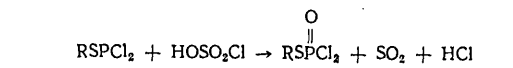
Studies on the thermal stability of P(III) acid thioesters using differential thermal analysis[20] indicate that the latter have quite a high stability when exposed to heat. In contrast to this, dialkyl phosphoranilidodithioites undergo thermal disproportionation even on distillation under vacuum or on heating in a sealed tube.[91] Products obtained from insertion of carbon disulphide into the exocyclic P–N bond of 2-dialkylamino-1,3,2-oxaphospholanes are also thermally unstable; on heating under vacuum they decompose to the original oxaphospholane with elimination of carbon disulphide.[65] At the same time, when 2-(*N*-dimethylthiocarbamoylthio)-4,5-benzo-1,3,2-oxaphospholane is exposed to heat, only 2-dimethylamino-2-thione-4,5-benzo-1,3,2-oxaphospholane is isolated:[65]

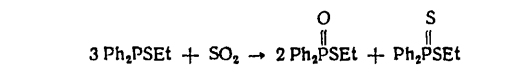
The change in the course of decomposition in this case is due to the presence of the condensed phenyl ring system.

The thermal thiol-thione isomerisation, due to *S,C*-migration of the phosphorus atom is of the greatest interest. Thus, phenyl diphenylphosphinothioite isomerises to triphenylphosphine sulphide only at 350 °C.[92] This type of rearrangement takes place much more readily in the case of ethyl phosphinothioites in the presence of iodosilane[93] and in a number of TTPA that contain electron-acceptor groups on the sulphur atom in the molecule, including those such as P(III) thioacid vinyl esters,[94] mixed thioanhydrides of P(III) acids and thioacetic[58,59] or dithiocarboxylic acids,[56] imidoyl phosphorothioites,[61] etc.

X = O, S, Nr'', CMe_3; R = alkyl, RO, R_2 R_2N, Ph;
R' = Me, iso-Pr, Ph, NHPh.

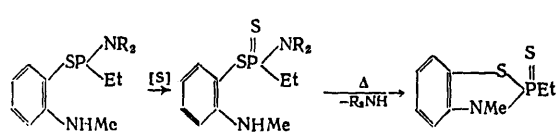


In the latter case it is necessary to isolate separately *S*-acetimidoyl phosphorothioites, which do not undergo thermal isomerisation but decompose to dialkyl phosphorothioites and acetonitrile, which is apparently due to the presence of a mobile proton on the imine nitrogen atom:[60]



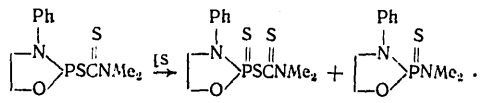
Thiol-thione isomerisation takes place on gentle heating of *S*-phosphorylated thioglycolic ester derivatives.[34]

2. Oxidation, addition of sulphur, and imination

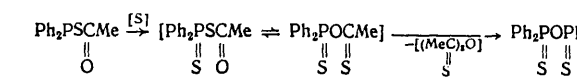


A characteristic feature of P(III) derivatives, including TTPA, is their tendency to undergo oxidation, addition of sulphur, and imination, which result in the formation of the corresponding P(V) derivatives. Thus, 2-benzthiazolyl phosphorothioites,[62] vinyl dialkyl phosphorothioite,[54] and *S*-thioacyl phosphorothioites[56] are readily oxidised with atmospheric oxygen to the corresponding phosphorothioates. Chlorosulphonic acid proved to be a convenient oxidising agent of TTPA such as alkyl phosphorodichloridothioite:[95]

The oxidation of diphenylphosphinothioite with sulphur dioxide[96] is accompanied by the formation of diphenylphosphinodithioate.

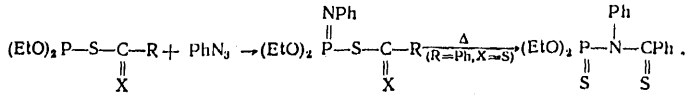


Reactions of elemental sulphur with TTPA have been studied quite extensively in recent years with the object of synthesising new types of P(V) acid derivatives, in particular, 3-thiophosphorylthioindoles,[49] 2-thiolobenzthiazolyl phosphorodithioates,[62] and optically active, *O,S*-dialkyl alkylphosphonodithioates.[97] The addition of sulphur to *S*-(*o*-methylaminophenyl) ethylphosphonamidothioite takes place in a similar manner.[46] However, in this case, the addition product cyclises during distillation to form 2-ethyl-2-thione-3-methyl-4,5-benzo-1,3,2-thiazaphospholane:



TTPA that contain electron-acceptor substituents react with sulphur in a more complex manner. Thus, as a result of the reaction of elemental sulphur with 2-dithiocarbamoyl-3-phenyl-1,3,2-oxazaphospholane, together with an addition product, 2-dimethylamino-2-thione-3-phenyl-1,3,2-oxaphospholane is also

formed by elimination of carbon disulphide from the dithiocarbamoyl derivative:[65]

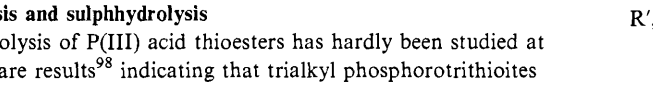


A dithionepyrophosphinate is obtained from *S*-acetyl diphenylphosphinothioite:[59]

It has been suggested[59] that at the first stage *S*-acetyl diphenylphosphinodithioate is formed, being converted to thioacetyl diphenylphosphinothioate as a result of phosphorotropic rearrangement; disproportionation of the latter gives the final product.

Trichlorophosphorus sulphide has been used in separate cases to introduce thione sulphur into TTPA molecules.[63]

Imination reactions of TTPA have in recent years only been studied in the case of the reaction of phenyl azide with vinyl phosphorothioites[54] and *S*-thioacyl phosphorothioites,[56] the corresponding phosphazo compounds being obtained:



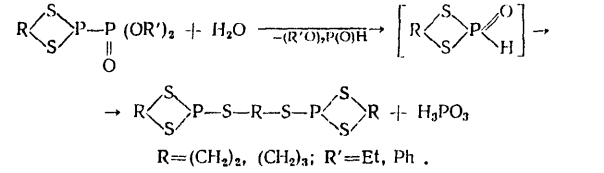
In the latter case[56] an imide-amide rearrangement can take place during distillation, which is due to migration of the thiocarbonyl group in the trio of atoms S–P–N.

3. Reactions of TTPA with proton-containing compounds

Substitution reactions on the trivalent phosphorus atom in a number of TTPA have been most effectively studied for reactions of the latter with compounds containing a mobile hydrogen atom. With these studies it was possible on the one hand to extend the methods for obtaining those TTPA already known in addition to new types and on the other hand to detect unusual pathways of particular reactions caused by the presence of alkylthio groups in the molecule.

(a) Hydrolysis and sulphhydrolysis

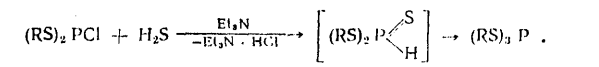
The hydrolysis of P(III) acid thioesters has hardly been studied at all. There are results[98] indicating that trialkyl phosphorotrithioites under normal conditions are stable to the action of water. At the same time, dialkyl phosphoramidodithioites are hydrolysed to ammonium salts of phosphorous acid and the corresponding phosphorotrithioites:[91,99]



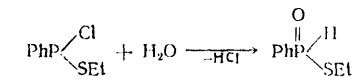
R=Et, Pr; R′=H, R″=Ph; R′=R″=Me .

It has been established that the rate of hydrolysis is dependent on the nature of the amide substituent on the trivalent phosphorus atom.[91,99]

In contrast to this, 2-benzthioazolyl phosphorodiamidothioites react with water and carbon disulphide with cleavage of the P–S bond and retention of the P–N bond[62] as a result of the pseudohalogen nature of the benzthiazolyl group.



The nature of the substituents also governs the rate of hydrolysis of 2-dialkoxyphosphoryl-1,3,2-dithiaphospholanes and the analogous dithiaphosphorinanes;[100] this takes place with an initial cleavage of the P–P bond followed by disproportionation of the phosphorodithioic acid formed:

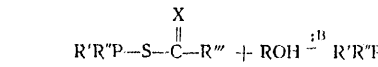


R=$(CH_2)_2$, $(CH_2)_3$; R′=Et, Ph .

It was shown[100] that hydrolysis can be accelerated by the action of acids and alkalis.

A similar disproportionation of intermediate dialkyl phosphorotrithioites has been suggested[101] in the sulphhydrolysis of cyclic and acyclic phosphorochloridodithioites.

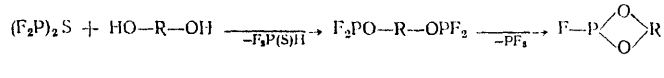
Only when the reaction of *S*-ethyl phenylphosphonochloridothioite with water was studied by ^{31}P NMR spectroscopy was the formation of *S*-ethyl hydrogen phenylphosphonothioite detected for the first time:[102]



The latter decomposes during the reaction in a similar manner to other derivatives of this class of products.[103]

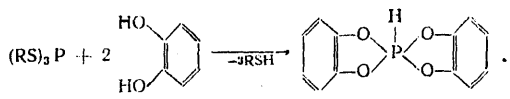
1-Chloro-1,5,2,3-phosphathiadiazole is readily hydrolysed by atmospheric moisture to give the initial dithiacarbazates.[63]

(b) Alcoholysis and thiolysis



Alcoholysis reactions have been studied in a fairly detailed manner for a number of TTPA. The ready cleavage of the P–S bond by treatment with alcohols occurs in those TTPA containing benzthiazolyl,[62] dithioacyl,[55] thioacetimidoyl,[60] dithiocarbamate,[65] and other[86] groups with electron-withdrawing substituents on the sulphur atom.

R′, R″=RO, R_2N, Ph; R′R″=OCH_2CH_2NPh; R‴=alkyl, aryl, R_2N; X=S, NH.

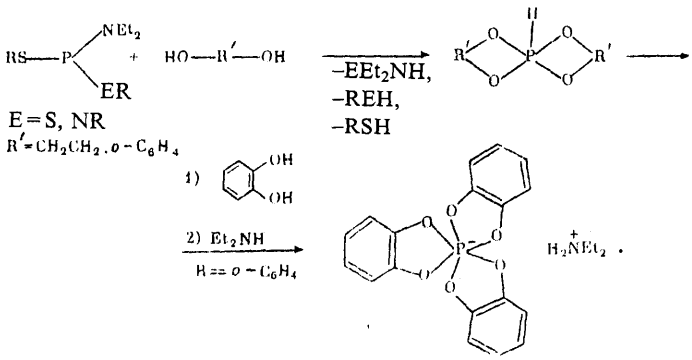


At the same time, alcoholysis of *tris*(*N*,*N*-dialkylaminothiocarbamoyl) phosphorotrithioite takes place under more severe conditions to give a complex mixture of products;[66] this is apparently due to the presence of intramolecular coordinate bonds in this type of TTPA.[72,104]

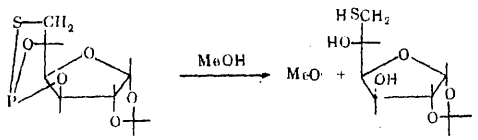
There has been extensive study of the reactions of bis(difluorophosphine) sulphide with alcohols, phenols, and diols, which give different types of phosphoromono- and phosphorodi-fluoridites:[105]

Cleavage of the P–S bond in trialkyl phosphorotrithioites is effected by sodium ethoxide[106] and also pyrocatechol.[107] In the latter case only *bis*(*o*-phenylenedioxy)phosphorane is formed,

whatever the ratio of the initial reactants.

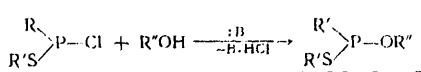


The reaction of dialkyl phosphoramidodithioites with alcohols takes place under severe conditions to give trialkyl phosphite and phosphorotrithioites:[99]



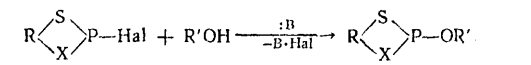
$$(RS)_3PNEt_2 + R'OH \xrightarrow{-Et_2NH} (RS)_2POR' \xrightarrow[-2RSH]{2R'OH} (R'O)_3P\,.$$
$$(RS)_2PNEt_2 + RSH \xrightarrow{-Et_2NH} (RS)_3P,\ R=R'=Et,\ Bu$$

Alcoholysis and phenolysis of bis(*N,N*-diethylcarbamoyl)diethylphosphoramidodithioite gives similar products.[66] It was established[99] that the amine generated at the first stage of the reaction catalyses the subsequent replacement of the alkylthio groups on the trivalent phosphorus atom by alkoxyl groups. When alcoholysis and phenolysis is carried out with removal of the amine, it is possible to stop the process at the stage where mixed *O,S,S*-phosphorodithioites are formed.[99] In this case the reaction is accelerated in the presence of acidic catalysts.



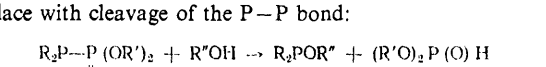
The reaction of phosphoromono- and phosphorodi-amidothioites with aliphatic and aromatic diols takes place with substitution of amide and alkylthio groups on the phosphorus atom, giving either a spirophosphorane with a P–H bond or compounds with a hexacoordinated phosphorus atom,[99] depending on the nature of the diol:

In a series of P(III) acid *O,S*-thioesters alcoholysis was only studied in the case of bicyclophosphorothioites of sugars:[51]



Anhydride derivatives of P(III) thioacids are widely used for the phosphorylation of alcohols and phenols. Thus, by alcoholysis of *S*-alkyl phosphonochloridothioites in the presence of the natural alkaloid, brucine, it was possible to obtain readily racemising optically active *O,S*-dialkyl phosphonothioites:[97]

R = Et, Bu; R′ = iso-Pr, iso-Bu, C_6H_{13}; R″ = Me, Et; B – brucine.



In the absence of a base, this type of reaction with phenylphosphonous acid derivatives does not stop at the stage where mixed *O,S*-thioesters are formed but gives partial *O*-alkyl phenylphosphonites by further phosphorylation of alcohol.[102]

A number of alkoxy derivatives of phosphorus-containing heterocycles have been obtained by phosphorylation of aliphatic alcohols and phenols with 2-halo-1,3-2-oxathiaphospholanes[42,43,108] and the analogous oxathiaphosphorinanes,[109] and also with 1-chloro-1,5,2,3-phosphathiadiazoles:[63]

R = $CH_2CH_2CH_2$, *o*-C_6H_4, RS–C=N, Hal = Cl, Br;
X = O, S, NR″; R′ = alkyl, Ph, *o*-FC_6H_4 etc.

Dialkyl acetyl phosphorodithioites,[110] 2-dialkyloxyphosphoryl-substituted 1,3,2-dithiaphospholanes or 1,3,2-dithiaphosphorinanes, and also their acyclic analogues can be used for the mild phosphorylation of aliphatic alcohols.[100] Alcoholysis of the latter takes place with cleavage of the P–P bond:

R_2 = S $(CH_2)_n$ S, $(BuS)_2$; *n* = 2, 3; R′ = Et, Ph; R″ = Me, Et .

For cyclic compounds the process is complicated by scission of the P–S bond in the ring, and the result depends on the structure of the compound, ratio of reactants, temperature, and reaction time.[100]

Phosphorylation of thiols with TTPA has not been studied very much. It was shown that the exocyclic P–Hal bond in 2-halo-1,3,2-dithia-[35,109] and 2-halo-1,3,2-oxathia-phospholanes[42,43] readily undergoes thiolysis in the presence of a base in a similar manner to the reactions with alcohols.

Information is also available on the thiolysis of P–S–P bonds:[105,111]

R′ = R″ = R‴ = F, X – unshared electron pair; R′ = Et, R″ = Ph, R‴ = EtO; X = S

In recent years it has been established that acyclic acyl phosphorodithioites[110,112] and phosphoramidodithioites,[99,113] in contrast to their oxygen analogues which when treated with thiols are converted in most cases to thiophosphoryl compounds, can be successfully used to phosphorylate thiols:

X = OCOMe, Et_2N, PhNH; R = Et, Bu; R′ = Et, Bu, $PhCH_2$, Ph .

(c) Aminolysis

The synthesis of various P(III) thioacid amides is usually carried out by phosphorylation of primary and secondary amines with suitable P(III) halides. In recent years this method has been widely used to obtain 2-amino derivatives of 1,3,2-diheterophospholanes and 1-amido-1,5,2,3-phosphathiadiazoles.[63]

R = C_6H_4, RS–C=N; X = O, NR″; R′ = H, alkyl, Ph.

Together with dialkyl phosphorochloridodithioite,[113] acyl phosphorodithioites[112] and also mixed anhydrides of phosphorodithious and phosphorodithioic acids[114] have been proposed as

phosphorylating agents for the synthesis of acyclic phosphoramidodithioites:

$$(RS)_2PX + 2\,R'R''NH \rightarrow (RS)_2PNR'R'' + R'R''NH\cdot HX$$
X=Cl, OCOMe, (RO)$_2$P (S) S; R'=R''=Et; R'=H, R''=Ph .

The difficult-to-prepare aminodifluorophosphines can readily be obtained by reaction of primary and secondary amines with bis(difluorophosphine) sulphide.[105] The P–S bond also readily undergoes aminolysis in those TTPA containing benzthiazolyl,[62] dithioacyl,[55] thioacetimidoyl,[60] and dithiocarbamate[65] groups which have a pseudohalogen nature.

(d) Reactions with acids

Up to the end of the 1970's there was virtually no information in the literature about the reactions of TTPA with acids. At the beginning of the 1980's, as a result of a systematic study of the chemical behaviour of P(III) acid thioesters reacting with acids it was established[98] that in contrast to the oxygen analogues—phosphites—the pathway of the Arbuzov reaction is not followed but cleavage of the P–S bond occurs. Thus, the reactions of HCl with trialkyl phosphorotrithioite,[115] *S*-phosphorylated thioglycolates,[34] and *O,O*-dialkyl *S*-acetimidoyl phosphorothioites[60] occur with replacement of the alkylthio group on the trivalent phosphorus atom:

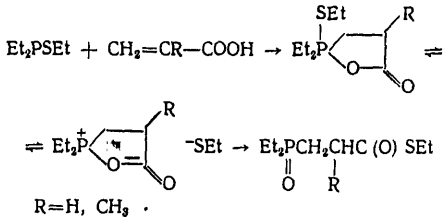
$$R_2'P-SR + HCl \rightleftharpoons R_2'P-Cl + RSH$$
R=Et, CH_2COOEt, C(Me)=NH; R'=EtS, RO, Cl .

Diphenylphosphinothioite esters react with HI in a similar manner,[116] but in this case the reaction is complicated by secondary processes.

Only in the case of *S*-germyl phosphorodifluoridothioite does cleavage of the S–Ge bond with hydrogen halides occur;[76] this is probably due to the greater electrophilicity of the germanium atom:

$$F_2PSGeH_3 + HX \rightarrow F_2P(S)H + XGeH_3$$
X=Cl, Br .

Studies of the reactions between P(III) acid thioesters and carboxylic acids showed[103,115] that they occur under severe conditions with cleavage of the P–S bond and formation of carboxylic acid thiol esters and *O*-containing phosphorus acids:



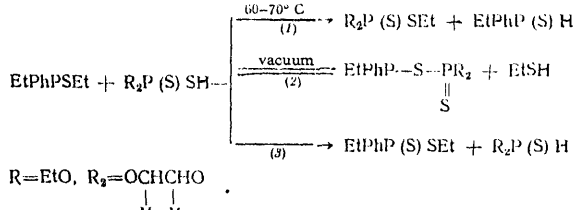
$$R'R''PSR + R'''COOH \xrightarrow{100-140^\circ C} R'R''POCOR''' + RSH$$
$$R'R''POCOR''' + R'''COOH \rightarrow R'R''P(O)H + (R'''CO)_2O$$
$$(R'''CO)_2O + RSH \rightarrow R'''C(O)SR + R'''COOH$$
R'=R''=SR; R=Et, Pr; R'''=Ph; R=R'=Et, R''=Ph, R'''=Me
R'=Et, Ph; R''=SR; R'''=Ph .

If there are alkylthio groups present on the phosphorus atom in the *O*-containing acids, they are unstable during the reaction and decompose with elimination of mercaptan to give P(III) acid anhydrides.[103]

Introduction of chlorine atoms into the acetic acid molecule has a substantial effect on the course of the reaction between the latter and P(III) acid thioesters.[117,118] In this case, instead of acidolysis, replacement of the alkylthio group on the trivalent phosphorus atoms by a chlorine atom takes place, giving the corresponding P(III) acid chlorides as well as oxidation products from the initial thioesters and products from dechlorination of carboxylic acids as the corresponding thiol esters:[118]

$$2\,\begin{matrix}R'\\R''\end{matrix}\!\!>\!PSR + CCl_nH_{3-n}COOH \rightarrow \begin{matrix}R'\\R''\end{matrix}\!\!>\!PCl + \begin{matrix}R'\\R''\end{matrix}\!\!>\!P(O)SR + CCl_{n-1}H_{4-n}C(O)SR$$
R'=R''=SR; R=Et, Pr; n=3; R'=Ph, R''=Et; n=3;
R'=Et, R''=Ph; R=Et, n=1–3 .

In studies on the reactions of phosphinothioites with α,β-unsaturated carboxylic acids, the previously unknown 1:1 addition products—diethyl-β-ethylthiocarbonylalkylphosphine oxides—were obtained:[119,120]



R=H, CH_3 .

When the reaction was monitored using IR and ^{31}P NMR spectroscopy[120] it was possible to detect an initially formed monocyclic phosphorane with a P–S bond, which probably then decomposes via an intermediate quasiphosphonium compound to the final phosphine oxide.

In contrast to phosphinothioites, phosphorotrithioites and phenylphosphonodithioites cause α,β-unsaturated carboxylic acids to polymerise.[120]

The reaction conditions have a significant effect on the course of the reaction between P(III) acid thioesters and organic acids. While ethylphenylphosphinothioite reacts with phosphorodithioic acids at 60–70 °C to form diethyl phosphorodithioate and ethylphenylphosphinothious acid [route (1)], at room temperature under vacuum a mixed anhydride of ethylphenylphosphinothious acid and the corresponding phosphorodithioic acid is obtained [route (2)]:[111]

R=EtO, R_2=OCHCHO (Me Me) .

It should be noted that whatever the method used to carry out the reaction it is accompanied by a subsidiary process involving desulphurisation of the phosphorodithioic acid by the initial phosphinothioite [route (3)].[111]

In a study of these reactions an unusual cleavage of the P–S bond in ethylphenylphosphinothioite on treatment with phosphorothious acid under vacuum was identified for the first time:[111]

$$EtPhPSEt + R_2P(S)H \xrightarrow[-EtSH]{vacuum} EtPhP(S)-PR_2 .$$

A similar route also occurs in the reaction of dialkyl phosphites with Schrader's anhydride[121] and related compounds[122] in the presence of a base:

$$R_2P(S)-P(OEt)_2 + (EtO)_2P(O)H \xrightarrow{Et_3N} R_2P(O)-P(OEt)_2 + (EtO)_2PSH\cdot NEt_3$$
R= (EtO)$_2$P (S) S; R_2=SCHMeCH$_2$S .

At the same time, dialkyl phosphoramidodithioites react with mineral[113] and organic[112,114] acids, retaining the P–S bond and replacing the amide group on the trivalent phosphorus atom to form

the corresponding P(III) thioacid anhydride derivatives:

$$(RS)_2PNR'R'' + 2HX \rightarrow (RS)_2PX + R'R''NH \cdot HX$$
R=Et, Pr; R'=R''=Et; R'=H, R''=Ph; X=Cl, OCOMe, $(RO)_2P(S)S$.

Acyclic[114,123,124] and cyclic[122] phosphorochloridodithioites in the presence of triethylamine react in a similar manner with organic acids:

$$(RS)_2PCl + HX \xrightarrow{Et_3N} (RS)_2PX + Et_3N \cdot HCl$$
R=Et, Pr; X=OCOMe, $(RO)_2P(S)S$, $(EtO)_2P(O)$.

In the absence of base, acidolysis of ethyl phosphorodichloridothioite takes place only on heating with removal of an alkylthio group and formation of ethyl thioacetate, acetyl chloride, and metaphosphorous anhydride:[125]

$$EtSPCl_2 + 2CH_3COOH \xrightarrow[-HCl]{70^\circ C} CH_3CSEt + CH_3CCl + 1/n\left[-\underset{\underset{O}{\|}}{\overset{\overset{H}{|}}{P}}-O-\right]_n.$$

According to the findings of ^{31}P NMR spectroscopy, *S*-ethyl phenylphosphonochloridothioite reacts with acetic acid at 0 °C to form phenyldichlorophosphine and products derived from its stepwise acidolysis—phenylphosphonous acid and its monochloride.[102]

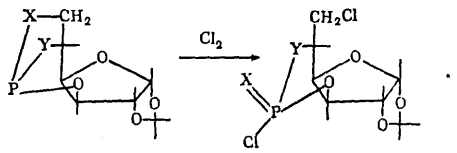
In their reactions with α,β-unsaturated acids dialkyl phosphorochloridodithioites behave similarly to other P(III) acid chlorides, being converted to the corresponding diethyl β-chloroformylalkylphosphonodithioates:[126]

$$(EtS)_2PCl + CH_2{=}CR{-}COOH \rightarrow (EtS)_2P\underset{\underset{O}{\|}}{C}H_2\underset{\underset{R}{|}}{C}HC(O)Cl$$
R=H, Me.

In studies on the reactions of acyl phosphorodithioites with mineral and organic acids[123,127] it was established that, in contrast to their oxygen analogues which react with acids according to the Arbuzov reaction mechanism, in these compounds replacement of the acetoxyl group on the trivalent phosphorus atom occurs with retention of its coordination:

$$(RS)_2POCOMe + HX \rightleftarrows (RS)_2PX + MeCOOH$$
R=Et, Pr; X=Cl, OCOPh, $(RO)_2P(S)S$

In this case the possiblity of transacylation of the acetoxyl group in acyl phosphite was demonstrated experimentally for the first time.[123]



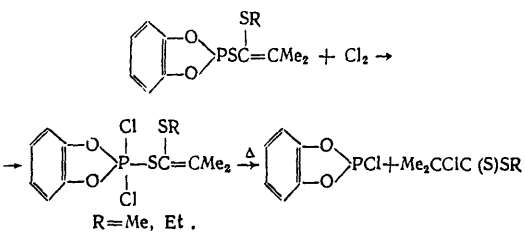
4. Reactions of TTPA with halogens and halogenated electrophilic reagents

The discovery by A E Arbuzov of the rearrangement of trivalent phosphorus acid esters to pentavalent phosphorus acid esters by treatment with alkyl halides formed the start of a systematic study of P(III) derivatives in reactions with halogenated electrophilic reagents. It is obvious that these studies could not also cover TTPA. By studying the chemical behaviour of the latter in reactions with alkyl and acyl halides in the 1960's and 1970's, with the most detailed treatment given in one review,[15] it was possible to establish some of these reaction mechanisms. It was found that in a number of cases the classical Arbuzov reaction route does not occur but the alkylthio group on the trivalent phosphorus atom is replaced and its coordination is retained. Moreover, there was a complete range of halogenated electrophilic reagents used up in this connection and there were virtually no studies on the reactions of TTPA with other compounds containing a halogen atom. At the beginning of the 1980's both in the USSR and abroad studies were published on the chemical behaviour of TTPA in reactions with halogens and halogenated reagents. Of particular interest are the results of those studies in which, as in the case of alkyl and acyl halides, there are deviations from the classical route of the Arbuzov reaction.

It was shown in 1980[76] that chlorine cleaves the S–Ge bond in *S*-germyl phosphorodifluoridothioite.

$$F_2P\underset{\underset{S}{\|}}{S}GeH_3 + Cl_2 \rightarrow F_2P\underset{\underset{S}{\|}}{C}l + ClGeH_3.$$

An interesting mechanism was found[128] in a study of the chlorination of 3,5,6-bicyclophosphorithioites of sugars:



It was shown that the direction of chlorination is determined stereochemically, in all cases nucleophilic substitution being most favourable on the sterically accessible primary C(6) carbon atom.[128]

On mixing equimolar quantities of diphenylphosphinothioite ester and iodine, unstable quasiphosphonium compounds were subsequently obtained.[116]

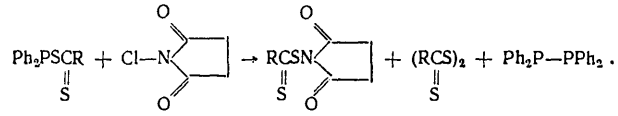
$$Ph_2PSR + I_2 \xrightarrow[CH_2Cl_2]{-30^\circ C} Ph_2\overset{\overset{I}{|}}{\overset{+}{P}}SRI^- \xrightarrow[-EtI]{(R=Et)} Ph_2P\underset{\underset{S}{\|}}{I}.$$

When R = Et, the quasiphosphonium compound decomposes in accordance with the second stage of the Arbuzov reaction.

Quasiphosphonium compounds[35] as well as chlorophosphoranes[43] are also formed by chlorination of 2-chloro-4,5-benzo-1,3,2-diheterophospholanes that contain an endocyclic P–S bond. As a result of the reaction between chlorine and *S*-vinyl pyrocatechyl phosphorothioite, the first examples of vinylthiochlorophosphoranes were obtained, partially decomposing when distilled under vacuum.[129] In this case products from replacement of the vinylthio group on the trivalent phosphorus atom—pyrocatechyl phosphorochloridite and methyl α-chloroisobutyrodithioate—are isolated:

R=Me, Et.

Chlorination and bromination of phosphorotrithioites take place with the formation of substitution products—dialkyl phosphorohalodithioites:[130]



$$2(RS)_3P + Hal_2 \rightarrow (RS)_2PHal + (RS)_3PS + RHal$$
R=Me, Et, Pr; Hal=Cl, Br.

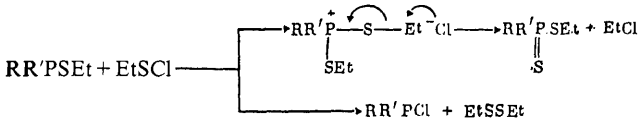
In this reaction phosphorotetrathioate and the respective alkyl halides are formed as by-products.[130]

The chlorination of trialkyl phosphorotrithioites with phosphorus pentachloride takes place in a similar manner:[130]

$$2(RS)_3P + PCl_5 \rightarrow (RS)_2PCl + (RS)_3PS + RCl + PCl_3$$
R=Et, Pr

The reaction of thioacyl phosphinothioites with *N*-chlorosuccinimide probably also leads to replacement of the *S*-thioacyl group by a chlorine atom, but products derived from further reactions are isolated in this case:[55]

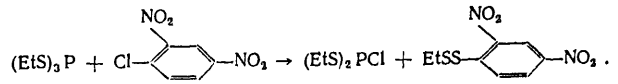
The possibility that TTPA take part in exchange reactions with sulphenyl chlorides was first shown in 1980:[19]



$$(CF_nCl_{3-n}S)_xPCl_{3-x} + xCF_nCl_{3-n}SCl \xrightarrow{-PCl_3} x(CF_nCl_{3-n}S)_2 .$$

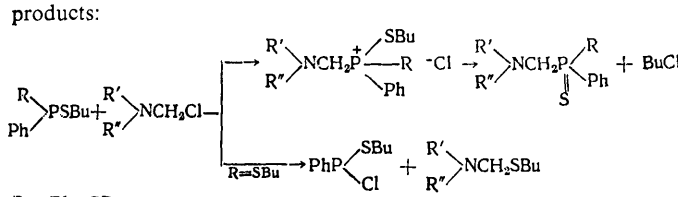
The rate of this reaction decreases as the degree of chlorination of the reaction partners increases.

