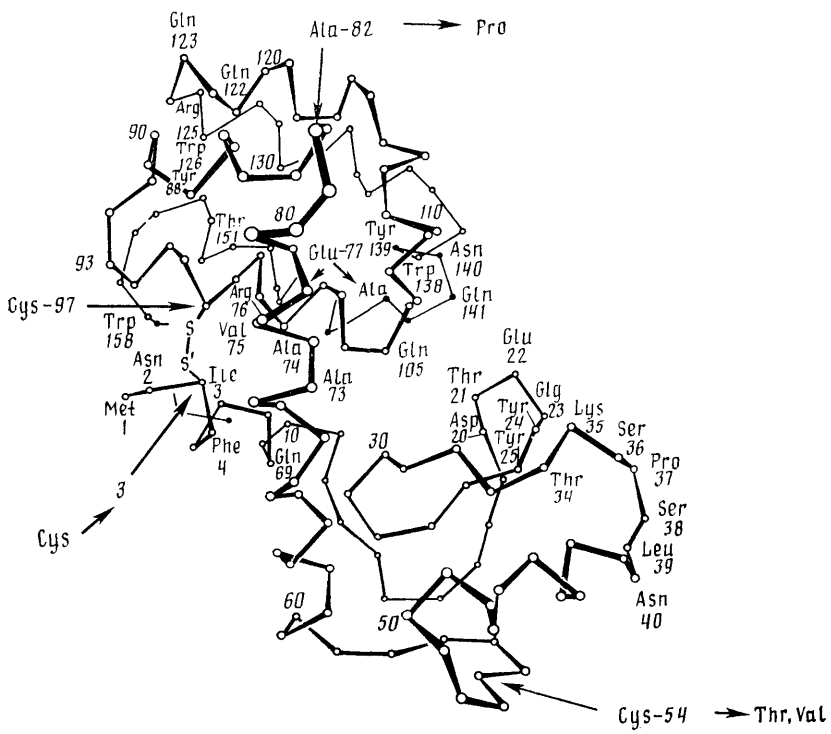


Figure 9. Steric structure of the T4 phage lysozyme.[277]

formation of oligomers linked by S—S bonds (this has been demonstrated electrophoretically). The removal of the Cys residue from lysozyme prevents the oxidative inactivation. On heating, this mutant uncoils reversibly with regeneration of the activity after treatment with guanidine hydrochloride (Gu.HCl). On the other hand, although the mutant with the 3—97 S—S bond, in which the Cys-54 → Val substitution has been carried out, does exhibit a higher stability, nevertheless the percentage regeneration of the activity after uncoiling in the presence of Gu.HCl and coiling up again is close to zero. Other proteins containing free Cys residues probably also undergo thermo-oxidative inactivation and can therefore be stabilised by similar aminoacid replacements.[277]

Dihydrofolate reductase (DFR) contains one polypeptide chain (159 residues). The Pro-39 residue is located opposite the Cys-85 residue. The distance between the α-carbon atoms is 6 Å, which is the same as in the S—S bond, and both residues are remote from the active centres. For this reason, the Pro-39 → Cys mutation leads to the formation of the 39—85 S—S bond after oxidation with dinitrobenzoate without a change in enzyme activity.[278] The DFR mutant obtained is more stable in relation to denaturation by urea and Gu.HCl to the extent of 1.8 kcal mol^{-1} and its coiling—uncoiling mechanism is altered.[279] Comparison of the crystal structures of the mutant and the native enzyme demonstrated their identity. The thermal stability of the mutant is approximately the same as that of the native DFR (T_m = 44 and 41 °C respectively).

Computer analysis for the λ-phage repressor protein[280] demonstrated the usefulness of the introduction of the (Cys-88)—(Cys-88′) S—S bond between the repressor subunits after the replacement of Thr-88 by the Cys residue.[281]

For the Thr-88 → Cys mutant, the S—S bond forms spontaneously; the mutant was more resistant to denaturation by urea than the native protein and T_m increased from 49 to 56—60 °C. On the other hand, the Tyr-85 → Cys mutant does not form a covalently bound dimer. Its chain structure is damaged and its stability is therefore lower than that of the native λ-repressor.[280]

For the subtilisin from *B.amyloliquefaciens*, which contains no S—S bonds, the Thr-22 and Ser-87 positions were selected for the production of such a bond. The Cys residues were introduced into these positions by the method of site-specific mutagenesis. They then formed spontaneously an S—S bond (either during the synthesis of the protein or during its secretion). These mutations did not affect the catalytic properties of subtilisin, while T_m increased from 58.9 to 62 °C. On the other hand, in the presence of DTT,† whereupon the S—S bond is ruptured, T_m = 56.2 °C. The rate of thermal inactivation of the Cys-22 → Cys-87 mutant is 1.5— 2 times lower, while $\tau_{1/2}$ in 8 M urea is higher by a factor of 2.[252]

Stabilisation of proteins by the replacement of residues with a high flexibility (Gly) in the uncoiled state of the protein by residues with a limited conformational freedom (Ala, Thr, Val, Ile, Pro). The replacement sites such that neither the tertiary structure of the protein nor the interactions with neighbouring residues were altered were selected for the T4 phage lysozyme by computer modelling. The selected candidates for replacement by the Ala residue were Gly-77 and Gly-113, while the Ala-82 residue was chosen for replacement by the Pro residue. Comparison of the crystal structures of the native and the Gly-77 → Ala and Ala-82 → Pro mutant lysozymes showed that they are virtually identical with the exception that the carbonyl carbon atom of the Glu-108 residue, closest to the Ala-77 residue, is displaced by 1.3 Å. Nevertheless the hydrogen bonds between the residues are unaffected. In the Ala-82 → Pro mutant, the H_2O molecule bound to the peptide nitrogen atom of the Ala-82 residue in the native protein is displaced. However, these are minor changes and do not influence the stability of lysozyme. For the Ala-77 and Pro-82 mutants, the T_m at pH 6.5 increase from 64.7 to 65.6 and 66.8 °C respectively, while the stabilisation energies are 0.4 and 0.8 kcal mol^{-1} respectively as a result of the decrease in the entropy of the uncoiling of the protein.[258] Similarly the Gly → Ala substitutions increase the stability of the *λ-repressor*[282] and of the *neutral protease from B. stearothermophilus* following the replacement Gly-144 → Ala.[283] This replacement was discovered on comparing the *t*- and *m*-enzymes. Admittedly, in such cases the increase in stability was explained by the replacement in the α-helix of the weakly helix-forming Gly residue by the effective helix-forming Ala residue.

The linear *correlation between the hydrophobicity of the substituted residues and the increase in* ΔG_{den} after point mutations was demonstrated for the α-subunit of tryptophan synthetase.[273,284] This correlation can be accounted for by the fact that the dielectric constant within the protein diminishes with increase in the hydrophobicity of the inner aminoacid residues, which intensifies the hydrophobic and electrostatic interactions. The point mutants of the α-subunit of tryptophan synthetase, isolated from mutant strains, are twice as stable as the native enzyme after the Glu-49 → Met, Gly-211 → Glu, and Gly-234 → Asp replacements and are less stable after the Phe-22 → Leu, Glu-49 → Gln, Leu-177 → Arg, Gly-211 → Arg, and Gly-213 → Val replacements. However, the tertiary structures of the mutants were not compared in these cases, which renders the results not altogether unambiguous.

Individual independent mutations can act additively on the stability of the protein and the accumulation of several such mutations with a stabilisation energy of 1 kcal mol^{-1} can give rise to a radical increase in ΔG_{den}. For example, the mutants of kanamycin-nucleotidyl transferase with the Asp-80 → Tyr and Thr-130 → Lys replacements and the Tyr-80/Lys-130 double mutant had maximum activities at 56, 60, and 62 °C respectively, while the native enzyme had a maximum activity at 52 °C. The resistance of the double mutant to proteolysis is greater than that of the point mutants and of the native enzyme.[285] The stabilisation is caused by additional hydrogen bonds and electrostatic interactions.

One of the causes of the instability of proteins is their oxidation with subsequent inactivation and denaturation. This refers particularly to proteins containing the Met, Cys, or Trp residues near the active centre. In subtilisin, the Met-50 and Met-222 residues are on the surface of the molecule, the Met-222 residue being close to the Ser-221 residue in the active centre. Following the replacement of Met-222 by the Cys-residue, the mutant had 138% of the original activity, while the replacements by the Ala and Ser residues resulted in mutants with 53% and 35% activities respectively. All other replacements led to a greater fall of the activity of subtilisin. Native subtilisin in 0.1 M H_2O_2 has $\tau_{1/2}$ = 2.5 min. The Met-222 → Ser, Ala, or Leu mutants are stable under these conditions for more than 1 h, while the

† Dithiothreitol (Translator).

Met-222 → Cys mutant is not oxidised by 0.1 M H_2O_2 at all. Thus the replacement of the Met-222 residue by residues resistant to oxidation increases the stability of subtilisin.[286]

The stability of proteins can be increased by reducing the surface area of the hydrophobic component in contact with the solvent, as shown for lactate dehydrogenase from *B. stearothermophilus*. The hydrophobic Ile-250 residue, located on the surface of the NAD binding pocket, was replaced by the hydrophilic Asn residue, whereupon k_{in} for the mutant diminished by a factor of 4.5 (at 90 °C), possibly as a result of the formation of the additional (Thr-246–(Asn-250) hydrogen bond.[287]

Examples confirming the general features of the variation of the stability of protein molecules and also examples where desirable results were achieved in the stabilisation of proteins on the basis of these features were considered above. However, many investigations showed that the influence of the aminoacid replacements on the stability is specific to each protein. As a rule, this applies to proteins with an unknown three-dimensional structure for which computer modelling of replacements and a reliable prediction of the effect are impossible.

In the monomeric form of iso-1-cytochrome *c* (the Cys-102 residue is blocked), the Pro-71 residue (the conservative residue as regards evolution) is important for the coiling of the protein and separates two short α-helical regions, defining the end of one and the beginning of the other helix. Its replacements by the Val, Thr, and Ile residues do not alter the functional properties of the structure but do alter the stability of the protein. Thus the stability of the mutants in relation to guanidine hydrochloride (ΔG_{den}, kcal mol^{-1}) diminishes in the following sequence: native; Val-71; Thr-71; Ile-71 (3.6, 2.6, 1.9, and 1.9 respectively).[288] The study of the denaturation kinetics showed that the location of the mutation in the primary structure determines the stage whose rate will change, while the nature of the substituent influences the change in the rate of the stage.[289]

The Pro-87 → Ser mutant of *adenylate kinase* from the temperature-sensitive strain of *E. coli* had k_{cat}/K_M smaller by a factor of 17 (at 27 °C) than the native enzyme and its thermal stability was lower. In the mutant adenylate kinase, the α-helix content diminished by 11%. Analysis of the CD spectra showed that the mutation broadens the structure of the enzyme. As a result, the sensitivity of the mutant to proteolysis increased. It has been suggested that the Pro-87 residue is located within the globule in the region of intensely interacting Asp-84, Phe-86, and Arg-88 residues and that its replacement by the more flexible and polar Ser residue disrupts these interactions and destabilises the structure of adenylate kinase.[290] The single point replacements in the α-subunit of *tryptophan synthetase*[291,292] and in dihydrofolate reductase[293] made it possible to discover the role of the individual aminoacid residues at each stage of the reversible denaturation of these enzymes by urea.

All the studies examined above were devoted to the stabilisation of enzymes in relation to reversible denaturation. The transition of the protein molecule to the irreversibly uncoiled state is caused by the aggregation of the protein molecules—the chemical modification of the functional groups more accessible to the solvent in the denatured state, as a result of which the molecule cannot coil up into the native conformation.

An attempt has been made to prevent the irreversible denaturation process with the aid of site-specific mutagenesis for *triose phosphate isomerase* (TPI)—an enzyme consisting of two identical subunits without S–S bonds and non-protein components. Analysis of the crystal structure established that the Asn residues located on the surface of the molecule between the subunits are deaminated in the thermal inactivation process with formation of charged Asp residues, which leads to the dissociation of the dimer into inactive monomers. The Asn-78 → Thr, Ile and Asn-14/Asn-78 → Thr/Ile mutants were obtained. Their half-lives at 100 °C increased from 13 to 17, 16, and 25 min respectively, and at the same time they had lower T_m (by 2–3 °C) than the native TPI, i.e. these mutations destabilise the enzyme in relation to reversible thermal inactivation.[294,295] This approach of the authors does not appear to be altogether correct, because the irreversible thermal inactivation of proteins involves not only (and not so much) the chemical modification of the functional groups but also physical processes leading to the aggregation of the denatured molecules after uncoiling. The stabilisation of the native conformation of the protein using the strategy described above appears more promising.

VI. Protein design

The construction of proteins with specified properties, structure, and stability, i.e. protein design, is a higher stage of development of genetic engineering. For a specific alteration of catalytic properties and substrate specificity, it is essential to investigate in detail the mechanism of the enzymic reaction and the structure of the substrate-binding section and of the active centre in order to alter the resistance to the effect of temperature or chemical reagents—factors which determine the stability of the protein, as well as the disposition of the groups, which are functionally important for catalysis, in order that the changes made in the structure to increase stability should not entail the loss of catalytic function. Protein design becomes possible provided that the X-ray diffraction structure of the protein has been obtained with a high degree of resolution. Such a structure serves as a basis for computer analysis and graphics.

For example, analysis of the steric disposition of the Met-222 group in subtilisin showed that its replacement by residues with small side chains (Glu, Ala, Ser, Cys, etc.) would not alter the conformation of the catalytic region and a high activity would be retained, while replacement by residues with long side chains would lower the activity of the enzyme. The results of mutagenesis confirmed the validity of the model. One of the mutants involving the replacement Met-222 → Cys showed a higher activity than the native subtilisin.[296]

Allowance for electrostatic effects in the active centre of subtilisin yielded mutants with an altered pH activity profile. Rules have been formulated for the construction of proteins with an altered pH dependence:[297] (1) the increase in the negative charge in the region of the active centre increases the pK_a for the acid groups, while an increase in the positive charge reduces the pK_a; (2) the change in the pH dependence is manifested at a low ionic strength; (3) the mutations should be carried out in such a way that the counterions do not concentrate in the region of the active centre. The change in the surface charge in the active centre of subtilisin (as a result of the replacement Asp-99 → Ser) (Fig. 10) led to an appreciable shift of the activity pH-profile to the acid region.[150,151,297]

The specific alteration of the substrate specificity of enzymes is achieved by altering the conformation of the substrate-binding region. The Gly-216 → Ala replacement in trypsin increased the catalytic activity in relation to arginine substrates, while the

Gly-226 → Ala replacement increased it in relation to lysine substrates.[141] In the case of lactate dehydrogenase, the active centre was reconstructed in the following way: Thr-246 → Gly (increase in the volume of the active centre), Asp-197 → Asn (neutralisation of the acid), and Glu-102 → Arg (introduction of a base to ensure the binding of a carboxylate). The ternary mutant oxidised malate 23 times more effectively than lactate and reduced oxaloacetate 500 times more effectively than pyruvate, while the native enzyme had a catalytic activity in relation to pyruvate 1000 times greater than in relation to oxaloacetate. Thus the mutant enzyme acquired the properties of malate dehydrogenase.[179]

In alcohol dehydrogenase, the long side chains of the Trp-93 and Thr-48 residues diminish the size of the substrate-binding pocket and the enzyme therefore catalyses most effectively the oxidation of alcohols with a short side chain (ethanol, 1-propanol). The replacement of these residues by residues of smaller size (Trp-93 → Phe and Thr-48 → Ser) increased the effectiveness of the oxidation of long-chain alcohols (1-octanol, 1-heptanol) compared with ethanol.[182]

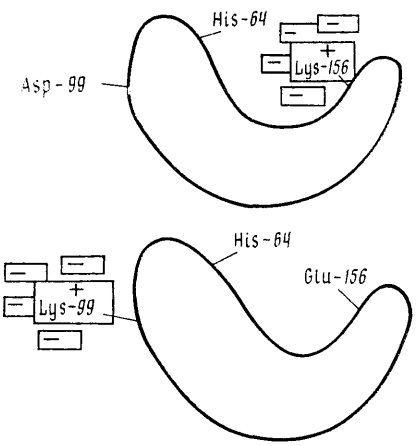

Figure 10. Schematic representation of the ionic atmosphere, made up of the Lys-99 and Lys-156 residues, of the active centre of subtilisin.[297]

The site-specific mutagenesis of haem ligands in cytochrome b_5 is an interesting example of the formation of a protein with new improved properties.[298]

The His-39 → Met replacement of the axial haem ligand greatly reduced the oxidation-reduction potential. The peroxidase activity in the reaction of the mutant protein with *o*-dianisidine increased by a factor of 30. In addition, the mutant acquired a new property—it catalysed the intermolecular oxidative demethylation of *NN*-dimethylaniline by H_2O_2. The native cytochrome b_5 is completely inactive in this reaction.

The C-terminal hydrophobic segment of penicillin-binding protein 5 from *E. coli*, which binds this protein to a membrane, was replaced by a shorter segment containing hydrophilic aminoacids, which led to the formation of a water-soluble protein with complete retention of its activity.[299]

The construction of proteins with a much higher stability by employing the general approaches and features examined in Section 5 is a brilliant example of protein design. The introduction of intramolecular disulphide bonds stabilised the T4 phage lysozyme,[276] subtilisin,[252] the N-terminal domain of the λ-repressor,[280] and dihydrofolate reductase.[180] The replacement of Met-222 in subtilisin by residues resistant to oxidation (Ser, Ala) greatly increased the stability of this enzyme.[286] The replacements of unbranched residues by branched β-carbon chains (Thr, Val, Ile) restricted the conformation of the protein and hence greatly increased the stability of the T4 lysozyme.[258]

Studies designed *to create protein-hybrids* possessing the set of properties of their constituent proteins are of interest. Thus the *E. coli* protein possessing adenylate cyclase and β-galactosidase activities has been constructed.[300] It consists of the first 556 (out of 848) aminoacid residues of adenylate cyclase (the enzyme responsible for the synthesis of cAMP), linked via the synthetic pentapeptide Val-Gly-Asp-Pro-Val to the eighth residue of β-galactosidase (M = 175 kD). The resulting chimeral protein is a tetramer. The pH optimum of the adenylate cyclase activity in the hybrid protein has been displaced to the alkaline region (from 8.5 to 9.5) and an excess of ATP does not inhibit the adenylate cyclase activity of the hybrid in contrast to the native enzyme, which can apparently be accounted for by the absence of a regulatory domain from the hybrid. The kinetic properties of the hybrid protein are close to those of both constituent proteins, but the hybrid is less stable than β-galactosidase. The hybrid of the human growth hormone and the signal peptide of the extramembrane *E. coli* protein OmpA has also been obtained by the genetic engineering method. The recombinant DNA was expressed in the cells of *E. coli* and the growth hormone synthesised was secreted into the periplasm of *E. coli*. It had the correct secondary structure and formed the required S–S bonds. Thus the addition of the signal peptide ensured the passage of the hybrid protein through the cell membrane of *E. coli* and the correct coiling of the protein synthesised with formation of the required disulphide bonds.[301]

—o0o—

The analysis of the literature described shows that the protein engineering technique is a revolutionary experimental instrument for the solution of fundamental problems in modern enzymology: the determination of the structure–function–stability of protein macromolecules relation. The study of numerous mutant proteins with the aid of computer graphics has provided an algorithm for the preparation of enzymes with properties specified beforehand in order to use them in biotechnology. The need for the employment of genetic engineering methods in modern protein chemistry is not only evident but is genuinely essential for the solution of both theoretical and applied problems.

The development of the concept of the chemical bond from hydrogen to cluster compounds

N P Gambaryan, I V Stankevich
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The principal types of chemical bond have been analysed, and their ranges of applicability noted. Fields in which the concept of a localised bond is inapplicable have been indicated, and, in particular, the electronic structure of Δ-polyhedral clusters has been examined. The principle of isolobal analogy has been discussed, and its unique importance for an understanding of the structure of organometallic compounds has been demonstrated.

The bibliography contains 136 references.

I. Introduction

The present-day theory of chemical structure is based on the apparatus of quantum chemistry and the generalisation of experimental data. The methods of quantum chemistry make it possible to obtain fairly reliable information on electronic structure and to predict the physicochemical properties of both existing specific molecules and hypothetical molecules. These characteristics are usually obtained by numerical experiments using computers, and are used either to interpret experimental data or to predict the properties of chemical compounds.[1] The solution of problems of this type has applications, however. It is of no less interest to develop the general principles of the classification of chemical compounds, to describe their structure, and to establish the relationships between structure and properties.[1,2]

Structural theories in chemistry are based on the concept of the chemical bond. This concept, which appeared long before the nature of chemical bonding became clear, arose as a result of the necessity, unavoidable in chemistry, to imagine the breakdown into parts of the integral objects of chemical studies, that is molecules. It was this breakdown of molecules into a set of known parts that made possible a clear description of their structure and the prediction of a number of their physicochemical properties.

The success of the classical theory of chemical structure and its subsequent development proves the appropriateness of the description of molecules by means of chemical bonds and structural formulae. Neither structural formulae nor chemical bonds are real objects. They are theoretical constructions, or ideal formulations.[3,4] The extremely fruitful nature of these abstract imaginary objects indicates, however, that they correctly reflect the most important features of chemical reality. The present review follows the devleopment of the concept of the chemical bond as it is applied to systems of increasing complexity, and indicates the ranges of applicability of this concept.

II. The hydrogen molecule and the chemical bond

The electron in the ground state of the hydrogen atom is in the single valence orbital of this atom, the 1*s*-atomic orbital (AO), which is a function of the spatial coordinates. In a pictorial interpretation, the square of this function defines the density of the electron cloud of the hydrogen atom at a given point in space.

In the hydrogen molecule, the electrons occupy not atomic orbitals but a molecular orbital (MO), encompassing both atoms. In the MO LCAO approximation, the molecular orbitals are constructed from the atomic orbitals. The two 1*s*-atomic orbitals φ_1 and φ_2 give two molecular orbitals: a bonding MO (BMO) $\psi_+ = (\varphi_1 + \varphi_2)/N_+$ which is favourable and whose energy is lower than that of the atomic orbitals, and an antibonding MO (AMO) $\psi_- = (\varphi_1 - \varphi_2)/N_-$ which is unfavourable and whose energy is higher than that of the atomic orbitals[5,6] (Fig. 1).

The density of the electron cloud in the molecule is proportional to the square of the molecular orbital $\psi_\pm^2 = (\varphi_1^2 + \varphi_2^2 \pm 2\varphi_1\varphi_2)/N_\pm^2$. In the expression obtained, the terms φ_1^2 and φ_2^2 correspond to the electron clouds of the atoms, but the most interesting term in it is the so-called interference term $2\varphi_1\varphi_2$. As a consequence of the existence of this term, the density of the electron cloud in the molecule is not equal to the sum of the densities of the atomic orbitals, that is the cloud is deformed.

In the case of the BMO, an excess of electron density arises between the atoms. The negative cloud attracts the positive nuclei. A two-electron two-centre chemical bond is formed.

In the case of the AMO, on the other hand, the interference term decreases the electron density between the atoms. The nuclei are as it were uncovered, their repulsion is not compensated by the attraction of the electrons, and in this state the molecule breaks apart.[7] This is of course a very crude description. Its value can be examined.

Progress in computer technology has provided extremely refined methods of calculation even for fairly complex systems. While they are of undoubted value in quantum chemistry, however, these studies provide comparatively little for its users. Fig. 2 helps to explain why this is so.[8] It gives the potential curves for the hydrogen molecular ion, characterising the change in energy with increase in the distance between the nuclei. Curve *1* was obtained in the approximation just described. The presence of the minimum on this curve reflects the fact that a bond is formed. The depth of this minimum correctly reflects the order of magnitude of the bond energy, and its position the bond length. The method of calculation can be improved. Thus if account is taken of the possible change in the effective charge of the atomic orbital, curve *2* is obtained for the optimum value of the effective charge. If account is also taken of the fact that in the field of a neighbouring nucleus the atomic orbital is polarised, losing its spherical symmetry, the result is curve *3*, part of which is shown in Fig. 2.

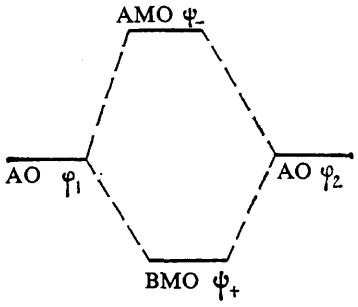

Figure 1. Correlation diagram for the H_2 molecule.

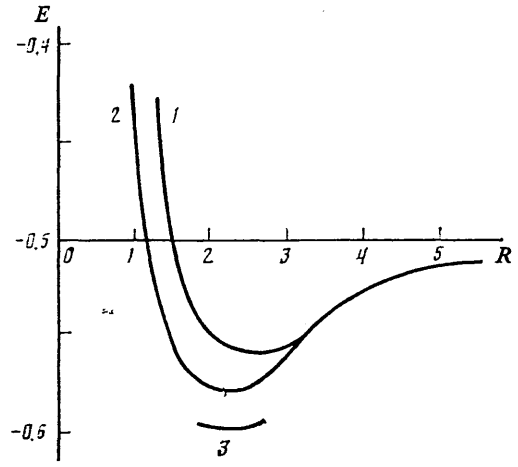

Figure 2. Potential curves for H_2^+ (in atomic units), obtained in different approximations of the MO method: *1*, molecular orbital constructed as a linear combination of the atomic orbitals of the hydrogen atoms; *2*, optimisation of the effective charge of the atomic orbitals carried out; *3*, a polarisation correction to the atomic orbitals introduced.

It is possible to improve the method of calculation even further, to expand the basis set, to abandon the MO LCAO approximation completely, and to proceed to an exact calculation. The results will be increasingly accurate, but this cannot be shown in Fig. 2, since the curves obtained coincide with curve *3*.

This situation is fairly general: the principal qualitative conclusions of greatest importance for chemistry are obtained even in the most approximate calculations. It is not accidental that Nobel Laureate R Hoffman, who has generated the most important theoretical concepts of the last quarter century, bases his work on the simplest quantum-chemical method, namely the extended Hückel method.[9]

Thus the chemical bonding in the two-electron diatomic system formed by the hydrogen molecule has been described by the two-electron two-centre bond. The description of polyatomic many-electron systems can now be considered.

III. The chemical bond and organic chemistry. The principle of isolobal analogy

A molecule is a single system bonded by forces of electrostatic interaction and consisting of relatively immobile nuclei and a cloud of rapidly moving electrons. In chemistry, however, the integral picture of chemical bonding is broken down, and replaced by a set of chemical bonds. It can be shown for the case of the methane molecule how the concept of the two-electron two-centre bond, which is strictly applicable to the hydrogen molecule and others, can be transferred to polyatomic molecules.

The carbon atom, like that of all the elements of the second period, has four valence orbitals. These are used to construct four equivalent tetrahedral hybride orbitals (HO),[10,11] each of which contains an electron. In the methane molecule, each of these HO is directed towards its own hydrogen atom. The hybrid orbital of the carbon atom and the atomic orbital of the corresponding hydrogen atom are used to construct localised molecular orbitals (exactly as in the case of the hydrogen molecule). The two atomic orbitals give two molecular orbitals: one bonding and one antibonding. The bonding orbital is occupied by two electrons. The four equivalent two-electron two-centre C—H bonds of methane are described in this way.[12]

The conceptual breakdown of a whole into parts is of course always arbitrary, so that the description of polyatomic molecules by means of two-centre bonds is also arbitrary, but the whole of chemical practice indicates that the concept of the chemical bond is extremely fruitful. The task is essentially to establish the fields of chemistry in which the concept of the two-centre bond reflects the principal features of chemical reality, and those in which it has to be replaced.

The electronic structure of the hydrides of the elements of period II following carbon can now be discussed, beginning with nitrogen. The nitrogen atom, like the carbon atom, has four valence orbitals; these can be used to obtain four tetrahedral orbitals, into which the valence electrons can be put. The nitrogen atom has five valence

electrons, however. If one of these is removed, then one electron remains in each hybrid orbital, so that it is possible, exactly as in the case of the methane molecule, to construct the four two-electron two-centre N–H bonds of the ammonium cation.

But what if the electron is not removed? One of the hybrid orbitals of nitrogen will then contain two electrons (Fig. 3). The bonding and antibonding molecular orbitals constructed from this orbital and the atomic orbital of hydrogen will then have to accommodate three electrons, and one electron enters the antibonding orbital. This is less favourable than remaining in the atomic orbital, and instead of a bond with the hydrogen atom, a lone pair of electrons appears on the nitrogen atom. Nitrogen forms only three N–H bonds. The oxygen atom has two lone pairs, the fluorine atom has three, and the neon atom has four lone pairs, and does not form any bonds.

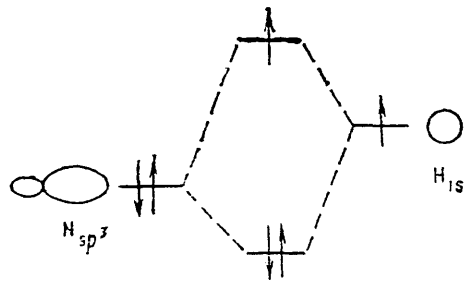

Figure 3. Correlation diagram of a three-electron system.

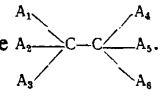
Thus when spare electrons appear, that is when the number of valence electrons becomes greater than the number of valence orbitals, lone pairs appear.[13] It will be seen that this is not the only way to distribute extra electrons, but it is the simplest and most widespread.

A number of simple groups can now be considered. Firstly, the fluorine atom, which is much more complex than the hydrogen atom. The only similarity between them is that the fluorine atom, like the hydrogen atom, has only one boundary orbital with an unpaired electron—one "working" boundary orbital.† The hydroxyl group also has only one boundary orbital with an unpaired electron, which coincides with one of the valence orbitals of the oxygen atom. Of the remaining three valence orbitals of oxygen, two are occupied by lone pairs and one is involved in the O–H bond. The NH_2 group also has only one orbital with an unpaired electron; of the remaining three valence orbitals of nitrogen, one is occupied by a lone pair, and the other two are involved in the formation of two N–H bonds.

The CH_3 group also has only one symmetrical boundary orbital containing an electron. The other three valence orbitals of the carbon atom are involved in C–H bonds.

† The boundary orbitals are the highest occupied and the lowest unoccupied orbitals.



Thus the groups CH_3, NH_2, OH, F, and H have the same number of boundary orbitals containing unpaired electrons. These groups are called isolobal (from "lobe"), and this is represented as follows:

$$CH_3 \overset{0}{\longleftrightarrow} NH_2 \overset{0}{\longleftrightarrow} OH \overset{0}{\longleftrightarrow} F \overset{0}{\longleftrightarrow} H.$$

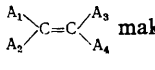
The well-known principle of isolobal analogy[14–17] can now be used.

According to this principle, isolobal groups can replace one another, so that as soon as methane is known to exist, it means that methyl fluoride may also exist, that the formation of methyl alcohol is probable, that the existence of methylamine is possible, and that ethane should be stable.

The statement that the replacement of a hydrogen atom in methane by a methyl group will give a stable molecule is based only on the fact that three valence orbitals of the carbon atom in the methyl group are involved in bond formation. The fact that they are involved in bonds with hydrogen atoms in particular is not important. Thus the principle of isolobal analogy suggests the existence of

molecules of the type  . The formula used the letter A,

to which no definite chemical significance is attached. This can be any group isolobal with hydrogen.



The ethylene molecule, which is made up of two methylene groups CH_2, can now be considered. Two of the sp^2 hybrid orbitals of the C atom of the methylene group are involved in C–H bonds. This leaves two boundary orbitals. The two-electron two-centre bonds of ethylene are constructed from these boundary orbitals: the σ-bond from the sp^2-orbitals and the π-bond from the *p*-orbitals orthogonal to them.[18–20]

Groups isolobal with the methylene group CH_2 can now be considered.

In the NR group, one of the valence orbitals of the nitrogen atom is involved in the N–R bond, and a second contains a lone pair. This leaves two boundary orbitals, in which the two remaining valence electrons of nitrogen are placed, so that this group is isolobal with the methylene group. The oxygen atom is also isolobal with the methylene group. Thus two of its four valence orbitals are occupied by lone pairs, and the remaining two are boundary orbitals, each containing an unpaired electron. Thus

$$CH_2 \overset{0}{\longleftrightarrow} NR \overset{0}{\longleftrightarrow} O$$

and according to the principle of isolobal analogy the existence of

ethylenes  makes it possible to assume the existence of

imines  and carbonyl compounds  .

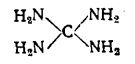
The acetylene molecule can now be considered. This molecule is made up of two methylidyne groups CH. One *sp*-hybrid orbital of the carbon atom of the CH group is involved in the C–H bond, leaving three orbitals: the symmetrical *sp*-orbital and two antisymmetric *p*-orbitals of the carbon atom perpendicular to it. Each of these boundary orbitals contains one electron. These orbitals are used to construct the three two-electron two-centre bonds of the acetylene molecule: one σ-bond and two π-bonds.[21] A group of any type, size, or structure, so long as it has three boundary orbitals with three electrons, will be isolobal with the CH group. In particular, the nitrogen atom is isolobal with the methylidyne group; one

valence orbital of the nitrogen atom is occupied by a lone pair, and the three remaining orbitals each contain one electron: CH ⟷ N. Thus hydrocyanic acid HCN and in general nitriles RCN exist.

The variety of isolobal groups and the infinite possibilities of their different combinations and superstructures indicates that by making use of the principle of isolobal analogy it is possible to "synthesise" on paper an unlimited number of molecules. And due credit must be given to chemists: very many of these compounds have also been obtained in flasks. Of course, when planning their syntheses, organic chemists did not know that they were using the principle of isolobal analogy.

The demonstration of the principle of isolobal analogy using the simplest examples was intended to emphasise its essential feature, namely the interchangeability of isolobal groups, which in turn is a consequence of the similarity in their ability to form chemical bonds. This ability is determined by the nature of the boundary orbitals.‡ A second, so to speak, technical aspect of the isolobal analogy is the establishment of the isolobal nature of groups. Groups are said to be isolobal if they have the same number of boundary orbitals with similar symmetry properties, similar three-dimensional structures, similar energy values, and the same number of electrons occupying these boundary orbitals.[16,17]

Organic chemistry has done extremely well without the isolobal analogy; more accurately, it has always used it, but only implicitly. the isolobal nature of the characteristic groups of organic chemistry was known to organic chemists, so to speak, historically, and was established empirically with no knowledge of the nature of boundary orbitals, long before the appearance of the concept of orbitals in general. To chemists, the isolobal nature of the above groups is obvious. The fruitfulness of the principle of isolobal analogy is revealed in non-traditional fields at the boundary between organic and inorganic chemistry, and in particular in organometallic chemistry.



Hoffmann was able not only to express clearly an idea which was in the air but also to select an extremely successful term,[14,15] which spread rapidly. Hoffmann, however, did not simply propose the term and the concept; he used it extensively and demonstrated its value. For most organometallic fragments, which are often very complex, isolobal character is neither obvious nor trivial. Hoffmann had therefore to determine the nature of the boundary orbitals of many organometallic fragments, and this led to the unique library of isolobal groups.[16]

The isolobal analogy makes it possible to understand the structure of complex organometallic compounds and clusters, reveals in so-called monsters usual organic structures in the most remarkable forms, and prompts the choice of completely unexpected directions in the search for new types of compound by analogy with organic chemistry. According to Hoffmann,[16] the isolobal analogy "... brings together different sub-fields of our central science. We are separated, split asunder — organic, inorganic, physical, biological, analytical chemists — by the very largesse of our creation. The variety of molecules we create, and the methods we use to study them, breed jargon and specialisation. Yet underneath the seeming complexity there must be a deep unity ...".

‡ Different boundary orbitals of the same group may be "working" orbitals, depending on the specific chemical situation. This explains the complexity and ambiguity of isolobal relationships, particularly when lone pairs are present together with unpaired electrons in the boundary orbitals.[16]

Chemistry lives and develops by analogies. An analogy, however, is an analogy, and not a law. Hoffmann often pointed this out, and warned that the isolobal analogy suggests possibilities, but does not necessarily guarantee their realisation.[16]

An example is provided by a molecule which is faultless from the viewpoint of the isolobal analogy, but which it has not yet been possible to synthesise:

Thus by using the concept of the two-electron two-centre chemical bond and the isolobal analogy it is possible to construct and describe an unlimited number of saturated and unsaturated molecules. It cannot be said, however, that all organic compounds are described completely by two-centre chemical bonds.

The conceptual breakdown of a molecule into two-centre bonds is fruitful only when it corresponds to chemical reality, that is when it is possible to regard these bonds as more or less independent of one another. In fact, of course, they do influence one another, but these influences should be slight. This condition is usually satisfied for carbon σ-bonds. This is due to the strength of these bonds, and the fact that they are compact and localised in space. π-Bonds are weaker, and more easily polarised. Their three-dimensional structure is such that the interaction of conjugated π-bonds is considerable. In large planar conjugated systems, individual π-bonds are often changed until they are unrecognisable, and in cyclic aromatic systems it is no longer possible to speak of two-centre π-bonds.

The π-electron systems of aromatic molecules are indivisible; they represent a single whole, to which the concept of two-centre bond is inapplicable.

IV. The chemical bonds formed by non-transition elements

The atoms of the elements of period III, like those of period II, each have four valence orbitals, in which their valence electrons are situated. The single but very significant difference between them and the elements of period II is that their valence orbitals are much larger and more diffuse.[22–24] This follows both from the most general physical considerations and from the fact that in the hydrogen atom and one-electron cations the average radius R of an orbital increases with increase in the principal quantum number n according to the law $R \sim n^2/Z$.[22] In many-electron atoms the relationship is naturally more complex, but the general trend is preserved. It is reflected, for example, in Slater's rules, which define the form of the Slater atomic orbitals.[23] The differences in the sizes of the valence orbitals of the atoms of the elements of periods II and III are also reflected in the positions of the radial density maxima[24] and in other characteristics.

As a result of the larger size of the valence orbitals, the simple bonds formed by the atoms of the elements of period III are longer, weaker, and more easily polarised. As a result, the interaction of these bonds with one another, and more particularly with π-bonds and with lone pairs, that is their ability to take part in hyperconjugation, is much greater. These interactions are not too strong, however, and the concept of the two-electron two-centre chemical bond is still applicable to the chemistry of the elements of period III.

Since the features of interest are those relating to the development of the concept of the chemical bond, and not the explanation of the properties of the elements of period III (see for example the review

by Bochvar and co-workers[25]), only two characteristics of these elements will be considered.

The atoms of the elements of period III are larger than those of period II, it is possible to place five or six atoms round them, and they form hypervalent compounds such as sulphur hexafluoride SF_6 and phosphorus pentachloride PCl_5.

The structure of the phosphorus pentachloride molecule[25,26] can be considered.

Three of the chlorine atoms lie in the equatorial plane. Phosphorus is joined to them by ordinary two-electron two-centre bonds lying at an angle of 120° to one another. These bonds are formed by three sp^2-hybrid orbitals of phosphorus. Phosphorus still has one $3p_z$-orbital at right angles to them (Fig. 4), containing its lone pair. Above and below the phosphorus atom there are two axial chlorine atoms. Phosphorus has two electrons with which to form two P—Cl bonds, but does not have two orbitals, one for a bond with the upper chlorine atom and another for a bond with the lower atom, and has only one, which has to interact with the two orbitals of the axial chlorine atoms.

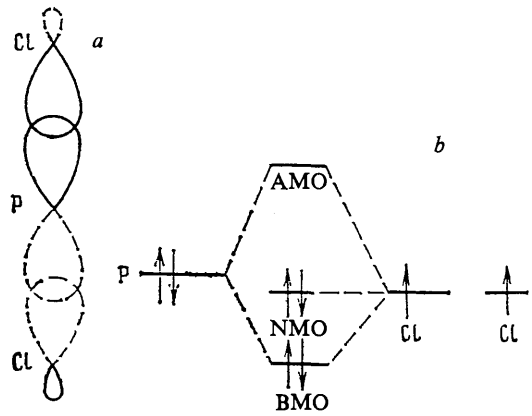


Figure 4. Three-centre bonds in hypervalent compounds: *a*, bonding molecular orbital of the three-centre bond; *b*, energy level diagram.

The three atomic orbitals give three molecular orbitals: one bonding (BMO), one non-bonding (NMO), and one antibonding (AMO). The four electrons are placed in these orbitals. Two enter the three-centre BMO. Three-centre BMO are much more favourable than two-centre BMO,[27] and the two electrons entering the three-centre BMO form the bond between phosphorus and the two axial chlorine atoms. The two remaining electrons enter the NMO; they are not involved in bonding, but do not hinder it.

This situation is characteristic of other hypervalent compounds. In hypervalent compounds a new type of bond appears — the two-electron three-centre chemical bond. The extra electrons not involved in bonding occupy non-bonding molecular orbitals.

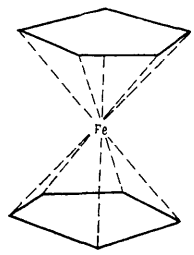
The second characteristic of the atoms of the elements of period III is also related to their size. As a result of the greater size of the valence orbitals of the atoms of the elements of period III, these atoms form longer bonds. At these distances, π-overlap is ineffective, and the elements of period III form extremely weak π-bonds.[28–30]

Thus in the nitrogen molecule N_2 the atoms are joined by three strong bonds, one σ-bond and two π-bonds, whereas the P_2 molecule does not exist under ordinary conditions, but is dimerised. It is more favourable for the phosphorus atom to form three strong bonds with three other phosphorus atoms situated at the vertices of a tetrahedron than to form one strong bond and two weak π-bonds in the P_2 molecule.[25]

The silicon atom, like the carbon atom, is tetravalent. One of the electrons of the lone pair, which in the ground state of the Si atom occupies the *s*-orbital, is transferred to the unoccupied *p*-orbital ("is unpaired"), and the energy expended is fully recovered in the formation of two additional strong bonds. The situation is quite different if the additional bonds are π-bonds, whose formation does not compensate the expenditure of energy for the "unpairing" of the lone pair of *s*-electrons.

Thus for carbon,[31] the equilibrium between hydrocyanic acid and its isomer is displaced towards the isomer containing tetravalent carbon HC≡N. The silicon analogue, on the other hand, exists in the form HN=Si with divalent silicon. The silicon π-bonds are so weak that the unpairing of the lone pair of silicon is unfavourable. For the same reason, silicon forms not the analogue of acetylene but its isomer with divalent silicon $H_2C=Si$.

The elements of period III form multiple bonds only when special conditions are fulfilled, for example when there is spatial protection of the multiple bond by bulky substituents.[32,33] The difficulty of synthesising compounds of the elements of period III with multiple bonds is leading to a search for the factors stabilising molecules containing these bonds.[34]



These examples have been considered in order to emphasise that because of the low strength of the π-bonds, the elements of period III do not form large planar conjugated molecules or more particularly aromatic compounds. Thus overall the concept of the two-centre bond plays an even greater role in the chemistry of the elements of period III than in organic chemistry.

V. The chemical bonds formed by transition metals

The situation is radically different for transition metals. Transition metals differ from non-transition elements in that, in addition to *s*- and *p*-valence orbitals, they also have five working *d*-orbitals,[35] that is they have a total of nine valence orbitals. They therefore obey not the octet rule but the effective atomic number (EAN) rule, that is their compounds are stable when the valence level of the transition metal atom contains 18 electrons.§ They can therefore form more bonds, and can have more lone pairs. The octahedral configuration with six bonds is most frequently encountered. The two-centre bonds formed by transition metals with other atoms and in particular with carbon do not differ essentially from the two-electron two-centre bonds formed by non-transition elements.[37] It is not these bonds, but the bonds in transition metal π-complexes, that are specific for transition metals.

§ For a modern substantiation of the Lewis—Sidgwick rule (the EAN rule), see the paper by Mingos and Hawes.[36]

The electronic structure of transition metal π-complexes cannot be described by two-centre bonds. It is possible to take as an example the molecule of ferrocene

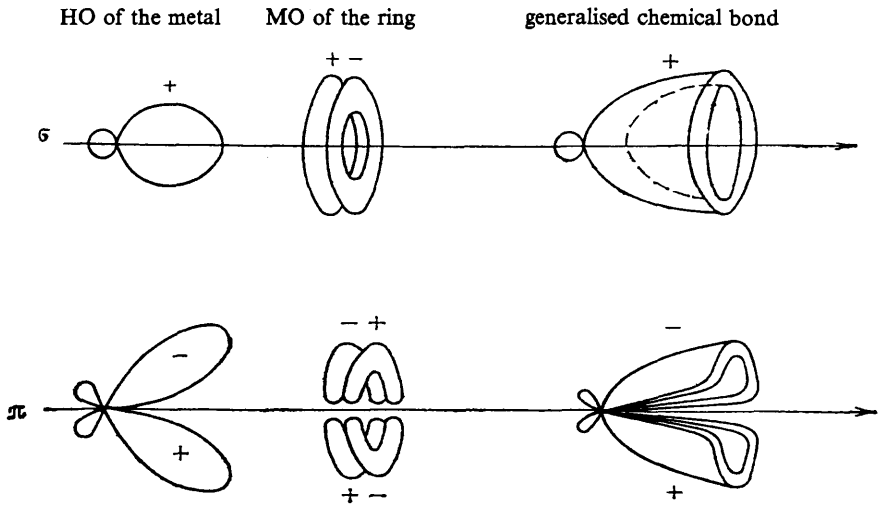
In this molecule the iron atom is situated between two parallel cyclopentadienyl rings so that it is next to ten carbon atoms. The iron atom cannot form ten bonds with carbon atoms, however. It has neither the electrons nor the orbitals for this. Since it is not possible to represent the π-complex uniquely using two-centre bonds, and a large number of structures usually have to be considered, the description using resonance theory is too cumbersome, and is used by hardly anyone apart from Pauling himself.[38,39] The opinion has grown that π-complexes have to be described by the molecular orbital method. The MO method, however, considers the molecule as a whole. The results are generally not readily transferable from one molecule to another. Moreover, it is difficult to interpret this description in a manner familiar to chemists.[40]

It is not necessary, however, for transition metal π-complexes, to give up ordinary chemical ideas based on the need for the conceptual breakdown of the whole into parts. It is simply because it is not possible in this case to represent the molecule by two-centre bonds that its conceptual breakdown into larger parts is necessary. In π-complexes the transition metal atom is bonded not to individual atoms of the π-ligand but to its entire π-electron system as a whole.

The bonding molecular orbital of an ordinary bond is constructed from the atomic orbitals of two atoms. It contains two electrons. This describes the two-electron two-centre chemical bond. The bonding molecular orbital of a generalised bond is constructed from an atomic orbital of the transition metal atom and a molecular π-orbital (MO) with appropriate symmetry from the ligand, which in its entirety acts as the second partner in the bond. This bonding molecular orbital contains two electrons. This describes the two-electron multi-centre generalised chemical bond.[40] Fig. 5 shows generalised chemical bonds (GCB) for the case where the ligand is a ring. The lowest-energy π-orbital of the ring is symmetrical with respect to the metal–ring Z axis. It can interact with a metal hybrid orbital (HO) symmetrical with respect to this axis. A headlight-shaped multi-centre generalised σ-bond is formed.[41] The ring π-orbitals of next lowest energy have one nodal surface, containing the Z axis, and are π-orbitals. They can interact with metal π-orbitals. Two-lobed generalised chemical π-bonds are formed. There are two such bonds.[40]

Generalised chemical bonds are localised metal–ligand (given ligand) bonds, independent of the number and nature of other ligands.[40] It has already been emphasised that the concept of bonds is meaningful only if the interaction of the local bonds into which it is possible to mentally break down the molecule is slight and if these local bonds are more or less independent of one another. A familiar example will show clearly that this condition is fulfilled for generalised chemical bonds.[35]

The example to be considered is benzenetricarbonylchromium. Chromium is joined to the ring by three two-electron multi-centre generalised chemical bonds: one headlamp-shaped σ-bond and two two-lobed π-bonds. The six electrons for these bonds are supplied by the ring. Chromium is joined to each of the carbonyl groups by a two-electron two-centre bond. The six electrons for these bonds are provided by the lone pairs of the carbon atoms of the carbonyl groups. The remaining three valence orbitals of the chromium atom are occupied by lone pairs. The six electrons of the generalised chromium–ring bonds, the six electrons of the bonds formed by chromium with the carbonyl groups, and the six valence electrons of chromium make up a total of eighteen electrons in the valence level of chromium, that is the molecule obeys the EAN rule and is stable. When the chromium atom is replaced by the manganese atom, there will again be 18 electrons if the number of electrons



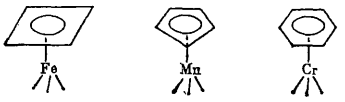


Figure 5. Generalised chemical σ- and π-bonds.

provided by the ring is reduced by one. In $(C_5H_5)Mn(CO)_3$, of the six electrons of the three bonds between the ring and the metal, one is provided by manganese, and five by the cyclopentadienyl ring, replacing the benzene ring. On going to iron, to satisfy the EAN rule, the cyclopentadienyl ring must be replaced by the cyclobutadienyl ring.

In the series of compounds considered, both the metal atom and the ring in the metal–ring bonds change, that is both partners of the generalised chemical bonds change. Nevertheless, the bonds with the carbonyl groups are not sensitive to this, and the arrangement and properties of the carbonyl groups remain almost unchanged in the series being considered.[42–48] Conversely, when the carbonyl groups are replaced by other groups, the changes in the properties of the ring also do not exceed those corresponding to the usual bond influences.[49–51] Thus generalised chemical bonds satisfy the requirement that they should be relatively independent of one another — the principal condition for the fruitful application of the concept of the chemical bond.

Two remarks may be added. Firstly, the similarity between the symmetry of the molecular π-orbital of the ligand and the symmetry of the atomic orbital of the transition metal can be only approximate. Generalised chemical bonds need not be as symmetrical as those between a metal and a ring. For example, the $Fe(CO)_3$ group can combine not only with cyclobutadiene but also with butadiene[52] and even with unsymmetrical heterobutadienes.[53,54] In this case, all that remains of the similarity in the symmetries of the orbitals of the metal and the ligand is the similarity in the distribution of the sign. The ligand π-orbital whose sign remains unchanged in the region between the ligand and the metal interacts with a hybrid σ-orbital of the metal; the ligand π-orbital whose sign changes only once in this region interacts mainly with hybrid π-orbitals of the metal, etc.

The second remark concerns the multiplicity of the metal–ligand bond.

For the atoms of transition metals in the middle of the series, the EAN rule applies rigorously, since they each have nine fully adequate valence orbitals. The ligand in a π-complex also has a whole set of molecular π-orbitals with different symmetry properties. Naturally, with the variety of these two sets of orbitals, it usually happens that there are not one but several pairs of orbitals in which the partners have symmetry suitable for interaction. Thus between a typical transition metal and a π-ligand, several generalised chemical bonds are formed simultaneously, that is the bonds in typical π-complexes are multiple bonds. For a metal of this kind, the bond with a π-ligand is much stronger than an ordinary metal–carbon σ-bond, so that competition between the two types of bond is unlikely.

For the transition metals at the start of the series, donor–acceptor bonds are weakened as a result of the high energy of the unoccupied *d*- and more particularly *p*-orbitals.[55] The formation of several such bonds is also unfavourable because it would lead to breakdown of the electrical neutrality principle, according to which the charges of the atoms in stable complexes should lie in the range from −1 to +1.[56] The most important feature, however, is that the small number of valence electrons in the metal atom excludes synergic stabilisation of the bonds as a result of the superposition of donor–acceptor and dative interactions. All this leads to breakdown of the EAN rule, and at the same time prevents the formation of additional generalised chemical bonds in π-complexes. Thus for example the compound Cp_2TiCl_2 can be described as a derivative of tetravalent titanium, whose four valence orbitals form two bonds with chlorine atoms and two bonds with the rings. The bond formed by titanium with the ring is an ordinary headlamp-shaped generalised chemical σ-bond. The strengths of the ordinary and generalised σ-bonds do not differ greatly from one another. This leads to competition between them.

An example is provided by the tetracyclopentadienyl derivatives of the transition metals at the start of the series. The competition between the ordinary and generalised chemical bonds in these molecules is also indicated by the easy exchange between the rings, joined to the metal in different ways,[57] and by the existence of a whole set of structures: with one h^5- and three h^1-rings (M = Mo [58]); with two h^5- and two h^1-rings (M = Ti,[59] Hf,[60] Nb, Ta [61]); with three h^5- and one h^1-ring (M = Zr [62]); and with four h^5-rings (M = U,[63] Th [64]). The EAN rule is not obeyed in any of these molecules.

Deviations from the EAN rule are also observed for the atoms at the end of the transition metal series. As a result of the rapid decrease in the energy of the *d*-orbitals of the transition metals at the end of the series, the *d*-electrons to a large extent lose the properties of valence electrons and become core electrons.[65] This brings to nought the synergic stabilisation of the donor–acceptor bonds by the dative interactions. At the same time, the increase in the difference in the energies of the *s*- and *p*-orbitals[66] leads to the successive exclusion of the latter from the bonding, leading to the appearance of 16-electron and then 14-electron complexes. The bonds formed by the π-ligands with the metal are no longer multiple bonds, and competition between the ordinary generalised chemical bond with the π-ligand and the ordinary simple two-centre metal–carbon bond again becomes possible.

Moving further down the periodic table does not lead to anything new in the development of the concept of the chemical bond. The non-transition elements of the subsequent periods are very similar to those of period III, and the transition metals of the later periods do not differ fundamentally from those of period IV.

VI. The chemical bond and electron-deficient compounds

The boron atom, like the carbon atom, has four valence orbitals, but only three valence electrons. The molecules of boron chloride BCl_3 and fluoride BF_3 are planar. The B–Hal bonds lying at an angle of 120° to one another are formed by the sp^2-hybrid orbitals of boron. The $2p_z$-orbital of boron remains unoccupied, but the p_z-orbitals of the halogens contain lone pairs of electrons. These pairs partly occupy the unoccupied p_z-orbital of boron, decreasing its unsaturation, and the molecules exist, although the two compounds are the strongest Lewis acids.[67] In boron hydride, the hydrogen atoms have nothing to give to the unoccupied p_z-orbital of boron and nothing with which to soften its unsaturation, and the hydride BH_3 does not exist, but dimerises. The structure of diborane B_2H_6 has been the subject of a discussion extending over several decades. The first workers[68–74] to establish the true structure of diborane included the Soviet scientists Nekrasov and Dyatkina.[70–74] Syrkin has told how Dyatkina's conclusion, based on quantum-chemical calculations, was not believed, because it was considered that the

structure of diborane had been established experimentally,[75,76] by methods including X-ray diffraction.[76] Diborane had been assigned an ethane-like structure. It was true that it was still not clear what held the two boron atoms together, since there were no electrons for a B—B bond (Fig. 6*a*). Many, including Lewis,[77] Sidgwick,[78] and Pauling,[79] tried to find a way out of this difficulty, and considered that the incomprehensible ethane-like structure of diborane had been "explained". Dyatkina was not stopped either by this Areopagus of theoreticians or by "experiment". Being a quantum chemist, she recalculated the diffraction pattern, and showed that the pattern agrees better with the diborane structure which she had proposed than with the ethane-like structure.[74]

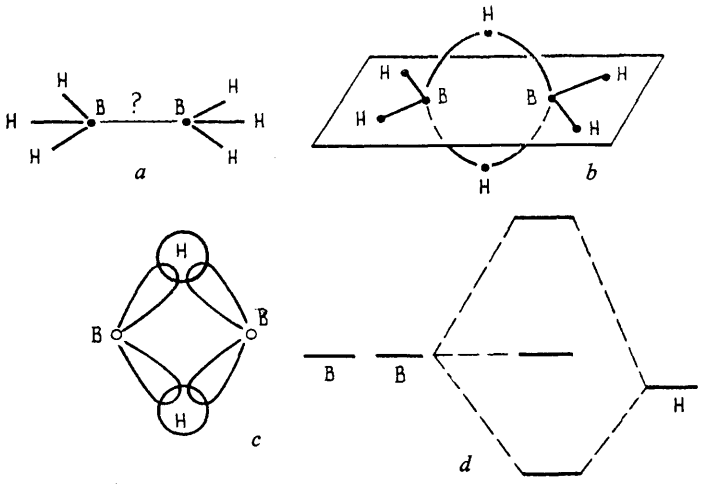

Figure 6. Diborane B_2H_6: *a*, ethane-like structure of diborane; *b*, actual structure of diborane; *c*, B—H—B bridging bonds of diborane; *d*, energy level diagram for the B—H—B bridging bond.

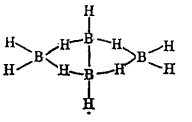
The structure of diborane has now been determined with limiting accuracy.[80] In the diborane molecule, four hydrogen atoms are joined to boron atoms by ordinary two-centre bonds. These four bonds lie in the horizontal plane, as in ethylene. The two remaining hydrogen atoms lie symmetrically above and below this plane, joining the boron atoms by two bent B—H—B bonds (Fig. 6*b*). The central part of diborane in the vertical plane is represented in Fig. 6*c*. These bonds are called bridging bonds.

The molecular orbitals of the bridging bond are constructed from the atomic orbitals of a hydrogen atom and two boron atoms. The three atomic orbitals give three molecular orbitals: bonding, non-bonding, and antibonding. The bonding orbital contains two electrons. A two-electron three-centre chemical bond is formed (Fig. 6*d*). Thus diborane contains a total of six two-electron localised bonds: four two-centre B—H bonds and two three-centre B—H—B bridging bonds. Thus 12 electrons are required, and these are provided by the six hydrogen atoms and two boron atoms.



Diborane is a representative of the so-called electron-deficient compounds, that is compounds in which the number of valence electrons is smaller than the number of orbitals. When the number of electrons is greater than the number of atomic orbitals, lone pairs are formed. When the number of electrons ($2n$) is exactly equal to the number of atomic orbitals ($2n$), two-centre bonds are formed. The $2n$ atomic orbitals form $2n$ two-centre molecular orbitals; of these, n are bonding, and n are antibonding. All the valence electrons occupy the n bonding molecular orbitals. If however the number of electrons is smaller, then some of the two-centre bonding molecular orbitals remain unoccupied, but molecules are stable only if all the BMO are occupied. The result is the formation of three-centre bonds. As before, two electrons are involved in the three-centre bond, but it is constructed from three atomic orbitals. Thus when there are insufficient electrons, the extra atomic orbitals can be absorbed by three-centre bonds. If for each extra atomic orbital a three-centre bond is formed instead of a two-centre bond, then all the bonding molecular orbitals will be occupied, and the molecule will be stable.[13,81]

The principle of isolobal analogy suggests that the role of bridge need not necessarily be played by hydrogen, and that the latter can be replaced by any group isolobal with it, for example the methyl group $CH_3 \leftrightarrow H$. In fact, the dimer of trimethylaluminium is constructed in exactly the same way as diborane. It contains two bridging Al—CH_3—Al bonds. The carbon atoms of the remaining methyl groups lie in a plane perpendicular to the plane of the bridges, and are joined to aluminium by ordinary two-centre bonds.[82]

Thus in electron-deficient compounds a new type of bond appears — the two-electron three-centre bridging bond.

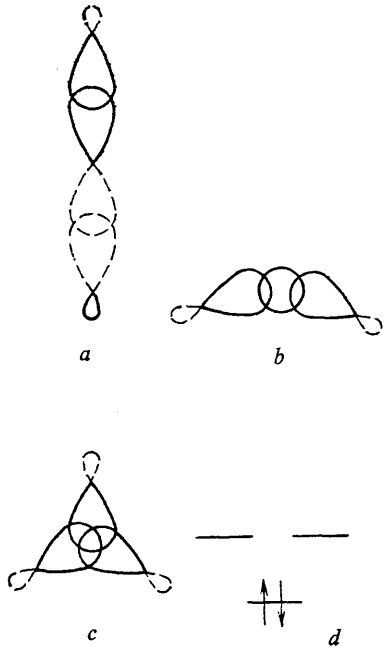
Next in order of complexity after diborane come the boron hydrides B_4H_{10} and B_5H_{11}. In the hydride B_4H_{10} [83,84] there are four boron atoms and therefore a deficit of four electrons. It should therefore contain four three-centre bonds to absorb the four extra atomic orbitals, so that the valence electrons will occupy all the BMO.

In fact, in the borane B_4H_{10} the boron atoms are joined by four hydrogen bridges. The remaining six hydrogen atoms are terminal, and are joined to boron by ordinary two-centre bonds. These ten bonds take up 20 electrons. The remaining two electrons join two boron atoms by a two-centre bond.

This description of one of the simplest boron hydrides is already not so simple, but, simple or complicated, it at least adequately reflects the structure of the molecule. Thus the structure is effectively described by more or less independent bonds with a definite location in space: seven two-centre and four three-centre bridging bonds. For the hydride B_5H_{11}, the situation is fundamentally less satisfactory. Before its structure is discussed, however, another type of three-centre bond can be considered (Fig. 7).

In the hypervalent compounds[26] examined above, the three-centre bond is produced because of a deficit of atomic orbitals; the central atom has only one orbital to form bonds with two ligands (Fig. 7*a*). The three-centre bridging bond,[13] formed because of a deficit of electrons, was then described. In this case the orbitals of the outer atoms overlap the orbital of the bridging atom (Fig. 7*b*). In addition to these open three-centre bonds, there exist central three-centre bonds,[13] where the atoms are situated at the vertices of a regular triangle, and their orbitals are directed towards the centre of the triangle. These three atomic orbitals give three MO: one

bonding and two antibonding. The symmetrical BMO contains the two electrons of the central three-centre bond joining three atoms (Fig. 7*c*).



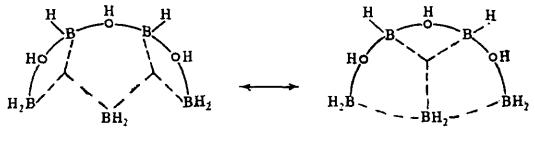


Figure 7. Three-centre bonds: *a*, three-centre bond in hypervalent compounds; *b*, bridging bond in electron-deficient compounds; *c*, central three-centre bond; *d*, energy level diagram of the central three-centre bond.

The boron hydride B_5H_{11},[85,84] in which there is a deficit of five electrons, has two central three-centre bonds and three bridging bonds with hydrogen bridges, that is five three-centre bonds are formed. The remaining eight hydrogen atoms are joined to boron by ordinary two-centre bonds. Another representation of the B_5H_{11} molecule is possible, however. All the localised bonds with hydrogen atoms, both the ordinary two-centre bonds and the three-centre bridging bonds, remain unchanged, but the bonding between the boron atoms can be represented not by two central three-centre bonds but by one central and one open, that is the B_5H_{11} molecule can be described by two different structures.

When a molecule can be described by different structures, it is a clear indication that the representation involving individual more or less isolated bonds does not correspond to chemical reality. The most complex non-conjugated organic molecule can be represented perfectly by a single structure, whereas the description of the simplest aromatic molecule, benzene, whose π-system forms a single whole, requires at least two structures.

The examination of aromatic systems is facilitated considerably by the fact that they are planar molecules whose framework is described by two-centre bonds. The indivisible whole is only their π-electron cloud, which in a first approximation does not interact with the framework[86,87] and can therefore be considered separately. The latent symmetry of π-systems,[88–90] and also the fact that they contain comparatively few electrons (one from each carbon atom), facilitate their examination considerably.

The situation with the boron hydrides is much more complicated. Boron hydrides form three-dimensional molecules, whose framework is usually a polyhedron. The framework of these molecules cannot be described by two-centre bonds. They can be described by a combination of two-centre and open and central three-centre bonds. A whole set of rules on how to do this has been developed[91] (some of these rules have been used implicitly in the description of the simplest hydrides given above). With increase in the size of the polyhedral molecule, the number of structures describing it increases. The description becomes ambiguous. The difficulties arise because the electronic system of the framework of these molecules is in fact a single whole. The attempt to break it down into individual bonds is artificial, and does not correspond to objective reality.

In contrast to the usual dismembering chemical approach, it is necessary to find a single indivisible system which can serve as a model of the electronic system of the boron hydrides, that is which can define their basic properties. The choice of such a model is suggested by the three-dimensional polyhedral structure of the boron hydrides. The greater the number of vertices in the polyhedron, the closer its similarity to the sphere on which its vertices are situated. The similarity between the three-dimensional structures of the boron hydrides and the sphere suggests the existence of an analogy in the basic properties of the wavefunctions of the electrons of these two systems.

Before describing the properties of the wavefunctions of an electron on a conducting sphere, however, the limits of applicability of this model can be considered, by comparing two polyhedra: the icosahedron with 12 vertices and 20 triangular faces, and its double the Archimedean polyhedron or dodecahedron, with 20 vertices and 12 pentagonal faces. The electron clouds of atoms situated at the vertices of the triangular faces of the icosahedron fill the entire face to its centre, so that the entire surface of the icosahedron is covered continuously by the electron cloud. The faces of the dodecahedron are much larger (Fig. 8), and in their central part the density of the electron cloud is negligible. The electrons do not cover the surface of the dodecahedron completely, but are localised along the edges. Thus the model of a sphere over which the electrons move in unhindered fashion is not appropriate for dodecahedral molecules. The model of the sphere is suitable for one-bond surfaces, and corresponds approximately only to polyhedra with triangular faces (Δ-polyhedra), that is Δ-polyhedral clusters.

The term "cluster" is used very broadly in chemistry.[92] It is often applied even to molecules containing simply two or more metal atoms joined to one another. Framework molecules such as cubane, prismane, dodecahedrane, etc. are also described as clusters.

For the present review, however, it is not specific molecules but the development of the concept of the chemical bond that is of interest. From this viewpoint, it is the Δ-polyhedral clusters that are of interest, and all the subsequent discussion will be devoted to them.

VII. The chemical bonding in Δ-polyhedral clusters

The form of the wavefunctions of electrons situated on a conducting sphere can be discussed.[93] The wavefunction of the ground state of an electron on a sphere has the same sign everywhere, and is distributed uniformly over the entire sphere. This totally symmetric state is one, and is conveniently represented as a ball uniformly coloured in a single colour. The next state on the energy scale can be described by a two-colour ball. The red half can be taken as corresponding to the positive sign of the wavefunction, and the blue half to the negative sign. The plane dividing the ball into red and blue halves—the equatorial plane—is the nodal plane of the function. On passing through this plane, the function changes sign, and on the actual plane the value of the function is zero. Thus in this state the wavefunction has one nodal surface.

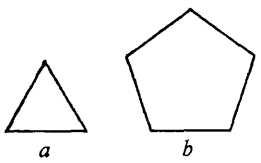

Figure 8. Comparative sizes of the faces of an icosahedron (*a*) and a dodecahedron (*b*) with edges of identical length.

In this case the electron density distribution is not uniform. The density is greatest at a pole, decreases gradually as the equator is approached, becomes equal to zero at the equator, and then increases again, reaching a maximum at the other pole.

The ball can be turned with its red pole upwards, forwards, or to the right. These three arrangements of the two-colour ball correspond to three states of the electron on the sphere with identical energies, that is to degenerate states.

The wavefunctions of the group of states next on the energy scale now have two nodal surfaces. There are five such states. These states are also degenerate. In each successive group of states on the energy scale, the number of nodal surfaces at which the wavefunction changes sign increases.

This is the most important property of the wavefunctions of an electron on a conducting sphere. The nodal properties of the wavefunctions are preserved even if the symmetry of the sphere is destroyed, for example by crumpling it. If bulges or dents appear on the sphere, the strict degeneracy of the wavefunctions is removed. Nevertheless, the ground state, in which the wavefunction has the same sign everywhere, is followed by a group of three wavefunctions with similar energies and one nodal surface, then by a group of five wavefunctions with similar energies and two nodal surfaces, etc.

The examination of the polyhedral boron hydrides can begin with the *closo*-hydrides. The *closo*-hydrides are hydrides in which the boron atoms are situated at the vertices of closed Δ-polyhedra. In these compounds, each boron atom is joined to a hydrogen atom, so that their formula is B_nH_n. The B—H bonds are directed outwards along the radius, and are *exo*-bonds. The *exo*-bonds are strongly localised, and undergo practically no interaction with the rest of the molecule. After the formation of one *exo*-bond, boron still has two electrons and three valence orbitals: one radial, directed towards the centre of the polyhedron, and two tangential, directed one along the parallel, and the other along the meridian. The bonding of the cluster framework involves these so-called framework electrons and orbitals. A boron hydride B_nH_n has a total of $2n$ framework electrons and $3n$ framework orbitals, of which n are radial, and $2n$ tangential. The $3n$ atomic orbitals of boron are used to construct the $3n$ molecular orbitals of the polyhedron. A pictorial representation of the structure of the molecular orbitals obtained from the radial atomic orbitals is provided by the wavefunctions of an electron on a conducting sphere, described above. A pictorial representation of the construction of the molecular orbitals from the tangential orbitals (although the nature of these orbitals is also determined by the form of the wavefunctions of an electron on a conducting sphere) is much more complicated. This will not be considered here, and the results will simply be presented.[94–96]

The most favourable lowest molecular orbital does not have a nodal surface, and the electron density is distributed uniformly over all the boron atoms. It is constructed only from the radial atomic orbitals of boron; the tangential orbitals cannot take part, from symmetry considerations. The $2n$ tangential orbitals of boron form $2n$ molecular orbitals, of which n are bonding, and n antibonding. The bonding molecular orbitals obtained from the tangential orbitals can interact with combinations of the radial orbitals having appropriate symmetry. As a result of this interaction, the bonding molecular orbitals are stabilised, but their number remains unchanged. This gives n bonding molecular orbitals constructed from tangential orbitals with an admixture of radial orbitals, and one totally symmetric bonding molecular orbital, constructed only from radial orbitals, that is a total of $n + 1$ bonding molecular orbitals.

These qualitative conclusions, based on the model approach, have been fully confirmed by MNDO calculations for the boranes.[97]

The $n + 1$ molecular orbitals obtained should contain $(n + 1)$ electron pairs. The boron *closo*-hydrides contain only $2n$ framework electrons, that is there is a deficit of two electrons. Since stability of the molecule requires that all the bonding molecular orbitals be occupied, the boron *closo*-hydrides are stable as the $B_nH_n^{2-}$ dianions.

The two electrons required can also be supplied to the polyhedron in other ways. The CH group also has three boundary orbitals, one σ and two π, that is the composition of the boundary orbitals is the same as that for the BH group, but the CH group has an extra electron. The two electrons required can therefore be obtained if the BH groups at two vertices of the boron hydride are replaced by CH groups. This gives the stable neutral *closo*-carboranes $C_2B_{n-2}H_n$.

The *closo*-boranes and *closo*-carboranes obtained can now be "broken down". This can be done for the case of the icosahedron, the hydride with 12 vertices. It has $12 + 1 = 13$ BMO, so that to be stable, it requires 26 framework electrons, that is this icosahedron will be stable (according to the general rule) either as the $B_{12}H_{12}^{2-}$ dianion (see its prediction,[98] synthesis,[99] and structure[100]) or as the carborane $C_2B_{10}H_{12}$ (see the synthesis of the 1,2-,[101–104] 1,7-,[105] and 1,12-isomers,[106,107] and the structure of the 1,2-,[108] 1,7-,[108] and 1,12-isomers[106]). The removal of BH from one of the vertices gives a molecule with a framework resembling a nest. These structures are called nest-like or *nido*-structures. In the distortion of the structure on going from the *closo*-borane to the *nido*-borane, the

number of bonding molecular orbitals remains unchanged,[109] that is the stability of the *nido*-borane still requires 26 electrons, but there are only 11 BH groups, that is there is a deficit of four electrons.

The electrons required can be obtained in very different ways:[110] the simplest is by replacing four BH groups by CH groups to give the neutral stable *nido*-carborane $C_4B_7H_{11}$. The four electrons can also be obtained by adding four hydrogen atoms to the $B_{11}H_{11}$ nest, to give the boron hydride $B_{11}H_{15}$. These four hydrogen atoms naturally are situated at the edge of the nest, as it were bringing the surface of the *nido*-borane up to spherical. The exact arrangement of these four hydrogen atoms has not been established. Different versions have been discussed: four bridges formed along the edge of the open pentagonal face, or an arrangement in which only some of these hydrogens are bridging, and the others terminal. These terminal B–H bonds are directed along the meridians towards the missing vertex (*endo*-bonds).

The removal of another vertex from the icosahedron gives a structure which is called a spider-web or *arachno*-structure. Surprisingly, this structure as it were preserves the memory of its origin from the icosahedron, and for its stability still requires the same 13 pairs of electrons.[109] Now, however, there remain only 10 vertices, so that there is a deficit of six electrons. Again, these can be obtained in different ways, for example as follows.

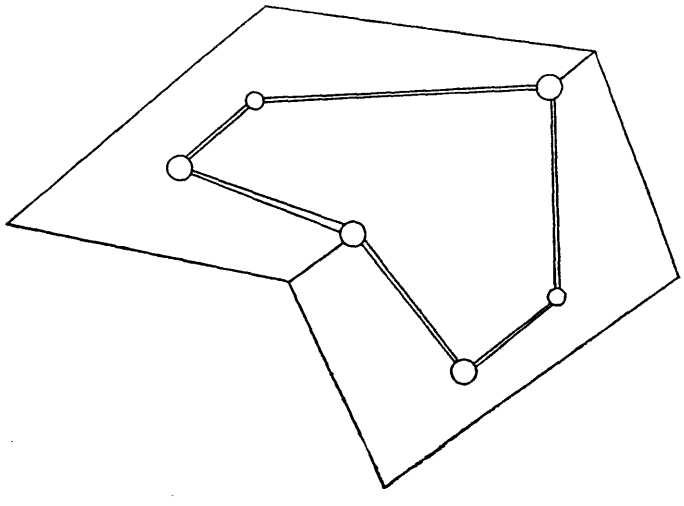

Figure 9. Boundary of the "hole" formed by the removal of two adjacent vertices of an icosahedron.

The edge of the hole produced by the removal of two vertices from the icosahedron forms a hexagon folded in half (Fig. 9). It would be possible to obtain the required six electrons by placing six bridging hydrogen atoms along the edge of this hexagon. They would interfere with one another, however, and the *arachno*-borane $B_{10}H_{16}$ is unstable.[110] Bridging hydrogen atoms are placed only on the two opposite sides of the hexagon farthest from the fold. The atoms in the position of the fold form *endo*-bonds with Lewis bases, which contribute their lone pairs to the cluster.[111] For example, the *arachno*-boranes $B_{10}H_{12}(CH_3CN)_2$,[112,113] $B_{10}H_{12}(NR_3)_2$,[114] and $B_{10}H_{12}(SR_2)_2$ [115] are formed in this way. The procedure involving breakdown of the icosahedron can be continued further. Another form of molecular design, based on the principle of isolobal analogy, that is on the replacement of a BH vertex in the neutral stable carborane $C_2B_{10}H_{12}$ by a group isolobal with it, can be considered. The alkylammonium group is naturally isolobal with the BH-group. The beryllium atom, like the boron atom, has four valence orbitals, but only two valence electrons. Thus to obtain a group isolobal with BH, Be must be joined to a base providing the electrons for the *exo*-bond. The $BeNR_3$ group is isolobal with BH. For the atoms of the group IV elements in the ground state, one valence electron is occupied by a lone pair, and the remaining three boundary orbitals contain two electrons, so that the tin atom, for example, is isolobal with the BH group.

More complex groups isolobal with the BH group can now be considered. The $Fe(CO)_3$ group can be taken first. Iron is a transition metal, so that it has nine valence orbitals. Of the eight valence electrons of the iron atom, six are situated in three valence orbitals, forming its lone pairs. Another three orbitals are involved in the formation of bonds with the carbonyl groups, which provide the electrons for these bonds. This leaves two electrons and three orbitals, one σ and two π. Thus the $Fe(CO)_3$ group, and also the $Ru(CO)_3$ group, are isolobal with the BH group. In the $(C_5H_5)Co$ group, cobalt is joined to the ring by three bonds: one headlamp-shaped σ-bond and two two-lobed π-bonds. The formation of these bonds uses three valence orbitals of cobalt and one of its electrons. Another three valence orbitals are occupied by the three lone pairs of cobalt. This leaves three valence orbitals and two electrons, that is the $(C_5H_5)Co$ group is also isolobal with the BH group. In the case of nickel, a group isolobal with the BH group is obtained when it combines with cyclobutadiene. In addition, the $Pd(C_4Ph_4)$ group is isolobal with the $Ni(C_4H_4)$ group, and hence with the BH group.

The isolobal groups

AlC_2H_5 (Ref.116) $\leftrightarrow$ $BeN(CH_3)_3$ (Ref.117) $\leftrightarrow$ Sn (Ref.118) $\leftrightarrow$

$Fe(CO)_3$ (Ref.119) $\leftrightarrow$ $Ru(CO)_3$ (Ref.120) $\leftrightarrow$ $Co(C_5H_5)$ (Ref.121)

$\leftrightarrow$ $Pd(C_4Ph_4)$ (Ref.122) $\leftrightarrow$ BH

can and do replace the BH group in the icosahedron of the carborane $C_2B_{10}H_{12}$. This gives metallocarboranes,[116–122] including compounds with transition metal atoms.

The ligands can be removed from a transition metal atom situated at a vertex of the icosahedron. This atom provided three valence orbitals and two electrons for the cluster. Six electrons form lone pairs. This leaves three valence orbitals, and if the transition metal is nickel, it leaves $10 - 2 - 6 = 2$ electrons, that is this icosahedron with the stripped nickel atom at a vertex forms a group isolobal with the BH group, so that it can replace this group in another carborane. This gives a structure in which two icosahedra have a nickel atom as a shared vertex (see its synthesis[123] and structure[124]). This iso-electronic cluster also exists for cobalt as the anion,[121] and for iron as the dianion.[125] These are the so-called *commo*-structures.[126]

The fruitfulness of the principle of isolobal analogy is sufficiently clear from the examples given. No more will be given, although it would be possible to describe a large number of other beautiful structures, since in accordance with the principle of isolobal analogy it is possible to replace other vertices and also to extend considerably the list of isolobal groups.

The chief importance of the principle of isolobal analogy is that it enables organometallic chemists to think freely about their field of chemistry. In other words, the principle of isolobal analogy in the chemistry of organometallic compounds fulfils a role analogous to that of the theory of chemical structure in organic chemistry. When the principle of isolobal analogy is used in this way, a considerable simplification of the definition of the isolobal nature of groups is possible. Groups can be described as isolobal if they have the same number of boundary orbitals and the same number of electrons in them. When these two conditions are observed, the requirement of an approximate correspondence in the three-dimensional structure, energy, and symmetry of the boundary orbitals[16] is usually satisfied automatically.

It should however be emphasised that the "isolobal analogy" suggests possibilities, but does not guarantee their existence.[16] The use of "libraries" of isolobal groups[16] may help to estimate more accurately the probability of realising conceived plans.

The naturally developed definition of isolobal groups, according to which the number of boundary orbitals should be the same and they should contain the same number of electrons, was adopted by Hoffmann slightly later,[16] and in his first papers[14,15] he emphasised that isolobal groups are groups with the same number of boundary orbitals, and the presence of the same number of electrons is not required. Although the definition now adopted undoubtedly has a much wider range of application, some advantages of the initial version of the definition of isolobal character are worth noting. In fact, analogous bonding ability and hence the possibility of the mutual replacement of groups are determined mainly by the number and nature of their boundary orbitals. The number of electrons required for bonding, however, can be provided in the most varied ways. Examples include the above-mentioned *commo*-polyhedra $(C_2B_9H_{11})_2Ni$, $[(C_2B_9H_{11})_2Co]^-$, and $[(C_2B_9H_{11})_2Fe]^{2-}$. All three groups $C_2B_9H_{11}M$ (M = Ni, Co, Fe) have the set of boundary orbitals required for the successful replacement of a BH vertex, and the electron deficit is made up by the fact that in the case of Co [121] and Fe [125] these structures are produced as singly- and doubly-charged anions.

The deficit of framework electrons is made up in an interesting way in the diferracarborane $[(C_5H_5)Fe]_2C_2B_6H_8$. In this *closo*-metallocarborane, two BH vertices are replaced by $Fe(C_5H_5)$ groups. The $Fe(C_5H_5)$ group also has the set of boundary orbitals required for the replacement of the BH vertex, but the three boundary orbitals of this group contain only one electron. It would therefore seem that the replacement would lead to a deficit of two framework electrons. In fact, this deficit is made up by the spontaneous ionisation of the iron atoms. This gives a paramagnetic cluster with two iron atoms in the ferricinium state and with the required (22) number of framework electrons.[127]

Another way of making up the deficit of framework electrons is found in the icosahedral rhodium cluster $[Rh_{12}(CO)_{27}Sb]^{3-}$.[128] In this complex, all the vertices of the icosahedron are occupied by rhodium atoms, from three rhodium tricarbonyls and two rhodium dicarbonyls. In the tricarbonyl, three valence orbitals of rhodium are involved in the formation of bonds with the carbonyl groups, which provide the electrons for these bonds. Three valence orbitals of rhodium are occupied by its lone pairs. The remaining three valence electrons of rhodium occupy its remaining three valence orbitals, that is this is a group with three boundary orbitals and three electrons in them. In rhodium dicarbonyl, two of its valence orbitals are involved in the formation of bonds with the carbonyl groups, four orbitals are occupied by lone pairs, and the three boundary orbitals contain only one electron. The rhodium atoms provide $(3 \times 3 + 9 \times 1) = 18$ electrons for the cluster,¶ but a total of 26 are required. From the charge of the cluster (–3), it follows that there is a deficit of five electrons. The cavity of the cluster, however, contains an antimony atom, which provides the five electrons required by the system of framework electrons.

This example introduces another type of bond — the interstitial bond. The interstitial atom is situated inside the cavity in the cluster; its valence orbitals interact with the framework bonding molecular orbitals of the cluster, stabilising them, without changing their number.

The cavities in transition metal clusters are naturally larger than those in boranes, and this method of satisfying the requirement for electrons and stabilising the structure is extremely common.[129] Clusters with interstitial hydrogen, carbon, nitrogen, phosphorus, arsenic, antimony, and sulphur are known.[129] The stabilising influence of the interstitial atom leads to the production of various exotic structures, such as the icosahedron of transition metal atoms given above.

Thus the isolobal analogy produces infinitely varied sets of clusters. The isolobal analogy clearly reveals the unity of the whole of chemistry, leading to the mutual replaceability of groups and atoms from completely different positions in the periodic table. In the attempt to emphasise the unity of chemistry, attention has been drawn primarily not to the differences between clusters but to what they have in common. What they have in common is determined by the similarity between the molecular orbitals of the cluster and the wavefunctions of the electrons of a conducting sphere,[94–96] which leads to the rule of $n + 1$ pairs of framework electrons.[130,131] Nevertheless, however, boranes and transition metal clusters differ significantly. Thus for boranes, polyatomic clusters and in particular icosahedral structures are stable, whereas for transition metal clusters, the octahedral structure is most characteristic. In the build-up of a cluster of transition metals, its polyhedron usually does not expand. Most frequently, the additional atom crowns a triangular face, and a cap consisting of the transition metal with its ligands appears above the face. What then happens to the framework MO? The metal–ligand group which has approached the face of the cluster has three boundary orbitals. The remaining six valence orbitals of the transition metal are involved in bonds with the ligands and are occupied by lone pairs. Of the three boundary orbitals, one is a σ-orbital, and the other two are π-orbitals. These orbitals should interact with the bonding MO of the cluster. Naturally, for this interaction the important feature is not the form of the MO as a whole but its structure at the face which the transition metal atom has approached. Among the BMO of the cluster there will always be some which will not change sign at this face, and some which will change sign once, that is σ- and π-orbitals. These will interact with the boundary orbitals of the approaching group. As a result of this interaction, the BMO of the cluster are stabilised, but their number remains unchanged. This is the so-called capping principle:[132] the number of framework electrons remains unchanged when a cap appears above a face of the polyhedron. Transition metal clusters grow mainly in this way; a cap appears above one face, then another, a third, and a fourth. Caps can appear, however, not only above

¶ The description is idealised. In fact, many of the carbonyl groups are bridging groups, but this does not alter the total electron count.

the original faces of the cluster but also above the newly formed faces. The more the cluster grows, the more frequently a part of the metal lattice can be recognised in its metallic framework.

How large must a cluster be to acquire the properties of the metal? There is as yet no definite answer to this question. The size of the cluster required for this, given by calculations using methods of the SCF-X_α-SW type (about 20 atoms), is much smaller than that given by EHM calculations.[133] In any case, when the number of atoms is sufficiently large, the cluster must be regarded basically as a metal particle.

Hoffmann, who so successfully built a bridge between organic and inorganic chemistry,[16] is now actively engaged in building a bridge between the theoretical approaches of quantum chemistry and the theory of the solid state.[134] This direction of the development of theory will not be considered here, and the review will end with a discussion of gold clusters.

Gold clusters apparently break all the cluster laws, but actually they provide clear confirmation that the electronic system of a cluster is a single entity, whose basic properties are determined by the properties of the wavefunctions of an electron on a conducting sphere.

VIII. The chemical bonding in gold clusters

In all the clusters examined so far in the present review — boranes, carboranes, heteroboranes, metallocarboranes, and transition metal clusters — the atoms of the cluster have formed framework bonds using three orbitals — one radial and two tangential.

This "material" has been used to construct the molecular orbitals of the clusters, which should be similar to the wavefunctions of an electron on a conducting sphere. These two features led to the rule of $n + 1$ electron pairs.

It has been seen how strictly this rule applies. It is possible to change the nature of the vertices in the cluster beyond recognition, it is even possible to remove them completely, yet when there are $n + 1$ electron pairs the framework of the cluster, no matter the number of atoms making it up, takes the form of an n-vertex polyhedron, or a fragment of one in the case where vertices have been removed.

Familiarity with clusters leads to never-ending amazement at the astonishing variety and refinement of the ways in which the rule is followed.

Gold does not obey this rule. What is happening?

Gold is the penultimate element in a transition metal series. At the end of a transition metal series, the energy of the *d*-orbitals is lowered considerably, and the lone pairs of electrons occupying them are gradually transferred to the core and become inactive. At the same time, the gap between the energies of the *s*- and *p*-orbitals increases. The *p*-orbitals become ineffective, and gradually cease to take part in bonding.

The cluster $(AuR)_n$ ($6 \leqslant n \leqslant 12$) can be considered.[135] The Au—R *exo*-bond is formed by an *sp*-hybrid orbital of gold, and is directed outwards along a radius of the cluster. The second *sp*-hybrid orbital of gold is directed along the radius towards the centre of the cluster. This is a radial orbital. The energies of the two unoccupied tangential *p*-orbitals of gold, directed along the parallels and meridians of the sphere, are high on the scale, and these orbitals practically do not function. Thus the gold cluster differs from all the clusters examined so far in the present review in that the tangential system of orbitals plays practically no part in bond formation, and the formation of the cluster involves only the interaction of the radial orbitals. Which of them form the molecular orbitals? The most favourable, that is the totally symmetrical orbital, is constructed only from radial orbitals (all clusters have one). This is followed (remembering the two-colour ball) by three orbitals with similar energies, each of which has one nodal surface. The next MO each have two nodal surfaces; in them, the sign of the function changes too frequently, and the orbitals are unfavourable and anti-bonding. Thus these radial orbitals give only four bonding molecular orbitals: one very favourable totally symmetrical orbital, and three orbitals with similar energies and one nodal surface. This statement is true, irrespective of the number of vertices in the cluster.

Thus because of the low effectiveness of the system of tangential orbitals, the number of BMO in the *closo*-clusters of gold ($6 \leqslant n \leqslant 12$) is four, so that the gold cluster is maintained by eight framework electrons. This is not quite enough for large clusters, but large gold clusters are stabilised by having an interstitial gold atom at the centre. The symmetry of the *s*- and *p*-orbitals of this atom ideally approaches that of the totally symmetrical and three degenerate BMO of the cluster, which are stabilised by the interstitial atom, without changing their number.

The cluster $[Au_{13}(PR_3)_{10}Cl_2]^{3+}$ can be taken as an example. It forms an icosahedron. The 12 gold atoms at the vertices of the icosahedron form *exo*-bonds with the 10 phosphine ligands and two chlorine atoms. The other Au atom is situated at the centre of the icosahedron. Of the 11 valence electrons of the gold atom, 10 are in deep-lying *d*-orbitals and have in fact entered the core, leaving only one electron from each gold atom. Of the total of 13 electrons, two are involved in bonds with the chlorine atoms (the electrons of the remaining *exo*-bonds are provided by the lone pairs of phosphorus), eight occupy the bonding molecular orbitals of the cluster, and three remain unused ($13 - 2 - 8 = 3$) and are removed. This cluster exists as the triply-charged cation.[136]

It is extremely interesting to compare the properties of gold clusters with those of other clusters. The absence of the tangential system of orbitals leads to significant differences between gold clusters and the clusters of other elements, and sometimes even to opposite properties. In particular, in other clusters, reduction leads to opening of the closed *closo*-structure, whereas in gold clusters, on the contrary, the addition of a pair of electrons leads to the conversion of the open toroidal structure of the cluster into a closed spheroidal structure.[135]

IX. Summary

The evolution of the concept of the chemical bond has been examined. The review began with the hydrogen molecule, which occupies a unique position among the millions of all molecules, since it is the only molecule for which the concept of the chemical bond has a completely unambiguous and rigorous significance. It has been shown how the concept of the two-electron chemical bond is transferred to polyatomic molecules, and that, despite the arbitrariness of this concept in polyatomic molecules, it is extremely fruitful, since it reflects the basic features of chemical reality.

The unusually broad range of applicability of the concept of two-centre bonds is due to the clearly-defined spatially directed character of the four hybrid valence orbitals of the atoms of the non-transition elements, as a consequence of which the bonds are relatively independent of one another. This explains the fruitfulness of the concept of individual bonds. If the number of electrons in an atom

is greater than the number required for the formation of two-centre bonds, no dramatic changes are observed; the extra electrons form lone pairs, and the number of bonds formed by the given atom decreases.

The change is more significant when the coordination number of the atom is greater than four, so that there are insufficient valence orbitals for the formation of two-centre bonds with all neighbouring atoms, and it is necessary to introduce the concept of three-centre bonds.

The comparatively large valence orbitals of transition metal atoms enable them to combine not with one but with several atoms of an unsaturated polyatomic ligand simultaneously. The presence of nine valence orbitals in a transition metal atom provides the prerequisite for the formation of a multiple metal–ligand bond (several multi-centre generalised chemical bonds) and hence leads to increased stability of the π-complex.

Thus both hypervalent compounds and transition metal π-complexes can be described in accustomed chemical fashion using three-centre bonds and multi-centre generalised chemical bonds in addition to two-centre bonds.

Thus neither the change from the elements of period II to the non-transition elements of later periods nor the introduction of transition metal atoms into the molecule requires the abandonment of chemistry's reigning ideology, since it is possible to retain the conceptual breakdown of molecules into individual more or less isolated bonds.

The changes in electronic structure resulting not from the replacement of individual atoms but from a change in the overall geometry of the molecule are much more radical. Thus for the atoms involved in the conjugation in planar conjugated systems, it is possible to distinguish valence orbitals having an axis of symmetry perpendicular to the plane of the molecule. The directed character of these orbitals is the same towards all neighbouring atoms. This is the reason for the strong interaction of the conjugated bonds and the delocalisation of the π-electrons in cyclic systems. The mesh of the network formed by the σ-framework of aromatic molecules is too large, so that the π-electron cloud is localised only in the region of the actual framework. Thus in this case there is one-dimensional (reticular) and not two-dimensional delocalisation of the electrons.†

Within the delocalisation region, the π-electrons move practically freely, and any conceptual breakdown of this single system into individual parts contradicts its factual integrity. Thus chemists are dealing every day with molecules to whose π-electron systems the concept of localised bonds is inapplicable.

Two-dimensional delocalisation of electrons takes place not in planar hexagonal network systems but in the closed or almost closed (*nido-*, *arachno-*, and *hypho*-clusters) surfaces of Δ-clusters, whose framework electrons also form a single integral system.

In three-dimensional space, in addition to one-dimensional (linear, reticular) and two-dimensional (Δ-clusters) delocalisation, three-dimensional delocalisation of electrons is also conceivable. It in fact exists in the depth of metals, but the study of this delocalisation belongs to physics. The traditional field of interest of chemistry deals with molecules. In a molecule, the negative cloud of delocalised electrons should be concentrated on a surface bounding a three-dimensional region, so long as positive nuclei are not introduced into this region. From this viewpoint, an example of compounds in which there is three-dimensional delocalisation of electrons is provided by interstitial compounds. These compounds are widely encountered, but they do not differ significantly from Δ-clusters.

It thus appears that all possible basic types of chemical bonding have been dealt with in the present review.

† The terms one-dimensional and two-dimensional are used in the mathematical sense.

The structural study of liquid crystals

P M Zorkii, T V Timofeeva, A P Polishchuk
Moscow State University
Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow
Institute of Physics, Ukrainian SSR Academy of Sciences, Kiev

ABSTRACT. Structural (mainly X-ray diffraction) studies of thermotropic liquid-crystalline mesophases have been reviewed. The classification of mesophases has been examined and refined. The discussion deals mainly with the structure of liquid crystals formed by rod-shaped molecules (calamitic mesophases). Mesophases of a new type, containing columnar associates of molecules joined by hydrogen bonds, have also been described.

The bibliography contains 141 references.

I. Introduction

The study of liquid crystals (LC) began as early as last century,[1,2] and its hundredth anniversary has already passed. It now covers a remarkable scale, but the increase in the number and range of these studies has not been smooth. It was only about 25 years ago that it became clear that LC do not represent an exotic phenomenon; they are widely encountered in living and non-living nature, and have found a large number of practical applications in technology and medicine, and in recent years in chemistry (as orienting solvents in the study of NMR spectra and for carrying out topochemical reactions). The intensive study of LC has also led to the development of theoretical ideas which make up an integral and important part of present-day physical chemistry.

As in other fields of chemistry, structural data have here been extremely important. In structural chemistry, an independent branch referred to as "the structure of mesophases" has been distinguished.†

Even in the early stages of the study of LC, they were classified according to the degree and nature of the ordering as nematic, smectic, and cholesteric.[2] Thus structural studies from the beginning have played an important role in the investigation of LC, although in many cases the descriptions of the structure suffered from lack of clarity and specificity, and sometimes contradicted physicochemical data and the principle of close packing of molecules. Since like liquids they retain a considerable degree of disorder, liquid-crystalline phases naturally cannot be characterised structurally in the same detail as solid crystals. The statistical nature of their structure, however, reflects objective reality, so that in principle it should in each specific case be described in completely definite fashion, albeit in statistical language. Compared with liquids, experimental diffraction methods in this case give much more information, although, as in the case of liquid phases, the details of the structure of individual molecules remain out of reach.

The present review gives a systematic analysis of the structural aspects of studies of LC, carried out mainly in the last 25 years. Liquid-crystalline phases can be classified as thermotropic (produced from liquids or crystals by change in temperature) and lyotropic (formed in solution). Only the former are considered in the present review.

For a long time it was considered that the role of mesogens, that is compounds capable of existing in the thermotropic liquid-crystalline state, was played only by substances with rod-shaped molecules (so-called calamitic mesophases). In 1977, however, LC formed by disc-shaped molecules were reported,[4] and in 1987, liquid-crystalline phases consisting of cup-shaped molecules were described.[5] There is no doubt that, other types of mesogen will be detected. Usually, however, when LC are mentioned, it is calamitic mesophases that are meant. The present review also deals mainly with these LC (it is proposed to devote a separate review to the structure of disc-shaped mesophases).

In a rod-shaped molecule it is possible to distinguish a long axis, denoted L. The vector indicating the average direction of these axes is called the director (this concept is most useful for nematic mesophases). A calamitic mesophase can apparently be defined as a liquid crystal whose structure is regarded as sufficiently fully characterised if the arrangements of the molecular axes L are described (with allowance for statistics). This definition corresponds to the picture of molecules as cylinders with a circular cross-section. In some important cases (for flattened molecules), however, this description of the structure cannot be regarded as sufficient, and it is necessary to represent the molecules as cylinders with an elliptical cross-section. It is then necessary to add to the structural parameters the angles characterising the orientation of the ellipses perpendicular to the axes L.

† The term "mesophase" is now often used as a synonym for "liquid crystal"; this use of these concepts has also proved convenient in the present review. It should be borne in mind, however, that the concept of "mesophase" is sometimes given a more general meaning, to include various partly disordered (and partly ordered) phases occupying an intermediate position between ideal crystals and isotropic liquids.[3]

Liquid crystals are practically always molecular compounds, but liquid-crystalline phases show a number of distinctive features, compared with molecular crystals. In addition to the appreciably statistical nature of the structure, a domain structure is highly characteristic of LC. Domains with coherent boundaries apparently are also fairly frequently present in solid molecular crystals (more frequently than is usually assumed[6]). Nevertheless, this is not typical of solid crystals, whereas in LC domains are observed as the rule. They are readily rearranged and change their orientation under the influence of external factors, in particular electric and magnetic fields.

In a liquid-crystalline material, the domains are often arranged completely randomly. In an electric or magnetic field, they are ordered, leading to the formation of so-called oriented mesophases. It is these phases that are usually studied by X-ray diffraction. For solid crystals, the influence of an external field (and even temperature) on the structure is studied comparatively rarely (studies of this kind are only beginning to develop on a large scale), whereas for LC the study of structure as a function of field intensity and temperature has been customary for a long time.

In the study of the structure of LC it is important to bear in mind that their structure is dynamic. The problem in principle is to give a specific description of not only the average arrangement of the molecules, preserved for a more or less long time, but also the dynamics of the structure, that is the vibrational and rotational movements of the molecules, and also their diffusion and transfer from one molecular agglomerate to another. The information at present available, however, relates mainly to the averaged static structure of LC; this information is obtained by optical, dilatometric, and other physicochemical studies, but the main source of structural information is diffraction, in particular optical modelling of the diffraction pattern. Information on molecular dynamics is also provided by NMR and experiments on quasi-elastic neutron scattering.‡

II. The structural classification of calamitic mesophases

The first classification of LC having a structural basis was proposed in 1922 by Friedel,[2] who classified the 42 liquid-crystalline substances known to him as nematic, smectic, and cholesteric. The distinctive feature of nematic LC is that the molecules in them are arranged in approximately parallel fashion, that is they are characterised by approximately parallel orientation of the long axes. In smectic LC, the molecules again are approximately parallel, but in addition they are arranged in parallel layers. The local structure of a cholesteric mesophase is analogous to the structure of a nematic, on the other hand, cholesteric LC are characterised by a gradual change in the orientation of the vector L in space, leading to a spiral arrangement, as a result of which these crystals are optically active.

Subsequent studies showed that there is considerable variety in the properties and structures of smectic phases. This led to the classification of smectics as types A, B, C, D, E, F, and G by Sackmann and Demus.[8] This classification was based on experimental data on the miscibility of the mesophases, but it was already known at that time from X-ray diffraction studies[9] that the miscibility criterion corresponds to definite structural characteristics. Subsequently, X-ray diffraction studies made it possible to characterise specifically each of the types $A-G$, and also to add the types H, I, J, and K.

Generally speaking, the picture of the molecules as rods with cylindrical symmetry is inadequate for the description of these types of structure. A more adequate model is that of a cylinder with an elliptical cross-section, or a ribbon, and in some cases it is also necessary to take into account the non-equivalence of the two sides of this ribbon. In the simplest version, the structure of smectics of different types is usually described without taking into account the polarity of the molecules and the possibility of dimer formation. It is also assumed that the smectic phase consists of "monolayers", in that the centres of gravity of the molecules forming the layer lie approximately in the same plane, and that the thickness of the layer d is determined by the length of the molecule l ($d = l\cos\varphi$, where φ is the angle between the axis L and the normal to the layer).

In the description and classification of the structure "monolayer" smectics, account is usually taken of the nature of the packing of the molecules in the layer, whether or not the molecules lie at an angle to the normal to the layer ($\varphi = 0$ or $\varphi \neq 0$), and the presence or absence of correlation in the superposition of the layers. Four types of packing of the molecules in the layer are distinguished: 1) disordered, 2) "hexatic" (having only short-range order), 3) hexagonal, and 4) herring-bone. According to Goodby and Gray,[10] who summarised structural data on smectic phases, this gives the following classification of known smectics (the notation of the phases in which there is a correlation in the superposition of the layers is underlined):

Packing in the layer	$\varphi=0$	$\varphi'\neq0$	$\varphi''\neq0$
Disordered	*SmA*	*SmC*	
"Hexatic"	SmB_h	*SmI*	*SmF*
Hexagonal	*SmB*	*SmJ(G')*	*SmG*
Herring-bone	*SmE*	*SmK(H')*	*SmH*

This Table corresponds to Fig. 1, taken from Goodby and Gray,[10] which shows schematically the packing of the molecules in the smectic layers. Here, the circles denote vertically arranged molecules, whose effective symmetry is cylindrical as a result of the statistical character of the azimuthal orientations (or because of the domain structure of the layer, discussed below). The triangles denote sloping molecules with cylindrical symmetry (in the case of molecules with an elliptical effective cross-section, the slope of their long axes is indicated by arrows). Two versions of the slope of the molecules relative to the section of the layer are distinguished (φ' and φ''), giving two series of "sloping" smectics ($I-J-K$ and $F-G-H$). Fig. 2 gives a clearer picture of the arrangement of the molecules in the bulk of some smectics.

It should be emphasised that the representations of the structure of the layers in the hexatic phases in Fig. 1 are highly arbitrary. In fact, the following is understood. In contrast to hexagonal and herring-bone packing, in which the arrangement of the centres of gravity of the molecules is characterised by long-range positional order (although not so perfect as in true crystals), hexatic phases show only short-range positional order, and the molecular coordination number 6 is the most probable; the symmetry of the immediate environment of a molecule in the layer is therefore hexagonal or pseudo-hexagonal. At the same time, in these phases there is bond-orientational order, in which all the coordination hexagons are oriented in approximately the same way. Analogous

‡ This method detected the diffusion of molecules in a direction perpendicular to the smectic layers.[7]

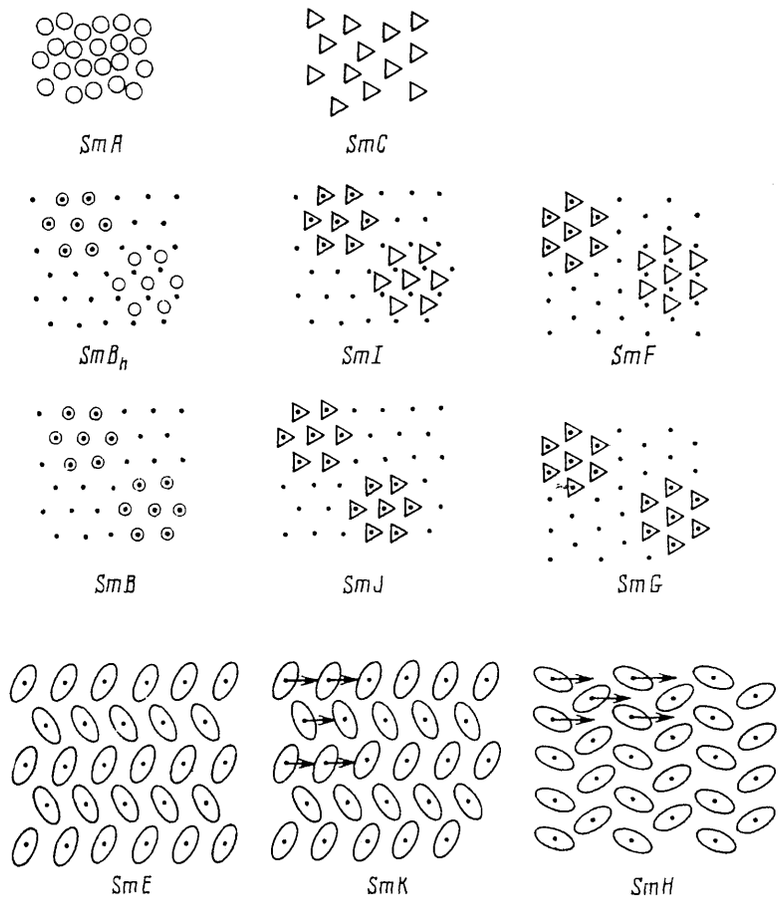

Figure 1. Arrangements of the molecules in smectic layers.[10]

phases with short-range order of a different type ("tetratic", etc.) are possible in principle, but these phases have not been reported in X-ray studies

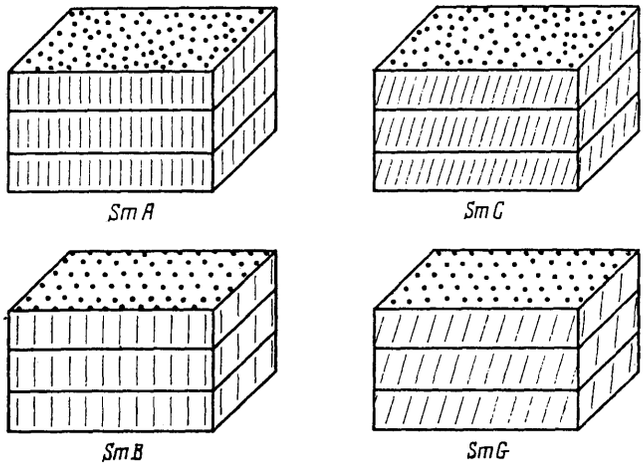

Figure 2. Schematic representation of the arrangement of the molecules in various smectics.

This classification gives a satisfactory description of experimental data on the structure of smectic mesophases. There is however some indeterminacy in the structural characterisation of *SmI* (this question will be examined later in section V). It should also be noted that the structural description sometimes contradicts experimental data on the miscibility of liquid-crystalline phases. The miscibility or immiscibility of two smectics apparently does not always indicate unambiguously a similarity or difference between their structures. A final conclusion can be reached only from special structural studies.

An unsatisfactory feature of the above systematisation is that it only reproduces the experimentally observed picture of the structure of smectics (more accurately, a set of models which has been used to interpret the experimental data); there is no possibility of predicting structures which are possible in principle but which have not yet been discovered.

A more *a priori* systematisation is that of de Vries,[11] which has been extended to lyotropic mesophases.[12] Here, the herring-bone arrangement of the molecules, denoted by the symbol "2", as taken as the basis of the structure of the smectic layers, but account is also taken of the possible production, at sufficiently high temperatures, of dynamic structures in which there is a spontaneous cooperative change in the azimuthal orientation, as a result of which the structure represented schematically in Fig. 3*a* is converted into the structure shown in Fig. 3*b*, and conversely. X-Ray diffraction records the

overall statistical structure (Fig. 3c), which is denoted by the symbol *m*. Moreover, according to de Vries it is possible to have a structure with three interconvertible azimuthal orientations of the molecules (Fig. 4), effectively having hexagonal symmetry (symbol "6"). To this is added a statistical structure with a non-fixed azimuthal orientation of the molecules, denoted by the symbol ∞.

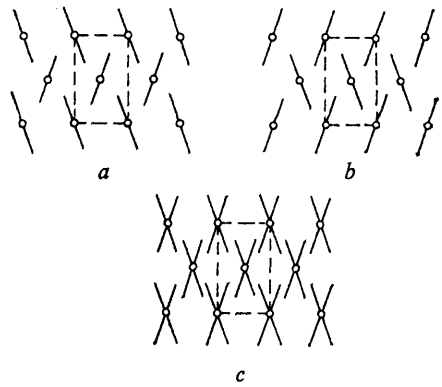

Figure 3. Structure of the layers 2 and *m* according to de Vries:[11] *a*, *b*, two equivalent herring-bone patterns; *c*, overall structure (detected by X-ray diffraction) in which versions *a* and *b* are equally probable.

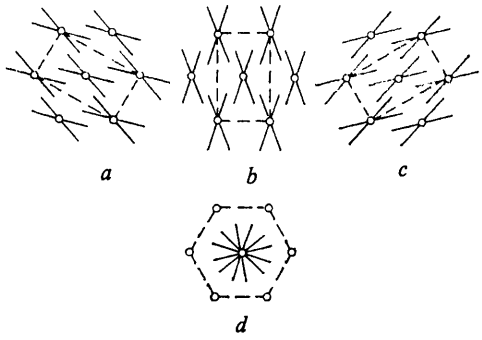

Figure 4. The formation of statistical layers according to de Vries:[11] *a*, *b*, *c*, three equivalent orientations of the layers *m*; *d*, overall structure.

The structure of a smectic phase as a whole is described by de Vries by means of a three-position symbol, where the type of packing of the molecules in the layer (2, *m*, 6, or ∞) is given by the first position, whether or not the director lies at a slope to the plane of the layer (∞ or *m*) is given by the second position, and the presence or absence of a correlation in the superposition of the layers (0 or 1) is given by the third position. This gives the 14 types of smectic structure shown in Table 1. De Vries identifies nine of them with types of smectic described in the literature; two types [*SmX* and *Sm*(*X*)] are said[11] to have been identified be de Vries and co-workers; and three types (6*m*1, 2∞0, 2*m*0) have apparently not yet been identified.

Table 1. Types of smectic mesophase (according to de Vries).

Type of packing of the molecules in the layer	Smectic mesophases			
	upright layers (∞)		sloping layers (*m*)	
	0	1	0	1
∞	∞∞0 (*SmA*)	—	∞*m*0 (*SmC*)	—
6	6∞0 (*SmB*)	6∞1 (*Sm*(*B*))	6*m*0 (*SmF*)	6*m*1 —
m	*m*∞0 (*SmX*)	*m*∞1 (*Sm*(*X*))	*mm*0 (*SmI*)	*mm*1 (*SmG*)
2	2∞0 —	2∞1 (*SmE*)	2*m*0 —	2*m*1 (*SmH*)

It should however be noted that there are discrepancies between de Vries' treatment and the structural systematisation of smectic phases described above.[10] This applies primarily to hexatic structures, which according to de Vries represent a fifth version of the packing of the molecules in the layer, so that they should be regarded as supplementing the 14 types listed in Table 1. At the same time, in de Vries' monograph,[10] the types *SmB*, *SmI*, and *SmF* are treated as hexatic phases (see also section V). Correspondingly, the interpretation of the types *SmI* and *SmG* as phases with structures corresponding to the symbols *mm*0 and *mm*1 differs from the description of these phases in de Vries' monograph.[10] In addition, de Vries' systematisation does not reflect different relations of the slope of the molecules to the section of the layer.

Moreover, the production of two or three spontaneously interconvertible orientations, proposed by de Vries, contradicts the principle of close packing, which should apparently be applicable not only to crystals but also to the liquid-crystalline state. A more probable model of the layers denoted by the symbols 6 and *m* is a domain structure (see Fig. 27) in which the boundaries of the domains can migrate either spontaneously or under the influence of external factors; there coexist three orientations of the domains in a layer of type 6, and two orientations in a layer of type *m*.

Another feature which apparently must be taken into account in an *a priori* systematisation of smectic phases is the following. It is known from organic crystal chemistry[13,14] that the characteristic packing of molecules includes not only the herring-bone pattern (layers with symmetry P_l2_1, P_lc, and P_l2_1/c) but also primitive packing with an oblique-angled cell (layers with symmetry P_l1 or $P_l\bar{1}$). If this mode of packing of the molecules in the layer is denoted by the symbol "1" and, following de Vries, the possible versions of the structure of a smectic with an oblique-angled planar cell are examined, then another four types of smectic phase are obtained: 1∞0, 1*m*0, 1∞1, and 1*m*1. Smectic phases of this type have not yet been detected by X-ray diffraction. This however is apparently due not to the fact that they do not exist in the systems studied but to the fact that the more symmetrical models used in the interpretation of the X-ray diffraction patterns have been fairly consistent with the experimental data. With increase in the accuracy

of X-ray diffraction studies, however, phases will possibly be found, whose X-ray diffraction patterns can be interpreted satisfactorily only on the basis of an oblique-angled structure of the smectic layers.

It is appropriate to supplement the above classification schemes by a parametric description of different types of liquid-crystalline structures. This description will make it possible to list structural parameters whose fixed values define the type of liquid-crystalline phase. An advantage of this approach is not only that it is quantitatively specific but also it makes it possible to regard polymorphic transformations of liquid-crystalline phases as the "de-freezing" (or "freezing") of individual degrees of freedom of the molecules. This opens up the way to a quantitative energetic analysis of mesomorphism.

The parameters characterising the structure of a calamitic LC include: 1) the angles φ, ψ, and θ describing the position of the long axis of the molecule and its azimuthal orientation (Fig. 5), 2) the distance between the axes of adjacent molecules D, and 3) for smectic phases, the thickness of the layer d. In the case of highly ordered smectics, the distances between the molecules are determined by the parameters of the two-dimensional lattice a and b (for hexatic phases by the parameters of the immediate environment a' and b'); for smectics with three-dimensional order, which in the literature are sometimes provisionally called "crystalline", the thickness of the layers is defined by the period c. Table 2 lists for each type of LC the parameters which make it possible to describe the principal features of the structure.

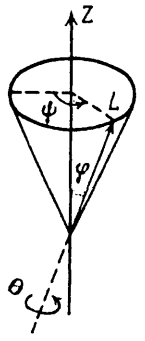

Figure 5. Angles characterising the orientation of a rod-shaped molecule.

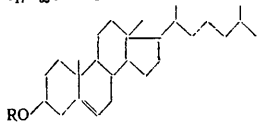
For a more detailed characterisation of the structure, it is necessary to take account of the actual conformation and to indicate the way in which the axis L is selected. Moreover, in the study of the structure of specific mesophases, the formation of dimeric molecular agglomerates (they are often called "dimers", although they do not correspond to dimers in the chemical sense of the term) and "bilayer" structures are often encountered. (These questions will be examined later.)

It is also necessary to take account of the characteristics of the structure of LC arising in sloping ($\varphi \neq 0$) smectics in connection with the chirality of the molecules.[15] In this case, optically active mesophases *SmC**, *SmI**, and *SmF** are formed, in which the superposition of the layers of chiral molecules leads to spiral twisting, together with mesophases *SmI**, *SmG**, *SmK**, and *SmH**, in which this twisting does not take place[10] (the optical activity of the substance is due to the chirality of the molecules).

Table 2. Characteristic structural parameters of mesophases of different types.



Type of mesophase	Notation	Fixed parameters
Nematics	*N*	$\varphi=0$, *D*
Smectics	*SmA*	$\varphi=0$, *D*, *d*
disordered	SmA_C	φ, *D*, *d*
	SmC	φ, ψ, *D*, *d*
hexatic	SmB_h	$\varphi=0$, $a'=b'$, $\gamma=120°$, *d*
	SmI	φ, $\psi=0$, $a'=b'$, $\gamma=120°$, *d*
	SmF	φ, $\psi=90°$, $a'=b'$, $\gamma=120°$, *d*
with three-dimensional order	*SmB*	$\varphi=0$, $a=b$, *c*, $\gamma=120°$
	SmG	φ, $\psi=0$, $a=b$, *c*, $\gamma=120°$
	SmI	φ, $\psi=90°$, $a=b$, *c*, $\gamma=120°$
	SmE	$\varphi=0$, $\theta=0$, 180°, *a*, *b*, *c*
	SmK	φ, $\psi=0$, $\theta=0$, 180°, *a*, *b*, *c*
	SmH	φ, $\psi=90°$, $\theta=0$, 180°, *a*, *b*, *c*

The calamitic mesogens for which X-ray diffraction data are available are listed in Table 3. They are arranged in a definite sequence (according to their chemical characteristics). Table 3 also gives the names of the compounds or groups of homologues, and the corresponding structural formulae. In some cases, letter abbreviations for the compounds, encountered in the literature, are given.

Table 3. List of calamitic mesogens studied by X-ray diffraction.

Compound	Name, abbreviation	Formula*
I	4-n-Octyl-4′-cyano-biphenyl	$C_8H_{17}—C_6H_4—C_6H_4—CN$
II	Alkoxycyanobiphenyl	$RO—C_6H_4—C_6H_4—CN$

XLV	Cholesteryl alkanoate	

*Here, R = C_nH_{2n+1}, R' = C_mH_{2m+1}.

Calamitic mesogenic molecules usually contain the following characteristic fragments: a) rigid rings (benzene, cyclohexane, adamantane, and heterocycle residues); b) bridges joining these rings [—CH=N—, CO—O—, —CH=CH—, —N(O)=N—, etc.]; c) groups joined to the rings (most frequently, alkyl or alkoxy groups). In Table 3, the compounds are arranged in the following order: 1) molecules not containing bridges (one-ring, two-ring, etc.) (I—XI); 2) molecules with one bridge (two-ring, three-ring, etc.) (XII—XXXIII); 3) molecules with two bridges (XXXIV—XLIII); 4) others (XILIV, XILV).

III. Nematic mesophases

Since the arrangement of the domains in non-oriented nematics is random, their X-ray diffraction patterns differ little from those of liquids. An oriented mesophase usually gives an X-ray diffraction pattern similar to that shown in Fig. 6. X-Ray diffraction patterns of this kind were obtained for compound XXV (n = 1, PAA) by Kast[16] (in an alternating electric field) and later by Kosterin and Chistyakov[17,18] (in direct and alternating fields). Here, equatorial and meridional reflections are observed. The former are usually represented by one or two pairs of intense crescent-shaped arcs, and are due to the approximately parallel orientation of the long axes of the molecules (L). The position of the equatorial reflections on the X-ray diffraction pattern makes it possible to determine the average distance between the long axes of neighbouring parallel molecules (D). The meridional reflections indicate the existence of a period a in the arrangement of the centres of gravity of the molecules along the direction of the direction **n**. This means that the nematic mesophase contains cylindrical rows of molecules (strings),[19] extending along **n** (Fig. 7). With the parallel orientation of the axes L this arrangement is the natural expression of the tendency to adopt a compact packing. The strings naturally exist only within certain molecular clusters (bundles). The width of the meridional reflections is determined by the average number of molecules in the string.

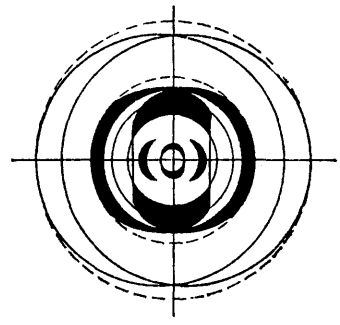

Figure 6. Diagram showing the positions of the reflections on the X-ray diffraction pattern of PAA (field intensity 4000 V cm^{-1}, temperature 123 °C).[17]

The PAA molecule shows negative dielectric anisotropy $\varepsilon_{\parallel} - \varepsilon_{\perp} < 0$ (the minimum value of ε in the direction of the long axis of the molecule with dipole moment forming an angle of 57° with this axis[20]). Thus in an electric field these molecules tend to be arranged in such a way that their axes L are perpendicular to the intensity vector (**n** ⊥ **E**). At the same time, in an electric field, a flux of the impurity ions usually present in the substance is produced; this flux also has an orienting influence, but it leads to the parallel arrangement of the axes L along the field lines (**n**||**E**).[21,22] The final result is determined by the competition between these two factors, and depends on the magnitude of the field strength. A published[17] set of X-ray diffraction patterns of a PAA mesophase at different direct field intensities shows that at E = 50 V cm^{-1}, only the orienting action of the field is felt (**n** ⊥ **E**), whereas at E > 10 V cm^{-1}, the

orienting action of the flux predominates (**n**||**E**). Similar X-ray diffraction patterns were obtained[23] for nematic specimens of compound XL.

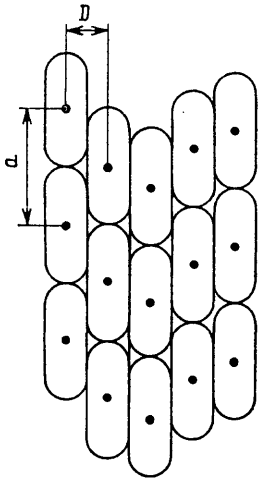

Figure 7. Arrangement of the molecules in a nematic mesophase.

Naturally, Fig. 7 gives a highly idealised picture of the structure of nematic mesophases. The relatively low intensities of the meridional reflections indicates that not all the molecules form periodic strings, and the weakness and vertical broadening of the equatorial reflections indicate that the orientation of the long axes of the molecules deviates from the strictly parallel. Distribution functions of the molecules with respect to orientation, and radial distribution functions of the atoms in the direction of the director, have been constructed.[17,18,23] The authors of these studies also report that they detected three preferred modes of relative azimuthal orientation of the molecules, corresponding to different values of D (D_1—the benzene rings of neighbouring molecules lie in the same plane, and their ends touch; D_2—the touching benzene rings are perpendicular to one another; and D_3—the benzene rings of neighbouring molecules are parallel). For PAA, these values were 6.2, 5.4, and 3.6 Å in a field with a strength of 200 V cm^{-1}, and 7.0, 5.3, and 3.6 Å in a field with a strength of 400 V cm^{-1}. Similar results were obtained for the nematic phase of compound XL. These data indicate that the effective shape of the molecule deviates from cylindrical.

A diffraction pattern similar to that described above is also obtained for cholesteric phases, in which the immediate environment of the molecules is approximately the same as in a nematic phase. In particular, this has been observed for specimens of derivatives of cholesterol (XLV, n = 8 and 13) which had not been subjected to special orienting treatment, but which evidently showed a considerable degree of orientation,[24] and for specimens oriented by a constant shear deformation (specimen in contact with a rotating rod).[25]

A more complex diffraction pattern was obtained for oriented nematic mesophases of homologues of compounds XXV and XLI.[26–28] An X-ray diffraction pattern typical of these phases is shown in Fig. 8. Here, the first meridional reflection has the form of a dumbbell, and the second meridional reflection is split. This type of meridional reflection indicates the appearance of order in a direction not coinciding with the director. To explain this pattern, de Vries[29] proposed the existence of so-called skewed cybotactic groups (Fig. 9), in which the molecules are arranged in layers§ as in the smectic *C*.

Figure 8. Schematic representation of the X-ray diffraction pattern of a nematic with splitting of the meridional reflections.[38]

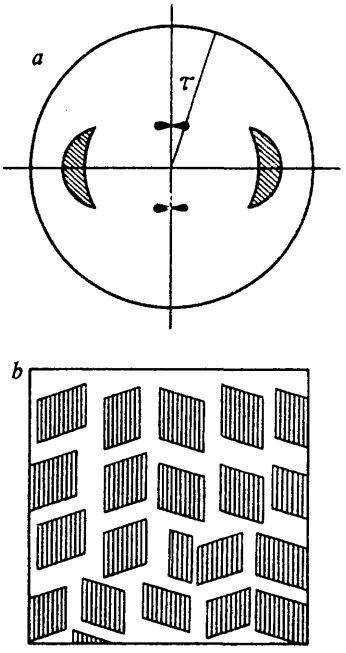

Figure 9. X-Ray diffraction pattern (*a*) and structure (*b*) of a nematic phase with cybotactic groups.