It was later found[131] that in the reaction between methyl phosphorodichloridothioite and trifluoromethylsulphenyl chloride the Arbuzov rearrangement does not occur and *S*-(trifluromethylthiomethyl) phosphorodichloridothioite is unexpectedly formed:



$$CH_3SPCl_2 + CF_3SCl \rightarrow CF_3SCH_2SPCl_2 + HCl .$$

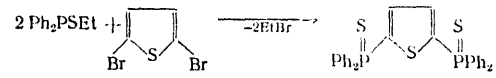
Retention of the same coordination of the phosphorus atom together with an Arbuzov rearrangement also take place for the reactions of phosphorothioites and phosphinothioites with ethylsulphenyl chloride:[132]



R=R'=SEt; R=Et, R'=Ph .

The course of the reaction is determined by the temperature, use of solvents, presence of acidic catalysts, and the nature of the sulphenyl chloride.[132] In particular, replacement of ethylsulphenyl chloride by 2,4-dinitrophenylsulphenyl chloride in a reaction with triethyl phosphorotrithioite has the result that the Arbuzov reaction pathway does not occur in this case but an alkylthio group on the trivalent phosphorus atom is replaced by a chlorine atom to give phosphorochloridodithioite and 2,4-dinitrophenyl ethyl disulphide:[132]

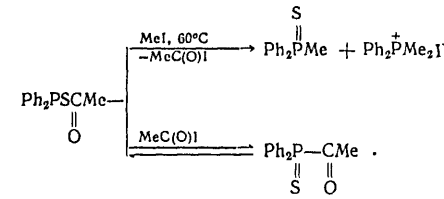
During the last ten years the study of the chemical behaviour of TTPA in reactions with alkyl and acyl halides has been continued. It transpired that chloromethyl derivatives of amines behave in a similar manner to alkyl halides in reactions with P(III) acid thioesters.[133] While phosphinothioites react with them on the phosphorus atom to form Arbuzov reaction products, phosphonodithioites give products from substitution of the alkylthio group on the trivalent phosphorus atom as well as Arbuzov rearrangement products:



R = Ph, SBu.

The course of the reaction is determined by the polarity of the C—Cl bond; as the latter increases there is a greater tendency towards a substitution reaction.[133]

Phosphoramidothioites also react with alkyl halides by two routes—the Arbuzov reaction pathway and replacement of an alkylthio group.[134] The occurrence of a particular route is determined by the nature of the initial reactants and the presence of a catalyst ($ZnCl_2$).



Mixed P(III) acid *O,S*-thioesters react with alkyl halides[36] and 2,5-dibromothiophene[135] in a complex and unclear manner.[135] Only in the case of reaction of the latter with *S*-ethyl diphenylphosphinothioite was it possible to isolate 2,5-bis(diphenylphosphinothioyl)-thiophene:[135]

New data has been obtained on the reactions of phosphorotrithioites with alkyl halides. Until recently it was generally thought[15] that these reactions occur with retention of the same coordination of the phosphorus atom. However, the first example of the formation of only classical Arbuzov reaction products was recently found:[136]

$$(EtS)_3P + MeI \rightarrow (EtS)_2P(=S)Me + EtI .$$

S-Acetyl diphenylphosphinothioite reacts with methyl iodide in an interesting manner.[59] Depending on the process conditions, either methyldiphenylphosphine sulphide and dimethyldiphenylphosphonium iodide or acetyldiphenylphosphine sulphide can be obtained, with the latter formed by a reversible isomerisation of the initial acetyl phosphinothioite under mild conditions by the action of trace quantities of acetyl iodide:[59]

In contrast to this, in the reaction between *S,S*-dialkyl acetyl phosphorodithioites and carboxylic acid halides the coordination of the phosphorus atom remains the same:[123,137]

$$(RS)_2POCOMe + R'C(O)X \rightarrow (RS)_2PX + R'C(O)OC(O)Me$$
R=Et, Pr; R'=Me, CCl_3, Ph; X=Cl, Br .

Dialkyl phosphoramidodithioites also react in a similar manner:[138]

$$(RS)_2PNEt_2 + R'C(O)X \rightarrow (RS)_2PX + R'C(O)NEt_2$$
R=Et, Pr; R'=Me, Ph; X=Cl, Br .

The Arbuzov reaction route, which is typical for the oxygen analogues, namely, acyl phosphites and phosphoramidites, does not occur in a single case, and the functional group is replaced by a halogen atom to give the corresponding phosphorohalodithioites.

In studies on the reactions of TTPA with acyl halides,[123,138,139] the effect of different factors, including the presence of acidic catalysts, on their rate was determined, and it was possible[140] to propose a general acid-catalysed mechanism for the reaction between TTPA and carboxylic acid halides.

$$(RS)_2P—A + HX \rightleftharpoons (RS)_2P—X + HA \xrightarrow{R'C(O)X} (RS)_2PX + R'C(O) + HX$$
A=SR, NR_2, OCOR'

Retention of the same coordination of the phosphorus atom also occurred in reactions of TTPA with polyhalomethanes. Thus, trialkyl phosphorotrithioites undergo a reaction with CCl_4 to form trichloromethylphosphonodithioite, phosphorochloridodithioite, and disulphide:[134,141]

$$2\,(RS)_3P + CCl_4 \rightarrow (RS)_2PCCl_3 + (RS)_2PCl + RSSR$$
$$R=Et,\ Pr,\ Bu\ .$$

At the same time, trichlorobromomethane under similar conditions gives phosphorotetrathioate and alkyl bromide together with trichloromethylphosphonodithioite:[134]

$$2\,(EtS)_3P + CCl_3Br \rightarrow (EtS)_2PCCl_3 + (EtS)_3PS + EtBr\ .$$

This contrast in the final reaction products is due to the different routes of side reactions.[134]

When phosphoramidothioites react with CCl_4 the alkylthio group on the trivalent phosphorus atom is also replaced and the coordination remains the same.[134,142] However, in this case the sole reaction products are the corresponding P(III) acid chlorides and trichloromethyl alkyl sulphide.

$$\begin{matrix} R' \\ Et_2N \end{matrix}\!\!>\!P\!-\!SR + CCl_4 \rightarrow \begin{matrix} R' \\ Et_2N \end{matrix}\!\!>\!P\!-\!Cl + CCl_3SR$$
$$R' = Et_2N,\ SR;\ R = Et,\ Pr\ .$$

In the case of phosphoramidothioites this reaction takes place only in the presence of Lewis acids.[142]

It was recently established that, in contrast to trialkyl phosphites, phosphorothioites[143] and phosphonothioites[144] reacted with dichloroacetylene not by the classical Arbuzov rearrangement route but they formed the previously unknown products derived by 'insertion' of dichloroacetylene into the P–S bond:

$$R'P(SR)_2 + Cl\!-\!C{\equiv}C\!-\!Cl \rightarrow \begin{matrix} R' \\ RS \end{matrix}\!\!>\!P\!-\!C(Cl){=}C(Cl)\!-\!SR$$
$$R' = Et,\ Ph,\ SR;\ R = Et,\ Pr\ .$$

5. Addition of TTPA to multiple bonds and to olefin oxides

Addition reactions of TTPA to C=O, C=C, C=N, N=N, and other multiple bonds have until recently constituted a little-studied area of organophosphorus chemistry; this was related to the low nucleophilicity of the trivalent phosphorus atom in TTPA. The preparation of new types of TTPA and the use of a number of synthetic procedures, in particular, the introduction of a third reagent into the reaction mixture, have made it possible in recent years to extend considerably the range of addition reactions involving TTPA.

(a) Addition to a carbon–oxygen multiple bond

Reactions with aldehydes and ketones. Phosphorotrithioites react with benzaldehyde at 130 °C in a complex manner to give α-alkylthiobenzylphosphonodithioates, trialkyl phosphorotrithioates, and 1-phenyl-1,1-bis(alkylthio)methanes:[145]

$$(EtS)_3P + PhCHO \xrightarrow{180^\circ C} (EtS)_2P(O)\!-\!CHPh(SEt) + (EtS)_3PO + (EtS)_2CHPh$$
$$(EtS)_3P + PhCHO \xrightarrow{200^\circ C} (EtS)_3PS + EtSCH_2Ph$$

It was shown[145] that the course of the reaction depends on the temperature. When this is increased to 200 °C, phosphorotetrathioate and ethyl benzyl sulphide are formed.

An effective synthetic procedure that made it possible to add on P(III) acid thioesters to aldehydes and ketones under mild conditions was the introduction of a third electrophilic reagent which served as an activator into the reaction mixture. Thus, phosphonothioites and phosphorothioites in the presence of an equimolar quantity of dry HCl underwent reaction with benzaldehyde[145] and acetone[146] even at room temperature to form α-alkylthio-substituted phosphonodithioates and phosphinothioates. The latter are formed as complexes with HCl, dissociating on distillation to give the final products;

$$RP(SEt)_2 + R'R''C{=}O + HCl \rightarrow \left[\begin{matrix} R & O\cdots HCl \\ & \| \\ & P\!-\!CR'R'' \\ EtS & SEt \end{matrix}\right] \xrightarrow[-HCl]{\Delta} \begin{matrix} R & O \\ & \| \\ & P\!-\!CR'R'' \\ EtS & SEt \end{matrix}$$
$$R = EtS,\ Et$$

Complex-formation apparently inhibits these reactions in the presence of catalytic quantities of HCl by deactivating the latter, so an equimolar quantity is required.[146]

At the same time, the reaction of *S*-acetyl diphenylphosphinothioite with benzaldehyde in the presence of HCl gives bis[α-(diphenylphosphoryl)benzyl] sulphide, which is isolated from the reaction mixture as a complex with two moles of HCl. In addition to that, α-acetoxybenzyldiphenylphosphine sulphide is formed in small quantity:[147]

$$Ph_2P(O)SCMe + PhCHO + HCl \rightarrow (Ph_2P(O)CHPh)_2S\cdot 2HCl + Ph_2P(S)\!-\!CHPh(OCOMe)$$
$$(Ph_2P(O)CHPh)_2S\cdot 2HCl \xrightarrow[-2Et_4N\cdot HCl]{2Et_4N} (Ph_2P(O)CHPh)_2S$$

This reaction route involves the initial replacement of the thioacetyl group by the action of HCl.[147]

When equimolar quantities of trimethylhalosilanes are used as activating agents in the reactions of phosphinothioites with benzaldehyde, two types of reaction take place depending on the nature of the halosilane. Benzaldehyde reacts with *S*-ethyl diphenylphosphinothioite in the presence of trimethylchlorosilane under mild conditions (–60 to –50 °C), resulting in the isolation of α-siloxybenzylphosphine sulphide as an addition product:[149]

$$Ph_2PSEt + PhCHO + Me_3SiCl \xrightarrow{200^\circ C} Ph_2P(S)\!-\!CHPh(SEt) + Ph_2PCl + (Me_3Si)_2O\ .$$

In contrast to trimethylchlorosilane, trimethyliodosilane can be used to carry out the reaction of phosphinothioites with benzaldehyde under mild conditions (–60 to –50 °C), resulting in the isolation of α-siloxybenzylphosphine sulphide as an addition product:[149]

$$\begin{matrix} Ph \\ R \end{matrix}\!\!>\!P\!-\!SEt + PhCHO + Me_3SiI \rightarrow \left[\begin{matrix} Ph & OSiMe_3 \\ & | \\ R & P\!-\!CHPh\ I^- \\ & | \\ & SEt \end{matrix}\right] \xrightarrow{-EtI} \begin{matrix} Ph & S \\ & \| \\ R & P\!-\!CHPh \\ & | \\ & OSiMe_3 \end{matrix}$$
$$R = Et,\ Ph$$

The formation of an intermediate quasiphosphonium compound has been detected by studying this reaction using ^{31}P NMR spectroscopy at different temperatures.[149] It was suggested[149] that coordination of the silicon atom with the oxygen of the carbonyl group must precede nucleophilic attack by the phosphorus atom.

By using PCl_3 as a third electrophilic reagent in the reaction of phosphorotrithioites with ketones it was possible to obtain a number of α-alkylthioalkylphosphonodichloridates:[150]

$$(RS)_3P + 3R'R''C{=}O + 2PCl_3 \rightarrow 3Cl_2P(O)CR'(SR)R''$$

R = Et, Pr; R′ = R″=Me; R′=Et, R″=Me .

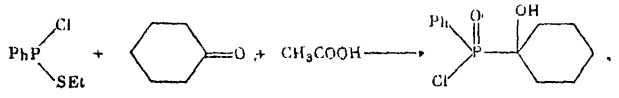
The formation of the latter is evidently due to an initial exchange reaction between phosphorotrithioite and PCl_3 which is already known in the literature[12] followed by addition of the resulting alkyl phosphorodichloridothioite to the carbonyl compound. It has been established[151] that the reaction of *S*-alkyl phosphorodichloridothioites with aldehydes and ketones takes place with retention of the P–Cl bond and cleavage of the P–S bond, in contrast to other P(III) acid chlorides:

$$Cl_2PSEt + RR'C{=}O \rightarrow Cl_2P(O)CRR'(SEt)$$

R=R′=Me; R=H, R′=Ph .

Hydrogen chloride catalyses this reaction.

It should be noted that before the study of Al'fonsov and co-workers[151] there was only information in the literature about the reactions of P(III) thioacid chlorides with carbonyl compounds in the presence of proton-containing reactants. Thus, reaction of P(III) thioacid chlorides with aldehydes and ketones in the presence of an equimolar quantity of water gives *S*-alkyl esters of α-hydroxy-substituted phosphinothioates and phosphonodithioates:[102]



$$(RS)(R')P(O)Cl + H_2O \xrightarrow{-HCl} (RS)(R')P(O)H \xrightarrow{R'''R''C{=}O} (RS)(R')P(O)CR''R'''(OH)$$

R′ = Et, Ph, RS; R = Me, Et, Pr; R″ = H, Me

R‴ = Me, Pr, $(CH_2)_4$, $(CH_2)_5$, CCl_3, Ph, *o*-$O_2NC_6H_4$.

A detailed study of this reaction using ^{31}P NMR spectroscopy formed the basis of the proposal by Kardanov and co-workers[102] that the reaction takes place via hydrolysis of the acid chlorides followed by addition of the resulting P(III) thioacids to the carbonyl compound.

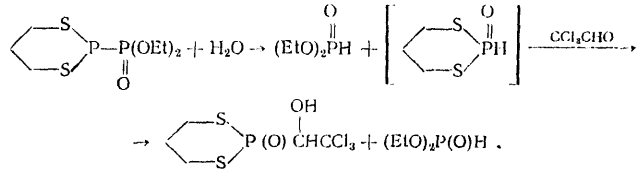
Replacement of water by acetic acid results in the formation of a product that does not contain sulphur:[102]

Recently[152] a simple and convenient method for the preparation of alkythio-substituted phosphinothioates and phosphonodithioates was developed on the basis of the reaction of P(III) thioacid chlorides with carbonyl compounds in the presence of thiols:

$$(R)(EtS)P(O)Cl + R'R''C{=}O + EtSH \rightarrow (R)(EtS)P(O)CR'(SEt)R'' + HCl$$

R = Et, EtS; R′=R″=Me; R′=H, R″—Ph .

However, compounds with an activated carbonyl group, in particular, acetyl phosphonates, do not undergo this reaction.[153] At the same time, the latter react with diethyl phosphorochloridodithioite in the presence of triethylamine to form α-(diethoxyphosphoryl)vinyl phosphorodithioites:[154]



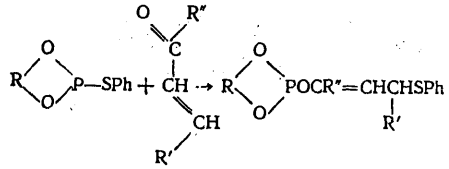
$$(EtS)_2PCl + (EtO)_2P(O)CH_3 \xrightarrow[-Et_3N\cdot HCl]{Et_3N} (EtS)_2POC(OEt)_2{=}CH_2 .$$

Other anhydride derivatives of P(III) thioacids have only been studied in a reaction with chloral. Thus, cyclic[155] and acyclic[110] acyl phosphorodithioites react with it to form new α-acetoxy-β,β,β-trichloroethylphosphonodithioates:

$$R_2POCOCX_3 + CCl_3CHO \rightarrow R_2P(O)CH(OCOCX_3)CCl_3$$

R=EtS, X=H; R_2 = SCH_2CH_2S, X=F .

2-Diethoxyphosphoryl-1,3,2-dithiaphosphorinane does not react with chloral even on boiling, but when water is added to the reaction mixture the P–P bond is cleaved even at room temperature to form 2-oxo-2-(β,β,β-trichloro-α-hydroxyethyl)-1,3,2-dithiaphosphorinane:[156]



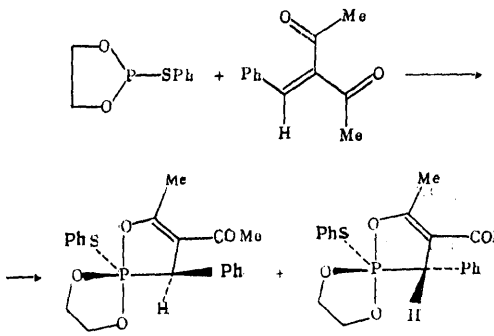
In a study of the addition of P(III) thioacid amides to carbonyl compounds it was established that the nature of the latter has no effect on the course of their reaction with phosphoranilidodithioites, in which α-anilidoaralkylphosphonodithioiates are formed:[157]

$$(EtS)_2PNHPh + n\text{-}XC_6H_4CHO \rightarrow (EtS)_2P(O)CH(NHPh)C_6H_4X\text{-}n$$

X = H, NO_2 .

There was not a single case where products with a P=N bond, namely, phosphonimidodithioates, which are characteristic for reactions of dialkyl phosphoranilidites with carbonyl compounds containing electron-withdrawing substituents, were formed.[157]

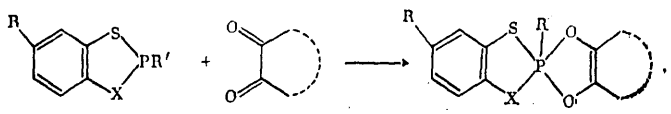
Reactions with conjugated carbonyl compounds. The reactions of TTPA with conjugated carbonyl systems, usually giving pentavalent phosphorus compounds, had by the end of the 1970's been studied in quite a detailed manner.[158] At the beginning of the 1980's, Ragulin and co-workers[159] showed that retention of the same coordination of the trivalent phosphorus atom in these reactions was possible by insertion of α,β-unsaturated aldehydes and ketones into the exocyclic P–S bond of phenyl ethylene- and 1,3-propylene-phosphorothioites:[159]



R = CH_3CH_2, $CH_2CH_2CH_2$; R′ = H, Me, Ph; R″ = H, Me .

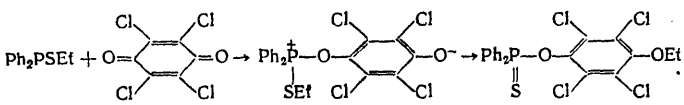
The rate of condensation decreases when the β-carbon atom of the conjugated system is shielded.

At the same time, insertion of 3-benzylideneacetylacetone in a reaction with phenyl ethylenephosphorothioite results in the formation of a mixture of diastereomeric spirophosphoranes



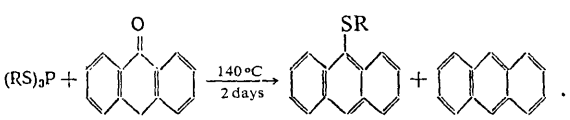
containing a P–S bond:[160]

anti – *syn* –



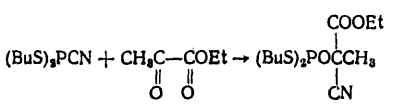
In this case the stereoisomer with the *syn*-configuration is the kinetically favourable product and the *anti*-isomer is the thermodynamically favourable reaction product. The fact that a thermodynamically nonequilibrium mixture of diastereomers is formed was taken by Ragulin and co-workers[160] as positive evidence for an almost synchronous 1,4-cycloaddition mechanism.

Spirophosphoranes containing a P–S bond are also obtained by reaction of α-dicarbonyl compounds with 1,3,2-dithia-[37] and 1,3,2-thiaza-phospholanes:[46]



R=H, Me ; R′=Et, Ph ; X=S, NH

Ethyl diphenylphosphinothioite reacts with chloranil in benzene to form *p*-ethoxytetrachlorophenyl diphenylphosphinothioate:[161]

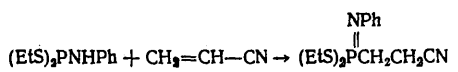


When benzene is replaced by the more polar DMSO and DMF it is possible to stop the process at the stage where a bipolar ion is formed, probably by stabilisation of the quasiphosphonium centre with solvent molecules. A study of this reaction by means of chemically induced polarisation of ^{31}P nuclei showed that there was also a radical route for formation of the final product.[161]

The reaction of trialkyl phosphorotrithioite with anthrone gives 9-alkythioanthracene and anthracene:[162]

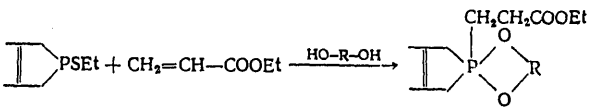
R = Et, Pr, iso-Pr, Bu, iso-Bu

P(III) thioacid cyanides react with ethyl pyruvate, retaining the same coordination of the phosphorus atom and forming α-cyanoalkyl esters of P(III) thioacids.[163]



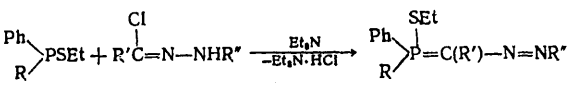
(b) Addition to other multiple bonds

Up to the present time there have been only isolated reports in the literature about the reactions of TTPA with compounds containing C=C, C=N, N=N, and other multiple bonds, which generally take place with retention of the P–S bond. When *S*-ethyl diphenylphosphinothioite reacts with 1-nitro-1-propene, instead of attack by the phosphorus atom on the β-carbon atom of the nitroolefin as occurs in the case of the oxygen analogues, only oxidation of the initial phosphinothioite occurs:[164]

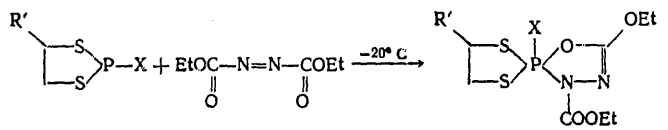


Using ^{31}P NMR spectroscopy, chemically induced polarisation of ^{31}P nuclei was detected on the initial and final products, so it could be assumed[164] that the reaction took place according to a one-electron transfer mechanism.

It was established[165] that cyclic phosphonodithioites do not react with acrylonitrile, while dialkyl phosphoranilidodithioites slowly add on to the latter with the formation of β-cyanoethylphosphonimidodithioates:[113]

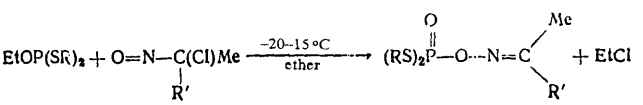


In reactions of phosphinothioites with ethyl acrylate in the presence of aliphatic and aromatic glycols the formation of cyclic phosphoranes was demonstrated:[165]



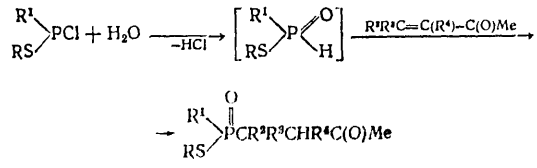
In this case there is probably an initial substitution of the alkythio group on the phosphorus atom.

The first examples of azomethylenephosphoranes containing a P–S bond were obtained in a study of the reaction of P(III) acid thioesters with nitrilimines in the presence of a base:[166,167]



R=Ph, SEt; R′=MeC(O), PhC(O), EtOC(O)
R″ = Ph, *p*-CrC_6H_4, *p*-$O_2NC_6H_4$

A new approach to the synthesis of certain spirophosphoranes containing a dithiophospholane residue is the reaction of cyclic amides and esters of phosphorodithious acid with diethyl azodicarboxylate in chloroform:[168]

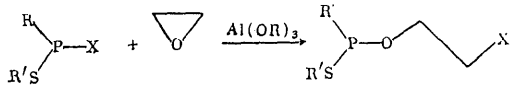


X=NMe_2, OMe; R′=H, Me

The previously unknown *O*-iminophosphonodithioates were readily formed by opening of the N=O bond in α-chloronitrosolkanes on treatment with mixed *O*,*S*-phosphorodithioites:[169]

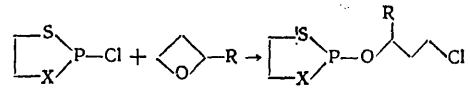
R=Et, Pr, Bu; R′=Cl, Me

P(III) acid chlorides add on to a C=C bond in the presence of H_2O [170] in a similar manner to the reaction with carbonyl compounds:[102]



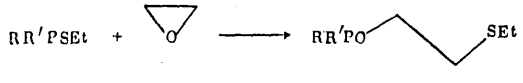
R = Et, Pr, Ph; R^1 = Et, Ph; R^2 = R^3 = R^4 = H, Me.

In the reaction of *S*-phenyl phenylphosphonochloridothioite the formation of a cyclic product—1,2-oxaphosphol-4-ene—occurs together with γ-ketophosphinothioates.[170] The proposed spontaneous cyclisation of γ-ketophosphinothioate was not confirmed experimentally.



(c) Addition to olefin oxides

In the mid-1970's there were reports[171,172] in the patent literature about the development of a method for hydroxyalkylation of P(III) thioacid chlorides with olefin oxides in the presence of organoaluminium catalysts:



X = Cl, Br; R' = alkyl, R'S, R'O, R'_2N.

This reaction was subsequently extended to cyclic P(III) thioacid chlorides and oxetanes and it transpired that scission of the 2-methyloxetane ring occurs on the C–O bond through the primary carbon atom in the absence of catalysts:

X = O, S, NBu-t; R = H, Me.

Only in the mid-1980's was the possibility shown for the first time that olefin oxides could be inserted into the P–S bond of phosphinothioites[174] and phosphoramidothioites:[175]

R = Et, R' = Ph; R = R' = Ph, NEt_2; R = EtS, R' = Et_2N.

The reactions are catalysed by organic acids, Lewis acids, and bases.

6. Exchange reactions in a number of TTPA

Exchange reactions in a number of TTPA can be successfully used for the synthesis of various organophosphorus compounds. However, these studies were only elaborated at the end of the 1970's, as a result of which it was established that exchange can be accompanied by processes leading to a change in coordination of the P(III) atom together with retention of the same valency for phosphorus. In this case the effect of different factors (nature of the reactants, temperature, presence of catalysts) on the rate and course of these reactions was shown.

P(III) acid thioesters have been studied in the greatest detail in reactions with phosphorus trihalides,[176,177] which provided the basis for the development of synthetic methods not only for P(III) thioacid chlorides as already reported in the literature but also for the previously unknown phosphoromono-[177] and phosphorodi-bromidothioites.[178]

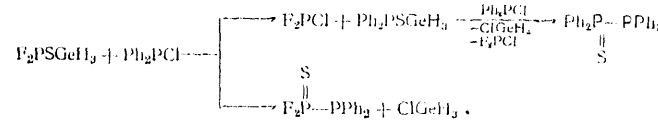
$$(RS)_3P + 2PX_3 \rightarrow 3RSPX_2;\quad 2(RS)_3P + PX_3 \rightarrow 3(RS)_2PX$$

R = Me, Et, Bu; X = Cl, Br.

It was later shown[179] that a similar reaction of tribenzyl phosphorotrithioite with phosphorus tribromide at 180 °C is accompanied by a change in coordination of the phosphorus atom and culminates in the formation of benzylphosphonothioic dibromide, although initial exchange products have been detected by ^{31}P NMR spectroscopy:

$$(PhCH_2S)_3P + 2PBr_3 \rightarrow 3PhCH_2P(S)Br_2.$$

In contrast to the reaction with phosphorus trihalides, the reaction between phosphorotrithioites and ethylphenylchlorophosphine is a reversible process:[177]



$$(RS)_3P + EtPhPCl \rightleftharpoons (RS)_2PCl + EtPhPSR$$

R = Me, Et, Pr.

At the same time, ethyl diphenylphosphinothioite reacts with diphenylchlorophosphine under severe conditions to form a complex mixture consisting of tetraphenyldiphosphine, ethyldiphenylphosphine sulphide, and diphenylchlorophosphine sulphide:[92]

$$Ph_2PSEt + Ph_2PCl \xrightarrow{250^\circ C} Ph_2P{-}PPh_2 + Ph_2P(S)Et + Ph_2PCl.$$

The reaction of *S*-germyl phosphorodifluoridothioite with diphenylchlorophosphine is also complex; cleavage of the S–Ge bond occurs together with formation of exchange products:[76]

At the beginning of the 1960's it was shown[176] that the reaction between trimethyl and tributyl phosphorotrithioites in the presence of trace amounts of HCl gives an equilibrium mixture consisting of four phosphorothioites:

$$(RS)_3P + (R'S)_3P \rightleftharpoons (RS)_2PSR' + RSP(SR')_2$$

R = Me; R' = Et, Bu.

It was established later[106] that the exchange of alkylthio groups in a number of phosphorotrithioites occurs only in the presence of catalytic quantities of acids and bases, the rate of exchange increasing on changing from acidic to basic catalysts.

The reaction of P(III) thioesters with trialkyl phosphites has only been studied in the case of Schrader's anhydride reacting with triethyl phosphite,[121] as a result of which a compound with a $P^{(III)}-P^{(V)}$ bond—*tris*(diethylphosphoryl)phosphine—is formed:

$$[(EtO)_2PS]_3P + 3(EtO)_3P \rightarrow [(EtO)_2P]_3P + 3(EtO)_2PSEt.$$

There is no information in the literature about the exchange of groups between P(III) acid thioesters and triaminophosphines, but the reactions of the latter with phosphoromono- and phosphorodichloridothioites[177] and also with 1,3,2-thiazaphospholanes containing an exocyclic P–Cl bond[180] have been studied, so it was possible to

obtain P(III) acid derivatives containing both a P–S bond and a P–N bond in the molecule:

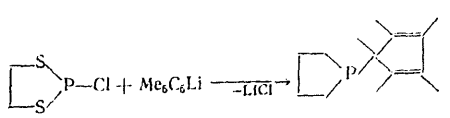
$$(EtS)_2PCl + (Et_2N)_3P \underset{-40\,^\circ C}{\overset{20\,^\circ C}{\rightleftharpoons}} \begin{cases} (EtS)_2PNEt_2 + (Et_2N)_2PCl \\ (EtS)_2P{-}\overset{+}{P}(NEt_2)_3Cl^- \end{cases}.$$

More recently, in a study[181] of the reaction between diethyl phosphorochloridodithioite with hexaethyltriaminophosphine at low temperatures using ^{31}P NMR specroscopy it was possible to identify the formation of a quasiphosphonium compound with a P–P bond, which on increasing the temperature decomposed with the subsequent formation of exchange products. A quasiphosphonium compound with a P–P bond is also formed by reaction of diethyl phosphorochloridodithioite with tripropylphosphine;[181] this compound is converted at 0 °C to tripropylethylphosphonium chloride:

$$(EtS)_2PCl + Pr_3P \underset{0\,^\circ C}{\overset{-60\,^\circ C}{\rightleftharpoons}} \begin{cases} (EtS)_2P{-}\overset{+}{P}Pr_3\ Cl^- \\ Pr_3\overset{+}{P}SEt\ Cl^- \end{cases}.$$

Products with a P–P bond were also obtained in the case of the reaction between diethyl phosphorochloridodithioite and silyl phosphites:[124]

$$(EtS)_2PCl + (RO)_2POSiMe_3 \xrightarrow{-Me_3SiCl} (EtS)_2P{-}\underset{\underset{O}{\|}}{P}(OR)_2$$



R=Et, Me_3Si.