According to de Vries,[29] the angle τ on the X-ray diffraction pattern (Fig. 9*a*) is equal to the average value of the angle between the long axes of the molecules and the normal to the plane of the

§ The presence in liquid phases of cybotactic groups of molecules (that is molecular aggregates with definite spatial order) was first postulated by Stewart,[30] who later pointed out[31] that these groups apparently play an important role in nematic mesophases.

layer. This X-ray diffraction pattern also makes it possible to determine the average thickness of the layer d and the average distance D between the long axes of the molecules. The temperature dependence of these parameters and the intensity of the reflections was determined[32] for nematic phases of compound XLI (homologues with n = 6, 8, 10, 12) oriented in a magnetic field. Some of the numerical data are given in Table 4. With increase in temperature, the values of D and d increase, the former linearly, and the latter non-linearly. The angle τ also undergoes a corresponding non-linear change; with increase in temperature from the point of the transition into the nematic phase (T_N) to the point of the transition into the isotropic liquid (T_I), the value of τ decreases by $\sim 10°$. With increase in temperature, the intensities of the reflections naturally decrease, but for the homologues with n = 6 and 8 at high temperatures the intensity of the meridional reflections remains almost constant (including the range of existence of the isotropic liquid). The last feature was attributed[32] to the preservation of the cybotactic groups in the isotropic liquid phase.¶

Table 4. Geometric characteristics of the nematic phases of homologues of compound XLI.

n	T_N, K	T_I, K	d, Å at T_N	d, Å at 420 K	D, Å at 420 K	$(\Delta D/\Delta T)\times$ $\times 10^{-3}$, Å K^{-1}
6	371.9	471.5	24.05	26.54	5.015	2.60
8	334.0	453.7	27.04	30.30	5.066	2.80
10	384.9	440.9	32.16	35.92	5.066	2.53
12	406.7	432.7	36.32	37.46	5.090	3.14

De Vries[36] also studied the liquid and nematic phases of compound XII (homologues with n = 5–7). The value of D in the mesophase was determined from the equatorial reflections (the outer diffuse ring), and the value of a in the liquid phase was obtained from the meridional reflections (the inner diffuse ring). The presence of the inner ring on the X-ray diffraction pattern of the isotropic phase itself indicates the preferred orientation of at least some of the molecules; in the present case this orientation was evidently due entirely to the orienting action of the walls of the capillary. An increase in a was observed with decrease in the temperature of the liquid. Extrapolation of this relationship from the point of the liquid–nematic transition gave the value of a corresponding to the limiting elongated conformation of the molecule. For all three homologues, this value was found to be close to that obtained for a model in which the *trans*-conformation was assumed for the alkyl chains, and the chains were assumed to be coplanar with the benzene rings. The decrease in a with increase in temperature indicates that this conformation is lost, although the broadening of the inner ring may also be due to a decrease in the orientational order. In the nematic phases, with increase in temperature, a linear decrease in D from 4.94 Å to 5.03 Å was observed, as in the nematic phases described above.[32]

¶ Calculations carried out by the methods of molecular dynamics[33–35] also indicate the existence, in the instantaneous structure of the nematic phase, of molecular clusters, that is regions with higher orientational and translational order. These molecular clusters can apparently be identified with the cybotactic groups.

The layer associates (cybotactic groups) are usually present in nematics which on cooling form smectic phases. An exception is provided by the homologues of compound XXXVII with n = 0, 1, 3, 5, 9, 12, and 16, where n is the number of carbon atoms in the side chain, which does not lie along the axis of the ring in the molecule. In this series, with increase in n from 0 to 6, the angle of slope of the central aromatic fragment within the layers increases, and then decreases.[37] The explanation put forward by the authors cited[37] is that the short lateral "tail" hinders the parallel orientation of the molecules, but with increase in its length it becomes more flexible and can be arranged parallel to the long axis of the molecule.

According to Azaroff,[38] the explanation for the observed[26,27] broadening of the meridional reflections in a direction perpendicular to the meridian is that in the oriented nematic mesophase, the periodic strings of rigid molecules form layers (Fig. 10), and periodicity is also produced in a direction perpendicular to the strings. In the stack of parallel layers there is no periodicity along any direction not lying in the plane of the layer; at the same time, the stacks are arranged regularly in space. Azaroff considers that this model basically explains the intensity distribution on the X-ray diffraction patterns obtained,[26,27] although a real nematic phase also contains randomly arranged (non-correlating) molecular strings. On heating, the number and size of the stacks decrease, and the number of non-correlating strings increases, leading to splitting of the reflection, which acquires the form of a dumbbell.

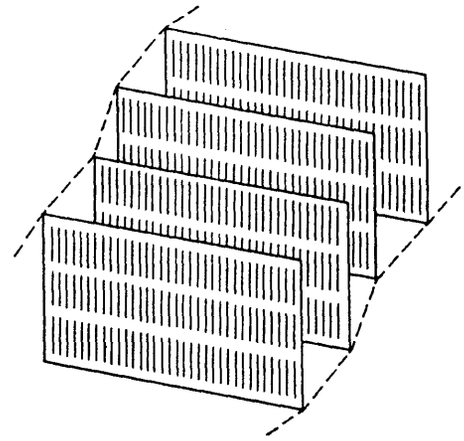

Figure 10. Stacks of parallel molecular layers in a nematic phase.[38]

Azaroff's model is criticised in a brief review by de Vries,[39] analysing published data on the structure of "cybotactic" nematics. The main argument against this model is that the existence of "planar layers" is not revealed in any properties of the nematic phase. According to de Vries, it is more probable that within this phase there are blocks of molecules with structures similar to those of the fragments of layers of the type *SmA* or *SmC*, whose appearance corresponds to the nucleation of the smectic layer order.

Optical modelling of diffraction on planar models of different molecular packings lead to similar conclusions about the structure of "cybotactic" nematics (Fig. 11).[40] In the opinion of the author cited, however, the value of the angle τ (see Fig. 9) is determined not by the slope of the molecules in the cybotactic groups (blocks) but by the average distance between these groups and their dimensions.

It is therefore suggested, in contrast to the work cited above,[32] that with increase in temperature the size of the blocks decreases.

Another possible increase in the complexity of the structure of the nematic phase may be due to the presence of dimeric associates of molecules, leading to the formation of molecular strings whose period is appreciably greater than the length of the molecule. This is apparently the situation in the cyanophenyl derivatives studied by Leadbetter and co-workers.[41-43] For these compounds, the ratio $a/l > 1$ and depends on the length of the aliphatic chains; at the same time, the period of the string a changes little with change in the central aromatic part of the molecule.

This last feature indicated to the authors cited a form of packing of the molecules in which their aromatic parts overlap (come into contact). The structure of the string is given approximately by the diagram in Fig. 12 (proposed by the present authors). The authors cited[41-43] talk about "bilayer" packing, but in the opinion of the present authors, when discussing the nematic phase, it is better to say that the string contains molecules oriented in antiparallel fashion, or that the strings are formed by dimers, which in the present case are most probably stable associates of molecules. These dimers are stabilised, in particular, by electrostatic interaction, since the molecules have an appreciable dipole moment (3.5–4.0 D).

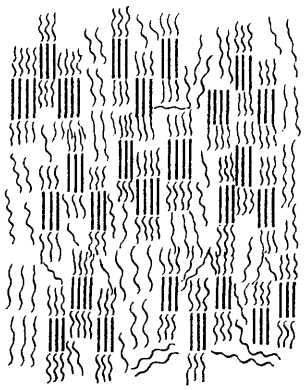

Figure 11. Model of the structure of a "cybotactic nematic", obtained by optical modelling.[40]

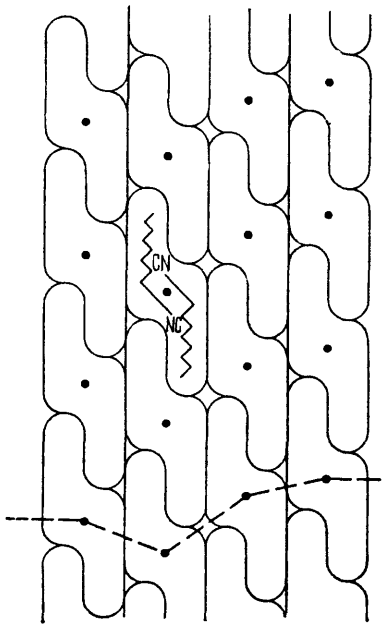

Figure 12. Structure of a nematic phase made up of dimers (for the case of cyano-derivatives).

Table 5 gives the values of l and a for a series of cyano-derivatives.[43] An interesting feature is that for compounds IV, VII, and XI, in addition to the reflectance given by the period a corresponding to the dimeric organisation of the strings, additional reflections indicating the existence of a period $a_2 < l$ are observed. This indicates the presence of strings in which dimers are not observed, and the molecules possibly do not have the most elongated conformation. The temperature dependence of the intensity of the reflections shows that strings with the period a_2 predominate at low temperatures, and strings with the period a_1 predominate at high temperatures.

A picture similar to that described above is also observed for a number of other compounds, for example compounds XXIX and X.[44,45] In the last case, the ratio a/l shows a marked dependence on the substituent, having the value ~1.4 for the cyano-derivatives, and ~1.1 for the halogeno-derivatives.

Table 5. Comparison of the lengths of the molecules (l) and the periods (a_1 and a_2) in the nematic phases of cyano-derivatives.

Compound	l*, Å	a_1, Å	a_2, Å
(II, n=6)	20.5	27.7	—
(IV)	19	24.9	13.2
(VII)	22	30.9	20.4
(XI)	23.5	30.7	18
(XX)	24	31.7	—
(XXVII)	22.2	32.2	—

* l is the maximum length of the molecule for the most elongated conformation.

IV. Smectic *A* and *C* phases

The X-ray diffraction patterns of a smectic mesophase oriented in an electric or magnetic field often have the form shown schematically in Fig. 13*a*. X-Ray diffraction patterns of this type have been obtained[46] for compound XXXI, and also in other studies.[47-52] In contrast to the X-ray diffraction patterns of nematics, in this case the meridional reflections have the form of fairly distinct spots. According to the simplest treatment, this type of X-ray diffraction pattern corresponds to an ideal smectic *A*, in which the molecular axes L are perpendicular to the layers ($\varphi = 0$); if however the axes L lie at a slope to the plane of the layer ($\varphi \neq 0$), that is in the case of an ideal smectic *C*, the straight line passing through the centres of the meridional reflections should make an angle ω with the equator (Fig. 13*b*). This picture has been observed fairly infrequently, however, and only for single-domain specimens. The distance between the meriodional reflections is determined by the thickness of the layer d, and the position of the equatorial reflections, as in the case of nematics, can be used to calculate the value of D.

In fact, smectics have a more complex structure. In particular, the condition $\varphi = 0$ for smectics *A* is usually satisfied only statistically.

Oriented liquid-crystalline specimens of compounds XXVI, XXXII, and XLIV, obtained on freshly split mica plates, have been studied by X-ray diffraction.[53] The X-ray diffraction patterns had the form corresponding to the type *SmA* (Fig. 13*a*), but the best agreement with experiment was given by a model in which the molecules were displaced relative to one another along their long axes by 5–6 Å, and their slope to the normal to the layer was 30° and 43° for compounds XXVI and XLIV respectively (for compound XXXII, a structural model corresponding to the experimental diffraction data could not be obtained). The structural analysis carried out in this study was based on an examination of the width and intensity of the meridional reflections as functions of the order of diffraction; these relationships should be different for different trial models, of which the following were considered: 1) monolayer *SmA*, 2) bilayer *SmA*, and 3) bilayer *SmC* (with allowance for the degree of disorder of the para-crystalline type). The best model was found to be the third model, which was constructed using X-ray diffraction data obtained for single crystals of these compounds or their analogues. Thus the order of the type *SmA* ($\varphi = 0$) is here achieved only effectively, as a result of averaging of the orientations with respect to the para-crystalline domains and with respect to the thickness of the specimen. Estimation of the linear dimensions of the crystallites gave the value ~400–800 Å.

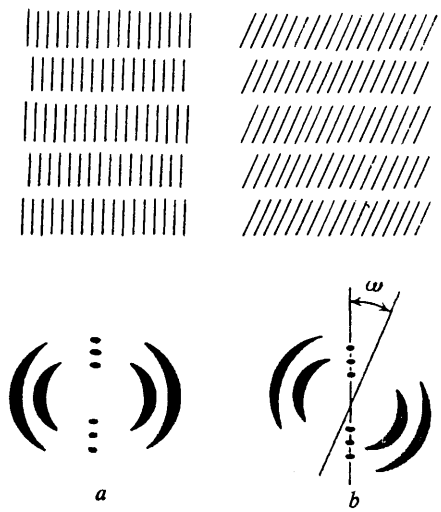

Figure 13. Arrangement of the molecules in upright (*a*) and sloping (*b*) smectic mesophases, and a schematic representation of the corresponding X-ray diffraction patterns.

For a deeper structural analysis of LC it is necessary to take into account the fact that the form of the molecules often differs significantly from cylindrical; this applies particularly to molecules containing long terminal aliphatic chains, which may extend in a direction which differs considerably from the direction in which the rigid central part extends.

The X-ray diffraction pattern obtained[54] for the smectic phase of compound XXXIX ($n = 6$) in a magnetic field had the form represented schematically in Fig. 14 ($\omega = 43°$). Assuming that the molecules retain the conformation found in the crystalline substance (the angle between the straight line passing through the centres of the benzene rings and the direction in which the aliphatic chains extend is 59°), the authors cited constructed a multi-domain model of this smectic. One of the two orientations of the layers represented in Fig. 15 is produced in each domain. Within the layer, the axes of the central parts of the molecules are arranged in sloping fashion, and make an angle of 47° with the plane of the layer, whereas the aliphatic chains are almost perpendicular to the plane of the layer (~74°). The proposed structure was confirmed by optical modelling. Here, a definite analogy with the structure of a nematic containing cybotactic groups is observed (Fig. 9). The smectic phase differs in that in it the layers are much more extensive than the cybotactic groups, and extend to the boundaries of each domain.

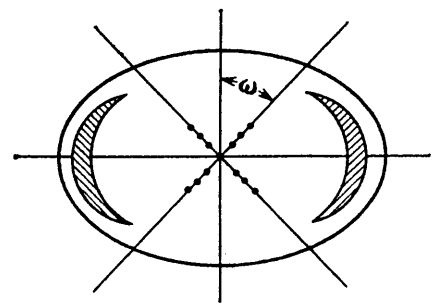

Figure 14. Schematic representation of the X-ray diffraction pattern compound XXXIX ($n = 6$).[54]

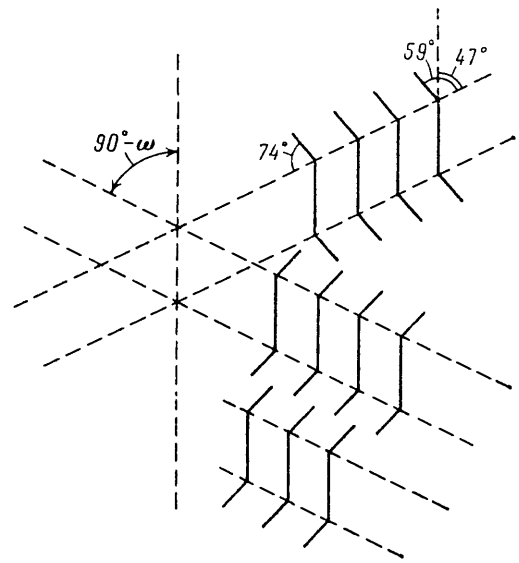

Figure 15. Polydomain model of the smectic phase of compound XXXIX ($n = 6$).[54]

The example given shows that allowance for the non-linearity of the molecules (an attempt to make this allowance was also undertaken in the work cited above[53]) blurs the classical structural representations of the calamitic phases *SmA* and *SmC*. To this must be added the possible sinusoidal corrugation of the layers, allowance for which, for example, gives best agreement with experiment in the optical modelling of the diffraction pattern of the smectic mesophase of compound XXV (n = 7).[55] The authors cited proposed the examination of various hypothetical layer structures formed from rod-shaped and zigzag molecules to explain the extended (parallel to the equator) form of the meridional reflections. The best model was found to be the model of type $SmA\tilde{}$ discussed below.

Recent studies have shown that in many cases, smectic phases have a bilayer structure. This important feature of their structure is usually related to the non-linear configuration and polarity of the molecules.

One of the first investigations in which the bilayer structure of a smectic mesophase was detected involved an X-ray diffraction and dilatometric study of compound I at different temperatures.[56] The proposed structural model, constructed with allowance for the angular configuration of the molecules, is shown in Fig. 16.

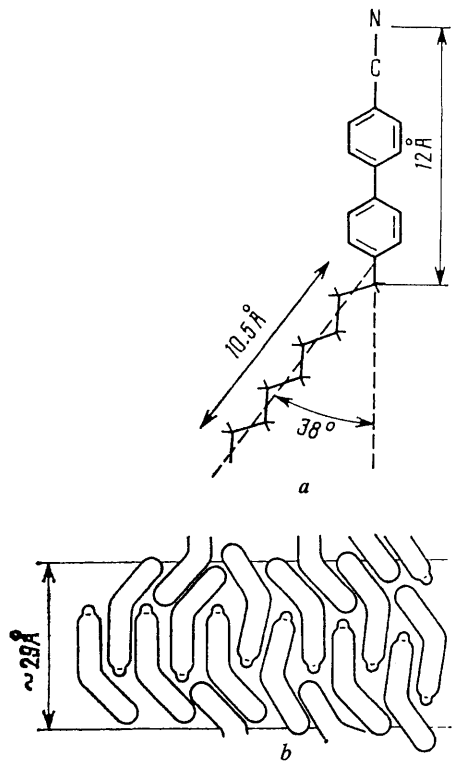

Figure 16. Structure of the molecule of compound I (*a*) and the packing of the molecules in the smectic phase (*b*).[56]

Dilatometric and X-ray diffraction data[57,58] were also combined in a study of the structure of the mesophases of compound XXX, of the type *SmA*. Two homologous series (m = 0 and 1) were studied, in each of which the central aromatic part remained unchanged, and the aliphatic chain joined to the ester group was varied (n = 1–16). The dilatometric study gave the molar volume, and the X-ray diffraction study gave the layer thickness (d) throughout the temperature range of existence of the mesophase. In the opinion of the authors cited, the experimental data show best agreement with the "bilayer" model (Fig. 17). The central part of the "bilayer" consists of the aromatic sub-layer, which contains practically no aliphatic "tails" and is therefore comparatively rigid and highly ordered. On both sides of the aromatic sub-layer there are much less ordered sub-layers consisting of aliphatic chains. The axes of the aromatic fragments of the molecules of the lower homologues of the series with m = 0 make an angle of 70–75° with the average plane of the layer, but are arranged approximately at right angles for the higher homologues and for all members of the series with m = 1. The thickness of the aromatic sub-layer for m = 0 and n = 2 is 16.7 Å, and for m = 0 and n = 14 it reaches 18.0 Å, which is practically equal to the length of the aromatic part, found from the model of the molecule; on going from one homologue to another, the total thickness of the layer increases by an average of 1.51 Å (m = 0) and 1.35 Å (m = 1), although according to model representations the increment in the length corresponding to a CH_2 group is 1.27 Å. This last feature is due to the specific structure of the bilayer. For m = 0, the thickness of the aliphatic part of the layer is determined by the average slope of the chains to the plane of the layer, which is equal to ~40°; for m = 1, the thickness of this part of the layer decreases, and the degree of order also decreases. With increase in temperature, the thickness of the bilayer increases slightly, according to a linear law. Using the X-ray diffraction patterns and the data on the structure of smectics described above, the authors cited tried to obtain information on the structure of the layers in the crystalline forms of the smectogens XXX being considered.[59] Unambiguous results could not be obtained, however (in principle, both bilayer and monolayer packings of the molecules are possible).

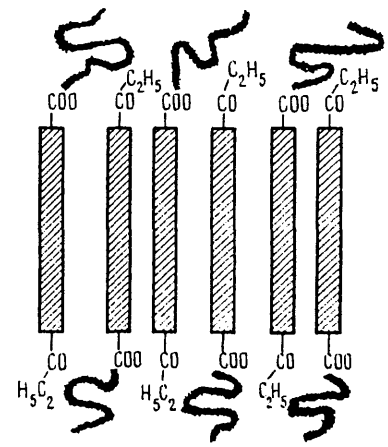

Figure 17. Structure of a smectic "bilayer".[57]

Similarly, a small-angle X-ray diffraction study[60] detected a "bilayer" structure in the phase of type *SmA* formed by compound VIII (the nematic phase of this substance contains molecular dimers, represented schematically in Fig. 12).

In addition to the nematic phases described in the previous section, smectics of the cyano-derivatives II (n = 10, 13, 16, 18), VII (n = 8), and XXII have been studied.[41–43] Here, three features are noteworthy. Firstly, for the phase *SmA* of compound XXII, decrease in temperature leads to the appearance of dumbbell-shaped reflections, indicating the production of skewed cybotactic groups, and the lines drawn through the centres of gravity of the molecules making up the cybotactic group make an angle of 27° with the *SmA* layers. Secondly, in this case also, bilayers in which the molecules are arranged in antiparallel orientations and are apparently joined to form dimers are also observed. Thirdly, and finally, in the smectic phase† of compound VII (n = 8), as in the nematic phase, a double periodicity is observed ($d_1 \simeq 1.4l$, $d_2 \lesssim l$). This apparently indicates the coexistence of bilayers and monolayers in which the molecules on the average have the parallel orientation.

Double periodicity of the smectic phase has also been observed[50] for compound XIX. In the weakly oriented state of the mesophase, splitting of the meridional reflections is observed; instead of the period 24.9 Å, periods of 32.5 Å and 26.6 Å appear for orientation in an electric field, and of 31.6 Å and 21.3 Å for orientation in a magnetic field. The authors cited pointed out, however, that both the existence of double periodicity in the packing of the layers and the presence of domains in which the smectic layers have the form of coaxial cylinders are possible in this case. According to Mineev,[51] the diffraction of X-rays on cylindrical smectic layers should lead to the observed splitting of the reflections.

The general picture of the bilayer structure of smectics, the phenomenon of double periodicity, and the reflection of these effects on the X-ray diffraction patterns were examined by Hardouin and co-workers.[61–63] According to the authors cited, there are three sub-types of mesophases *SmA* (Fig. 18) constructed from polar molecules: 1) the smectic A_1, consisting of non-polar monolayers (in a special case, the molecules in this layer may be joined to form dimers); in this smectic, $d \simeq l$; 2) the smectic A_2, consisting of double layers, each of which includes two polar monolayers; in this case, $d \simeq 2l$; and 3) the smectic A_d, formed by bilayers, where $l < d < 2l$. To this must be added the phase of type $Sm\tilde{A}$ with periodic modulation.[61]

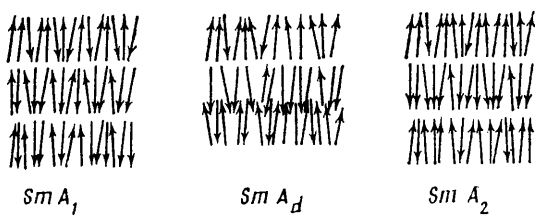

Figure 18. Structure of mesophases *SmA* belonging to different sub-types.

Fig. 19 compares the diffraction patterns (meridional reflections) characteristic of these three types of smectic with that for the nematic mesophase. The two diffuse haloes on the X-ray diffraction pattern of the nematic are characterised by the wave vectors $\mathbf{q}_2 = (2\pi/l)\mathbf{n}$ and $\mathbf{q}_1 > (2\pi/2l)\mathbf{n}$, where $\mathbf{n}$ is a vector showing the direction of the director; the vector $\mathbf{q}_1$ is due to the periodicity of the strings formed by individual molecules, and the vector $\mathbf{q}_2$ is due to the periodicity of the strings consisting of dimers. The smectic A_2 gives two Bragg peaks, corresponding to the polar monolayers and the double layers. For the smectic A_d, two Bragg peaks are observed, corresponding to the first and second order of diffraction from the bilayers. Here, however, a diffuse halo is usually observed in the region corresponding to the wave vector $\mathbf{q}_2 = (2\pi/l)\mathbf{n}$; this is due to the fact that the bilayer structure generally contains regions having a monolayer structure (see Fig. 23). For the smectic A_1, a Bragg peak corresponding to monolayer packing is observed, together with a diffuse halo, which indicates that this smectic is usually impregnated with the bilayer structure. The modulation of the layers, characteristic of smectic *A*, leads to doubling of the meridional reflection. If this modulation is sinusoidal, the reflection may be not split, but elongated along the equator.

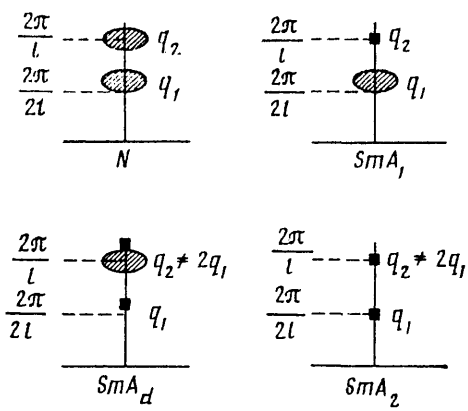

Figure 19. Schematic representation of the X-ray diffraction patterns of a nematic and of mesophases *SmA* belonging to different sub-types.[63] The black points denote the Bragg peaks corresponding to highly ordered elements of the structure; the hatched regions represent the diffuse peaks corresponding to structural features with a low degree of order.

These characteristics of the X-ray diffraction patterns can be established and studied systematically only by highly accurate measurements, examples of which have been published.[63] Thus compound XXXV in a narrow temperature range is converted from the nematic to the smectic phase SmA_d, and then to SmA_2. A mixture of compounds XXXV and XXXVIII (n = 4) with decrease in temperature passes through stages involving the formation of a nematic and then the successive phases SmA_1 and SmA_2. A study of the temperature dependence of the thickness of the smectic layer, carried out[64] for individual compounds and mixtures, showed that in the transformation $SmA_d \rightarrow SmA_2$ the value of d increases smoothly and continuously, indicating, in the opinion of the authors cited, that this transformation is not a phase transformation. Examples of mixtures of mesogens whose structure corresponds to the type $Sm\tilde{A}$ have been given.[61]

† This phase is a phase of the type *SmE*; these smectics are described in section V.

phases $N(1)$ and $N(2)$ reduces to a difference in the structures of the strings, which have a larger period in the first case. The lateral interaction of these strings in the regions of the equilibrium diagram corresponding to the nematic mesophases is insufficient for their relative displacement to be detected. When the nematic is converted into the smectic phase, a rearrangement takes place, as a result of which the layer structure is detected.

The structural interpretation of the transformations proposed by Cladis and co-workers,[66] and also the model represented in Fig. 21, apparently have an arbitrary element; the existence of dimers is assumed *a priori*, although in fact they may not be present in some of the phases examined. In one of their papers,[65] the authors cited also took account of the possibility of rearrangement (or breakdown) of the dimers in the phase transformation, but this alternative does not appear in their subsequent paper.[66]

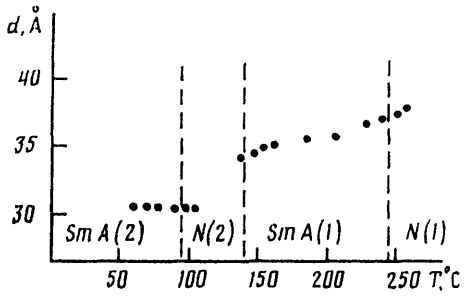

Figure 22. Temperature dependence of the thickness of the smectic layers of compound XLII.[69]

A completely different interpretation of the reverse mesomorphism observed for compound XLII was given by other workers.[68,69] In this case the following chain of thermotropic transformations was detected:

$$C \xleftrightarrow{95\,^\circ C} SmA\,(2) \xleftrightarrow{96\,^\circ C} N\,(2) \xleftrightarrow{138.9\,^\circ C} SmA\,(1) \xleftrightarrow{247\,^\circ C} N\,(1) \longleftrightarrow I,$$

where C represents the crystal, and I the isotropic liquid. The thickness of the layer in the phase $SmA(2)$ in fact is independent of temperature and approximately equal to the length of the molecules (31.4 Å), whereas in the phase $SmA(1)$ the thickness of the layer increases considerably with increase in temperature (Fig. 22). The diagram in Fig. 22 confirms the difference in the periods of the strings in the nematics $N(1)$ and $N(2)$ mentioned above. The authors cited[68,69] also measured the average distances between the long axes of the molecules D for all the phases:

Phase	Temperature, °C	d, Å
N (1)	263	5.3
SmA (1)	150	5.1
N (2)	115	5.0
SmA (2)	75	4.85

They consider that the structure $SmA(2)$ is a monolayer structure, and that $SmA(1)$ is predominantly bilayer. At the same time, with decrease in temperature, the X-ray diffraction patterns of the phase $SmA(1)$ show an additional periodicity, corresponding approximately to four times the length of the molecules (~120 Å). This last feature was attributed to the appearance of monolayer regions. A schematic representation of the structure of the mesophase assumed by the authors cited in this temperature range is shown in Fig. 23, which explains the modulation with a period of ~120 Å. A study of the diffuse spots corresponding to small angles of scattering on the X-ray diffraction patterns of the phase $N(2)$ indicated the presence of cybotactic groups, which are similar to the monolayers of the phase $SmA(2)$ in the lower part of the temperature range, and similar to the bilayers of the phase $SmA(1)$ in the upper part; in the middle of this range, both types of group are observed.

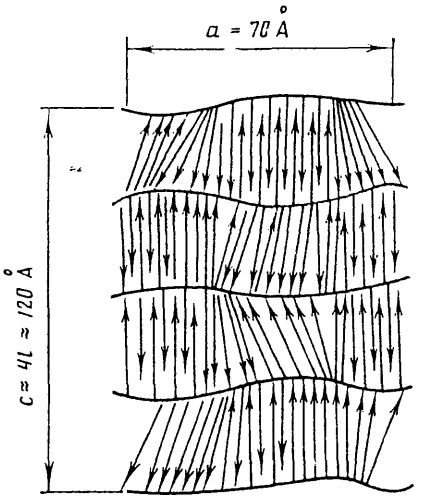

Figure 23. Structure of the mesophase of compound XLIII.[69]

Similar results were obtained[7] for the compound XLIII (n = 9), which differs from the compound XLII studied by Hardouin and co-workers[68,69] only in the bridging group: the group $-CH=CH-$ is replaced by the group $-N=N-$. Here, the following phase transformations are observed:

$$C \xrightarrow{94.0\,^\circ C} N\,(2) \xrightarrow{116.0\,^\circ C} SmA\,(1) \xrightarrow{212.4\,^\circ C} N\,(1) \xrightarrow{242.9\,^\circ C} I.$$
$$\searrow SmA\,(2) \swarrow 70.9\,^\circ C$$

The temperature dependence of the value of d for specimens oriented in a magnetic field is analogous to that represented in Fig. 22, but in this case it was also possible to measure the change in the period of the strings in the range corresponding to the reverse nematic $N(2)$. Here, the interpretation of the results is similar; it is considered that the phase $SmA(2)$ consists of monolayers, the phase $SmA(1)$ is partly bilayer, and in the range of existence of the phase $N(2)$ there is a gradual change from the first to the second structure.

The same compound XLIII (n = 9) and its homologue with n = 8 has been studied at a high pressure.[71] For the homologue with n = 8, reverse mesomorphism was not observed; the change in the temperature of the transformation of the monolayer phase $SmA(1)$ into the nematic phase was linear (Fig. 24*a*). A fundamentally different result was obtained for the bilayer reverse phase $SmA(1)$ of the homologue with n = 9 (Fig. 24*b*). In the last case the phase boundary is represented by a symmetrical curved line; at a pressure of 0.51 kbar the bilayer phase $SmA(1)$ disappears. Thus pressure

stabilises the monolayer structure and destabilises the bilayer structure, converting the latter into a nematic structure (the authors cited point out that their interpretation of the results was based on the model proposed by Cladis and co-workers[65,66]).

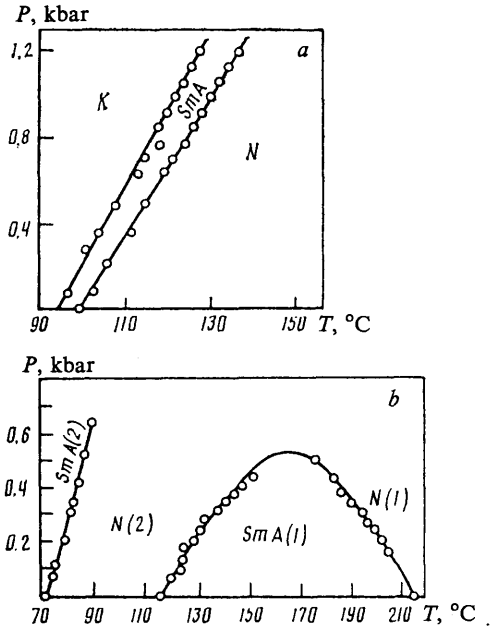

Figure 24. Equilibrium diagrams of homologues of compound XLIII:[71] *a*, homologue with $n = 8$; *b*, homologue with $n = 9$.

In a recent paper[72] it was shown that the number of smectic–nematic reverse phase transformations observed in a single system may be fairly large. Thus for compound XXXIV the following sequence of mesomorphic phases (in the notation of the authors cited) is observed; the types of phase were confirmed by X-ray diffraction data:

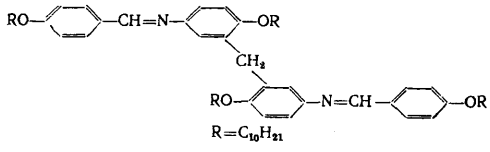
$$I \xrightarrow{224\ ^\circ C} N \xrightarrow{195\ ^\circ C} Sm(\text{bilayer}) \xrightarrow{156\ ^\circ C} N(1R) \xrightarrow{138.5\ ^\circ C} Sm(\text{bilayer})$$
$$\xrightarrow{124\ ^\circ C} N\,(2R) \xrightarrow{121\ ^\circ C} SmA\,(1) \xrightarrow{119\ ^\circ C} SmC \xrightarrow{100\ ^\circ C} SmA\,(2) \xrightarrow{96\ ^\circ C} SmC\,(2).$$

The authors cited relate this variety of phases, firstly to the change with change in temperature in the conformational mobility of the terminal alkyl chains, leading to a change in the effective length of the molecule, and secondly to the possible formation or breakdown of dimers.

Before considering papers dealing with the study of smectics of type *C*, it may be noted that X-ray diffraction data on these mesophases are fairly sparse. The tilt angle φ of the molecules in the phase *SmC* is determined in different ways: 1) from the position of the reflections on the X-ray diffraction patterns, 2) from the ratio of the length of the thicknesses of the layers in the phases *SmC* and *SmA* of a given compound. These estimates are clearly always more or less approximate, since they involve the assumption that the molecules have a cylindrical form, or (and) other approximations.

For compound XXV ($n = 7, 8$), the phase *SmC* is formed directly from the nematic, and the angle φ (~30°) changes little compared with the angle of slope of the molecules in the cybotactic groups of the nematic phase.[73] For a typical representative of smectics of type *C*, namely compound XXXVIII (TBBA), the classical sequence of phase transformations $N \rightarrow SmA \rightarrow SmC$ is observed on cooling. The transformation $SmA \rightarrow SmC$ is accompanied by an increase in the angle φ from 0 to 25 °C, and the results of the direct measurement of φ from the X-ray diffraction patterns (the value φ_P) and its calculation from the thickness of the smectic layers ($\cos\varphi_X = d_C/d_A$) show good agreement.[74]

The temperature dependence of the angle φ in *SmC* has been studied[37] for compound XXI; with increase in temperature, the angle φ increases, and φ_P and φ_X diverge. The authors cited attribute this last feature to the zigzag form of the molecules, and suggest that the thickness of the smectic layer be described by the expression



$$d = a_0 \cos\varphi_1 + (l_1 + l_2)\cos\varphi_2,$$

where a_0, l_1, and l_2 are the lengths of the central aromatic part and the terminal fragments of the molecule, and φ_1 and φ_2 the angles of slope of the aromatic ring and the "tails" to the plane of the layer ($\varphi_1 = \varphi_P$). It was found that in the substance studied, the terminal chains are arranged almost at right angles to the layer, and the aromatic rings are sloping.

The thickness of the smectic layer of the phase *SmC* of compound XXV ($n = 7$) has been measured at different pressures up to 1.5 kbar [75] and up to 3.8 kbar,[76] and the angle of slope of the molecules to the plane of the layer determined. For $d = 23.5$ Å, atmospheric pressure, and a molecule length of 32.1 Å (found from the model), $\varphi = 43°$. An interesting feature is that with increase in pressure, the value of *d* and hence the angle of slope remain practically unchanged. The authors cited[76] point out that the nature of the change in the structure with the smectic *C* is compressed is still not clear. The $P-T$ diagram shows a triple point at a pressure of 6.67 kbar and a temperature of 164 °C. Above this pressure, the solid phase is converted directly into the nematic phase.

A characteristic feature of the smectic phase of the chiral compound XV [75] is its spiral character (type *SmC**). This phase is produced from the phase *SmA* with increase in pressure, and the thickness of the layer, which in *SmA* was independent of pressure, decreases considerably in *SmC** (the slope of the molecules increases) (Fig. 25); the substance is then converted into *SmI**. The authors cited compared the behaviour of this substance with that of compound XXV ($n = 7$); in the last case the phase *SmC* is formed directly from the nematic phase (the stage *SmA* is not observed), and the thickness of the sloping smectic layer is practically independent of temperature and pressure. An attempt to relate the difference described to the structures of the molecules of the compounds being compared was unsuccessful, however.

An analysis of the structure of mesophases of the type *SmC* for the compound

proved to be extremely complicated, because of the conformational non-rigidity of the molecules and the possible coexistence of completely different conformers in the same mesophase. Three

specimens (obtained in different ways) of this compound, called "Siamese twins", were studied.[77] Specimen *A*, obtained by crystallising from a solvent, in both the crystalline (28 °C) and the smectic (122 °C) phases gave a diffraction maximum indicating the presence of layers with d = 23 Å. Specimen *B*, obtained by cooling the melt, at the same temperatures in both the crystalline and smectic phases gave a maximum corresponding to layers with d = 32 Å. Finally, for specimen *C*, obtained by rapid heating to 125 °C, a diffraction pattern with two maxima (d = 23 Å and 32 Å) was observed. The authors cited consider that the phases *A* and *B* are formed by different conformers (*a* and *b*) (this naturally leads to the production of layers with different structure and thickness), and that the phase *C* is a mixture of the conformers and contains two types of smectic domain. In the interpretation of the results, the conformers *a* and *b* were assigned structures in which the $C_{10}H_{21}O-C_6H_4-CH=N-C_6H_3(OC_{10}H_{21})$ chains are directed in different directions in one case, and in the same direction in the other. It was also noted that the smectic phase of the compound $C_{10}H_{21}O-C_6H_4-CH=N-C_6H_4-O-C_{10}H_{21}$ (corresponding approximately to half of the "twins" molecule) also give a diffraction maximum corresponding to a layer with d = 32 Å. (This obviously means that in specimens *A* and *B* the extended parts of the molecules are oriented in different ways relative to the planes of the smectic layers.) It is clear, however, that the interpretation of the diffraction data given in the work cited is indefinite. Such complex molecules have an extremely wide range of conformational possibilities; these molecules can also be arranged in layers in different ways.

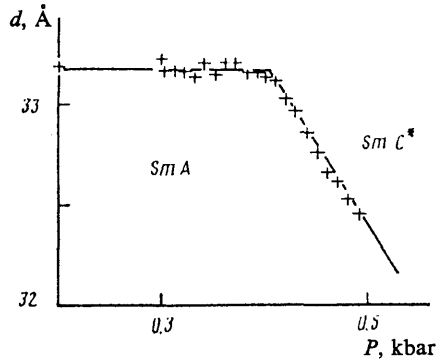


Figure 25. Pressure dependence of the thickness of the smectic layer in compound XV.[75]

Like the smectic phases of the *SmA* type, the sloping smectics show monolayer structures (SmC_1) and structures with double layers (SmC_2).[61] Cases of modulation of the layers are known,[78,79] giving the sub-type *SmC*; here, sinusoidal modulation is replaced by corrugation of the layers, "like the teeth of a saw".[78]

V. Smectic phases with a high degree of ordering

This section is devoted to a systematic examination of X-ray diffraction studies of "crystalline" smectics (the two lowest rows in Fig. 1), and then the less ordered hexatic smectics (second row in Fig. 1). This sequence of presentation is dictated by the chronology: the first detailed studies of the structure of "crystalline" LC preceded slightly the detailed study of hexatic phases.

It should be emphasised that the term "crystalline smectic" indicates the possibility of the experimental determination of the three parameters of a statistical lattice, but does not imply the three-dimensional periodicity characteristic of solid crystals. In addition to local breakdown of the order (for example, faults in the orientation due to the isometric character of the molecules in certain directions), considerable dispersion of the orientational and positional parameters is usually observed in this case, and domain structures of different types are often encountered, together with structural modulations which do not correspond to the effective period. In this case the dynamic parameters naturally have values appreciably higher than those characteristic of solid crystals. It is also important to emphasise that many liquid-crystalline systems are sufficiently ordered (suitable for structural studies) only under special conditions (for example in an electric or magnetic field).

A significant contribution to the study of highly ordered smectic phases was made by Doucet, who summarised his work in a review.[80] In particular, "crystalline" smectics of the compound XXXVIII (n = 4) (TBBA) were studied by X-ray diffraction;[81] the following transformations were observed between the large number of mesomorphic phases:

$$C(9) \xrightarrow{-33\,^\circ C} C(8) \xrightarrow{113\,^\circ C} (SmG)\,(5) \xrightarrow{144\,^\circ C} SmC\,(4) \xrightarrow{172\,^\circ C}$$
$$52\,^\circ C \uparrow \qquad \uparrow 84\,^\circ C$$
$$(7) \xrightarrow[68\,^\circ C]{} (6)$$
$$\longrightarrow SmA\,(3) \xrightarrow{200\,^\circ C} N\,(2) \xrightarrow{236\,^\circ C} I\,(1).$$

A "single crystal" of phase (5), obtained by melting the single crystal (8) without applying an external field, gave two types of X-ray diffraction pattern. These X-ray diffraction patterns, and the arrangements of the molecules deduced from them are shown in Fig. 26. When the X-ray beam is perpendicular to the long molecular axes *L*, the diffraction pattern (Fig. 26*a*) consists of a series of parallel diffuse bands (layer lines), the distances between which are proportional to the reciprocal of the length of the molecule (1/29 Å). This indicates the presence of molecular string along the *c* axis. The thickness of the diffuse layer lines depends on the extent of the ordered section of the string; in the present case it is close to 200 Å, which corresponds to approximately seven molecules. The length of the diffuse bands can be used to find the mean-square deviations of individual molecules from the direction of the string (2°) and the mean-square displacements of the molecules along the string (2.5 Å). Unlike the diffuse bands given by nematics, the diffuse bands in the present case are not curved, indicating that there is little departure from the parallel arrangement of the strings. The intense spots forming a regular row on the layer lines are produced by the smectic layers. The angle between the long molecular axes and the normal to the plane of the layer is 32° at 115 °C (it can be measured directly on the X-ray diffraction pattern). Strings are formed when the layers are superimposed.

The other X-ray diffraction pattern (Fig. 26*b*) corresponds to the equatorial plane *ab*, which is perpendicular to the long axes of the molecules. The 6 Bragg reflections observed in this case indicate two-dimensional translational ordering of the smectic layers (a pseudo-hexagonal lattice). This X-ray diffraction pattern also contains diffuse spots, which can be grouped into three sets of four, lying at an angle of 120 ° to one another. This last feature was interpreted as corresponding to three orientations of the domains. Doucet[80] constructed a scheme for the coherent coupling of

domains oriented in different ways (Fig. 27). Within each domain the cell is monoclinic. The X-ray diffraction patterns described, and also the "powder diagrams", were used to determine the parameters of this cell (at 125 °C):

$$a=10.10(5),\ b=5.18(2),\ c=28.3(2)\ \text{Å},\ \beta=119.0(5)^\circ.$$

According to the current structural classification of smectics (see section II), this structure of the domain corresponds to the type *SmH*. The coexistence of three orientations of the domains, leading to the pseudo-hexagonal nature of the layers, makes it possible to assign the mesophase described to the type *SmG*. In the works cited,[80,81] this mesophase was first regarded as a representative of the smectics of type *SmB* (from the miscibility criterion). Having established the sloping arrangement of the molecules relative to the layers, Doucet suggested that the smectics of type *B* be sub-divided into "upright" (B_A) and "sloping" (B_C). In his review,[80] however, he points out that the X-ray diffraction data show that the phases classified as *SmG* according to the miscibility criterion are identical to phases of the type SmB_C.

In the model described for the structure of the phase (5) of TBBA, the question of the nature of the azimuthal disorder remains open; it may be static (there are no reorientational movements of the molecules involving rotation of the molecules about their long axes) or dynamic (reorientational movements take place, so that the orientation of the domains is constantly changing). Inelastic neutron scattering has shown[82] that the molecules in the phase being considered change their orientation, by rotating through 60°. This is consistent with the proposed model (Fig. 27) if it is assumed that the molecules situated at the vertices of the cell and at its centre are rotated through 60° relative to one another and that they change their orientation in synchronous fashion.

The degree of crystallinity, revealed in the correlation of the relative arrangement of the smectic layers, can be estimated by analysing the profile of the diffuse spots surrounding the Bragg reflections (Fig. 28). An analysis of the phonons generating these diffuse spots at different temperatures was carried out.[80] The intensity profile of the diffuse scattering is described by the function $I(q) = I/q^\alpha$, where q is the distance from the centre of the reflection in reciprocal space, and α the crystallinity criterion. If there is no correlation between the layers of the smectic phase, then, as shown by de Gennes and Sarma,[83] $\alpha < 2$. On the contrary, for phase (5) close to the point corresponding to its formation from the crystal, the value of α is close to 2, indicating a high degree of crystallinity.

A similarity is observed between the structures of the phase (5) and the crystals (8). According to X-ray diffraction data,[84] the crystals (8) contain molecular layers parallel to the plane *ab*, and also strings extending along the *c* axis. The lattice parameters are: $a = 17.56$, $b = 5.75$, $c = 53.2$ Å, $\beta = 115.47°$, structural class $C2/c$, $Z = 8(1)$. Thus the structures of the layers in the mesophase (5) and in the crystalline substance (8) differ considerably, but the

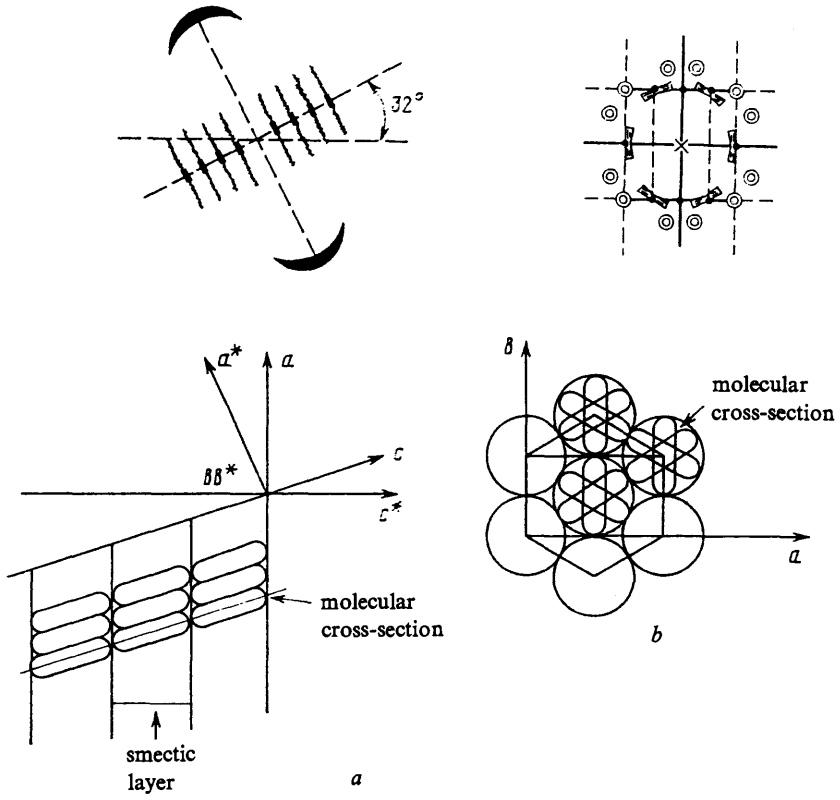

Figure 26. X-Ray diffraction patterns (schematic representations) and arrangement of the molecules in the highly ordered smectic phase of the compound TBBA:[80] *a*, projection perpendicular to the axis *L*; *b*, projection along the axis *L*.

angle between the long axes of the molecules and the normal to the plane of the layer in the crystals is 35°, that is it is close to the corresponding value found for the smectic phase (5). Disorder is observed in the arrangement of the terminal methyl groups, and there is extremely little penetration of the butyl chains into adjacent layers. These two factors weaken considerably the cohesion of the layers, enabling the latter, on fusion of the crystal, to be converted into the smectic phase with comparatively little rearrangement.

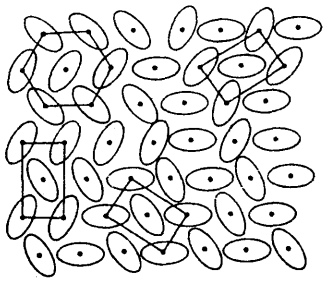

Figure 27. Arrangement of the molecules in the smectic layer of the highly ordered mesophase of compound XXXVIII;[80] three orientations of the cell of the layer are shown.

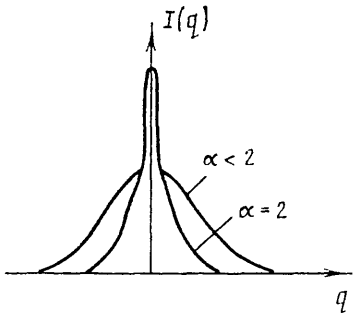

Figure 28. Profile of a Bragg peak surrounded by a background of diffuse scattering.

The conversion of the phase (5) into the crystalline state takes place with the formation of the intermediate mesophases (6) and (7), which are also highly ordered smectics. The X-ray diffraction patterns of phase (6) are similar to those of phase (5), but differ in that only four diffuse spots, that is one orientation of the domains, is observed. Thus the phase (6) can be classified as type *SmH*. In this case the monoclinic cell parameters are: a = 10.38, b = 5.24, c = 28.31 Å, β = 123°. The disorder apparently involves mainly rotation of the molecules through 180° about their long axes (statistical distribution in two azimuthal orientations), in agreement with neutron scattering data.[85] In the phase (7), doubling of the period along the long molecular axes is observed (cell parameters: a = 10.17, b = 5.27, c = 55.24 Å, β = 122.3°). According to the current classification, the phase (7) is evidently a bilayer smectic of the same type.

The X-ray diffraction data[80,85] indicate that the structures of the phases (5) and (6) of TBBA are similar to those of the phases *SmB* and *SmE* of compound XVI (n = 5). The latter undergoes the following mesomorphic transformations:

$$C \overset{92\,^\circ C}{\longleftrightarrow} SmE \overset{101.5\,^\circ C}{\longleftrightarrow} SmB \overset{168\,^\circ C}{\longleftrightarrow} SmA \overset{204\,^\circ C}{\longleftrightarrow} I.$$

The phases *SmB* and *SmE* of compound XVI (n = 5) differ from the phases (5) and (6) of TBBA in that the molecules are approximately perpendicular to the plane of the layer. The X-ray diffraction patterns of the phase *SmB* of this compound do not contain rings with index l equal to 1, indicating a decrease in the correlation of the layers in the transformation *SmE* → *SmB*. Doucet[80] points out that this is not a property typical of all smectics of type *B*; in other compounds, phases of type *B* give reflections with l = 1.§ In the phase *SmB* the azimuthal disorder is such that all the molecules behave as translationally equivalent; this evidently corresponds to the existence of three orientations of the domains with the "herring-bone" arrangement of the molecules. In the phase *SmE* the disorder corresponds to reorientational rotations of the molecules round their long axes through 180°. Neutron diffraction data[87] indicate that this disorder is dynamic.

The phase *SmE* of the homologue of compound XVI with n = 4 has been studied.[88,89] In contrast to the work of Doucet and co-workers,[80,86] it was established that the smectic is "bilayer" (in this case this term apparently means that in a period perpendicular to the plane of the layers *ab* there are two "sub-layers", whose thickness (26.8 Å) is slightly greater than the length of the molecule (25.3 Å); each "sub-layer" is displaced by a distance $a/2$ relative to its neighbour, as shown by X-ray diffraction data for the crystalline phase). The conversion of the crystals into the mesophase *SmE* is accompanied by a marked change in entropy (70% of the entropy effect of the conversion of the crystal into the isotropic liquid). This corresponds to an appreciable structural rearrangement; the angle between the long axis of the molecules and the normal to the layer decreases from ~40° to a value close to 0°.[89] In the specimens obtained by melting the crystal, domains with six different orientations are observed. Incoherent quasi-elastic neutron scattering showed that the relaxation time of the azimuthal rotation of the molecules does not exceed 10^{-10} s, and this rotation is not free (height of the barrier ~10 kT).

"Bilayer" packing of the molecules in a smectic of type *SmE* was also found for compound XVIII (n = 7).[90] X-Ray diffraction showed that the phase *SmE* has an orthogonal cell with parameters a = 8.29, b = 5.17, c = 58.0 Å. By making use of the nature of the absences, which indicates the presence of a glide plane of reflection n, and also by constructing close packing from three-dimensional models of the molecules (with length L = 29.5 Å), the authors cited obtained a model of the structure of the meso-phase (Fig. 29). In their opinion, the unfavourable contact between the CN groups of molecules belonging to different layers (Fig. 29*a*) is compensated by the close packing in the layers, where the benzene rings are in contact with the alkyl chains.

For compound XVIII (n = 7), the following sequence of mesomorphic transformations was observed:

$$C(II) \overset{65\,^\circ C}{\longleftrightarrow} C(I) \overset{73\,^\circ C}{\longleftrightarrow} SmE \overset{95\,^\circ C}{\longleftrightarrow} SmB \overset{111\,^\circ C}{\longleftrightarrow} N_1 \overset{140\,^\circ C}{\longleftrightarrow}$$
$$\underset{51\,^\circ C}{\overset{\uparrow}{\underset{\downarrow}{S_X}}}$$
$$\rightarrow SmA \overset{222\,^\circ C}{\longleftrightarrow} N_2 \overset{273\,^\circ C}{\longleftrightarrow} I.$$

§ According to the ideas presented in section II, the phase *SmB* of compound XVI (n = 5) is to some extent hexatic (*SmB*$_h$).

It is suggested that the transformation *SmE* → *SmB* is accompanied by a relative displacement of the layers, which acquire a hexagonal structure as a result of the orientational disorder, by the magnitude of the vector 1/6*a* + 1/2*b* to give packing of the type ...*ABAB*... With further increase in temperature, on formation of the phases N_1 and *SmA*, adjacent molecules are displaced relative to one another to give "dimers" in which the aromatic parts of the molecules are in contact; this produces a "bilayer" structure with $d/L > 1$ (layer thickness 41.5 Å). At the same time, a non-matching density wave with a period of 34.5 Å is produced. This is interpreted as due to the coexistence of dimers and monomers. The packing of the paired molecules ("dimers" with a bulky central region) in the smectic layers leads to the production of cavities between the alkyl chains. These cavities are occupied by monomers (the ratio of the numbers of dimers and monomers is 1 : 1).

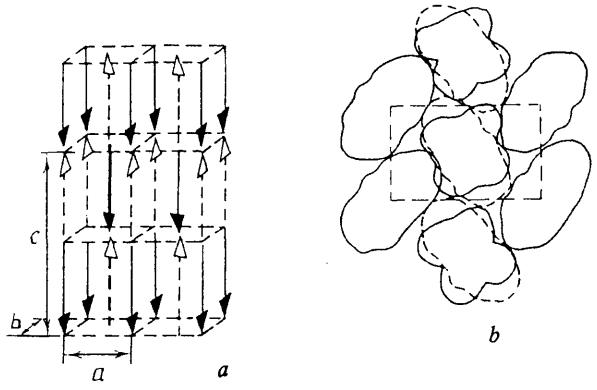

Figure 29. Structure of the phase *SmE* of compound XVIII: *a*, arrangement of the molecules in the volume; the arrows indicate the positions of the CN groups; *b*, section perpendicular to the long axes of the molecules.[90]

A number of detailed studies of the structure and transformations of smectics of type *B* have been carried out in recent years.

Thus Pershan and co-workers[91] studied the phase *SmB* of compound XII ($n = 4$, $m = 8$), which undergoes the following mesomorphic transformations:

$$C \overset{33\,^\circ C}{\longleftrightarrow} SmB \overset{49.6\,^\circ C}{\longleftrightarrow} SmA \overset{63.6\,^\circ C}{\longleftrightarrow} N \overset{78.8\,^\circ C}{\longleftrightarrow} I.$$

Specimens oriented by a magnetic field were studied on a three-circle diffractometer. It was established that the phase *SmB* has three-dimensional long-range positional order. At the same time, an appreciable contribution is made by diffuse scattering. Fig. 30 gives a diagram showing the arrangement of the molecules in the layer and the way in which the layers are superimposed; the packing of the layers is of the type ...*ABAB*... The correlation length is close to 1.4 μm (1.4×10^4 Å) in the plane of the layers, and about 0.14 μm in the perpendicular direction. In the phase *SmA* the correlation length in the plane of the layer is ~20 Å. Thus the conversion of *SmB* into *SmA* is accompanied by very considerable disordering.

The phase *SmB* of this compound was also studied with a higher resolution (synchrotron radiation).[92] The specimens consisted of suspended films, so that it was possible to study the orientational structure of the layers. Sufficiently thick films (number of layers $N = 100$) showed the existence of three-dimensional long-range order. With decrease in the thickness of the film, the inter-layer correlation decreased. In thin films ($N = 4$), which are actually two-dimensional crystals, a correlation length of more than 800 Å was observed, indicating long-range positional order within the layers.

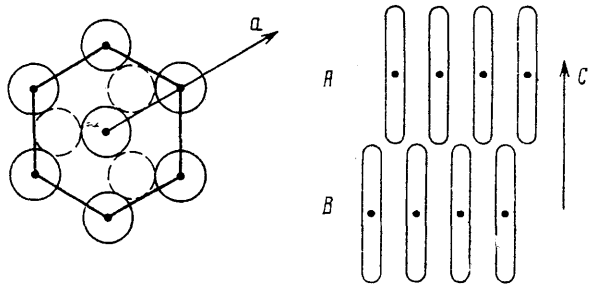

Figure 30. Schematic representation of the superposition of the layers in the smectic phase *B*.

Strong diffuse scattering, not characteristic of ordinary crystals, was also observed for this phase.[82] This scattering was attributed to the existence of a soft displacement mode of the molecular vibrations, due to the weakness of the interaction of the layers. The weakness of this interaction is confirmed by the fact that compound XII ($n = 4$, $m = 8$) in the range 27–5 °C undergoes three structural phase transformations involving a change in the way in which the layers are superimposed. This last feature indicates that the potential energy of the interaction of the layers depends little on their relative displacement.

Similar studies of the phase *SmB* of the compounds XII ($n = m = 4$) and XXXVI established in these cases also the existence of long-range positional order in all three dimensions.[93]

A new and effective method for obtaining oriented single-domain specimens on a hydrophobised support[94] has been used[95,96] to study the mesophases of compound XVIII ($n = 7$), which are formed in the following sequence:

$$X - SmE - SmB - N_{reverse} - SmA - N.$$

The phase originally denoted *X* was found to be a reverse smectic of type *SmB*. This is the first case of the detection of a phase *SmB* below the temperature of the existence of the phase *SmE*.

The structure of the smectic phase of the type *SmG*, and the change in the structure of the LC in the *SmB* → *SmG* transformation, were studied[97–99] for compound XII ($n = 5$, $m = 7$), for which the following phase transformations are observed (°C):

$$C \overset{15\,^\circ C}{\longleftrightarrow} SmG \overset{36\,^\circ C}{\longleftrightarrow} SmB \overset{51\,^\circ C}{\longleftrightarrow} SmC \overset{54\,^\circ C}{\longleftrightarrow} SmA \overset{64\,^\circ C}{\longleftrightarrow} N \overset{78\,^\circ C}{\longleftrightarrow} I.$$

The smectic *SmG* has a monoclinic base-centred (*C*) cell with parameters: $a = 9.54$, $b = 5.02$, $c = 27.9$ Å, $\beta = 114.8°$. The period *c* is approximately equal to the length of the molecule; from this it

follows that the long axes of the molecules form an angle of ~25° with the normal to the plane of the layer. The hexagonal phase *SmB* has a cell with parameters: a = 5.07 Å, c = 28.4 Å.

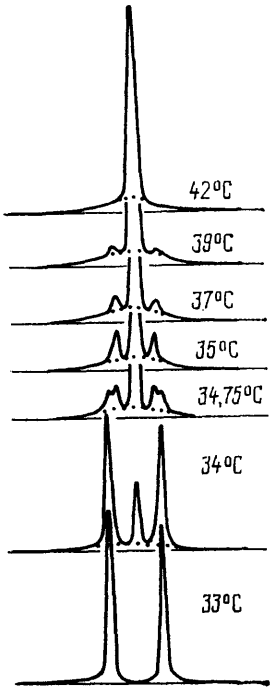

Figure 31. Temperature dependence of the profile of the meridional reflections (l = 1) in the region of the transformation *SmB* → *SmG* for compound XII (n = 5, m = 7).[97]

On the X-ray diffraction pattern of the phase *SmB*, the meridional reflections are extensively broadened and contain a pair of satellite spots, which become stronger and more isolated with decrease in temperature (Fig. 31). The transformation *SmB* → *SmG* leads to doubling of the meridional reflections (only the satellite spots remain). This transformation is preceded by the production of sinusoidal modulation (parallel to the layers) with a wavelength of ~78 ± 3 Å, which is approximately 17 times the period a of the hexagonal lattice. This last result follows from an analysis[98] of the evolution of the satellite spots with change in temperature. The authors cited consider that these spots are produced by the modulated displacement of the molecules at right angles to the layers with an amplitude H, and that the intensity of the satellites is proportional to H^2. The broadening of the meridional reflections is due to the bending of the layers, and the discrete satellite reflections are generated by the wave character of these bends. The amplitude of the modulation increases regularly with decrease in temperature, and reaches a maximum value (4 Å) at 35.5. °C, when the phase *SmG* is produced. There is an abrupt change in the orientation of the long axes of the molecules, which make an angle of 25° with the normal.