The reaction takes place under mild conditions and is accompanied by the liberation of heat.

7. Reactions of TTPA with organometallic and complex compounds

In recent years studies on the reactions of TTPA with organometallic and complex compounds have been published in the literature. This is related to the fact that a number of metal-complex compounds containing TTPA as ligands have been used as catalysts for liquid-phase hydrogenation[182] and hydroformylation.[183] Moreover, new types and classes of organophosphorus compounds, including those with an unusual structure and coordination of the phosphorus atom, have been obtained from reactions of TTPA with organometallic compounds.

Thus, in the reaction of pentamethylcyclopentadienyllithium with 2-chloro-1,3,2-dithiaphospholane, 2-(pentamethyl-2,4-cyclopentadiene-1-yl)-1,3,2-dithiaphospholane is formed, having a 'fluxional' structure as a result of a 1,5-sigmatropic rearrangement of the dithiaphospholane residue:[184]

Previously unknown compounds with a pentavalent tricoordinated phosphorus atom—*bis*(methylene)phosphoranes—were synthesised from alkyl or aryl phosphorodichloridothioites and lithium *bis*(trimethylsilyl)methanide:[185,186]

$$RS{-}PCl_2 + 3LiCCl(SiMe_3)_2 \xrightarrow[-3LiCl\ -Cl_2C(SiMe_3)_2]{-110\,^\circ C} RS{-}P\!\left(\!=\!C(SiMe_3)_2\right)\!C(SiMe_3)_2$$

R = iso-Pr, C_5H_{11}, Ph.

Cleavage of the P–S bond in TTPA on treatment with organolithium compounds was shown only in the case of the reaction between *S*-thiobenzoyl diphenylphosphinothioite and phenyllithium:[55]

$$Ph_2PSCPh + PhLi \rightarrow Ph_2P + PhCS_2^-Li^+,$$
$$\qquad\qquad\quad \|\ S$$

The cleavage of the P–S bond in P(III) acid thioesters by organic hydrides of Group 4b metals was studied in greater detail.[187,188] On the basis of these investigations, for the first time a general method was developed for the synthesis of a new class of organophosphorus compounds—alkyl- and phenyl-alkylthiophosphines[189] and the previously unknown acyclic thioesters of hypophosphorous acid:[190]

$$RP(SR')_2 + Bu_3SnH \rightarrow RP\!\begin{cases} SR' \\ H \end{cases} + Bu_3SnSR'$$

R = Me, Et, iso-Bu, Ph, SR'; R' = Me, Et, Pr.

It is interesting that in the reaction of trialkylstannanes with trichloromethylphosphonodithioite the P–S bond is retained while a C–Cl bond in the trichloromethyl group is cleaved:[188]

$$CCl_3P(SEt)_2 + R_3SnH \rightarrow CHCl_2P(SEt)_2 + R_3SnCl$$
$$R = Et,\ Bu.$$

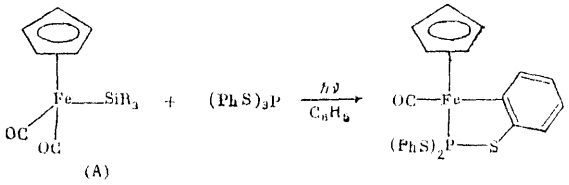
At the same time, it is not possible to use complex alkali metal hydrides, in particular, lithium aluminium hydride, as reducing agents in reactions with TTPA for carrying out a selective reduction, since all the P–S bonds are cleaved in phosphinothioites, phosphonothioites,[191,192] and phosphorodiamidothioites,[192] resulting in the formation of the corresponding primary or secondary phosphines and hypophosphorous acid diamides:

$$PhP(SEt)_2 \xrightarrow[\text{dibenzo-18-crown-6}]{LiAlH_4} PhPH_2$$
$$(Et_2N)_2PSR \xrightarrow[\text{ether}]{LiAlH_4} (Et_2N)_2PH.$$

It was shown for the first time[191,192] that the use of crown ethers as phase-transfer catalysts in these reactions considerably increases the rate of reduction and the yields of the final products.

During the last ten years there has been a considerable increase in interest concerning metal derivatives of TTPA, particularly in transition metal complexes. A number of mono- and di-substituted phosphinothioite and phosphonodithioite complexes of chromium,[193–196] molybdenum,[194,195,197] and tungsten[194,195] have been obtained from transition metal carbonyl complexes containing readily detachable ligands such as tetrahydrofuran (THF) or norbornadiene (NBD):

$$M(CO)_5THF + R_2PSR' \xrightarrow{-THF} M(CO)_5PR_2SR'$$
$$cis\text{-}M(CO)_4NBD + 2RP\!\begin{cases} S \\ S \end{cases}\!R'' \xrightarrow{-NBD} cis\text{-}M(CO)_4\left(RP\!\begin{cases} S \\ S \end{cases}\!R''\right)_2$$
M=Cr, Mo, W; R, R'=CH_3, CF_3; R''=CH_2CH_2, *o*-C_6H_4.



It was established that in all cases phosphorus coordinates with the metal atom, and the rate of ligand exchange depends on the nature of the substituents and the metal atom.[194,195] It should be noted that in the case of disubstituted complexes the compound with a *cis*-configuration that is formed initially can be converted to the *trans*-isomer, with the rate of isomerisation depending on the nature of the substituents, the metal atom, and the temperature.[195,196] The reaction of tetracarbonyl(norbornadiene)molybdenum with *S*-germyl phosphorodifluoridothioite takes place in a similar manner.[76]

More recently the synthesis of phosphinothioites of binuclear manganese carbonyl complexes has been carried out[198] by direct displacement of carbon monoxide from manganese carbonyls:

$$Mn_2(CO)_{10} + (CF_3)_2PSR \xrightarrow{90\text{-}130^\circ C} Mn_2(CO)_8P(CF_3)_2SR$$

R = alkyl, aryl, perfluoroalkyl, perfluoroaryl, $P(CF_3)_2$

Cyclometallated iron complexes with a triphenyl phosphorotrithioite ligand are readily formed by UV irradiation of a complex of the type (A) in the presence of triphenyl phosphorotrithioite:[199]

The replacement of ligands in platinum complexes with the involvement of *S*-germyl phosphorodifluoridothioite has been studied.[76]

---0o0---

Thus, the introduction of alkythio groups on to the trivalent phosphorus atom produces a substantial change in the reactivity of P(III) acid derivatives. The Arbuzov reaction route, which is typical for oxygen analogues of TTPA, does not occur in the majority of cases and substitution at the trivalent phosphorus atom with retention of the same coordination takes place. This trend is particularly marked in the reactions of TTPA with acids and halogenated electrophilic reagents. The addition of TTPA to carbonyl compounds resulting in the cleavage of a P—S bond, as a rule, only occurs in the presence of a third reagent which assumes the role of activator for the process.

The effect of different factors, including acidic catalysts, on the rate of substitution and exchange reactions involving TTPA has been established, placing them in the same series with other trivalent phosphorus acid derivatives.

The mechanism established for the chemical behaviour of TTPA in substitution and addition reactions now make it possible not only to carry out the directed synthesis of compounds with a predetermined structure and properties but also to predict the course of TTPA reactions that have not yet been studied. Everything that has been reported above and the existence of a considerable number of convenient methods for obtaining TTPA mean that further studies of this class of compounds will have future potential.

Pentacoordinate fluorosilicate anions

V O Gel'mbol'dt, A A Ennan
Mechnikov Odessa State University

ABSTRACT. The literature data on the synthesis and properties of salts with pentacoordinate fluorosilicate anions have been classified and correlated. The geometric structural features of the pentafluorosilicate anion and its substituted derivatives are analysed, taking into account the hypervalent nature of the bonding in silicon(IV) complexes.
The bibliography includes 94 references.

I. Introduction

From the date of publication of Sommer's well-known monograph[1], which correlated the main results on the dynamic stereochemistry of organosilicon compounds, research workers have taken a greater interest in pentacoordinate fluorosilicate anions. Compounds of this type are potential intermediates in various reactions involving tetra- and hexa-coordinate silicon fluoro-complexes. In particular, the pentafluorosilicate anion and its substituted derivatives may be regarded as stable 'models' of S_N2 Si intermediates in nucleophilic substitution reactions involving the respective tetrahedral fluorosilanes.[1] The formation of pentacoordinate silicon fluoro-complexes as intermediates was postulated in a discussion of the probable mechanism of the dehydro-fluorination of octahedral complexes of silicon tetrafluoride with nitrogen- and oxygen-containing donor ligands giving organofluorosilicon compounds such as fluorosilylamines, fluorosilazanes, and alkoxysilanes with a valuable set of physicochemical properties.[2]

Two reviews[3,4] have been devoted to various aspects of the chemistry of pentacoordinate silicon fluoro-complexes, but a limited amount of correlation of the information on pentacoordinate fluorosilicate anions is only presented in one study.[3] Moreover, in recent years a considerable number of interesting studies in this field have been published, and evidently the time was ripe for a new review. The aim of the present review is to classify and correlate the information published during the last decade on the synthetic methods, geometric structure, dynamic stereochemistry and ligand exchange processes in solution, properties, and use of pentacoordinate anions of silicon fluoro-complexes in preparative synthesis.

II. Synthetic methods

The earliest information about the preparation of pentafluorosilicates—salts of the simplest pentacoordinate fluorosilicate anion—was published in 1967. Clark et al.[5] discovered that the reaction of *trans*-$[PtHCl(Et_3P)_2]$ with tetrafluoroethylene in a Pyrex tube gave *trans*-$[PtCl(CO)(Et_3P)_2]SiF_5$. In subsequent reports[6,7] a simple method for the synthesis of pentafluorosilicates was proposed, being based on the reaction of equimolar quantities of tetraalkylammonium chloride or bromide with silica in an aqueous methanol solution of HF. This method was used to obtain $(R_4N)SiF_5$, where R = Et, n-Pr, n-Bu. A similar method has been reported by Behrends and Kiel.[8] It is interesting that the product of the reaction between SiF_4 and $Pt(PPh_3)_3$, which was first identified[9] as the complex $SiF_4.Pt(PPh_3)_3$, according to later results[10] is hydrido-tris(triphenylphosphine)platinum pentafluorosilicate $[PtH(PPh_3)_3].SiF_5$. A similar reaction between BF_3 and $Pt(PPh_3)_3$ leads to the formation of tetrafluoroborate salts. Bird et al.[10] stressed the need to make a critical assessment of the results of a synthesis based on covalent fluorides and basic metal complexes when the reactions are carried out in a glass apparatus.

Dehydrofluorination of complexes of silicon tetrafluoride with alcohols and primary amines in the presence of tertiary amines were used[11,12] for the synthesis of a number of trialkylammonium pentafluorosilicates:

$$5SiF_4 + 4ROH + 4R_3N \rightarrow Si(OR)_4 + 4(R_3NH)SiF_5,$$
$$3SiF_4 + RNH_2 + 2R_3N \rightarrow 1/n(RNSiF_2)_n + 2(R_3NH)SiF_5.$$

Gel'mbol'dt et al.[13,14] proposed a method for the synthesis of dialkyl- and trialkyl-ammonium pentafluorosilicates based on dehydrofluorination in the system SiF_4–acetone–amine, where the enol form of acetone acts as a proton donor:

$$5SiF_4 + 4Me_2CO + 4R_nNH_{3-n} \rightarrow \left(CH_2{=}\overset{\overset{Me}{|}}{C}{-}O\right)_4 Si + 4(R_nNH_{4-n})SiF_5, \quad n = 2, 3.$$

This method was recently used to obtain *N*,*N*-dialkylanilinium pentafluorosilicates $(PhNHR_2)SiF_5$ (R = Et, n-Pr, n-Bu).[15]

As was demonstrated in two studies,[12,16] a fairly general method for the synthesis of trialkyl- and tetraalkyl-ammonium pentafluorosilicates consists of the treatment of the respective hexafluorosilicates or 'complex' fluorosilicates containing anions of the stoichiometric composition $Si_2F_{11}^{3-}$ and $Si_3F_{16}^{4-}$ with an excess of silicon tetrafluoride in a suitable solvent (benzene, acetonitrile, methylene chloride). Since fluorosilicates of the type $(R_3NH)_3Si_2F_{11}$

or $(R_3NH)_4Si_3F_{16}$ are the double salts $(R_3NH)_2SiF_6.n(R_3NH)SiF_5$ (n = 1, 2),[17-20] the chemical nature of the conversion of fluorosilicates higher in fluorine to pentafluorosilicates can be represented by the general scheme:

$$SiF_6^{2-} + SiF_4 \rightarrow 2SiF_5^-.$$

The use of this method in the preparative synthesis of pentafluorosilicates may only be limited by the poor solubility of the initial hexafluorosilicates or double fluorosilicates in aprotic solvents.

A general method for the synthesis of pentafluorosilicates and also mixed pentacoordinate tetraalkylammonium alkyl- and aryl-fluorosilicates has been proposed. It is based on the reaction between SiF_4 or R_nSiF_{4-n} (n = 1, 2) and R_4NF in methanol:[21]

$$R_nSiF_{4-n} + F^- \rightarrow [R_nSiF_{5-n}]^-.$$

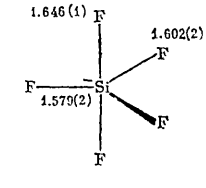
Despite the complexity of obtaining a tetraalkylammonium fluoride that is free of impurities, the latter method has been widely applied. In particular, it has been used in the synthesis of virtually all samples of salts with pentacoordinate fluorosilicate anions for X-ray diffraction studies.

There has been a report on a similar method for obtaining mixed anions of the type $[XSiF_4]^-$ by reaction between silicon tetrafluoride and Me_4NX (X = CF_3COO^-, $MeCOO^-$, $HCOO^-$, NO_2^-, CN^-, etc.) in liquid sulphur dioxide or methylene chloride:[22]

$$SiF_4 + X^- \rightarrow [XSiF_4]^-.$$

An excess of silicon tetrafluoride reacted with acetate ion leads to the formation of a binuclear anion with a bridging fluorine atom and an equatorial configuration of the monodentate $MeCOO^-$ groups:

$$5SiF_4 + 4MeCOO^- \rightarrow 2[Si_2F_7(MeCOO)_2]^- + SiF_6^{2-}.$$

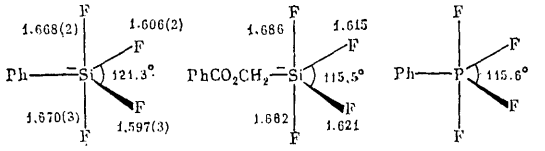


A proposed[21,22] route for the synthesis of pentacoordinate fluorosilicate anions was further developed by Ault and Tandoc,[23,24] who used the technique of low-temperature matrix isolation in order to obtain caesium salts with SiF_5^-, $[SiF_{5-n}Cl_n]^-$ (n = 1-4), and $[Me_nSiF_{5-n}]^-$ (n = 1, 2) anions. The compound $KSiF_5$ was also obtained. The synthetic method consisted of evaporating the respective metal fluoride (CsF, KF) followed by its cocondensation with samples of SiF_4, $SiF_{4-n}Cl_n$ (n = 1-4) or Me_nSiF_{4-n} (n = 1, 2) in an argon matrix at low temperatures.

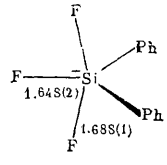
In conclusion we should mention a simple method for synthesising tripropylammonium pentafluorosilicate by reaction of tripropylamine with a solution of fluorosilicic acid (molar ratio 1 : 3).[25] Unfortunately, this method is not a general one and when other tertiary amines are used, double trialkylammonium hexa- and penta-fluorosilicates are formed.

III. Electronic structure and stereochemistry

It was pointed out[2,3] that the specific nature of the structure and reactivity of fluoro-complexes of non-transition elements is most adequately expressed in terms of hypervalent bonds.[26] The elements of Subgroup IVB are not formally classified among the types of hypervalency as proposed by Musher for the electron-rich elements of Subgroups VB–VIIB. The scope of Musher's ideas[26] was extended by Voronkov et al.,[27-30] who modified the initial scheme for formation of a four-electron, three-centre bond [unshared electron pair (UEP) of the central atom and two unpaired electrons from ligands] for representing the mechanism of axial bonding in pentacoordinate silicon(IV) complexes such as silatranes, (aroyloxymethyl)trifluorosilanes, and related compounds. In the complexes $X-Si(OCH_2CH_2)_3N$ and $XC_6H_4COOCH_2SiF_3$ the coordination of the silicon polyhedron is a slightly distorted trigonal bipyramid. The formation of the hypervalent axial fragments X–Si ← N and F–Si ← O occurs as a result of intramolecular coordination using the UEP of the ligand (a nitrogen or oxygen atom). Out of the four valence atomic orbitals of silicon, three ($3s$, $3p_x$, $3p_y$) participate in equatorial bonding as sp^2 hybrids, forming three two-electron two-centre bonds. The bond in the linear X–Si ← N fragment and the slightly bent F–Si ← O fragment ($\angle$FSiO = 175–179°) arises from the $3p_z$ atomic orbital of silicon and the atomic orbitals of the axial ligands (one from each atom), in other words, it is a three-orbital three-central or hypervalent-II bond according to Musher.[26] This scheme for axial bonding has been extended to the pentafluorosilicate anion and its substituted derivatives.



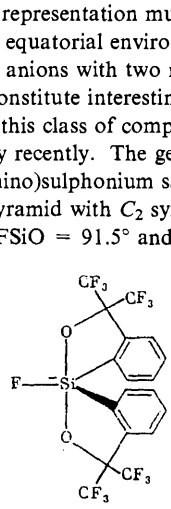
The first arguments in favour of a trigonal bipyramidal structure for the SiF_5^- anion were based on the results of spectroscopic studies.[7,21] In particular, according to the results of one study,[7] in the Raman spectrum of an acetonitrile solution of tetra-n-propylammonium pentafluorosilicate there was an intense polarised band at 708 cm^{-1} (A_1 mode), which was inactive in the IR spectrum; this was consistent with the SiF_5^- anion having D_{3h} symmetry. The marked similarities in the IR and Raman spectra of SiF_5^- and PF_5 (a trigonal bipyramidal configuration has been reliably established for the latter compound) support such a conclusion. An attempt to determine the structural parameters of the pentafluorosilicate anion in crystals of the salt $(Ph_4As)SiF_5$ proved unsuccessful because of the complex form of crystallographic randomisation.[31] More recently the results of an X-ray diffraction analysis of the complex salt $[IrH_2CO(PPh_3)_3]SiF_5$ were published.[10] The geometry of the SiF_5^- anion differed only slightly from the ideal trigonal bipyramidal form, but the accuracy in determining the structural parameters was limited by the intense vibrational movements of the anion and it amounted to 0.04 Å for the bond lengths and 4° for the bond angles. The lengths of the axial and equatorial Si–F bond coincided within the limits of experimental error and constituted 1.69 Å on average. A precise determination of the molecular structure of the SiF_5^- anion in the salt $(PhCH_2NMe_3)SiF_5$ was carried out only comparatively recently.[32] The pentafluorosilicate anion has a slightly distorted trigonal bipyramidal configuration with C_2 symmetry (the second-order axis passes through the silicon atom and one of the equatorial ligands), and in complete conformity with the model of Musher[26] the axial Si–F bonds are longer (weaker) than the equatorial bonds:



The axial F–Si–F fragment is virtually linear ($\angle F_aSiF_a$ = 179.4°). It is interesting that according to the results of an IR spectroscopic study, the pentafluorosilicate anion in matrix-isolated salts $MSiF_5$ (M = K^+ or Cs^+, which are comparable in size to the unsubstituted NH_4^+ cation) has an axially distorted geometry with C_{3v} symmetry.[23]

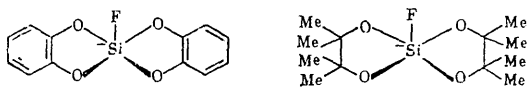
This observation can also have a natural explanation within the scope of the hypervalent bond model.[26] Since the scheme for three-centre bonding envisages a significant transfer of electron density within the axial F–Si–F group, the latter has high polarity and must have the maximum sensitivity towards the perturbing effect of small cations with high charge density and high polarising capacity.

The results of X-ray diffraction analysis of tetrapropylammonium phenyltetrafluorosilicate and 1,10-phenanthrolinium (benzoxymethyl)-tetrafluorosilicate are given in two reports.[33,34] The $[PhSiF_4]^-$ and $[PhCOOCH_2SiF_4]^-$ anions have a distorted trigonal bipyramidal structure with the phenyl or benzyloxymethyl group in an equatorial position:



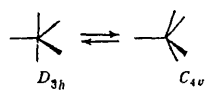
A similar structure was found for the isoelectronic phenyltetrafluorophosphorane.[35] The arrangement of electropositive ligands in the equatorial plane of the compounds and the nature of the angle deformations of the complexes when there is substitution are consistent with the concepts of hypervalency. The structure of the three-centre axial bonds is only stable in the case of highly electronegative ligands, whereby it follows from this model[26] that the axial and equatorial groups of bonds to a certain extent act independently in the transfer of electronic effects. It is logical to assume from this that the virtually identical angular distortion of the F_a-Si-F_a group in $[PhSiF_4]^-$ and the F_a-P-F_a group in $PhPF_4$ is due to the similar steric effect of the phenyl ligand in both complexes, whereas the differences in the equatorial angle deformations is caused by the steric and electronic effects acting in opposite directions. While the former compresses the angles in F_eSiF_e and F_ePF_e, the latter, on the other hand, increases them compared to the ideal angle for sp^2 hybrid atomic orbitals (120°) as a result of an increased *s* atomic orbital contribution in the Si–C and P–C bonds and a decreased *s* atomic orbital contribution in the Si–F and P–F bonds (Bent's rule[36]). For a complex of the more electropositive silicon ($EN_{Si} < EN_P$), the contribution of the 'electronic' component of the deformational forces proves to be greater than for the phosphorus derivative (the share of the *s* atomic orbital of Si in a Si–C bond is greater than the share of the *s* atomic orbital of P in a P–C bond), which, when the contribution of the steric effect from the phenyl group is deducted, results in the observed differences in the deformations of the equatorial angles ($\angle F_eSiF_e > \angle F_ePF_e$). An alternative interpretation of the nature of the angle deformations in the isoelectronic compounds $[PhSiF_4]^-$ and $PhPF_4$, based on the concepts of the Gillespie–Nyholm model,[37] is given by Schomburg.[33] According to the results of Schomburg and Krebs[32] a structural feature of the diphenyltrifluorosilicate anion in crystals of $(Me_4N)[Ph_2SiF_3]$ is the almost identical increase in length of the axial and equatorial Si–F bonds in comparision to the unsubstituted SiF_5^- anion. The angles of C_e-Si-C_e and F_a-Si-F_a are equal to 118.9 and 187.5° with ideal values of 120 and 180° respectively:

It should be noted that an equatorial configuration of the phenyl ligands in the trigonal bipyramidal structure of the $[Ph_2SiF_3]^-$ anion had previously been established in an analysis of the low-temperature ^{19}F NMR spectra of solutions of the salt $(Et_4N)[Ph_2SiF_3]$ in methylene chloride.[21] Similarly, the nature of the IR spectrum of the $[MeSiF_4]^-$ anion in the vibrational region for ν(SiF) (absorption bands at 712, 825, 837, and 862 cm^{-1}) and δ(SiF) (450 cm^{-1}) indicate that the anion has a symmetry which is of the type C_{2v} or lower, with the methyl group in the equatorial position.[24]

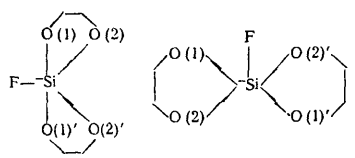


The structures of substituted anions of the type $[R_nSiF_{5-n}]^-$ (n = 1, 2) which have been examined above illustrate the validity of the well-known empirical rule of Muetterties,[38] which states that for a trigonal bipyramidal configuration of the complexes of non-transition elements, isomers with an axial orientation of the most electronegative substituents are stable. However, $SiF_4(L)$ complexes, L = Me_nNH_{3-n}, (n = 0–3) [39,40] or Py,[41] judging from the IR spectroscopy data, have a structure with the molecular ligands in the axial position, which is unexpected in relation to the models of Musher[26] and Gillespie.[37] This geometry, for the $SiF_4(NH_3)$ complex at least, has been accurately reproduced in *ab initio* calculations.[42,43] Out of the four alternative configurations of the coordination polyhedron of SiF_4N with C_{3v}, C_{2v}, C_{4v}, and C_s symmetry, the C_{3v} structure has the minimum energy, and according to the data of Mulliken population analysis the magnitude of the effective negative charge on the nitrogen atom (–1.15) is higher than the charges on the fluorine atoms [–0.49 (*a*), –0.48 (*e*)]. Subsequent to the study by Marsden,[42] if an attempt is made to correlate the electronegativities (Pauling) with the effective charges of the atoms (Mulliken), the axial position of the formally less electronegative nitrogen atom of the ammonia molecule in the trigonal bipyramidal structure of $SiF_4(NH_3)$ becomes clear. The results of quantum-chemical analysis show[44,45] (semiempirical MNDO method) that formation of the hypothetical anions $[XSiH_4]^-$ (X = H^-, F^-, Cl^-) and the molecular complex $FSiH_3(O=CH-OH)$ by the reaction $XSiH_3$ + Y (Y = H^-, O=CH–OH) is accompanied by a more substantial change (increase) in the interatomic distance of X_a-Si compared to the distance in H_e-Si. The latter is an indication of the *trans*-weakening effect on the axial bonds with a strengthening of coordination and is a logical consequence of the hypothetical models of Musher and Voronkov.[26,27] Frolov et al.[44,45] recorded significant contributions from the atomic orbitals of the equatorial ligands in the highest occupied molecular orbital (HOMO) representing the X_a-Si-H fragment in $[XSiH_4]^-$ anions. It was thus stressed that a complete hypervalent representation must take into account the atomic orbitals of the equatorial environment of the silicon atom.

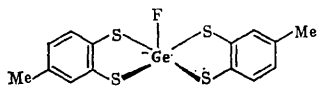
Monofluorosilicate anions with two ring-forming *O*-donor ligands (λ^5-Si-spirosilicates) constitute interesting stereochemical compounds. The first examples of this class of compounds underwent structural analysis comparatively recently. The geometry of the anion (A) in the tris(dimethylamino)sulphonium salt is that of a slightly distorted trigonal bipyramid with C_2 symmetry: $\angle SiO$ = 176.6°, $\angle CSiC$ = 132.2°, $\angle FSiO$ = 91.5° and 91.9°, bond length of $Si-F_e$ 1.632(3) Å:[46]



(A)



The structures of the spirobicyclic anions $[(OC_6H_4O)_2SiF]^-$ and $[(OCMe_2CMe_2O)_2SiF]^-$ have a different form of coordination polyhedron for silicon(IV):[47,48]



The immediate environment of the silicon atom in these complexes has a distorted tetragonal pyramidal (TP) structure. It was shown[49,50] that the structures of all known pentacoordinate complexes can be arranged in a series that exhibits a smooth transition from an ideal trigonal bipyramidal (TBP) geometry (D_{3h} symmetry) via an intermediate configuration with C_{2v} symmetry to a limiting TP geometry (C_{4v}). The observed deviations of the real structures of MX_5 complexes from the ideal D_{3h} and C_{4v} configurations corresponds to the C_{2v} coordinate in Berry pseudorotation:[51]

By using the formal procedures suggested by Porai-Koshits and Aslanov,[52] it is possible to make a quantitative comparison between the real structure of the pentacoordinate complex with C_{2v} symmetry and the D_{3h} and C_{4v} limiting configurations. The TBP limit is built up by arranging the O(1) and O(1)′ atoms of the spirobicyclic anion in axial positions and the O(2) and O(2)′ atoms in equatorial positions, while the TP limit is developed with an axial orientation of the fluorine atom:

In the Berry process the fluorine atom is a pivotal ligand. According to the results of two studies,[47,48] each of the $[(OC_6H_4O)_2SiF]^-$ and $[(OCMe_2CMe_2O)_2SiF]^-$ anions in tetraalkylammonium salts forms two crystallographically independent forms, which are distorted towards the TP limit by 68.7 and 52.8% or 69.1 and 52.3% respectively. It is interesting that distortion of the structure of the isoelectronic anion $[(OC_6H_4O)_2SiF]^-$ towards the TP limit even reaches 81%,[53] while similar deformations in the structure of the phosphorus analogue $(OC_6H_4O)_2PF$ amount to 65%.[54] Evidently the degrees of distortion of the coordination polyhedra of silicon(IV) and phosphorus(V) are fairly similar, while for a complex of the most electropositive of the three elements, germanium(IV), the deformation towards the C_{4v} limit are the greatest. The features of the structural deformations in pentacoordinate complexes of *p*-elements have been discussed in a review,[55] which includes the ideas of Gillespie and Nyholm. According to the hypervalent bond model, the TP structure of spirobicyclic monofluorosilicate anions and their isoelectronic analogues can be represented in terms of two hypervalent O–Si–O groups involving the $3p_x$ and $3p_y$ atomic orbitals of silicon, forming the equatorial plane of the complexes, and the sp_z hybrid for the Si–F bond. The increased stability of the TP configuration in the $[(OC_6H_4O)_2GeF]^-$ anion compared to the corresponding silicon(IV) and phosphorus(V) derivatives is completely natural since it is for the most electropositive germanium that the maximum stabilisation of the hypervalent three-centre groups is achieved. The importance of the condition $EN_A \ll EN_L$ being fulfilled for ensuring the stability of hypervalent L–A–L bonds becomes evident when the structures of $[(OC_6H_4O)_2CHF]^-$ and $[(SC_7H_6S)_2GeF]^-$ anions are compared.[53] Despite the structural similarity of the chelate ligands in these complexes, the thio analogue

is distorted towards the ideal TP configuration by only 40%.

The similarity noted above between the quantitative characteristics of structural deformations in pentacoordinate isoelectronic fluorocomplexes of silicon(IV) and phosphorus(V) may be related to the ideas of Bartlett[5] on the characteristic separation energy of *ns* and *np* orbitals for non-transition elements of a given *n*th Period. His hypothesis[56] was based on the known fact that the bond angles have an approximately equal value in each of the series of isoelectronic compounds of *p*-elements in an incomplete valency state: $PF_3-SF_3^+$, $AsF_3-SeF_3^+$, $SbF_5^{2-}-TeF_5^-$, $IF-XeF_5^+$. Subsequently, Bartlett's ideas[56] were used to account for the similarity in the values of isomerisation constants of isoelectronic hexacoordinate tetrafluoro-complexes of *p*-elements of Groups IV–VI in the third to fifth Periods.[57] We can show that the automatic extension of Bartlett's ideas[56] to complexes with central atoms in higher oxidation states is not absolutely correct. While for TP complexes of the type AF_5E (E = UEP) the equatorial F–A–F bonds have a pure *p* character (hypervalent-I bonds in the terminology of Musher[26]), in TBP and TP structures of complexes of Group IV–V elements the axial and equatorial bonding based on three-centre L–A–L groups requires a given contribution from the *ns* atomic orbital of atom A (hypervalent-II bond). For symmetry considerations this contribution is usually neglected,[27] but it is very probable that the observed differences in the structural deformations of pentacoordinate silicon(IV) and phosphorus(V) fluoro-complexes are due to the varying degree of disproportionation of the hypervalent bonding system[58] of these elements with unequal contributions from the 3*s* atomic orbitals of the central atoms.