The corrugated character of the layers in the phase *SmB* of compound XII (n = 5, m = 7) is confirmed by a study[100] using optical modelling. In the opinion of the authors cited, the diffraction pattern shows best agreement with a model containing, between the layers, cavities separated from one another by an average of 80 Å (Fig. 32). It is suggested that this model is dynamic—the cavities migrate along the layers. The fluidity of this phase was attributed to this migration.

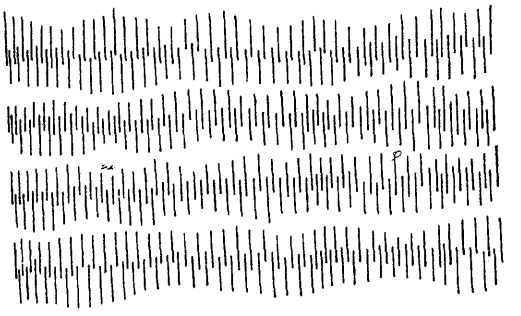

Figure 32. Schematic representation of the arrangement of the molecules in the phase *SmB* of compound XII (n = 5, m = 7), from optical modelling data.[100]

The dynamics of the mesophase of this compound were studied by neutron diffraction. Incoherent quasi-elastic neutron scattering showed[101] that the constant characterising the reorientation of the molecules round their long axes is 1.8 × 10^{11} rad^2 s^{-1} for the phase *SmB* and 1.7 × 10^{11} rad^2 s^{-1} for the phase *SmG*. In the second of these phases, two azimuthal orientations of the molecules, differing by rotation through 180°, predominate. Movement in the direction of the long axes of the molecules is observed in both phases, with a mean-square displacement of 1.4 Å in *SmB* and 1.1 Å in *SmG*. The relaxation time of this movement is comparable with the rotation time of the molecule round its long axis (~5 × 10^{11} s).

The coherent inelastic scattering of neutrons on a completely deuteriated specimen oriented in a magnetic field showed[102] that the relaxation time associated with the modulation of the phase *SmB* is close to 10^{-7} s. Since the longitudinal displacements of the molecules (1.4 Å) takes place in ~5 × 10^{-11} s, the authors cited[102] conclude that the modulation of the phase *SmB* is static (for dynamic modulation the relaxation time should be close to 5 × 10^{-11} s). Thus increase in the amplitude of the modulation with decrease in temperature ensures a minimum value of the free energy; simultaneously, in the opinion of the authors cited, synchronisation of the wave distortion of the layers takes place (more accurately, the displacement with respect to phase for adjacent layers tends to zero), leading to the phase transformation *SmB* → *SmG*.

The description of smectics ordered in three dimensions can be concluded by considering the phases *SmJ*(*SmG'*) and *SmK*(*SmH'*), detected for compound XXXIX (n = 7):[103]

$$C \xrightarrow{127\ ^\circ C} C_1 \xrightarrow{130\ ^\circ C} C_2 \xrightarrow{146\ ^\circ C} SmH' \xrightarrow{154\ ^\circ C} SmG' \xrightarrow{157\ ^\circ C} SmI \xrightarrow{164\ ^\circ C} \rightarrow SmC \xrightarrow{197\ ^\circ C} N \xrightarrow{241\ ^\circ C} I.$$

These phases, however, were also encountered earlier for compounds XVII (the phase *SmG'*) [104] and XXIV (the phases *SmG'* and *SmH'*).[105] The phase *SmX* has been reported[106] for compound XXVIII, whose structural characteristics can be obtained from Table 1. The existence of these phases was not confirmed in subsequent papers, however.

Hexatic phases were predicted in theoretical studies,[107,108] and aroused considerable interest because of an important specific characteristic: with no inter-layer correlations and with only short-range positional order within the layers in these phases, it was suggested that there is long-range order in the orientation of the vectors connecting the centres of gravity of the molecules (bond-orientational order). According to the theoretical hypotheses,[109–111] these phases should be produced by the step-wise fusion of solids. Hexatic character was apparently first established for the smectics *F*. Here, however, the phases of type *B* will be considered first, since they represent the most characteristic hexatic structure, which has also been the subject of a theoretical analysis.

As already noted, different degrees of correlation of the layers in the phases *SmB* have been detected in a number of studies (in particular, temperature-dependent inter-layer correlations have been studied[101]). In addition to the phases *SmB* with crystalline order described above, phases in which there is no inter-layer correlation have been detected.[112] The X-ray diffraction patterns of these phases showed extended rods of scattering with a length of $\sim \pm C^*$, parallel to c^* and centred at sites of the reciprocal lattice *hkl* of low order. Compound XXIII, which exists in the form of a phase *SmB* in the temperature range 107–119 °C, has been studied.[103] The complete absence of reflections *hkl* indicated disordered superposition of the layers. An analysis of the profile of the reflections gave the value of the correlation length within the layer; this was found to be $\gtrsim 350$ Å, which apparently indicates the existence of only short-range order in the layers.

An X-ray diffraction study of freely suspended films of compound III in the phase *SmB*[93] with a thickness of 4 molecular layers established definitely that this phase is hexatic. In this case, analysis of the profile of the peak gave the correlation length $\xi = 150$ Å. At the same time, the very broad form of the maximum for the inter-layer correlations indicates that the latter extend to only one layer.

Smectic phases of the type *F* were first detected in experiments on miscibility in the 1970's; they were later studied by X-ray diffraction[101,103,105,113,114,115,116] in the compounds XXXVIII ($n = 5$) (TBPA) and XXXVIII ($n = 10$) (TBDA), for which the following sequence of phase transformations is observed:

$$C \xrightarrow{68\,^\circ C} SmG \xrightarrow{140\,^\circ C} SmF \xrightarrow{149\,^\circ C} SmC \xrightarrow{179\,^\circ C} SmA \xrightarrow{212\,^\circ C} N \xrightarrow{233\,^\circ C} I$$
$$\nwarrow SmH \overset{61\,^\circ C}{\swarrow}$$

$$C \xrightarrow{73\,^\circ C} SmG \xrightarrow{120\,^\circ C} SmF \xrightarrow{150\,^\circ C} SmI \xrightarrow{158\,^\circ C} SmC \xrightarrow{160.8\,^\circ C} SmA \xrightarrow{192.4\,^\circ C} I.$$

Single-domain specimens obtained by slowly melting single crystals or by cooling the isotropic liquid (with a transition through the phase *SmA*), and a polycrystalline (polydomain) specimen, placed in a capillary subjected to a strong magnetic field, and then cooled in the absence of the field to the temperature corresponding to the formation of the phase *SmF*, were studied.[116]

X-Ray diffraction patterns of two types were examined. In the first case the primary beam was directed parallel to the smectic layers. In this case, sharp 00*l* ($l = 1, 2$) reflections were observed, indicating a layer structure (similar to the phase *SmG*). The *hk*0 reflections (in contrast to those observed for the phase *SmG*) were elongated along the c^* axis, that is along the normal to the layers, and *hkl* reflections with $l \neq 0$ were not observed at all. These features indicate the absence of three-dimensional order. The elongated *hk*0 reflections, which had the form of rods, correspond to the two-dimensional lattice of the layer.

The X-ray diffraction patterns of the second type were obtained with the beam directed parallel to the long molecular axes. Here, six diffuse *hk*0 reflections were observed, indicating (as in the case of the phase *SmG*) a pseudo-hexagonal arrangement of the axes *L* (no signs of herring-bone packing of the molecules were detected).

The X-ray diffraction patterns of polydomain specimens gave the following values of the parameters of the monoclinic *C*-centred cell (Fig. 33): for TBPA at 132 °C, $a = 9.62$, $b = 5.14$, $c \simeq 31.2$ Å, $\beta = 114°$; for TBDA at ~120 °C, $a = 9.64$, $b = 5.22$, $\beta \simeq 112°$ (the angle $180° - \beta$ characterises the slope of the axes *L* to the plane of the layer).

Thus the structure of the phase *SmF* is extremely similar to that of the phase *SmG*. The main differences are that in the phase *SmF* there is almost no inter-layer correlation and, apparently, no elements of the herring-bone pattern in the layers (isotropic rotation or *pseudorotation* of the molecules about the axes *L*).¶

The general features of the X-ray diffraction patterns obtained for the phase *SmI* of compound XXXVIII ($n = 10$) are similar to those for the phase *SmF*; here, however, instead of the rods with indices 200, an extended reflection with indices 020 appears (Fig. 33). This last feature is due to a change in the direction of the axis *L* relative to the lattice of the layer. At 152 °C, the lattice parameters of the phase *SmI* have the values: $a \simeq 5.57$, $b \simeq 9.0$, $c \simeq 42$ Å, $\beta \simeq 116°$. As in the case of *SmF*, the angle $180° - \beta$ is equal to the angle of slope of the axis *L* to the plane of the layer, but in this case the axis *L* forms this angle not with the long period but with the short period of the orthogonal lattice of the layer (Fig. 33). Here, as in *SmF*, the molecules are most probably in a state of rotation or pseudo-rotation about their long axes.

The mechanism of the *SmF* → *SmI* transformation assuming the existence of a phase boundary along which molecules with coordination 5 and 7 alternate in the layer (Fig. 34)[116] is of considerable interest. The displacement of this boundary leaves the positions of the axes *L* unchanged, but rotates the lattice of the layer through 30°. In the opinion of the authors cited,[116] however, an alternative interpretation of the transformation as a collective change in the direction of the axes *L* is possible.

An important part of the works cited[103,116,117] was the analysis of the profile of the diffraction maxima. It was established that the profile of the diffuse "rods" in the direction perpendicular to c^* is described by a Lorenzian curve with correlation length $\xi > 50$ Å for *SmF* and $\xi > 180$ Å for *SmI*. Thus the degree of ordering of the molecules is greater in the layers *SmI* than in the layers *SmF*, although the phase *SmI* is produced at a higher temperature. This is confirmed by the X-ray diffraction patterns of the "polycrystalline" specimens, where the half-width of the diffuse *hk*0 rings for *SmI* is one quarter of that for *SmF*.

Finally, mention may be made of one of the latest practical applications of highly-ordered smectics, closely related to their structure, namely the use of LC as orienting solvents in organic synthesis.[118–120] An example is provided by the isomerisation of benzenesulphonates.

¶ Interestingly, the transformation *SmG* → *SmF* is of first order for TBPA and of second order for TBDA.

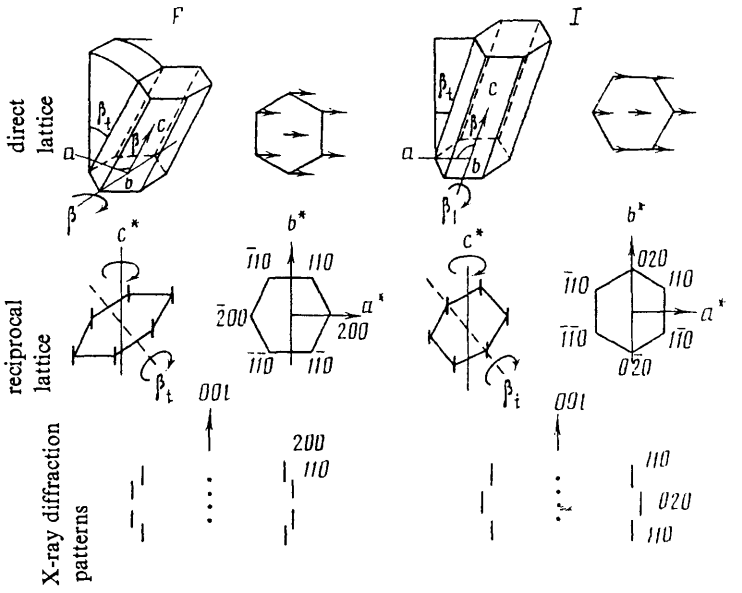

Figure 33. Real and reciprocal lattices and X-ray diffraction patterns of the phases *SmF* and *SmI*, obtained by recording along the layers (specimens oriented in a magnetic field);[103] the arrows indicate the direction of slope of the axes *L*.

Thus the isomerisation of methyl *p*-(dimethylamino)benzenesulphonate, involving the intermolecular migration of a methyl group:

has been studied in detail.[118,121,122] At room temperature, this reaction takes place in the crystal, where the arrangement of the molecules is convenient for this (antiparallel), but does not take place in solution (this question has been examined in detail[123]). The isomerisation of the related compound

does not take place either in solution or in the crystal. Both of these benzenesulphonates isomerise, however, when dissolved in the smectic phase of compound IX,[118] for which the following phase transformations have been detected:

$$C \xleftrightarrow{34.4\,^{\circ}C} SmB \xleftrightarrow{146.4\,^{\circ}C} N \xleftrightarrow{164.7\,^{\circ}C} I$$

An interesting feature is that the isomerisation takes place only in the temperature range of existence of the phase *SmB*. X-Ray diffraction data[121,122] indicate that this phase is highly ordered. The distances between the molecules in the layer (5.50 ± 0.03 Å) differ little from the distances *D* in the nematic phase (5.52 ± 0.06 Å). The thickness of the layer (21.4 ± 0.2 Å) is close to the length of the molecule (23.5 ± 0.5 Å), indicating a perpendicular arrangement of the molecules. Rigid aromatic sub-layers situated between less rigid aliphatic layers are distinguished. Benzenesulphonate molecules have almost no influence on the geometic characteristics of the phase *SmB*. It is suggested that clusters (dimers or larger agglomerates) of the benzenesulphonate molecules are inserted in "head to tail" fashion into the aromatic sub-layer of the phase SmB. This creates conditions for the migration of the methyl groups from one molecule to another for both benzenesulphonates studied. The influence of the molecular packing on the isomerisation is proved by the sharp decrease in its rate on going to the nematic phase of the solvent.

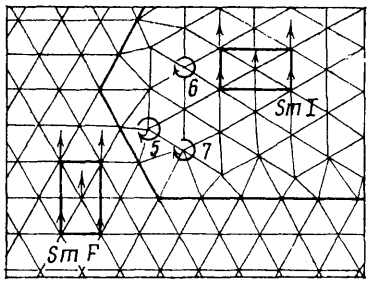

Figure 34. Structure of the boundary separating the phases *SmF* and *SmI*, consisting of 5-, 6-, and 7-coordinate molecules;[116] the arrows indicate the slope of the axes *L*.

VI. Cubic phases

A unique place among calamitic mesophases is occupied by the LC called smectics *D*, although it will be seen that this name does not give a correct picture of their structure. The first homologous series of compounds for which mesophases of this type were found as synthesised in 1957 [124] (compounds V, VI, and XXXIII in Table 3). The homologues of compound V with $n = 16$ and 18

undergo the following phase transformations, detected by differential scanning calorimetry:[125]

$$n=16: C \xleftrightarrow{126.8\,^\circ C} SmC \xleftrightarrow{171.0\,^\circ C} SmD \xleftrightarrow{197.2\,^\circ C} SmA \xleftrightarrow{201.9\,^\circ C} I,$$

$$n=18: C \xleftrightarrow{124.6\,^\circ C} SmC \xleftrightarrow{158.9\,^\circ C} SmD \xleftrightarrow{195.0\,^\circ C} I.$$

X-Ray diffraction showed[126] that the phases *D* do not have the layer arrangement of the molecules characteristic of smectics. Here, the X-ray diffraction patterns of polycrystalline specimens revealed a cubic lattice (space group $Ia3d$) with parameter a = 102 Å and $Z \simeq 1150$ molecules per cell.

A sufficiently well-founded model of the arrangement of the molecules in this mesophase has not yet been constructed. It is considered that in this case, as a result of hydrogen bond formation (or other sufficiently strong intermolecular interactions), the molecules are joined in stable associates as spherical or rod-shaped micellar formations similar to the supermolecular formations in lyotropic LC. (These micelles form a cubic lattice.) The important role of specific intermolecular interactions in the formation of the phase *D* is indicated by the fact that the replacement of the nitro-group in compound V by Cl, Br, or CH_3 leads to the disappearance of this phase.

A cubic phase is also formed by the acid VI (n = 16, 18), which is similar to compound V, but in which the NO_2 group has been replaced by CN. A recent study[127] of the homologue of this compound with n = 18 detected a primitive cubic lattice with symmetry $P23$ or $Pm3$ and parameter a = 86 Å.

The study of the phases *D* is made difficult by the fact that they are formed by only a limited number of compounds. Examples are the hydrazine derivatives XXXIII, which undergo the following sequence of phase transformations:

$$C \rightarrow SmD \rightarrow SmC \rightarrow I.$$

The homologues of compound XXXIII with n = 8, 9, and 10 have cubic lattices with parameters a = 45.7, 48.8, and 51.7 Å respectively.[128] In this case it is considered that intermolecular H-bonds between the NH and CO groups are responsible for the formation of the cubic phase. The polymorphic forms of the compound with similar structure containing the $-CH=N-$ group instead of the $-CO-NH-$ group (which excludes the formation of H-bonds) do not form a cubic phase (the phase *SmC* of this compound with n = 10 has the usual structure for LC of this type).

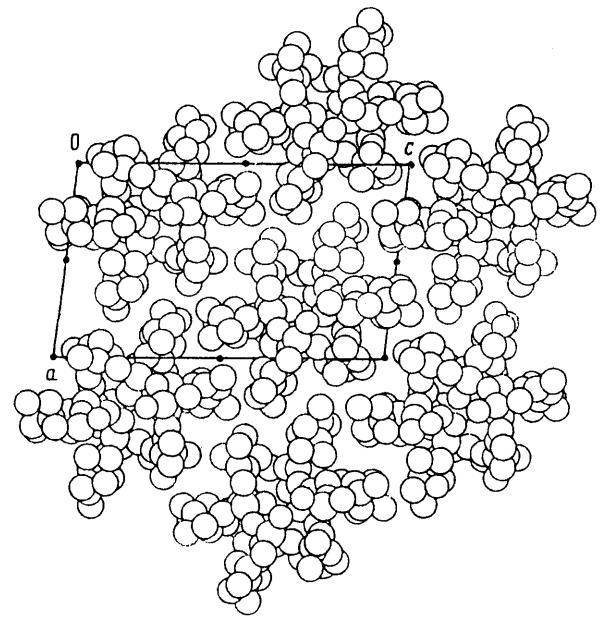
Another type of mesophase with a cubic lattice is the so-called cholesteric "blue" phase, which exists in a narrow temperature range (less than 1 K) between the ordinary cholesteric phases, which have a one-dimensional spiral structure, the blue phase shows three-dimensional spatial periodicity. This phase has been studied mainly by the optical methods, the use of which in this case is analogous to X-ray diffraction studies, since here the parameter of the cubic lattice is commensurate with the wavelength of visible light.

The present state of structural studies of the blue phases has been reviewed.[129,130]† Several possible models are discussed, including: 1) a three-dimensional lattice of disclinations, and 2) an emulsion model, which assumed that the isotropic liquid is disseminated in the cholesteric structure. None of these models has yet been reliably established, however.

† Since the present manuscipt was prepared, another review has been published: H Stegemeyer, T Blümel, K Hiltrop, et al. *Liq. Cryst.*, 1986, **1** 1

VII. Phases with columnar H-associates

The previous sections dealt with mesophases formed by rod-shaped molecules. The liquid-crystalline state is also often observed for compounds whose molecules have a quite different shape. These include primarily the disc-like mesophases, which have been intensively studied in recent years and are the subject of a number of reviews.[131–133] They are formed by molecules containing a rigid disc-shaped nucleus (benzene, triphenylene, truxene, etc.) with alkoxy or alkanoyl substituents attached. The most characteristic forms of discotic is the columnar mesophase, in which the molecules are arranged in periodic or aperiodic stacks. It has recently been found, however, that thermotropic columnar LC may be formed by molecules with shapes completely different from discs. In this case the construction of the columns involves the formation of a system of hydrogen bonds. Examples of these compounds are described below.



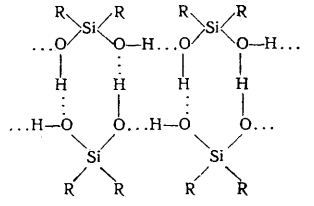


Figure 35. Projection of the crystal structure of $[(n\text{-}Pr)_2Si(OH)]_2O$ on the (010) plane, perpendicular to the axes of the columns.[140]

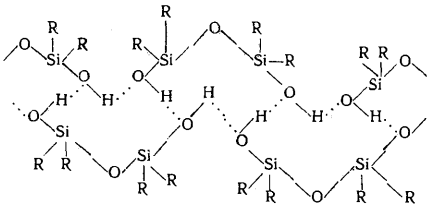
As early as the 1950s it was noted that a mesophase is formed by the silanol $R_2Si(OH)_2$ with R = iso-Bu, whereas other members of the series (R = Me, Et, Ph, iso-Pr, t-Bu) did not show mesomorphism.[134,135] At the time, this mesophase was characterised as smectic, but it was later established[136] that the optical texture of the mesophase of $(iso\text{-}Bu)_2Si(OH)_2$ is similar to that of discotics (in addition, unlimited miscibility of this substance with the classical discotic benzenehexa-n-heptanoate was observed). In the opinion of the authors cited,[136] the similarity in the heats of the phase transformations $C \rightarrow$ LC and LC $\rightarrow I$ (7.6 kJ mol^{-1} and 7.2 kJ mol^{-1} respectively) indicates that each of these transformations involves the rupture of a certain fraction of the H-bonds present in the crystal.

An X-ray diffraction study of single crystals of this compound could not be carried out. An X-ray diffraction study of close homologues of this compound (R = iso-Pr, t-Bu) showed,[137,138] however, that the crystals are made up of infinite H-associates containing cyclic dimers:



The silanediol with R = iso-Bu should apparently have a similar structure. The authors cited[136] liken this associate to a discotic column, where the role of the discs is played by "platforms" approximately perpendicular to the ribbon and each containing two SiR_2 groups.

Similar phase transformations were also observed for various dihydroxysiloxanes. The most extensively studied $[(n\text{-}Pr)_2Si(OH)]_2O$ undergoes the following transformations:[139]

$$C \xrightarrow[29.3\ kJ\ mol^{-1}]{43\ ^\circ C} LC \xrightarrow[20\ kJ\ mol^{-1}]{69\ ^\circ C} I.$$

An X-ray diffraction study[140] of a single crystal of this siloxane grown in a capillary directly from the mesophase showed that in the crystal the molecules are joined in columns (Fig. 35). The outer layer of the columns is formed by the aliphatic substituents, and the core of the column consists of a cooperative system of H-bonds:

The packing of the columns is pseudohexagonal (the crystal belongs to the triclinic system); the averaged parameter of the pseudo-hexagonal two-dimensional lattice is a = 12.66 Å. A planar hexagonal lattice with a = 12.58 Å was also detected in the mesophase of this compound. This suggests that cylindrical columnar H-associates similar to those found in the crystal are preserved in the mesophase. This is confirmed by the similarity in the spectral characteristics of the crystal and the mesophase.

The number of examples of this kind should apparently increase considerably in the near future. It will then be possible to speak of a separate class of liquid-crystalline phases, differing considerably from both calamitic and discotic mesophases.

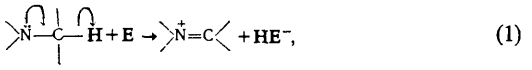
Amines acting as hydride ion donors in reactions with unsaturated electrophilic compounds

G S Kaitmazova, N P Gambaryan, E M Rokhlin (deceased)
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The reactions involving reduction of electrophilic double bonds (C=C, C=O, C=N, and N=N) with amines (usually tertiary) that contain hydrogen atoms at the α-position have been classified. The key stage in such reactions is formation of an iminium salt, which can formally be regarded as the transfer of a hydride ion from the amine to the compound with a double bond, although the actual mechanism may be different. The subsequent reactions of the intermediates formed (iminium cations, enamines, aminocarbenes), including acylation and cycloaddition, are examined. The synthetic potentialities of these reactions for obtaining different functionally substituted linear and heterocyclic compounds are discussed.



The bibliography includes 127 references.

I. Introduction

Aliphatic, alicyclic, and heterocyclic amines that contain hydrogen atoms at the α-position are potential donors of hydride ions and can participate in the reduction of sufficiently active electrophilic compounds [equation (1)]. This ability to eliminate a hydride ion and form an iminium cation is in many cases suppressed by competing reactions which start with addition of the electrophilic partner [equation (2)].[1]

(1)

(2)

Nevertheless, oxidation reactions of hydrocarbon residues in amines occur quite widely and can be effected by treatment with stronger or weaker oxidising agents such as free halogens,[2,3] other inorganic oxidising agents,[4] and also classical hydride ion acceptors[5,6] such as triarylcarbenium ions:1,7–12

A reaction of the latter type is responsible for the thermal decolorisation of triarylmethane dyes containing a carbocation site together with dialkylamino groups.[13]

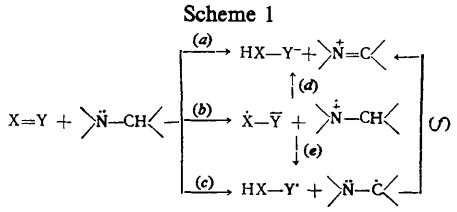
The electrochemical oxidation of amines is also well known.[14] Their fermentative oxidation is of considerable significance in nature.[4]

Among those reagents capable of reactions which may formally be regarded as the elimination of a hydride ion from the α-position of the amine are various unsaturated electrophilic compounds containing double bonds—activated olefins, carbonyl compounds, their hetero analogues, etc. Quite a considerable amount of material on reactions of this type [equation (3)] has been collected to date.

(3)

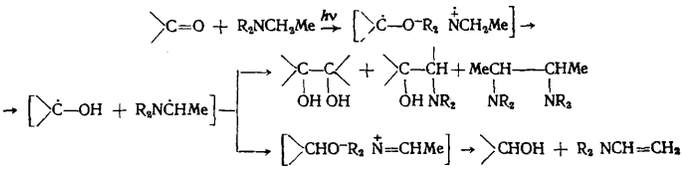
An attempt has been made in this review to classify this material, with thermal reactions mainly being studied. The electrochemical[14] and photochemical[15] oxidation of amines have been the subjects of extensive reviews.

Tertiary amines are usually involved in reactions of type (3), secondary or primary amines are involved less frequently. This is probably because in the latter cases there is the possibility of other reactions, mainly addition to the double bond [equation (4)]. Tertiary amines can also add on to double bonds such as C=C[16–19] or C=O[20–22] but as a rule these reactions are reversible [equation (5)].



(4)

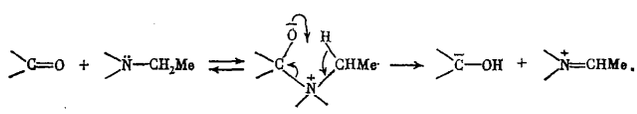
(5)



In principle reactions of type (3) can occur by at least four routes (Scheme 1): 1) direct hydride transfer (*a*); 2) transfer of e^- to form a radical ion pair [usually via a charge-transfer complex (CTC)], then transfer of H^+ and transfer of e^- again (*b*)–(*e*)–(*f*); 3) transfer of e^-, then transfer of $H^\cdot$ (*b*)–(*d*); 4) transfer of $H^\cdot$ followed by transfer of e^- (*c*)–(*f*).

Scheme 1

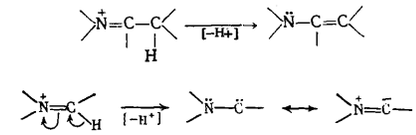
Sometimes the direct transfer of a hydride ion [variant (1)] is assumed for these types of reactions, but mechanisms involving the formation of an intermediate CTC [variants (2) and (3)] would usually appear to be more likely.[4,23–27] Evidence in favour of these is the frequently observed instant colour change when the reactants are mixed and the frequent cases of complexes of amines with different electron acceptors being formed, unaccompanied by further reactions.[23–25,28,29]



Variant (2) usually occurs in the photochemical oxidation of amines.[15,30–33] Free radicals formed at stage (*e*) can both disproportionate to an anion and cation [stage (*f*) and also couple,[15,30–32,34–37] for example:

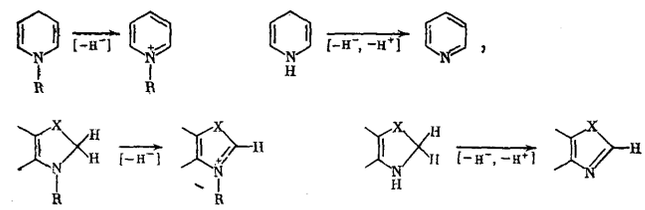
In addition, these free radicals can be identified using t-nitrosobutane as a "trap".[38] It cannot be excluded that in certain photochemical reactions a radical pair is formed directly from the reactants by H· transfer [variant (4)] and avoiding the radical ion stage.[32,39,40] There is evidence that the mechanism depends on the nature of the solvent; in nonpolar media a radical pair is formed directly while in polar media the reaction occurs via radical ions.[39,40]

Variant (3) usually occurs in thermal reactions and formation of free radicals is not observed†[23] (compare, however, the results of Ohno et al.[43]). The overall trend is that in photochemical reactions mainly free-radical coupling products are formed (for example, pinacones from carbonyl compounds[15,30–32]), while in thermal reactions products derived from the reaction of iminium salts are formed.



One further possible scheme for the oxidation of an amine by an unsaturated compound is fragmentation of the intermediate betaine with an "unconventional" transfer of the electron pair on cleavage of the C–N bond,[44–46] for example:‡

But however the reaction might occur—via a CTC, via a betaine, or as a result of direct hydride ion transfer—the oxidation of the amine leads to an iminium salt. In the majority of cases the actual mechanism has not been investigated; nevertheless, taking the result of the reaction as a basis, this type of conversion is usually called a hydride transfer.



In some cases the iminium salt is the final product, in other cases it is an intermediate (identified by NMR, for example, or only postulated).

The anion component of the iminium salt HX–Y⁻ (⁻CHO⁻, ⁻CHN⁻, etc.) can add on a proton from the medium or deprotonate the iminium cation. An enamine is formed as a result of elimination of a proton from the β-position. When there are no hydrogen atoms at this position, an aminocarbene can be formed by α-elimination:

These reactive species are usually not isolated but undergo further reactions, for example, those involving a further molecule of the initial unsaturated compound.

Some of the most effective donors of hydride ions are dihydroaromatic heterocycles such as 1,4-dihydropyridines,§ thiazolines, and imidazolines. Thus, they can reduce hexafluoroacetone,[49,50] hexachloroacetone,[28,51,52] thiobenzophenone,[53] trifluoroacetophenone,[26,27] imines and enamines,[54] unsaturated carbonyl compounds,[55–57] haloquinones,[23] and carboxylic acid chlorides.[58] The driving force of these reactions is formation of an aromatic system:

However, sufficiently electrophilic double bonds can also be reduced by normal aliphatic, aliphatic-aromatic, or saturated heterocyclic amines.

It should be emphasised that the redox conversions that occur when amines react with unsaturated compounds are important from different viewpoints. Thus they can be used to synthesise from simple and accessible reactants, compounds which are difficult to obtain by another route. Typical examples are the syntheses based on triethylamine via an unstable intermediate diethylvinylamine (see below). Moreover, it is necessary to take into account the limitations that are imposed by the possibility of side reactions with the traditional use of tertiary amines as basic (or nucleophilic) reactants or catalysts.

II. Reduction of a C=C bond

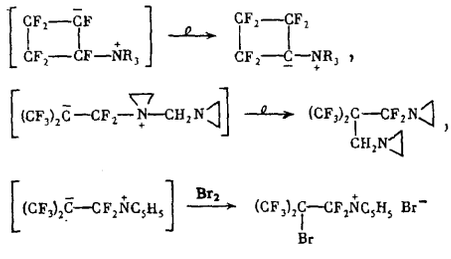
For an olefinic double bond to have sufficient electrophilic reactivity, it must be activated with electron-withdrawing substituents. This condition is also necessary in the case of reactions with amine hydride ion donors.

1. Fluoroolefins

Fluoroolefins are fairly active in reactions with nucleophiles. However, tetrafluoroethylene does not react under normal conditions with tertiary amines. Some tertiary amines have been used as

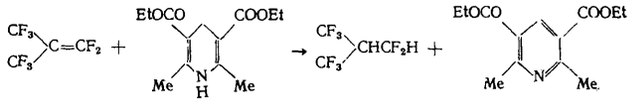
† The acidity of radical cations of tertiary amines is low ($pK_a \sim 15$). This fact, together with the substantial decrease in strength of the α-C–H bond on going from an amine to its radical cation, is evidence in favour of variant (3) involving H· transfer.[41] For the different routes of radical cation fragmentation see Todres.[42]

‡ A "conventional" route is taken to mean the transfer of the bonding electron pair to the positively charged nitrogen atom, leading to decomposition of the betaine to the initial components.



§ Coenzymes of the type NADH, which contain a dihydropyridine ring, play a most important part in biochemical oxidation-reduction processes.[47,48]

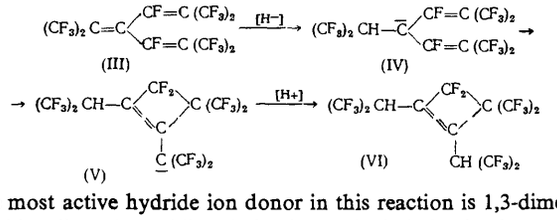
stabilisers to prevent spontaneous polymerisation of tetrafluoroethylene.[59] The reaction of tetrafluoroethylene with triethylamine on exposure to γ-radiation leads only to telomerisation products $Et_2NCHMe(CF_2CF_2)_nH$.[60]



The more electrophilic perfluorocyclobutene and perfluoroisobutylene when reacted with tertiary amines evidently give bipolar ions, for example:

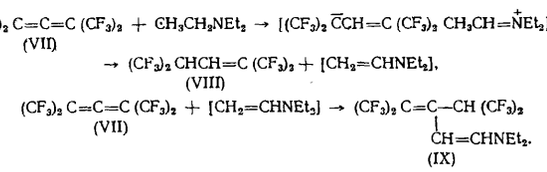
$$(CF_3)_2C{=}CF_2 + NR_3 \rightleftarrows (CF_3)_2\bar{C}{-}CF_2\overset{+}{N}R_3.$$

Indirect confirmation of this type of reaction is that the capacity of tertiary amines to catalyse the dimerisation of bis(trifluoromethyl)ketenimines is suppressed by the addition of perfluoroisobutylene (the rate of reaction is reduced by a factor of over 100).[16] In certain cases products derived by reaction of bipolar intermediates, being formed by rearrangements[16,17,61] or by reaction with an "external" electrophile,[62] have been isolated.



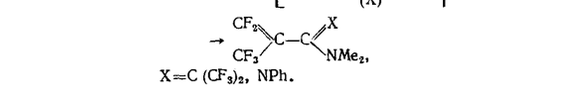
The tendency to form bipolar ions in which the hydride activity of hydrogen atoms is low may possibly also account for the fact that perfluoroisobutylene is not reduced by aliphatic or aliphatic-aromatic tertiary amines and only with Hantzsch ester does it give small quantities of dihydride at 120 °C:[63]

Perfluoroisobutylene reacts as a dehydrofluorinating agent with α,α-difluorotrimethylamine, converting it to the aminocarbene (I); the latter, on reacting with a further molecule of perfluoroisobutylene, is inserted into a C–F bond and gives amine (II):[64]



$$HCF_2NMe_2 \xrightarrow[-(CF_3)_3CH]{(CF_3)_2C=CF_2} [\ddot{C}FNMe_2] \xrightarrow{(CF_3)_2C=CF_2} (CF_3)_2C{=}CFCF_2NMe_2$$
(I) (II)

Introduction of two bulky perfluoroisobutenyl groups into the perfluoroisobutylene molecule inhibits the formation of a bipolar ion with a tertiary amine, at the same time not reducing the electrophilicity of the fluoroolefin. Therefore, the cross-conjugated perfluorotriene (III) readily removes a hydride ion from tertiary amines even at room temperature to form carbanion (IV). This linear carbanion then isomerises to the cyclic carbanion (V), and protonation of the latter gives the substituted cyclobutene (VI):[65]

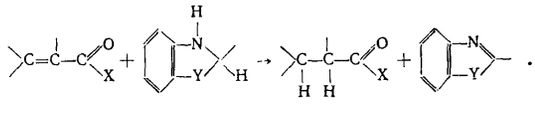


The most active hydride ion donor in this reaction is 1,3-dimethylbenzimidazoline; benzyldimethylamine and triethylamine have comparable activity.

Tertiary amines also reduce the cumulated C=C bond in tetrakis(trifluoromethyl)allene (VII).[66] Reaction with triethylamine at 65 °C results in the formation of the dihydroolefin (VIII) and dienamine (IX). The latter is evidently a product from the condensation of the initial allene (VII) and the intermediate diethylvinylamine:

With 1,3-dimethylbenzimidazoline, allene (VII) gives dihydroolefin (VIII) even at room temperature. Triphenylmethane and phenylacetylene have been used as proton donors in this reaction.[50]

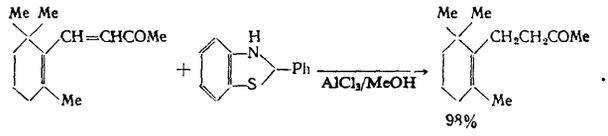
Bis(dimethylamino)methane must have a greater hydride activity than triethylamine. However, when it is reacted with tetrakis(trifluoromethyl)allene or *N*-phenyl-bis(trifluoromethyl)ketenimine, reduction does not occur and there is an "allylic" substitution of a fluorine atom by a dimethylamino group [probably with formation of the intermediate betaine (X)], and the cumulated system of double bonds is converted to a 1,3-diene (or heterodiene) system:[67]



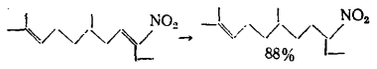
This type of cleavage on treatment with electrophilic reagents to form a dimethylaminomethyl cation which bonds with the anionic part of the electrophile is generally typical for bis(dimethylamino)methane.[68,69]

Thus, out of the fluoroolefins and related compounds studied only perfluorotriene (III) and allene (VII) undergo nucleophilic ionic hydrogenation (compare the results of three studies[6,50,65]) when treated with tertiary aliphatic and aliphatic-aromatic amines.

2. α,β-Unsaturated carbonyl compounds and their analogues



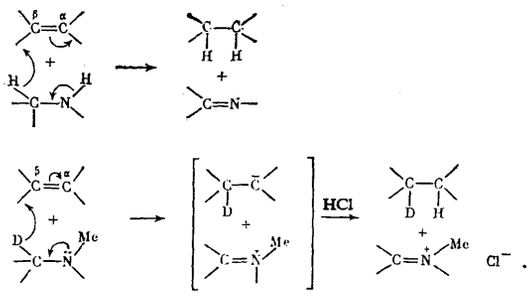
By using nitrogen-containing dihydroheteroaromatic compounds as reducing agents it has been possible in recent years to develop preparative methods for the hydrogenation of the C=C bond without affecting functional groups:



The reduction of a large number of activated olefins $RR^1C{=}CXY$ showed that the ease of reduction of the C=C bond decreases in the series of X, Y: CN, CN > CN, COOR > NO_2, H > COOR, COOR.[57] Replacement of R and R^1 by cyano groups increases the activity of the olefin even further, so that tetracyanoethylene is reduced not only by dihydroheteroaromatic but also by dihydroaromatic compounds such as 1,2-dihydronaphthalene.[70,71]

α,β-Unsaturated carboxylate esters and α,β-unsaturated ketones are reduced by dihydroheteroaromatic compounds only in the presence of Lewis acids.[56] In conjugated dienones it is possible to

reduce selectively just the α,β-C=C bond:[55]



α,β-Unsaturated nitrocompounds and ketones are reduced with Hantzsch ester or 2-phenylbenzimidazoline in the presence of silica gel,[72–74] for example:

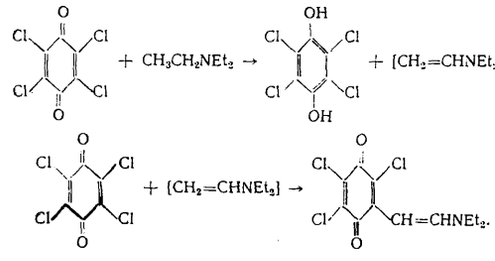
The increased hydride activity in 2-phenylbenzthiazolines from the introduction of electron-donating substituents into the *para*-position of the phenyl ring increases the rate of hydrogenation. This indicates that transfer of a hydride ion is the rate-determining stage of the reaction.[55] The use of benzthiazolines and benzimidazolines that were deuterated at the 2- and 3-positions showed that a hydrogen atom was transferred from the 2-position to the β-position and the hydrogen atom at the 3-position was transferred to the α-position of the compound undergoing hydrogenation.[55,57] In the reduction with 1,3-dimethyl-2-phenylbenzimidazoline, the hydrogen atom at the α-position relative to the functional group of the compound being reduced is derived from the solvent.[56]

In the reaction of (*Z*)-1,2-dibenzoyl-1,2-diphenylethylene with 2-phenylbenzthiazoline only *meso*-1,2-dibenzoyl-1,2-diphenylethane is formed stereospecifically. *cis*-Hydrogenation also takes place in the reduction of ethyl phenylpropiolate.[55]

When these results are combined it can be seen that in hydrogenation with benzthiazolines and benzimidazolines that have an unsubstituted nitrogen atom, transfer of the two hydrogen atoms to the C=C bond being reduced takes place simultaneously or almost simultaneously, while in hydrogenation with 1,3-dimethyl-2-benzimidazoline transfer of a hydride ion occurs [or correspondingly an electron and then a hydrogen atom (see Scheme 1)] followed by addition of a proton from the medium:[55–57]

Cyclic α,β-unsaturated carbonyl compounds such as halogenated quinones are some of the strongest electron acceptors. Their reactions with tertiary amines are examined in Section III.

If the C=C bond in the unsaturated compound is activated only by aryl substituents, this is insufficient for nucleophilic ionic hydrogenation by amines. Olefins such as styrene and stilbene react with tertiary amines only on irradiation, forming products from addition, hydrogenation, hydrodimerisation, etc.[36,39,40,75,76]



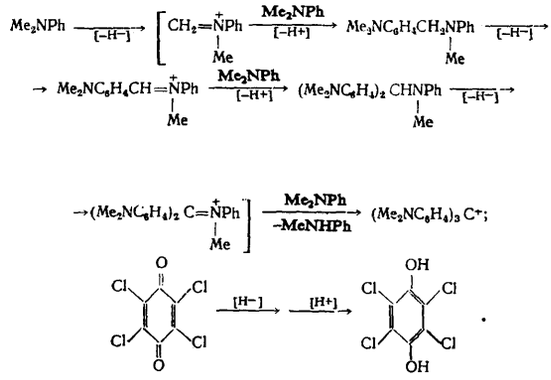
III. Reduction of a C=O bond

Although carbonyl compounds exhibit more marked electrophilic properties than do olefins, in the absence of electron-withdrawing substituents their activity is usually still insufficient for reduction by amines. Only on irradiation are benzophenone, acetophenone, and similar compounds reduced by amines since electron-transfer reactions are typical for the photochemically excited carbonyl group.[15] However, the presence of strong electron-withdrawing substituents in a carbonyl compound enables a hydride ion to be transferred to the unexcited C=O group. In this case reduction via decomposition of a betaine cannot be excluded (see Section I).

1. Haloquinones

Chloranil forms a CTC with tetramethyl-*p*-phenylenediamine[23] or 1,4-diazabicyclo[2.2.2]octane[29] and partially or completely (in polar solvents) isolated radical ion pairs.

When chloranil reacts with triethylamine, it is reduced to tetrachlorohydroquinone, and the resulting diethylvinylamine reacts with a further molecule of choranil, giving a compound with a blue colour—*N*, *N*-diethylaminovinyltrichlorobenzoquinone:[23,77]



Other chlorinated quinones and also bromanil react in a similar manner to chloranil; iodanil does not react with triethylamine.[77,78]

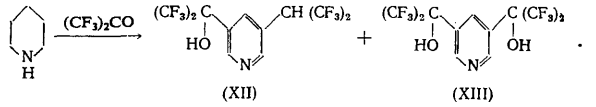
Diethylcyclohexylamine, *N*-ethylpiperidine, diethylaniline, tetramethylethylenediamine, tribenzylamine, benzyldimethylamine, trimethylamine, tributylamine, and dimethylisobutylamine also have reducing properties in relation to chloranil. In the latter case the resulting enamine $Me_2C=CHNMe_2$ has been determined as isobutanal 2,4-dinitrophenylhydrazone.[77]

Replacement of the chlorine atoms in chloranil by methoxy groups leads to a weakening in oxidising properties; dichlorodimethoxybenzoquinones do not oxidise tertiary amines.

The formation of Crystal Violet when dimethylaniline is treated with chloranil under mild conditions may be due to the successive alternation of a hydride ion transfer to chloranil and electrophilic attack by the intermediate iminium cation at the *para*-position of a dimethylaniline molecule:[23]

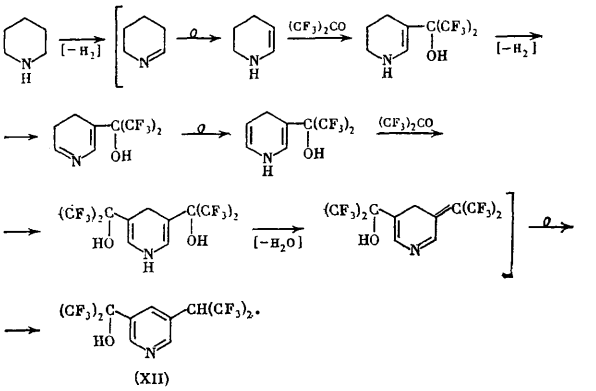
2. Aldehydes and ketones

Hexafluoroacetone, which is a strong electrophile,[79] forms a stable iminium salt (XI)[49] with benzyldimethylamine. On hydrolysis of the salt, hexafluoroisopropanol and *N, N'*-dibenzyl-*N, N'*-dimethyldiaminomethane—a product of the condensation of methylbenzylamine with formaldehyde—are isolated. The hydride ion is mainly removed from a methyl group rather than the methylene group, which Gambaryan and Knunyants[49] attribute to steric hindrance:



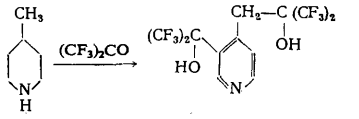
$$(CF_3)_2C{=}O + Me_2NCH_2Ph \rightarrow (CF_3)_2CHO\ CH_2{=}\overset{+}{N}CH_2Ph \xrightarrow{H_2O}$$
$$\rightarrow (CF_3)_2CHOH + PhCH_2\underset{Me}{N}CH_2\underset{Me}{N}CH_2Ph\,.$$
(XI)

Hexafluoroacetone is also reduced to hexafluoroisopropanol when treated with triethylamine,[49] dimethylisopropylamine,[49] and dicyclohexylethylamine[80] (the fate of the respective iminium cations has not been studied). Benzyldiethylamine and tribenzylamine do not react with hexafluoroacetone even on heating to above 100 °C,[49] while a stronger acceptor—the triphenylcarbenium cation—can remove a hydride ion from tribenzylamine.[8]



Benzylamine reacts with hexafluoroacetone to give the adduct $(CF_3)_2C(OH)NHCH_2Ph$; heating the adduct to 160 °C followed by hydrolysis yields hexafluoroisopropanol.[49,81]

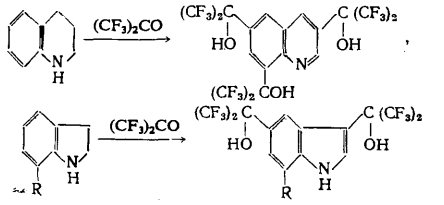
The $(CF_3)_2CHO^-$ anion has been detected by ^1H NMR spectroscopy in mixtures of hexafluoroacetone and trimethylamine, triethylamine, or diethylmethylamine. When there is excess hexafluoroacetone, there is a signal from the $(CF_3)_2CHOC(CF_3)_2O^-$ anion. Both anions have been isolated as *O*-trimethylsilyl derivatives on addition of trimethylchlorosilane.[82]



Hexafluoroacetone can also oxidise indoline, piperidine, and tetrahydroquinoline systems¶.[83–86] Thus, in the reaction of piperidine with excess hexafluoroacetone, substituted pyridines (XII) and (XIII) are formed:[83,85]

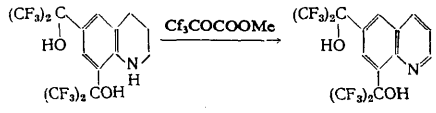
(XII) (XIII)

In this case aromatisation evidently results from a complex succession of reactions, involving not only the oxidation of amines by hexafluoroacetone but also the hydroxyalkylation of enamines, isomerisation of the intermediates with a double bond displacement, and also the dehydration of hydroxyalkyl-substituted enamines, for example:



(XII)

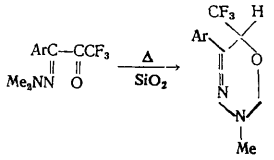
In the case of α- and γ-pipecolines and also 2,6-dimethylpiperidine, hydroxyalkylation of both the heterocyclic ring and the methyl group occurs in addition to oxidation:[85]



β-Pipecoline is substituted only in the ring.

In condensed systems such as tetrahydroquinoline and indolines, both rings can undergo hydroxyalkylation:[84,86]

It has been shown that in the reactions of piperidines and tetrahydroquinolines substitution takes place until the system is aromatised, as the corresponding aromatic heterocycles do not react with hexafluoroacetone under these conditions.[84,85]



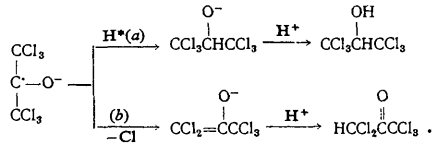
Methyl trifluoropyruvate, in a similar manner to hexafluoroacetone, can oxidise substituted tetrahydroquinoline:[84]

The reaction of hexafluoroacetone with tetramethyl-*p*-phenylenediamine stops at the stage where a CTC is formed.[28] On mixing the reactants the solution at first turns orange ("external complex") and after a few seconds it becomes blue ("internal complex").†

Dimethylaniline is attacked by hexafluoroacetone at the *para*-position,[89] in other words, its potential oxidation to a methyleniminium cation is suppressed by the competing electrophilic substitution in the benzene ring.

Intramolecular oxidation—reduction involving CF_3CO- and $CH_3N<$ groups—takes place on heating 1,1,1-trifluoro-3-arylpropan-2,3-dione phenylhydrazones, giving substituted oxadiazines:[90,91]

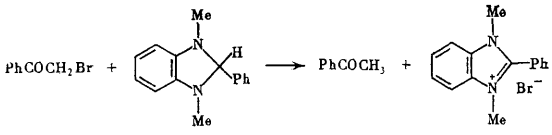
Hexachloroacetone, like hexafluoroacetone, proves to be sufficiently electrophilic to remove a hydride ion from triethylamine. However, the reaction does not stop when an iminium salt is formed. The iminium cation is deprotonated and the intermediate vinylamine is attacked by a second hexachloroacetone molecule with simultaneous haloform decomposition to give the aminovinylketone (XIV):[44]



$$(CCl_3)_2CO + CH_3CH_2NEt_2 \rightarrow (CCl_3)_2CHOH + [CH_2{=}CHNEt_2],$$
$$(CCl_3)_2CO + [CH_2{=}CHNEt_2] \rightarrow CCl_3COCH{=}CHNEt_2 + CHCl_3.$$
(XIV)

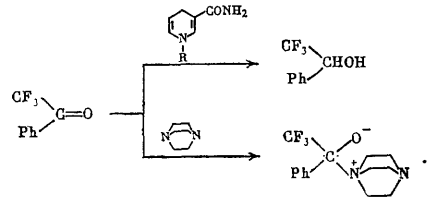
¶Secondary heterocyclic amines are also oxidised by nitrobenzene (in the presence of transition metal salts).[87,88]

† Charge-transfer complexes and their corresponding terminology have been covered in three reviews.[23–25]



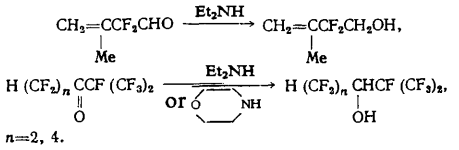
Diisopropylethylamine reacts in a similar manner, with only the ethyl group being oxidised.

When hexachloroacetone is treated with tri-n-propylamine, the product derived from replacing a chlorine atom by hydrogen—pentachloroacetone—is formed in addition to hexachloroisopropanol.[44] Talley[44] suggests that in this case hexachloroacetone acts as a chlorinating agent towards the enamine (compare the results of Laskovics and Schulman[92,93]). It cannot be excluded that both products are formed from a single intermediate—the hexachloroacetone radical anion—by the competing reactions of addition of a hydrogen atom (*a*) and elimination of a halogen atom (*b*):



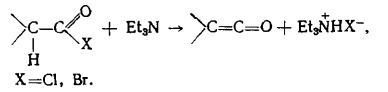
Tetramethyl-*p*-phenylenediamine forms a blue complex with hexachloroacetone;[28] pentachloroacetone and tetrachloroacetone are isolated from the reaction mixture.

An effective reagent for the reduction of α-halocarbonyl compounds which does not affect the carbonyl group is 1,3-dimethyl-2-phenylbenzimidazoline,[58] for example:

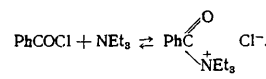


It is assumed that direct hydride transfer occurs in this case.

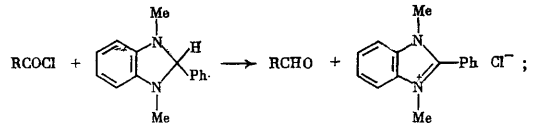
Trifluoroacetophenone, which is less active than hexafluoroacetone, is readily reduced by 1,4-dihydropyridine derivatives[26,27] but with triethylamine, quinuclidine and 1,4-diazabicyclo[2.2.2]octane it forms only betaines:[20]



Cases are known where fluorine-containing carbonyl compounds are reduced by diethylamine. Thus, 2,2-difluoro-3-methyl-3-butenal[94] and polyfluoroalkyl heptafluoroisopropyl ketones[95] are converted to the corresponding alcohols:



3. Anhydrides and halides of carboxylic acids



As has already been mentioned above, reactions of hydride transfer from tertiary amines compete with the direct addition of an electrophile to the amine, leading to ammonium salts. This has a particularly clear effect on the reactions of triethylamine with carboxylic acid halides. Thus, if the acid halide contains α-hydrogen atoms, dehydrohalogenation occurs, in other words, the amine acts as a base:[96]

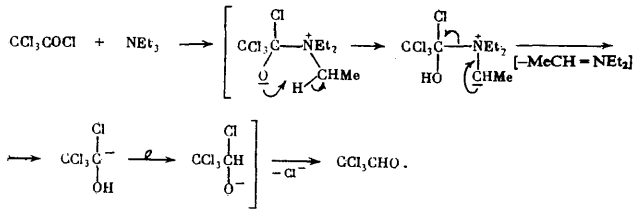
With phosgene[97] and with carboxylic acid chlorides not containing α-hydrogen atoms[98–100] tertiary amines usually form acylammonium complexes, for example:

However, the very strong hydride ion donor—1,3-dimethyl-2-phenylbenzimidazoline—can reduce carboxylic acid chlorides to aldehydes:[58]

R = Ph, *p*-$O_2NC_6H_4$, *p*-$MeOC_6H_4$, n-C_7H_{15}, C_6H_{11}.

In addition, polyhalocarboxylic acid derivatives such as anhydrides,[101–103] acid chlorides,[46,102–105] and acid fluorides[104,105] contain a sufficiently electrophilic carbonyl carbon atom in their molecules that it can remove a hydride ion also from triethylamine.

Thus, acid halides are converted to aldehydes and the resulting diethylvinylamine is acylated by a second molecule of reactant to give aminovinyl ketones:



$$RCOX + NEt_3 \rightarrow RCHO + [CH_2{=}CHNEt_2],$$
$$RCOX + [CH_2{=}CHNEt_2] \rightarrow RCOCH{=}CHNEt_2,$$

R = CCl_3, CF_3, n-C_3F_7, iso-Pr; X = Cl, F.

The reaction is a convenient method for synthesising dialkylaminovinyl ketones, the yields of which are 30–90%. The aldehydes formed are usually not isolated since they are unstable under the reaction conditions. However, chloral is obtained in about 60% yield from trichloroacetyl chloride and perfluorobutyraldehyde is obtained (as its 2,4-dinitrophenylhydrazone) in 16% yield from perfluorobutyryl chloride.[104,105]

The reactions of carboxylic acid halides with tertiary amines most probably involve a single-electron transfer to form a CTC. Evidence in favour of this is the detection of characteristic absorption bands on mixing tetramethyl-*p*-phenylenediamine with trichloroacetyl chloride and also the coloration when diethylaniline, tributylamine, and other tertiary amines are added to trichloroacetyl chloride.[104,105]

Fraser and Swingle[46] suggest that the reduction of trichloroacetyl chloride with triethylamine involves the formation of an intermediate betaine:

They assume that the isolation of small quantities of ethylene and trichloroacetic acid diethylamide results from attack by the *O*-anion site in the betaine on to the β-hydrogen atom rather than the

α-hydrogen atom. However, these by-products could also be formed by decomposition of an acylammonium salt:[104]

$$RCONEt_3^+Cl^- \begin{cases} \longrightarrow RCONEt_2 + EtCl \\ \longrightarrow RCONEt_2 + CH_2{=}CH_2 + HCl\,. \end{cases}$$

The formation of an acylammonium salt should not in principle inhibit reduction of the carbonyl group provided that there is an excess of amine reducing agent, since the electrophilicity of the carbonyl carbon atom in an acylammonium cation should be even higher than in the initial acid halide. In fact, when trichloroacetyl chloride is gradually added to an excess of triethylamine, an aminovinyl ketone is formed in about 90% yield. With the reverse order of mixing reactants, only trace amounts of the aminovinyl ketone are isolated and products derived from decomposition of the fairly unstable acylammonium salt—triethylamine hydrochloride, trichloroacetic acid diethylamide, and a considerable amount of tar—are mainly obtained:

$$CCl_3COCl + NEt_3 \begin{cases} \longrightarrow CCl_3COCH{=}CHNEt_2 \\ \longrightarrow CCl_3C^+(Cl)NEt_3Cl \rightarrow CCl_3CONEt_2 + EtCl + CH_2{=}CH_2 + NEt_3 \cdot HCl. \end{cases}$$

Acid fluorides do not form acylammonium complexes (as a result of the high strength of the C–F bond) and the result of the reaction is virtually independent of the order of mixing the reactants.[104]

In the reaction of perfluoropivaloyl fluoride, carbon monoxide and monohydroperfluoroisobutane, which are products derived from the decomposition of the intermediate perfluoropivalaldehyde, are produced:[104,105]

$$(CF_3)_3CCOF \xrightarrow{NEt_3} [(CF_3)_3CCHO] + (CF_3)_3COCH{=}CHNEt_2 \begin{cases} \\ \longrightarrow (CF_3)_3CH + CO\,. \end{cases}$$

α-Chlorohexafluoroisobutyryl fluoride reacts to form an aminovinyl ketone and a product in which the chlorine atom is replaced by hydrogen:[104,105]

$$(CF_3)_2CClCOF + NEt_3 \rightarrow (CF_3)_2CHCOF + (CF_3)_2ClCOCH{=}CHNEt_2.$$

A similar replacement of the bromine atom by hydrogen on treatment with triethylamine is known for bromides CF_3CXYBr (X, Y = CF_3, COOR).[106]

Tributylamine reacts with trichloroacetyl chloride in a similar manner to triethylamine:[104]

$$CCl_3COCl + EtCH_2CH_2NBu_2 \rightarrow CCl_3CHO + CCl_3COC(Et){=}CHNBu_2.$$

When trichloroacetyl chloride is reacted with trimethylamine, only products from the decomposition of the acylammonium salt are found.[104,105]

In the case of diethylaniline small quantities of aminovinyl ketone are formed, but the main reaction route, as also for dimethylaniline, proved to be acylation at the *para*-position of the benzene ring:[104,105]

$$CCl_3COCl + C_6H_4(NR_2) \begin{cases} \xrightarrow{R=Et} CCl_3COCH{=}CHN(Et)C_6H_4 \quad 7\% \\ \xrightarrow{R=Me,\,Et} CCl_3CO\,C_6H_4(NR_2)\,. \quad \sim 60\% \end{cases}$$

Perfluorobutyryl chloride also acylates diethylaniline at the *para*-position. Moreover, in both cases trace amounts of the corresponding triarylmethane dye—Ethyl Violet or Crystal Violet—are formed (see III.1).

Sources of perfluoroacyl fluorides in reactions with triethylamine can be provided by perfluoroolefin oxides,[104,105] which are known[107] to isomerise readily in the presence of catalytic quantities of tertiary amines

$$(CF_3)_2C(O)CF_2 \xrightarrow{NEt_3} (CF_3)_2CFCOF \xrightarrow{NEt_3} (CF_3)_2CFCOCH{=}CHNEt_2.$$

In a similar manner to perhalocarboxylic acid halides, trifluoromethanesulphenyl chloride can also oxidise triethylamine and undergo condensation with the resulting diethylvinylamine:[108]

$$CF_3SCl + CH_3CH_2NEt_2 \rightarrow (CF_3S)_2C{=}CHNEt_2.$$

In the presence of transition metal compounds as catalysts, perfluoroalkyl iodides also undergo a similar reaction.[109,110] Hydrolysis of the resulting amine (XV) gives an aminovinyl ketone or saturated and unsaturated fluorine-containing aldehydes:

$$R_FCF_2I + (RCH_2CH_2)_3N \xrightarrow{(Ph_3P)_4Pd} \rightarrow R_FCF_2C(R){=}CHN(CH_2CH_2R)_2 + R_FCF_2H + (RCH_2CH_2)_3N \cdot HI,$$

(XV)

$$(XV) \xrightarrow{H_2O} \begin{cases} \xrightarrow{(R=H)} R_FCOCH{=}CHNEt_2 \\ \longrightarrow R_FCF_2CH(R)CHO \xrightarrow{-HF} R_FCF{=}CCHO\,(R). \end{cases}$$

Zhou and Huang[109,110] propose a free-radical mechanism for this reaction as it is suppressed when *p*-dinitrobenzene and *p*-benzoquinone are added.

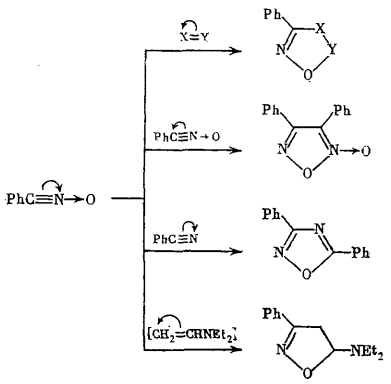
The photochemical reduction of various polyhaloalkanes with triethylamine also occurs by a free-radical mechanism.[111–113]

Trifluoroacetyl bromide phenylhydrazone (XVI) is reduced by triethylamine, with trifluoroacetaldehyde phenylhydrazone and diethylvinylamine being formed. The usual dehydrohalogenation to a nitrilimine occurs together with this; the latter undergoes a [3 + 2]-cycloaddition reaction with the vinylamine, and the subsequent elimination of diethylamine leads to a substituted pyrazole:[114]

$$CF_3C(Br){=}NNHPh \text{ (XVI)} \xrightarrow{NEt_3} \begin{cases} \longrightarrow CF_3CH{=}NNHPh + [CH_2{=}CHNEt_2] \\ \longrightarrow [CF_3C{\equiv}\overset{+}{N}\overline{N}Ph] + Et_3N \cdot HBr \end{cases}$$

$$[CF_3C{\equiv}\overset{+}{N}\overline{N}Ph] + [CH_2{=}CHNEt_2] \rightarrow \left[\text{pyrazolidine intermediate}\right] \xrightarrow{-Et_2NH} \text{1-phenyl-3-trifluoromethylpyrazole}.$$

When bromide (XVI) is reacted with *N*-methylpyrrolidine, only a quaternary salt is formed and reduction is not found to occur:[114]



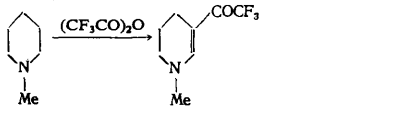
$$CF_3C(Br){=}NNHPh \text{ (XVI)} \xrightarrow{MeN} CF_3C(=NNHPh)\,[Me{-}\overset{+}{N}\,Br^-]$$

The oxidation of triethylamine to diethylvinylamine also occurs in the reaction with benzhydroxamoyl chloride (XVII).[115] The oxidising agent in this case is probably not acid chloride (XVII) but its dehydrochlorination product, a nitrile oxide, which is reduced to a nitrile. Thus, there are two dipolarophiles in the mixture—nitrile and enamine—which can compete for cycloaddition to the nitrile

oxide both with the separate addition of an "external" dipolarophile reagent and with the nitrile oxide itself:

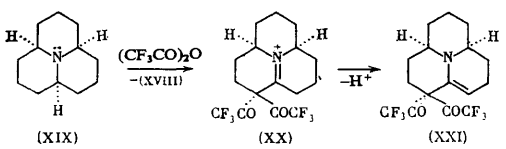
$$PhC(Cl)=NOH + NEt_3 \rightarrow [PhC\equiv N \rightarrow O],$$
(XVII)

$$[PhC\equiv N \rightarrow O] + NEt_3 \rightarrow PhCN + [CH_2=CHNEt_2]$$



The ratio of products depends on the activity of the "external" dipolarophile, the quantity of trimethylamine, and the nature of the solvent.

In addition to acid chlorides, polyhalocarboxylic anhydrides are also readily reduced by tertiary amines, which is shown in the case of trifluoroacetic anhydride.[101,102] The resulting trifluoroacetaldehyde is isolated as acylal (XVIII). The intermediate enamine undergoes acylation, and in contrast to the reactions with acid chlorides, one[101] or both[102] hydrogen atoms can be replaced:



$$(CF_3CO)_2O + Et_3N \rightarrow \underset{\text{(XVIII)}}{(CF_3CO)_2C=CHNEt_2} + CF_3CH(OCOCF_3)_2 + CF_3COO^-\overset{+}{H}NEt_3.$$

Diisopropylethylamine reacts in a similar manner, with only the ethyl group being oxidised. In the case of methylpiperidine the heterocycle is oxidised:[102]

$$CH_3CH_2N(Pr\text{-}iso)_2 \xrightarrow{(CF_3CO)_2O} (CF_3CO)_2C=CHN(Pr(iso)_2 + CF_3COCH=CHN(Pr\text{-}iso)_2,$$

Diisopropylmethylamine is also oxidised by trifluoroacetic anhydride; in this case acylal (XVIII) is isolated but the product from conversion of the amine has not been studied. Treatment of the tricyclic amine (XIX) with trifluoroacetic anhydride gives acylal (XVIII) and the iminium salt (XX), which after treatment with base is isolated as enamine (XXI):[102]

(XIX) (XX) (XXI)

Schreiber[102] suggests various schemes for the mechanism of oxidation, including those that involve single-electron transfer. As the α-hydrogen atoms and unshared electron pair in amine (XIX) lie in different directions from the molecular plane, a mechanism via a cyclic transition state involving a betaine (see Section I) is impossible. However, elimination of a proton could occur on treatment with another amine molecule. Direct hydride transfer also cannot be excluded.

IV. Compounds containing other double bonds

1. Acylimines of fluoroketones

Acylimines of fluoroketones have clearly defined electrophilic activity. Moreover, cycloaddition reactions are typical for these compounds.[116] These properties are exhibited in reactions with tertiary amines.

Hexafluoroacetone benzoylimine readily reacts with triethylamine, oxidising it to diethylvinylamine.[117] When this intermediate reacts with the initial imine, a [4 + 2]-cycloaddition product is formed together with a linear product from addition to the C=N bond:

$$(CF_3)_2C=NCOPh + NEt_3 \rightarrow (CF_3)_2CHNHCOPh + [CH_2=CHNEt_2]$$

$$(CF_3)_2C=NCOPh + [CH_2=CHNEt_2] \rightarrow (CF_3)_2C\langle \text{CH}_2\text{—CH}(\text{NEt}_2)\text{—O—C(Ph)=N} \rangle + (CF_3)_2C(\text{NHCOPh})\text{CH=CHNEt}_2.$$

Hexafluoroacetone carbethoxyimine reacts with greater difficulty, forming only linear products:[117]

$$(CF_3)_2C=NCOOEt + NEt_3 \rightarrow (CF_3)_2CHNHCOOEt + (CF_3)_2C(\text{NHCOOEt})\text{CH=CHNEt}_2.$$

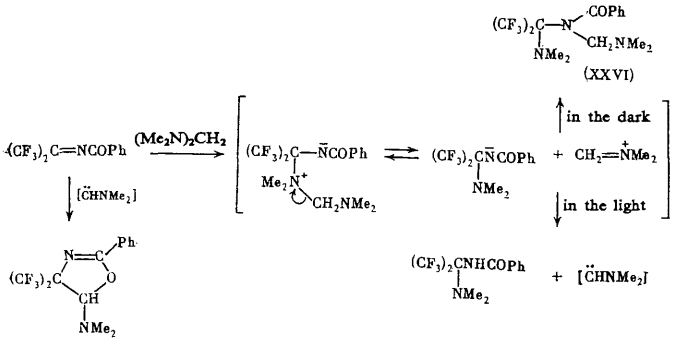
Benzyldimethylamine contains no β-hydrogen atoms in the molecule and the iminium cation that is formed at the first stage of the reaction is deprotonated to an aminocarbene which traps a second hexafluoroacetone benzoylimine molecule to form a [4 + 1]-cycloaddition product:[118]

$$(CF_3)_2C=NCOPh + Me_2NCH_2Ph \rightarrow (CF_3)_2CH\bar{N}COPh\ \overset{CH_2}{Me}\!\!\diagdown\!\!\overset{+}{N}\!\!\diagup\!\!CH_2Ph \rightarrow$$
(XXII)

$$\rightarrow (CF_3)_2CHNHCOPh + \left[\begin{matrix}\ddot{C}H\\ Me\end{matrix}\!\!\diagdown\!\!\diagup\!\!NCH_2Ph\right],$$
(XXIII)

$$(CF_3)_2C=NCOPh + \left[\begin{matrix}\ddot{C}H\\ Me\end{matrix}\!\!\diagdown\!\!\diagup\!\!NCH_2Ph\right] \rightarrow (CF_3)_2C\langle \text{N=C(Ph)—O—CH(Me—N—CH}_2\text{Ph)} \rangle.$$

Exposure to visible light assists the formation of the aminocarbene (the oxidation stage—formation of the iminium salt—does not require light exposure, so this reaction cannot be classed as a photochemical oxidation). The addition of pyridine also accelerates the reaction.‡ The iminium salt (XXII) can be preserved in the dark for a long time but on heating it is converted to the reduction product (XXIII). The products derived from conversion of the amine have not been established in this case.



When hexafluoroacetone benzoylimine is reacted with bis-(dimethylamino)methane,[122] elimination of a dimethylaminomethyl group as a cationoid species also occurs together with hydride transfer (see II.1). As a result of hydride transfer, there is the formation of iminium salt (XXIV), which has been identified by

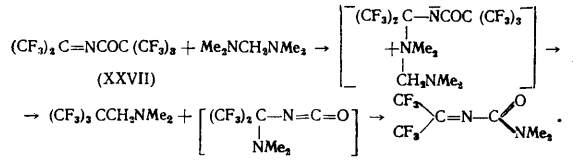
‡ For the generation of aminocarbenes by deprotonation of iminium cations, see the studies of Böhme et al.[7,119,121] Another route for the formation of an aminocarbene from a tertiary amine is dehydrofluorination of α,α-difluorotrimethylamine (see also II.1). The carbene Me_2NCF: undergoes cycloaddition with two moles of hexafluoroacetone to form a substituted dioxolane.[64]

NMR spectroscopy. When this salt is treated with an alcohol it is converted to *N*-benzoylhexafluoroisopropylamine (XXV):

$$(CF_3)_2C{=}NCOPh + (Me_2N)_2CH_2 \rightarrow$$
$$\rightarrow (CF_3)_2CH\bar{N}COPh\ \overset{+}{C}H(NMe_2)_2 \xrightarrow{ROH} (CF_3)_2CHNHCOPh\ .$$
(XXIV) (XXV)

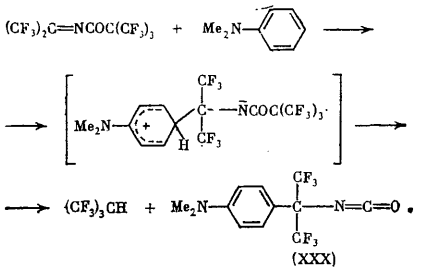
The second reaction route is formation of a betaine followed by dissociation to an anion and the dimethylaminomethyl cation. Subsequently addition occurs in the dark with the formation of triamine (XXVI) while in the light the dimethylaminomethyl cation is deprotonated to dimethylaminocarbene, which traps a second molecule of hexafluoroacetone benzoylimine and a [4 + 1]-cycloaddition product is obtained as a result:

Thus in this reaction bis(dimethylamino)methane serves as the source of a hydride ion, dimethylaminomethyl cation, and dimethylamiocarbene.



The molecule of hexafluoroacetone perfluoropivaloylimine (XXVII) contains a perfluoro-t-butyl group which is readily eliminated as an anion.[16] This property, as a rule, determines the course of the reactions of imine (XXVII).

Benzyldimethylamine donates a hydride ion to imine (XXVII), the resulting iminium salt having been identified by ^{19}F NMR spectroscopy. The cation of the iminium salt then combines with the perfluoro-t-butyl anion being eliminated, as a result of which amine (XXVIII) and monohydroperfluoroisopropyl isocyanate (XXIX) are obtained:[123]

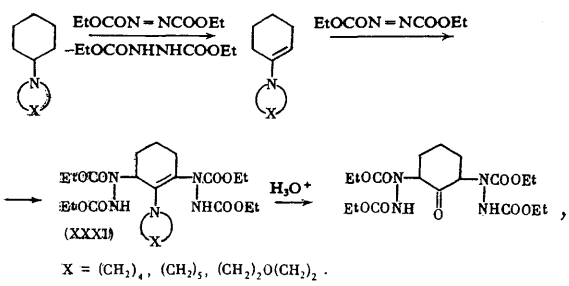


$$(CF_3)_2C{=}NCOC(CF_3)_3 + Me_2NCH_2Ph \rightarrow (CF_3)_2CH\bar{N}COC(CF_3)_3 \rightarrow$$
(XXVII)
$$\rightarrow (CF_3)_2CHN{=}C{=}O + (CF_3)_3CCH_2NCH_2Ph$$
(XXIX) (XXVIII)

Triethylamine also reacts as a hydride ion source with imine (XXVII); in this case isocyanate (XXIX) and monohydroperfluoroisobutane $(CF_3)_3CH$ are isolated.

When bis(dimethylamino)methane reacts with imine (XXVII) it acts only as a source of the dimethylaminomethyl cation; hydride transfer was not found to occur:[122]

Dimethylaniline is attacked by imine (XXVII) at the *para*-position of the benzene ring; elimination of monohydroperfluoroisobutane yields isocyanate (XXX):[123]

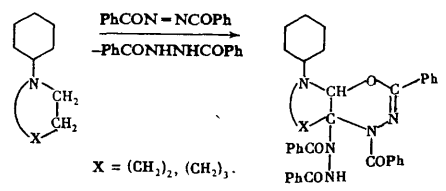


2. Azo compounds

Reactions of tertiary amines with dibenzoyldiimide and diethyl azodicarboxylate resemble the corresponding reactions with hexafluoroacetone benzoylimine. Azo compounds give the reduction products—dibenzoylhydrazine and diethyl hydrazodicarboxylate—in high yield, and the intermediate enamine reacts with the initial azo compound to give either vinyl substitution products of [2 + 4]-cycloaddition products.

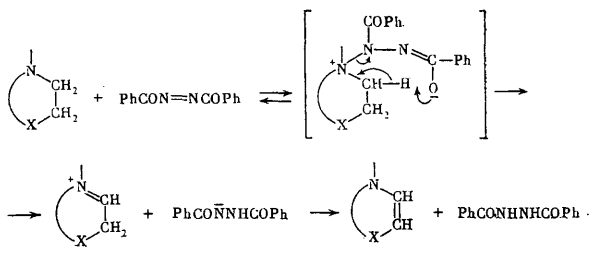
Thus, diethyl azodicarboxylate reacts with triethylamine to form a product derived from double substitution in the intermediate enamine:[124]

$$EtOCON{=}NCOOEt + NEt_3 \rightarrow EtOCONHNHCOOEt + [CH_2{=}CHNEt_2],$$
$$EtOCON{=}NCOOEt + [CH_2{=}CHNEt_2] \rightarrow (EtOCONH)_2C{=}CHNEt_2.$$



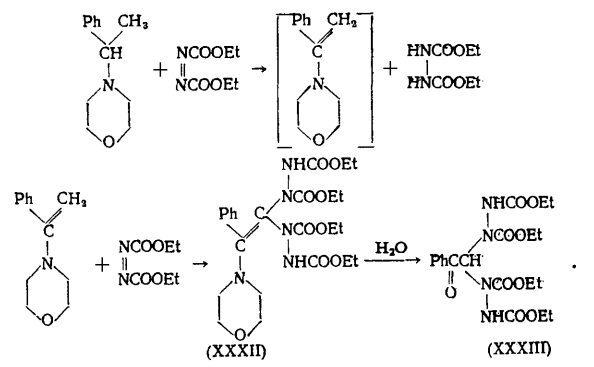
The cyclohexane ring is oxidised in *N*-cyclohexyl-substituted pyrrolidine, piperidine, and morpholine.[124] The azo compound attacks the intermediate enamine to form bis-hydrazines (XXXI):

X = $(CH_2)_4$, $(CH_2)_5$, $(CH_2)_2O(CH_2)_2$.



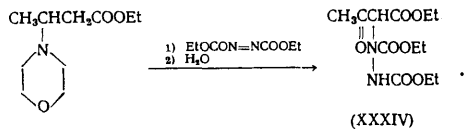
Acid hydrolysis gives a 2,6-disubstituted cyclohexanone. The formation of 2,6-disubstituted compounds (XXXI) is due to the known[125] migration of the double bond in enamines of this type.

Treatment with benzoyldiimide, on the other hand, leads to oxidation of the heterocycle rather than the carbocycle.[45] The resulting enamine reacts with two molecules of initial azo compound to give a product which corresponds to two reaction routes occurring at the same time—replacement of a vinyl hydrogen atom and cycloaddition:

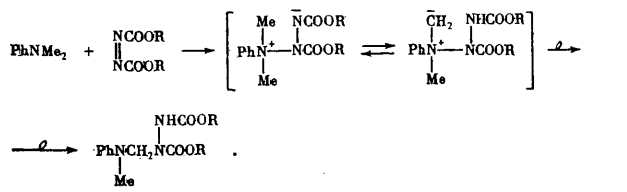


X = $(CH_2)_2$, $(CH_2)_3$.

The variation in oxidation route is attributed to the different mechanisms of these reactions.[45] For diethyl azodicarboxylate a mechanism via the formation of an intermediate CTC and free radicals (styrene added to the reaction mixture undergoes 20% conversion to polystyrene) has been suggested, while for dibenzoyldiimide a mechanism via a betaine has been proposed:

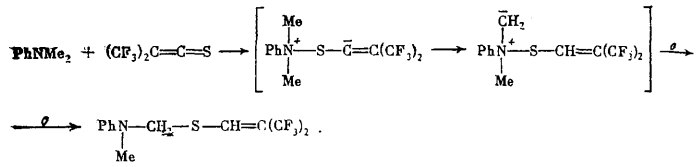


Marchetti[45] considers this to be the explanation for the different behaviour of *N*-cyclohexylmorpholine. Dibenzoyldiimide, in contrast to diethyl azodicarboxylate, does not react with this amine. This appears natural as the basicity of morpholine is less than the basicity of pyrrolidine and piperidine by a factor of 10^3, so the formation of a betaine is inhibited. *N*-(α-Methylbenzyl)morpholine also does not react with dibenzoyldiimide but reacts with diethyl azodicarboxylate.[124] As a result, adduct (XXXII) is formed, and after hydrolysis ketone (XXXIII) is obtained:



The same product is obtained when starting from a known sample of α-morpholinostyrene.

The hydrazine-substituted ethyl acetoacetate (XXXIV) is obtained in a similar manner from ethyl β-morpholinobutyrate:[124]



N-Ethylpiperidine, *N*-methylcyclohexylamine, and *N,N*-diethylaniline also reduce diethyl azodicarboxylate.[124] The products derived from dehydrogenation of the amines were not isolated, but after acid hydrolysis piperidine was found in the reaction mixture in the case of *N*-ethylpiperidine and *N*-ethylaniline was found in the case of *N,N*-diethylaniline.

Dimethylaniline adds on to azodicarboxylate esters with cleavage of a C–H bond in a methyl group. An ionic mechanism via a betaine and ylide rearrangement has been proposed:[126]

This reaction can also be interpreted as a hydride transfer followed by addition of the iminium cation to the aza anion.

Dimethylaniline adds on to bis(trifluoromethyl)thioketene in a similar manner:[127]

The mechanism of this reaction is evidently ionic; it is not suppressed by the addition of diphenylpicrylhydrazyl and is retarded by the introduction of electron-withdrawing substituents into the benzene ring of the amine. A similar addition of ethers to bis(trifluoromethyl)thioketene is sensitive to the addition of peroxides, so the reaction with ethers is possibly a free-radical reaction.[127] Thus, the mechanism of these reactions can vary fundamentally with small changes in the nature of the reactants.

- - - o0o - - -

It is clear from the material presented here that the reduction of unsaturated electrophilic compounds by amines (usually tertiary) occurs quite widely in organic chemistry. In certain cases such reactions are of importance synthetically, and further progress is to be expected in this direction. The study of reactions of this type is increasingly important because they are proving to be undesirable as they can compete with "normal" reactions in which amines are used, for example, as basic catalysts. The authors hope that the present review will to some extent stimulate research in this field.

Binuclear molybdenum(III) complexes

P E Kazin, V I Spitsyn (deceased), V V Zelentsov
Lomonosov Moscow State University

ABSTRACT. The methods of synthesis, properties, structure, and electronic structure of binuclear molybdenum(III) complexes are reviewed. Dimers without monatomic bridges and dimers with oxygen, sulphur, and halogen bridging atoms are described. The effect of the bridging ligands on the nature of the M–M bond and the dependence of the distance between the metal atoms in dimeric halomolybdates(III) on the nature of the internal and external coordination spheres are discussed.

The bibliography includes 132 references.

I. Introduction

Molybdenum has gained a firm reputation as the element which holds the record for the range of cluster systems and compounds with an M–M (metal–metal) bond, including a quadruple bond,[1] formed by it.

A large number of polynuclear complexes in which the M–M bonds differ markedly in length and energy are known for trivalent molybdenum. The diversity of the chemistry of molybdenum(III) clusters is an indication that even for a single electronic configuration, the degree of interaction between metal atoms can vary over wide limits as a function of the ligand environment. In the present review we shall examine binuclear molybdenum(III) complexes, which are the simplest systems in which the Mo–Mo bond can occur.

Dimeric molybdenum(III) complexes can be divided into two groups: 1) complexes whose stability is mainly determined by the Mo–Mo interaction; 2) compounds in which both the Mo–Mo interaction and the ligand bridges make a specific contribution to their stabilisation. To the first group belong dimers without bridging ligands and also complexes which in addition to a strong Mo–Mo bond have bidentate ligands that form polyatomic bridges. The presence of such ligands does not cause any significant change in the structure of the complexes compared to bridgeless dimers. To the second group belong complexes in which the metal atoms are connected by monatomic bridges. The properties and structure of such compounds depend to a considerable extent on the nature of the bridging ligand.

II. Binuclear complexes without monatomic bridges

Molybdenum(III) is capable of forming strong M≡M triple bonds. Such bonds occur in dimers of the type Mo_2L_6 (L = OR^-, R^-, NR_2^-) and their derivatives. A feature of these compounds is the presence of bulky terminal ligands which contain, as a rule, atoms with strong donor properties.[2–7]

Amide, trimethylsilylmethyl, and thiophenol derivatives of the type Mo_2L_6 are obtained by reaction of molybdenum chlorides with LiL. The remaining complexes are synthesised by exchange or addition of ligands or by the insertion of unsaturated molecules into the Mo–L bond in initial Mo_2L_6 dimers in hydrocarbon solvents.[1,5,8–28]

The most commonly occurring structures of the dimers are shown in Fig. 1. Information about the synthesis of the complexes and data on the Mo–Mo interatomic distances are given in Table 1.

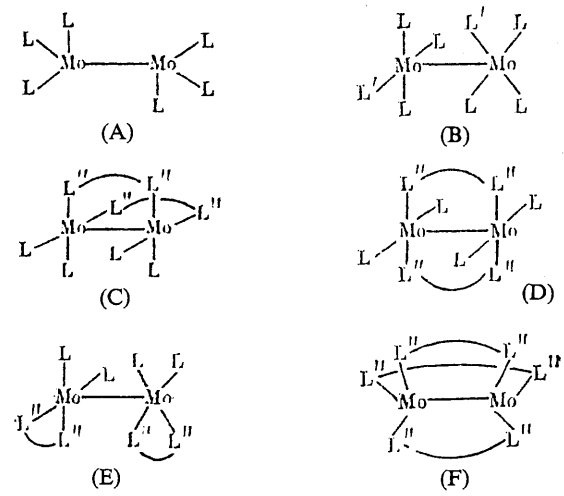

Figure 1. Structures of dimers without monatomic bridges.

Mo_2L_6 molecules have an ethane-like conformation (A). When two ligands are replaced, 1,2-isomers having an *anti* or *gauche* conformation are usually obtained, although 1,1-isomers have also been detected using NMR.[25] For products obtained from the addition of Lewis bases (L′) to Mo_2L_6, a "staggered" configuration of the ligands with an almost planar MoL_3L' square is typical (B). Chelating ligands (L″) can be coordinated in bidentate manner

Table 1. Information on the synthesis and structure of dimers without monatomic bridges.

*Abbreviations adopted: LutH = 2,6-lutidine; DttaH = ditolyltriazine; MhpH = 2-hydroxy-6-methylpyridine; AcacH = acetylacetone.
**Disubstituted phenols and thiophenols contain substituents at the 2- and 6-positions; trisubstituted products have substituents at the 2-, 4-, and 6-positions.

either with a single molybdenum atom [structure (E)] or they form bridges [structures (C), (D), (F)]. The conformation of complexes with bridging ligands is close to eclipsed.

The compounds listed in Table 1 are solid, diamagnetic products which are fairly volatile under vacuum; they have colours ranging from yellow to red and are very sensitive to the effect of atmospheric oxygen and moisture.

The lengths of the Mo−Mo bonds in the dimers are about 2.2 Å, which corresponds to the length of an Mo≡Mo triple bond. From a qualitative examination of the orbitals of the metal ions it must be assumed that there is overlap of the d_{z^2} orbitals of the molybdenum atoms to form a σ-bond and overlap of the d_{xz} and d_{yz} orbitals to form two π-bonds. This assumption is confirmed by calculations using the self-consistent field of X_α-scattered waves (SCF-X_α-SW) method (see Ref. 1, p. 443).

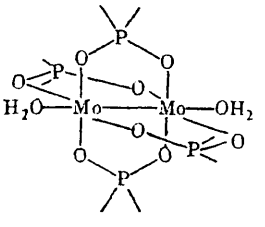

Figure 2. Structure of the $[Mo_2(HPO_4)_4(H_2O)_2]^{2-}$ ion.

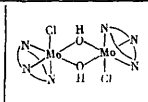
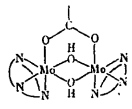
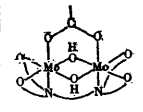
The following chemical reactions are typical for complexes of the type Mo_2L_6: a) partial or complete replacement of ligands ($Mo_2L_6^1 \rightarrow Mo_2L_6^2$); b) addition of Lewis bases [$Mo_2(OR)_6 \rightarrow Mo_2(OR)_6L_2'$]; c) insertion of unsaturated molecules into Mo−L bonds; d) reductive elimination [$Mo_2R_2(NMe)_4 + CO_2 \rightarrow CO_2 \rightarrow Mo_2^{4+}$ + alkene + alkane]; e) oxidative addition [$Mo_2(OR)_6$ + ROOR → $Mo_2.(OR)_8$]; f) reactions with NO and CO, accompanied by reduction in the bond order of Mo−Mo; g) formation of polynuclear complexes, oligomerisation of $Mo_2(OR)_6$, and replacement of OR^- groups in $Mo_2(OR)_6$ by halide ions to form tetranuclear products.[2,4,6]

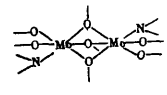
Apart from the compounds considered above, a molybdenum(III) phosphate complex—$[Mo_2(HPO_4)_4]^{2-}$—is also known; it was obtained by dissolving $K_4Mo_2Cl_8.2H_2O$ in 2 M H_3PO_4 in air.[29,30] The salts $(PyH)_3[Mo_2(HPO_4)_4Cl]$ and $Cs_2[Mo_2(HPO_4)_4(H_2O)_2]$, which are stable to air, have been synthesised (Fig. 2).[29,30]

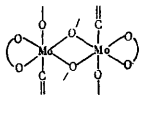
III. Binuclear complexes with bridging oxygen atoms

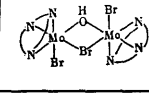












Molybdenum atoms in dimers can be connected by bridging oxygen atoms forming part of hydroxo, alkoxo, or phenoxo groups.

The green ion $[(H_2O)_4Mo(\mu\text{-}OH)_2Mo(H_2O)_4]^{4+}$ occurs in aqueous solutions of Mo(III) in the presence of noncomplexing acids.[31] Reduction of a hydrochloric acid solution of MoO_3 with zinc followed by addition of bis(diphenylphosphino)ethane (DPPE) in 8 M HCl results in the formation of the sky-blue complex $[DPPEH_2]_2[Mo_2(OH)_2Cl_8]$.[32] On hydrolysis of $MoCl_3(C_6H_{15}N_3)$ ($C_6H_{15}N_3$ = triazacyclononane) in the presence of $MeCOO^-$ or HCO_3^-, the green dimers $[Mo_2(OH)_2(MeCOO)(C_6H_{15}N_3)_2]I_3.H_2O$ and $[Mo_2(OH)_2(CO_3)(C_6H_{15}N_3)_2]I_2.H_2O$ are isolated. When the latter is reacted with $MeSO_3H$, HCOOH, and HCl in aqueous solution, $[Mo_2(OH)_2(C_6H_{15}N_3)_2(H_2O)_2]I_4$, $[Mo_2(OH)_2(HCOO)(C_6H_{15}N_3)_2].I_3.2H_2O$, and $[Mo_2(OH)_2(C_6H_{15}N_3)_2Cl_2]I_2$ are synthesised.[33] On reduction of the dimeric molybdenum(V) oxo-complex, $[Mo_2O_4.(C_9H_{21}N_3)_2].[ClO_4]_2.2H_2O$ ($C_9H_{21}N_3$ = 1,5,9-triazacyclododecane), with zinc amalgam in aqueous solutions of HBF_4, RCOOH, HCl followed by the introduction of I^- or ClO_4^-, the complexes [Mo_2.

$.(OH)_2(C_9H_{21}N_3)_2(H_2O)_2]I_4.2H_2O$, $[Mo_2(OH)_2(RCOO)(C_9H_{21}N_3)_2]I_3$, and $[Mo_2(OH)_2(C_9H_{21}N_3)_2Cl_2][ClO_4]_2$ are obtained respectively.[34] Reduction of the ethylenediaminetetraacetate complex $[Mo_2(V).O_4(EDTA)]^{2-}$ in an acetic acid solution gives the di-μ-hydroxo dimers $[Mo_2(OH)_2(Me_3COO)(EDTA)]^-$, $[Mo_2(OH)_2(EDTA)(H_2O)_2]$, and $[Mo_2(OH)_2(EDTA)(SCN)_2]^{2-}$.[35,36] When an aqueous solution of $KMoOCl_2$ and $(NH_4)_2C_2O_4$ is evaporated, $[Mo_2(OH)_2(C_2O_4)_2].6H_2O$ is obtained.[37]

Structural studies of dimers that contain 1,4,7-triazacyclononane or EDTA have shown that geometrically the complexes are distorted octahedra formed by ligand atoms with a common edge of $(\mu\text{-}OH)_2$ (Table 2).[33,35,38] The M—M distances in them are 0.2—0.3 Å longer than in dimers without bridging atoms. A bridging carboxylate ion to all appearances has little effect on the length of the Mo—Mo bond and the weakening of this bond is most probably due to the presence of bridging hydroxo groups.

Table 2. Structure of dimers containing bridging oxygen atoms.

Compound	R_{M-M}, Å	Structure	Refs.
$[Mo_2(OH)_2(C_6H_{15}N_3)_2Cl_2]I_2$	2.501		[33]
$[Mo_2(OH)_2(CH_3COO)(C_6H_{15}N_3)_2]I_3\cdot H_2O$	2.471		[33]
$K[Mo_2(OH)_2(EDTA)(CH_3COO)]$	2.430		[35.38]
$(Me_2NH_2)[Mo_2(OC_6H_4Me)_7(HNMe_2)_2]\cdot C_6H_{14}$	2.601		[39]
$Mo_2(OCH_2Bu\text{-}t)_4(CNBu\text{-}t)_2(Me_2C_3HO_2)_2$	2.508		[40]
$[Mo_2(OH)Br(C_6H_{15}N_3)Br_2]$	2 558		[40]

The formal bond order in di-μ-hydroxo dimers is equal to 3 ($\sigma^2\pi^2\delta^2$).[33] However, the greater M—M distances compared with those in dimers with bridges are due to the lower contribution of a π-interaction.

Dimeric complexes containing EDTA[36] and 1,5,9-triazacyclododecane[34] are diamagnetic. The complex $[Mo_2(OH)_2(C_2O_4)_2].6H_2O$ is characterised by a small paramagnetism, which indicates the weakening of the bond between the metal atoms.[37]

Reaction of $Mo_2(NMe_2)_6$ with 4-methylphenol in hexane gives a dimer with three bridging phenolate ions $(Me_2NH_2)[Mo_2(OC_6H_4Me)_7.(HNMe_2)_2].C_6H_{14}$ (Table 2) in which the overlying paramagnetic states become thermally populated as a result of the increase in the Mo—Mo distance to 2.601 Å.[39]

Dimeric Mo complexes with two alcoxide bridges containing μ-OH and μ-Br ligands are known (Table 2).[40]

The oxychloride $Mo_2O_2Cl_2(H_2O)_6$ has been isolated from a hydrochloric acid solution of molybdenum(III) and acetone;[41–43] its dimeric structure and the oxo bridges present in it have been established hypothetically from an analysis of its magnetic properties and IR spectra. A number of derivatives of this dimer with acetylacetone, carboxylic acids, and *S*-donor ligands (LH) of the type $Mo_2OL_4(H_2O)_x$ and Mo_2OClL_3 have been obtained.[41–44] Reaction of $Mo(OH)_3$ with oxalic acid in an aqueous acetone solution gives $Mo_2O(C_2O_4)_2.6H_2O$.[45] $Mo_2OF_4(H_2O)_6$, which hypothetically contains an Mo—O—Mo fragment, is synthesised by electrolysis of a solution of molybdenum(VI) in 1 M HF.[46]

IV. Binuclear complexes with bridging sulphur atoms

Structural data on dimers containing bridging sulphur atoms are given in Table 3. The Mo—Mo distance in them is even greater than in complexes with bridging oxygen atoms.

Reaction of $(NH_4)_5Mo_2Cl_9.H_2O$ with RSSR in the presence of dithiaoctane (DTO), dithiadecane (DTD), and bis(dimethylphosphino)ethane (DMPE) (LL) results in formation of the dimer $Mo_2(SR)_2Cl_4(LL)_2$.[47] Cotton et al[48] studied the magnetic properties of such dimers and carried out calculations of the electronic structures of hypothetical molecules using the Fenske—Hall and

$Cp_2Mo_2[S_2C_2(CF_3)_2]_2(CO)_2$	3.256		[56]

*For the sake of simplicity, hydrocarbon substituents are not shown.

Reaction of $Mo_2(MeCOO)_4$ with $K(EtOCS_2)$ in ethanol followed by oxidation of the product with a free halogen in a dichloroethane solution led to the synthesis of the ethyl xanthate complex $Mo_2(EtOCS_2)_4X_2$ (X = Cl, Br), containing four bridging sulphur atoms from two xanthate ions.[54]

A large number of diamagnetic cyclopentadienyl molybdenum(III) dimers with four bridging sulphur atoms have been reported.[55–60,63–65] On reacting $CpMoH(CO)_3$ or $[CpMo(CO_3)_3]_2$ (Cp = cyclopentadienyl) with thioepoxides in tetrahydrofuran, $Cp_2Mo_2(SC_nH_{2n}S)_2$ complexes, where n = 2 or 3, were isolated, from which Cp_2Mo_2.$(SCHRCHRS)_2$ and $Cp_2Mo_2(SCRCRS)_2$ complexes were obtained by reaction with alkenes and alkynes.[64] As a result of treating $[CpMo(CO)_3]_2$ with dimethyl disulphide, $Cp_2Mo_2(SMe)_4$ was isolated.[59] Reaction of $Cp'_2Mo_2S_2(S_2CR_2)$ (Cp′ = methylcyclopentadienyl) with the same alkenes and alkynes results in the formation of the dithiol and dithiolene derivatives Cp'_2Mo_2.$(S_2CR_2)(SC_2H_4S)$ and $Cp'_2Mo_2(S_2CR_2)(SC_2H_2S)$, while with LiMe the complex $Cp'_2Mo_2(S_2CH_2)(SMe)_2$ is formed.[55] The dimers $Cp'_2Mo_2(SC_2H_2S)(S_2CS)$, $[Cp'_2Mo_2SC_2H_2S)(S_2CSMe)]I$,[57] $[Cp_2Mo_2(S_2CH_2)(S_2CMe)]Br.\frac{1}{2}EtOH$,[58] $Cp_2Mo_2(S_2CNR)_2$, and $[Cp_2Mo_2(S_2CNRR')_2]X_2$ have also been synthesised.[63]

On reacting $[(PhR)MoPy_3][PF_6]$ (R = H, Me) with an excess of an aqueous solution of MeSH and MeOH followed by extraction with HPF_6 in acetone, orange complexes $[(PhR)_2Mo_2(SMe)_4][PF_6]_2$ were isolated; as a result of anion exchange $[(PhMe)_2Mo_2(SMe)_4]$.$[BPh_4]_2$ was obtained.[60] Reduction of these compounds with zinc amalgam in the presence of 1-methylimidazole (MeIM) in acetonitrile, oxidation with oxygen, and extraction with HPF_6 in acetone gives the green paramagnetic (μ_{eff} = 1.45 B.M.) complex $[Mo_2(SMe)_3(MeIm)_6][PF_6]_3$ in which there are hypothetically three bridging thiolate ligands.

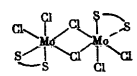
In dimers with four bridging sulphur atoms the Mo–Mo distance varies from 2.60 to 2.72 Å (Table 3). Calculation using the extended Hückel method (EHM) gives the electronic configuration a_{1g} (σ-Mo–Mo), b_{1u} (δ*-Mo–Mo), b_{2g}(δ-Mo–Mo) or $\sigma^2\delta^{*2}\delta^2$, which virtually corresponds to a single Mo–Mo bond.

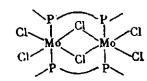
Carbonyl-containing molybdenum dimers with μ-*S*-ligands are known: $Cp_2Mo_2[S_2C_2(CF_3)_2]_2(CO)_2$,[56] $[Cp_2Mo_2(SMe)_3(CO)_2]$.$Br.H_2O$,[61] and $[Cp_2Mo_2(SBu\text{-}t)_2(CO)_4][BF_4]_2$.[62] In the first of these the molybdenum atoms are at a distance of 3.256 Å and there is apparently no Mo–Mo bond.

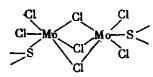
The synthesis of dimeric complexes with N-, O-, and S-containing thiols of the type $Mo_2Cl_6L_m$, m = 2, 3, has been reported.[66] The values of the effective magnetic moments of these complexes is lower than the pure spin values. The existence of sulphide bridges in these complexes has been proposed.

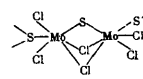
SCF-X_α-SW methods. The effective multiplicity of the Mo–Mo bond proved to be close to 2 ($\sigma^2\pi^2$), while the δ-interaction was very weak. On the assumption that $^1A_{1g}$ ($\sigma^2\pi^2\delta^2$) is the ground state of the dimers, the energies of the thermally populated states $^3B_{1u}$, $^1B_{1u}$, and $^1A^*_{1g}$, corresponding to filling with electrons from the δ^* orbital, were calculated from magnetic data.

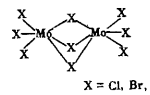
The complexes $K_6[Mo_2S_2(CN)_8]$ and $Ba_3[Mo_2S_2(CN)_8]$, each containing two sulphide bridges, have been obtained.[49–51] Oxidation of the complex anion $[Mo_2S_2(CN)_8]^{6-}$ with atmospheric oxygen results in the formation of $[Mo_2S_2(SO_2)(CN)_8]^{4-}$, in which the molybdenum atoms are connected by a disulphide ion and an SO_2 molecule coordinated via its sulphur atom.[52,53]

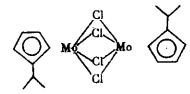


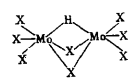


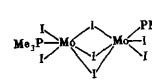












V. Binuclear complexes with halide bridges

In dimeric molybdenum(III) complexes with halide bridges (Cl, Br, I) the Mo–Mo bonds are of approximately the same length as in dimers containing bridging sulphur atoms (Table 4).

When a dichloromethane solution of $Mo_2Cl_4(DTO)_2$ is kept under a layer of hexane, crystals of $Mo_2Cl_6(DTO)_2$ are formed. The $Mo_2Cl_6(DTO)_2$ complex consists of two octahedra connected by a Cl–Cl edge.[67] $Mo_2Cl_6(Ph_2PCH_2PPh_2)_2$, obtained by the reaction of $K_2Mo_2Cl_8$ with $HC(PPh_2)_3$, has a similar structure.

Reduction of $MoCl_4(Me_2S)_2$ using EtSiH in dichloromethane leads to the synthesis of $Mo_2Cl_6(Me_2S)_3$, from which the complex $Ph_4P[Mo_2Cl_7(Me_2S)_2$ is obtained by exchanging an Me_2S group for Cl^-.[68] The NMR data indicate that there is thermal population of the electronic states of the latter complex with spins $S \neq 0$. A similar structure (with three halide bridges) occurs for $Mo_2X_9^{3-}$ ions (X = Cl, Br, I), which will be examined in Section VI.

*According to X-ray powder diffraction analysis.

Molybdenum(III) complexes of the type $Mo_2(C_5H_4-R)_2Cl_4$ (R = iso-Pr), which contain four bridging chlorine atoms, have been obtained by treatment of $Mo(C_6H_6)(C_5H_4-R)$ with hydrogen chloride in toluene.[71]

The complexes $[PHMe_3][Mo_2I_7(PMe_3)_2]$ and $[AsPh_4][Mo_2I_7.(PMe_3)_2]$, each containing three iodide bridges, have been synthesised by reaction of $MoI_3(THF)_3$ with PMe_3, NMe_4I and $AsPh_4I$.[78]

Association of $MoCl_3(THF)_3$ in CH_2Cl_2 solution results in the formation of the dimeric $Mo_2Cl_6(THF)_3$, and reaction of $MoCl_5$ with MeCN gives $Mo_2Cl_6(MeCN)_3$.[79] By replacing the organic ligands in such complexes with tertiary phosphines, pyridine, and nitriles, products of the type $Mo_2Cl_6L_3$ can be obtained.[79,80] Thermolysis of monomeric halomolybdates(III) results in the formation of compounds that contain $Mo_2Cl_{10}^{4-}$ ions.[81] Thermal decomposition of $(oxineH_2)_3Mo_2Cl_9.3H_2O$ gives $Mo_2Cl_6(oxineH)_3$ (oxineH = 8-hydroxyquinoline).[82] Similar tri-μ-chloride complexes with thiourea[83] and bis(diphenylphosphino)ethane[84] derivatives are known.

Diamagnetic halogen-hydrido bridge complexes of the type $A_3Mo_2X_8H$ (X = Cl, Br, I; A is a single-charged cation) have been studied in detail (Table 4). They were synthesised by dissolving $Mo_2(MeCOO)_4$ in a concentrated acid HX at 60 °C and precipitating out the resulting $Mo_2X_8H^{3-}$ with a suitable cation.[72–77,85] Complexes of this type are readily converted to Mo(III) ($Mo_2X_9^{3-}$, MoX_3Py_3) or Mo(II) ($Mo_2Cl_4Py_4$) compounds.[86] Introduction of the hydride bridge reduces the Mo–Mo distance by ~0.4 Å compared to that in purely chloride-bridged dimers. This is due to the small size of the hydride ion compared to halide ions, which prevent the molybdenum atoms converging.[85] As can be seen from Table 4, the ligand environment has little effect on the length of the Mo–Mo bond in the $Mo_2X_8H^{3-}$ ion, which is an indication of the high rigidity of the Mo(μ-H)(μ-X_2)Mo group, the geometry of which is determined to a large extent by the presence of the hydride ion.

VI. Nonahalodimolybdates(III)

$Mo_2X_9^{3-}$ anions (X = Cl, Br) are of considerable interest as interaction between the *d* electrons of the two molybdenum atoms results in the formation of a relatively weak Mo–Mo, with the result that the ligand environment and even the outer coordination sphere of the complex appreciably affect the bonding of the molybdenum atoms.

A single iodide complex $Cs_3Mo_2I_9$ is known. Its IR spectra have been studied,[87] and the Mo–Mo distance in the dimer has been determined by X-ray powder photography.[70] Information is also available on the synthesis of $K_3Mo_2F_9.2H_2O$ (see Ref. 88, p. 111).

Nonachloro- and nonabromo-dimolybdates(III) can be obtained by the following methods: a) disproportionation of MoX_6^{2-} in liquid ammonia;[89] b) oxidation of Mo(II) and Mo(II, III)[90–92] dimers or electrolytic oxidation of the $Mo_2X_8H^{3-}$ ion in concentrated HX;[72] c) fusing metal halides ($2MoX_3 + 3CsX$) are 800 °C;[93] d) coproportionating Mo(0) and Mo(II) carbonyl complexes with Mo(IV) and Mo(V) halides;[94–96] e) precipitation of Mo(III) with a suitable cation in hydrochloric acid;[97] f) replacement of ligands in Mo(III) dimers by halide ions;[90,98] g) electrolytic reduction of MoO_3 in concentrated hydrochloric acid, evaporation of an Mo(III) solution in concentrated hydrochloric or hydrobromic acid and precipitation of nonahalomolybdate(III) with a suitable cation.[82,99–105]

The latter synthetic method is the most convenient. It is based on the reaction between MoX_6^{3-} and $[MoX_5(H_2O)]^{2-}$ ions that occurs when the concentration of molybdenum(III) in hydrohalic acid is increased, leading to the formation of the $Mo_2X_9^{3-}$ ion.[99,104] If the Mo(III) solution is evaporated in a mixture of HCl and HBr, the mixed-ligand anions $Mo_2Cl_3Br_6^{3-}$ and $Mo_2Cl_6Br_3^{3-}$ can be obtained.[102]

The dimerisation of halomolybdate(III) ions takes place according to the following scheme:

$$2\,MoX_6^{3-} + 3\,H_3O^+ \rightarrow Mo_2X_9^{3-} + 3H_2O\uparrow + 3HX\uparrow.$$

A similar reaction takes place on thermolysis of the "acid" halomolybdates(III) $(PimH_2)(H_5O_2)MoX_6$ (Pim = 2-amino-4,6-dihydroxypyrimidine) and $(oxineH_2)_2H[MoBr_6].3H_2O$, from which $(PimH)_3Mo_2X_9$ and $(oxineH_2)_3Mo_2Br_9$ are obtained by isothermal decomposition.[82,105]

The monoethanolammonium (MeaH) salts $(MeaH)_3Mo_2X_9$, which are readily soluble in HX, have proved to be convenient reagents for the synthesis of nonachloro- and nonabromo-dimolybdates(III) with organic cations. A number of compounds, including both cation and anion mixed salts, have been synthesised from these reagents by cation exchange.[106–108]

The chloro- and bromo-complexes are solid compounds, red and brown in colour. They are more or less stable towards atmospheric oxygen and moisture; in solution they are slowly oxidised by air. In hydrohalic acid solutions a slow decomposition of the $Mo_2X_9^{3-}$ dimer occurs, giving MoX_6^{3-} and $[MoX_5(H_2O)]^{2-}$ ions (at room temperature over a period of several hours).[102,109] However, in the presence of 4,4′-dipyridyl in a mixture of concentrated HCl and ethanol, $Mo_2Cl_9^{3-}$ very rapidly decomposes to monomeric complexes.[108] Reaction of $Cs_3Mo_2X_9$ with pyridine at 200 °C results in the formation of *trans*-MoX_3Py_3.[86] In contrast to monomeric halomolybdates(III), the $Mo_2Cl_9^{3-}$ ion is readily reduced by zinc amalgam to Mo(II) dimers.[110]

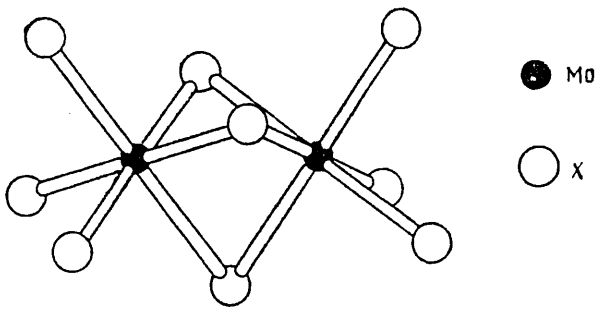

Figure 3. Structure of the $Mo_2X_9^{3-}$ ion (X = Cl, Br).[69]

The complete X-ray diffraction analysis of $Cs_3Mo_2Cl_9$ and $Cs_3Mo_2Br_9$ which was carried out for the first time by Saillant et al[69] made it possible to establish the structure of the anion, which is shown in Fig. 3. By comparing the geometric characteristics of $M_2X_9^{3-}$ ions, where M = Cr, Mo, W; X = Cl, Br (Table 5) it was possible to identify interesting structural features of molybdenum dimers. In $Cr_2X_9^{3-}$ ions the Cr atoms are displaced from the octahedral centres towards the outer halogen atoms and there is no Cr–Cr bond. This is confirmed by the presence of three unpaired electrons in each Cr^{3+} ion according to the results of magnetic measurements.[111] In the $W_2Cl_9^{3-}$ ion the W–W distance is ~0.7 Å shorter than the Cr–Cr distance in $Cr_2Cl_9^{3-}$. The tungsten atoms are very considerably displaced from the octahedral centres towards each other, forming a W–W bond. As a result of this, $K_3W_2Cl_9$ has only a temperature-independent paramagnetism. In $Mo_2X_9^{3-}$ the Mo atoms are displaced from the octahedral centres towards each other to a lesser degree than in $W_2Cl_9^{3-}$. The Mo–Mo bond is weaker than the W–W bond, so compounds $A_3Mo_2X_9$ display a weak paramagnetism, the temperature dependence of which indicates that there is a considerable antiferromagnetic coupling between the molybdenum atoms in such dimers. In systems where direct exchange takes place between the molybdenum atoms, the antiferromagnetic interaction energy can characterise the strength of the Mo–Mo bond (see Ref. 113, p. 125).

Table 5. Structural characteristics of $M_2X_9^{3-}$ ions (M = Cr, Mo, W).[69]

Compound	R_{M-M}, Å	Angle of X_B-M-X_B, deg.*
$Cs_3Cr_2Cl_9$	3.12	85.8

$Cs_3Mo_2Br_9$	2.82	93.9
$K_3W_2Cl_9$	2.41	98.4

*X_B is bridging halogen atom.

As long ago as the late 1960's it was found that the magnitude of the antiferromagnetic exchange coupling in the nonahalodimolybdate(III) ion depended to a considerable extent on the nature of the cation, and at the time attempts were made to relate this phenomenon to the change in Mo–Mo distance in the dimer.[103,104,114]

Grey and Smith[114] studied the dependence of the exchange integral on the Mo–Mo distance in a number of nonachlorodimolybdates with different cations. However, these distances were known only for the compounds $K_3Mo_2Cl_9$ and $Cs_3Mo_2Cl_9$, and as it subsequently transpired, the correlation found proved to be incorrect. A relationship between the stretching vibrational frequencies of the bridging chloride atoms and the size of the cation was established by Grey and Smith.[103] By making a combined analysis of the IR spectra and structural characteristics of $Cs_3Cr_2Cl_9$ and $Cs_3Mo_2Cl_9$ it could be assumed that on increasing the $Cl_B-Mo-Cl_B$ angle (Cl_B is bridging chlorine atom), namely, by axial compression of the dimer, the difference between the vibrational frequencies of a_2'' and e' of the $Mo-Cl_B$ bond will also increase. The $Cl_B-Mo-Cl_B$ angle increases on going from $K_3Mo_2Cl_9$ to $Cs_3Mo_2Cl_9$, but the $Cl_T-Mo-Cl_T$ angle (Cl_T is terminal chlorine atom) changes only slightly.[69,103] Consequently, the difference between the vibrational frequencies of a_2'' and e' of the $Mo-Cl_T$ bond will be small, but it will be considerable for the $Mo-Cl_B$ bond. This assumption is also confirmed by IR spectroscopic analysis.[103] What is more, as the size of the cation increases the difference between the frequencies of a_2'' and e' of the $Mo-Cl_B$ bond decreases, in other words, the $Cl_B-Mo-Cl_B$ angle decreases, hence (if the change in distance of $Mo-Cl_B$ is ignored) in the cation series K^+, NH_4^+, Cs^+, Me_4N^+, Et_4N^+ the dimer becomes more and more "extended" axially.[103]

The dependence of the chemical shift (ΔE) of the L_{α_1,α_2} line in the X-ray emission spectra of $K_3Mo_2Cl_9$, $Cs_3Mo_2Cl_9$, $MoCl_3$, K_3MoCl_6 on the Mo—Mo distance has been studied.[115] As the Mo—Mo distance decreases ΔE increases, which corresponds to an increase in the degree of bonding between the *d* electrons of the molybdenum atoms.

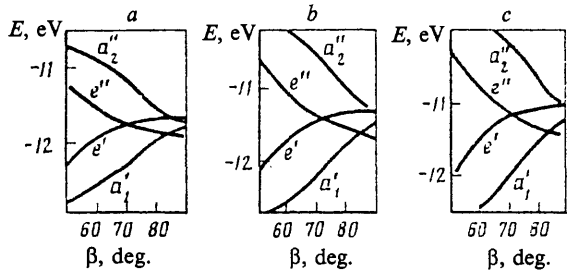

Figure 4. Dependence of the energy of the electron levels in the $M_2Cl_9^{3-}$ ion on the magnitude of the M—Cl_B—M angle, where M = Cr (*a*), Mo (*b*), W (*c*).[118]

The first calculations of the electronic structure of the $Mo_2Cl_9^{3-}$ ion were carried out using the RMK[116] and Fenske—Hall methods. An examination was subsequently made of the dependence of the energies of the orbitals responsible for the M—M bonding on the degree of axial distortion of the dimeric $M_2Cl_9^{3-}$ anion (M = Cr, Mo, W) (Fig. 4).[118] The M—Cl_B—M angle was taken as a parameter for the magnitude of distortion, in accordance with the method suggested by Cotton and Ucko[119] for studying such dimers. As can be seen from Fig. 4, on reducing the M—Cl_B—M angle (this corresponds to a convergence of the metal atoms for a fixed length of the M—Cl_B bond), there is a reduction in energy of the $a_1'(\sigma)$ and $e'(\pi)$ bonding orbitals of M—M and an increase in energy of the $a_2''(\sigma^*)$ and $e''(\pi^*)$ antibonding orbitals. In the series M = Cr, Mo, W, the gap between the bonding and antibonding orbitals in the dimer increases, with the strengthening of the bond between the metal atoms assisting the compression of the dioctahedron despite the repulsion between the terminal and bridging chlorine atoms and the rigidity of the M—Cl_B—M angle.[118]

More rigorous calculations of the electronic structure of the $Mo_2Cl_9^{3-}$ ion in the salts $Cs_3Mo_2Cl_9$ and $K_3Mo_2Cl_9$ were carried out by Ginsberg[120] using the SCF-X_α-SW method. The energies of the antiferromagnetic exchange coupling were determined theoretically and correlated with the experimental data. The data on the structure of the upper molecular orbitals of $Cs_2Mo_2Cl_9$ salt are given in Table 6. The successively grouped $21a_1'$, $22e'$, $17e''$, and $18a_2''$ orbitals retain the nature of 4*d* orbitals of Mo to the extent of 64—81% and constitute respectively the following orbitals of the Mo—Mo bond: σ, $2(1/3\pi + 2/3\delta)$, $2(1/3\pi^* + 2/3\delta^*)$, and σ^*. The electronic configuration of the ground state $\sigma^2(1/3\pi + 2/3\delta)^4$ formally corresponds to the formation of an Mo≡Mo triple bond. However, whereas the $\sigma-\sigma^*$ separation is quite large (~2 eV), the difference between the energy of the $22e'$ and $17e''$ orbitals is ten times less, in other words, the bond between the molybdenum atoms is essentially a single bond.

In order to determine the contribution of superexchange interactions through the bridging chlorine atoms to the total exchange coupling, the electronic structure of the dimeric anion in $K_3Mo_2Cl_9$ was calculated when the Mo—Cl_B distance was reduced by 0.06 Å.[120] The change in the magnitude of exchange integral in this case was less than 1%. Such a result was to be expected since the Mo—Mo bonding orbitals, although overlapping with the orbitals of the bridging chlorine atoms, are nonbonding in relation to them and hence they do not make a substantial contribution to the Mo—Mo coupling.[120]

In the electronic spectra of $Mo_2X_9^{3-}$ ions there are usually four absorption bands.[91,93–95,99–101,121] The appearance of bands at ~13000 and ~15000 cm^{-1} is due to the formation of the Mo—Mo bond.[91] By studying the absorption spectra, circular dichroism, and

Table 6. Energy levels of the $Mo_2Cl_9^{3-}$ ion in $Cs_3Mo_2Cl_9$. (Calculation using the SCF—X_α—SW method[120]).

Zeeman splitting for $Cs_3Mo_2Cl_9$ monocrystals,[122] it was possible to detect and interpret the fine structure of the absorption bands due to the Mo—Mo interaction. The absorption bands were attributed to the following transitions: $^1A_1' \rightarrow {}^3E$ (7800 cm^{-1}), $^1A_1' \rightarrow {}^3A_1''$ (~11600 cm^{-1}), $^1A_1' \rightarrow {}^1A_1'$, $^1A_1''$ (12600 → 14000 cm^{-1}), $^1A_1' \rightarrow {}^1E'$ (~15300 cm^{-1}). On the basis of the theoretical calculations it was concluded that there was a very weak Mo—Mo π-interaction when the strength of the Mo—Mo σ-bond was high.

The geometry and magnetic properties of the $Mo_2Cl_9^{3-}$ ion in relation to the crystal environment were studied in detail and the structures of ten nonachlorodimolybdates(III) with different organic cations and ammonia were determined.[109,123–127] In the crystal lattice of each compound this ion undergoes low-symmetry distortions. The average geometric parameters determined when it was assumed that the dimeric anion has D_{3h} symmetry are given in Table 7.

The $Mo_2Cl_9^{3-}$ anion has the following characteristics. The Mo—Cl_B—Mo angle in all cases is less than 70.5° (for a true dioctahedron) and the molybdenum atoms have converged as a result of Mo—Mo bonding. The dimeric anion is slightly distorted along the Mo—Mo axis from the effect of the crystal environment. The distance between the metal atoms in the dimer varies from 2.815 Å in the tetrabutylammonium salt (I) to 2.569 Å in the simple ammonium salt (XI). As the Mo—Mo distance decreases, the Mo—Cl_B—Mo angle also decreases, but the lengths of the Mo—Cl_B and Mo—Cl_T bonds and the Cl_T—Mo—Cl_T angle show little variation. It follows from this that in essence only the bridging $Mo(Cl_B)_3Mo$ fragment is distorted.

The geometry of the dimeric anion is determined by two forces acting in opposition: 1) the mutual attraction of the molybdenum atoms, leading to compression of the dimer; and 2) the effect of "pushing apart" from the bridging chlorine atoms, which is due to the increase in overlap of atomic orbitals in the system Mo—Cl_B—Mo and at the same time the mutual repulsion of the bridging and terminal chlorine atoms. The balance of forces probably leads to the energy curve near the minimum on the z coordinate (the axis passes along the Mo—Mo bond) having a small bend, and hence even with a significant change in Mo—Mo distance the energy of the $Mo_2Cl_9^{3-}$ ion varies only slightly.

In an $Mo_2Cl_9^{3-}$ ion free from external effects the repulsion between the chlorine atoms assists the extension of the dimer along the Mo—Mo axis. In the crystal lattice the interligand repulsion is weakened by the effect of the positive charges of the cations; this together with the Mo—Mo interaction leads to compression of the $Mo(Cl_B)_3Mo$ fragment and a reduction in Mo—Mo distance.

Cations that form hydrogen bonds have the most marked effect. Thus, in $(Bu_4N)_4[Mo_2(III)Cl_9][Mo(V)OCl_4(H_2O)]$ the positive cation centres are at a considerable distance from the chlorine atoms, the effect of the cations is small, and the Mo—Mo distance is the greatest (see Table 7). In the structure of $(Et_4N)_2(H_7O_3)Mo_2Cl_9$ only one of the cations, namely, the hydrated proton, has any appreciable effect on the geometry of the dimer as a result of the formation of hydrogen bonds; the Mo—Mo distance is 2.743 Å. In the crystal lattices of compounds (III)—(VI) all cations have their positive centres directed towards the chlorine atoms, so N—H...Cl hydrogen bonds are formed and the Mo—Mo distance is reduced. In the structures of nonachlorodimolybdates(III) containing doubly charged cations, a further compression of the bridging group occurs. These structures display a trimeric network of hydrogen bonds joining all cations and anions. The ammonium cation has the maximum effect on the Mo—Mo distance; it is lowest in $(NH_4)_3Mo_2Cl_9$. It is worth noting that in compounds (VII)—(X) (Table 7), which contain organic cations that are much larger than in $Cs_3Mo_2Cl_9$, the length of the Mo—Mo bond is less than in the caesium salt. This demonstrates the strong effect of hydrogen bonding on the geometry of the dimeric group.

It may be assumed that the minimum effect of the cations and correspondingly the maximum Mo—Mo distance in the $Mo_2Cl_9^{3-}$ ion in the crystal lattice will occur when there are bulky low-polarity cations present. If cations, even those of large volume, can form strong hydrogen bonds with the anion, the Mo—Mo distance in nonahalodimolybdates(III) will be relatively short.

The values of the exchange integrals for structurally determined nonachlorodimolybdates(III) have been calculated from magnetic susceptibility data [for compounds (I)—(V) and (VII)—(XI), see the study by Kazin;[109] for $Cs_3Mo_2Cl_9$ and $Cs_3Mo_2Br_9$, see the study by Grey and Smith.[104]]

To all appearances a direct Mo—Mo exchange coupling mainly occurs in $Mo_2Cl_9^{3-}$ ions.[120] The dependence of the exchange integral ($-2J$) on the Mo—Mo distance in a dimer is shown in Fig. 5. As the relative change in parameters is low, this dependence approximates to a linear function.[109] The tendency for the exchange coupling to increase as the Mo—Mo distance decreases is apparent, but deviations from a linear dependence are considerable.