IV. Properties

Tetraalkylammonium pentafluorosilicates as solutions in nitromethane behave as 1:1 electrolytes.[7] In aqueous solution pentafluorosilicates are hydrolysed to a considerable degree.[7] According to the studies of Harris and Rudner[11] the hydrolysis of trimethylammonium pentafluorosilicate in moist air is given by the equation:

$$2SiF_5^- + 2H_2O \rightarrow SiF_6^{2-} + SiO_2 + 4HF.$$

Judging by the IR spectroscopic data, the SiF_5^- anion undergoes a similar conversion when the double salt $(Et_2NH_2)_2SiF_6(Et_2NH_2)SiF_5$ is dissolved in water.[13] The ^{19}F NMR spectra of a 19.1% aqueous solution of $(Pr_3NH)SiF_5$ indicate that a more complex equilibrium occurs:[59]

$$3SiF_5^- + 3H_2O \rightarrow SiF_6^{2-} + [SiF_5(H_2O)]^- + SiO_2 + 4HF.$$

Heating of an aqueous solution of $(Ph_4As)SiF_5$ leads to rapid and quantitative hydrolysis[8] in accordance with the equation:

$$SiF_5^- + 2H_2O \rightarrow F^- + SiO_2 + 4HF.$$

At the same time Kleboth[60] made a satisfactory interpretation of the IR and Raman spectra of an aqueous solution of tetraethylammonium

pentafluorosilicate by proposing C_{4v} symmetry for the coordination polyhedron of silicon, in other words, the formation of an aqueous pentafluoroaquo-complex is not accompanied by disproportionation of fluorine [sic] in solution:

$$SiF_5^- + H_2O \rightarrow [SiF_5(H_2O)]^-.$$

The stability of dialkyl-, trialkyl- and tetraalkyl-ammonium pentafluorosilicates regularly increases with the size of the cation,[7,12,13] which is due to the decrease in its polarising effect. For example, diisopropylethylamine forms a stable pentafluorosilicate. Triethylammonium pentafluorosilicate is stable in benzene and acetonitrile solutions but when the solvent is removed SiF_4 is lost and there is formation of the compound $(Et_3NH)_4Si_3F_{16}$, which is the double salt $(Et_3NH)_2SiF_6.2(Et_3NH)SiF_5$.[20] The salt $(Me_3NH)SiF_5$, with a smaller cation, is stable in acetonitrile but not in benzene solutions. However, all attempts to isolate trimethylammonium pentafluorosilicate by crystallisation at low temperatures have led to a product of composition $(Me_3NH)_3Si_2F_{11}$.[12] Similarly, diethyl- and dibutylammonium pentafluorosilicates are stable in a solvating acetone medium; removal of the solvent is accompanied by the formation of the double salt $(R_2NH_2)_2SiF_6.(R_2NH_2)SiF_5$.[13] According to Durkin and Schram,[9] the compound $(Pr_4N)SiF_5$ is stable on heating to 230 °C in a vacuum whereas tetramethylammonium pentafluorosilicate disproportionates at 100 °C according to the equation

$$2(Me_4N)SiF_5 \rightarrow SiF_4 + (Me_4N)_2SiF_6.$$

This was confirmed by the IR spectrum of the solid residue.[61] According to the results of thermogravimetric analysis,[25] tripropylammonium pentafluorosilicate dissociates over the temperature range 207–273 °C with the components passing complete into the gas phase:

$$(Pr_3NH)SiF_5 \rightarrow SiF_4 + HF + Pr_3N.$$

In two studies[13,62] it is proposed that the act of dissociation of pentafluorosilicates should be regarded as the vibrational movement of an anion of the type A_2'' smoothly converting the SiF_5^- complex of D_{3h} symmetry to an SiF_4 molecule (T_d). The intermediate distorted structures of the SiF_5^- anion, which link the initial geometry of the complex with the tetrahedral reaction product, should have C_{3v} symmetry:

$$SiF_5^-(D_{3h}) \rightleftarrows SiF_5^-(C_{3v}) \rightleftarrows SiF_4(T_d) + F^-.$$

According to the method of structural correlations,[63] the A_2'' route for the SiF_5^- anion may be reconstructed by analysing the geometric deformation of the anion in crystalline structures of pentafluorosilicates with cations of varying polarising effect. As was mentioned above, the geometry of the SiF_5^- anion in salts with large cations only slightly differs from an ideal TBP, while in $MSiF_5$ ($M = K^+$, Cs^+) salts that were isolated in a low-temperature matrix an axially distorted structure of the anion with C_{3v} symmetry was found as expected.

Having marked acceptor properties, tetraalkylammonium pentafluorosilicates react with ammonia[7,61,64] and methylamines[61] to form complex salts $(R_4N)[SiF_5(Me_nNH_{3-n})]$ ($n = 0$–3) which are isolated in a pure state. By using spectroscopic methods it was possible to study the donor-acceptor interaction between the SiF_5^- anion and a number of bases in non-aqueous media. Clark et al.[7] used IR spectroscopy to study complex formation in the system $SiF_5^- - L - MeCN$, having previously established that the process of dissolving pentafluorosilicate in acetonitrile is not accompanied by coordination of solvent molecules. An increase in concentration of the molecular ligand L produced a decrease in the intensity of the $\nu(Si-F)$ absorption band at ~ 874 cm^{-1} that is characteristic for the SiF_5^- anion. On the basis of this the following order of change in ligand donor capacity relative to SiF_5^- was established:

$$Et_2NH > Et_3N > n\text{-}Pr_3N > Py \sim Et_3P.$$

The basicity of these ligands decreases in the same series. According to the results of Gibson et al.,[65] introduction of ammonia or diethylamine into a solution of $(Pr_4N)SiF_5$ in methylene chloride results in the equilibrium

$$SiF_5^- + L \rightleftarrows [SiF_5(L)]^-,$$

which can be monitored by ^{19}F NMR spectroscopy. When the temperature is lowered, there is a shift in the equilibrium towards the formation of the pseudooctahedral anion.

It is interesting that by studying the interaction of $(Pr_4N)[PhSiF_4]$ and Pr_4NF in methylene chloride it was possible to resolve the problem concerning the structure of complex anions $[RSiF_5]^{2-}$ which had remained the subject of controversy for a considerable length of time. The opinion was held[21,66] that in the absence of structural data compounds with the empirical formula $M_2[RSiF_5]$ (M is an alkali metal, ammonium, or alkylammonium cation) should be regarded as double salts $M_2[RSiF_4]F$ containing pentacoordinate anions $[RSiF_4]^-$ rather than substituted derivatives of the corresponding hexafluorosilicates. However, Marat and Janzen[66] established that the $[PhSiF_4]^-$ anion accepts a fluoride ion to give a hexacoordinate complex $[PhSiF_5]^{2-}$, which has a structure that can be clearly demonstrated by low-temperature ^{19}F NMR spectroscopy.

The pentafluorosilicate anion may be regarded as the product of partial compensation of the acceptor capacity of silicon tetrafluoride by coordination of a single fluoride ion with the latter. Consequently the SiF_5^- anion should have a lower Lewis acidity than the initial SiF_4 molecule. This fairly obvious conclusion has been confirmed from quantitative data on the enthalpy of dissociation of the complexes $(R_4N)[SiF_4(L)]$ and $SiF_4(L)_2$:

$$(R_4N)[SiF_5(L)](s) \rightarrow (R_4N)SiF_5(s) + L(g),$$
$$SiF_4(L)_2(s) \rightarrow SiF_4(g) + 2L(g).$$

The determination was made using the results of tensiometric measurements (Table 1).

The noticeable difference in the values of the enthalpy of dissociation that were obtained by different research workers attracts attention. According to Wharf and Onyszchuk[64] the value $\Delta H = 7.9$ kcal mol^{-1} is not the true enthalpy of dissociation of the complex but is an average enthalpy for two processes—the adsorption of ammonia on the surface of solid pentafluorosilicate and the actual dissociation of the complex. It follows from the data of Table 1 that the enthalpies of dissociation of complexes $(R_4N)[SiF_5(NH_3)]$ depend on the size of the cation, increasing in the series $Et_4N^+ < Pr_4N^+ < Bu_4N^+ \sim Pent_4N^+$. The following thermodynamic cycle was examined in one report:[61]

$$\begin{array}{ccc} (R_4N)[SiF_5(NH_3)](s) & \xrightarrow{\Delta H_1} & NH_3(g) + (R_4N)SiF_5(s) \\ \downarrow & & \downarrow \\ R_4N^+(g) + [SiF_5(NH_3)]^-(g) & \xrightarrow{\Delta H_2} & NH_3(g) + R_4N^+(g) + SiF_5^-(g), \end{array}$$

From which

$$\Delta H_1 = \Delta H_2 + (U_1 - U_2).$$

It was proposed[61] that for complexes $(R_4N)SiF_5$ and $(R_4N)[SiF_5(NH_3)]$ with cations that are greater in size than the anions SiF_5^- and

$[SiF_5(NH_3)]^-$ the structure of the crystal lattice is mainly determined by the packing of the cation and the crystal lattice energies of the complexes are very similar. When this approximation is used ($U_1 = U_2$), the experimentally determined enthalpy of dissociation (ΔH_1) and the corresponding value (ΔH_2) for the process in the gas phase which is not dependent on the nature of the cation become equal. Wharf and Onyszchuk[61] assumed that the condition $U_1 = U_2$ was met for the tetrabutyl- and tetrapentyl-ammonium complexes and the slight difference in enthalpy of dissociation for these compounds could occur because the term $(U_1 - U_2)$ was the difference between two large quantities. A value of $\Delta H^0 = 16.8 \pm 0.6$ kcal mol^{-1} was taken by Wharf and Onyszchuk[61] to be the lower limit of the enthalpy of dissociation of the complex anion $[SiF_5(NH_3)]^-$ in the gas phase. If the crystal lattice energies of the complexes $(R_4N)[SiF_5(L)]$ and $SiF_4(L)_2$ are assumed to have similar values,[64] the thermochemical data given in Table 1 indicate that the SiF_5^- anion has a lower acceptor capacity than silicon tetrafluoride relative to this group of donors.

V. Mechanisms of intra- and inter-molecular ligand exchange in solution

IR and Raman spectroscopic studies indicate[7] that the SiF_5^- anion in the solid state and in non-aqueous solution exists in the TBP configuration with non-equivalent axial and equatorial Si–F bonds. At the same time ^{19}F NMR spectra of pentafluorosilicates show that all the fluorine atoms are equivalent.[16,21,65] This apparent contradiction may be due to the difference in time-scale characteristics of these methods and to the rapid (on the time-scale of NMR) exchange of axial and equatorial fluorine atoms. It can be seen from the data given in Table 2 that spectroscopic equivalence of the fluorine atom is also exhibited in the monosubstituted anions $[RSiF_4]^-$ and $[XSiF_4]^-$ but the low-temperature ^{19}F NMR spectra of the disubstituted anions $[Ph_2SiF_3]^-$ and $[PhMeSiF_3]^-$ contain separate signals from the non-equivalent F_a and F_e.

The fact that $^{29}Si-^{19}F$ spin-spin coupling is preserved in the ^{19}F NMR spectra of solutions of pentafluorosilicates at temperatures below –60 °C has been related[21] to the intramolecular nature of ligand exchange, which most probably occurs by the pseudorotation mechanism proposed by Berry.[51] It may be recalled that exchange results in the transposition of two axial and two equatorial ligands in the TBP anion structure. The TP configuration acts as an intermediate state in this polytopic rearrangement.[71] The temperature dependence of the shape of the lines in the NMR spectra[46,70,72,73] is consistent with the pseudorotation mechanism of Berry for pentacoordinate fluorosilicate anions, although alternative mechanisms cannot be entirely excluded.[61,64] Damrauer and Danahey[70] calculated the activation parameters for intramolecular fluorine exchange in $[Ph_2SiF_3]^-$ and $[PhMeSiF_3]^-$ anions. The results obtained are given in Table 3 together with data for related pentacoordinate trifluorosilyl molecular complexes.

Table 2. ^{19}F NMR spectroscopic parameters of pentacoordinate fluorosilicate anions in non-aqueous solution.[21,22,70]

It is evident from the data of Table 3 that the energy barriers for intramolecular exchange of fluorine in pentacoordinate anionic and molecular SiF_3 derivative forms are very similar. It should be noted that the results from temperature-dependent ^{19}F NMR spectroscopic studies on 2-{(methyltrifluorosilylamino)methyl}pyridine[79] and 1-(trifluorosilyl)-1,2,3,4-tetrahydro-1,10-phenanthroline [80] (energy barriers for fluorine exchange are 13.2 and 7.5 kcal mol^{-1} respectively) were interpreted by the authors of these studies in terms of an exchange model which incorporated the cleavage of an intramolecular Si ← N coordinate bond followed by rotation of the SiF_3 group in the tetrahedral intermediate. It was suggested[80] that this type of scheme for fluorine exchange is to be preferred to the alternative mechanisms for compounds with relatively weak intramolecular Si ← N coordinate bonds.

Wilhite and Spialter[81] carried out non-empirical calculations on the mechanism of the Berry pseudorotation for the hypothetical anions SiH_5^- and $[SiH_{5-n}X_n]^-$ (n = 1–5), where introduction of a more electronegative substituent X (EN_X = 2.9 on the Pauling scale) was formally effected by increasing the charge of the hydrogen atomic nucleus to +1.1. It was found that the pseudorotation barriers for SiH_5^- and SiX_5^- complexes were small (2.87 and

2.94 kcal mol^{-1} respectively) and that rearrangement took place almost freely whereas pseudorotation in the mixed anion $[SiH_2X_3]^-$ occurred via several alternative configurations and required a greater consumption of energy (about 7.03 kcal mol^{-1}). According to similar *ab initio* calculations on the rearrangements of PF_5 and PF_3H_2 molecules,[82,83] the change to trifluorophosphorane, as in the case of the substituted anion $[SiH_2X_3]^-$, is accompanied by an increase in the pseudorotation barrier and a greater complexity of rearrangement mechanism, the calculated values of the energy barriers being similar to the experimental values. If it is assumed that SiX_5^- and $[SiH_2X_3]^-$ complexes to a given approximation simulate the behaviour of the real anions SiF_5^-, $[Ph_2SiF_3]^-$, and $[PhMeSiF_3]^-$, the decrease in rate of axial-equatorial exchange of fluorine atoms on going from SiF_5^- to $[Ph_2SiF_3]^-$ and $[PhMeSiF_3]^-$ becomes clear.[21,70] Calculations[81-83] confirm the empirical rule of Muetterties and Schunn,[38] according to which isomers with an axial orientation of the electronegative substituents are the most stable for the TBP configuration of complexes of non-transition elements.

Table 3. Activation parameters for intramolecular exchange of fluorine in pentacoordinate trifluorosilyl complexes.

Compound	$\Delta G^{\neq}$, kcal mol^{-1}	$\Delta H^{\neq}$, kcal mol^{-1}	$\Delta S^{\neq}$, cal deg^{-1} mol	Refs.
$[Ph_2SiF_3]^-$	11.7	11.2	2.5	[70]
$[PhMeSiF_3]^-$	9.9	9.4	−4.4	[70]
	7.4—9.0	—	—	[75]
	9.5	—	—	[76]
	13.1	—	—	[77]
	12.0	—	—	[78]

A discussion of the probable mechanisms for intermolecular exchange of fluorine in pentacoordinate fluorosilicate anions first appeared in a study of Klanberg and Muetterties.[21] These authors proposed that the broadening of the ^{19}F NMR resonance signal from the SiF_5^- anion for a solution of tetrapropylammonium pentafluorosilicate in methylene chloride with a loss of the fine structure from $^{29}Si-^{19}F$ at temperatures above −60 °C could be due to either the dissociation:

$$SiF_5^- \rightleftarrows SiF_4 + F^-,$$

or association with formation of polymeric anions with fluoride bridges:

$$nSiF_5^- \rightleftarrows (nSiF_5)^-,$$

with both equilibria accompanied by cleavage of Si−F bonds. When the Lewis acidity of the pentafluorosilicate anion was taken into consideration, an associative mechanism was considered[21] to be the most favourable. On the other hand, alkyl- and aryl-substituted $[R_nSiF_{5-n}]^-$ anions have a much lower acceptor capacity than SiF_5^- and so dissociation is more probable for such compounds:

$$[Ph_2SiF_3]^- \rightleftarrows Ph_2SiF_2 + F^-.$$

This conclusion is indirectly confirmed by the results of a non-empirical calculation on the energy of the intermolecular ligand exchange in hypothetical $[SiH_{5-n}X_n]^-$ anions[81] (Table 4). However, the results of Damrauer and Danahey,[70] which demonstrate the absence of dissociative exchange of fluorine in solutions of $[Ph_2SiF_3]^-$ over a wide temperature range (^{19}F and ^{29}Si NMR data), should be noted. An important factor in this case is the relatively high dielectric constant of the solvent used[70] (acetone-d_6/vinyl chloride), which should favour this particular dissociative process involving the $[Ph_2SiF_3]^-$ anion.

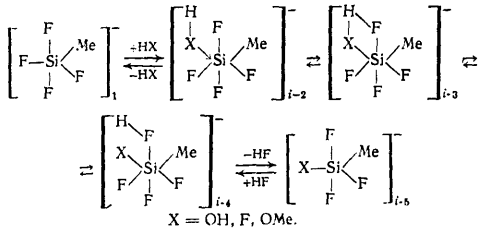
Table 4. Calculated values of ΔH for intermolecular exchange in the hypothetical systems $[SiH_{5-n}X_n]^-$.

n	Reaction	ΔH, kcal mol^{-1}*
0	$SiH_4 + H^- \rightleftarrows SiH_5^-$	16.97 (16.97)
1	$SiH_4 + X^- \rightleftarrows [SiH_4X]^-$	12.59 (35.77)
2	$SiH_3X + X^- \rightleftarrows [SiH_3X_2]^-$	30.16 (55.08)
3	$SiH_2X_2 + X^- \rightleftarrows [SiH_2X_3]^-$	44.05 (70.72)
4	$SiHX_3 + X^- \rightleftarrows [SiHX_4]^-$	58.27 (86.73)
5	$SiX_4 + X^- \rightleftarrows SiX_5^-$	72.79

*Values in brackets refer to a reaction with hydride ion as the leaving group.

It cannot be ruled out that the occurrence of a given mechanism for fluorine exchange in the diphenyltrifluorosilicate anion—intermolecular dissociative exchange for a solution of $(Et_4N)[Ph_2SiF_3]$ in methylene chloride[21] and the intramolecular Berry process for a solution of (18-crown-6.K)$[Ph_2SiF_3]$ in an acetone-d_6/vinyl chloride mixture[70]—is due to the differences in polarising effects of the external cations. When the higher charge density on the Et_4N^+ cation compared to $(18\text{-crown-6.K})^+$ is taken into account, these difference in the mechanism for fluorine exchange in diphenyltrifluorosilicates then become completely consistent. In this connection there are some interesting results[84] which indicate that in non-aqueous solutions of trialkyl- and dialkyl-ammonium pentafluorosilicates dissociative intermolecular exchange of fluorine is occurring:

$$2SiF_5^- \rightleftarrows SiF_4 + SiF_6^{2-}.$$

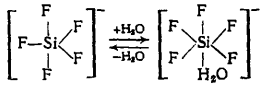


It was indicated[21] that intermolecular exchange processes with cleavage of Si–F bonds in pentacoordinate fluorosilicate anions may be caused by the presence of impurities in the samples studied. This question has been the subject of special studies.[65,85] The connection between exchange and hydrolysis processes is the most obvious. For example, the reversible loss of fine structure in ^{19}F NMR spectra of non-aqueous solutions of tetraalkylammonium pentafluorosilicate and methyltetrafluorosilicate when water is added to the samples followed by treatment with hexamethyldisilazane is consistent[65,85] with a hydrolysis mechanism of intermolecular fluorine exchange:

$$SiF_5^- + H_2O \rightleftarrows [SiF_4OH]^- + HF,$$
$$[MeSiF_4]^- + H_2O \rightleftarrows [MeSiF_3OH]^- + HF.$$

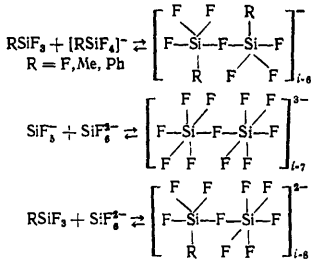
The action of $(Me_3Si)_2NH$ leads to HF, which is a fluorine carrier in the exchange process, being removed from the system by the reaction:

$$(Me_3Si)_2NH + 2HF \rightarrow 2Me_3SiF + NH_3.$$



By using the concept of the change in coordination numbers of elements during the reaction, namely, Si(5) ⇆ Si(6), H(1) ⇆ H(2), F(1) ⇆ F(2), O(2) ⇆ O(3), Marat and Janzen[85] proposed the following generalised mechanism for intermolecular exchange of fluorine in the $[MeSiF_4]^-$ anion in the presence of H_2O, HF, or MeOH:

X = OH, F, OMe.

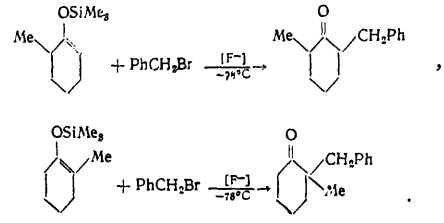


At the first stage the formation of the hexacoordinate intermediate *i*-2 is postulated, which is converted by a four-centre mechanism to *i*-3. The subsequent cleavage of the X–H bond and elimination of an HF molecule leads to the substitution product *i*-5.

It was demonstated[16,65] that the Lewis acid-base interaction in the system $SiF_5 - H_2O$ and the rapid exchange between penta- and hexacoordinate complexes can be taken as the basis for the mechanism of low-temperature intramolecular axial-equatorial ligand exchange in the SiF_5^- anion:

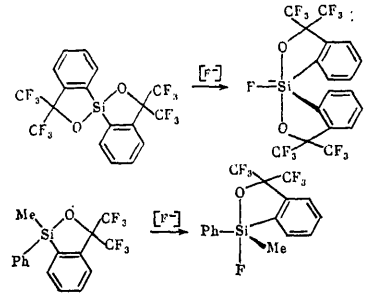
Exchange leads to 'averaging out' of the position of the fluorine atoms in the coordination polyhedron, but their bond with the silicon atom is preserved.

In conclusion, mention should be made of the results of the study by Marat and Janzen[16] on the intermolecular exchange of fluorine in the systems $SiF_4^- - SiF_5^-$, $MeSiF_3 - [MeSiF_4]^-$, $PhSiF_3 - [PhSiF_4]^-$, $SiF_5^- - SiF_6^{2-}$, $SiF_4 - SiF_6^{2-}$, and $MeSiF_3 - SiF_6^{2-}$ (external cation Pr_4N^+). The ^{19}F, ^1H, and ^{13}C NMR spectroscopic data obtained[16] were interpreted on the basis of the coordination model of the reaction mechanism[85] involving a change in coordination numbers Si(4) ⇆ Si(5), Si(5) ⇆ Si(6), Si(4) ⇆ Si(5) ⇆ Si(6), F(1) ⇆ F(2) in formation of the intermediates *i*-6, *i*-7, and *i*-8:



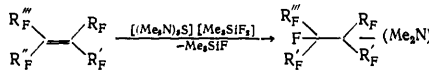
According to the results of this study[16] intermolecular exchange of fluorine is rapid (on the time-scale of NMR) if the fluoro-complexes participating in exchange have different coordination numbers. For example, introduction of excess ammonia into the system $SiF_5^- - SiF_6^{2-}$ inhibits exchange because of the formation of the hexacoordinate complex $[SiF_5(NH_3)]^-$. On the other hand, addition of diethylamine to a sample of $MeSiF_3$ is accompanied by a loss of fine structure from $^{19}F-Si-C-^1H$ spin-spin coupling in its ^{19}F and ^1H NMR spectra since $MeSiF_3$ is involved in exchange with penta- and hexacoordinate products of donor-acceptor interaction.

VI. Use in preparative synthesis



The known examples where salts of pentacoordinate fluorosilicate anions have been used in preparative synthesis are few in number but they serve as a good illustration of the synthetic possibilities of this class of compounds. Thus, tris(dialkylamino)sulphonium trimethyldifluorosilicates, which are fairly readily available and stable, serve as useful sources of the unhydrated fluoride ion:[86]

$$[(R_2N)_3S][Me_3SiF_2] \rightleftarrows (R_2N)_3S^+ + F^- + Me_3SiF.$$



In the presence of $[(Et_2N)_3S][Me_3SiF_2]$, silyl enol ethers readily react under very mild conditions with primary alkyl bromides and alkyl iodides to form products from regiospecific *C*-monoalkylation (yield 60–95%):[87]

The analogous derivative, $[(Me_2N)_3S][Me_3SiF_2]$, was used in the synthesis of pentacoordinate monofluorosilicates:[46]

It was recently shown[88] that tris(dimethylamino)sulphonium trimethyldifluorosilicate reacts with perfluoroolefins in THF or acetonitrile to form stable fluorocarbanion salts:

Reactions of $(Me_2N)_3S^+CF_3(CF_2)_2C^-(CF_3)_2$ with a number of organic compounds have been reported, demonstrating the synthetic value of the salts obtained.

In two studies Gel'mbol'dt[89,90] has proposed a method for the synthesis of hexacoordinate silicon tetrafluoride complexes with molecular nitrogen-donor ligands by reaction of tripropylammonium pentafluorosilicate or the double fluorosilicates $(R_3NH)_2SiF_6.2(R_3NH)SiF_5$ (R = Et, Bu) with the respective bases in methylene chloride or acetonitrile, for example:

$$2SiF_5^- + \alpha,\alpha'\text{-Bipy} \rightarrow SiF_4(\alpha,\alpha'\text{-Bipy}) + SiF_6^{2-}.$$

This method of synthesis does not require operations involving gaseous silicon tetrafluoride; $SiF_4(L)$ complexes are virtually insoluble in the solvents used and are readily separated from a solution of trialkylammonium hexafluorosilicate. The use of alcohol solutions of silicon tetrafluoride[91] to obtain such compounds is unacceptable since even a base of medium strength such as aniline and especially highly basic amines bring about the alcoholysis of SiF_4.[92]

Finally, we should mention a simple and effective variant of the synthesis of graphite intercalation compounds by reaction of the readily available salt $C_{24}SiF_5$ [93,94] with strong Lewis acids such as PF_5, BF_3, or $C_6F_5PF_4$:

$$C_{24}SiF_5 + 2PF_5 \rightarrow C_{24}PF_6 \cdot PF_5 + SiF_4,$$
$$C_{24}PF_6 \cdot PF_5 \xrightarrow{20\ ^\circ C,\ \text{vacuum}} C_{24}PF_6 + PF_5,$$
$$C_{24}SiF_5 + C_6F_5PF_4 \rightarrow C_{24}C_6F_5PF_5 + SiF_4.$$

This method compares favourably with the traditional scheme for the synthesis of salts of graphite with fluorine-containing anions because of the possibility of using Lewis acids such as $C_6F_5PF_4$ which are unstable towards elemental fluorine.

Mechanodegradation of polymers. The method of molecular dynamics

L S Zarkhin, S V Sheberstov, N V Panfilovich, L I Manevich
Institure of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The experimental results in the field of the mechanodegradation of polymers, indicating significant differences between this process and thermal degradation, are discussed; the mechanism of both processes have been subjected to a comparative analysis. The principal results obtained by the method of molecular dynamics in the study of related processes such as mechanodegradation and the effect of shock waves are examined. Attention is concentrated on the mechanisms of ruptures, the formation of excited low-molecular-weight products, and the process energetics. The prospects for further research are discussed.

The bibliography includes 30 references.

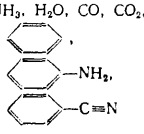
I. Introduction



Mechanodegradation is one of the main chemical processes occurring in polymers both during their processing and during their use under load. The most effective physical method for the investigation of molecular mechanodegradation products is mass spectrometry.[1-5]

In the field of the mechanodegradation of polymers, it is now possible to distinguish two groups of experimental facts on the explanation of which the understanding of the mechanism of this process depends to a large extent. The first group includes results indicating a significant difference between the compositions of the molecular thermal degradation and mechanodegradation products (Table 1). For a number of polymers investigated by different workers[1-3] by mass spectrometry, it has been established that heavy fragments characteristic of thermal degradation are completely absent from the mechanodegradation products. The formation of only light products in mechanodegradation apparently shows that the vibrational energy is distributed significantly non-uniformly in mechanodegradation and is localised in regions whose size does not exceed 10 Å. This result is difficult to understand within the framework of the generally accepted thermofluctuation concept.[6]

The second group of experimental facts, which does not fit within the framework of the thermofluctuation concept, is the discovery of high-energy molecular products of the mechanodegradation of a series of polymeric materials (Table 2).[5] A linear polymer—poly(methyl methacrylate) (PMMA), a network epoxide polymer based on the diglycidyl ether of resorcinol and *m*-phenylenediamine (DGER–MPDA), and a composite material (ebonite) have been investigated. Table 2 shows that the molecular mechanodegradation products—both the main products (MMA, acetaldehyde) and the occluded water—have extremely high kinetic energies of translational motion ranging from 0.25 to 0.70 eV, which corresponds to translational temperatures ranging from 2000 to 5400 K.

The impossibility of explaining the results described above within the framework of the thermofluctuation concept necessitates a theoretical study of the mechanodegradation of polymers by a method which would be free from *a priori* postulates similar to those

Table 1. The molecular products of the thermal degradation and mechanodegradation of polymers.

Polymer	Volatile thermal degradation products	Volatile mechanodegradation products	Agreement between product compositions	Refs.
Poly(methylmethacrylate) (PMMA)	monomer	monomer	ec	[1]
Polystyrene (PS)	monomer, oligomers	monomer, dimer	no	[1]
Poly-α-methyl-styrene-(isotactic) (P-α-MS)	monomer	monomer	yes	[1]
Polyformaldehyde (PFA)	monomer	monomer, unidentified products	no	[1]
Polyethylene (PE)	low-molecular-weight saturated and unsaturated hydrocarbons	low-molecular-weight saturated and unsaturated hydrocarbons	?	[1]
Polypropylene (PP)	low-molecular-weight saturated and unsaturated hdyrocarbons	low-molecular-weight saturated and unsaturated hydrocarbons	?	[1]
Polyacrylonitrile (PAN)	HC ≡ N, monomer	unidentified products	no	[1]
Nitrocellulose (NC)	CO, CO_2, H_2O, NO, NO_2, CH_2O	CO, CO_2, H_2O, CH_2O	no	[1]
Polycapramide (PCA)[1]	H_2O, CO_2, NH_3, hydrocarbons	CO_2, NH_3, hydrocarbons	no	[1]
Polyepoxide	H_2, CO, CH_4, C_2H_4, C_2H_6, C_6H_6, C_8H_8	H_2, CO, CH_4, C_2H_6	no	[1]
DGER-MPDA	CH_3CHO, H_2O, resorcinol, decomposed aromatic compounds	CH_3CHO, H_2O, H, CH_4, HC≡N, CH≡CH	no	[2]
Poly-*m*-phenylene-isophthalamide (PMPIA) (nomex, phenylon); poly-*p*-phenylene-terephthalamide (PPTA) (kevlar, arenka); poly-*p*-benzamide; polyamidebenzimidazole (PABI)	NH_3, H_2O, CO, CO_2, 	NH_3, H_2O, CO, CO_2	no	[3]

underlying the thermofluctuation concept. If the treatment is restricted to the investigation of the mechanodegradation of a macromolecule only within the framework of classical mechanics, then one can expect that the method of molecular dynamics (MD) will prove most compatible with the significantly non-linear character of the mechanodegradation process and will be most effective in the given instance.

At the present time, this method has been developing vigorously on the basis of modern computer techniques. With the aid of the MD method, it is possible to investigate in detail the molecular dynamics of various processes in the time range 10^{-14}–10^{-11} s.