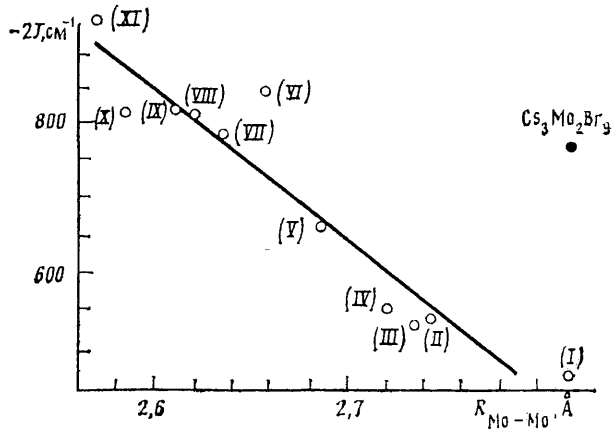

Figure 5. Dependence of the exchange integrals on the Mo—Mo distance in $Mo_2Cl_9^{3-}$ ions.[109] For the numbering of the compounds, see Table 7.

For a more accurate representation of the exchange interaction, the values of the exchange integrals were expressed as a two-parameter function of R and α (the geometry of the bridging fragment $Mo(Cl_B)_3Mo$ in D_{3h} symmetry is determined by these two parameters).[109] The derived dependences of the antiferromagnetic interaction energy on the geometric parameters of the $Mo_2Cl_9^{3-}$ ion can prove useful for predicting the structure of similar dimers from their magnetic properties.

The value of $-2J$ for the structurally determined compound $Cs_3Mo_2Br_9$ is substantially higher than that which should occur if the linear dependence of $-2J$ on R_{Mo-Mo} obtained for $Mo_2Cl_9^{3-}$ ions were applied to it (Fig. 5). The most probable reason for the increase in the exchange coupling is the lesser electronegativity of bromine compared to chlorine. Consequently, the effective positive charge on the molybdenum atoms in the bromide complex is less, giving rise to a greater diffuseness of the $4d$ orbitals of the metal atoms and correspondingly a greater overlap of the orbitals in the direction of the Mo—Mo bond than in the chloride dimer at the same distance between the molybdenum atoms.

For isomorphous nonabromodimolybdates(III) the values of $-2J$ are usually less than their chloride analogues.[104,109] Evidently the decrease in exchange resulting from the increase in Mo—Mo distance in bromo-complexes exceeds the increase caused by the greater diffuseness of the $4d$ orbitals of the molybdenum atoms.

Reaction of $(Bu_4N)_3Mo_2Cl_8H$ with I_2 in dichloroethane solution followed by addition of diethyl ether led to the synthesis of $(Bu_4N)_3$. Mo_2Cl_8I, and $(NH_4)_3Mo_2Cl_8I$ was isolated by exchanging cations in methanol. The dimeric anions contain bridging iodine atoms in addition to chlorine atoms.[128] The values of $-2J$, calculated from the magnetic susceptibility of the ammonium and tetrabutylammonium salts differ substantially. The nature of the cation probably has a similar strong effect on the geometry of the $Mo_2Cl_8I^{3-}$ ion as on the structure of nonachloro- and nonabromodimolybdate(III) ions.

Compounds containing $[Mo_2Cl_8.(H_2O)]^{2-}$ and $Mo_2X_8^{2-}$ (X = Cl, Br) ions have been obtained by thermal decomposition of "acidic" nonahalodimolybdates(III) in the solid state.[129–132] A study of the temperature dependence of magnetic susceptibility showed that exchange couplings in such compounds are localised within the dimers.[109] To all appearances the bridging $Mo(X_B)_3Mo$ group is preserved in the crystal lattice.

The values of the exchange integrals for an $(Et_4N)_3Mo_2X_9$ complex, the initial "acidic" tetraethylammonium salts, and their thermolysis products are given below.

Compound	$-2J$, cm^{-1}	Compound	$-2J$, cm^{-1}
$(Et_4N)_3Mo_2Cl_9$	480±13	$(Et_4N)_3Mo_2Br_9$	430±10
$(Et_4N)_2(H_9O_4)Mo_2Cl_9$	540±15	$(Et_4N)_2(H_9O_4)Mo_2Br_9$	490±15
$(Et_4N)_2(H_5O_2)Mo_2Cl_9$	600±15	$(Et_4N)_2(H_5O_2)Mo_2Br_9$	555±15
$(Et_4N)_2[Mo_2Cl_8(H_2O)]$	580±15	$(Et_4N)_2Mo_2Br_8$	515±15
$(Et_4N)_2Mo_2Cl_8$	575±15		

On replacing a single Et_4N^+ cation in $(Et_4N)_3Mo_2Cl_9$ by the proton tetrahydrate $H_9O_4^+$ cation in $(Et_4N)_3Mo_2Cl_9$ by the proton tetrahydrate $H_9O_4^+$, which forms hydrogen bonds with anions and thus assists in compressing the dimer, the exchange coupling increases. In the complex $(Et_4N)_2(H_5O_2)Mo_2Cl_9$, which contains a proton dihydrate, a further increase in the exchange coupling occurs, which may be due to the strengthening of the hydrogen bonds between the hydroxonium ion and the complex anion. The values of $-2J$ for $(Et_4N)_2[Mo_2Cl_8(H_2O)]$ and $(Et_4N)_2Mo_2Cl_8$ occur within the limits of the exchange integral values for the previous two compounds. The same pattern occurs for tetraethylammonium bromo-complexes. Consequently, replacement of the terminal ligands in the $Mo_2X_9^{3-}$ ion leads to a change in exchange coupling to about the same extent as replacing one of the cations; and the effect of the ligand environment on the magnetic properties and geometry of the $Mo(X_B)_3Mo$ fragment is comparable with the effect of exterior cations.

An analysis of the literature data shows that molybdenum(III) in binuclear complexes can form strong Mo≡Mo triple bonds. However, such a situation occurs only in dimers without bridges and in complexes containing polyatomic bridges. The occurrence of monatomic bridges results in a considerable weakening of the Mo—Mo bond. What are the main reasons for this?

Calculations of the electronic structure of dimers without bridges indicate that the Mo—Mo bond is formed by being filled with electrons in σ and 2π orbitals. The dimers with monatomic bridges have the following electronic configuration: with two bridges—$\sigma^2\pi^2\delta^2$; with three bridges—$\sigma^2(1/3\pi + 2/3\delta)^4$; with four bridges—$\sigma^2\delta^{*2}\delta^2$. Thus, the bridging ligands use some of the $4d$ orbitals of the metal atoms to form Mo—L—Mo bonds. In this case the Mo—Mo σ bond remains unchanged while as the number of bridges increases the Mo—Mo π bonds are gradually replaced by the much less effective δ bonds. At the same time the Mo—Mo bond order decreases, so that in a four-bridged dimer it reduces to 1. However, as follows from Tables 2—4, there are no clear correlations between the length of the Mo—Mo bond and the number of monatomic bridges, but on the other hand the dimensions of the

bridging atoms have a marked effect. The literature data on the Mo—Mo distances in molybdenum(III) dimers are correlated in Table 8.

Table 8. Mo—Mo distances in molybdenum(III) dimers with different bridging ligands.

Bridging fragment	Range of Mo—Mo distances, Å	Number of known compounds	Refs.
Without bridging ligands	2.17—2.27	16	[4,7—20, 23, 24]
Polyatomic bridges	2.17—2.24	4	[4,7, 21, 22]
Monatomic bridges			
(μ-H) + 2(μ-X), X = Cl, Br, I	2.37—2.41	7	[72—77]
2(μ-O), 3(μ-O)	2.43—2.60	4	[33, 35, 38, 39]
(μ-S) + 2(μ-Cl)	2.46	1	[68]
2(μ-S), 3(μ-S), 4(μ-S)	2.60—2.79 3.01; 3.26	15	[47—62]
2(μ-Cl), 3(μ-Cl), 4(μ-Cl)	2.57—2.82	16	[67—71, 123]
3(μ-Br)	2.82	1	[69]
3(μ-I)	3.02—3.07	3	[70, 78]

Mo—Mo bonds are shortest in length in dimers without bridges and in complexes with polyatomic bridges. In $Mo_2X_8H^{3-}$ complexes, whose geometry is determined by the hydride ion, the Mo—Mo distances are 0.2 Å greater on average than in dimers without bridges. In binuclear complexes with oxygen bridges the lengths of the Mo—Mo bonds are slightly greater than in complexes with hydride bridges. A further increase in Mo—Mo distance is characteristic of dimers that have bridging sulphur or chlorine atoms.

In $Cs_3Mo_2Br_9$ the Mo—Mo distance is at the upper limit of the range of these distances for chloride-bridged dimer. If the lengths of the Mo—Mo bonds in the isomorphous salts $Cs_3Mo_2Cl_9$ and $Cs_3Mo_2Br_9$ (2.655 and 2.815 Å respectively) are compared, it may be assumed that the Mo—Mo distance in bromide dimers will on average be 0.15 Å greater.

In complexes with iodide bridges the Mo—Mo distances exceed 3 Å, which results form the large size of the iodide ion.

Thus, although monatomic bridges weaken the Mo—Mo interaction in dimers by involving the 4*d* orbitals of the molybdenum atoms in the formation of the Mo—L bond, in all probability the main result of their presence in the molecule is their influence on the geometric structure of the dimers, resulting in a considerable extension of the Mo—Mo bond. The weakening of this bond in turn is accompanied by a decrease in the rigidity of the bridging group. In this case, as studies on dimeric halomolybdates(III) have shown, the effect of the internal and external coordination spheres on the characteristics of Mo—Mo bonds must be considered in totality.

Electron-transfer reactions in polymer matrices

A V Vannikov, A D Grishina
Frumkin Institute of Electrochemistry, USSR Academy of Sciences, Moscow

ABSTRACT. This paper discusses the dark reactions and photoreactions that occur with transfer of an electron from a donor to an acceptor in polymer matrices under electron tunnelling conditions and when forming change-transfer complexes. The main emphasis is on an analysis of the factors that determine the rate of electron transfer, which, in accordance with the advanced theory of electron transfer, are the magnitude of the exchange interaction, the free energy of the process, and the reorganisation energies of the medium and the reacting donor and acceptor molecules.

The existing models for the movement of charge carriers between single-type transport sites are discussed. The limits of applicability of the different models have been determined. The reorganisation energy of a polymer matrix is shown to have a considerable effect on the rate of movement of charge carriers on introduced transport molecules. The effect of the dielectric properties and free volume of polymer matrices on the characteristics of electron phototransfer in donor-acceptor complexes is discussed.

The bibliography includes 126 references.

I. Introduction

With the production of polymeric materials for electrophotography and films for photochemical recording of optical information, and with the development of solar energy converters and the synthesis of conductive and semiconductive polymers, electron-transfer reactions in polymer matrices have started to stimulate an increasing interest among research workers in recent years.[1–13] Moreover, polymer matrices with transport sites constitute an effective model system for the study of charge transfer in disordered media.

In the present study we shall restrict ourselves to an examination of dark and photolytic electron-transfer processes in systems involving a polymer matrix as the dielectric medium and donor (D) and acceptor (A) components distributed in it.

In this case D and A components can be chemically bonded to polymer chains. An analysis of the factors that determine the rate of electron transfer in polymer donor-acceptor systems is given below together with the quantum yield of products of electron phototransfer and the effect of temperature, the concentration of the transport sites, electric field, and characteristics of the polymer matrix on the mobility of the charge carriers (electrons or holes) in polymers.

An examination will be made of systems in which the distance between the components (R) is greater than the sum of the van der Waals radii of the molecules (the notation D ... A is given for such systems) and electron transfer is due to a quantum effect— tunnelling,[14,15] and also of composites based on charge-transfer complexes (CTC, denoted as D·A) in which the value of R as a result of efficient packing can be less than the van der Waals radii of the components.[16]

A common feature of these systems is the fact that electron transfer in them under dark conditions and with photoexcitation is due to overlap of the wave functions of the states without electron transfer— ψ_0(D, A)—and the states that correspond to complete electron transfer from D to A—$\psi_1(D^+, A^-)$.[16–19]

$$\psi_i(DA) = \psi_0(D, A) + \lambda\psi_1(D^+, A^-), \quad (1)$$

$$\psi_{f,ex}(D^+A^-) = \psi_1(D^+A^-) - \lambda\psi_0(D, A), \quad (2)$$

Here ψ_i(DA) and $\psi_f(D^+, A^-)$ are the wave functions of the initial and final states of the system with thermal electron transfer; ψ_i(DA) and $\psi_{ex}(D^+, A^-)$ represent the ground and excited state of the system with electron phototransfer; $\lambda = V_{01}/\Delta G$, where V_{01} is the energy of the exchange interaction; ΔG is the free energy of electron transfer.

$$\Delta G = E_0 - E_1, \quad (3)$$

where E_0 and E_1 are the energies of the states without bonding and with complete electron transfer respectively:

$$E_0 = \int\psi_0^*(D, A)H\psi_0(D, A)dv,$$

$$E_1 = \int\psi_1^*(D^+A^-)H\psi_1(D^+A^-)dv,$$

where ψ^*(D, A) and $\psi^*(D^+, A^-)$ are complex associated wave functions, v is a combination of the spatial and spin coordinates of the electron.

The thermal reaction

$$D ... A \rightleftarrows D^+ ... A^- \quad (4)$$

occurs as a result of "horizontal" electron transfer.

The transition between the two equilibrium states D ... A and $D^+ ... A^-$ involves surmounting the potential barrier $G^{\neq}$ (Fig. 1*a*). According to two analyses,[17,18] with values of $V_{01} < 20$ cm^{-1} (i.e., 2.48×10^{-3} eV) electron transfer occurs under nonadiabatic conditions when the D ... A system, existing in the transition state (near the point $q^{\neq}$, see Fig. 1*a*), repeatedly crosses the $q^{\neq}$ point along its own potential curve before undergoing transfer to a lower trajectory corresponding to the $D^+ ... A^-$ state. Adiabatic conditions (Fig. 2), in other words, transfer of the D ... A system to the $D^+ ... A^-$ state at each crossing of the $q^{\neq}$ point, correspond to the values $20 < V_{01} < 400$ cm^{-1} ($\sim$0.05 eV).

The convergence of the components on conversion to D·A complexes gives rise to an exponential increase in V_{01} from 0.05 to 0.5 eV. The rate of electron transfer corresponds to the value $\nu = V_{01}/h \sim 10^{13}$ s^{-1} (h is Planck's constant). In this case we are dealing with the dipole $D^{+\delta}A^{-\delta}$ (D·A $\rightleftharpoons$ ($D^+ \cdot A^-$).[16,19] As a result of mixing the states

without bonding and with complete charge transfer [$\lambda > 0$ in expressions (1) and (2)], an optical transition with charge transfer is possible in both systems

$$D...A \text{ (or } D.A) \xrightarrow{h\nu_{et}} D^{+}...A^{-} \text{ (or } D^{+}A^{-})$$

(Fig. 1*a* or Fig. 2).[16–19]

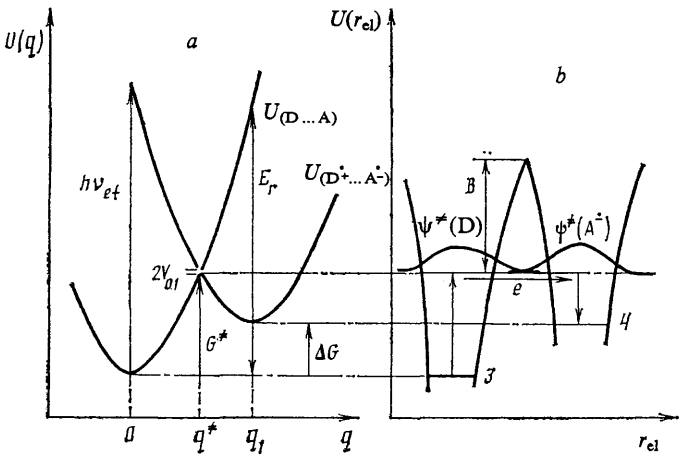

Figure 1. *a*) Dependence of the potential energies $U_{(D...A)}$ and $U_{(D^{+}...A^{-})}$ on the generalised coordinate q. The parameters that determine the rate of thermal reaction (4) and electron phototransfer under non-adiabatic conditions ($V_{01} < 20$ cm^{-1}) are given. *b*) Dependence of the electron energy $U(r_{el})$ on the coordinate r_{el}. The levels cor-respond to: *3*) equilibrium potential $E_{1/2}(^{1}D_0/D^{+})$; *4*) $E_{1/2}(A^{-}/A)$. For further explanation, see text.

II. Thermal electron transfer

The polaron theory of electric conductivity[20] has been developed in relation to ionic semiconductors. According to this theory the movement of an electron can be represented as the successive transfer between lattice points (by a distance R) when there is strong polarisation of the lattice. Polaron theory proposes that the energy barrier for movement of an electron is determined by the change in polarisation of the lattice on transfer of the electron from one transport site to another $M^{+}...M \rightarrow M...M^{+} \rightarrow$ etc. The main conclusions of the polaron theory were used to develop the quantum-chemical theory of thermal electron transfer in liquid media (the model of the dielectric continuum).[17,21–29] The latter model extends the polaron theory by taking into account the expenditure of energy on intramolecular reorganisation in the change from a molecule to a radical ion. This model is becoming more common because it is suitable for a wide range of donor-acceptor systems $D...A \rightarrow D^{+}...A^{-}$ for which the driving force of electron transfer is the free energy of this process.

According to the Marcus–Levich–Dogonadze–Kuznetsov model of the dielectric continuum, the rate of charge transfer is determined by a combination of processes that take place in a "supermolecule" consisting of the D...A system and the neighbouring sphere of the surrounding dielectric continuum (in our case the polymer medium). As a result of thermal motion there is a fluctuation of such parameters as the mutual orientation of the D...A components and the molecules of the medium, the distance between the D...A components, and the internuclear distances in the D and A molecules, and a redistribution of charge occurs in the D...A system and the molecules of the medium, etc. This causes fluctuations in the generalised coordinate q, which characterises the interaction between D...A and the dielectric medium and inside the D...A system.

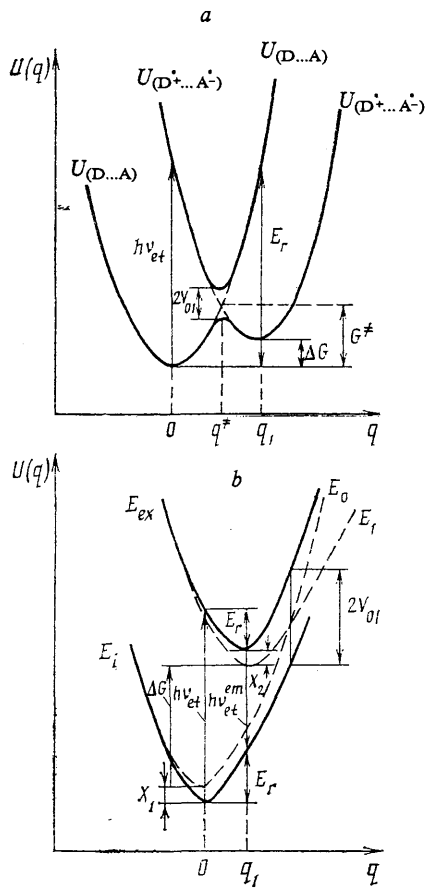

Figure 2. *a*) Dependence of the potential energies $U_{(D...A)}$ and $U_{(D^{+}...A^{-})}$ on the generalised coordinate q. The parameters that determine the rate of thermal reaction (4) and electron phototransfer under adiabatic conditions ($20 < V_{01} < 400$ cm^{-1}) are given. *b*) Relative position of the ground E_i ($\equiv U_{(D.A)}$) and excited E_{ex} ($\equiv U_{(D^{+}.A^{-})}$) levels of the D.A complex. The parameters that determine electron phototransfer are given. For further explanation, see text.

The potential energies of the fluctuating system that occurs in the initial (D...A) and final ($D^{+}...A^{-}$) states are represented as two parabolae (see Fig. 1):

$$U_{(D...A)}(q) = aq^2, \tag{5}$$

$$U_{(D^{+}...A^{-})}(q) = b(q - q_1)^2 + \Delta G, \tag{6}$$

where q_1 is the equilibrium coordinate of the final state. The

coefficient a corresponds to the potential energy value of the initial state at the equilibrium coordinate of the final state ($q = q_1$):

$$U_{(D...A)}(q_1) = aq_1^2 \equiv E_r,$$
$$a = E_r/q_1^2,$$

where E_r is the reorganisation energy of the "supermolecule" brought about by electron transfer in the D ... A system. The coefficient b corresponds to the potential energy of the final state at the equilibrium coordinate of the initial state ($q = 0$):

$$U_{(D^{\cdot+}...A^{\cdot-})}(0) = b(-q_1)^2 + \Delta G = E_r + \Delta G.$$

In reversible reactions $E_r = E_r'$ and correspondingly $a = b$. Thus, for reversible reactions we obtain

$$U_{(D...A)}(q) = E_r(q/q_1)^2, \quad (5a)$$
$$U_{(D^{\cdot+}...A^{\cdot-})}(q) = E_r\left(\frac{q - q_1}{q_1}\right)^2 + \Delta G,$$
$$E_r = E_{in} + E_s, \quad (6a)$$

where E_{in} is the energy expended on the transition from D ... A to $D^{\cdot+}$... $A^{\cdot-}$ ion radicals, resulting from the change in distance between the components of the complex as well as the distances between the nuclei and the bond angles in these same molecules D and A (the "inner-sphere" energy, including intramolecular reorganisation); E_s is the reorganisation energy of the medium (the "outer-sphere" reorganisation).

(a) Rate of electron transfer in condensed media

The rate constant of thermal electron transfer (k_{et}) in the reaction D ... A < $D^{\cdot+}$... $A^{\cdot-}$ under nonadiabatic conditions (na) is determined by the relationship

$$k_{et}(na) = (2\pi/\hbar)|V_{01}|^2 FC, \quad (7)$$

where FC is the Franck–Condon factor.

Necessary conditions for electron transfer in accordance with reaction (4) are: 1) adherence to the Franck–Condon principle; and 2) overlap of the wave functions of the donor and the acceptor radical anion in a Franck–Condon state (see Fig. 1*b*); then

$$V_{01} = \int \psi^{\neq}(D ... A) H \psi^{\neq}(D^{\cdot+} ... A^{\cdot-}) dv > 0. \quad (8)$$

A Franck–Condon state conforms to the isoenergetic condition (Fig. 1*b*):

$$\int \psi^{*\neq}(D ... A) H \psi(D ... A) dv = \int \psi^{*\neq}(D^{\cdot+} ... A^{\cdot-}) H \psi^{\neq}(D^{\cdot+} ... A^{\cdot-}) dv.$$

In accordance with the Franck–Condon principle, electron transfer occurs with an unchanged nuclear configuration as a result of the high rate of the act of electron transfer ($t < 10^{-13}$ s). Only the electronic polarisation of the medium is synchronous to this process whereas the other forms of polarisation, which are related to the movement of nuclei (atomic, configurational) are established much more slowly in $> 10^{-13}$ s and $10^{-12}-10^{-9}$ s respectively.[24] Consequently, electron transfer from molecule D to A will only occur after the "supermolecule" acquires from thermal fluctuations a nonequilibrium configuration (along the $q^{\neq}$ coordinate) in which the potential energies of the initial and final states coincide; i.e., when

$$E_r(q^{\neq}/q_1)^2 = E_r\left(\frac{q^{\neq} - q_1}{q_1}\right)^2 + \Delta G.$$

hence

$$q^{\neq}/q_1 = (E_r + \Delta G)/2E_r.$$

According to equation (5a) the energy of activation for transfer of the D ... A system to the Franck–Condon state ($G^{\neq}$, see Fig. 1) is equal to:

$$U_{(D...A)}(q^{\neq}) \equiv G^{\neq} = (E_r + \Delta G)^2/4E_r. \quad (9)$$

Hence the FC factor in equation (7) is given by

$$FC = A\exp(-G^{\neq}/kT) = A\exp[-(E_r + \Delta G)^2/4E_r kT], \quad (10)$$

where

$$A = (4\pi E_r kT)^{-1/2}.$$

Equation (10) represents the state of the system in the classical approximation, i.e., when $\hbar\omega \ll kT$, where ω is the effective angular frequency of the fluctuations in the "supermolecule" (related to E_r by the relationship $E_r = \hbar\omega q_1^2/2$). The FC factor has a maximum value $FC = A$ when there is a negative free energy $-\Delta G = E_r$.

According to expression (10), in isoenergetic systems (when $\Delta G = 0$) $G^{\neq} \equiv G^{\neq}(0) = E_r/4$.

The free energy of the thermal reaction (4) is equal to

$$\Delta G = E_0 - E_1 = e[E_{1/2}(D/D^{\cdot+}) - E_{1/2}(A^{\cdot-}/A)] + e^2/\varepsilon R, \quad (11)$$

where $E_{1/2}(D/D^{\cdot+})$ and $E_{1/2}(A^{\cdot-}/A)$ are the equilibrium potentials of oxidation of the donor and reduction of the acceptor respectively, $e^2/\varepsilon R$ is the Coulomb attraction energy of the radical ions $D^{\cdot+}$ and $A^{\cdot-}$, having their own solvation shells; ε is the dielectric constant of the medium.

The reorganisation energy of the medium due to electron transfer is calculated from the equation of Marcus:[21,25]

$$E_s = e^2(1/n^2 - 1/\varepsilon) f(r, R), \quad (12)$$

where n is refractive index of the medium, $f(r, R)$ is a function that depends on the radius of the components and on the distance of electron transfer R. For exchange reactions

$$M^{\cdot+} ... M \overset{k_{et}}{\rightleftharpoons} M ... M^{\cdot+}, \quad (13a)$$

$$M^{\cdot-} ... M \overset{k_{et}}{\rightleftharpoons} M ... M^{\cdot-} \quad (13b)$$

function $f(r, R) = (1/r - 1/R)$, which for reaction (4): $f(r, R) = (1/2r_D - 1/2r_A - 1/R)$. Here r, r_D, and r_A are the radii of the transport site M, the donor molecule, and acceptor molecule respectively.

The "inner-sphere" reorganisation energy E_{in}, such as for reaction (13a), can be determined experimentally from the difference in gas-phase ionisation potentials:[30–33]

$$E_{in} = I^V - I, \quad (14)$$

where I^V is the vertical or Franck–Condon ionisation potential, which is equal to that quantum of energy ($I^V = h\nu_{max}$) at which are formed the maximum number of electrons from photodecomposition; I is the adiabatic ionisation potential. In two studies[30,31] I was calculated from the equation $I = h\nu + 0.15$ eV, where $h\nu$ is that quantum of energy at which the number of electron from photodecomposition is 1% of those that are formed at $h\nu_{max}$. The value of E_{in} determined thus for a series of 25 alkylamines is 0.6–0.7 eV.

The complete reorganisation energy of a "supermolecule" is given by the difference

$$E_r = E^V - [eE_{1/2}(M/M^{\cdot+}) + E_0], \quad (15)$$

where E^V is that quantum of energy which corresponds to photoionisation of molecules in the liquid phase when the energy of the electrons emitted into the gas phase is close to zero. $E_{1/2}(M/M^{\cdot+})$ is the equilibrium oxidation potential of the molecule compared to a reference electrode (S.H.E.). E_0 is the energy level of the reference

electrode relative to vacuum [E_0 = 4.43 eV for a standard hydrogen electrode (S.H.E.)].[34] Thus, [$eE_{1/2}(M/M^+)$ + E_0] is the energy of the radical cation M^+ relative to vacuum in a completely relaxed state, namely, after completion of both "inner-sphere" and "outer-sphere" reorganisation. The value of E_r was determined from the experimental values of E^V and $E_{1/2}(M/M^+)$ for a number of alkylamines[32] (Table 1) and for all methyl-substituted benzenes.[32,33] The "intramolecular" reorganisation energy, calculated from the expression $E_{in} = E_r - E_s$, is also given in Table 1.[31] In the calculation of E_s it was suggested that $r = r_{eff} = R/2$. The effective radius r_{eff} of M molecules was determined from the experimentally determined electron polarisation energy, taken as equal to $P_e = [(I^V + I)/2] - E^V$ and related to r_{eff} by the expression $P_e = e^2(1-1/n^2)/2r_{eff}$.[31,32] Thus

$$r_{eff} = e^2(1 - 1/n^2)/(I^V + I - 2E^V).$$

Table 1. Reorganisation energy E_r of a "supermolecule" and the medium E_s for exchange reaction (13a) of a number of alkylamines in acetonitrile calculated from equations (15) and (12) and the intramolecular reorganisation energy $E_{in} = E_r - E_s$.[31]

Compound	E_r, eV*	E_s, eV	E_{in}, eV*
Butylamine	1.67	1.17	0.5
Isobutylamine	1.64	1.23	0.41
t-Butylamine	1.6	1.22	0.38
Dibutylamine	1.3	1.07	0.23
Tributylamine	1.23	0.82	0.41
Tetramethyl-*p*-phenylenediamine			0.365**

*The value of E_0 = 4.5 eV used by Watanabe et al[31] has been replaced by 4.43 eV for a S.H.E.[34]
**Value taken from two studies.[35,36]

It was shown[31] that values of r_{eff} calculated from this expression agree with the values that are calculated from the volume occupied by the molecule: $4\pi r_{eff}^3/3 = MW/dN_A$, if the coefficient 0.5 is used instead of $(3/4\pi)^{1/3}$ (MW is the molecular weight of alkylamine, d is the density of alkylamine, N_A is the Avogadro number).

The most common method for determining E_r, and hence E_{in}, is a determination of the energy of activation $G^{\neq}$ of exchange reactions, for which, as has already been mentioned, $G^{\neq} \equiv G^{\neq}(0) = (E_{in} + E_s)/4$. The energy E_{in} thus obtained for the exchange reaction of *N,N,N',N'*-tetra-methyl-*p*-phenylenediamine (TMPD) in different solvents is given in Table 1. The value of E_{in} was determined by extrapolating the dependence of $4G^{\neq}$ on $(1/n^2 - 1/\varepsilon)$ to $(1/n^2 - 1/\varepsilon) = 0$, i.e., when $E_s = 0$ [see (equation 12)].[35,36] The value of E_{in} obtained for TMPD by this method (0.365 eV, see Table 1) is close to that calculated by the Pariser–Parr–Pople method (0.337 eV). For methyl-substituted benzenes ($C_6H_{6-n}(CH_3)_n$, $n = 1-6$) the experimental value E_{in} = 0.26 eV.[32,33]

It should be mentioned in addition that the total polarisation energy of the medium by a radical cation $M^+(D^+)$ is determined from the adiabatic ionisation potential:

$$p^+ = e^2(1 - 1/\varepsilon)/2r_{eff} = \{I - [eE_{1/2}(M/M^+) + E_0]\}.$$

The energy of the exchange interaction in a Franck–Condon state (8) is given by the equation[37,38]

$$V_{01} \equiv V(R) = V(R_0)\exp[-(R - R_0)/\alpha], \quad (16)$$

where R_0 is the sum of the van der Waals radii of D and A^-, α is the attenuation factor of the wave function in the Franck–Condon state.

$$\alpha = 1/0.511B^{1/2}, \text{ Å}. \quad (17)$$

here B is the height of the barrier or difference between the position of the highest occupied orbital of the donor and the energy of the lowest conducting state of the medium (in eV) (see Fig. 1*b*).

Thus the rate constant of electron transfer under nonadiabatic conditions in accordance with equations (7), (10), and (16) can be written in the general form

$$k_{et}(na) = (2\pi/\hbar)(4\pi E_r kT)^{-1/2} V^2(R_0)\exp[-2(R - R_0)/\alpha] \cdot \exp[-(E_r + \Delta G)^2/4E_r kT]. \quad (18)$$

It is necessary to bear in mind that because of steric hindrance in the formation of molecular conformations with minimum potential energies in polymer matrices, a nonuniform distribution of ionisation potentials and electron affinities (i.e., ΔG), steric variation in the dielectric constant of the medium ε (i.e., E_r), and other factors giving rise to a variation in k_{et} are possible.

In organic systems there is a common situation when the frequency of the "outer-sphere" fluctuations ω_s ($E_s = \hbar\omega_s q^2/2$) conforms with the inequality $\hbar\omega_s \ll kT$, while the distance between the vibrational levels in the donor and acceptor molecules conforms with the inequality $\hbar\omega_{in} \gg kT$. Under these conditions, the lowest vibrational level is occupied in the initial system D ... A, while the final state (D^+... A^-) is represented by a set of parabolae, given by equation (6a), separated from each other on the y-axis by a quantum of vibrational energy $\hbar\omega_{in}$.[17,39] Electron transfer can occur by conversion to different vibrational levels of the acceptor [$n_i\hbar\omega_{in}$, where $v_i = (v + 1/2)$] (v is the vibrational quantum number, equal to 0, 1, 2, 3...). The overall constant results from summation of the rate constants of electron transfer to different vibrational levels and is given by:[39]

$$k_{et} = (2\pi/\hbar)V_{01}^2(4\pi E_r kT)^{-1/2}\sum_{v_i=0}^{\infty}\frac{\exp(-S)S^{v_i}}{v_i!}\times \times\exp\left[-\frac{(\Delta G + v_i\hbar\omega_{in} + E_s)^2}{4E_s kT}\right]. \quad (18a)$$

where $S = E_{in}/\hbar\omega_{in}$. For large negative values of ΔG (when $|\Delta G| > E_s$) the main channel for electron transfer reduces to a vibrational term corresponding to the value $G^{\neq} = 0$, i.e., $v_i = (\Delta G - E_s)/\hbar\omega_{in}$.

At the adiabatic (*a*) limit (Fig. 2*a*)[40,41]

$$k_{et}(a) = \frac{\varepsilon}{\tau_D n^2}\left(\frac{E_s}{4\pi kT}\right)^{1/2}\exp\left[-\frac{G^{\neq} - V_{01}}{kT}\right]. \quad (19)$$

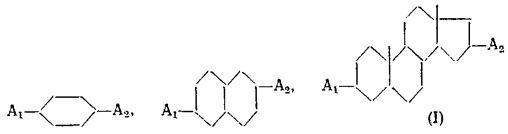
where τ_D is the dielectric relaxation time of the medium after electron transfer. In contrast to nonadiabatic conditions, in which the rate of electron transfer is controlled by the exchange interaction V_{01}^2, under adiabatic conditions k_{et} is mainly determined by the longitudinal relaxation time of the medium $\tau_L : \tau_L = \tau_D n^2/\varepsilon$.

In contrast to liquid media in which an electron transfer reaction mainly occurs after the diffusional approach of components to the distance R_0, equal to the sum of the van der Waals radii, in polymer systems D and A are either fragments of a polymer chain and are separated by a fixed distance or are dissolved in the polymer matrix

and have a random distribution with an interaction radius R. In this case the pattern of electron transfer can be complicated by the effect of the free volume and other polymer effects.

Donor-acceptor compounds with bridging groups (B) constitute a model of dielectric polymer media. Charge transfer along the saturated bonds $-CH_2-$ is caused by hyperconjugation[42,43] (superexchange interaction), namely, by overlap of the π-orbitals of the organic aromatic groups D and A with the atomic $p\sigma$-orbital of an unsaturated $-CH_2-$ fragment. The extent of this overlap depends on the rotation angle of the aromatic rings relative to the bridging group.[42,44] The $-CH_2-Ar-CH_2-$ groups are regarded as bridges (Ar is aromatic fragment).[44,45] The stepwise transfer of an electron via bridging groups can occur with complete reorganisation of the "supermolecule" at each transition step as well as a dynamic transfer when short-lived bridging states participate in electron transfer.[17] The energy of the exchange interaction for bridging systems is determined from the equation:[44,45]

$$V_{01}=\sum_{B} V_{0B}V_{B_i}/(G_1^{\neq}-E_B),$$



where the index B relates to a bridging group; E_B is the energy at the minimum of the potential curve of the bridging group; $G_1^{\neq}$ is the energy of the initial state of the D...A system at the point of intersection of the initial potential curve of $U_{(D...A)}$ with the potential curve of the bridging fragment; V_{0B} and V_{B1} are the energies of the exchange interaction of the orbitals of D and B^- and B^- and A^- respectively.

Under conditions of superexchange the attenuation factor α in expression (16) takes the form

$$\alpha=\frac{1}{R}\ln\left(\frac{B}{V_{B^-B}}\right),$$

where R and V_{B^-B} (or V_{B^-B}) are respectively the distance and exchange integral between bridging groups on which the movement of a charge occurs.

Electron transfer has been studied[28,46,47] in compounds of the type A_1-B-A_2 such as substituted cyclohexanes, decalins, and steroids:

(I)

where A_1 is biphenyl (electron affinity 2.4 eV), A_2 are aromatic compounds with different values of the equilibrium potential $E_{1/2}(A_2^-/A_2)$ corresponding to a free energy of electron transfer

$$\Delta GT=e[E_{1/2}(A_1^-/A_1)-E_{1/2}(A_1^-/A_2)]=0 \text{ to } -0.25 \text{ eV}.$$

Pulsed radiolysis was used to study the reaction

$$A_1-B-A_2 \xrightarrow{e} \begin{cases} \rightarrow A_1^- - B - A_2 \\ \rightarrow A_1 - B - A_2^- \end{cases} \quad (20)$$

The first step in reaction (20) is capture by an A_1-B-A_2 molecule of an electron formed during pulsed irradiation of solvents such as methyltetrahydrofuran (MTHF), tetrahydrofuran, and isooctane at 296 K.

The interconversion of the optical spectra of A_1^- and A_2^- is an indication of electron transfer, in accordance with reaction (20), via saturated $-CH_2-$ (or $>CH-$) bonds. When substituted steroids (I) are used, the dependence of k_{et} on $-\Delta G$ acquires a bell-shaped form. The experimentally determined dependence is in agreement with that calculated from expression (18a) when E_{in} = 0.45 eV, $\hbar\omega_{in}$ = 1500 cm^{-1}, V_{01} = 6.2 cm^{-1}, E_s = 0.75 eV in MTHF and 0.15 eV in isooctane. In the calculation of E_s from equation (12) it is assumed that $r_{A_1}=r_{A_2}$ = 2.95 Å, R = 17.3 Å. The value of the constant k_{et} decreases from 5×10^9 to 10^6 s^{-1} on increasing the number of saturated bonds (n) that separate A_1 and A_2 from 4 to 10. A relationship was established[47] between the energy of the exchange interaction V_{01} and n when $V_0=1.1\times10^3$ cm^{-1}: $2\ln V_{01}=2\ln V_0-1.15(n-1)$.

(b) Electron transfer between single-type transport sites

Electron transfer between single-type transport sites that are situated in a disordered manner in a solid dielectric medium is of particular interest from a theoretical viewpoint and important for practical application. Polymers with a glass transition temperature (T_g) that exceeds the temperature at which the electron transfer measurements are carried out are usually chosen as the medium. An important feature of these systems is the participation of the oxidised (or reduced) form of the neutral transport site (M) in electron transfer and the occurrence of fixed distances between the transport sites [reaction (13a) and (13b)]. When an external electric field F is applied, these reactions determine the flow of hole (or electron) current through the sample:

etc.

The transport of holes is simpler to study experimentally in systems with transport sites that are characterised by low ionisation potentials I_M (or low oxidation potentials of M), while the transport of electrons is simpler to study in systems with high values of electron affinity E_M. This is related to the fact that in polymer matrices there are chemical impurities and structural defects which in the case of electron transport are electron traps if their electron affinity is higher than E_M. Capture of electrons in traps considerably complicates their transport through a sample. The effect of additional traps on the transport of charges has been studied experimentally and theoretically.[48] In the present review this question is not considered as it is possible to select experimental conditions that exclude the effect of additional traps.

In this section four types of systems will be examined: 1) polymers in which the transport sites are substituents in the main chain, for example, the carbazolyl group in polyvinylcarbazole (PVCA), polyepoxypropylcarbazole (PEPCA), etc.; 2) polymers in which the transport sites occur in the main chain, for example, polyimides,[49] polyphenylene sulphides,[50] polyepoxyamino adduct,[51] and others; 3) molecularly doped polymers, namely, inert polymer matrices [polystyrene (PS), polycarbonate (PC), and others] in which are dissolved low-molecular weight transport molecules such as triphenylmethane (TPM) and its derivatives, triphenylamine (TPA), isopropylcarbazole (IPCA), and others; 4) mixed systems, for example, PVCA in which TPA is dissolved, PC containing IPCA and TPA in different proportions, and also the system that has been the most studied—PVCA + trinitrofluorenone (TNF).

The electron transfer reaction in the systems is the simplest of those considered above, it is completely reversible, and the composition of the reaction products is no different from that of the initial reactants. Serious problems in the theoretical treatment arise because the distances between the neighbouring transport sites are fixed but

differ over quite a wide range. The result of this is that the energy of the bond between the electron and the transport site, which depends on the local environment, also varies for specific transport sites, the distribution of energy of the bond reaching a width of several magnitudes of kT.

This electron transfer process determines the electron conductivity of photoconductive organic materials by nonequilibrium charge carriers. These materials are extensively used as electron-transport media in electrophotographic films, high energy transformers, etc. An experimental study of these reactions for the determination of k_{et} and the kinetic mechanisms presents certain difficulties because of the identification of the chemical composition of the reactants and the reaction products, the spin state, and spectroscopic characteristics. However, charge transfer in an external field F has the result that the charge acquires an additional drift rate in the direction of the field, and a current arises in the electric circuit which includes the polymer sample; the charge mobility μ is determined by analysing the current. The rate constant k_{et} and charge mobility μ are related through the diffusion coefficient

$$\mu = De/kT; \quad D = \rho^2 k_{et}$$

by the relationship

$$\mu = \rho^2 k_{et} e/kT, \tag{21}$$

where ρ is the length of electron hop.

In accordance with expression (21) all subsequent treatment of electron mobility in polymer matrices is also fully related to a study of the rate constant of the electron transfer reaction between identical sites. The most informative method for studying electron (hole) transport is the measurement of transit times. A packet of nonequilibrium charge carriers is produced on the surface of a polymer film at the time $t = 0$ (by injection from a catalyst or by direct photoexcitation with strongly absorbed light). If the transport sites are arranged in an ordered manner, the packet of charge carriers will move in the external field through the polymer film to the collector electrode, spreading out through drift but retaining a Gaussian form. In the process the distribution of charge carriers on the coordinate (σ) increases its width according to the principle $\sigma \sim t^{1/2}$. In this case the transport is called Gaussian and the current in the external circuit (i) has a constant value during drift (transit) of the packet through the film and rapidly decreases when it reaches the collector electrode at time t_{tr}. The drift mobility is determined here as $\mu = l/F t_{tr}$ (l is thickness of sample), and the current during drift can be expressed as

$$i = \mu e N \text{ (for } t < t_{tr}), \tag{22}$$

where N is the concentration of drifting charges. If the transport sites are arranged in a disordered manner, the hopping times between neighbouring sites vary over a wide range. Because of this, the packet of charges loses its Gaussian form, the plateau on the $i-t$ curve disappears, and it takes the form of a diminishing curve with a considerably elongated tail. In this case a determination of t_{tr} from the relationship $i = f(t)$ becomes impossible. However, in the logarithmic coordinates $\log i - \log t$ the current curve is converted into two linear sections which correspond to the relationships

$$i(t) \sim t^{-(1-\beta_1)} \text{ when } t < t_{tr},$$

$$i(t) \sim t^{-(1+\beta_2)} \text{ when } t > t_{tr}, \tag{23}$$

where β_1 and β_2 are constants which are independent of t; they have values within the limits $0 \leqslant (\beta_1, \beta_2) \leqslant 1$. The transit time occurs at the point of intersection of the linear segments, but in this case it corresponds to the arrival at the collector electrode (and mobility) of the fastest charges. The prolonged decrease after the break point can only be accounted for if it is assumed that there is a sufficiently large scatter (deviation) of t_{tr} for different groups of drifting charges. Hence charge transfer with the cited anomalous current characteristics is called dispersive. It is possible to determine the value of the current if the average displacement $\bar{x}$ of the packet of charges in relation to t is known. For Gaussian transport, $\bar{x} \sim t$, in accordance with equation (22), we obtain $i \sim d\bar{x}/dt = \text{const}$. If it is assumed that the displacement of the packet does not occur at a constant rate but gradually slows down, so that $\bar{x} \sim t^{\beta_1}$, for the current we obtain the dependence[52] $i(t) \sim d\bar{x}/dt \sim t^{-(1-\beta_1)}$, which is in agreement with equation (23).

It should be mentioned that the rate of movement of the packet $d\bar{x}/dt$ is proportional to the rate constant k_{et}; therefore, if Gaussian transport occurs, k_{et} is independent of t, but if dispersive transport takes place, $k_{et} = At^{-(1-\beta_1)}$, where A is a constant independent of t. A rate constant that varies with time in accordance with this relationship correlates well with a number of experimental results on the fate of captured electrons in vitreous matrices at 77 K.[53]

Relationships (23) were first obtained by Sher and Montroll[54] using the continuous time random walk (CTRW) model. In order to take account of the dispersion of t_{tr} occurring as a result of the dispersion in hopping times between neighbouring transport sites in the CTRW model, a disordered medium is broken down into single units composing a regular lattice. Each unit contains a sufficiently large number of transport sites so that the units have an equivalent concentration of M. The distribution of hopping times for the neighbouring sites in each unit is expressed as a prolonged distribution function for the probability of hops between units [$\psi(t) \sim t^{-(1+\beta)}$], which leads to dependence (23) with $\beta_1 = \beta_2 = \beta$. In Gaussian transport the distribution function decreases exponentially with time and has a single characteristic time τ_0:

$$\psi(t) = (1/\tau_0) \exp(-t/\tau_0).$$

It was originally supposed that the CTRW model represents electron hops between neighbouring sites by a tunnel mechanism. In this case it is clear that the relationship $h' > \rho$ holds true between the linear dimensions of a unit (h') and ρ. Subsequent analysis showed[15,55] that the condition for the CTRW model to be applicable was the inequality with an opposite form: $h' \ll \rho$. This indicates that the transport of electrons occurs in a conduction zone (a zone mechanism) with repeated capture on traps with an energy distribution in a certain range.

Dispersive current with the decreasing curve (23) must occur during nonequilibrium transport of electrons, namely, in the absence of thermal equilibrium between mobile (electrons in the conduction zone) and localised (electrons in localised states) fractions. In this case the time of electron motion in the conduction zone determines the probability of their being trapped, while the dispersive characteristics of transport determine the energy distribution of trap depths. For example, for an exponential distribution of trap depths:

$$g(E) = (N_t/E_0) \exp(-E/E_0),$$

(N_t is trap density), the relationships $\beta_1 = \beta_2 = \beta$ and $\beta = kT/E_0$ are fulfilled.[56]

A condition for nonequilibrium transport is that the relationship $\tau_l(E) > t_{tr}$, where $\tau_l(E)$ is the distribution of charge localisation times in traps of varying depth E, holds for a substantial fraction of the traps. After generation (injection or photoexcitation of the surface

layer of the film sample) the charges are localised in traps according to their concentration and independent of depth. In order to establish thermal equilibrium repeated escape of the charges from the traps into the conduction zone is necessary. If the condition $\tau_l(E) \ll t_{tr}$ is fulfilled for all traps, during the time of drift of a packet through the sample the current has a constant value and on reaching t_{tr} it falls more or less abruptly.

The temperature dependence of μ is determined by trap depth, and by extrapolating the dependence $\mu - T$ in the Arrhenius curve to $T^{-1} \to 0$ it is possible to determine the charge mobility in the conduction zone μ_0. For organic polymer systems (in contrast to, for example, chalcogenide glasses) μ_0 has the value $\mu_0 \sim 1$ cm^2 V^{-1} s^{-1}, and this corresponds to the limiting value that determines the applicability of the zone model, since when $\mu_0 < 1$ cm^2 V^{-1} s^{-1} the length of the electron path becomes comparable with or less than R in the polymer. Therefore, even though direct simulation of the transient current $i(t)$ using Monte Carlo curves for the zone model with repeated capture of charges by traps effectively represents the characteristics of hole transfer in PVCA[57,58] (including the lack of dependence of μ on l, the disappearance of the inflection on the transient current curve when the temperature is decreased, the prolonged decrease of transient current when $t > t_{tr}$, etc.), the suitability of the zone model for representing charge transfer in a polymer matrix is in doubt.

This difficulty can be overcome in the percolation of model of dispersive transport, developed in several studies,[15,55,59,60] which can be used to replace the CTRW approximation when the condition $h' \gg \rho, \rho = R - R_0$, is fulfilled, namely, when tunnel electron transfer occurs between transport sites. The rate of electron transfer between neighbouring sites depends exponentially on R and the height of the energy barrier.

In the percolation model it is considered that in an amorphous solid with a considerable concentration of transport sites it is possible to distinguish "rapid" trajectories of the movement of electrons through sites, the distance between which is less than a given optimum distance R_m, and "slow" trajectories for which $R > R_m$. On increasing the concentration of transport sites to a threshold concentration C_0, the rapid trajectories combine to form an endless cluster on which rapid electron transfer through the sample from electrode to electrode occurs. A further increase in the concentration of transport sites leads to an increase in density of the endless cluster, so that $i = (C - C_0)^\gamma$, where γ is a constant.

If the energy of the bonding between the electrons and the sites is distributed over the range δE and $kT > \delta E$ (quite high temperatures), it may be assumed that the energy of the electron on hopping does not vary and the only variable that determines the rate of transit is R. As a result, as analysis has shown,[15] when $t < t_{tr}$ the current remains constant, but when $t > t_{tr}$ the current displays a prolonged non-exponential decay. If the important role played by the energy scatter of the bond between the electrons and sites when $\delta E > kT$ is taken into account in the percolation model, the current is given by expression (23), $\beta_1 = \beta_2 = \beta$.

Thus, in measurements of electron transfer, the percolation model predicts the possibility when the measurement temperature is increased of changing from a purely dispersive transport to a Gaussian one with a constant current when $t < t_{tr}$. However, such a change is also predicted by the zone model with repeated capture on replacing nonequilibrium transport with quasi-equilibrium (with an increase in temperature), which is due to the decrease of $\tau_l(E)$ so that for all depths $\tau_l(E) < t_{tr}$. Such a change has been observed more than once experimentally, for example, in PVCA it occurs at 424 K,[61] while in poly(*p*-phenylene sulphide) it occurs at 310 K.[62] It should be emphasised that in the initial CTRW model, transport is regarded as dispersive, regardless of the temperature and other factors, which is at variance with the results obtained for these systems.

The percolation model effectively accounts for the kinetic characteristics of electron transfer between transport sites, the dependence of μ on the width of the sample (l), and other phenomena, but it follows from it that

$$i(t, T, F) = (eF\mu/l)\hat{f}(T, t), \tag{24}$$

namely, that the mobility μ is independent of F. This is at variance with the experimental data, according to which the dependence μ on F is almost exponential. A similar situation occurs in the CTRW model.

The discrepancies between the theoretical models and experiment that have been detected are so serious that, in order to simplify the interpretation of the experimental results, in recent years measurements have been conducted on polymer systems in which dispersive transport is absent and i = const when $t < t_{tr}$. In this case the mobility does not depend on the width of the film sample. It is these systems, mainly polymer dielectric matrices (PC, PS) doped with aromatic amines and diamines,[63] which are examined below. In such systems the average distances between the neighbouring sites can readily be varied by changing the concentration of transport sites. In the majority of the experiments carried out the dependence of μ on the three main parameters—R, T, and F—has been studied. All of the experimental results are effectively related by the equation

$$\mu = \frac{eR^2}{kT} \exp[f_1(R)] \exp[f_2(T, R)] \exp[f_3(F, T, R)], \tag{25}$$

when $F \to 0$, $f_3(F, T, R) \to 0$, and the absence of the cofactor $[f_3(F, T, R)]$ in expression (25) gives a zero-field approximation. Attention was drawn for the first time by Gill[65] to the fact that in amorphous polymer systems the mobility μ is related to R by:

$$\mu \sim R^2 \exp[-2(R - R_0)/\alpha]. \tag{26}$$

Hence it follows that $f_1(R) = -2(R - R_0)/\alpha$. Thus, $\exp[f_1(R)]$ in expression (25) is the factor for overlap of wave functions of the neighbouring sites [see equations (8) and (16)]. In the majority of cases an activation dependence of μ on T occurs. On Arrhenius coordinates when measurements are made over a wide temperature range, a reduction in the energy of activation ΔE_a sometimes occurs in the high-temperature region (above 300 K). Furthermore, ΔE_a usually increases with an increase in R, in other words, it may be assumed that $f_2(T, R) = -\Delta E_a(R)/kT$. In all of the experimental and theoretical models[66,67] the cofactor $f_3(F, T, R)$ reflects the reduction in the energy barrier for electron transfer in an electric field and is usually written as $f_3(F, T, R) = e(R - R_0)F/kT$.

As a result, in representing the experimental data use is made of a simple relationship of the form:

$$\mu = \frac{eR^2}{kT} \exp[-(R - R_0)/\alpha] \exp\{-[\Delta E_a - e(R - R_0)F]/kT\}. \tag{27}$$

For a more complete representation of the experimental data it is necessary to find more exact relationships and to select the most realistic models of charge transfer in polymer systems.

The exponential dependence of μ on F in the model of repeated capture on traps in the case of quasi-equilibrium transport is due to the Frenkel–Poole effect; in this case $f_3 = \eta F^{1/2}/kT$, where η is the Frenkel–Poole constant. However, the suitability of this model for polymer systems, as has already been mentioned, raises serious

objections and the Frenkel–Poole effect itself assumes the existence of a large concentration of charged traps in which charges are captured during transport. The latter is not likely for the single-component systems doped with molecules that are commonly studied such as PC + TPA, and also for PVCA and other transport polymers without added components.

Bassler et al.[66,68] used the Monte Carlo method to resolve the problem of electron transfer in a transport system that meets the following conditions:

1) the energy distribution of the bonding of the charges on sites is Gaussian:

$$\varphi(E) = (2\pi\sigma)^{-1/2} \exp(-E^2/2\sigma^2);$$

2) the factor for overlap of wave functions of the neighbouring transport sites is written in the form

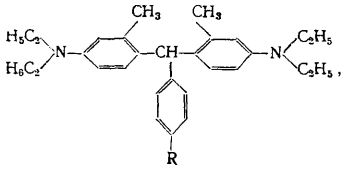
$$\exp[f_1(R)] = \exp[-2(R - R_0)/\alpha];$$

3) the probability of a hop from the ith transport site to the jth site when $E_j > E_i$ is taken into account using the Boltzmann constant:

$$W_{ij} = \nu_0 \exp[-2(R - R_0)/\alpha] \exp[-(E_j - E_i)/kT]$$
$$W_{ji} = \nu_0 \exp[-2(R - R_0)/\alpha],$$

i.e.

$$W_{ij} \exp(-E_j/kT) = W_{ji} \exp(-E_i/kT).$$



4) the electric field increases the number of transport sites on to which an electron can hop without activation; this occurs when $E_i + e(R - R_0)F > E_j$.

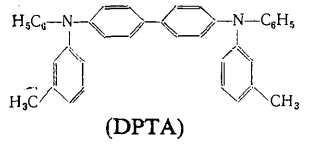
It was shown that the temperature dependence of mobility in such systems does not follow the Arrhenius equation, but in expression (25) $f_2 = -(T_0/T)^2$ and $f_3 = F/F_0$. Here $T_0 = K\sigma$ and

$$F_0 = \frac{T^2 R_0}{2B' eK^2 \sigma},$$

where K and B' are constants.

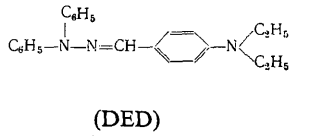
An analytical solution of this problem [69,70] leads to similar results: in this case K = 7400 Kl eV^{-1}, B' = 0.15. The values of T_0 and F_0 were calculated for different TPM derivatives–PC (TPM concentration of 40 wt.%) from the experimental dependences of μ on T and F determined by Pai et al.[71] and Bassler.[72]

where R = N$(C_2H_5)_2$; H; OH; Br; OCH_3; CN; NO_2.



It was found for this series of derivatives that as the electron affinity of substituent R increases, the mobility of the charge carriers decreases by a factor of 10^4. It was suggested[72] that with an increase in electron affinity of substituent R, there is an increase in dopole moment (κ) of the TPM derivative, and consequently an increase in the polarity of the medium (ε).

According to Bassler[72] the spread of distances between neighbouring transport sites M results in a scatter (σ) of interaction energies between a charge on a site and the medium, and σ increases as ε increases, changing the values of F_0 and T_0. Even though the values of T_0 and F_0 vary considerably for the different TPM derivatives, their product remains constant $T_0/F_0 \simeq 310 \pm 4$ mV K cm^{-1} when T = const; this accords with the model under consideration: $T_0F_0 = T^2R_0/(2B'eK)$, and does not depend on σ. We should emphasise that the increase in the slope of the temperature dependences of $T_0 = K\sigma$ with an increase in κ does not unequivocally prove that there is a direct relationship between κ and σ. The slope may also depend on the intramolecular reorganisation energy (E_{in}) of the transport site M during an electron hop. This reorganisation energy naturally depends on the structure of M. Moreover, according to the Bassler model, for different values of F, straight lines on the coordinates of $\log\mu = f(T_0/T)^2$ should intersect at the same point on the y-axis [when $(1/T)^2 \to 0$] in accordance with equation (25). In fact, this characteristic was found for PVCA + TNF (1 : 0.2) systems.[72,73]



However, this model is not valid for polymers doped with aromatic amines since the relationships between μ, T and F do not hold in this case.

It should be mentioned that the relationship $\log\mu \sim (1/T)^2$ can reflect the temperature change of the energy of activation, which is possible for a Gaussian distribution of energy of the bonding of the charges on the transport sites; at which values of σ it ceases to be observed and what form it takes with other types of distribution is not clear at the present time (further investigation of this problem is required). Moreover, as has been indicated above, deviations from an Arrhenius relationship may be due to a change in the state of the polymer matrix as T increases and thus the relationship $f_2 = -(T_0/T)^2$ may be regarded as a special case of the temperature dependence of μ. A more general case is the Arrhenius dependence of μ on T with ΔE_a = const.

Interesting results were obtained for two systems based on PC doped with di (*N*-phenyl-*N*-*m*-tolyl)-*p*-aminobiphenyl (DPTA)[63] and *p*-diethylaminobenzaldehyde diphenylhydrazone (DED).[64]

(DPTA)

(DED)

It transpired that in DED the energy of activation (ΔE_a) does not depend on the distance R between the dopant molecules on changing R from 8 to 18 Å, while in DPTA it increases from 0.35 to 0.53 on changing R from 10 to 15.5 Å. The distance was determined from the equation $R = 3 \times 10^{27}/(4\pi \times N_A C^{1/3})$ Å, where C is the molar concentration of dopant. Values of μ [extrapolated to $F = 0$ ($f_3 = 0$)] and the energies of activation ΔE_a determined at different concentrations of C were used to calculate $f_1(R)$ from equation (25).[64] The result was that with these limits for varying R in DPTA, f_1 = const, namely, the $\exp(f_1)$ term in equation (25) does not depend on R, while in DED $f_1(R) = -2(R - R_0)/\alpha$ (where α = 1.7 Å). These results may be accounted for using a simple model of activated hops by polarons of small radius,[64,74] for which, as has been mentioned above, $\Delta G = 0$, $E_{in} = 0$, $G^{\neq} = E_s/4$.[20] For a nonadiabatic case in a zero-field approximation the mobility of a polaron of small radius is given by the expression:[64,74]

$$\mu = (eR^2/kT)\nu_0 \exp[-2(R - R_0)/\alpha] \exp(-G^{\neq}/kT). \quad (28)$$

where ν_0 is the frequency of optical phonons (without taking into account dispersion within the simple model), $G^{\neq} = e^2(1/r - 1/R)/4\varepsilon_p$, r is the radius of localisation if the charge, $1/\varepsilon_p = (1/n^2 - 1/\varepsilon)$. On comparing expressions (25) and (28) it is clear that

$$\exp(f_1) = \nu_0 \exp[-2(R - R_0)/\alpha]; \quad f_2 = -G^{\neq}/kT.$$

For small-sized DED molecules, for which $1/R < 1/r$, the effect of R on $G^{\neq}$ is small, which is in line with experiment. For the large DPTA

molecules, at all of the concentrations used R was comparable with $2r$ (i.e., there was contact between the molecules) and adiabatic electron transfer can be assumed. In this case

$$\exp(f_1) \approx \nu_0; \quad f_2 = -(G^{\neq} - V_{01})/kT. \tag{29}$$

Namely, in accordance with experiment f_1 does not depend on R, while the energy of activation in f_2 varies with R. This treatment is qualitative, but we should mention that, in accordance with (21), the rate constant of electron transfer $k_{et} = \exp(f_1)\exp(f_2)$ enters into the equations for μ [(25), (28) and (29)]. Expressions for the rate constant in the model for small-radius polaron hops constitute a special case of relationships (18) and (19) (when $\Delta G = 0$ and $E_{in} = 0$) for the rate constant of electron transfer between donor and acceptor components in a dielectric medium (model of the dielectric continuum).

The possibility of using the Marcus–Levich–Dogonadze–Kuznetsov[17] theory for the elucidation of electron transport in polymer media was demonstrated by Sahyun,[4] and the experimental proof was obtained by Vannikov et al.[75,76] in studying the effect of the polarity of the matrix on charge transport in a TPA + PC system. In this case the polarity was varied not by replacing the substituents in transport sites, as was carried out by Pai et al.,[71] but by the introduction of added components with different κ values that did not participate in transport. The added components were *p*-, *m*-, and *o*-dinitrobenzenes (DNB), which have dipole moments of 0.5, 4, and 6 D respectively. The concentration of TPA was 33 wt.% and that of DNB varied from 0 to 6 wt.%. It can be seen in Fig. 3 that at the same concentrations of DNB, *o*-DNB had the greatest effect on μ and ΔE_a and *p*-DNB had no effect.

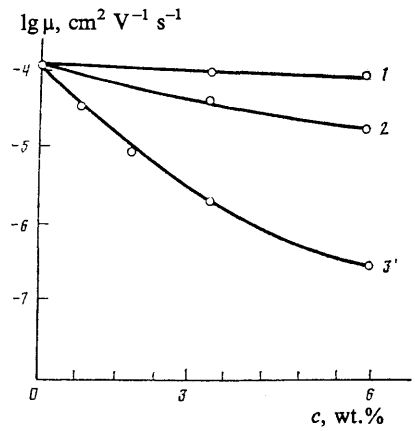


Figure 3. Dependence of the drift mobility of holes μ in the system PS + TPA on the concentration of added quantities of: *1*) *p*-DNB; *2*) *m*-DNB; *3*) *o*-DNB. TPA concentration = 33 wt.%.[75,76]

The ionisation potential of DNB in the gas phase is 10.5 eV, which is considerably higher than the ionisation potential of TPA (6.8 eV), therefore DNB molecules cannot be traps for holes, the transport of which occurs in TPA + PC systems. On increasing the concentrations of *o*-DNB to a value of 6 wt.%, the dielectric constant increases from 2.9 to 4.9 (in this system, $n^2 = 2.4$). The energy of activation for electron transfer may be determined, in accordance with what has been stated above, as

$$\Delta E_a \equiv G^{\neq} = \frac{(E_s + E_{in} + \Delta G)^2}{4(E_s + E_{in})}, \tag{30}$$

where ΔG is given by expression (11), $E_r = (E_s + E_{in})$, and E_s and E_{in} are determined from equations (15), (12), and (14) respectively.

For electron transfer through identical sites in an electric field F we can write $\Delta G = e(R - R_0)F$.

When the concentration of TPA is equal to 33 wt.%, $R = 10$ Å. In electron transfer from a neutral TPA molecule to a TPA^+ radical cation, a change in valence state of the nitrogen atom occurs. In TPA the nitrogen atom has a tetrahedral structure while in TPA^+ it is planar. The "inner-sphere" reorganisation energy E_{in} of the molecule, namely, the energy required for converting TPA to a TPA^+ form in the gas phase is 0.8–1.0 eV.[4] The experimental results of the dependence of μ and ΔE_a on the dielectric constant ε of the polymer matrix are shown in Fig. 4.[75,76] As can be seen, when ε increases from 2.9 to 4.9 μ decreases by a factor of 320 while ΔE_a increases from 0.18 to 0.46 eV. The curve of ΔE_a against ε, calculated from equation (30) [in calculating E_s from equation (12) it was assumed that $R = 25$, $r = 3$ Å, $E_{in} = 0.6$ eV, $F = 3 \times 10^5$ V cm^{-1}), is also given on Fig. 4. This value of E_{in} (less than that calculated in the gas phase) may occur because in the polymer matrix conformations of TPA^+ with different bond angles of the nitrogen atom are frozen,[77] resulting in a reduction in magnitude of E_{in}. On the whole the form of the curve agrees with the experimental results. The value of μ_1/μ_2, calculated from the equation

$$\mu_1/\mu_2 = \left[\exp\left(-\frac{\Delta E_{a1}}{kT}\right) \Big/ \exp\left(-\frac{\Delta E_{a2}}{kT}\right)\right] \simeq 320,$$

agrees with that obtained experimentally. Here the values of ΔE_{a1} and ΔE_{a2} are calculated from equation (30) when $\varepsilon = 2.9$ and 4.9 respectively. The difference between the experimental value of ΔE_a and that calculated for a maximum $\varepsilon = 4.9$ (see Fig. 4) may be due to the above-mentioned effect of the polarity of the medium on the energy spread of the bonding between a hole and M.

It should be mentioned that the models considered above (with the exception of the models of the polaron of small radius and the dielectric continuum) do not take into account the effect of the polarity of the medium on electron transfer in a polymer matrix. The cited experiment that involved a varying polarity of the medium showed that there is a dependence of the mobility of the charge carriers on the dielectric properties of the medium and also on the intramolecular reorganisation energy, which can only be explained on the basis of the dielectric continuum model of Marcus–Levich–Dogonadze–Kuznetsov.

II. Electron phototransfer

1. Tunnel electron phototransfer during exchange interaction in the ground state

The interaction of the wave functions [see (1) and (2)] results in stabilisation of the ground state of the system ($X_1 = E_i - E_0$) and destabilisation of the excited state ($X_2 = E_1 - E_{ex}$) by the amount (see Fig. 2*b*):[16,78–80]

$$X_{1,2} = \mp [\Delta G/2 - (\Delta G^2/4 + V_{01}^2)^{1/2}], \tag{31}$$

where E_i and E_{ex} are the energies of the ground and excited states of the D ... A system respectively (Fig. 2*b*); ΔG is given by equations (3) and (11). When $V_{01} \ll \Delta G/2$, expression (31) frequently reduces to the form:[16,79,80]

$$X_{1,2} = \mp\left\{\frac{\Delta G}{2} - \left[\frac{\Delta G}{2}\left(1 + \frac{4V_{01}^2}{\Delta G^2}\right)^{1/2}\right]\right\} = \pm\frac{V_{01}^2}{\Delta G}. \qquad (32)$$

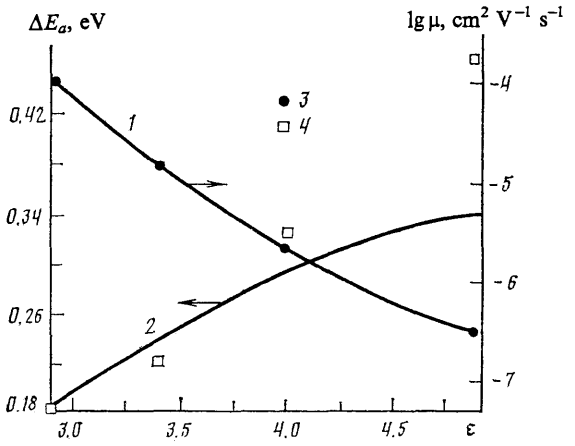

Figure 4. Dependence of the drift mobility of holes μ (curves *1* and *3*) and the energy of activation ΔE_a (curves *2* and *4*) on the dielectric constant of the polymer matrix ε. *1*) Calculation from expression (28); *2*) calculation from expression (30). Curves *3* and *4* are experimental results.[75,76]

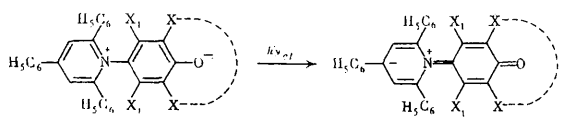

The spectroscopic distribution of the optical density $D(\nu)$ of the charge-transfer band (Fig. 1) is determined by the *FC* factor:[17,18]

$$D(\nu) = D(\nu_{max}) \exp\left[-\frac{(E_r + \Delta G - h\nu_{et})^2}{4E_r kT}\right], \qquad (33)$$

where $D(\nu_{max}) \sim V_{01}^2$ is the optical density at the maximum of the charge-transfer band, namely, when $h\nu_{et}^{max} = E_r + \Delta G$. According to expression (33), the width of the charge-transfer band is given by

$$h\Delta\nu_{1/2} = (2\ln 2)^{1/2}(2E_r kT)^{1/2}. \qquad (34)$$

The dependence of the position and shape of the charge-transfer band on E_r in liquid media has been studied experimentally.[83–86] In aqueous solution containing a high concentration of ferri- and ferrocyanide ions the shape of the electron-transfer band ($\lambda_{max} \sim 800$ nm) is determined by the "outer-sphere" reorganisation, to which the reorganisation energy of the solvent and the reorganisation of the ionic atmosphere make contributions.[83] Kjaer and Ulstrup[84,85] have studied the solvatochromism of intramolecular charge transfer in *N*-substituted 2,4,6-triphenylpyridines (betaines):

The position of the maximum of the charge-transfer band $h\nu_{et}^{max}$ in solutions of the betaines forms the basis for developing a polarity scale of the solvents.

In accordance with their effect on the width of the charge-transfer band, the solvents were divided into three groups: polar aprotic solvents, alcohols, and nonpolar aprotic solvents. In polar aprotic solvents, in accordance with equation (34), the shape of the band is determined by the relationship $E_r = E_s + E_{in}$, where the energy of intramolecular reorganisation results from the change in the C–O, N–C, and C–C bond lengths ($E_{in} = 0.2$ eV) on changing the distribution of charge by exposure to light with energy $h\nu_{et}$. In alcohols the change in vibrational frequencies of the hydrogen bonds formed between an alcohol and betaine makes an additional contribution to E_r. In nonpolar aprotic solvents the width of the charge-transfer band is determined not by E_r but by other forms of electrostatic interaction between the betaines and the solvent (dispersion forces, etc.).

A temperature-dependent ($\sim T^{1/2}$) broadening of the charge-transfer band in a mesitylene–tetracyanoethylene complex in hexane was established by Novikov et al.;[86] this was in complete agreement with expression (34).

According to Hopfield[18] the dipole moment of an optical transition $h\nu_{et}$ is given by

$$\mu_{ex,i} = \int \psi_{ex}^{*}\mu_{0d}\psi_i d\tau \simeq eRV_{0i}/\Delta G,$$

Here μ_{0d} is the dipole moment operator. The molar extinction coefficient of the $h\nu_{et}$ band is proportional to $(\mu_{ex,i})^2$.[16]

$$\varepsilon_{max} \sim \nu_{et}^{max}\mu_{ex,i}^2/\Delta\nu_{1/2}.$$

Where ε_{max} is the extinction coefficient at the charge-transfer band maximum (at ν_{et}^{max}), $\Delta\nu_{1/2}$ is the width of the spectrum or the distance between the points at which $\varepsilon_{1/2} = \varepsilon_{max}/2$. Thus,

$$\varepsilon_{max}^{na} : \varepsilon_{max}^{a} : \varepsilon_{max}^{DA} = (R^{na}V_{01}^{na})^2 : (R^{a}V_{01}^{a})^2 : [R_0V(R_0)]^2.$$

The values of ε_{max}^{na} and ε_{max}^{a} can be determined from the above-mentioned values of V_{01} of ~20 and 400 cm^{-1} respectively for non-adiabatic and adiabatic conditions of charge transfer and also from expression (16) for R, for example, in the approximation $V(R_0) = 1100$ cm^{-1}, $\alpha = 1$ Å, $R_0 = 7.4$ Å.[12] (For D·A complexes $R \simeq R_0$, i.e., $V_{01} \simeq V(R_0)$. After substitution we obtain

$$\varepsilon_{max}^{na} : \varepsilon_{max}^{a} : \varepsilon_{max}^{DA} = (11{,}4^2 \cdot 4 \cdot 10^2) : (8{,}4^2 \cdot 16 \cdot 10^4) : (7{,}4^2 \cdot 1{,}1^2 \cdot 10^6).$$

For D·A complexes $\varepsilon_{max}^{DA} \sim 10^3$ dm^3 mol^{-1} cm^{-1}, hence $\varepsilon_{max}^{a} \simeq 170$ and $\varepsilon_{max}^{na} \simeq 0.78$ dm^3 mol^{-1} cm^{-1}. The latter value agrees with the estimate obtained in two studies,[18,87] in which it is observed that ε usually does not exceed 1 dm^3 mol^{-1} cm^{-1}.

2. Tunnel phototransfer of electrons in the absence of an exchange interaction in the ground state

In the absence of a D·A interaction in the ground state, overlap of the orbitals of the components which gives rise to electron transfer can occur through photoexcitation of one of the components (Fig. 5). In contrast to a liquid, in which electron transfer mainly occurs after diffusion convergence of the components, in a solid (including a polymer) matrix noncontact exciplexes $(D \ldots A)^* \rightarrow (D^{+} \ldots A^{-})$, where $(D \ldots A)^*$ means $(^{1,3}D_1 \ldots {}^1A_0)$ or $(^1D_0 \ldots {}^{1,3}A_1)$, can participate in electron-transfer reactions. The wave functions of the initial excited and ionic state have the form [by analogy with expressions (1) and (2)]:

$$\psi_1(D \ldots A)^* = \psi_0(D \ldots A)^* + \lambda\psi_1(D^{+} \ldots A^{-}),$$

$$\psi_{11}(D^{+} \ldots A^{-}) = \psi_1(D^{+} \ldots A^{-}) - \lambda\psi_0(D \ldots A)^*.$$

The free energy $\Delta G'$ (Fig. 5) and λ are given by expression (3) when E_0 is replaced by $E_{0'}$ and V_{01} is replaced by $V_{01'}$.

$$E_0' = \int \psi_0^*(\mathrm{D}\ldots\mathrm{A})^* H \psi_0(\mathrm{D}\ldots\mathrm{A}) d\tau,$$

$$V_{01}' = \int \psi_0^*(\mathrm{D}\ldots\mathrm{A})^* H \psi_1(\mathrm{D}^{\dot{+}}\ldots\mathrm{A}^{\dot{-}}) d\tau.$$

The transformation of a noncontact exciplex into a contact form when the D and A components are brought closer together, i.e., when V_{01}' is increased, is similar to that shown in Figs. 1 and 2 for donor-acceptor systems interacting in the ground state.

In the present section we shall consider systems in which the distance R between the D ... A components is greater than the van der Waals radii. In these systems when component D or A undergoes photoexcitation in solid matrices, reactions leading to formation of the radical ion pair $^{1,3}[\mathrm{D}^{\dot{+}}\ldots\mathrm{A}^{\dot{-}}]$ can occur:

$$\left.\begin{array}{l} {}^{1,3}\mathrm{D}_1 + {}^1\mathrm{A}_0 \rightarrow {}^{1,3}\mathrm{D}_1 \ldots {}^1\mathrm{A}_0 \\ {}^1\mathrm{D}_0 + {}^{1,3}\mathrm{A}_1 \rightarrow {}^1\mathrm{D}_0 \ldots {}^{1,3}\mathrm{A}_1 \end{array}\right\} \rightarrow {}^{1,3}(\mathrm{D}^{\dot{+}}\ldots\mathrm{A}^{\dot{-}}) \rightarrow \left\{\begin{array}{l} \mathrm{D}^{\dot{+}} + \mathrm{A}^{\dot{-}} \\ \text{products} \\ {}^1\mathrm{D}_0 + {}^1\mathrm{A}_0 \end{array}\right. \quad (35)$$

$$({}^2(\mathrm{D}^{\dot{+}}\ldots{}^2\mathrm{A}^{\dot{-}}))$$

(The equilibrium $^{1,3}[\mathrm{D}^{\dot{+}}\ldots\mathrm{A}^{\dot{-}}] \rightleftharpoons [{}^2\mathrm{D}^{\dot{+}}\ldots{}^2\mathrm{A}^{\dot{-}}]$ corresponds to a weak spin correlation (or its absence) of radical ions that are separated by a distance greater than the van der Waals radii.)

In reactions (35) a photoexcited charge-transfer complex involving a bridging molecule (B) can act as one of the components:

$$\left.\begin{array}{l} {}^{1,3}(\mathrm{D.B})_1 + {}^1\mathrm{A}_0 \rightarrow {}^{1,3}(\mathrm{D.B})_1 \ldots {}^1\mathrm{A}_0 \\ {}^1\mathrm{D}_0 + {}^{1,3}(\mathrm{B.A})_1 \rightarrow {}^1\mathrm{D}_0 \ldots {}^{1,3}(\mathrm{B.A})_1 \end{array}\right\} \rightarrow {}^1\mathrm{B}_0 + \left\{\begin{array}{l} {}^{1,3}[\mathrm{D}^{\dot{+}}\ldots\mathrm{A}^{\dot{-}}] \\ {}^2[\mathrm{D}^{\dot{+}}\ldots\mathrm{A}^{\dot{-}}] \end{array}\right.$$

and subsequently as in reaction (35). Reactions of this type have been studied in detail in a review,[12] in which various classes of dyes that can cause spectroscopic sensitization of electron transfer in donor-acceptor systems are used as a bridging molecule. The free energy of electron transfer according to reaction (35) is given by (Fig. 5):

$$\Delta G' = eE_{1/2}({}^{1,3}\mathrm{D}_1/\mathrm{D}^{\dot{+}}) - eE_{1/2}(\mathrm{A}^{\dot{-}}/{}^1\mathrm{A}_0) + e^2/\varepsilon_s R \quad (36)$$

or

$$\Delta G' = eE_{1/2}({}^1\mathrm{D}_0/\mathrm{D}^{\dot{+}}) - eE_{1/2}(\mathrm{A}^{\dot{-}}/{}^{1,3}\mathrm{A}_1) + e^2/\varepsilon_s R. \quad (36a)$$

Here

$$E_{1/2}({}^{1,3}\mathrm{D}_1/\mathrm{D}^{\dot{+}}) = E_{1/2}({}^1\mathrm{D}_0/\mathrm{D}^{\dot{+}}) - E({}^{1,3}\mathrm{D}_1),$$

$$E_{1/2}(\mathrm{A}^{\dot{-}}/{}^{1,3}\mathrm{A}_1) = E_{1/2}(\mathrm{A}^{\dot{-}}/{}^1\mathrm{A}_0) + E({}^{1,3}\mathrm{A}_1),$$

where $E(^{1,3}\mathrm{D}_1)$ or $E(^{1,3}\mathrm{A}_1)$ is the distance from the ground to excited singlet or triplet level of molecule D or A; $E(^1\mathrm{D}_1)$ and $E(^1\mathrm{A}_1)$ are the energies that correspond to unrelaxed Franck–Condon or relaxed excited states of the molecules. When excited molecules of D or A participate in phototransfer of an electron in a Franck–Condon state [reactions (35)], the probability of a radical ion pair being formed is determined from the difference $E_e - G^{\neq}$ (see Fig. 5*a* and 5*b*), where E_e is the excess energy of the (D ... A) system that occurs in a Franck–Condon state above the energy at the minimum of the potential curve. In the region $E_e < G^{\neq}$, the probability of electron transfer increases exponentially as E_e increases

$$P_{et} = A' \exp\left[-\frac{-E_e + G^{\neq}}{c}\right],$$

and reaches a maximum value at $G^{\neq} - E_e = 0$. (In this equation $c = kT$ if $\hbar\omega \ll kT$ and $c = \hbar\omega$ if $\hbar\omega \gg kT$.) Under nonadiabatic conditions P_{et} decreases as the kinetic energy $\Gamma = E_e - G^{\neq}$ increases in the region $E_e > G^{\neq}$ because of the increased probability of passing through the intersection point of the potential curves on its pathway, i.e., without electron transfer (Fig. 5*a*).[88]

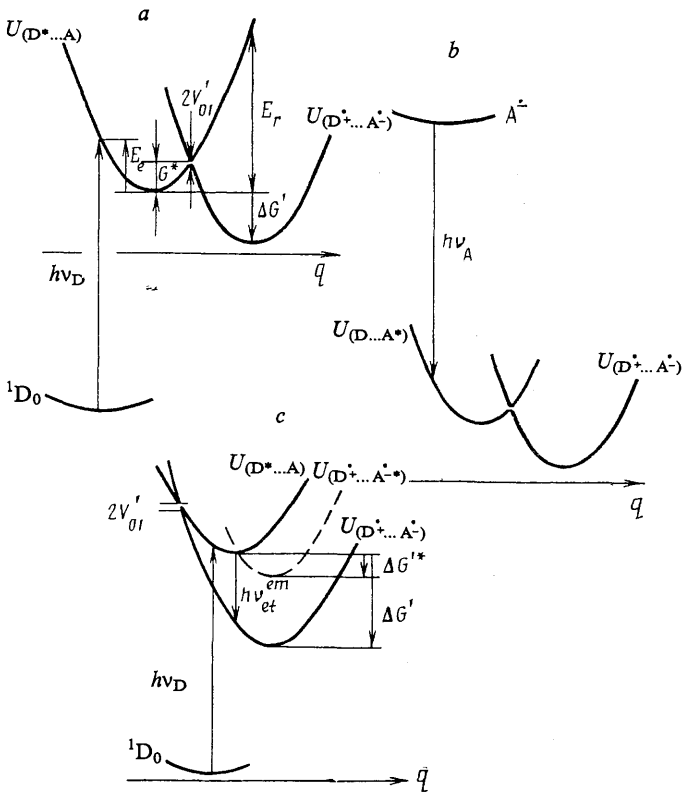

Figure 5. Dependence of the potential energies $U_{(D^*\ldots A)}$ (*a* and *c*), $U_{(D\ldots A^*)}$ (*b*), $U_{(D^{\dot{+}}\ldots A^{\dot{-}})}$, and $U_{(D^{\dot{+}}\ldots A^{\dot{-}*})}$ on the generalised coordinate q. The parameters that determine the probability of electron phototransfer under nonadiabatic conditions without an exchange interaction in the ground state during photoexcitation of the donor $h\nu_D$ (*a* and *c*) or acceptor $h\nu_A$ (*b*) are given. $^1D_0$ (*a* and *c*) and $A^{\dot{-}}$ (*b*) correspond to the energies of the donor in the ground state and of the radical anion of the acceptor respectively. The free energy $\Delta G'^*$ corresponds to the transfer of an electron to an electronically or vibrationally excited energy level of the acceptor.

When relaxed $^{1,3}(\mathrm{D}\ldots\mathrm{A})_1$ states participate in electron transfer the probability of electron transfer corresponds to the relationship $P_{et} = A' \exp(-G^{\neq}/c)$. In systems with a large negative free energy $-\Delta G'$ (Fig. 5*c*) the rate constant may be determined by electron transfer not to the lowest unfilled acceptor orbital but to a higher level that corresponds to formation of an acceptor radical anion in an electronically excited or vibrationally excited state. In both cases

$$k_{et} = A' \exp\{-[(\Delta G' - E') + E_s]^2/4E_s c\}.$$

In the first case $E' = E(\mathrm{A}^{\dot{-}*})$, in the second $E' = \nu\hbar\omega_{in}$; E_s is calculated from equation (12).

With high negative values of $-\Delta G'$ an emissive charge-transfer transition is to be expected (Fig. 5*c*)

$$(D \ldots A)^* \rightarrow (D^{\ddagger} \ldots A^{\dot{-}}) + h\nu_{et}^{em}$$

and also emission from an excited A^{-*} state:

$$(D^{\ddagger} \ldots A^{\dot{-}*}) \rightarrow (D^{\ddagger} \ldots A^{\dot{-}}) + h\nu_{A}^{em}.$$

It should be mentioned that electron transfer by route (35) can occur with local excitation of one of the components of the D ... A system in which there is an exchange interaction in the ground state (Fig. 6). Under nonadiabatic conditions this route is more effective than electron transfer on exposure to light $h\nu_{et}$, since, as was mentioned above, the charge-transfer band has a low extinction coefficient. Under these conditions light with energy $h\nu_D$ (or $h\nu_A$) accelerates the charge-transfer reaction.[3]

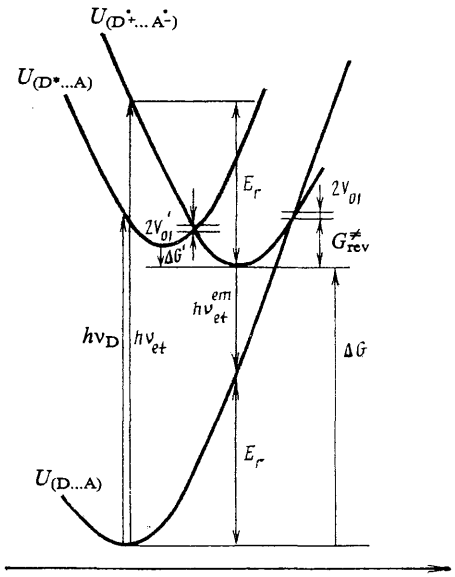

Figure 6. Dependence of the potential energies $U_{(D \ldots A)}$, $U_{(D^* \ldots A)}$, $U_{(D^{\dot{+}} \ldots A^{\dot{-}})}$ on the generalised coordinate q. The parameters that determine the probability of electron phototransfer under nonadiabatic conditions when there is an exchange interaction in the ground state during photoexcitation of the donor $h\nu_D$ or the D ... A system $h\nu_{et}$; $G^{\neq}_{rev}$ is the energy of activation of the reverse reaction of (4).

When there is an exchange interaction (V_{01}) in the ground state (Fig. 6), reverse electron transfer can occur both by a route that involves surmounting the potential barrier $G^{\neq}_{rev}$ and with emission of $h\nu^{em}_{et}$:[89,90]

$$D^{\ddagger} \ldots A^{\dot{-}} \rightarrow D \ldots A + h\nu_{et}^{em}.$$

It follows from the positions of the levels shown in Fig. 6 that $h\nu_{et} + h\nu_{et}^{em} = 2\Delta G$ and the Stokes shift is given by $h\nu_{et} - h\nu_{et}^{em} = 2E_r$.[89,90]

A number of studies[91–101] examine the factors that determine the tunnelling distance during photoexcitation of the D (or A) components over a wide temperature range, including room temperature, in higher alcohols[91,92] and polymer matrices [polycarbonate,[93] cellulose,[94–97] polyvinylpyrrolidone (PVP),[98] polystyrene,[99] polyvinyl acetate (PVA) and polymethylstyrene (PMS)[100,101]]. The tunnelling distance was determined from the dependence of the intensity (I) of luminescence of the excited component in a D ... A system on the concentration of quencher Q (where Q ≡ D or A).

The quenching of luminescence, which occurs by an electron-transfer mechanism in these systems, is given by the Perrin model:

$$I/I_0 = \exp(-N_A V[Q]), \qquad (37)$$

where V is the volume of the "active" sphere containing a quencher molecule. According to this model, excitation of a molecule is either quenched or not quenched at all depending on whether the molecule is within the "active" sphere or outside it. The radius of the "active" sphere R_q is determined from the relationship:

$$N_A V [Q]_0 = (4\pi/3) R_q^3 N_A [Q]_0 = 1, \qquad (38)$$

where $[Q]_0$ is the concentration of quencher at which the intensity of luminescence calculated from (37) is e times weaker than in the absence of quencher. Hence

$$R_q = (3 \cdot 10^{27}/4\pi N_A [Q]_0)^{1/3}, \text{ Å}.$$

The relationship between R_q and the energy characteristics of electron transfer was determined from equation (18) when $R = R_q$:[91]

$$(R_q - R_0) = \frac{\alpha}{2} [\ln(\nu_0/k_{et}) - (\Delta G' + E_r)^2/4E_r kT]. \qquad (39)$$

Here $R_q - R_0$ is the tunnelling distance. The constant k_{et} may be obtained experimentally from kinetic measurements of luminescence from the expression $k_{et} = (1/\tau_f) - (1/\tau_0)$, where τ_0 is the inherent lifetime of excitation and τ_f is the lifetime of excitation in the presence of a quencher at concentration $[Q]_0$.

The dependence of R_q on $\Delta G'$ in electron phototransfer reactions from excited ruthenium complexes with different types of ligands to a methyl viologen quencher (MV^{2+}) has been determined.[92] This dependence has a maximum ($R_q - R_0$) = 3 Å when $-\Delta G' = E_r = 0.7$ eV. In reactions involving the quenching of excited acceptors (rubrene, tetracene, perylene, 9-methylanthracene, 9,10-diphenylanthracene, fluoranthrene, acridinium) by amines (TMPD and diethylamine), the tunnelling distance determined from expression (39) is given by ($R_q - R_0$) = 7–10 Å and α = 0.75 Å. Expression (39) effectively represents the dependence of R_q on $\Delta G'$ obtained experimentally[98] in the quenching of the singlet excited dye rhodamine B by electron transfer to the dye from such donors as TMPD, 10-methylphenothiazine, ferrocene, pentamethylferrocene, ascorbic acid and also from the dye to acceptors such as dipyridinium salts with various substituents in a PVP matrix. It was established that ($R_q - R_0$) increases from 0 to 16 Å as $\Delta G'$ decreases from 0.2 to –1.0 eV.

Palazzotto et al.[100,101] have studied the fluorescence quenching of rhodamine 6G (R6G) by donor quenchers such as carbazole, triphenylamine (TPA), *N,N*-dimethyl-*p*-toluidine (DMT), phenothiazine (PT), *N*-methylphenothiazine (MPT), 1,4-diazabicyclo[2.2.2]octane, *N,N'*-diphenyl-*p*-phenylenediamine (DPPD), and *N*-phenyl-*p*-phenylenediamine (PPD) in PVA and PMS films. It has been shown[101] that R6G forms charge-transfer complexes with these donors (in the ground state). The complex formation constant (K, $dm^3\ mol^{-1}$) depends on the nature of the polymer matrix and for different donors (in brackets) is for PVA and PMS respectively: 2.8 and undetermined (TPA), 5.9 and 5.8 (DMT), 5.7 and 8.7 (MPT), 7.5 and 56.3 (PT), 9 and 35.9 (DPPD), 10.3 and 41.7 (PPD). Molecules of R6G that do not form a complex are responsible for fluorescence in this case; the

proportion of these is given by

$$([R6G]_0 - [D.R6G])/[R6G]_0 = 1/(1 + K[D])^{-1}.$$

where $[R6G]_0$ and [D·R6G] are the total concentration of dye and the final concentration of dye forming a complex respectively. When the radius R_q was calculated[101] from equation (38) the volume of the "active" sphere was determined from the experimental dependence of the intensity of fluorescence of R6G molecules on the concentration of donor (quencher) according to the equation:

$$I/I_0 = (1 + K[D])^{-1} \exp(-N_A V[D]). \quad (40)$$

The free energy $\Delta G'$ was calculated from expression (36a) (for the approximation $e^2\varepsilon_s R = 0$). It was found[101] that when $\Delta G'$ decreased from –0.55 to –1.11 eV, R_q increases from 3 to 10.9 Å in a PVA matrix and from 9.6 to 12.1 Å in a PMS matrix.

In several studies[93–97,99] a model[102,103] which takes into account the random distribution of interaction distances R was applied to polymer systems. According to this model

$$I/I_0 = \exp\{-k_0 t - A[\ln^3(\nu_0 t) + 1.73165 \ln^2(\nu_0 t) + 5.9343 \ln(\nu_0 t) + 5.44]\}.$$

Here $A = \alpha[Q]/R_q^3[Q]_0$.[93–97,99] The value of Q_0 is calculated from expression (38). The dependence of the tunnelling distance $(R_q - R_0)$ on the free energy $-\Delta G'$ calculated from this expression is given in Table 2. The increase in the disance $(R_q - R_0)$ as $-\Delta G'$ increases and as the temperature rises is demonstrated. This model satisfactorily represents the fluorescence quenching of TMPD and tetramethylbenzidine (TMB) with phthalic anhydride (PA)[99] and methyl viologen[97] respectively. Determinations of R_q (17 Å) and α (1.73 Å) have been made for the system $^3TMPD_1...^1PA_0$ in polystyrene[99] and also R_q = 38 Å and α = 3.4 Å for $^3TMB_1...^1(MV^{2+})_0$ in cellulose.[97] Unfortunately, in all of the studies mentioned above, in the calculation of $(R_q - R_0)$ and α, the possible increase in the size of the molecule (i.e. R_0) on going to an excited singlet and triplet state was not taken into account. The considerable tunnelling distances obtained in a number of systems are due to a superexchange mechanism, with fragments or defects in the polymer chains being regarded as bridging groups.[93]

3. Effects of the polymer matrix on the optical absorption properties of charge-transfer complexes

D ... A systems in which the distance between the components is greater than the sum of their van der Waals radii have been examined above. In these systems radical ions with separate solvation shells are formed through electron transfer. In the case of excited contact D·A complexes the point dipole model[19,81,89,104] has been used. The transformation of a two-sphere model, namely, a model with separate solvation shells in which the reorganisation energy of the medium is given by expression (12), into a single-sphere system that corresponds to a point dipole model has been reported.[89] The dipole κ [$\kappa \equiv e[r_D + r_A)$] produces an Onsager reaction field in the dielectric:

$$R(\varepsilon) = \frac{2\kappa}{a^3} F(\varepsilon) \quad \text{or} \quad R(n) = \frac{2\kappa}{a^3} F(n),$$

where $R(n)$ is the electronic component of the reaction field, $F(\varepsilon) = (\varepsilon - 1)/(2\varepsilon + 1)$ and $F(n) = (n^2 - 1)/(2n^2 + 1)$, a is the radius of the cavity occupied by the polarising dipole. The interaction energy of the dipole κ with the reactive field is given by

$$-\kappa R(\varepsilon) = -\frac{2\kappa^2}{a^3}\left(\frac{\varepsilon - 1}{2\varepsilon + 1}\right) \quad \text{or} \quad -\kappa R(n) = -\frac{2\kappa^2}{a^3}\left(\frac{n^2 - 1}{2n^2 + 1}\right). \quad (41)$$

As in the case of the two-sphere model the Stokes shift between the excitation maxima and fluorescence emission of the D·A complex is determined by the reorganisation energy ($E_r = E_{in} + E_s$) and is given by the Lippert – Mataga expression[19,104] (see Fig. 2*b* and Fig. 6):

$$h\nu_{et} - h\nu_{et}^{em} = 2E_r = 2E_{in} - [\kappa R(\varepsilon) - \kappa R(n)] = 2E_{in} + \frac{2\kappa^2}{a^3}\left(\frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{n^2 - 1}{2n^2 + 1}\right). \quad (42)$$

Table 2. Increase in $(R_q - R_0)$ as $-\Delta G'$ increases in the fluorescence quenching of RuL_3^{2+} ruthenium complexes by methyl viologen (L = ligand).[93]

Ligand in RuL_3^{2+}	$-\Delta G'$, eV	$(R_q - R_0)$, Å at:

5-Chlorophenanthroline	—0.49	10.5	14.6
2,2'-Bipyridine 4,4'-diisopropyl ether	—0.88	15.9	18.9

*Reported value.[94]

Expression (42) has been successfully used for an experimental determination from the Stokes shift of the phase (ε, n) in which a D·A complex is formed in complex biological systems.[104]

A detailed analysis of the effect of dielectric properties in liquid media on the position of the maximum in the optical spectrum of D·A molecular complexes is given in a number of review articles (a general treatment of them is given by Davis[81]). In accordance with expression (33), in condensed media

$$h\nu_{et}^{max} = \Delta G' + E_r \equiv (\Delta G' + E_{in}) + E_s.$$

Since the optical absorption spectrum corresponds to a transition from the ground to an excited Franck – Condon state, the electronic polarisation of the medium $\kappa R(n)$ is synchronous with this process. Hence,

$$h\nu_{et}^{max} = h\nu_{et}^{max}(\text{gas}) - \frac{2\kappa^2}{a^3}\left(\frac{n^2 - 1}{2n^2 + 1}\right). \quad (43)$$

Here

$$h\nu_{et}^{max}(\text{gas}) = I_D - E_A - e^2/R + 2X + E_{in}, \quad (44)$$

where, according to (31) and (32), $2X = |X_1| + |X_2|$. The dependence of $h\nu_{et}^{max}$ on the dielectric properties of the medium (including polymer matrices) for the complexes $(C_5H_5)_2Fe.CBr_4$, $DPBA.CBr_4$, and $DPBA.CBr_3SO_2CBr_3$ (DPBA = diphenylbenzylamine) has been determined.[105] An analysis of the long-wavelength decrease in optical absorption of these complexes showed that in all the media studied the optical spectrum has a Gaussian form

$$D(\nu) = D(\nu_{max}) \exp[-(\nu_{max} - \nu)^2/2(\sigma \cdot 10^3)^2], \quad (45)$$

where $\sigma \times 10^3 = (\nu_{max} - \nu_{1/2}) \times (2 \ln 2)^{1/2}$. It was established experimentally (Fig. 7) that the position of the maximum in the optical absorption spectrum of a $(C_5H_5)_2Fe.CBr_4$ complex conforms to a relationship which is common to liquid systems and solid polymer

matrices:

$$h\nu^{max} = 3.9 - 3.1\,(n^2 - 1)/(2n^2 + 1). \quad (46)$$

The degree of charge transfer (δ^*) in the excited state of the complex $[(C_5H_5)_2Fe^{+\delta^*}.CBr_4^{-\delta^*}]$ was determined approximately from the assumption that $r_D = r_A = r$, $R_0 = 2r$, $a = 2r$, i.e., according to expressions (43) and (46) $(2\kappa^2/a^3) = (e^2\delta^{*2}/r) = 3.1$. An estimated value of $e^2/r = 3.8$ was obtained[12] by correlating a large number of experimental results in the literature on the polarisation of liquid media by radical cations of aromatic hydrocarbons, radical anions and cations of different types of dyes, and radical anions of various acceptors. By using this value for $(C_5H_5)_2Fe.CBr_4$ complexes, the degree of charge transfer in the excited state $\delta^* = (3.1/3.8)^{1/2} \simeq 0.9$ was calculated. The degree of charge transfer in this complex in the ground state ($\delta = 0.1$) was determined from the reported[106] dependence of δ on $I_D - E_A$ for complexes of this type. The fulfillment of the relationship $\delta^* = 1 - \delta$ is an indication that the excited state of the $(C_5H_5)_2Fe.CBr_4$ complex corresponds only to electron transfer ($h\nu^{max} = h\nu_{et}^{max}$) and does not contain contributions from local excitations of the individual donor or acceptor components. The half-width of the optical spectrum of this complex has a constant value in all of the media studied (both liquid and polymer)

$$(\nu_{max} - \nu_{1/2}) = \sigma \cdot 10^3\,(2\ln 2)^{1/2} = 3850 \pm 140 \text{ см}^{-1}$$

and is due to an electronic-vibrational interaction.[77]

It may be noted that for exciplexes (which, as was mentioned above, do not have an optical absorption spectrum since they are only formed by photoexcitation of the D or A component) the emission energy from a relaxed state is given by the expression:[79,80,107]

$$h\nu_{et}^{em} = h\nu_{et}^{em}(\text{gas}) - \frac{2\kappa^2}{a^3}\left[\frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{1}{2}\,\frac{n^2 - 1}{2n^2 + 1}\right],$$

from which the dipole moment κ and degree of charge transfer in a relaxed exciplex can be determined.[107] In this case the energy of the relaxed exciplex is assumed to be equal to

$$E^* = E^*(\text{gas}) - \frac{\kappa^2}{a^3}\left(\frac{\varepsilon - 1}{2\varepsilon + 1}\right).$$

A characteristic feature of the optical spectra of DPBA.CBr_4 and DPBA.$CBr_3SO_2CBr_3$ is their broadening on going from liquid media to polymer matrices (retaining a Gaussian form) and a subsequent increase in the width of the spectrum on reducing the generalised free volume V_E' of the polymer composite.[105] Table 3 gives the values of $(\nu_{max} - \nu_{1/2})$, the free volume V_E of the polymer, and the generalised free volume V_E' of the composite, calculated on the assumption that it is an additive function of the free volume of the components:

$$V_E' = \Sigma \Phi_i V_{E,i}.$$

Here Φ_i is the volume fraction of an individual component in the polymer and $V_{E,i}$ is its free volume.

It follows from Table 3 that the width of the optical spectrum of the DPBA.$CBr_3SO_2CBr_3$ complex remains constant on changing the liquid solvent. The increase in $(\nu_{max} - \nu_{1/2})$ in the series of polymers (Table 3) may be due to the reduction in generalised free volume V_E'.

It was established using PVC matrices that the optical spectrum of the DPBA.$CBr_3SO_2CBr_3$ complex contracts reversibly when the temperature is increased. The spectra recorded as the temperature was reduced from 80° to 77° and then 60 °C are shown in Fig. 8. It is clear that as a result of reducing the temperature the optical density decreases in the region of maximum absorption of the complex (about 365 nm) but increases at longer wavelengths in the spectrum (420–650 nm). In this case the change in optical density on reducing the temperature from 77 to 60 °C is comparable in magnitude with the change over the narrow temperature region (80 → 77 °C) of the glass transition temperature of PVC ($T_g \sim 78$ °C).

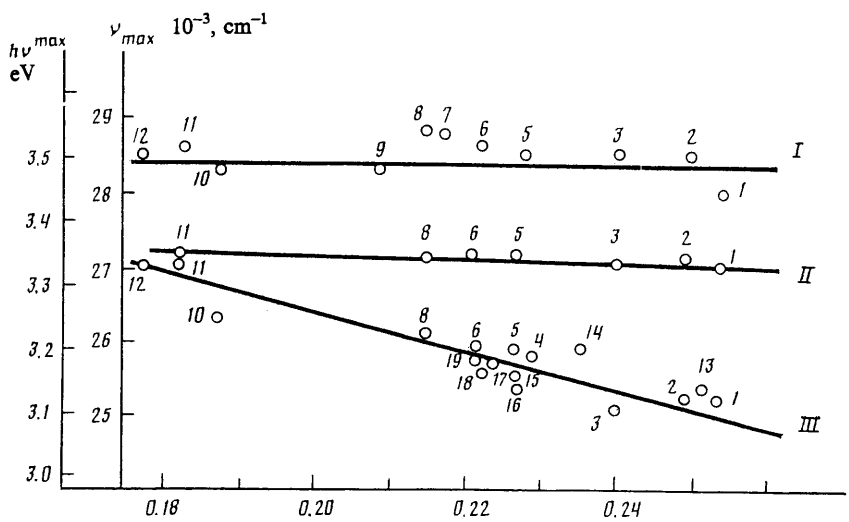

Figure 7. Dependence of ν_{max} and $h\nu_{max}$ on $(n^2 - 1)/(2n^2 + 1)$ in composites containing the following complexes: *I*) DPBA.CBr_4; *II*) DPBA.$CBr_3SO_2CBr_3$; *III*) $(C_5H_5)_2Fe.CBr_4$. The experimental results were obtained by Grishina et al.[105] The points correspond to: *1*) PS; *2*) CPVC; *3*) PVC; *4*) benzene; *5*) toluene; *6*) PMMA; *7*) dimethyl sulphoxide; *8*) PVA; *9*) dichloroethane; *10*) n-hexane; *11*) acetone; *12*) acetonitrile; *13*) PC; *14*) PVP; *15*) polyvinylethylal; *16*) polyvinylformalethylal; *17*) polybutyral; *18*) polybutyl metha-crylate; *19*) acetylcellulose.

It was suggested[108] that the broadening of the spectra of such complexes on going from liquid media to polymer matrices is due to the formation of mD·nA complexes with different ratios of m/n. In a polymer matrix the alteration in the ratio between complexes with different compositions when the temperature is varied is suppressed and it cannot be regarded as the only reason for the temperature dependence of the width of the optical spectrum.

Table 3. Free volume of liquid or polymer (V_E), generalised from volume of composite (V_E'), width of optical spectrum ($\nu_{max} - \nu_{1/2}$), calculated for a DPBA.$CBr_3SO_2CBr_3$ complex in liquid media and polymer matrices.[105]

**chlorinated poly(vinyl chloride)

The combined experimental data, namely, the broadening of the optical spectra on going from liquid media to polymer matrices, the broadening as the free volume of a polymer is reduced, the temperature-dependent contraction of the spectrum in a polymer matrix (Fig. 8) have been accounted for[77,105] on the basis of the conformational isomerism of benzylanilines (including DPBA) and the freezing in a limited free volume of conformations which do not occur under equilibrium conditions in a liquid. Conformational isomerism is taken to mean the existence amongst benzylanilines of a "set" of structures which differ according to the rotation angle (φ) of the nonbonding orbital of the amino group relative to the plane of the benzene ring (Fig. 9).

Freezing out of isomers with a different angle of rotation φ (twist angle) account for the photophysical properties of substituted anilines that are introduced into the polymer matrix; donor (amino group) and, in a *para*-position relative to it, acceptor (cyano, ester, 9-anthryl, or other groups) fragments are combined in a single aniline molecule.[109–114] The slowing down in the reorientation of angle φ in polymer matrices at room temperature causes a nonuniform broadening of the fluorescence excitation spectrum of these compounds. This broadening appears as an enlargment of the spectrum at longer wavelength, at which there is no absorption in the liquid phase.[111,112] On exposure to light at longer wavelength isomers with an increased twist angle are selectively exicted, being converted with high probability to an excited charge-transfer state corresponding to $\varphi = 90°$.

The formation of molecular conformations with different equilibrium rotation angles of the aromatic ring about the C(1)–N bond in substituted *N*-benzylidenanilines

has an effect on a number of physicochemical properties of these compounds.,[115–117] Thus, introduction of a substituent into the 2-position (or 2- and 6-positions), which results in the aromatic ring being forced out of conjugation with the n orbital of the nitrogen ring, causes a decrease in ionisation potential (in the gas phase) from 8.25 (with no substituents) to 8.06 (or 8.00) eV.[116] It was established by NMR that introduction of an NO_2 group at a *para*-position relative to the C(1)–N bond increases the degree of conjugation of the aromatic ring with the nonbonding orbital of the nitrogen atom.[116] According to Akaba et al.[117] this results in an increase in ionisation potential of the molecule to 8.76 eV.

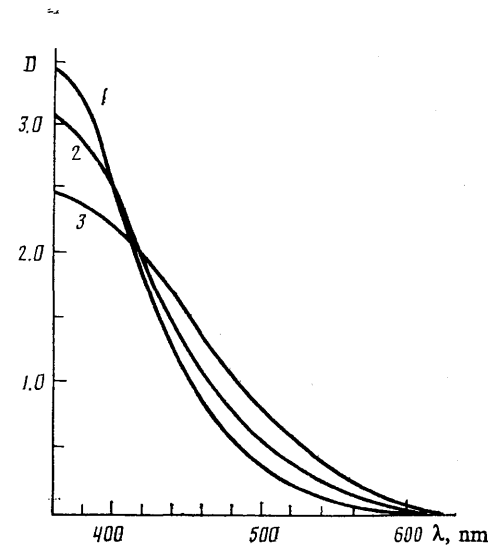

Figure 8. Optical spectra of the DPBA.$CBr_3SO_2CBr_3$ complex in a PVC matrix recorded as the temperature is decreased from 80 °C (1) to 77 °C (2) and 60 °C (3).

Benzylanilines (including DPBA) in polymer matrices where there is a limited free volume also exist in various conformations that differ according to the magnitude of their angle of rotation φ as a result of steric hindrance produced by the matrix (Fig. 9). These orientations of φ are frozen because of the long relaxation times of the polymer. It can be seen from Fig. 9 that a change in angle φ gives rise to a change in the degree of overlap of the π-electron orbitals of the aromatic ring and the n orbital of the unshared electron pair (UEP) of the nitrogen atom. This overlap is at minimum when $\varphi = 90°$ and increases as φ decreases to 0°.

In the formation of an intermolecular $n-\sigma^*$ complex in which the acceptor is coordinated with the nitrogen atom of benzylaniline, the n orbital of the nitrogen atom is involved as the donor in the interaction with the acceptor if $\varphi = 90°$, in other words, if the amino group is not conjugated with the benzene ring. If $\varphi = 0°$ the donor properties of benzylaniline are determined by the system of conjugated bonds that include the benzene ring and the UEP of the

nitrogen atom. For this reason,[44] instead of the statistically averaged gas-phase potential I_D it is necessary to use the inverse of the energy of that benzylaniline orbital (I_{BA}) which undergoes a donor-acceptor interaction.[77,105] Its magnitude is determined by the expression

$$I_{BA} = I_0 + I\cos^2\varphi. \quad (47)$$

When $\varphi = 0°$ $I_{BA} = I_0 + I$, where $I_0 + I$ is the ionisation potential of the system of conjugated bonds. It is close to the ionisation potential of aniline ($I_0 + I$) = 7.7 eV.[118] When $\varphi = 90°$ $I_{BA} = I_0$, where I_0 is the "ionisation potential" of the UEP orbital of the nitrogen atoms. It is presumed that I_0 is close to the ionisation potential of TPA (I = 6.88 eV), in which the aromatic groups are turned through 45° relative to the UEP of the nitrogen atom.[119]

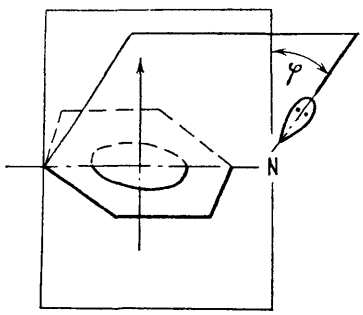

Figure 9. Angle of rotation φ of the nonbonding orbital of the nitrogen atom relative to the plane of the benzene ring in benzylanilines.[77]

In the possible formation of a $\pi-\sigma^*$ complex, namely, in coordination of the acceptor with the benzene ring of benzylaniline, when φ increases from 0 to 90°, i.e., as the UEP moves out of the system of conjugated bonds, the energy of the orbital involved in the D·A interaction varies in accordance with the relationship:

$$I_{BA} = (I_0 + I) + I'\sin^2\varphi,$$

from I_{BA} = (I_0 + I) = 7.7 eV to the value (I_0 + I) + I', which is close to the ionisation potential of benzene (9.25 eV[118]).

The calculations carried out by Novikov and Vannikov[77] showed that in compounds such as DPBA in which $\varphi \sim 45°$, the broadening of the optical spectra of the complex DPBA.$CBr_3SO_2CBr_3$ on transferring to polymer matrices by $\sim 10^{-3}$ cm^{-1} (Table 3) corresponds to a scatter in values of angle φ by $\sim 5-8°$ and that this scatter leads to a broadening of the long-wavelength region of the optical absorption in the case of $n-\sigma^*$ complexes but causes an extension of the spectrum to shorter wavelength when the acceptor is coordinated to the benzene ring of benzylaniline.

The series of results considered above corresponds to the relative position of the energy levels (shown in Fig. 10) in complexes based on DPBA, particularly in DPBA.CBr_4 and DPBA.$CBr_3SO_2CBr_3$ complexes. In a liquid medium the electron level corresponds to a single equilibrium conformation of DPBA. The broadening of the optical absorption band of a DPBA.A complex, as in the case of $(C_5H_5)_2Fe.CBr_4$, is due to an electronic-vibrational interaction.[77] The extensive set of energy levels of BA.A complexes in a polymer matrix is shown in Fig. 10; the levels correspond to the different rotation angles of the phenyl group relative to the UEP of the nitrogen atom, changes in which are regarded by the polymer matrix.

The position of the optical absorption maximum of DPBA.A complexes in all media has a constant value of $h\nu^{max}$ = 3.5 eV when A = CBr_4 and 3.38 eV when A = $CBr_3SO_2CBr_3$ (see Fig. 7). The 0.12 eV decrease in the position of the maximum for A = $CBr_3SO_2CBr_3$ is caused by a corresponding increase in the electron affinity of this acceptor.[120] The lack of dependence of $h\nu^{max}$ on the dielectric properties of the medium is consistent with a small degree of charge transfer in the excited Franck–Condon state of that group of complexes, which determines the position of $h\nu^{max}$. This may be due to the close position of the energy levels of the charge-transfer state

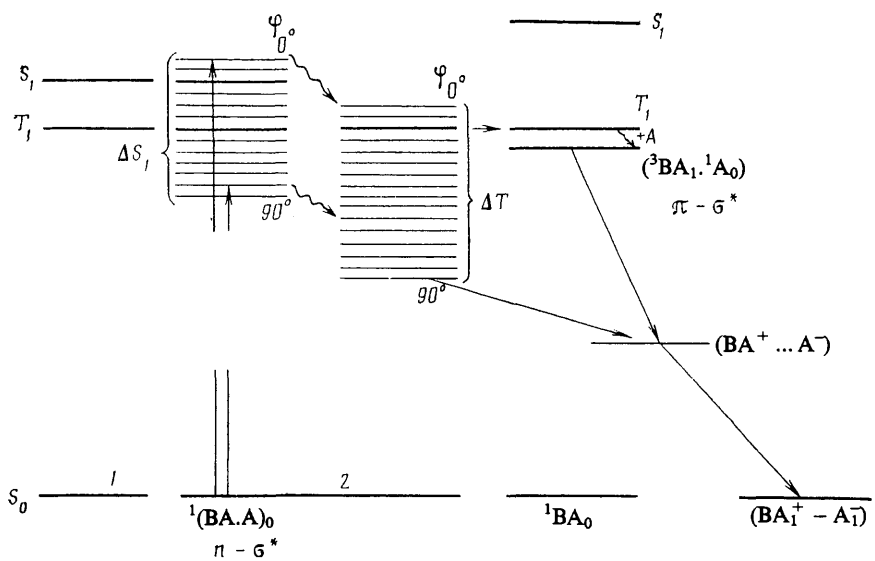

Figure 10. Position of energy levels and scheme for photoprocesses in complexes of benzylanilines (DPBA, dibenzylaniline) with acceptors (CBr_4, $CBr_3SO_2CBr_3$) in a liquid medium (*1*) and polymer matrix (*2*).

$(D^{+\delta^*}-A^{-\delta^*})$ and the local excitation of the donor ($^1D_1.A$), which causes a mixing of the wave functions of these states:

$$\psi^1(D^{+\delta_1}-A^{-\delta_1})_1 = a_1\psi(D^{+\delta^*}-A^{-\delta^*}) + b_1\psi(^1D_1.A),$$

where a_1 and b_1 are the contributions of the charge-transfer state $(D^{+\delta^*}-A^{-\delta^*})$ and the local excitation of the donor ($^1D_1.A$) respectively to the wave function. As a result of mixing the states the degree of charge transfer (δ_1) in the excited complex $^1(D^{+\delta_1}-A^{-\delta_1})_1$ is less than in the "pure" charge-transfer state (δ^*) and is given by $\delta_1 = \delta^* a_1^2/(a_1^2 + b_1^2)$. (It was shown above that $b_1 = 0$ and $\delta_1 = \delta^*$ for the complex $(C_5H_5)_2Fe.CBr_4$.)

The first stages of photolysis of the complex $DPBA.CBr_3SO_2CBr_3$ in a PVC matrix when exposed to laser irradiation with a wavelength of 353 nm were studied by Mal'tsev et al.[121,122] It was established that

$$\begin{matrix} O^{\cdot} \\ | \end{matrix}$$

the charge-transfer products $DPBA^+$ and $CBr_2=S(O)-CBr_3...Br^-$) and the excited triplet donor ($^3DPBA_1$) are formed at the same time, which is also an indication of the close relative position of the triplet levels of the locally excited donor and the charge-transfer state in the group of high-energy complexes. The wave function of the triplet state of this group can be represented as

$$\psi^3(D^{+\delta_2}.A^{-\delta_2})_1 = a_1'\psi^3(D^{+}.A^{-})_1 + b_1'\psi(^3D_1.A), \qquad (48)$$

where $\delta_2 = (a_1')^2/[(a_1')^2 + (b_1')^2]$, the degree of charge transfer. In this case the wave functions are represented by $\psi^3(D^+.A^-)_1$—the triplet charge-transfer state—and $^3D_1.A$—the locally excited triplet state of the donor. The magnitude of δ_2 is markedly dependent on small changes in the relative position of the levels of the states with complete charge transfer

$$E_1' = \int\psi^3(D^+A^-)H\psi^3(D^+A^-)dv$$

and the locally excited donor

$$E_2' = \int\psi(^3D_1.A)H\psi(^3D_1.A)dv.$$

For DPBA, $E_2' = E(^3D_1) = 3.00$ eV. The ratio (b_1'/a_1') may be determined from the expression

$$(b_1'/a_1') = V_{01}/(E_2' - E_1'), \qquad (49)$$

where V_{01} is the energy of the exchange interaction between the triplet charge-transfer state and the locally excited triplet donor

$$V_{01} = \int\psi^3(D^+A^-)_1H\psi(^3D_1.A)dv.$$

It is estimated that $V_{01} = 0.05-0.5$ eV. It was established[121,122] that when DPBA is replaced by diphenylamine (DPA, $E_2' = 3.14$ eV[123]), the excited triplet state of the donor is not formed on exposure to a laser with $\lambda = 353$ nm. This may be due to the corresponding decrease in contribution of b_1' from the locally excited triplet state of the donor to the wave function. (48) In fact, the energy $E_1' = h\nu_{et}^{max}$(gas) [see expressions (44) and (49)] in a DPA.A complex is ~0.34 eV less than in a DPBA.A complex (here A = $CBr_3SO_2CBr_3$). [Determined, in accordance with (44), from the difference $E_1'(DPBA) - E_1'(DPA) = I_D(DPBA) - I_D(DPA) = e[E_{1/2}(DPBA/DPBA^+) - E_{1/2}(DPA/DPA^+)]$, where $E_{1/2}(DPBA/DPBA^+) = 0.98$ V[12] and $E_{1/2}(DPA/DPA^+) = 0.64$ V—the equilibrium oxidation potentials of DPBA and DPA respectively.]

From the dependence of the quantum yield of the products of ionic photodissociation of the $DPBA.CBr_4$ complex in the presence of an acceptor with triplet energy (1-naphthol, etc.) on the concentration of these components, it was concluded[124] that on exposure to light with $\lambda = 365$ nm the products of ionic dissociation are mainly formed by transfer of triplet energy from the complex to a molecule of amine (see scheme in Fig. 10) to form a $\pi-\sigma^*$ exciplex ($^3DPBA_1.CBr_4$), which dissociates to radical ions. It is to be expected that the probability of direct ionic photodissociation of excited triplet $DPBA.CBr_4$ complexes will increase with the wavelength of stimulating light since when I_{BA} decreases [see expressions (44)] the E_1' level decreases and hence the contribution of the locally excited triplet state of the DPBA donor diminishes [see expressions (48) and (49)].

Thus, the polymer effect, which consists of the freezing out of different conformations of benzylaniline molecules, results firstly in a bathochromic shift of the optical spectrum by about 10^3 cm^{-1} on going from liquid media to polymer matrices. It has been shown[105] that this causes the sensitivity of photographic materials based on benzylanilines to be extended into the visible region. Secondly, as the wavelength of stimulating light is increased, polymer matrices are probably responsible for a change in mechanism of the formation of ionic photodissociation products from mainly a primary transfer of triplet energy (see Fig. 10) in the case of high-energy complexes to direct dissociation into radical ions of low-energy complexes.

It has been pointed out[77] that in $(C_5H_5)_2Fe.CBr_4$ complexes the nonuniform broadening of the optical spectrum in polymers is absent as a result of the high symmetry for ferrocene molecules. It is because of the absence of specific polymer effects in these complexes that the dependence of $h\nu_{et}^{max}$ on the dielectric properties of the medium [see expression (46)] as predicted by electron-transfer theory is found to occur.

- - - o0o - - -

It should be mentioned in conclusion that the basic concepts of electron-transfer theory developed for liquid media are applicable to donor-acceptor systems in polymer matrices.

However, in contrast to liquids, different conformations of complex organic molecules can occur in rigid polymer matrices when there is a limited free volume; this gives rise to a nonuniform distribution of parameters such as the ionisation potential or electron affinity, intramolecular reorganisation energy and reorganisation energy of the medium during electron transfer. The magnitudes of these effects depend on the size and symmetry of the donor and acceptor molecules as well as on the total magnitude and distribution of the free volume and mobility of the polymer chains.[125,126] These effects can completely mask the processes which accompany electron transfer in liquid media.

In turn, the disorder of a polymer matrix causes a spatial variation in dielectric constant and hence in reorganisation energy of the medium. Because of steric hindrance in a polymer matrix only partial intramolecular reorganisation can occur when the molecule changes to a radical cation or anion form. For a complete elucidation of the available experimental data it is necessary to develop a model which simultaneously takes into account these factors and also the form of energy distribution of the interaction between the reaction (transport) sites and the medium, the distribution of distances between neighbouring sites, and the effect of the dielectric properties of the medium on electron transfer between sites.

Methods for the regulation of the functional properties of isolated myofibrillar proteins in order to expand their use as foodstuffs

L A Pavlova, L G Damshkaln, E S Vainerman, S V Rogozhin
Nesmeyanov Institute of Organoelement Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. Data characterising the specific features of the chemical, enzymic, mechanical, and combined modifications of myofibrillar proteins are described systematically with the aim of expanding their possible use in food systems. Attention is concentrated on the mechanisms of the enzymic and chemical reactions with food proteins of myofibrillar origin, carried out in order to regulate specific functional properties of the protein systems.

The problem of toxicity, biological value, bioavailability, and metabolic pathways of the modified food proteins is discussed.

The prospects and limitations of enzymic and chemical modification of myofibrillar proteins are indicated.

The bibliography includes 194 references.

I. Introduction

For a successful solution of the problem of food supply, it is timely to take into account and assess the possibility of using new sources of food protein, including those which had been previously neglected.[1,2] Apart from the non-traditional sources of proteins of plant origin, to which a fair amount of attention has been devoted,[3,4] rich resources of proteins with a high food value are provided by various objects in the Pacific Ocean: the Antarctic krill,[5–10] certain species of fish, in particular myctophid fish,[11–13] as well as fish with a low commercial value.[14–18]

Isolated fish proteins, free from sarcoplasmic proteins and lipids, have no specific taste or smell and can be used in any food system ranging from delicatessen fish products and meat substitutes to dessert dishes.[5,6,19,20] The isolation of proteins from non-traditional sources requires additional stages involving the removal of toxic, ballast, or antinutritive components (specific pigments, proteolytic enzymes, lipids which are difficult to remove, etc.). Myofibrillar proteins are more sensitive to chemical and physical effects than plant proteins. The proteins isolated from muscle tissue do not therefore meet the current requirements from the standpoint of functional properties. On the other hand, the possibility of the wide scale application of proteins of this kind in food products does in fact depend on the level of their functional properties.

Functional properties (FP) is the term given to a set of physicochemical characteristics of an individual protein, which determines its behaviour in aqueous media (swellability, solubility, gel formation, etc.), and in the heterophase systems of the type water–oil, oil–water (emulsifying capacity), or water–gas (capacity for foam formation), as well as in multicomponent mixtures. The functional properties of the protein are manifested as a function of its nature and the character of its interaction with other components of the given food system.