Table 2. High-energy molecular products of the mechanodegradation of polymeric materials.[5]

Polymer	Products	V, m s^{-1}	E_{trans}, eV	T_{tr}, K
PMMA	MMA	1160^{+160}	$0.70^{+0.21}$	5410^{+1530}
	H_2O	1580^{+338}	$0.23^{+0.11}$	2190^{+460}
DGER–MPDA	CH_3CHO	1210^{+100}	$0.33^{+0.08}$	2570^{+450}
	H_2O	1680^{+305}_{-100}	$0.26^{+0.11}_{-0.03}$	2040^{+810}_{-280}
Ebonite	H_2O	1690	27	2065

Note. V is the velocity of the translational motion of the moelcules, $E_{trans} = mV^2/2$ the kinetic energy of the translational motion of the molecules, T_{tr} the translational temperature [the experimental errors ($\pm$), determined by the accuracy of the method, are indicated for V, E_{trans}, and T_{tr}].

II. The application of the method of molecular dynamics

1. Mechanodegradation

The decomposition of an extended chain of atoms was investigated by the MD method for the first time by Toda et al.[7] on a one-dimensional model. The interaction between neighbouring atoms was specified by a potential of a special type:

$$\Phi(r) = \begin{cases} e^{-r} + r + \text{const}, & r < r_{cr} \\ \text{const}, & r > r_{cr}, \end{cases}$$

since simple analytical solutions of the equations of motion $f_n = \Omega^2 \operatorname{sech}^2(kn \pm \Omega t)$, where f_n is the force of the compression of the nth bond, $\Omega = m^{-1/2} \sin nk$, r is the deviation of the position of the atom from equilibrium (bond deformation), m the mass of the atom, k a constant, and t the time, are known for a chain with such a potential. These solutions represent unified compression waves (solitons) propagated along the chain of atoms.

The following sequence of events after the rupture of a uniformly extended chain has been noted:[7] (1) immediately after rupture, a wave of stresses is generated and is propagated in the direction towards the fixed end; (2) after reflection from the latter, the wave is transformed into a sequence of compression pulses (solitons); (3) each soliton reaching the free end of the chain leads to the extension of the extreme bond, which exceeds by several per cent the initial extension r_{init}. However, since the critical stretching deformation of the bond r_{cr} was always specified by the authors[7] in the range $(1.015–1.07)r_{init}$, then such extension always leads to the abstraction of the extreme atom of the chain. Thus, in the initial degradation stage consecutive removal of atoms from the free end takes place and is followed by random breaks of the chain in different places. The above degradation sequence holds for a wide range of initial extensions of the chain.

The fragmentation of a uniformly extended one-dimensional chain of atoms has also been studied by the MD method in other investigations.[8,9] In contrast to Toda, Mel'ker et al.[8] and Grigoryan et al.[9] used the Morse potential for the description of the interaction between neighbouring atoms of the chain. The generation of large-amplitude compression pulses on reflection of the relaxation wave from the fixed end, analogous to those observed by Toda,[7] was noted. However, in contrast to Toda's work,[7] the rupture of the extreme bond was not observed on reflection of the compression pulses from the free end despite the fact that the stretching deformation exceeded ε_{cr}.† The kinetic energy of the motion of the centres of mass of the fragments was considerable and amounted to 25% of the total energy of the system. The deformation of the individual bonds in the fragments reached $2.2\varepsilon_{cr}$ although further fragmentation was not observed.

The occurrence of low-frequency vibrations in the extended chain has been noted by Mel'ker and Kuznetsova,[10] which the authors attribute to the "two-well nature" of the potential for any internal chain atom.[11] The two-well form of the potential is responsible for the existence of stable lengthened bonds capable of migrating. It has been suggested[10] that they be referred to as quasi-particles—dilatons, and the dissociation of an extended chain has been interpreted[12] as a result of the merging of dilatons.

A series of studies by Mel'ker and co-workers has been devoted to the mechanism of the dissociation of an interatomic bond in an extended chain of atoms.[13–15] Two types of ruptures are distinguished. The first type of rupture—the single-step rupture—is associated with the generation of a dissociative energy fluctuation embracing approximately 10 atoms. In the region of the fluctuation, the deformation of the interatomic bonds exceeds the average value and the motion of the atoms is correlated.[13] In rupture, the energy of the fluctuation is concentrated on one bond, which is rapidly and monotonically lengthened up to dissociation. This type of rupture is characteristic of a relatively high energy density in the deformed chain of atoms, when its lifetime does not exceed 10^3 periods of the atomic vibrations. The second type of rupture of the interatomic bond—the two-step rupture, whose probability increases with decrease in the energy density in the chain, has been noted by Mikhailin and Mel'ker.[14,15] The interatomic bond is rapidly lengthened up to values in the range $\varepsilon = (2–4)\varepsilon_{cr}$ and oscillates about the level attained over a period $(2–7)\tau_0$. The bond dissociation is then rapidly completed.

The longevity of the polymer chain under load at a specified temperature has been investigated by Zaitsev and Razumovskaya.[16] A one-dimensional chain of atoms, whose interaction is described by the Morse potential, was used as the model. The appearance of two compression regions (lattice solitons), diverging from the site of chain rupture at ultrasonic velocities, was noted.

†The bond deformation $\varepsilon \equiv (r - r_0)/r_0$, where r is the distance between the atoms and r_0 its equilibrium value. The critical bond formation $\varepsilon_{cr} = \ln 2/\alpha r_0$ corresponds to the ultimate strength of the interatomic bond $F_m = \alpha U_0/2$, where α and U_0 are parameters of the Morse potential.

Taking into account the fact that the principal characteristics of the mechanodegradation of the polymer chain are determined by the strong anharmonicity of the vibrational-wave excitations, arising during the different stages, it is useful to analyse the instances of intense shock interaction of polyatomic systems in which anharmonicity plays a decisive role.

2. Shock waves

A study by Bettech and Powell was devoted to the numerical modelling of the propagation of a shock wave in a one-dimensional chain.[17] The investigation established that the development of the process involving the oscillation of particles behind the shock wave front is determined in the early stage by the dispersion, after which non-linear effects become increasingly more significant. During the propagation of a shock wave, decaying oscillations are converted into a sequence of distinct pulses—solitons (Fig.1*a*). The stability of solitons (*A*, *B*, *C*) in relation to collisions and the thermal background (Fig.1*b*) leads to the absence of a tendency towards the "disordering" of the energy, i.e. towards the attainment of thermal equilibrium. The energy is not thermalised behind the shock wave front and hence the temperature does not increase.

The propagation of a shock wave in an iron crystal has been investigated by Walker et al.[18] The behaviour of impurity diatomic molecular H_2 and C–H species (probes) in the three-dimensional iron lattice during the passage of the shock wave front was investigated by the MD method. Figs.2 and 3 illustrate the time variation of the translational (*a*), rotational (*b*) and vibrational (*c*) energies of the H_2 and C–H probe molecules respectively as well as the disposition of the iron atoms and probe molecules in the system before the impacts (*d*) of the plate against the block and at the instant corresponding to 40 time units (1 time unit = 10^{-14} s) (*e*) corresponding to the attainment of the end of the block by the shock wave. The iron

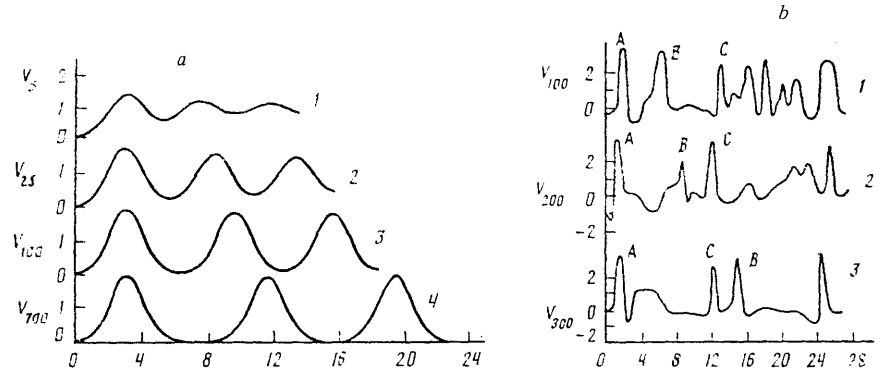


Figure 1. Variation with time τ of the velocities V of different particles (5th, 25th, 100th, and 700th) in the chain:[17] *a*) initially unperturbed; *b*) at a non-zero initial temperature; τ_0 (arbitrary units)—the instant when each particle is acted upon by the shock wave: *a*: *1*) τ_0 = 5.6; *2*) τ_0 = 36.5; *3*) τ_0 = 148.9; *4*) τ_0 = 1041.0; *b*: *1*) τ_0 = 73; *2*) τ_0 = 140; *3*) τ_0 = 209.

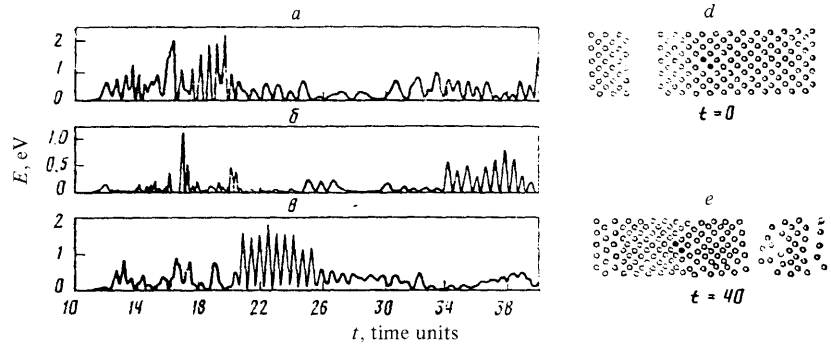

Figure 2. Time variation of the energy E [*a*) translational; *b*) rotational; *c*) vibrational] of the H_2 probe molecule in the Fe lattice during the passage of the shock wave front; *d*) disposition of atoms in the system before impact; *e*) instantaneous disposition of atoms in the system after 40 time units have elapsed (1 unit = 10^{-14} s) corresponding to the shock wave reaching the end of the block; Fe atoms are represented by open circles and the atoms of the H_2 probe molecule by filled circles.[18]

atoms are represented by circles and the atoms of the probe molecules are represented by points. Figs.2 and 3 show that the variation of the kinetic energy of the translational motion of the diatomic probe molecules reaches 6 eV and has the form of a sequence of unified brief ($\sim 10^{-14}$ s) pulses resembling solitons. The changes in the energies of rotational and vibrational motions (b) and (c), reaching several eV, have a similar form. Such large energies of the vibrational motion lead to the dissociation of molecules: for a short period if the molecule is in a 'cage' and irreversibly if the molecule is at the boundary of the free volume.

3. Elementary thermal excitations

In his analysis by means of the procedure described by Battech and Powell[17] of the thermal vibrations in a one-dimensional chain of 500 atoms, whose interaction is described by the Morse potential, Zhukov[19] showed that two types of lattice excitations coexist in the thermalised chain: solitons and phonons. The solitons are in fact the high energy carriers and their contribution to the overall thermal energy of the thermalised lattice amounts to tens per cent and increases with increase in temperature. Fig.4 illustrates the instantaneous velocities of the atoms in the middle part of a 500-atom chain. In the initial instant (*a*), only a small zone in the centre of the chain comprising 20 atoms (from the 250th to the 270th) is heated and the rest of the chain is "cold". The migration of energy from "hot" to the "cold" zone is effected both by phonons and solitons. However, since the velocity of the soliton is greater than the velocity of sound, the solitons emerge from the heated zone, overtaking the phonons. Figs.4*b* and 4*c* illustrate the instantaneous velocities of atoms after 2000 and 4000 time steps respectively and the solitons which have emerged are designated by vertical arrows.

The occurrence of stable elementary excitations of the soliton type in a chain of atoms fixed at the edges, whose interaction is described by the Morse potential, has been demonstrated analytically by Collins[20] and numerically by Rolfe et al.[21] Rolfe et al.[21] not only demonstrated the possibility of the existence of solitons in one-dimensional chains with different interatomic interaction potentials (Morse, Lennard-Jones 6–12 and 16–32) but also established that the reflection of the solitons from the fixed and free ends as well as the collision of the solitons with one another are similar to the behaviour of solitons in a Toda chain for all the potentials examined.

The appearance of such excitations in the mechanodegradation of a uniformly extended one-dimensional chain of Morse oscillators and the interaction of solitons having different energies with the extended chain have been described.[22,23] In addition, a study has been made[22] of the dependence of the mass spectrum of the mechanodegradation products on the length and degree of extension of the chain.

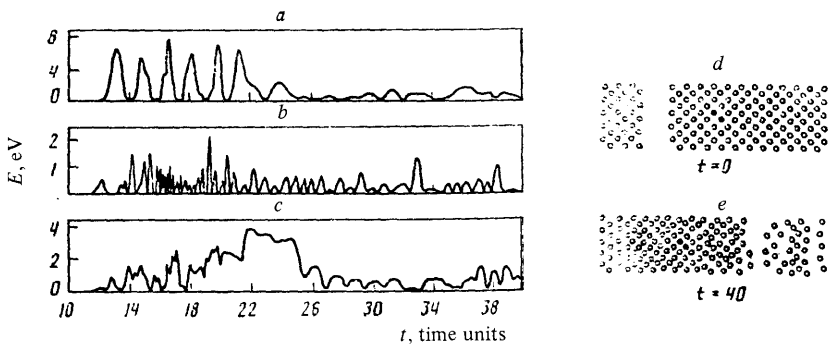

Figure 3. See the caption to Fig. 2; C–H molecular probe in the Fe lattice.[18]

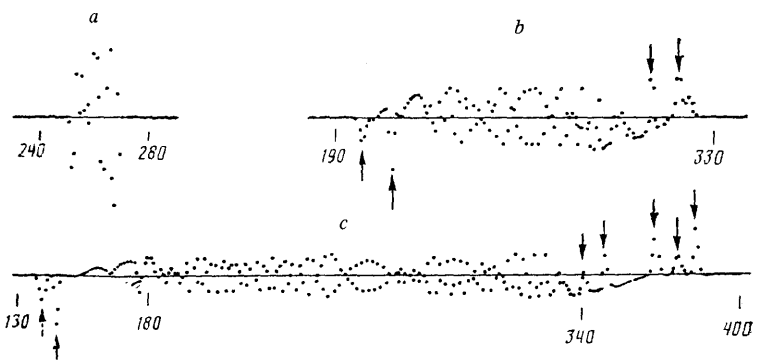

Figure 4. Instantaneous velocities of the atoms in the chain: *a*) in the initial instant; *b*) after 2000 time steps; *c*) after 4000 time steps;[19] the numerals denote the numbering of the atoms.

In his study of the properties of the elementary thermal excitations in a strongly heated chain of atoms, whose interaction is described by the Lennard-Jones potential, Lagunov[24] established that, as in the case of the Morse potential, they are equivalent to the lattice solitons existing in the Toda chain.[25] On the basis of this conclusion, he examined[24] the thermal fluctuation-induced dissociation of a uniformly extended chain either as a result of the interaction of countercurrent streams of solitons and antisolitons or as a result of the interaction of dilatons with antidilatons. It is suggested that the large-scale regions between the centres of solitons, migrating together with them, rather than the highly extended chain as in the study of Mel'ker et al.,[12] be regarded as dilatons functioning as elementary carriers of the stretching deformation. Lagunov[24] analysed the dissociation step solely in "dilaton" and "antidilaton" terms, referring, however, to the dissociation mechanism itself as a "soliton" mechanism. Furthermore, he noted[24] that a pair comprising a kink and an antikink (i.e. a pair of solitions of the topological type) diverge from the rupture site, which leads to a gradual relaxation of the chain.

Unfortunately, on the basis of the individual experimental[1-5] and theoretical[7-24] results available at present in the field of the mechanodegradation of polymers, it is impossible to achieve a clear understanding of the mechanism of this process. The theoretical results of different workers are contradictory and unrelated to the available experimental data. However, one should note that the intense anharmonic excitations resembling solitons observed by different workers undoubtedly play an important role. This complex situation in the mechanodegradation of polymers, which has a great practical importance, has led the present authors to carry out a more detailed investigation of this process.[26,27]

The stretching (as far as rupture) and subsequent mechanodegradation of a continuous polymer chain in an amorphous layer of a linearly oriented polymer with a fibrillar structure was investigated by the method of molecular dynamics. One-dimensional chains made up of 50 and 100 atoms were chosen as the object of study. The masses of all the atoms were the same and equal to that of the carbon atom (2×10^{-23} g). The interatomic interaction was described by the Morse potential with the parameters characteristic of the C–C bond in polyethylene. Account was taken only of the interaction between nearest neighbour atoms. For the numerical solution of the system of differential equations of motion of the chain atoms, the RKF 45 program[28] was used with the automatic selection of the integration step, based on the modified fourth–fifth order Runge-Kutta method. In order to avoid the unjustified decrease in the step after the sharp cut-off of the potential, a "smooth" cut-off was achieved with the aid of a cubic polynomial. Thus the potential employed had the form

$$U(r) = \begin{cases} D\left[e^{-2b(r-r_0)} - 2e^{-b(r-r_0)}\right], & r \leqslant r_1, \\ C_1(r-r_2)^2 + C_2(r-r_2)^3, & r_1 \leqslant r \leqslant r_2, \\ 0, & r_2 \leqslant r. \end{cases}$$

The parameters of the Morse potential were $D = 3.5$ eV, $b = 2$ Å^{-1}, and $r_0 = 1.54$ Å.

The constants C_1 and C_2 were selected on the basis of the condition of the continuity of the potential and of its first derivative at the point r_1.

At the initial instant, the distances between neighbouring atoms are r_0 and the velocities of all the atoms are zero (the chain is at the temperature 0 K). The first atom is fixed so that it is immobile. The extension of the chain was specified by the movement of the last atom in the positive direction at a constant velocity V. The calculations were performed for two rates of stretching: $V = 0.1V_{so}$ and $V = 0.05V_{so}$, where $V_{so} = r_0 b(2D/m)^{1/2} = 23.08 \times 10^3$ m s$^{-1} \simeq$ 231 Å ps^{-1} is the velocity of sound. The stretching of chains at such high rates takes place at the apex of a major crack at the concluding stage of its growth at a rate close to the velocity of sound. In an experimental study of precisely this stage of the rupture process,[5] it was possible to detect high-energy molecular products of the mechanodegradation of polymers (Table 2).

The time used to observe the trajectories of the motion of atoms was 3.5–7 ps.

III. Characteristic features of the mechanodegradation of polymer chains

1. The mechanisms of the ruptures

We shall consider the principal characteristics of the mechanodegradation in relation to a 50-atom chain stretched at a rate of 23 Å ps^{-1} $\simeq 0.1V_{so}$. In the initial instant, the velocities of all the atoms are zero, i.e. the chain is at the temperature 0 K.

Fig.5 presents the trajectories of the motion of all the 50 chain atoms. The coordinates $X_i(t)$ (i = 1–50) of all the atoms (in Å) are plotted along the left-hand ordinate axis and the time t [in time units (1 time unit = 10^{-14} s)] is plotted on the abscissa axis. Scale divisions, in steps of 1 Å are indicated on the right-hand ordinate axis to facilitate analysis of the process. The upper straight line represents the trajectory of the motion of the last (51st) atom at a constant velocity $V_{51} = 23$ Å ps^{-1}. The figure clearly shows the sites and instants of all the ruptures. Certain ruptures are "healed", i.e. recombination takes place, which is associated with the presence of two boundaries, one stationary and one moving at a constant velocity, which prevent the free movement of the degradation products by virtue of the one-dimensional nature of the model. It can be assumed that the first four breaks, indicated in the figure by filled circles, occurred without being influenced by the boundaries (if one disregards the reflection from the stationary boundary of the extension wave, which initiates the first chain rupture, as will be shown below). The first stage of the chain extension process is fully determined by the propagation of the extension wave (Fig.6). Each curve represents the distribution of the bond deformations along the chain at a fixed instant. The numbers of the bonds are plotted along the abscissa axis and the number of the curve is plotted on the left-hand side ordinate axis (the position of the number on the ordinate axis specifies the zero deformation level for the corresponding curve). On the left, the time (in time units) elapsed from the instant of the start of the extension is indicated above each curve and the deformation scale (in 10^{-1} Å) is indicated on the right-hand ordinate axis. The extension wave is propagated along the chain from right to left, i.e. from the extreme (51st) atom, moving at a constant velocity, to the fixed end. The velocity of the potential wave front is 245 Å ps^{-1}, which is close to the velocity of sound calculated from the formula $V_{so} = r_0 b(2D/m)^{1/2} \simeq 231$ Å ps^{-1}.

By virtue of the dispersion of the system considered, decaying atomic vibrations, also propagated along the chain in the form of a wave, are observed behind the wave front. However, the vibration wave is propagated along a chain which has already been stretched (whose effective force constants are smaller than those of the unstretched chain) and its velocity is therefore lower than that of sound. This factor leads to the "spreading" of the extension wave front. At the instant corresponding to 31 time units, the front

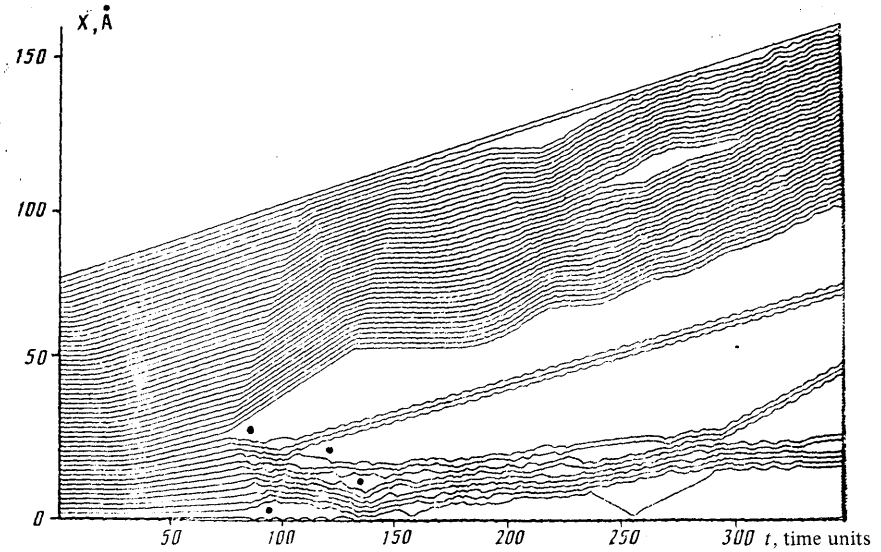

Figure 5. Time variation of the coordinates of the atoms of a 50-atom chain stretched at the rate $V_{str} = 0.1V_{so}$;[27] in the initial instant, the chain temperature is 0 K.

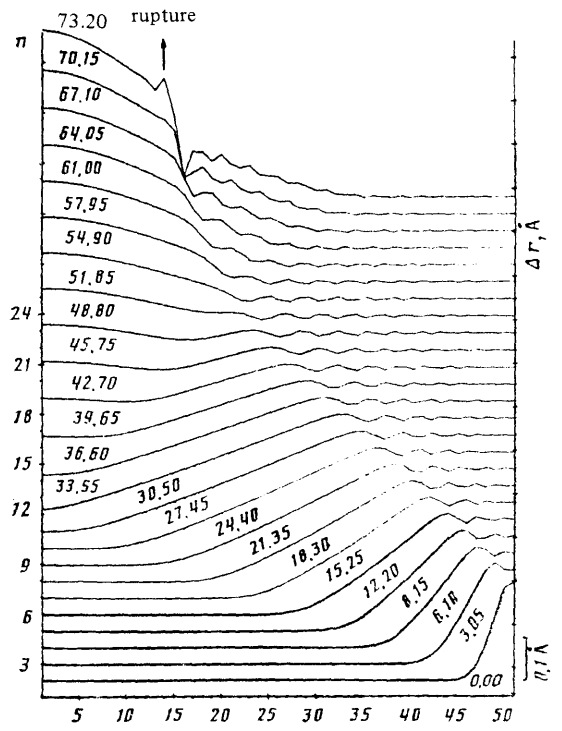

Figure 6. Time variation of the distribution of the bond deformations $\Delta r \equiv r - r_0$ along the chain from the initial instant up to the instant of the first rupture;[27] i = number of the bond; n = number of the atom.

reaches the fixed end and is reflected from it in the form of a high-amplitude wave. From this instant, the high-amplitude extension wave is propagated towards the vibration wave. Collision of these two waves occurs at time $t \simeq 50$ time units in the 22nd bond. The velocity of the vibration wave then diminishes as it passes to the increasingly stretched regions of the extension wave front. When the vibration wave front reaches the region with the deformation $\varepsilon > \varepsilon_{cr} = 0.224$, the chain ruptures (in the given instance, the 14th bond is ruptured).

Thus the mechanism of the first rupture of the "cold" chain stretched at a rate $V = 0.1V_{so}$ is due to the collision of the dispersion vibration wave with the extension wave moving in opposition to it, the rupture step itself occurring at the site where the following two conditions are satisfied simultaneously at the instant of the arrival of the first vibration: $\varepsilon > \varepsilon_{cr}$ and $\dot{\varepsilon} > 0$.

At the instant of rupture (73 time units), the propagation of the deformation along the chain is significantly non-uniform: $\varepsilon > \varepsilon_{cr}$ for bonds 1–14 and $\varepsilon < \varepsilon_{cr}$ for bonds 15–50. The forms of the relaxation waves propagated from the rupture site are therefore different in the chain fragments 1–13 and 14–51 (Fig.7). The relaxation wave front in the fragment 1–13 ($\varepsilon > \varepsilon_{cr}$) represents a kink (a topological soliton) and that in the fragment 14–51 is a lattice soliton. The propagation of kinks from the rupture site has also been noted by Grigoryan et al.[23]

For a slower ($V_{ext} = 0.05V_{so}$) extension of the cold chain, a different rupture mechanism, associated with a structural transition in the most stretched part of the chain, is observed. When the stretching deformation reaches $\varepsilon_{cr} = 0.224$, there is an abrupt transition of the chain atoms to a new state of equilibrium. The chain structure then changes in such a way that, instead of uniformly extended bonds, a sequence of long (L) and normal (N) bonds alternating along the chain arises: ...LNLNLNLN...

The length of the L-bond is $l_L \simeq r_0 + 2\varepsilon_{cr}r_0 = (1 + 2\varepsilon_{cr})r_0$, where $\varepsilon_{cr} \simeq 0.224$, while the length of the N-bond is $l_N \simeq r_0$. This structural transition is associated with the fact that, when the stretching deformation reaches the critical value ε_{cr}, there is a qualitative change in the form of the effective potential for each internal chain atom: the potential changes from the one-well type to the two-well type. A similar change in the form of the potential for an internal atom of the chain when the latter was stretched was investigated previously by Mel'ker and Kusnetsova.[11] Fig.8 shows how the form of the potential for an internal atom in a three-atom one-dimensional system changes when the extreme atoms move apart by 0.3, 0.5, and 0.7 Å. Evidently the transition from the one-well to the two-well potential takes place for stretching deformations in the range 0.3 to 0.5 Å.

Figs.9 and 10 illustrate the slow extension of a 50-atom chain in which a structural transition, terminating in two chain ruptures, takes place over a long segment. Fig.9 illustrates the trajectories of the motion of all the 50 atoms. The numbers of the atoms are

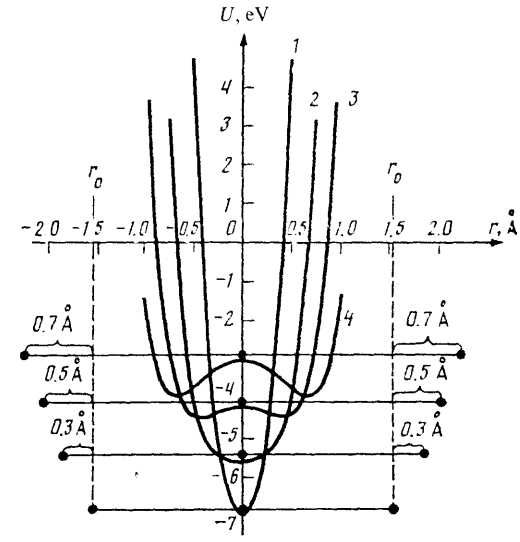

Figure 8. The change in the form of the potential for an internal atom of the chain on extension of the latter; $\Delta r \equiv r - r_0$ (Å): *1*) 0; *2*) 0.3; *3*) 0.5; *4*) 0.7.[27]

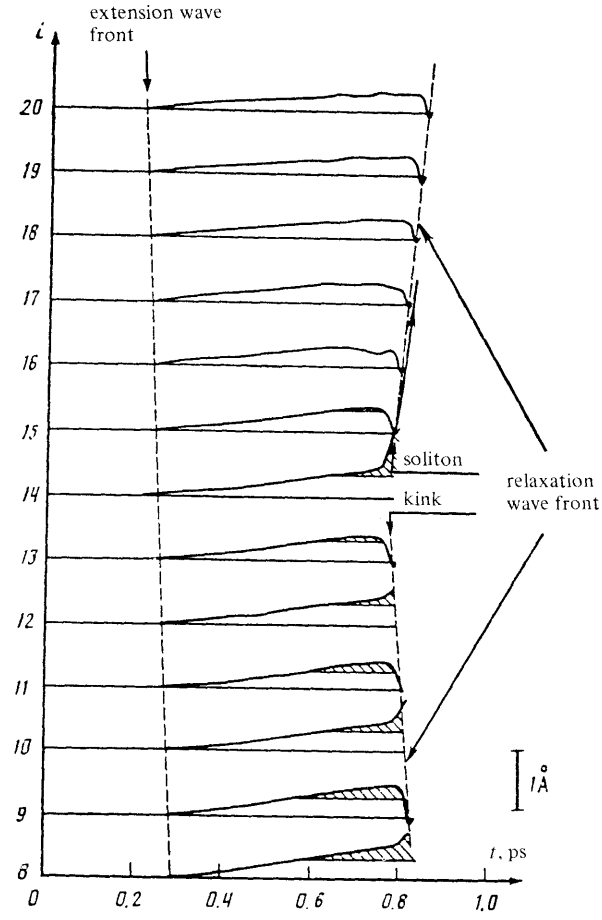

Figure 7. Time variation of the bond deformations in the vicinity of the first rupture; qualitative difference between the relaxation waves propagated at the site of the first rupture in the highly stretched ($\varepsilon > \varepsilon_{cr}$) fragment 1–13 and in the slightly stretched ($\varepsilon < \varepsilon_{cr}$) fragment 14–51;[27] *i* = number of the bond.

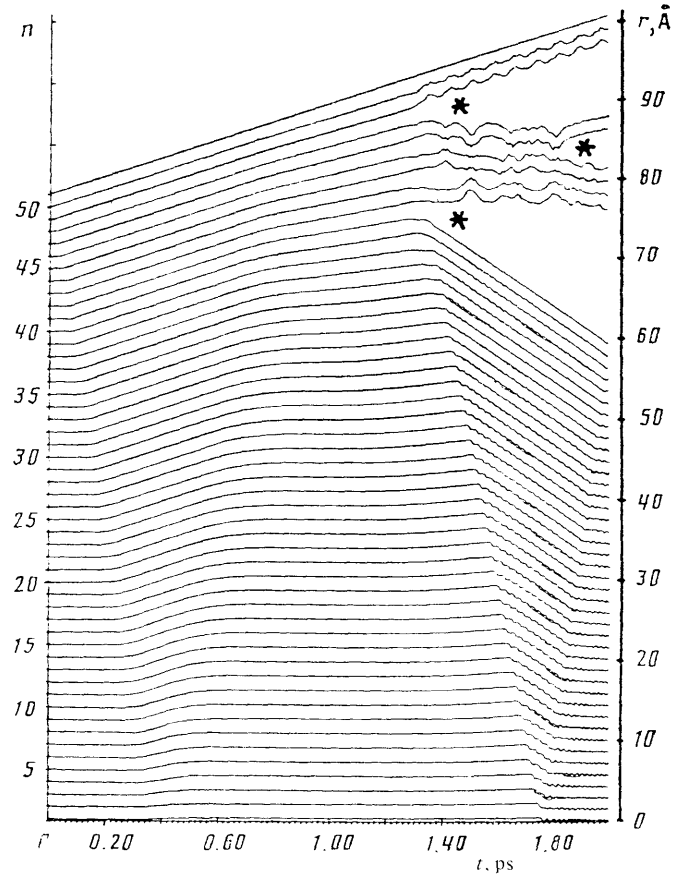

Figure 9. The trajectories of the motion of the atoms of a 50-atom chain stretched at the rate $V_{str} = 0.05V_{so}$. The ruptures are designated by an asterisk (*);[27] *n* = the number of the atom; *t* = time; *r* = atomic coordinate.