Studies in which the relation between the structure of the protein and its functional properties is determined are believed to play virtually the main role in modern food protein chemistry.[21–25] Chemical modification of proteins makes a considerable contribution to the solution of this problem making it possible to trace the correlation between certain physicochemical parameters of the protein and the manifestation of a particular functional property.

In selecting a method for the regulation of the functional properties of a food protein, one must take into account all the characteristic features of its structure and the character of the changes entailed by a particular type of modification.

The functional properties of the protein are determined by many factors:

(a) They are determined mainly by its surface characteristics, which are in turn determined by the quaternary structure of the protein (the size and shape of the protein molecule, its overall surface charge, and its surface hydrophobicity). The stability of the protein depends on the type of bond between the subunits and the ease of their dissociation.

(b) The relation between the intermolecular and intramolecular bonds of various types (hydrogen, ionic, hydrophobic, electrostatic, van der Waals) characterises the flexibility of the molecule, i.e. its capacity for conformational changes without the disruption of the native structure of the protein.

(c) The aminoacid sequence dictates the charge distribution in the molecule and the type of packing of the peptide chains, i.e. the geometrical disposition of the hydrophobic sections.

(d) The secondary and tertiary structures of the protein determine ultimately the steric accessbility and the reactivity of the functional groups of the protein.

The set of the above factors does in the main determine the individual features of the protein.[26]

Any kind of modification alters a whole set of physicochemical properties of the protein and these processes must be examined in detail, since they open a pathway to the deliberate regulation of the functional properties of food protein systems.

The aim of the present review is to give a systematic account of the available information about the ways in which food proteins isolated from muscle tissue are treated in order to regulate their functional properties. The narrow selection of the subjects for discussion makes it possible to trace the trend in the changes of particular properties of the protein as a function of the type of influence on the latter.

It is possible to differentiate three main aspects of the regulation of the functional properties of food proteins: enzymic treatment, chemical modification, and physicochemical methods of influencing the protein. These processes are not mutually exclusive and can be successfully used in a combined procedure.

II. Enzymic treatment of proteins

The processes involving the regulation of the functional properties of myofibrillar food proteins with the aid of enzymes (usually proteolytic) have been widely discussed in the literature.[27–36]

By means of the partial hydrolysis of the protein, it is possible to achieve an increase in its solubility, emulsifying activity, foam-forming capacity, and ability to stabilise emulsions and foams.

In the treatment of muscle tissue by proteases, micro-organisms were used initially: *Thamnidium sp.* in order to soften meat and *Aspergillus glaucus* in order to alter the consistency and taste of fish.[37] The proteases produced by micro-organisms apparently caused the breakdown in the first place of the structure of the sarcomers, increasing thereby the softness of the tissues but at the same time increasing also the viscosity and stickiness of the product. This procedure has not been found extensive application because of the considerable losses of the product.

The most effective method of increasing the solubility of a protein is enzyme hydrolysis. Proteolytic enzymes cleave specific peptide bonds causing the breakdown of the protein molecule into definite fragments. In contrast to acid or alkaline hydrolysis, this process is not accompanied by any side reactions. Myosin, as the main component of myofibrils and having the most complex structure, is most frequently used for a detailed investigation of the behaviour of muscle proteins. The mechanism of the hydrolysis of myosin by food digesting enzymes of the series of peptidases has been studied in fair detail.[38]

For example, trypsin initially splits the myosin molecule into two large fragments: the heavy meromyosin (MW = 200 000) and the light meromyosin (MW = 150 000). Globular fragments or myosin "heads" (MW = 120 000) are then split off from the heavy meromyosin leaving the C-2 subfragment (MW = 100 000).

Papain abstracts in the first place the myosin heads, acting subsequently in a similar manner.

The high degree of hydrolysis of the protein achieved on treatment by active enzymes such as pepsin, papain, and pronase[39–41] is undesirable since it frequently entails the loss of the emulsifying and foam-forming capacities[42] and leads to the appearance of an appreciable bitter taste due to hydrophobic peptides.[41,43] It is very difficult to optimise this process.[44]

In many cases, enzymic treatment was resorted to in order to stabilise the muscle tissue homogenates before extracting the protein.[45,46] This method is especially convenient in isolating proteins from small oceanic fish. The fish are wholly ground up and are then subjected to enzymolysis, whereupon the partially hydrolysed protein can be extracted to a large extent. Amylosubtilin and protosubtilin were used on fish objects,[45] while papain and ficin were employed for the analogous treatment of the skeletal muscle tissue of cattle.[46]

A successful version of the enzymic modification of isolated *Rockfish* fish proteins has been achieved using the "Rhozyme P-11" preparation.[47,48] After 15 min hydrolysis at pH 6.5–6.7 and 30 °C (enzyme : substrate = 1 : 75), an emulsifying activity exceeding the control parameter for the initial isolated protein by a factor of almost 1.5 was obtained. For higher degrees of hydrolysis the emulsifying activity fell, while the stability of the emulsions increased (to a maximum after hydrolysis for 30–60 min) but subsequently it too decreased. The solubility in water of the fish hydrolysate obtained reached 20%. The authors do not mention a bitter taste.[47]

It is of interest to note that weak hydrolytic treatment of the *Rockfish* isolated protein with bromelin (10 min at pH 7; temperature 25 °C) only slightly diminished its emulsifying and foam-forming capacities, whereas the above properties of the same isolated proteins subjected to preliminary acylation were increased sharply[49–51] (for details, see Section IV).

The traditional employment of meat proteins in food systems imposes certain requirements on the latter. Solubility is not as important for them as a high emulsifying capacity, gel formation, and ability to bind high- and low-molecular-weight components of the system.

By treating the myofibrillar proteins of bovine skeletal muscle with papain, it was possible to increase their emulsifying capacity by 40% with formation of very stable emulsions.[46]

Owing to their low level of functional properties, proteins isolated from bovine cardiac muscle tissue have not found extensive applications despite their high biological value. Modification using ficin made it possible to employ such isolated proteins as a valuable additive for the replacement of beef in meat systems (up to 30%) without impairing their nutrient and organoleptic properties.[52]

In order to improve the emulsifying and gel forming capacities of myofibrillar proteins from the skeletal muscles of domestic birds, treatment with the preparation "Milezyme AFP-2000" was tried. It was noted that, with increase in the degree of hydrolysis, the solubility of the proteins rises but the capacity for gel formation falls rapidly at the same time.[53] It is possible to obtain a modified product, which has been recommended as an active emulsifying additive to meat systems.[54]

Enzyming processes used for the modification of myofibrillar proteins hardly extend beyond the framework of proteolysis. There have been several communications on the use of transferases which can serve as activators for the covalent attachment of aminoacids or aminoacid esters to proteins[55,56] (see Section IV).

It can be inferred from the data presented that the spectrum of functional properties which can be improved by treating myofibrillar proteins with enzymes is so far relatively narrow. The principal factor determining the level of the required functional properties in the modified object is the degree of hydrolysis of the protein. On the other hand, the main difficulty in carrying out proteolytic processes is in monitoring the degree of decomposition of protein molecules.

The application of immobilised enzymes was predicted a fairly long time ago,[57] but this technique has not so far found an application in practice.

Despite the difficulty of controlling enzymic processes on an industrial scale, some workers believe that this aspect of the modification is the most promising on the grounds that such treatment does not entail the loss of nutrient properties and in addition increases the assimilability of the isolated proteins.[3,5,58]

In our view, the use of enzymic processes on isolated proteins subjected to a preliminary chemical modification is effective (for further details, see Section IV).

III. Chemical modification

Chemical modification is of great interest for the regulation of the functional properties of food proteins.[21,58–67] It involves many more possibilities for the transformation of proteins than enzymic modification. Apart from the simplest operations associated with the degradation of peptide chains and the hydrolysis of amide groups of asparagine and glutamine, it makes it possible to alter the structure of the protein by creating new covalent or ionic bonds.

With the aid of chemical reagents, it is possible to introduce hydrophilic and hydrophobic groups into the protein molecule, to enrich the protein in aminoacids present in insufficient amounts, and to attach polyaminoacid chains. By taking into account the nature of the groups introduced and by regulating the degree of modification, it is possible to alter specifically the overall charge and hydrophobicity of the protein system, which in fact determines its functional properties.

1. Alkaline and acid hydrolysis of proteins

One of the simplest methods of solubilising proteins is alkaline and acid hydrolysis. Since 1970, alkaline hydrolysis has been used widely for the improvement of the functional properties of fish protein concentrates.[68–70] Such treatment usually increases the solubility and the emulsifying and foam-forming capacities of the protein.

Treatment of myofibrillar proteins with alkalies and acids in order to cleave the peptide bonds induces profound irreversible denaturation changes and is accompanied by the appearance of a number of side reactions. Alkaline hydrolysis is also accompanied by the degradation of alkali-labile aminoacids, the partial racemisation of aminoacids, and the β-elimination process with participation of hydroxy- and mercapto-aminoacids leading to the formation of dehydroalanine, which readily interacts with lysine, cysteine, ornithine, and ammonia.[71–74] The products of these reactions are respectively lysinoalanine, lanthioline, ornithinoalanine, and β-aminoalanine. This diminishes the food value of the protein by depleting it in essential aminoacids, by the partial loss of assimilability as a result of the formation of intermolecular cross-links, and by the accumulation of antinutrient substances. The question of the toxicity or harmlessness to man of dehydroalanine derivatives still remains open.[3,72]

Comparatively recently it has been demonstrated experimentally (on skeletal muscles in fish) that lysinoalanine is formed only under very severe alkaline conditions at pH 12 and above and at temperatures not below 90 °C.[75] Thus the possibility of using relatively mild hydrolysis for food proteins has not been rejected at the present time.[3,36] Acid hydrolysis of myofibrillar proteins has not come to be widely employed although according to some specialists[5] it has advantages compared with alkaline hydrolysis mainly as a result of the lower degree of racemisation of aminoacids.

One of the principal disadvantages of hydrolytic processes is the formation of bitter peptides (even for low degrees of hydrolysis of the protein), which is especially characteristic of isolated fish proteins.[20,42]

2. Solubilisation of proteins by salt formation

Proteins, which are polymeric ampholytes, have the characteristic ability to interact with cations and anions. Two types of interaction are possible: the formation of salt "bridges" and the specific sorption of ions on the surface of the protein.

In terms of their positive influence on the solubility of proteins, cations and anions can be arranged in the following sequence:[76]

$$Ca^{2+} > Mg^{2+} > Li^{+} > Cs^{+} > Na^{+} > K^{+} > NH_4^{+}$$

$$SCN^{-} > ClO_4^{-} > I^{-} > NO_3^{-} > Br^{-} > Cl^{-} > CH_3COO^{-} > F^{-} > HPO_4^{2-} > SO_4^{2-} >$$

$$> {}^{-}OOC{-}CHOH{-}CHOH{-}COO^{-} > {}^{-}OOC{-}CH_2{-}\underset{\displaystyle COOH}{\overset{\displaystyle |}{C}}(OH){-}CH_2{-}COO^{-}.$$

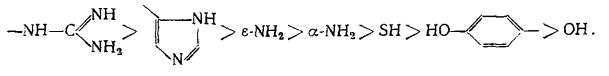
Proteinates have a much higher solubility than desalinated proteins. The change in the solubility of proteins is attributed to the specific interaction of ions (not only electrostatic interaction), which entails changes in the surface charge of the protein and in its conformation, ensuring a higher degree of hydration. A change in the ionic strength of the solution also promotes an increase in the solubility of the protein.[3,76,77]

The use of salt components in food protein systems is limited by their toxicity and cost. The most widely used additives are sodium chloride and inorganic phosphates.[78–85]

The moisture retaining capacity of meat systems is frequently regulated with the aid of salts. Sodium chloride, pyrophosphate, or triphosphate is usually introduced to increase such capacity.[78,86] The affinity of myosin for various inorganic phosphates is not unambiguous. It has been demonstrated for the interaction of myosin and with sodium pyrophosphate, triphosphate, and hexametaphosphate.[83,84] Among them, hexametaphosphate shows the greatest affinity for myosin, the character of its binding to myosin differing from that of the other phosphates. In the presence of Na^+ and especially Mg^{2+} or Ca^{2+} cations, the affinity of triphosphate and pyrophosphate for myosin increases sharply. More precisely, the affinity of myosin for these metal phosphate complexes is greater than for the phosphates themselves. This rule does not extend to hexametaphosphate. On the contrary, the presence of NaCl inhibits the interaction of myosin with hexametaphosphate.[83,84] These data indicate a high degree of specificity of the ionic interactions of myofibrillar proteins.

The modern concept concerning the influence of phosphate and chloride anions on the solubility of myofibrillar proteins reduces mainly to electrostatic effects. As a result of the interaction of anions with myosin filaments, electrostatic repulsion forces arise and weaken the binding of the filaments. It has been suggested that at the critical salt concentration in solution, certain types of bonding of the filaments (as a rule in the regions of the *M*- and *Z*-lines) can break down. Furthermore, the bonding of the myosin heads to actin weakens until complete dissociation. Thus the introduction of anions promotes the depolarisation of thick filaments with liberation of myosin molecules.[76] In general, it has been found that inorganic phosphates are universal polyfunctional additives to isolated muscle tissue proteins. For example, sodium hexametaphosphate is introduced to ensure the complete precipitation of fish protein in the form of the phosphate complex,[47] while the addition of sodium triphosphate to the isolated fish protein is recommended in order to optimise the drying process.[87] Phosphates can be used conveniently to modify myofibrillar proteins, because they possess also antidenaturing,[88–90] antiseptic,[82,91–93] and antioxidant activities.[82,87,94] Phosphates have proved useful as active synergistic agents in relation to phenolic antioxidants.[94] On the other hand, the presence of polyphosphates increases the affinity binding of carbonyl compounds

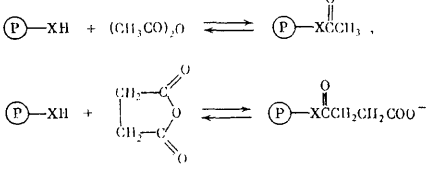
formed on oxidative decomposition of lipids; actomyosin phosphate should not therefore be added to isolated proteins which need to be defatted.[95]



Mention should also be made of the ability of certain anions to protect actomyosin against cryodenaturation. For this purpose, glutamate, tartrate, and maleate are used together with phosphates at low temperatures.[96–98]

3. Acylation of myofibrillar proteins

One of the most widely used procedures in the chemical modification of food proteins is acylation.[21,59,61,63,64,99,100] Among acylating agents, acetic and succinic anhydrides are the most widely used. They are cheap, convenient to employ, and relatively harmless, they do not form toxic derivatives with proteins, and are distinguished by a high activity. The acylation reaction is usually carried out at a reduced or room temperature at alkaline pH.

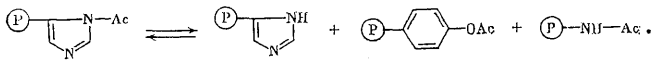


The degree of involvement of the different nucleophilic groups of the protein in the reaction varies as a function of the conditions (mainly the pH), the character of the anhydride, and the influence of inhibiting additives.

In the series based on decreasing nucleophilicity, the functional groups of the side chains in the aminoacid residues are arranged in accordance with their dissociation constants:

However, their reactivity can be influenced by adjoining groups in the peptide chain with which donor–acceptor or electrostatic interaction is possible or hydrogen bonds may be formed.[77]

The reaction of the protein with acetic and succinic anhydrides can be represented in a general form by the following scheme:



X = NH, O, S; Ⓟ = protein.

The fundamental difference between these processes is that the groups formed as a result of the interaction of the protein with acetic anhydride are compact and electrically neutral. On the other hand, the reaction with succinic anhydride introduces into the protein molecule more bulky negatively charged substituents. The latter reaction induces a sharper shift of the isoelectric point of the modified protein to the region of acid pH and more profound conformational changes than in the case of acetylation. This is in fact the cause of the greater possibilities, even when the degrees of modification are low, for the improvement of the solubility and the emulsifying and foam-forming capacities by succinylation rather than by acetylation.

In principle, all types of basic groups of the protein can interact with carboxylic acid anhydrides. In practice, however, the principal reaction centres are the ε- and α-amino-groups, mercapto-groups, and the most active hydroxy-groups of the protein.

The highly basic guanidine groups of the arginine residue are not acylated because under the reaction conditions (at a pH usually not exceeding 9.5) they exist in the protonated state.[77]

The *N*-acylimidazole derivatives of the histidine residue are so active that they themselves function as acylating agents, i.e. the *N*-acyl group migrates from the imidazole ring to the neighbouring sterically accessible amino- or phenoxy-groups of the protein:[63,64]

The half-life of *N*-succinylimidazole at pH 8.5 is 1 min.[101]

The terminal amino-groups of the protein, the ε-amino-groups of lysine, the SH groups of cysteine, and the OH groups of tyrosine are readily acylated, while the hydroxy-groups of serine and threonine are less reactive.[100] The amide bonds formed are stable, while the *O*- and *S*-acyl bonds, which are relatively stable in acid media, are rapidly hydrolysed in weakly alkaline media (already at pH 8.0). Tyrosine derivatives are especially labile. For example, the *N*-hydroxysuccinimide ester of tyrosine (*O*-Suc-tyrosine) is spontaneously deacylated at pH 8.0–8.5.[100,102]

It has been established with the aid of the reaction with salicylaldehyde that the accessible and active ε-amino-groups of lysine in native myosin constitute only 2.5% of the total number of lysine ε-amino-groups, while moderately active residues constitute about 30%. Other residues are sterically inaccessible and can react with the modifying agent only after the denaturation of the protein.[103]

The effect of acylation on the conformation of the myofibrillar proteins has been studied in detail on myosin and actin.[104–111] When only the surface ε-amino-groups of lysine have been modified, the conformation of myosin does not change.[104,105] Succinylation under conditions ruling out the denaturation of myosin (pH 7.0; 0 °C) showed that such chemical action induces only the dissociation of the light chains of myosin, while in other respects the structure of the protein remains intact.[106] These observations were confirmed in the analogous acetylation of myosin. Fractions with molecular weights of 17 000, 19 000, and 20 000, representing the light chains of myosin bound non-covalently to the C-1 subfragment, have been isolated and identified.[107,108]

When the degree of modification is above 3%, the myosin molecules acquire a more open-chain conformation and the degree of coiling into a helix diminishes.[107] On succinylation up to 50% and above, the conformation of proteins is seriously damaged.[112]

As regards biological activity, on succinylation (even for low degrees of the latter), myosin loses the ATPase activity and the ability to bind to F-actin.[107]

Acetylated myosin is distinguished by a high thermal stability, i.e. resistance to thermocoagulation.[107] It is believed[105,108] that the lysine ε-amino-groups located on the surface (the most accessible) are responsible for the thermal stability of myosin. On modification with a reagent specific to amino-groups (β-naphthoquinone-4-sulphonic acid), the thermal stability of myosin increased linearly with increase in the degree of substitution of amino-groups from 0 to 2.5%. The blocking of the surface lysine ε-amino-groups probably reduces the capacity of the heavy myosin chains for aggregation during their thermocoagulation.[76,109,110]

Studies of the influence of chemical modification on the properties of actin have been shown that up to 30% of the amino-groups and up to 40% of the SH groups are capable of entering into the succinylation reaction, as a result of which actin becomes biologically inert, losing the capacity for polymerisation and for binding to myosin. It is of interest that the selective blocking of the mercapto-groups of F- and G-actin does not affect their biological activity.[111]

Apparently the ε-amino-groups of lysine play the main role in actin, as in myosin.

Modelling of biochemical reactions has shown how specific and complex are the processes involving the changes in the conformation of the muscle tissue proteins. For example, enzymic phosphorylation of the light chains of myosin (LC-2) alters only the steric orientation of the heads of the C-1 myosin subfragment.[113,114]

Proteins isolated from animal sources, containing many different components of structural proteins, were subjected to chemical modification in the studies discussed below. Sarcoplasmic proteins and lipids are as a rule removed in order to avoid the oxidative spoliation of the isolated proteins during storage and to eliminate their specific smell and taste. Thus the principal components of the isolated proteins are myosin, actin, and tropomyosin, while the minor components are troponin and actinin.[76] According to the literature,[76] myosin contains only 17% of the basic aminoacid residues and 38% of the polar functional groups, actin contains 13% of the basic residues and 33% of the polar residues, while tropomyosin contains 19% of the basic residues and 50% of the polar residues. The cysteine residues are concentrated predominantly in myosin (65% of all the SH groups) and actin (29% of the SH groups). The accessibility of the groups enumerated above to chemical reagents is various, depending on the degree of denaturation of the modified protein system and on the nature of the selected agent.

The composition of the isolated proteins depends on the object, the kind of muscle tissues, the method of isolation and treatment, and the degree of denaturation of the proteins — on the conditions used in carrying out each stage of the process. The available literature data on the modification of isolated proteins can therefore be compared only fairly arbitrarily.

The influence of the conditions in the acylation reaction on the properties of isolated fish proteins has been investigated[100] with quantitative determination of the functional groups of the protein involved in the reaction. It was established that the rate of acylation depends mainly on the pH of the medium. For example, at 0 °C and pH 9.5, 90% of all the ε-amino-groups of lysin are acetylated, the corresponding figures at other pH values being 85% at pH from 8 to 8.5,[115] 75% at pH 7.5, and 65% at pH 6.5. Nevertheless, in the presence of a large excess of acetic anhydride and for longer reaction times, complete acylation is attained even at pH 6.5.[100]

The rate of the reaction between acetic anhydride and the SH and OH polar groups of the protein falls appreciably as the pH is reduced. Whereas 35% of all the polar groups (SH and OH) are acetylated at pH 9.5 and 25% at pH 7.5, not more than 20% are acetylated at pH 6.5. Under these conditions, the mercapto-groups of the cysteine residue were modified even at low concentrations of acetic anhydride, while the rate of acylation of tyrosine increased only at high concentrations of the anhydride. More than 50% of the SH groups of cysteine, 30–40% of the OH groups of tyrosine, and of the order of 20% of the hydroxy-groups of serine and threonine were acetylated in the pH range 7.5–9.5. On succinylation, the same proportions were observed, but the degree of involvement of all the groups was somewhat lower because of the lower reactivity of succinic anhydride.

The introduction of an inhibiting additive (sodium sulphite) alters the pattern in the acetylation of fish protein: the involvement of the ε-amino-groups is reduced by 20%, that of the SH groups is reduced by 60%, and that of the OH groups of serine and threonine is reduced by a factor of two. Tyrosine is not then acetylated at all.[100] In the succinylation process, sodium sulphate inhibits most strongly the SH groups without affecting the reactivity of the OH groups of serine and threonine; *O*-Suc-tyrosine was not detected.[100] One should recall that it is readily deacylated.[102]

It is seen that, regardless of the acylation conditions, the main reaction centres (apart from the terminal α-amino-groups) are the ε-amino-groups of lysine and the degree of modification of the protein by acylation has therefore come to be estimated in terms of the percentage of the substituted ε-NH_2 group (the number of the accessible ε-NH_2 groups of lysine in the given protein system is adopted as 100%).

There exist biological, microbiological, and chemical methods for the determination of the accessible lysine in proteins.[116–119] One of the most reliable and trustworthy chemical methods is based on the reaction of the primary amino-groups with trinitrobenzene-sulphonic acid.[119]

A number of studies have been devoted to the investigation of the functional properties of acylated isolated fish proteins.[50,51,87,120–125] The emulsifying activity of the succinylated *Rockfish* isolated protein increased in proportion to the degree of modification. For example, it amounted to 1.3 g per mg of the protein for 30% modification and increased by a factor of two for 77% modification.[120] The isolated hake proteins acquired emulsifying properties as a result of succinylation which were superior to those of gelatine. The stability of the emulsions obtained was specially emphasised.[121] It is important to note that the changes in the emulsifying capacity of the succinylated isolated proteins at different pH and after the introduction of monovalent and divalent cations (Na^+, Ca^{2+}) were of a fundamentally different character than for the unmodified proteins.[121]

Acetylation and especially succinylation appreciably increased the foam-forming capacity of fish proteins, but the stability of the foams diminished compared with the control.[51]

By subjecting the homogenates of plant and animal tissues to acetylation simultaneously with succinylation, protein products with effective emulsifying and foam-forming properties are obtained together with a high solubility and water-absorption capacities. It has been recommended that such products be used as food surfactants.[122–124] Acylated myofibrillar proteins have a characteristic solubility profile: they are almost insoluble in an acid medium below the isoelectric point of the protein. The isoelectric point is displaced towards acid pH in proportion to the degree of modification of the protein. This is associated with the decrease in the number of free ε-amino-groups of lysine. The solubility increases sharply at neutral and weakly alkaline pH precisely because of the displacement of the isoelectric point.[121]

The absorption of water by the *Rockfish* isolated protein increases by a factor of two on acetylation and by a factor of five on succinylation.[51] Succinylation increases the capacity of the isolated protein for rehydration and its thermal stability (it did not coagulate even at 100 °C).[120]

It has been noted that acylation lowers somewhat the capacity for gel formation but does not destroy it: 3% solutions of the acetylated protein and 7% solutions of the succinylated protein formed gels of the same kind as a 2% solution of gelatine.[51]

A method has been proposed for the preparation of viscoelastic gels from fish proteins succinylated to a low extent (up to 10%), the stability of the gels being inversely correlated with the degree of modification.[125]

It has become evident that the acylation of isolated fish proteins makes it possible to use them as powerful emulsifying and foam-forming additives to food systems (Table 1).

Since the foam-forming and foam-stabilising properties of the succinylated fish protein are not inferior even to those of egg albumin, it is believed[87] that it can replace egg protein up to 50% in confectionery, for example in sweets or in whipped dessert dishes, and can be used in fruit desserts instead of gelatine[51] and in ice cream instead of caseine.[50]

Table 1. Functional properties of acetylated and succinylated fish proteins (the degrees of modification are equivalent and amount to 50–60%).[87]

Properties	Ac	Suc
Emulsifying activity at a protein concentration of 5 mg × ml^{-1}, % emulsion	61	97
Emulsifying capacity, g of oil/100 mg of protein	53	132
Capacity for gel formation, minimum concentration of protein solution (%) for the formation of a stable gel	4	3
Foam-forming capacity, volume of foam in ml	550	600
Stability of foam, syneresis volume in ml	71	32
Water absorption, ml of water/1 g of protein	15	20

The addition of succinylated fish protein to meat products in an amount of 10–20% does not impair their organoleptic properties.[87]

Similar results have been obtained in studies on the modification of structural meat proteins by acylation.[58,126] Acetylated and succinylated heart muscle proteins from cattle proved to be satisfactorily soluble in aqueous media at a low ionic strength and exhibited a higher emulsifying activity even at pH 6.0 than that of the native protein at pH 7.4, which is sufficient for meat systems.[126] Furthermore, anhydrides with a more complex structure were used for modification, such as benzene-1,2,4-tricarboxylic anhydride (BTCA) and benzene-2,3,4,5-tetracarboxylic dianhydride (BTCDA). In the reactivity series, they occupy an intermediate position between acetic anhydride (AA) and succinic anhydride (SA):

$$AA > BTCDA > BTCA > SA.$$

All the anhydrides quoted, with the exception of AA, reacted much more slowly with the SH and OH group of the protein than with the amino-groups. In the presence of the greatest excess of the anhydride, not more than 1/4 of all the SH groups of cysteine reacted and the products of the reaction of SA with serine and threonine were not detected. A sharp increase in the solubility of the derivatives was noted in all cases even for low degrees of modification.[126] Unfortunately no data have been quoted on the assimilability of the new modified proteins.

Summarising the data on the acylation of myofibrillar proteins, one must emphasise that acylation alters to different extents (depending on the nature of the acylating agent and the reaction conditions) the overall charge on the macromolecule, the isoelectric point being displaced to the acid region. As a rule the structure of the protein becomes less helical, which entails an enhancement in its hydrophobic properties. The tendency towards dissociation into subunits increases and the tendency towards specific polymerisation diminishes. Simplifying the pattern of the real changes in the modified protein system, the increase in solubility, in the moisture retaining capacity, and in swellability are usually attributed to the shift of the hydrophilic–hydrophobic balance towards an increased hydrophilicity; the increase in the emulsifying and foam-forming capacities is frequently explained by an enhancement of hydrophobic properties.

The set of chemical reagents used for the modification of myofibrillar food proteins is unfortunately extremely small. There is no information in the literature concerning isolated muscle proteins about promising methods such as, for example, phosphorylation, deamidation, and esterification.

When the chemical agents for the regulation of the functional properties are compared with enzymes, the following features may be noted. Chemical modification does not lead to the loss of the binding and gel-forming properties of proteins, of the kind observed in enzymic reactions. The degree of proteolytic decomposition has a stronger influence on the functional properties of the protein system than the degree of chemical modification. On the other hand, the specified level of chemical modification can be more readily ensured than a rigorously defined degree of proteolysis. From the standpoint of the preparation of highly functional isolated proteins, which remain stable on storage and during treatment in a specific food system, chemical modification has advantages compared with enzymic modification (see Section VI). However, certain types of chemical modification lower to different extents the nutrient value of food proteins and their assimilability, which does not occur in the enzymic treatment.

IV. Combined chemical and enzymic modification of proteins

In a number of instances, combined chemical and enzymic treatment of food muscle proteins has been applied extremely effectively.[50,51] The weak hydrolytic effect of bromeline on the succinylated *Rockfish* protein makes it possible to obtain excellent foams, as regards bulk and stability, at protein concentrations of 3–4% over a wide pH range. The stability of these foams was greater than that of the foams based on egg and soya proteins.[50] The maximum positive effect in the improvement of the foam-forming properties was obtained by mild proteolysis of 40–50% succinylated fish proteins.[51,127] However, under all the conditions tested, this procedure reduced the emulsifying activity, gel formation, and swellability.[51,127]

It has been reported[20] that, regardless of the sequence in which the acylation and proteolytic processes are carried out on fish proteins, products with similar functional properties are obtained, although, in principle the results should not be the same. If chemical modification is carried out in the first stage and the acylated proteins are then subjected to proteolysis, then in this instance proteolysis proceeds more slowly and certain peptide bonds are not split at all. Larger fragments of the protein molecules, chemically modified to a lesser extent, should be obtained in this way. If, other conditions being equal, the above processes are interchanged, then proteolysis proceeds without obstacles and the resulting protein fragments, having a larger number of accessible reaction groups, react chemically. This procedure should lead to more profound chemical transformations of smaller protein fragments.

Using these hypotheses, one may recommend the first method for the activation of the surface properties of a protein and the second

for increasing its solubility. From the standpoint of the retention of the nutrient value of the protein, the first method is preferable.

Another aspect of the successful use of the combined chemical and enzymic modification of the protein involves the covalent attachment of aminoacids or their esters with the aid of enzymes.[55,56,127,128] Using papain, the covalent attachment of the alkyl esters of leucine to succinylated fish protein has been achieved.[127] By varying the length of the hydrocarbon chain of the alkyl ester of leucine, the authors obtained superactive emulsifying and foam-forming agents: the C_4-C_8 alkyl groups correspond to the maximum foam-forming activity and the $C_{10}-C_{12}$ groups correspond to the maximum stability of the foams and emulsifying activity.

Transglutaminase is frequently used for the covalent "attachment" of aminoacids to the protein.[55,56,128,129] The efficiency of the reaction involving the attachment of the aminoacid residue increases if the amino-groups in the attacked protein were acylated beforehand. Intermolecular cross-links, which reduce the digestibility of the protein, are not then formed. After the enzymic treatment, the amino-groups can be regenerated. Maleic, 2,3-dimethylmaleic, and citraconic anhydrides, whose *N*-acyl residues are cleaved in an acid medium, were used for the reversible acylation. This procedure has been recommended for increasing the solubility and emulsifying capacity of isolated proteins from plant and animal raw materials.[55,56]

It has been suggested that fish proteins, to which hydrophobic aminoacid (leucine, norleucine, and alanine) have been "attached" enzymically, be used as food antifreeze agents. The alkyl residue of the ester group should also be hydrophobic ($R = C_8-C_{10}$). An antifreeze of this kind is non-toxic and is very effective in the storage of food products in a fresh form at low temperatures.[129]

V. Physicochemical modification methods

The physicochemical methods for the treatment of isolated food proteins include the following procedures: complex formation with natural biopolymers (proteins, polysaccharides, etc.) and also with monomeric compounds (carbohydrates, lipids); mechanical treatment of different kinds, heat treatment, etc.

Extensive studies on these lines have been carried out by Tolstoguzov and co-workers on proteins of plant origin.[3,130]

Changes in the functional properties of food proteins can be achieved by varying the hydrophilic–hydrophobic balance in the protein system as a result of specific protein–protein interactions. Studies of the conjugates of myosin with plant proteins have aroused considerable interest.[131–138] It has been noted that, when mixed solutions of myosin and 11S soya globulins are heated, hybrid aggregates are formed.[131] Basic subunits, formed on partial dissociation of the 11S globulins, and the heavy chains of myosin are capable of interacting. The degree of binding increases on raising the temperature in the range from 85 to 100 °C. As a result of thermal denaturation, the subunits undergo a conformational rearrangement accompanied by aggregation with formation of qualitatively new energetically more favourable protein complexes. Hydrophobic interactions play a significant role in this process.[132]

Myosin is able to aggregate with β-conglycinin in a similar way at temperatures above 85 °C.[133] The formation of mixed conjugates can be detected by gel electrophoresis. The aggregates obtained are distinguished by a high solubility and thermal stability. The latter property permitted the pasteurisation of meat systems with added soya protein.[134,135]

When solutions of actomyosin were heated with the "CIF" fraction of soya protein, the formation of stable gel structures of a new type was observed.[136,138] The denatured soya protein was associated in a definite manner with the actomyosin network, and, according to the scanning electron microscope data, the resulting structure differed appreciably from that of the thermogels formed by the individual components. According to the authors' hypothesis, the formation of disulphide linkages between the two protein partners is possible in this instance.[136]

Hybrid protein complexes can also be obtained by intermolecular cross-linking. The possibility of the covalent binding of myosin to globular proteins such as soya protein, casein, and gluten as a result of the formation of an amide bond between the γ-carboxy-groups of glutamic acid and the ε-amino-groups of lysine, both in the presence and absence of an activator enzyme (transglutaminase), was investigated.[55,56,128,137] The optimum binding conditions depend on the nature of both components. The percentage binding of soya protein and fibrin to myosin increased on raising the pH of the medium and temperature, while the binding of caseine was favoured by an increase in temperature and a decrease in pH. With participation of the enzyme, the maximum amounts of proteins bound to 1 g of myosin are 0.58 g of caseine, 0.30 g of gluten, and 0.15 g of soya protein.[128]

Complex formation of the type of protein–protein interaction found a practical application before its theoretical interpretation. It was noted in an early study[87] that, when proteins of different nature are dried together, not only are highly nutritious protein mixtures obtained but their functional properties are also retained at a high level. For example, instead of adding sodium chloride and phosphates to fish proteins in order to optimise their drying, it is more convenient to dry mixtures of fish and grain proteins which, together with a gain in the functional properties of the protein concentrate, has a positive economic effect. The grain additives (from 10 to 30 wt.%) can be wheat, rice, and virtually any kind of flour.[87,139]

The addition of plant proteins to semi-finished meat products ensures, by virtue of complex formation, the minimum losses of the moisture-retaining capacity of the system on heat treatment.[140]

Conjugates formed by proteins with carbohydrates possess as a rule highly effective functional properties. The ability of carbohydrates to protect muscle proteins against denaturation under both low-temperature conditions and on heat treatment has been known for a long time.[19] The antidenaturing capacity of saccharides in relation to fish proteins decreases in the sequence maltose > sorbital > sucrose ≃ maltitol > glucose > lactitol. At negative temperatures, carbohydrates exhibit under these conditions a highly protecting effect at lower concentrations.[141–143] When fish proteins are dried together with monosaccharides, highly hydrophilic complexes are produced. The solubility of such complexes is proportional to the percentage content of the saccharide and depends on the nature of the latter. In terms of their influence on the solubility of the adduct with fish protein, the monosaccharides tested can be arranged in the following sequence: glucose ⩾ sucrose > fructose.[19] Glycerol and partly hydrolysed starch have similar properties.[19] The solubility of conjugates of fish protein with starch is 25% of the solubility of the freshly isolated protein.

By drying fish protein with 10% of added glucose, sorbital, or sucrose, complexes with a high emulsifying activity and an enhanced thermal stability are obtained. However, they partly lose their nutrient value as a consequence of the Mayar reaction.[19]

With the aid of complex formation (for example with carbohydrates), it is possible to improve the capacity of acylated myofibrillar proteins for gel formation. For example, the aggregation of succinylated fish proteins with glucono-delta-lactone leads to the formation of gels distinguished by a high stability and formed even in oil-containing systems.[121]

The addition of glucono-delta-lactone and citric acid promotes the retention of functional properties by ground beef.[86]

Together with nucleotides, lipids bound to myofibrillar proteins protect them against denaturation. The mechanism of the protecting action requires further study.[62,144,145]

Certain functional properties of meat systems can be altered by simple procedures such as heat treatment. By selecting the optimum conditions (temperature and pressure), the moisture retaining capacity, tenderness, succulence, and other properties of meat specimens of different quality can be regulated.[146–148] The changes occurring in the properties can be explained by the partial or complete decomposition of individual components of the myofilaments: connectin and nebulin.[148]

Simple mechanical treatment of proteins, both animal and plant, for example, grinding in a vibromill, are known to be capable of improving their solubility and moisture-retaining capacity as a consequence of the mechanical degradation of sarcomers.[148,149]

Combined mechanochemical modification is much more effective. Under different conditions in the treatment of fish homogenates with acetic or succinic anhydride in a vibromill, it is possible to increase greatly their moisture-retaining and foam-forming capacities and their ability to stabilise foams.[149,150]

Presumably, among the physicochemical methods of treatment, the complex formation procedure is the most promising: it has no pronounced disadvantages or limitations of the kind charactersitic of chemical or enzymic modification (from the standpoint of toxicity or the loss of nutrient value). In general, practice has shown that the best results in the transformation of the functional properties of food proteins can be obtained by an appropriate combination of various modification procedures, for example, chemical and enzymic methods or chemical methods and complex formation.

VI. The nutrient value and the bioavailability of the modified food proteins

Among all the procedures for the modification of food proteins enumerated above, chemical treatment gives rise to special risks from the standpoint of the toxicity and bioavailability of the protein. The principal disadvantage of the chemical modification is believed to be the decrease in the nutrient value of the food proteins. Indeed, the action of chemical reagents leads to a definite loss of the bioavailability of the protein (different for each kind of chemical modification and for each type of modified objects). At the same time, the blocking of the most reactive groups of the protein leads to the formation of more stable, albeit less nutritious, non-toxic products.

The loss of nutrient value and the decrease in the assimilability of the protein products are the negative phenomena which accompany any traditional treatment of the protein (drying, canning, cooking, and even the storage process).[36,151] They are due to the involvement of particular chemical reactions of the active functional side groups in essential aminoacids. The ε-amino-groups of lysine and the SH groups of cysteine are believed to belong to the class of the most reactive groups. For example, during the storage of both frozen fish and of dry isolated fish proteins, undesirable side products are formed, one of which is formaldehyde. The latter reacts readily with the amino-, mercapto-, and hydroxy-groups of the protein and to a lesser extent with the amide groups, reducing the assimilability of the protein.[152,153] Myosin interacts with certain free aminoacids even at –20 °C, the reactions of the protein with taurine, lysine, and histidine accelerating the denaturation aggregation of the protein.[97]

In the oxidative degradation of lipids, the percentage of the ultilised protein (fish or meat) can be reduced by a factor of two, the maximum loss involving under these conditions tryptophan, lysine, histidine, methionine, and cysteine.[36,154,155]

During the heat treatment of fish at temperatures starting from 50 °C, the mercapto-groups of cysteine undergo vigorous oxidation with formation of disulphide bonds. A greater decrease in assimilability was observed for lean fish compared with fat fish. The SH groups responsible for the binding to lipids are apparently protected against oxidation.[156] When proteins are heated to temperatures ranging from 80 °C upwards, there is also the possibility of the interaction of the lysine ε-amino-groups with the accessible carboxy-groups of glutamic and aspartic acids.[157,158] The same reaction can be initiated by enzyme action rather than heat,[159] which naturally leads to a decrease in the amount of the accessible lysine.

A shift of the isoelectric point of the protein in fish concentrates from pH 5.0 to 4.5 as a result of lyophilic drying has been noted, which is incontrovertible evidence for the involvement of the ε-amino-groups in the intramolecular and intermolecular cross-links of the protein.[19]

When fish is canned, not only is it not possible to avoid a decrease in the assimilability of the protein by approximately 15% [160] but it is also necessary to achieve constant monitoring of the accumulation of the potentially toxic compounds formed as a consequence of the occurrence of the Mayar reaction during sterilisation as has been shown for salmon and plaice.[161]

Among aminoacids, lysine is the most active participant in the reaction with sugars.[162] A linear decrease in assimilability as a consequence of the loss of accessible lysine, in fact as a result of the Mayar reaction, has been noted for a whole series of food proteins.[74] It is therefore recommended that serious attention should be paid to the analysis of food products with a relatively high carbohydrate content if they are heat treated.[74,163] For example, it has been shown that 19 days after the addition of 10% glucose to a system based on fish protein with an 18% moisture content at 35 °C half the accessible lysine is lost.[163] Sodium sulphite (or SO_2) is added to inhibit the Mayar reaction but this measure is not universal.[153]

Acylation of proteins appreciably reduces the possibility of the occurrence of this undesirable reaction and also of other side reactions undergone by the unmodified protein under the conditions of alkaline and heat treatment, on storage, and on drying.[36,153,157,158,164,165]

Individual types of modification of food proteins, especially chemical modification, lead to profound changes in the protein structure. Studies on bioavailability, assimilability, and metabolic pathways for the modified systems are therefore of primary importance together with other complex medicobiological problems as regards toxicity and carginogenic and mutagenic properties of new products.[166–169]

A definite trend has arisen in recent years towards reducing the content of common salt in food products for man.[58] When food proteins are used in the form of proteinates, an optimum limit to the content of inorganic ions, which does not affect the health of man,

must also be found. In those cases where alkaline hydrolysis is used to solubilise proteins, it is essential to desalinate the product.[87,170–172]

The nutrient properties of protein isolated from chicken muscle tissue have been compared in detail[173] with those of the muscle tissue separated mechanically in the form of a homogenate. It was shown that alkaline extraction followed by acid precipitation does not entail any appreciable loss of nutrient value of the protein, but its functional properties are then appreciably impaired.[173]

As regards chemically modified food proteins, most information concerning medicobiological tests refers to acylated proteins. Since the available literature data are fairly contradictory, it is apparently desirable to compare data referring to acylated proteins of different kinds.

The content of accessible lysine is known to diminish during the acylation of protein. The role of lysine in human and animal nutrition is extremely important. The deficiency of this essential aminoacid induces serious disturbances in metabolic processes, in the first place in the lipid metabolism.[174] Despite the fact that the set of methods for the determination of the available lysin *in vivo* is entirely satisfactory,[2] the interpretation of the experimental data is frequently complicated by side effects.[172] The prospects for the chemical modification of food proteins depend on the validity of biological tests. The question of the assimilability of lysine from its ε-amide derivatives is mainly disputed. The deacylase activity has been investigated on animals in fair detail. As early as 1943, data were obtained on the partial assimilation of ε-Ac-lysine by young rats.[175] The rate of growth of experimental animals receiving ε-Ac-lysine perorally was lower than for the controls. However, on doubling the dose of ε-Ac-lysine, the difference in the growth of rats was indistinguishable. When ε-Ac-lysine was administered intra-abdominally, partial assimilation of lysine by the animals was also noted.[175] These data agree with the conclusions reached in a whole series of studies on these lines namely that rats assimilate approximately 50% of lysine and mice assimilate about 30% from a diet containing ε-Ac-lysine.[157,158,176–178]

Using di-, tri-, and tetra-peptides containing the ε-Ac- and ε-Suc-lysine residues as models of the fragments of the acylated protein, their proteolysis was investigated *in vitro* under the influence of enzymes from the gastrointestinal tract.[179,180] All the α-peptide bonds adjoining the modified lysine were cleaved, (in contrast to the ε-amide bond) in conformity with the nature of the enzyme tested. However, the initial rates of proteolysis were lower in attack on ε-Ac- and especially ε-Suc-peptides.[179]

One of the little investigated aspects of the assimilation of acylated proteins is the stage where their hydrolysis products are absorbed. In experiments on the isolated small intestine of the chicken, it has been shown that ε-Ac-lysine is absorbed by the cells of the mucous membrane almost just as readily as free lysine, while ε-Suc-lysine is absorbed much less effectively. Lysine modified by aliphatic acid or glutamic acid derivatives is hardly transported through the small intestine of chicks.[180]

The results of Leclerc and Benoiton[181] demonstrate the selective activity of animal kidney acylases: only the ε-formyl and ε-acetyl derivatives of lysine deacylated. The deacetylation of the ε-Ac-lysine by the chick kidney tissue homogenate takes place fairly vigorously (30% of the ε-Ac groups are split off in 4 h). The data presented show that, although the ε-acylated proteins are biodegradable, from the standpoint of their true utilisation acetylated derivatives have undoubted advantages over all other acylated proteins.

With the aid of a microbiological test, it has been demonstrated convincingly that the acylation of the hydroxy- and mercapto-groups of caseine does not lower its nutrient value. In those cases where the ε-amino-groups of lysine were acylated, the biological value of the protein fell with increase in the size of the acyl group. The biological value of caseine fell from 100 to 48% on acetylation (degree of modification 35%) and to 12% on succinylation (degree of modification 74%).[182] The low and moderate degrees of succinylation of caseine and lactalbumin hardly lower their nutrient value, as shown enzymically *in vitro* and by growth tests on rats.[183,184] It has been reported that mice fed on highly acetylated caseine grew, developed, and multiplied.[178] However, they were smaller and leaner than the control animals and had fewer offspring. Chicks receiving acetylated egg albumin (degree of modification 67%) and succinylated egg albumin (degree of modification 55%) showed a weight increment during growth which was greater in the first instance and smaller in the second. However, both groups grew more slowly than the control animals. In those cases where lysine had been added to the acetylated egg albumin, the growth of the chicks was normalised.[172]

The bioavailability of the succinylated protein of unicellular organisms fell by a factor of 10. The estimate was carried out *in vitro* using the pepsin–pancreatin enzyme system.[185]

When proteins deficient in lysine were acetylated, the decrease in biological value was inappreciable. After the complete acetylation of the protein isolated from *Vicia-faba*, a decrease in nutrient value was not noted.[186] We shall compare these data with the available information concerning the nutrient value of acylated muscle proteins.

Groninger and Miller[115] investigated *in vitro* the susceptibility to attack by pepsin and trypsin of fish protein 50% acetylated and 40% succinylated. They reported that the rate of proteolysis by pepsin did not change compared with the unmodified protein. On the other hand, trypsin hydrolysed less effectively the succinylated protein and still less so the acetylated protein, in agreement with other data.[187]

The bioavailability of 90% succinylated fish protein has been estimated[121] from the percentage of the lysine liberated on treatment with pancreatin *in vitro*. The bioavailability of the modified protein fell by a factor of 10.

It has been demonstrated on several generations of rats and mice that the consumption of acetylated and succinylated fish proteins[87] as well as acetylcaseine is not harmful.[188] Histological studies on sections of the liver, the lungs, the kidneys, and the adrenal glands of the experimental animals did not reveal pathological effects and no changes in the internal organs themselves were noted.[187,188]

The metabolism of the acetylated and succinylated fish proteins was investigated on rats by introducing the ^{14}C radioactive label into the ε-amide groups of the protein.[115] The degree of utilisation of the protein was estimated from the distribution of ^{14}C in the carbon dioxide and urine from the animals. After the intravenous administration of a solution of ε-Suc-lysine or the hydrolysate of the Suc-protein, 87 and 93% of ε-Suc-lysine was eliminated with urine respectively, while after the above substances were administered perorally 75 and 72% of ε-Suc-lysine was eliminated from the organism. According to the final data, after intravenous administration, ε-Suc-lysine is not assimilated at all, while ε-Ac-lysine is assimilated to an extent of approximately 25%. After the peroral administration to rats, about 14% of the lysine from ε-Ac-lysine and approximately 50% of lysine from the acetylated protein are assimilated.[115] It has been noted that the metabolism of the succinylated derivatives is much slower than that of the acetylated derivatives.[115]

It has been suggested that the partial utilisation of lysine after the peroral consumption of acyllysine derivatives or acylated proteins can be achieved as a result of the activity of their intestinal microflora.[180,189,190]

The assimilation of lysine on biodegradation of acylated proteins takes place with a higher coefficient of utilisation than the assimilation of lysine from its ε-amide derivatives.[166,190,191] The difference between the mechanisms of these processes has been confirmed experimentally.[180] When the membrane food digestion process was modelled on the isolated chick small intestine, it was noted that the ε-Ac-lysine-containing peptides are partly deacylated, although the elimination of the ε-Ac-group from ε-Ac-lysine was not observed under these conditions[180] (Table 2).

Table 2. Biological value of acylated food proteins.

Protein	Degree of modification, %	Coefficient of effectiveness of protein, %	Refs.
Caseine	0	100	—
Ac-casein	35	48	[182]
Suc-casein	74	12	[182]
Ac-casein	100	64	[188]
Suc-casein	100	12	[188]
FPC*	0	110	[120]
Suc-FPC	30—40	79	[120]
FPC	0	101	[115]
Ac-FPC	50	103	[115]
Ac-FPC	75	85	[115]
Suc-FPC	25	96	[115]
Suc-FPC	40	73	[115]
Suc-FPC	75	35	[87]
FPC	0	41	[121]
Suc-FPC	90	4	[121]
Caseine	—	2,5**	[58]
Myofibrillar protein from ox heart muscle (MPOHM)	—	2,83**	[58]
Acetylated MPOHM	—	2,55**	[58]
Succinylated MPOHM	—	2,36**	[58]

*FPC = fish protein concentrate.
**In grammes per gramme of increment.

The utilisation of proteins with covalently attached aminoacids requires additional study. The metabolism of such proteins is undoubtedly difficult,[117] because the isopeptide bond formed is not cleaved by digesting enzymes and the isopeptides themselves are not absorbed into the blood, as shown in relation to glutamylisopeptides.[180] From the standpoint of Feeney and others,[64–66] the bioavailability of proteins with isopeptide fragments is determined by the nature of the grafted aminoacids and their steric accessibility to the enzyme.

In our view, instead of the covalent binding of the aminoacids, it is more rational to enrich the isolated proteins by adding polyaminoacids. The excellent assimilation of polylysine is the basis for this recommendation.[66,192]

There are doubts concerning the bioavailability of hybrid protein conjugates obtained by grafting glutamic acid and lysine residues.[128,137] However, it is believed[137,193,194] that glutamyllysine-cross-linked proteins are fully assimilated in the intestine, although as a rule the rate of metabolism is extremely low.

Objective assessment and timely introduction of promising methods for the modification of isolated proteins makes it possible to intensify the ultilisation of food proteins from traditional and non-traditional sources in order to obtain new products for mass consumption.

All-Union School on new methods in molecular spectroscopy

The Scientific Councils of the USSR Academy of Sciences on Chemical Kinetics and Structure and on the Spectroscopy of Atoms and Molecules organised in October, 1989, an All-Union School on New Methods in Molecular Spectroscopy. Its aim was to acquaint the participants in the enormous progress achieved in this field during the last 10–15 years as a result of the development of experimental, mainly laser, techniques.

More than 400 persons from 42 cities of the Soviet Union took part in this School. It involved the delivery of 23 lectures and 9 round table discussions. Major specialists in the field of molecular spectroscopy were invited to deliver lectures.

The lectures by R I Personov (Institute of Spectroscopy, USSR Academy of Sciences, Troitsk) examined the principles and the wide variety of applications of the selective laser spectroscopy of molecules and matrices — the selective excitation of luminescence and the method for recording the narrow stable minima in absorption bands. These methods, which have nowadays come to be widely used, make it possible to discover the fine structure in inhomogeneously broadened spectral bands and to increase the "spectral resoluton" by a factor of 10^3-10^4. This leads to fundamentally new possibilities for a wide variety of theoretical and practical applications. Together with the fundamental principles of selective methods, a wide variety of their applications were considered. They include the fine structure of the luminescence and absorption spectra of molecules of different classes, a wide variety of intermolecular interactions, one- and two-quantum photochemical reactions in the condensed phase, the Stark and Zeeman effects in the spectra of complex molecules, the spectra of adsorbed molecules, the problems of increasing the memory of optical memory devices with the aid of methods for the recording of minima, etc.

The lecture by O M Sarkisov (Institute of Chemical Physics, USSR Academy of Sciences, Moscow) was devoted to the physical principles of the method of the laser-induced luminescence, its experimental realisation, and its application to the study of elementary atomic-molecular processes in the gas phase. The interaction of atoms and radicals, the distribution of energy in the products of elementary chemical reactions, the transmission of energy in collisions, and unimolecular reactions with participation of molecules subjected to high vibrational excitation were examined. The same range of problems but using other laser methods such as the intraresonator laser spectroscopy (IRLS) and the method of modulated intraresonator laser absorption was examined in the lectures by E A Sviridenkov (The Physical Institute, USSR Academy of Sciences, Moscow) and O M Sarkisov and Yu M Gershenzon (Institute of Chemical Physics, USSR Academy of Sciences, Moscow). It was emphasised in the former lecture that, by virtue of the extremely high sensitivity of the IRLS, it is possible to investigate "forbidden" optical transitions and high overtones and to apply these methods to the solution of various problems in chemical physics; in the latter lecture, the possibility of achieving an ultrahigh resolution in the spectra by virtue of magnetic and electrical modulation of the intraresonator laser absorption was demonstrated. Examples of the highly sensitive recording of chemically active radicals were also presented.

The lectures by A N Rubinov (Institute of Physics, Academy of Sciences of the Belorussian SSR, Minsk) were devoted to advances in the spectroscopy of molecules in liquid solutions. It was established that the electronic absorption and luminescence spectra of dye solutions are inhomogeneously broadened and that the broad continuous bands are due to the fluctuations in the solvation shell. A model was proposed for a polar solvent, which explains the static and dynamic inhomogeneous broadening of the spectra of dyes as well as a number of other spectral features. It was shown how it is possible to investigate the hydrogen bond between the electronically excited dye molecules and the solvent with the aid of picosecond spectroscopy by measuring the rate of rotation of molecules.

The lecture by E E Nikitin (Institute of Chemical Physics, USSR Academy of Sciences, Moscow) was devoted to a new aspect of laser molecular spectroscopy with a short time resolution. The idea of the method consists in the application of ultrashort laser pulses lasting $10^{-14}-10^{-13}$ s, i. e. tens and hundreds of femtoseconds. This leads to unique possibilities for the investigation of intramolecular movements and the dynamics of the transition state; in the simplest cases, it is possible to obtain information about the movement of fragments of the transition complex on the real time scale. It is difficult to overestimate the usefulness of femtosecond spectroscopy for the development of chemical physics.

The gas-dynamic method for the attainment of low temperatures — the method of the ultrasonic stream expanding adiabatically into a vacuum — has come to be widely used during the last 10 years. The lecture by A M Pyndik (Institute of Spectroscopy, USSR Academy of Sciences, Troitsk) was devoted to this topic. Any gaseous substance can be cooled to temperatures of several degrees Kelvin (and sometimes to a fraction of a degree Kelvin) under the conditions of an ultrasonic stream. It is then easy to achieve fairly high concentrations (from 10^{12} to 10^{15} cm^{-3}) which permit the use of various spectroscopic methods such as fluorescence, phosphorescence, multiphotonionisation, Raman light scattering, and many others. Since at low temperatures the molecules are in the lowest vibrational and rotational states, this creates many advantages for the spectroscopic investigation. These include the narrowing of the absorption band by two orders of magnitude, the disappearance of "hot" bands, an increase in optical selectivity, and the possibility of attaining appreciable concentrations of "van der Waals" molecular complexes.

One of the effective spectroscopic methods for the study of such compounds under the conditions of ultracold streams and beams is the microwave spectroscopy in the centimetre and millimetre ranges, to which the lecture by A F Krupnov (Institute of Polymer Physics, USSR Academy of Sciences, Gorky) was devoted. At the present time, the wavelength range used in modern microwave spectroscopy has greatly expanded, as a result of which cold equilibrium gases, molecular ions, the interstellar space, etc. have become the objects of study by this procedure. Microwave spectroscopy not only makes it possible to measure frequencies with a very high accuracy

but also to create on this basis a new generation of frequency standards.

Several lectures were devoted to the vibrational spectroscopy of molecules. Yu A Kuritsyn (Institute of Spectroscopy, USSR Academy of Sciences, Troitsk) talked about the methods of high resolution diode laser IR spectroscopy. E A Ryabov (Institute of Spectroscopy, USSR Academy of Sciences, Troitsk) dealt with a new phenomenon — the laser multiphoton vibrational excitation of molecules. For a sufficiently high emission intensity, the molecule absorbs a large number of IR quanta and can be excited up to the dissociation limit. The use of multiphoton excitation for the study of intramolecular dynamics, the non-equilibrium selective IR photochemistry, the laser isotope separation, and chemical synthesis under non-equilibrium conditions was discussed.

The lectures by B V Lokshin (Institute of Organoelement Compounds, USSR Academy of Sciences) were devoted to chemical applications of IR Fourier spectroscopy. During the last decade, this method has been rapidly introduced into practice as a result of progress in the field of computers and lasers and the creation of new effective algorithms for the Fourier transformation. The possibilities of the method for the analysis of substances in those cases where the application of traditional spectroscopy is limited by the energy, resolution, or the duration of the experiment were demonstrated: the determination of contaminants in the atmosphere, the identification of gas-chromatographic fractions, the measurement of the spectra of microspecimens, adsorbed molecules, and aqueous solutions, the study of electrochemical processes, semiconductors, molecules isolated in matrices at low temperatures, phase transitions, and polymer oxidation and degradation processes, and kinetic research. The application of IR Fourier spectroscopy to the measurement of photothermal ionisation IR emission and reflection spectra, IR circular dichroism, photoacoustic spectra, and near infrared Raman spectra was discussed. It was shown that the presence in the apparatus of a built-in computer creates new possibilities such as the treatment and transformation of the spectra, differential spectroscopy, and the creation and use of libraries of spectroscopic data.

Resonance Raman spectroscopy (RRS) was discussed in the lecture by G E Blyumberg (IKhBF,† Academy of Sciences of the Estonian SSR, Tallin). The principal features of resonance Raman spectra, the spectral profiles, and the information which can be extracted from them about vibronic interactions in the electronically excited state, the correspondence between the vibrational modes in the ground and excited states, the evolution of the system in the excited vibronic state, etc. were examined. A model was proposed for the behaviour of a molecular electronically excited impurity centre in the crystal participating in the multimodal interaction with the medium.

The lecture by D P Chernyakovskii (Yaroslavl' Polytechnic Institute, Yaroslavl') was devoted to electrochromism as a method for spectroscopic analysis. It dealt with the application of electrochromism spectra to the determination of the electrical parameters of molecules in the ground and electronically excited states, to the study of the migration of the electronic excitation energy, to the study of the thermomobility of macromolecules in polymer systems, to the observation of the shift of the chemical equilibrium in an electric field, etc.

The new trends in the application of vibrational spectroscopy to the study of adsorbed complexes and surface layers were reviewed in the lecture by V I Lygin (Moscow State University, Moscow). It was emphasised that the application of new methods, in the first place Fourier spectroscopy and Raman spectra with laser excitation, has raised surface research to a qualitatively new level. They make it possible to investigate virtually all types of catalysts and adsorbents even at a very low (down to 10^{-2} of a monolayer) degrees of surface coverage. By virtue of the application of the highly sensitive Fourier spectroscopy, it is possible to separate the spectrum of the surface layers from that of the bulk phase, to obtain differential spectra at different surface coverages, and to investigate the kinetics of adsorption and surface reactions. The measurement of the diffuse scattering spectra has led to appreciable progress in the study of highly scattering powdered adsorbents. New possibilities have arisen following the application of the method of incomplete internal reflection to the study of film adsorbents, membranes, electrochemical processes, etc.

Together with lectures on optical spectroscopy, two lectures devoted to methods of "electronic" spectroscopy were delivered. One of these, by Yu V Chizhov (Leningrad State University, Leningrad), concerned molecular photoelectron spectroscopy. It was emphasised that the modern techniques of the physical experiment, particularly the high monochromaticity of laser radiation, make it possible to increase greatly the accuracy of the measurement of the energy levels in molecules and to investigate various interactions between the electronic states in chemical compounds.

Another lecture was delivered by V I Panov (Moscow State University, Moscow). It reported new methods for the investigation of the surface, which permit the study of its microtopography and its atomic and electronic properties with atomic spatial resolution. These methods are based on the use of the scanning tunnel microscope (STM) and the atomic force microscope (AFM). The question of the application of the STM to the study of the atomic structure and of the electronic properties of single surface lattices of layered crystals, and to the observation of surface diffusion and the observation of single adsorbed atoms and molecules on the surfaces of solids was discussed in detail. The special interest in this method arose because of the possibility of a detailed study of the changes in the electronic and atomic properties of atoms in adsorption and catalysis. The ability of the method to determine the character of the chemical bonds formed by single atoms within a single unit cell was demonstrated in relation to the reaction of H_3 with the surface of silicon.

The possiblity of using the AFM in the study of the relief and interatomic interactions of non-conducting substances was demonstrated in the lecture. In contrast to the STM, it is possible to determine by this method the interatomic interaction constants for single atoms and molecules. Thus the combinaton of these methods permitted for the first time the observation of single atoms and the investigation of their electronic properties and of their interatomic interactions with atomic spatial resolution.

On the whole, the school was successful. The round table discussions, devoted to problems in modern spectroscopy of greatest current interest, in particular kinetic spectroscopy with time resolution, new spectroscopic instruments, and the spectroscopy of the surface, were very popular. In the concluding session, the participants expressed the unanimous view that it is essential that schools on new methods in molecular spectroscopy should be held regularly.