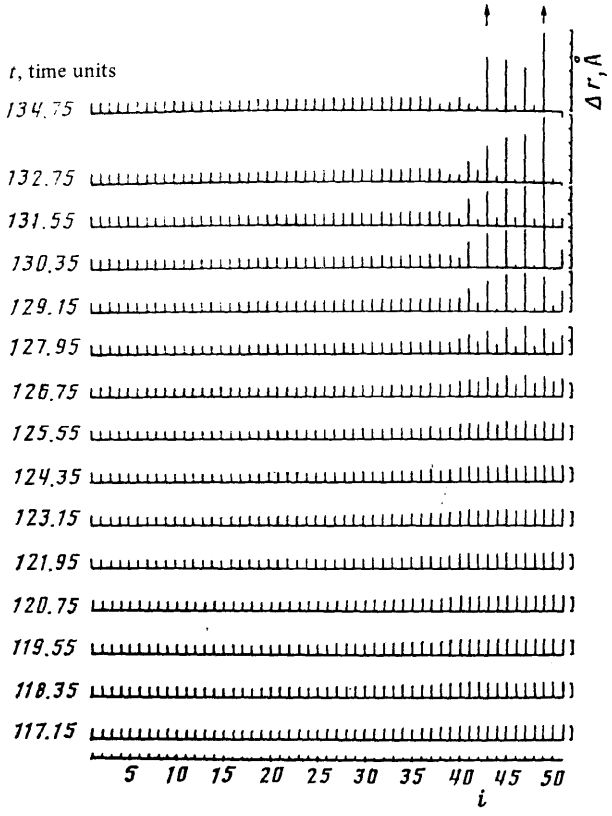

Figure 10. The structural transition in a 50-atom chain stretched at the rate $V_{str} = 0.05V_{so}$ in the pre-rupture stage:[27] i = the number of the bond in the chain; $\Delta r \equiv r - r_0$ the stretching deformation in Å; 1 division = 0.3 Å; t = time expressed in time units (1 time unit = 10^{-14} s).

plotted on the left-hand ordinate axis, the atomic coordinates (r) (in Å) are plotted on the right-hand ordinate axis, and the times (in ps) are plotted on the abscissa. In the time interval 1.20–1.35 ps in the section between the 40th and 50th atom, the critical stretching deformation $\varepsilon_{cr} = 0.224$ is attained and leads to a structural transition with subsequent ruptures of the 43rd and 49th bonds and the formation of a free 6-atom fragment 43–48. This structural transition in the pre-rupture stage is illustrated in greater detail in Fig.10. The time variation of the deformations of all the chain bonds is illustrated here at intervals of 1.2 time units.

We shall consider the characteristic features of the rapid extension of a polymer chain ($V_{ext} = 0.1V_{so}$). The wave process arising on rapid chain extension leads to a significantly non-uniform distribution of the deformation and energy along the chain. This fact has been disregarded in studies,[7–9,22] devoted to the degradation of "cold" stretched one-dimensional chains. It has been assumed that, at the instant of the first rupture, all the bonds of the chain, except that which is ruptured, are equally stretched. Fig.11 presents the distribution of the potential (curve *1*) and kinetic (curve *2*) energies along the chain at the instant 0.73 ps, i.e. immediately before the first rupture of the 50-atom chain illustrated in Fig.5. The non-uniformity of the energy distribution at the pre-rupture instant is in this case so considerable that significantly different excitation levels are characteristic of the chain fragment formed after the first rupture: thus the energy densities are 1.66 and 0.83 eV/bond in the fragments 1–13 and 14–50 respectively. This fact is responsible not only for the different character of the wave processes in the two fragments (Fig.7) but also leads to more rapid and vigorous degradation of the fragment 1–13 (three ruptures after ~0.5 ps) compared with the slow degradation of the fragment 14–50 (two ruptures after ~3 ps).

We shall now consider the wave processes developing after the first rupture of the chain stretched at a rate $0.1V_{so}$. Fig.12 illustrates the time variation for the kinetic energy of all the chain atoms (see also Fig.5). The numbers of the chain atoms (on the left) and the

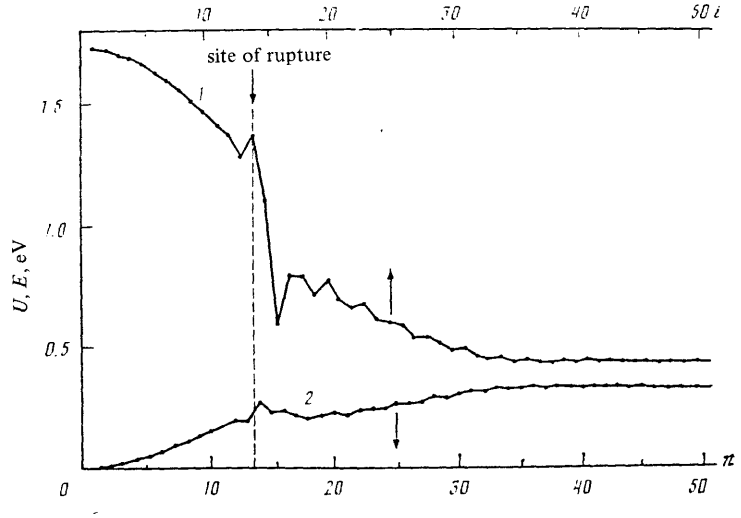

Figure 11. Distribution of the potential energy U (curve *1*) and the kinetic energy E (curve *2*) along the chain at the instant of the first rupture (t = 0.73 ps) of a 50-atom chain stretched at the rate $V_{str} = 0.1V_{so}$;[27] n = number of the atom; i = number of the bond.

kinetic energy scale with 1 division = 1 eV (on the right) are plotted along the ordinate axes and the time (in time units) is plotted along the abscissa axis. As before, the fixed end of the chain is at the lower end of the figure and the end moving at a constant velocity corresponds to the upper part of the figure.

After the first chain rupture (t_1 = 76 time units), individual irregular high-energy (more than 3 eV) localised waves of the type of solitons arise in the fragment 1–13, while a regular sequence of primary solitons, propagated from the site of the first rupture at the upper end of the chain moving at a constant velocity, is formed in the fragment 14–50. On reaching the upper end of the chain, the solitons are reflected and move towards the arriving stream of primary solitons. Interference then occurs between the incoming and reflected streams of solitons, which leads to the amplitude modulation of the soliton sequence. Thus we see that the process developed after the first rupture in both sections of the ruptured chain is quite different from what might have been expected on the basis of the existing ideas about the thermofluctuation character of the degradation process.[6] Instead of the expected conversion of elastic energy into thermal energy and the subsequent appearance of large thermofluctuations under the conditions of random motion, in the initial stages of the degradation process highly ordered modes are observed in the form of localised running waves—solitons. The size of the soliton depends only slightly on the degree of extension (compression) of the part of the chain in which it is located in the given instant and amounts to two–three units. At the instant when the soliton reaches the free end of the chain, its entire energy is converted into the potential energy of the extension of the extreme bond. The energy of the soliton can be determined accurately in this way.

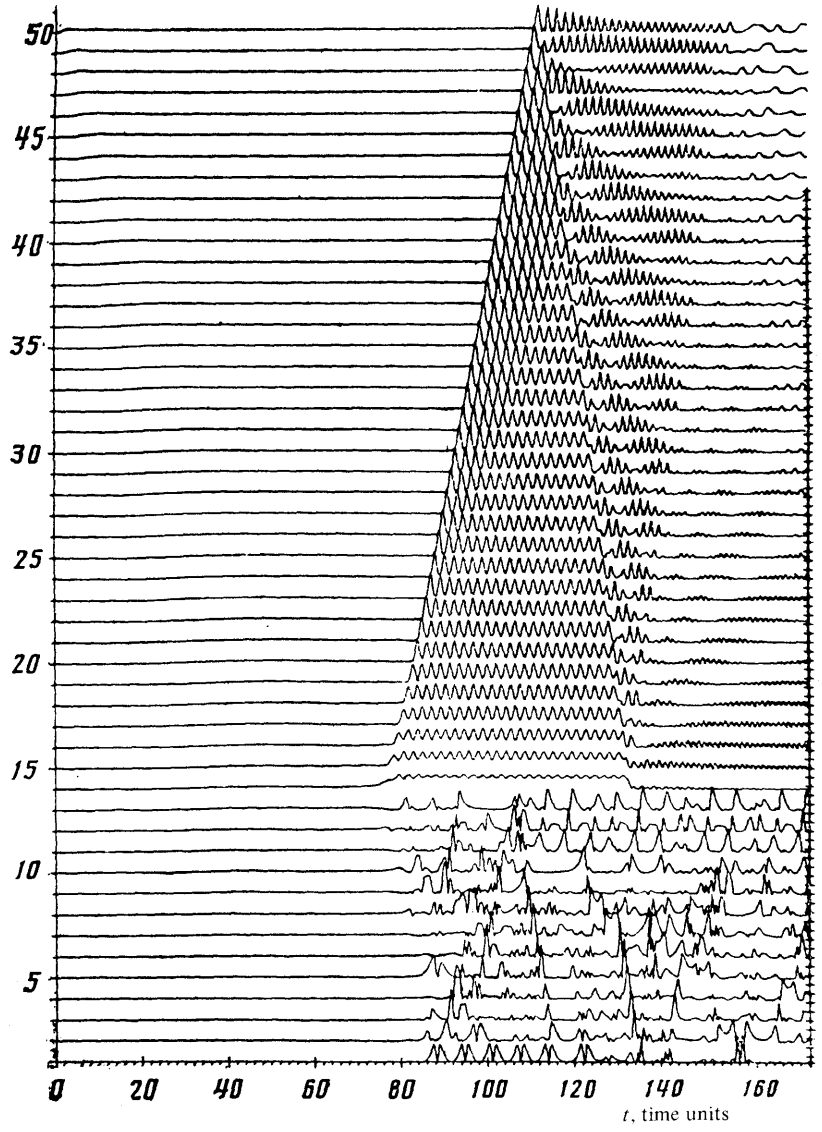

Figure 12. Time variation of the kinetic energy of the atoms of a 50-atom chain stretched at the rate $V_{str} = 0.1V_{so}$; on the right—1 division = 1 eV; n = the number of the atom; t = time expressed in time units (1 time unit = 10^{-14} s).

By analysing the observed secondary ruptures and then comparing them, it has been possible to identify two most characteristic mechanisms of the rupture processes. The first mechanism, characteristic of the rupture of short fragments (starting from the free ends of larger fragments) is determined by the arrival at the given free end of a packet of solitons moving in one direction. The following feature then holds: the packet, containing N solitons, breaks off a fragment containing N atoms. This mechanism can be briefly formulated as follows: N_{sol} + free end → $N_{atom.fragm.}$. For example, consider the abstraction of the three-atom fragment 20–22 from the 14-atom freely moving fragment 9–22 (Fig.13)—one of the intermediate products of the mechanodegradation of a 100-atom chain. The trajectories of the motion of all the atoms of the freely moving fragment 9–22 are illustrated in Fig.13*a*. At the instant $t \simeq 469$ time units, the 20th bond is ruptured and the three-atom fragment 20–22 is broken off. Fig.13*b* illustrates the time variation of the velocities of all the atoms of the fragment 9–22. The packet of three solitons (numbers *1*, *2*, and *3* in Fig.13*b*), moving from the 9th to the 22nd atom, is clearly seen. Having reached the free end, the first soliton alters sharply the trajectory of the motion of the extreme (22nd) atom. The second soliton, which immediately follows the first, also alters sharply the trajectory of the 21st atom. As a result of this, the diatomic fragment 21–22 begins to separate and the 21st bond is lengthened. Having reached the 20th atom, the somewhat lagging third soliton transfers to this atom its momentum and "throws it over" to the fragment 21–22 being eliminated. As a result the 21st bond is restored and the 20th is lengthened until rupture. In the pre-rupture state ($t \simeq 469$ time units) in the region of the future break, a correlated motion of the atoms in the opposite directions from the site of the future break is observed. The occurrence of the correlated motion of atoms in the pre-rupture instant has been pointed out by Mel'ker and co-workers.[13–15] However, the causes of such correlated motion of atoms were not considered. We suggested that such a cause is the movement of the packets of solitons *1–3* and *4–6* towards each other (Fig.3*b*), resulting in rupture. The size of the packet of solitons determines the size of the region of the correlated motion of atoms.

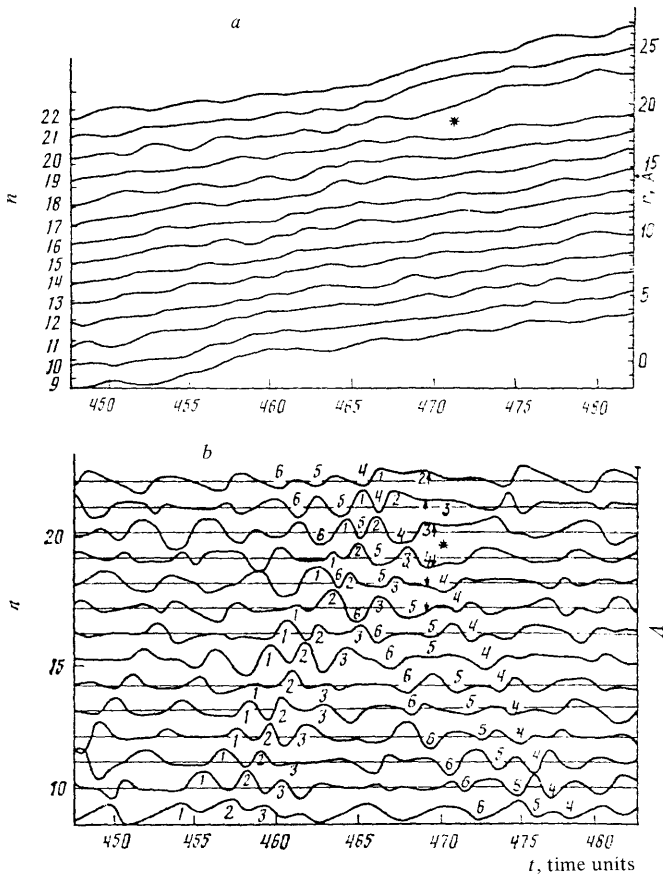

Figure 13. The abstraction of a three-atom fragment by a three-solition packet: *a*) trajectories of the motion of the atoms in the dissociating fragment 9–22; *b*) time variation of the velocities of the atoms in the dissociating fragment 9–22;[27] n = number of the atom; r = atomic coordinate in Å (1 division = 1 Å); V = velocity of the atom (arbitrary units); t = time expressed in time units.

The second rupture mechanism involves the entry of a soliton into the stretching region of the chain, i.e. into the zone for which the following two conditions are fulfilled simultaneously: $\varepsilon > \varepsilon_{cr}$ and $\varepsilon > 0$. This mechanism is similar to the mechanism of the first rupture considered above (Fig.6) and therefore does not require special illustrations.

2. The formation of C = C double bonds and excited products

In the intense excitation of the chain observed after its first rupture, there is a possibility of the formation of multiple bonds (C = C double bonds and even C ≡ C triple bonds) together with degradation. Since a soliton is a zone of compressed bonds and at the same time a zone with a high kinetic energy (momentum), the movement of high-energy (1–3 eV) solitons entails the compression of bonds to lengths equal to and even smaller than the length of the C = C double bond and the simultaneous transfer of momentum to the lateral atoms sufficient to break them off. The time variation of only those compressive deformations which exceed 0.2 Å, which correspond to the formation of a C = C double bond, is illustrated in Fig.14 for the first molecular product (2–13) of the mechanodegradation of a 50-atom chain (the stretching and degradation are illustrated in Fig.5). It is seen from Fig.14 that, even after the very short lifetime of the free fragment, all its bonds undergo repeatedly strong compressions under the influence of the high-energy solitons. Thus one may expect that the propagation of high-energy solitons in a real macromolecule leads to the formation of C = C double bonds and the "shedding" of side groups. A similar result was obtained in a quantum-mechanical study[29] of the behaviour of terminal alkyl radicals following intense compression of the $C_\alpha - C_\beta$ bond.

Another important result is the formation in the course of the mechanodegradation of the chain of excited low-molecular-weight products with an excess vibrational energy (up to 1.0–1.5 eV/bond) and translational energy E_{trans} (a few eV) (Table 3) which are hence capable of initiating the decomposition of the surrounding polymer chains on collision with the latter. The fact that several "hot", highly excited molecular products, each of which is capable of transmitting excitation and initiating the rupture of one of the neighbouring stressed chains, are formed on rupture and subsequent decomposition of one polymer chain is especially important. Thus there is a possibility of the branching of the mechanodegradation process. Similar considerations have been put forward by Mel'ker and Kuznetsova.[8]

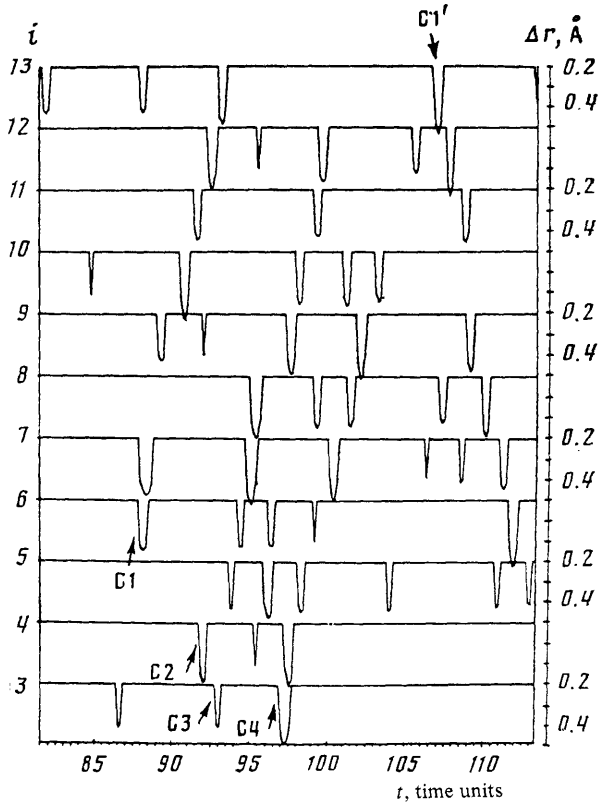

Figure 14. Compression of the C–C bonds by high-energy solitons (~3 eV) to lengths less than the length of the C = C double bond;[27] Δr = compressive deformation (in Å) exceeding 0.2 Å (1 division = 1 Å); C1, C2, C3, C4, and C1′ = high-energy solitons; i = number of the bond; t = time expressed in time units (1 time unit = 10^{-14} s).

		19—22	307.930	4	0.259	2.20	0.73

Note. N is the number of atoms in the chain, V_{str} the rate of stretching of the chain, τ the instant of the formation of the product, n' the number of atoms in the product, E_{trans} the kinetic energy of the translational motion of the product, E_{vibr} the vibrational energy of the product, $n' - 1$ the number of bonds in the product, and $E_{vibr}/(n' - 1)$ the density of the vibrational energy in the product.

The proposed branched chain mechanism of the breakdown of polymer chains can explain the known explosive character of the formation of submicrocracks and microcracks.

3. The energetics of the mechanodegradation process

In order to determine the mechanodegradation yields, we shall consider the energetics of the entire process. The energy balance will be expressed by the equation

$$U_0 = nD + \sum_{i=2}^{n-1} E_i + E_1 + E_n,$$

where U_0 is the elastic (potential) energy stored in the initial polymer chain at the instant of the first rupture, n the number of ruptures, D the C–C bond dissociation energy, E_i the total energy of the ith molecular product ($E_i = E_{vibr} + E_{trans}$), and E_1 and E_n are the total energies of the two ends of the chain remaining after mechanodegradation and linked to the polymer matrix.

The first term (nD) on the right-hand side of the equation represents the "pure" energy expenditure on the mechanodegradation. We shall call the ratio nD/U_0 the energy yield of the mechanodegradation and shall designate it by the letter Y. We also introduce the following quantities: the yield of mechanodegradation in terms of ruptures Y', defined as the number of ruptures per 10 eV of the stored elastic energy, and the yield of the mechanodegradation in terms of molecular products Y'', defined as the amount of molecular products formed as a result of the mechanodegradation per 10 eV of the stored elastic energy.

The quantities Y' and Y'' were introduced because they can be determined in a physical experiment, for example, by EPR, IR spectroscopy, and mass spectrometry, and can be compared with the results of numerical modelling. Table 4 presents the yields Y, Y', and Y'' for the case investigated.

Table 4. The mechanodegradation yields.

N	V_{str}, Å ps^{-1}	U_0, eV	n	Y	Y', $n/(10$ eV)	$n-1$	Y'', $(n-1)/(10$ eV)
50	23	42.5	3	0.247	0.7	2	0.47
50	11.5	30.0	3	0.350	1.0	2	0.66
100	23	76.0	4	0.184	0.5	3	0.40

Note. T = 0 K, U_0 is the potential energy stored in the chain at the instant of the first rupture, and $n - 1$ is the number of products.

The energy of the molecular mechanodegradation products

$$\left(\text{the sum } E_1 + \sum_{i=2}^{n-1} E_i + E_n\right)$$

over a period of ~10^{-12} s is transmitted to the macromolecules nearest to the rupture site and then spreads into the bulk of the polymer already in the form of waves of the type of solitons. The high stability of solitons suggests that the scattering of their energy requires an appreciable number of scattering centres, as a result of which the energy of the relaxation wave is thermalised over a large ensemble of atoms and the heating of the polymer in the vicinity of the rupture is therefore insufficient for the occurrence of secondary thermal degradation reactions. This factor is apparently the cause of

the difference between the compositions of the molecular products of thermal degradation of mechanodegradation, established experimentally by different investigators for different polymers (Table 1).

IV. Principal results and prospects

The study of the mechanodegradation of a one-dimensional model of a polymer chain by the method of molecular dynamics and analysis of the results in terms of the theory of non-linear waves have shown that unified non-linear waves of the type of solitons, which are the only high-energy agents in the process, play a decisive role in mechanodegradation. For a long time ($\sim$10 ps) after the rupture of the stretched chain, there is no significant thermalisation of the elastic energy stored in it and no thermofluctuations are observed in the generally accepted sense.[6] The high-energy molecular mechanodegradation products observed experimentally by Enikolopian et al.[5] are formed only in the initial stage of the degradation of the polymer chain over a time range 10^{-2}–1 ps after its first rupture.

Comparative analysis of all the observed ruptures established that the ruptures occur via three main mechanisms. The first mechanism, characteristic solely of primary ruptures, involves a structural transition in the most stretched section of the polymer chain. The second mechanism, characteristic solely of secondary ruptures in the initial stage of the mechanodegradation in those sections of the polymer chain where the energy density is very high ($\sim$1 eV/unit), is determined by the arrival at the free end of the chain (or a large fragment) of a packet of N solitons moving in one direction. The following feature has been established: a packet of N solitons breaks off a fragment containing N atoms. The third mechanism, characteristic of both primary and secondary ruptures in sections of the polymer chain with a low energy density ($\sim$0.1 eV/unit), involves the entry of a soliton into the stretching region of the chain, i.e. into the zone for which the following two conditions are fulfilled simultaneously: $\varepsilon > \varepsilon_{cr}$ and $\varepsilon > 0$.

It has been shown that high-energy solitons, which are localised compression waves with a high kinetic energy (momentum), can lead to conditions under which there is a possibility of the formation of C = C double bonds and the shedding of lateral atoms. It has been observed that, on rupture of a single chain, there is a possibility of the formation of several high-energy molecular products, each of which is capable of 'damaging' the surrounding polymer chains. Thus the rupture of one chain can be the cause of the branching of the chain process, leading to the explosive formation of submicrocracks and microcracks.

It has been established that an appreciable proportion (tens per cent) of the elastic energy stored in the chain is expended on its degradation.

Despite the satisfactory agreement of the results of MD calculations of the kinetic energy of the translational motion of the moelcular mechanodegradation products (Table 3) and the experimental data (Table 2), further theoretical studies are necessary for the following reasons.

Firstly, the one-dimensional nature of the model precludes the determination of the contribution to the intramolecular dynamics of the deformation of the valence angles and of conformational rearrangements by the motion of lateral atoms and groups and by intermolecular interactions.

Secondly, the "rigid" fixation of the chain at the boundaries leads to its unrealistic isolation. The complete (100%) reflection of the compression and relaxation waves as well as solitons from the boundaries makes the energy level of the entire mechanodegradation process unduly high. A decrease in the influence of the boundaries may be expected in the rupture of "hot" and longer chains.

Thirdly, the consideration of the macromolecules solely in terms of classical mechanics does not permit a direct observation of the quantum-mechanical pathway leading to changes in its structure (for example, hybridisation) under the conditions of high deformations.

In a more complete consideration of the macromolecule as a quantum-mechanical object, it is necessary to take into account the possible conversion of part of the stored energy on extension into the electronic excitation and ionisation energy, which may be observed, as shown by Zarkhin et al.,[30] for considerable deformations of the macromolecule both in the stage involving its extension and after rupture—in the stage of intense intramolecular dynamics.

The formation of polymers on the surfaces of disperse carbon materials

M T Bryk, A F Burban
Institute of Colloid Chemistry and the Chemistry of Water, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. The characteristic features of the synthesis of polymers (radical and ionic polymerisation, polyaddition, polycondensation) on the surfaces of disperse carbon materials (graphite, carbon black, and diamond) are examined. The processes involving the formation of polymers, their structures, and their properties are analysed taking into account the chemistry of the surfaces of disperse carbon fillers, which plays an important role in the preparation of filled polymeric materials by the method of polymerisation filling.

I. Introduction

The introduction of solid disperse or fibrous substances into the polymer phase makes it possible in a number of instances to improve significantly the physicochemical, mechanical, thermal, electrical, frictional, and other properties of the polymers. The chemical properties of the solid surfaces of fillers influence the efficacy of their use in compositions with high molecular weight compounds. The surfaces of fillers frequently contain functional groups, which can participate in various chemical reactions and determine to a large extent the character of the solid–polymer interaction. By altering specifically the chemical properties of the surface, it is possible to influence the nature of the interaction of the polymer with the filler surface and ultimately to improve significantly the operating properties of the polymeric material.

The graft polymerisation of monomers initiated by complex catalysts, organometallic compounds, free radicals, or ions fixed on the surface is a promising method, from the theoretical and applied points of view, of obtaining filled polymeric materials.

Among the fillers used to obtain filled polymeric materials, disperse carbon materials (carbon black, graphite) are widely used. In connection with the wide-scale development of the manufacture of synthetic diamond powders in our country, there has been a sharp increase in the interest of investigators in the creation on their basis of filled polymeric materials having many interesting and even unique properties.

However, the results of numerous novel investigations of the corresponding polymerisation processes have not so far been subjected to a due analysis, especially from the standpoint of the influence of the chemistry of the surfaces of carbon fillers and the formation processes and structures of the polymers. The aim of the present review is to fill this gap.

II. The chemistry of the surfaces of disperse carbon materials and the structure and morphology of their particles

Since carbon atoms are capable of forming chemical bonds of different types as a result of the different degrees of hybridisation of the orbitals of their valence electrons, there exist a wide variety of structures of solid carbon compounds. Among them three principal forms can be distinguished—diamond, graphite, and carbyne and in addition carbon fibres and carbon black. We shall consider briefly the chemical structure and the properties of the surfaces of these materials.

Diamond. The surface of diamond, like that of any other solid, can be regarded as one of the main defects of the three-dimensional structure of the crystal.[1] The edge of the structure of the diamond skeleton, where the coordination sphere of the surface carbon atoms is altered, as well as the high enthalpy of formation of the ideal surface promote the spontaneous occurrence of processes lowering the energy of the system. One of such processes may be the formation of surface functional groups.[2]

The existence of unsaturated bonds on the diamond surface ensures the possibility of the formation of various surface compounds. The interaction of the atomically clean diamond surface with low-molecular-weight compounds leads to the appearance of surface functional groups. Using chemical analytical, spectroscopic, and resonance methods,[2] the existence on the surface of diamond of carboxy-, hydroxy-, carbonyl, lactone, ether, $=CH_2$, $=CF_2$, and $-CH_3$ groups has been established.

Studies have been published recently concerning the fixation on the surfaces of carbon materials, including diamond powders, of functional groups having a definite chemical nature.[3–7] In order to remove various impurities (non-recrystallised graphite, metals, metal carbides, and organic substances) from their surface, diamond powders are first etched with $HClO_4$.[6] Concentrated HNO_3 and the chromic acid mixture (conc. H_2SO_4 + $K_2Cr_2O_7$) are also used to obtain a chemically clean diamond surface.[6]

As a result of the action of oxidants and the subsequent vacuum heat treatment, the surface of diamond powders is freed from the majority of oxygen-containing groups and can be used for the

fixation on it of various functional groups, for example, halide and hydride groups.

Experimental data have established that, when the diamond surface is halogenated, the following chemical reactions take place:[5]

$$2[C]+Hal_2 \rightarrow 2[C-]-Hal,$$
$$[C-]-H+Hal_2 \rightarrow [C-]-Hal+HHal.$$

The maximum amount of chloride groups (~ 11 μmol m^{-2}) add to the diamond surface at 523–673 K which corresponds to a monolayer surface coverage.[5] When the surface of diamond which is modified with Cl groups is hydrogenated and treated with methane, the following reactions take place:[4]

$$[C-]-Cl+H_2 \rightarrow [C-]-H+HCl,$$
$$[C-]_m-Cl_n+nCH_4 \rightarrow [C-]_{m+n}-H_{3n}+nHCl.$$

An increase in temperature promotes a gradual increase in the degree of surface coverage by hydride and methyl groups (the maximum chemical monolayer coverage is attained at 823 K).

The formation of highly polar reactive functional groups of the type OH, COOH, and NH_2 on the surface of carbon, including diamond, powders, is of special interest. Thus the substitution of chlorine atoms on the surfaces of carbon substances on treatment with steam at 373–733 K results in the formation of an equivalent amount of surface OH groups:[4,8]

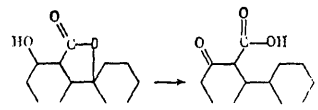
$$[C-]-Cl + H_2O(steam) \rightarrow [C-]-OH + HCl.$$

The fixation of COOH groups is observed when specimens of carbon materials are heated with concentrated HNO_3 for 5 h.[9]

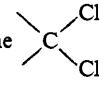
Apart from nitric acid, the chromic acid mixture and perchloric acid are also used to oxidise carbon-graphite materials.[5] When carbon substances are boiled for 3 h in the oxidants indicated, acid groups and activated hydrogen are produced on the surfaces of the carbon-graphite materials. The number of these groups increases in the sequence initial powder < HNO_3-treated powder < chromic acid mixture-treated powder < $HClO_4$-treated powder.[5]

The NH_2 functional groups are fixed on the carbon surface when its chlorine atoms are treated with gaseous ammonia at 623–673 K:[4–6]

$$[C-]-Cl+NH_3 \rightarrow [C-]-NH_2+HCl.$$



Graphite. One of the crystalline forms of carbon, widely used in various branches of industry and technology, is graphite.[10] The prospects for the intensive utilisation of graphite are associated, in particular, with the creation on its basis of anti-friction materials and filled materials with optimum properties.[11]



The interaction of graphite with polymers is known to be influenced significantly by the nature and concentration of its surface functional groups. Various oxygen-containing functional groups, both acid and basic, are present on the surface of graphite stored in air,[12,13] their ratio depending on the method of preparation, the subsequent treatment, and the conditions of storage of the specimens. Sub-groups include the carbonyl, phenolic, hydroxy-, and lactone groups.

The results of chemical analysis[16] indicate a relatively high concentration of COOH groups and also the presence of hydroxy- and hydroperoxy-groups, which arise on hydration of the oxidised graphite surface by water vapour. Apparently, unidentified oxygen partly enters into the composition of heterocyclic compounds, radicals, and internal oxygen bridges.[14]

It is notable that the names employed above for the oxygen-containing groups are rather conventional in character, since neighbouring groups interact in solid carbon compounds, especially in conjugated systems, which results in the formation of oxygen-containing groups with a more complex polyfunctional composition.[14]

Analysis of the real surfaces of graphites with the aid of physico-chemical (mass spectrometric and IR and EPR spectroscopic) and chemical (reactions with CH_3Mg and CH_2N_2) methods established the structures of the acid oxygen-containing groups, which were identified as cyclic esters (lactones) existing as tautomeric forms:[13,15]

Important information about the chemical nature of the graphite surface can be obtained by investigating the adsorption interaction with it by substances of different types. Only prismatic faces of graphite are known[16] to be reactive, since all the bonds in the basal plane are saturated. The sorption of hydrogen on an atomically clean graphite surface at 300 K is fully irreversible and the amount of hydrogen adsorbed on the prismatic faces is $N_H = 1.1 \times 10^{14}$ atoms cm^{-2}, which is almost 13 times smaller than the corresponding value for oxygen. The chemisorption of oxygen on a graphite specimen after it had been kept in a hydrogen atmosphere followed by desorption differs little from the adsorption of oxygen on the atomically clean surface. The number of adsorbed H and O atoms is the same as the number of carbon atoms forming the prismatic graphite faces.[16] The adsorption of molecular chlorine on an atomically clean graphite surface proceeds similarly to the adsorption of hydrogen and leads to the formation of the  groups.

Analysis of data on the surface chemistry of graphite confirms the reactivity of its prismatic faces and the possibility of the formation of surface groups of the same type as on diamond. The presence of functional groups creates the possibility for the chemical grafting of polymers on the graphite surface and for increasing its reinforcing effect in polymer compositions.

Carbon black. The wide scale and great variety of the applications of carbon blacks in the national economy makes the study of their structure, methods of preparation, and modification of current interest. The existing views on the structure of carbon black particles, as a molecular and supermolecular organisation of condensed carbon, cannot be regarded as fully established. Fairly contradictory views are frequently expressed in the literature on this question.[17] Apart from the generally accepted models of the structure of carbon black—the 'graphite' and condensed carbon models—others have also been suggested on the basis of all the forms of the organisation of carbon known at the present time. Furthermore, there exist views in conflict with traditional ideas about the structure of carbon materials and especially carbon black.[18]

Transitional forms of carbon, including carbon black and carbon fibre, have a more complex structure, in contrast to the principal crystalline forms (diamond and graphite) owing to the different nature of the surface carbon atoms on the carbon black particles, existing in different hybrid states (sp^3, sp^2, sp). The edge atoms in carbon black crystallites, like those in the graphite crystal, have less than three neighbours, i.e. their valences are not fully saturated. They are saturated by hydrogen or hydrocarbon radicals formed in the carbon black formation process.

Apart from carbon, carbon black also contains hydrogen, sulphur, oxygen, and minerals. Hydrogen and oxygen enter into the composition of various chemical groups of the surface layer, determining its chemical properties. The existence on the surface of carbon blacks of both acid and basic groups, whose ratio depends on the method of preparation and the subsequent treatment of the carbon blacks, has been established by physicochemical and chemical methods.[14] Carboxy-, carbonyl, phenolic, and lactone groups[19,20] as well as the groups formed by nitrogen and sulphur atoms[19] have been detected on the surfaces of carbon black and graphite.

The functional groups are bound mainly to edge carbon atoms in the basal planes. These carbon atoms influence strongly the properties of the groups linked to them. Thus the COOH groups retain their acidity, which may even increase: they are in fact responsible for the low pH of aqueous suspensions of certain carbon blacks and also for their ability to absorb bases. The carboxy-groups bound to aromatic rings enter into the composition of quinones. The quinone oxidation and reduction processes can occur on the surfaces of carbon blacks, which determines certain properties of the surface layer.[13,15]

The presence of oxygen on the surface of the carbon black predetermines to a large extent its physical, physicochemical, and operating properties.[21] The enhancement of the polar character of the surfaces of carbon blacks when they are partly coated by oxygen has a significant influence on the adsorption properties: the degree of adsorption of polar substances increases in this case[22,23] but the ability of carbon blacks to absorb non-polar substances never fully disappears under these conditions.[20]

The oxygen-containing groups formed on the surfaces of graphite and carbon black are in principle identical. However, it has been demonstrated by enthalpymetric titration that the acidity of the oxygen-containing groups on graphite is greater than on carbon black.[15] Consequently, the nature of the substrate undoubtedly influences the properties of the surface compounds (the degree of conjugation of the chemical bonds in graphite is greater and the proton participating in the reaction is therefore more mobile).[16]

Carbon blacks contain (mainly in the bulk of the particles) paramagnetic centres which do not interact with free radicals under the usual conditions. The complexity of the EPR spectra of carbon black[24,25] is explained by the presence of at least two types of paramagnetic centres and several types of unpaired electrons weakly interacting with one another. Furthermore, the form of the EPR spectrum may become complicated as a result of the appearance of lines corresponding to the radical oxidation products.

The interaction of free radicals, including growing polymer radicals, with radicals present on the surface of the carbon black leads to the firm fixation of the macromolecules or to grafting. The fixation of free radicals on carbon black can also be due to the presence of surface quinonoid groups, since the number of radicals bound to the surface is greatly diminished when such groups are reduced.[26]

The surface of carbon black particles is physically and chemically inhomogeneous. In many instances, this makes it impossible to obtain sufficiently reliable results in the study of chemical processes with its participation. In order to impart to the surface of the carbon black specific properties and to improve the adhesion interaction in carbon black compositions, specific modification of the chemical composition of the surface is carried out.[24,27-29] The methods used to obtain functional groups on the surface of the carbon black are analogous to those already described for diamond and graphite.

The specific features of carbon fillers of different types are determined by two principal factors: the structure of the skeleton of the particles and the chemistry of the surface which depends on it. In particular, the presence in the structure of graphite (and partly also carbon black) of aromatic rings increases the reactivity of the surface groups bound to the carbon atoms in these rings. The identical chemical reactivities of the functional groups on the surface of diamond is due to the equivalence of all the carbon atoms in its crystal structure.

III. The formation of polymers on the surfaces of disperse carbon materials

Much attention has been devoted in recent years to the preparation of composite polymeric materials by synthesising polymers in the presence of fillers.[30,31] Carbon materials with a fairly high reactivity in polymerisation initiation processes, which in many cases makes it possible to obtain graft polymers even without any preliminary treatment of the filler surface, are therefore of considerable interest. The nature of the interaction of polymer molecules with the carbon black surface has been investigated fairly thoroughly, while the monomer polymerisation processes on the surfaces of carbon black and graphite have been inadequately studied. Very few studies have been devoted to the nature of the active polymerisation centres on the newly formed surfaces of carbon blacks and graphite and for diamond such data have until recently been virtually lacking.

1. Free-radical polymerisation in the presence of carbon substances

Vibromilling of carbon blacks and graphite without access of air in vinyl monomers results in the graft polymerisation of the latter.[16] The ground carbon substances retain for a long time their ability to initiate polymerisation after dispersion. It has been suggested[16] that polymerisation is initiated by the free radicals formed on rupture of the C–C bonds and also by carbon atoms in the singlet state.

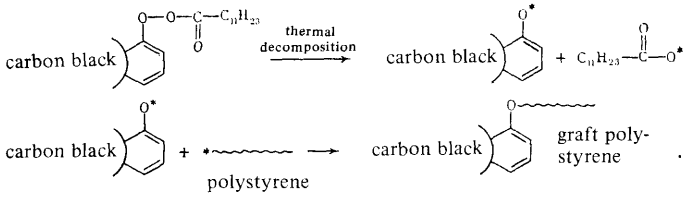
In the presence of graphite, the rate of polymerisation of methyl methacrylate under the influence of $NaHSO_3$ in an aqueous medium increases while the activation energy falls compared with the unfilled monomer.[32,33]

The molecular weight of poly(methyl methacrylate) diminishes with increase in the amount of filler, which is apparently due to processes involving the transfer of the growing chain to graphite. It has been suggested that polymerisation is initiated by the radicals $H\dot{S}O_3$ formed on interaction of $NaHSO_3$ with methyl methacrylate and water in accordance with the following scheme:

$$2HSO_3^{\ominus} + CH_2{=}\underset{\displaystyle COOCH_3}{\overset{\displaystyle CH_3}{\underset{|}{\overset{|}{C}}}} + 2H_2O \rightarrow 2H\dot{S}O_3 + 2OH^{\ominus} + CH_3{-}\underset{\displaystyle COOCH_3}{\overset{\displaystyle CH_3}{\underset{|}{\overset{|}{CH}}}}\ .$$

In general, much attention has been devoted to the thermal graft polymerisation of vinyl monomers on the surface of carbon black. It has been established that, when a carbon black is introduced into the monomer during the thermal polymerisation of styrene, the yield of the polymer diminishes.[34] The inhibiting effect of carbon black has been explained[16] by the interaction of the growing polymer radicals with the free radicals on the carbon black surface. It has been pointed out that the carbon black free radicals are incapable of initiating the polymerisation of monomers under the usual conditions

but they readily interact with the radicals of the growing macromolecular chain. The duration of the inhibition period is a function of the amount of carbon black introduced into the monomer.[35]

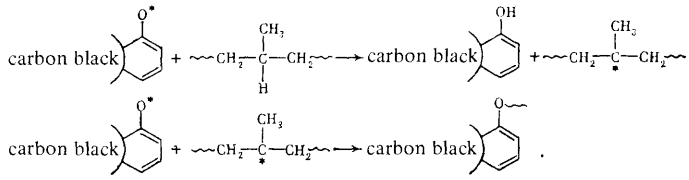


The inhibiting effect of carbon black has been attributed[34–36] to the presence on its surface of quinone groups which are reduced to hydroquinones groups in the course of polymerisation. The hydrogen atoms in the hydroxy-groups of the latter are mobile and capable of adding to the double bond of styrene, initiating its polymerisation. At the end of the inhibition period, the polymerisation of styrene is greatly accelerated in the presence of the carbon black. Both the inhibition stage and the acceleration stage are attributed to the presence on the surface of the carbon black of oxygen, which influences the duration of the inhibition period.[37–39]

The usual but accelerated thermal polymerisation takes place in the concluding stage of the reaction, which is explained by the fact that the chain termination rate constant is smaller in the presence of the carbon black than in the pure solution.[35,40]

It has been established[40] that part of the polymer formed in the presence of the carbon black is strongly bound to its surface, which indicates the grafting of the polymer chains. The amount of the grafted polymer can reach in many instances 15–20%. Since there are many radical centres on the surface of the carbon black capable of reacting with peroxy- and cyanoisopropyl radicals,[16,34] one can assume that the polystyrene radicals can also react with these centres, forming grafted chains.

In order to diminish the inhibiting effect of the carbon black and to increase the yield of the graft polymer, its surface is treated by peroxides. The surfaces of carbon substances promote in most cases the decomposition of peroxides, whose mechanism depends on the composition of the surface functional groups.[34,41–43] The fixation of peroxide initiators, especially 4,4-peroxobis(4-oxo)butanoic acid, on PM-100 carbon black[42] increases considerably their decomposition rate constant compared with the process occurring in the absence of the carbon black.



The rate of polymerisation in the presence of initiators fixed on the surface of the carbon black increases.[34] This effect can be accounted for by assuming that the growing chains are adsorbed on the surface of the carbon black and that such adsorption obeys the Langmuir–Hinshelwood law.[16] The mechanism of the formation of the graft polymer can be represented schematically as follows

As a result of the treatment of the carbon black by peroxides, the polymerisation interaction period can vanish (for example, on treatment with lauryl peroxide[16]), which indicates the blocking of the surface quinone groups or their reduction to hydroquinone groups, or it may increase (for example, on treatment with benzoyl peroxide[44]).

The efficacy of the grafting of polymers on the surfaces of carbon materials depends both on the nature of the initiator and on the chemistry of the surface. Measurements have been made[45] of the constants for chain transfer to the surfaces of oxidised carbon fibres during polymerisation carried out in the presence of lauroyl peroxide, benzoyl peroxide, and azobisisobutyronitrile. In the system with lauroyl peroxide, the chain transfer rate constant exceeds by a factor greater than 2 the corresponding value in the system with azobisisobutyronitrile. A highly oxidised surface with an increased content of carboxy-groups is the most reactive in the reaction with primary radicals.[34]

The quinone and aryloxy-groups present on the carbon black surface are capable of abstracting a hydrogen atom from a tertiary carbon atom. The radical derived from the polymer or an organic compound, formed under these conditions, can add to the surface of the carbon black:[40]

Despite the large number of studies on the polymerisation of monomers on carbon black, the influence of the chemistry of the filler surface on the characteristics of the formation of polymers was not studied in most of them, since the nature and number of surface functional groups on carbon black were as a rule unknown. In connection with the recent appearance of data on the chemical homogenisation of the surfaces of disperse carbon substances,[4–7] we investigated the influence of the chemistry of the surfaces of carbon fillers on the kinetics and characteristic features of the radical polymerisation and copolymerisation of vinyl monomers.[49,50]

One of the ways of modifying the surfaces of fillers by polymers is known to be[47,48] radical polymerisation which is initiated in this instance by the radicals fixed on the filler surface and formed as a result of the thermal decomposition of the initiators.[39] In particular azoisobutyronitrile (AIBN) and 4,4′-azobis-4-cyanovaleric acid (ACVA) have been used as initiators.[49] The latter initiator is of special interest in view of its ability to be chemisorbed in a number of instances on the substrate surface. A study of the adsorption of AIBN and ACVA from solutions on powdered ASM 1/0 diamond, ARV graphite, and GG-10 carbon black with specific surfaces of 10 000, 5000, and 10 000 $m^2\ kg^{-1}$ respectively and containing surface groups of a specific type (H, Cl, COOH, or NH_2 [2–6]) made it possible to establish that the equilibrium degree of adsorption of AIBN and ACVA depends both on the nature of the surface functional groups and on the nature of the filler skeleton. In all the instances investigated, the degree of adsorption of AIBN and ACVA on carbon substances containing different surface groups increased in the sequence H < Cl < COOH < NH_2. The degrees of the equilibrium adsorption of AIBN and ACVA on fillers with identical functional groups, referred to their concentration, differ significantly and increase as a function of the nature of the filler in the sequence carbon black < diamond < graphite, which is probably associated with the different structures of the carbon skeletons of the fillers and their influence on the reactivity of the surface groups. At the same time, the degree of equilibrium adsorption calculated per unit surface of the test powders is significantly higher for ACVA than for AIBN (by a factor of 1.5 on carbon black, 3–4 on graphite, and 10 on diamond). This demonstrates a significant influence of the polarity of the COOH functional groups in the initiator molecules on its sorption interaction with the surfaces of disperse carbon substances.

In order to elucidate the characteristics of the modification of the surfaces of disperse carbon fillers by polymers, a study was made of the influence of the nature of the adsorption on the kinetic parameters of the thermal decomposition of the sorbed azo-initiators.[50] With increase in the polarity of the surface

functional groups of the carbon materials in the sequence H < Cl < COOH < NH_2, the decomposition constants of the adsorbed AIBN and ACVA increased, while their activation energy for the thermal decomposition fell. It has been suggested[50,51] that the significant influence of the adsorption of initiators on their thermal stability may be due to the following causes:

(1) the decrease in the number of degrees of freedom of the initiator molecules as a result of their fixation on the surfaces of the carbon materials;

(2) the possibility of the addition of ACVA molecules via both end groups to the surfaces of disperse carbon materials and the formation of strained rings, which are apparently less stable than the linear molecule.[52]

The fixation of initiators on a solid surface is known[35,53] to entail in many instances a sharp decrease in the rate of polymerisation. This effect has been explained by the limitation of the diffusional mobility of the primary radicals bound to the solid phase, which leads to their rapid recombination, and also by topochemical factors determined by the localisation of the chain initiation, propagation, and termination processes at the surface of the filler particles.[53]

Table 1. The influence of the chemistry of the surfaces of disperse carbon materials on the amount (wt.%) of polystyrene not extractable from their surfaces.[46,49,50]

Initiator	Surface groups	Amount* of polystyrene not extractable from the surface		
		graphite	diamond	carbon black
AIBN	—H	1.2/0.8	0.30/—	1.4/1.0
	—Cl	1.3/0.7	0.58/—	1.6/1.2
	Initial specimen	3.2/2.2	2.0/0.6	4.0/2.4

Note. The polystyrene was obtained by radical polymerisation in suspension in the presence of the adsorbed initiators AIBN and ACVA.

*The numerator and denominator indicate respectively data obtained in the presence and absence of the initiator.

The polystyrene formed on polymerisation of styrene in the presence of an initiator sorbed on the filler surface and introduced into the monomer (0.5% relative to the monomer) is a mixture of a non-extractable polymer grafted to the surfaces of the disperse carbon materials and a homopolymer extractable by hot toluene and benzene.[46,49,50] Table 1 shows that the nature of the functional groups on the surfaces of disperse carbon materials influences significantly the amount of polystyrene non-extractable from the surfaces, which is especially notable in the polymerisation of styrene initiated by ACVA. A much greater amount of non-extractable polystyrene is formed on the surfaces of graphite and carbon black containing H groups than on the surface of diamond, which is apparently associated with the presence on the graphite and carbon black surfaces of free radicals capable of reacting with the growing polystyrene macroradicals. This leads to the termination of the polymer chain and the grafting of polystyrene to the surface. Such radicals have not been detected on the surface of diamond stored in air, which is apparently the reason for the smaller amount of polystyrene grafted to its surface.

The amount of polystyrene grafted on carbon substances containing different surface groups increases in all the systems investigated in the sequence H < Cl < initial specimen† < COOH < NH_2, which is correlated with the increase in the amount of adsorbed azo-initiators on these surfaces.[46]

As in the studies of Ivanchev and co-workers,[34,37] Bryk and Burban[46] observed a low efficacy of the initiation of the polymerisation of monomers by initiators (especially ACVA) fixed on the surfaces of carbon substances and a deviation of the kinetics of such a reaction from those characteristic of radical polymerisation. The latter is expressed by a decrease in the polymerisation reaction order with respect to the initiator from 1 to 0.3–0.7. According to Ivanchev and co-workers,[34,47] the observed phenomena can be attributed to the localisation of the initiator on the surface of the solid phase. The approach of the monomer molecules to a surface reaction centre 'shielded' by the polymer can be hindered in many instances and the rate of reaction is then controlled by diffusional factors.[34] The lower rates of formation of graft polystyrene compared with the homopolymer may be associated with the increase in the probability of the recombination of the primary radicals in the surface layer and their involvement in the termination of the growing chains.[47]

Analysis of the results of these studies carried out permit the conclusion that the grafting of the polymers onto the surfaces of carbon fillers can proceed via several mechanisms:

(1) as a result of the termination of the growing macroradicals on the radical centres present on the surfaces of the fillers.

(2) as a result of polymerisation initiated by the active centres on the surfaces of carbon black and graphite.

(3) in the interaction of the surface functional groups of the filler with the macroradicals.

(4) as a consequence of the transfer of the growing polymer chain to the surfaces of the carbon materials.

The molecular weight of the polystyrene obtained in the presence of disperse carbon materials with adsorbed AIBN and ACVA depends significantly on the chemistry of the surfaces of the fillers. The increase in the rate constant for the decomposition of the adsorbed initiators[50] leads to an increase in both the rate of initiation and in the rate of termination of the growing chains, which promote a decrease in the molecular weight of the polymer (Table 2).[34]

The presence in the polymer matrix of a solid and, what is most important, an active surface is known[54] to influence significantly the properties of the polymer. The change in the main characteristics of thermoplastics in the presence of fillers is associated with the alteration of the physical structure of the polymer at the polymer–solid interface. When disperse fillers are introduced into amorphous polymers, the adsorption interaction of the polymer molecules with the surface leads to the formation of a definite structure, inducing changes in the thermomechanical properties of the polymer.[54–56]

†The specimen of the carbon material which has not been treated in order to generate functional groups of a specific type and containing different surface functional groups.

Thus the introduction of carbon fillers diminishes the mobility of the polymer macromolecules as a consequence of their interaction with the surfaces of the particles.

Table 2. Dependence of the molecular weight of the polystyrene obtained at 353 K by ACVA-initiated polymerisation on the rate constant for the decomposition of ACVA.[46,49,50]

Carbon material	Surface groups	$10^{-5} k_d$, s^{-1}	Molecular weight of graft polystyrene
Diamond	—H	10.1	57000
	—Cl	10.9	52000
	—COOH	12.0	32000
	—NH_2	14.0	30000

	—Cl	12.8	52000
	—COOH	13.3	30000
	—NH_2	16.0	28000
Carbon black	—H	8.97	56000
	—Cl	9.70	54000
	—COOH	10.30	36000
	—NH_2	11.70	34000

The glass point of the polymer increases in this instance in the sequence of the following functional groups present on the fillers: H < Cl < COOH.[46,57] Such variation is characteristic of polystyrene obtained in the presence of AIBN and ACVA adsorbed on the surfaces of carbon substances and is more pronounced for ACVA apparently due to the higher energy of the interaction of the ACVA molecules and of the radicals formed on their decomposition with the surface.[50]

It has been established[46,57] that the presence of a carbon filler (especially one containing the COOH and NH_2 surface groups) appreciably increases the resistance of the polymer to thermo-oxidative degradation. This can apparently be accounted for by the structure-forming effect of the filler, whose particles become the nodes of a structural network arising as a result of the interaction of the polymer molecules with the surface.[57] The stabilising effect of the filler on the thermal properties of the polymer is manifested to a greater extent the stronger the bond between the polymer and the surface.

The energy of the interaction of the polymer with the surface influences appreciably also the mechanical properties of the compositions obtained by the polymerisation of filled monomers. Thus the ultimate compressive strength of compositions of polystyrene with disperse carbon materials increases with increasing adsorption and chemical interactions of the macromolecules with the surface, which is in many respects determined by the chemistry of the surface of the solid phase.[54]

The effect involving the strengthening of the polymers depends greatly on the nature of the fillers and their structure. The number of surface functional groups and their reactivity are then of primary importance.[58] The geometry of the surfaces of the disperse materials is also very important.

Among the multiplicity of polymeric materials, filled three-dimensional polymers, in the preparation of which polymerisation and structure formation processes are carried out in the presence of a filler with an active surface, should be given special consideration.

Studies on the characteristic features of the radical copolymerisation of styrene with divinylbenzene (DVB) in the presence of disperse carbon materials with initiators (AIBN and ACVA) adsorbed on their surfaces have shown that the yield of the copolymer diminishes with increase in the polarity of the surface groups of the fillers in the sequence H < Cl < COOH < NH_2.[59] This is apparently associated with the decrease in the rate of polymerisation when the initiator is fixed on a solid surface.[34,52]

Table 3. Dependence of M_c of the styrene–divinylbenzene copolymer obtained in the presence of disperse carbon materials on the chemistry of their surfaces.[59]

Initiator	Surface groups	M_c^* of the copolymer on		
		diamond	graphite	carbon black
AIBN	—H	415	420	410
	—Cl	418	426	420
	Initial specimen	440	456	438
	—COOH	455	466	450
	—NH_2	458	470	456
ACVA	—H	418	416	415
	—Cl	422	420	425
	Initial specimen	480	490	475
	—COOH	506	517	502
	—NH_2	515	530	510

Note. Divinylbenzene content 10 wt.%; polymerisation temperature 343 K.
*M_c = 400 for the unfilled copolymer.

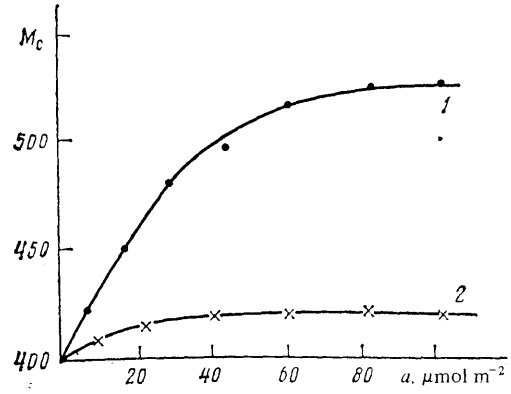

Figure 1. Dependence of M_c of the styrene–divinylbenzene (10 wt.%) copolymer, obtained in the presence of diamond containing surface NH_2 (curve *1*) and H (curve *2*) groups, on the concentration of the adsorbed ACVA initiator.[59]

Table 3 shows that the presence of fillers influences the density of the three-dimensional network [the molecular weight of the polymer between the nodes of the cross-linked structure (M_c)]: in all cases M_c for filled systems is greater than for the corresponding unfilled systems. This effect is manifested more strongly when fillers

containing the COOH and NH_2 surface groups are used. Furthermore, with increase in the amount of adsorbed initiator, the M_c of the copolymer formed increases only up to a specific initiator concentration (Fig. 1). Along the initial section of the curve, the dependence of M_c on the ACVA concentration is linear, which can apparently be explained by the dominant contribution of the surface to the termination of the polymer chain, which results in the formation of a defective three-dimensional network. On further increase in the amount of adsorbed initiator, a break in the curve is observed, which may be due to the initiation of the copolymerisation process by a much greater number of radicals, formed as a result of the thermal decomposition of the adsorbed initiators, and with their contribution to the formation of the polymer network of the copolymer. The final structure of the copolymer is determined by the overall effect of these factors acting in opposition.

2. Ionic polymerisation on the surfaces of disperse carbon substances

Studies have been published recently in which the ionic polymerisation of alkenes initiated by transition metal complexes fixed on the surfaces of fillers, including carbon fillers, was considered.[59-64] The presence on the carbon black surface of various oxygen-containing functional groups permits the fixation of $TiCl_4$ on the filler surfaces as a result of the formation of covalent bonds with the oxygen atoms:[60,61]

$$[C]_m(OH)_n \xrightarrow[-n\,HCl]{n\,TiCl_4} [C]_m(OTiCl_3)_n,$$

$$[C]_m(OH)_n \xrightarrow[-n\,HCl]{n/2\,TiCl_4} [C]_m(O_2{-}TiCl_2)_{n/2}.$$

Also possible is the addition of $TiCl_4$ to the carbonyl groups of the carbon black surface with formation of compounds having the composition (carbon black)—O.$TiCl_4$, which corresponds, according to Krasnobryzhii et al.,[61] to the "undissociated form of chemisorption" of $TiCl_4$. $TiCl_4$ adds to the graphite and diamond surfaces via a similar mechanism.[62-65]

Transition metal complexes fixed on the filler surface form the active centres for polymerisation. The characteristic features of the stereospecific polymerisation of ethylene initiated on the complexes of $TiCl_4$ with triethylaluminium have been determined.[62-65] In particular, the kinetics of this process under non-stationary conditions have been elucidated using graphite and diamond as fillers.[62] The much lower rate of polymerisation on graphite has been explained by the more pronounced reducing properties of its surface compared with the surface of diamond. In combination with the effect of alkyl groups, this gives rise to the possibility of the reduction of Ti(IV) ions to give a lower oxidation state, i.e. of their conversion into an inactive form.[66] The high rate of reaction on diamond is attributed to the formation of active complexes on interaction of the titanium chloride groups fixed on diamond with the triethylaluminium in the reaction medium.[62]

The study of the polymerisation of propene on stereospecific Ziegler–Natta catalysts, obtained by the alternate deposition of $TiCl_4$ and $(C_2H_5)AlCl_3$ on different carriers, established that the activity of the catalyst on graphite is several times greater than on perlite, talc, tuff, and other fillers.[67,68] The high activity and stereospecificity of the catalysts fixed on the graphite surface are determined both by the layered structure of graphite and by its electron-donating properties, which influence the structure of the polymerisation active centres.[67]

Further detailed studies on the kinetics and other features of the polymerisation of olefins on carbon fillers should give rise to the possibility of regulating the amount of the polymer formed on their surface in order to impart the required physicomechanical properties to the compositions.

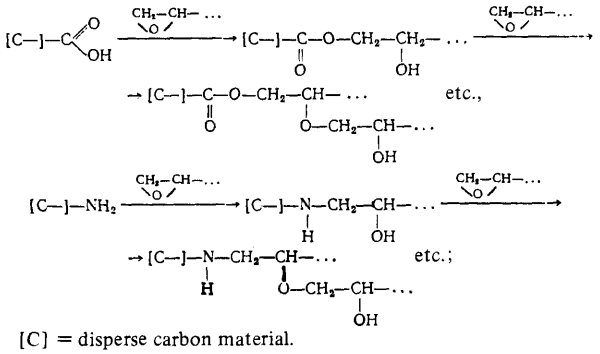
Apart from the fixation of transition metal complexes, other methods for the modification of the surfaces of carbon black and graphite, used in the ionic polymerisation of monomers of different nature, are also known. It is known[69,70] that the inclusion compounds of alkali metals in graphite, having the general formula MC_n, are active catalysts of anionic polymerisation. It has been suggested that metal cations are inserted between the graphite layers, which then acquire a negative charge and ability to initiate polymerisation. The negative charge on the carbon network of graphite and hence the initiating activity depend significantly on the nature of the alkali metal and increase in the sequence Li < Na < K.[71,72] Polymerisation can occur both on the surfaces of the graphite layers and between the carbon networks. In the former case, chain propagation takes place following the adsorption of the monomer on the catalyst surface and in the latter after the insertion of the monomer between the graphite networks in the anion–graphite bonds.[72]

The possibility of using variable composition potassium–carbon black compounds as the catalyst of the anionic polymerisation of vinyl monomers has been studied.[77] It has been suggested that the polymerisation of monomers with strongly electro-negative groups may be initiated by radical-ions of the type R–$\dot{C}$H–$\overline{C}H_2$ arising as a result of electron transfer from the conductivity band of the catalyst to the monomer molecule adsorbed on its surface.

The direct propagation of ionic chains on the carbon black surface becomes possible as a result of a preliminary treatment which leads to the replacement of some of the hydrogen atoms, forming part of the polyaromatic structure, by lithium atoms.[16] Butyllithium, forming part of the composition of a complex with tetramethylenediamine, has been used for such "metallation" of the carbon black.[73-76]

An interesting way of obtaining graft polymers on the carbon black surface involves the initiation of the polymerisation by alkali metal and ammonium carboxylates.[78-80] It has been observed that, in the polymerisation of propiolactone, accompanied by ring opening and initiated by the COOM groups on the carbon black surface, the efficacy of the grafting diminishes with increase in the degree of conversion of the monomer.[78,79] This effect has been attributed to chain transfer to the monomer and the formation of the homopolymer. The reactivity of the COOM groups on carbon black depends on the nature of the alkali metal and increases in the sequence Li < Na < K < Rb < Cs.

Studies dealing with the modification of the carbon black surface by polymers formed via a cationic mechanism have been published recently.[81-85] A study has been made of the cationic polymerisation of α-methylstyrene, isobutyl vinyl ether, indene, and *N*-vinyl-2-pyrrolidinone on a carbon black surface.[83,84] It has been suggested that the polymerisation is initiated by the surface carboxy-groups of the carbon black.[81] In the polymerisation of *N*-vinylcarbazole on carbon black,[85] the polymerisation active centres are formed as a result of electron transfer from the monomer to the carbon black and the recombination of the radical-cation formed with the surface of the carbon black. The monomer cations fixed on the surface in this way function as the polymerisation active centres. The rate of polymerisation is directly proportional to the monomer concentration and the amount of the carbon black.



The cationic polymerisation of styrene on the surface of carbon black containing the $CO^+ClO_4^-$ functional groups has been studied.[86] The overall yield of the graft polymer increases linearly with increasing polymerisation time and reaches 85% at 313 K. The grafted $CO^+ClO_4^-$ groups are also capable of initiating the polymerisation of vinylpyridines and cyclic monomers.

3. Polyaddition and polycondensation on the surfaces of disperse carbon materials

The presence of reactive functional groups, especially COOH or NH_2, on the surfaces of carbon materials leads to the possibility of obtaining graft polymers by methods involving the polyaddition of oligomers and their polycondensation with the corresponding groups.

Modern ideas about the interaction of polymers with fillers are to a large extend based on the study of the adsorption of polymers and oligomers from solutions.[56] Thus, in the investigation of the adsorption interaction of the ED-20 epoxide resin on the phenol-formaldehyde Novolac resin with the surfaces of diamond, carbon black, and graphite powders, containing the H, Cl, COOH, or NH_2 groups, established that the degree of adsorption of the oligomers increases in the sequence H < Cl < COOH < NH_2.[87,88] This has been attributed to the differences between the energies of the sorption interactions of the oligomers with the surface. The hardening of the epoxide and phenolformaldehyde resins in the presence of disperse carbon materials without the introduction of a hardening agent into the system is induced by the participation of the surface groups of the carbon substances in this process.[9,89,90]

An IR spectroscopic study has led to the hypothesis[87,88] that the interaction of the epoxide resin with the COOH and NH_2 groups proceeds via the mechanisms

[C] = disperse carbon material.

There have been numerous studies in which the formation of three-dimensional polymer networks in the presence of disperse fillers was considered,[9,30,31] but at the present time the influence of the nature of the filler on the formation of network polymers and their structure still remains little investigated.[90]

The questions of the molecular interaction of the polymer–filler surface and of the mechanism of the influence of the filler on the polymer at comparatively large distances from its surface, greatly exceeding the radius of action of intermolecular forces (up to 150 to 200 μm), are also controversial.[91]

In order to ensure a strong adhesion bond between the polymer and the filler, both the chemistry of the surface of the filler[90,91] and the structure of the interfacial oligomeric adsorption layer[64,91,92] are very important. Depending on the nature of the oligomer and the filler, either rigid or elastic networks can be formed near the surface, which is also determined by the distance of the polymer layer formed from the surface.[90,91]

It is known[54,92] that the influence of the filler on the formation reactions of network polymers can be characterised by two opposed effects:

(1) By the chemisorption interaction between the macromolecules on the surface and also by the formation of strong physical adsorption bonds between them, which tends to reduce the degree of swelling of the compositions.

(2) By the termination of the reactions involving the growth of the macromolecules on the filler surface with formation of a defective network, which increases the degree of swelling of the filled network polymers.

In each specific case, the contributions of these processes acting in opposition are different and the final properties of the composition are determined by their overall effect.

Table 4. Dependence of the density of the polymer network (M_c) and the Huggins constant (χ) of the ED-20 epoxide resin, hardened in the presence of disperse diamond, graphite, and carbon black containing NH_2 groups, on the concentration of the filler.[88,89]

Filler	Filler concentration, wt.%	M_c^* at		χ at	
		298 K	333 K	298 K	333 K
Diamond	10	112	342	1.09	0.80
	30	103	—	1.10	—
	50	95	315	1.11	0.84
	90	82	300	1.14	0.84
Graphite	10	92	330	1.10	0.82
	30	88	—	1.10	—
	50	84	311	1.17	0.83
	90	71	292	1.26	0.85
Carbon black	10	216	424	0.85	0.44
	30	169	—	0.86	—
	50	146	391	0.92	0.46
	90	109	373	0.94	0.50

* M_c = 323 in the absence of the filler at 333 K.

The study of the structure of three-dimensional polymer networks has shown[88,89] that, with increase in the degree of filling of the resins, M_c diminishes (Table 4). This effect is associated with the increase in the total number of the surface COOH and NH_2 groups, functioning as centres for grafting and for the hardening of the resin on the surface, and leads to a diminution of M_c. The increase in the Huggins constant with the degree of filling can be explained, according to Burban et al.[93] and Lipatov et al.,[94] by the fact that the increase in the amount of filler diminishes the thermodynamic stability of the polymer–solvent system.

Fig. 2 shows that the degree of sorption of acetone vapour by the epoxide resin, hardening in the presence of carbon black (30% filling), depends significantly on the chemistry of its surface and increases in the sequence NH_2 < COOH < initial specimen < Cl < H.[88] The values of M_c for the corresponding compositions, amounting to 169, 182, 201, 221, and 254, increase in the same sequence. The phenomena indicated are apparently associated with the different kinds of interactions (chemical and physical with different energies)[93,95,96] of the epoxy-groups of the oligomers with the functional groups on the carbon black surface.

The values of M_c measured on the specimens swollen in solvent vapour at an elevated temperature (Table 5) characterise in the main the chemical nodes of the three-dimensional polymer network.[95,96]

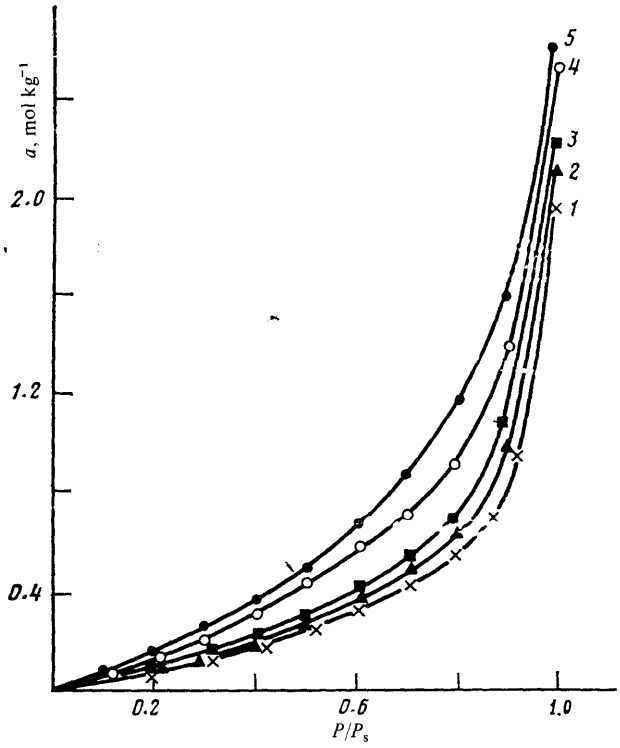


Figure 2. Isotherms of the sorption of acetone vapour by the ED-20 epoxide resin hardened in the presence of carbon black (30 wt.%) containing different surface groups at 298 K:[95] *1*, NH_2; *2*, COOH; *3*, initial carbon black; *4*, Cl; *5*, H.

Thus the structure of the polymer networks, formed when the epoxide and phenol formaldehyde resins are hardened on the surfaces of disperse carbon materials, depend significantly both on the chemistry of the surface and the structure of the fillers and on the total number of the chemical and physical cross links. Comprehensive investigation of the structure of three-dimensional polymers at different temperatures has made possible certain reliable conclusions about different interactions leading to the formation of the network structures.

The nature of the adsorption interaction of the oligomers and the structure of the polymer networks, formed when the epoxide and phenolformaldehyde resins are hardened on the surfaces of disperse carbon fillers, undoubtedly influence the properties of the polymeric materials obtained.

The increase in the glass point T_g of the network polymer in the presence of an active surface is due to the strong physical or chemical interaction of the polymer molecules with the solid phase, which limits the mobility of sections of the polymer chain, this being equivalent to the formation of an additional number of cross links.[91,92] In particular, the glass point of the composition is influenced by the state of the filler surface:[90,97-99] if the filler is subjected to the surface antiadhesion treatment, which eliminates the possibility of chemical interaction, then the T_g of the composition based on epoxide polymers does not increase and remains almost the same as for the unfilled resins.

It has been established[93] that the T_g of the epoxide and phenol-formaldehyde resins hardened in the presence of carbon materials increase significantly with increase in the content of the solid phase from 10 to 90% (Table 5). With increase in the polarity of the surface functional groups of the carbon materials, the glass point of the resin also increases.[88]

Table 5. Dependence of the glass points (T_g, K) of compositions based on epoxide and phenolformaldehyde resins on the degree of their filling by disperse carbon materials containing COOH and NH_2 surface groups.[93]

Resin	Degree of filling, wt.%	Diamond		Graphite		Carbon black

* T_g = 431 K in the absence of the filler.
** T_g = 460 K in the absence of the filler.

The improvement in the adhesion interaction at the polymer–solid interface and an increase in the strength of the material are important practical tasks in the creation of polymer compositions.

The question of the dependence of the mechanical properties of vitreous polymers on the concentration of chemical and physical nodes of polymer networks has been fairly adequately reflected in the literature.[100-103] The introduction of relatively small amounts of active fillers into polymers, including network polymers, increases the mechanical strength of the compositions as a consequence of the formation of additional cross links and the limitation of the mobility of segments of the macromolecules.[104]

For low and moderate degrees of filling of the epoxide and phenolformaldehyde resins, the ultimate compressive strength of the compositions increases with increase in the amount of carbon substances containing the COOH and NH_2 surface groups.[87,88,93] This phenomenon can evidently be attributed both to an increase in the density of the three-dimensional polymer network, formed in the presence of the filler, and to the formation on its surface of a more rigid boundary layer.[97] On the other hand, the decrease in the strength of the compositions in the region of high degrees of filling is apparently induced by the increase in the residual stresses at the polymer–solid surface interface and the increase in the defectiveness of the polymer network.[105,106]

The state of the filler surfaces also influences significantly the mechanical strength of the composition, since the adhesion bond between the polymer and the solid phase and the orientation and fixation of the oligomers on the surfaces of the particles depend on it.[91] The reinforcing effect of carbon fillers containing various surface groups increases in the sequence H < Cl < initial powder < COOH < NH_2. This is apparently associated with the increase in the same sequence in the density of the polymer networks formed as a result of the hardening of the epoxide and phenolformaldehyde resins on the surfaces of disperse carbon materials.

- - -o0o- - -

The above analysis of the studies on the synthesis of polymers in the presence of disperse carbon materials shows that the chemistry of the filler surfaces influences significantly the process kinetics, the degree of grafting, and the molecular weight of the polymers formed and also the density of the three-dimensional networks of the polymers formed in the three-dimensional polymerisation and polycondensation of filled monomers and oligomers.

The physicochemical properties (glass points and degradation temperatures) and the mechanical properties (compressive strength) of the polymers obtained in the presence of carbon black, graphite, and diamond also depend on the chemistry of the filler surfaces. For the same type of surface functional groups, the polymerisation kinetics, the degree of grafting, and the structure and properties of the polymers formed on the graphite, carbon black, and diamond surfaces are influenced appreciably by the structure of the skeleton of the disperse carbon materials.

It is notable that ionic polymerisation and polycondensation processes on the surfaces of carbon materials with homofunctional groups have been inadequately investigated. Studies on the elementary stages of the free-radical polymerisation process on the surfaces of carbon materials containing surface groups of different kinds and having different structures of the skeleton require further development.

Ion exchangers based on modified mineral carriers

G V Kudryavtsev, S Z Bernadyuk, G V Lisichkin
Moscow State University

ABSTRACT. Methods for the synthesis of ion exchangers based on modified mineral carriers, such as chemical modification of the surface by organosilicon compounds, adsorption and chemical modification of the surface by low-molecular-weight and polymeric organic compounds, the polymerisation of monomers on the surface of mineral carriers, and the hydrolytic polycondensation of organosilicon compounds, have been examined. A list of the most widely encountered commercial sorbents has been given. The possibilities provided by the use of ion exchangers based on mineral carriers for the sorption and separation of inorganic ions, in the high-performance liquid chromatography of organic compounds and biopolymers, and also in catalysis, have been demonstrated.

The bibliography contains 261 references.

IV. Applications of ion exchangers based on modified mineral carriers 413

I. Introduction

Until recently, two main classes of ion exchanger were known: synthetic organic polymers containing ionogenic functional groups, and inorganic materials, primarily silica, aluminium oxide, and zeolites. The extensive practical application of organic polymeric ion exchangers is due to their universal action, the high concentration of ionogenic groups, the ease of regeneration, and the possibility of varing widely the nature and concentration of the functional groups and hence the sorptive and catalytic characteristics of these materials. The advantages of inorganic ion exchangers are their mechanical strength, their stability to heat and radiation, and the fact that they do not swell in solvents. In general, it can also be said that they have better mass-exchange characteristics, as is clearly seen by comparing the sorptive properties of meso-porous and large-pore mineral materials and organic sorbents with a gel structure. In addition, certain types of inorganic ion exchanger have unique catalytic properties.

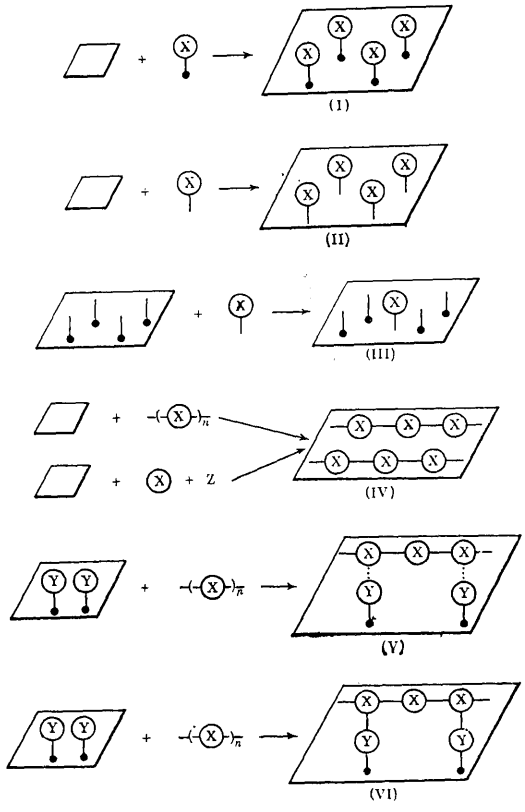
At the same time, the development of chemistry and biochemisty has raised problems, for the solution of which both known classes of ion exchanger have proved unsuitable. For example, the use of organic ion exchangers in the intensively developing high-performance liquid chromatography is prevented by their poor average mass-exchange characteristics and the fact that the volume of the sorbent layer in the chromatographic column is not constant. Although mineral sorbents do not have these disadvantages, they can be used to solve only a restricted range of problems, because of the non-uniformity and narrow variability of the surface properties.

It has thus become necessary to create materials of a new type, combining the advantages of the previously known classes of ion exchanger. The mechanical and mass-exchange characteristics of these materials should be determined primarily by the rigid wide-pore mineral framework of the carrier, and their ion-exchange characteristics by the nature of the attached functional groups. The production of these materials has involved the modification of the surface of inorganic materials by organic compounds containing ion-exchanger functional groups.

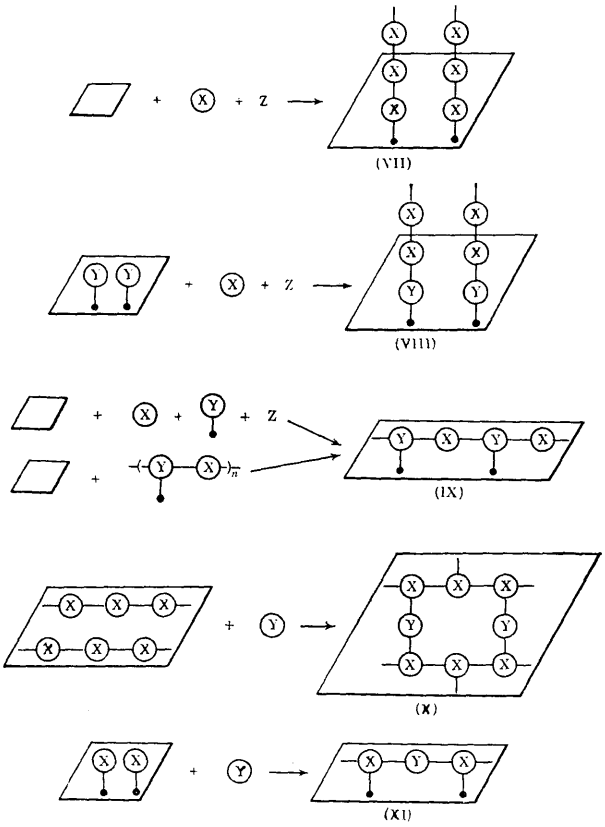
The ion exchangers being considered form part of an extensive class of modified mineral carriers which find varied applications in sorption, chromatography, catalysis, and other branches of science and technology. The methods of preparation, properties, and applications of these materials have been described in a large number of publications (see for example the published monographs[1–11] and reviews[12–19]), but no general review of ion exchangers based on modified mineral carriers has been published. Such a review is appropriate, because of the specific characteristics of the synthesis of these materials and the fields of application in which only these materials are used, such as high-pressure ion chromatography, the ion-exchange chromatography of proteins and other natural compounds, and acid–base and phase transfer catalysis.

The present review describes methods for obtaining ion exchangers based on mineral carriers, some of their properties, and their applications in sorption, catalysis, and chromatography.

II. Methods for obtaining ion exchangers based on modified mineral carriers



A large number of functional groups capable of taking part in ion exchange have been attached to the surface of mineral carriers. It was decided to restrict the present review to a narrow range of classical ion exchangers. Thus the cation exchangers examined include strongly, moderately, and weakly acidic materials containing sulphonic, phosphonic, and carboxylic acid groups, and the anion exchangers include strongly basic materials with quaternary ammonium and phosphonium groups and weakly basic materials with mono- and polyamine groups. The last sorbents, and also phosphonic and carboxylic acid cation exchangers, in a number of cases may show complex-forming power. The properties and applications of these sorbents associated with complex formation are not examined in the present review. Other materials excluded from the present review are modified mineral carriers with grafted tertiary phosphines or ionogenic molecules of aminoacids, dithiocarbamates, dithiocarboxylic acids, hydroxamic acids, and other compounds for which complex-forming properties or affinity are most characteristic.



A wide range of mineral materials are used as carriers for the attachment of organic compounds, primarily silica, and also aluminium,[20–24] titanium,[22–26] zirconium,[22,27] tin(IV),[25,26,28] ruthenium(IV),[25,29] etc. oxides. The great majority of studies have been devoted to the attachment of organic compounds to silica, since this material has been extensively studied, is easily modified, and is readily available. Subsequently, except in certain special cases, the discussion will deal with the modification of the surface of silica. It should be noted that the approaches to the modification of the surface of different oxides are identical, and in most cases are based on the reaction with the hydroxyl groups of the surface. The regular features of the modification established for silica can in a first approximation be extended to other oxide carriers.

Ionogenic groups cannot be attached directly to the surface of mineral carriers, because of the instability (primarily to hydrolysis) of the bonds Si–O–C, Si–N, Si–S, Si–O–S, Si–P, Si–O–P, etc. This makes it necessary to introduce an organic "binder" joined to the carrier surface, and then to attach ion-exchanger groups to it by strong covalent bonds.

A large number of methods for modifying the surface of mineral carriers have now been developed, making it possible to vary the nature of the organic modifying layer (monomeric, polymeric) and the nature of the bond between the carrier and the organic modifier (covalent, ionic, hydrogen bonds, topological fixation). The variety of methods of preparation and structures formed on the surface is illustrated in Scheme 1. Additional possibilities for the synthesis of modified mineral carriers are provided by the conversion of attached functional groups X into other ion-exchanger groups.

Scheme 1

= the surface of the mineral carrier;

● = the anchoring group forming a covalent bond with the carrier;
– = a hydrocarbon chain;

Ⓧ = an ionogenic group or molecule containing an ionogenic group;

Ⓨ = a cross-linking molecule or group with no ion-exchange properties;

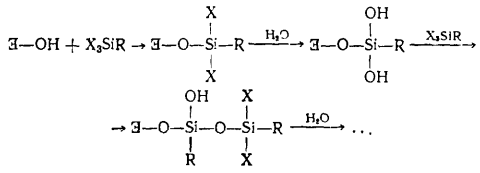
Z = initiation (in polymerisation).

The synthesis paths represented in the scheme are based on the use of prepared mineral carriers. An alternative method for obtaining modified silicas is by the hydrolytic polycondensation of organosilicon compounds.

Specific examples of the synthesis of ion exchangers based on modified mineral carriers can now be considered.

1. Covalent attachment of monomeric organic compounds (structure I)

Modification of the carrier surface by organosilicon compounds has been most widely used to synthesise ion exchangers based on silica:

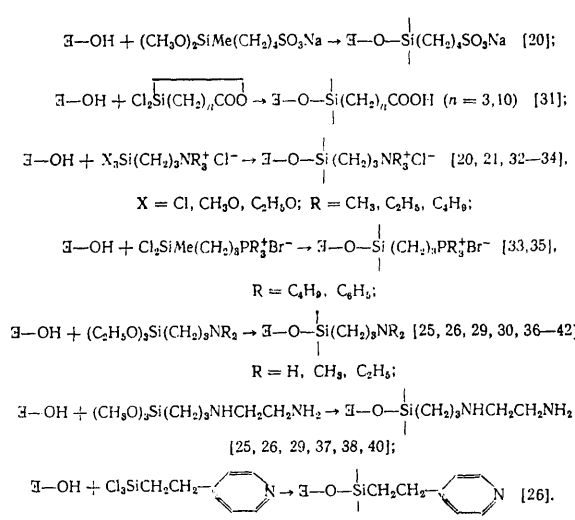


$$\exists\text{—OH} + XX^1X^2SiR \rightarrow \exists\text{—O—}\underset{|}{\overset{|}{Si}}\text{—R},$$

where ∃ represents the surface of the mineral carrier, X (and possibly X^1 and X^2) = Cl or OAlk, and R represents an organic group, which may include the required functional group.

The attachment of organosilicon compounds to the carrier surface may give two types of grafted-layer structure: "brush" and "polymeric". When the brush structure is formed, the molecules of the modifier are attached to the carrier surface as a result of their reaction

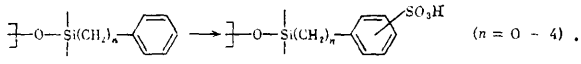
with the hydroxyl groups of the carrier, giving a uniform monomolecular layer. The surface concentration of grafted compounds is determined by the size of the XX^1X^2Si anchor group, and for ion exchangers with the brush structure it does not exceed 2–3 molecule nm^{-2}. For carriers with $S_{sp} = 100\ m^2\ g^{-1}$, this quantity is ~ 0.4 mmol g^{-1}, which is much lower than that for organic polymers.



The surface concentration of grafted organic compounds can be increased by carrying out the modification in the presence of water. The following processes take place, giving the grafted layer a polymeric structure:

Sorbents with a polymeric structure have a higher surface concentration of grafted organic molecules, compared with sorbents with a brush structure, but when more than four molecules nm^{-2} are attached to the surface, a uniform covering cannot be expected.[30]

Not all hydroxyl groups of the carrier surface react with organosilicon compounds. Residual silanol groups, which show weakly acidic ion-exchange properties and are also capable of bringing about the specific adsorption of many organic molecules, in many cases have an unwanted influence on the properties of ion exchangers particularly when they are used in high-performance liquid chromatography (HPLC). The surface concentration of silanol groups can be decreased by using so-called monofunctional monomers $XSiMe_2R$ or by carrying out additional silanisation by small silanising agents, usually trimethylchlorosilane or hexamethyldisilazane.

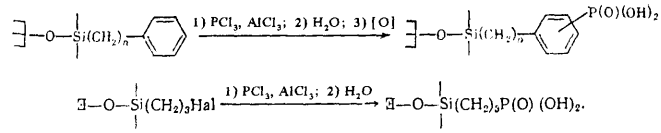


In principle, all the ion exchangers considered can be obtained by single-stage modification of the carrier surface:

Of the modifiers listed, however, only the organosilicon derivatives of amines, primarily γ-aminopropyltriethoxysilane (trade mark AGM-9), are readily available. Research workers therefore prefer first to attach a relatively simple and readily available organosilicon compound to the surface, and then to introduce into it the required ion-exchange group, using familiar reactions of organic synthesis.

The yields of the reactions on the surface are usually not quantitative, and this leads to the presence of functional groups of different types. When selecting a method for synthesising an ion exchanger, it is preferable that the original functional groups to be subjected to subsequent transformations, and also the intermediate products of their transformation, should not have ion-exchange properties.

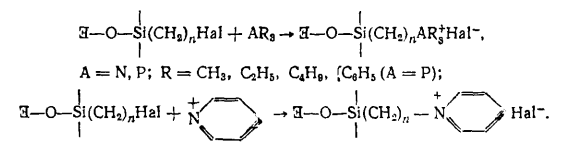
Strongly acidic cation exchangers are most frequently obtained by sulphonating aromatic compounds attached to the surface:[43–48]



The advantages of this method are the availability of the original organosilicon modifiers and the high degree of sulphonation, which reaches 100% when chlorosulphonic acid is used as sulphonating agent.

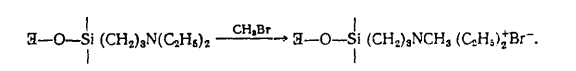
The oxidation of grafted thiols is equally effective:[49,50]

Other methods of synthesis include radical chlorosulphonation of attached alkyl groups,[49] the reaction of grafted halogenoalkyl groups with sodium sulphite[51] or ammonia,[49] the reaction of a grafted glycidyl ester with sodium sulphite,[52] and the oxidation of a grafted isothiouronium salt.[20]



The following methods can be recommended for synthesising phosphonate cation exchangers:[53,54]

The attachment and hydrolysis of esters of alkyl or phenyl hydrogen phosphates[55,56] and the chlorides of alkyl hydrogen phosphates[57] have also been described.



The best method for obtaining carboxylic acid cation exchangers is by the acid hydrolysis of attached esters[44,58,59] and nitriles,[46,58] where the yields are quantitative.

The most widely used method for synthesising strongly basic anion exchangers is by the reaction of attached halogenoalkyl groups with tertiary amines,[45,46,60,61] phosphines,[33,35,62] or pyridine:[61]

When an aromatic compound is grafted initially to the silica surface, it is first chloromethylated, for example with methyl chloromethyl ether in the presence of zinc chloride, and then aminated.[48,63] The advantage of the method is the high yield (>80%) at all stages of the transformation.

It is possible in principle to synthesise strongly basic anion exchangers by the exhaustive alkylation of attached amines, for example:[33]

However, since there is no guarantee that the reaction on the surface will be quantitative, the product may contain not only the required tetra-alkylammonium compounds but also alkylamines, which also have ion-exchange properties.

The method of synthesis on the surface in the production of weakly basic anion exchangers is usually employed to attach polyamine groups:[40,64]

$$\equiv Si{-}O{-}Si{\equiv}\,(CH_2)_3Hal + NH_2(CH_2CH_2NH)_nH \rightarrow \equiv Si{-}O{-}Si{\equiv}\,(CH_2)_3NH(CH_2CH_2NH)_nH.$$

Extensive synthetic possibilities are provided by the use of silica specimens modified by epoxy-groups.[52] The sorbents are obtained by treating silica with γ-glycidoxypropyltrialkoxysilanes followed by reaction with compounds capable of opening the epoxy-ring:

$$\equiv Si{-}OH + (RO)_3Si(CH_2)_3OCH_2CH{-}CH_2 \rightarrow$$

$$\rightarrow \equiv Si{-}O{-}Si{\equiv}\,(CH_2)_3OCH_2CH{-}CH_2 \xrightarrow{HX} \equiv Si{-}O{-}Si{\equiv}\,(CH_2)_3OCH_2CHOH{-}CH_2X,$$

$$X = N(C_2H_5)_2,\ OCH_2CH_2N(CH_3)_2,\ OCH_2CH_2N(C_2H_5)_2,$$
$$(NHCH_2CH_2)_nNH_2,\ OCH_2COOH,\ SO_3H.$$

When silica with grafted epoxy-groups is treated with water at pH 3, the product is a sorbent with grafted diol groups (X = OH). This sorbent and its derivatives are widely used in the chromatography of biopolymers, since there is no non-specific adsorption of proteins. It may also be noted that the oxidation of a grafted alcohol by a mixture of sodium metaperiodate and potassium permanganate in a weakly alkaline medium provides a convenient method for obtaining weakly acidic carboxylic acid cation exchangers.

The advantages of the method involving the covalent attachment of monomeric organosilicon compounds also include the possibility of obtaining polyfunctional sorbents (so-called multi-phases); chromatographic separation on these sorbents involves the coordinated combination of reactions of two or more types between the substances being analysed and the sorbent. The need for sorbents of this kind arises most frequently in the analysis of biopolymers, where the use of only one method of separation (for example reversed-phase or ion-exchange methods) does not give the required selectivity. To solve this problem, the carrier surface is modified using a mixture of organosilicon compounds, and the required functional groups are introduced to give sorbents of the following type:[65–68]

$$\equiv Si{-}O{-}Si(CH_3)_2(CH_2)_nCH_3$$
$$\equiv Si{-}O{-}Si(CH_3)_2(CH_2)_3R$$

$$R = C_6H_4SO_3H,\ N^+(CH_3)_2CH_2C_6H_5.$$

The best ratio of "hydrophobic" and ion-exchange interactions in the separation can be achieved by varying the quantities of the original organosilicon compounds. These results often cannot be achieved simply by mixing two different sorbents.

An alternative method of varying the contributions of the "hydrophobic" and ion-exchange interactions in retention is by changing the length of the hydrocarbon chain connecting the ionogenic group to the carrier surface.[69] This method gives sorbents with highly reproducible properties, but the need for the special synthesis of a set of organosilicon modifiers restricts its application.

A promising method for synthesising ion exchangers with variable ion-exchange capacity has been proposed;[70] the first stage involves the exhaustive modification of the silica surface by diol groups (using γ-glycidoxypropyltriethoxysilane), and in the second stage these groups are acylated using the cyclic anhydrides of dibasic acids. The concentration of carboxyl groups introduced can be varied to give the best ion-exchange retention of proteins; the complete shielding of the surface by the diol groups ensures that non-specific adsorption of proteins does not take place.

The covalent attachment of monomeric organosilicon compounds to the surface of mineral carriers ensures uniformity of the sorption centres and high reproducibility and predictability of the synthesis. In the case of sorbents with a brush structure, the modifier forms a lining in all the pores of the carrier consisting of a thin regular layer, allowing the diffusion of the substances from the solution into the interior of the particle and ensuring a high rate of mass exchange. This gives modified sorbents of this type a dominant position in HPLC. At the same time, these sorbents have a number of disadvantages.

Firstly, these sorbents have a low stability to hydrolysis. Modified silica specimens in which the grafted layer has a brush structure are not recommended for use at pH < 1 and pH > 9. The degradation of weakly basic anion exchangers is often observed on prolonged use even at pH > 7. The hydrolytic stability of sorbents in the alkaline range up to pH 10 can be increased by using other inorganc carriers, in particular aluminium oxide and aluminated or zirconated silica specimens.

Secondly, the exchange capacity of these sorbents is several times lower than that of ion exchangers based on organic polymers. This represents a significant obstacle to their use in technological sorption processes, and restricts their sphere of application to mainly analytical problems.

Thirdly, their synthesis is relatively complicated, and the use of organosilicon compounds which in many cases are expensive and difficult to obtain increases their cost considerably, compared with their organic-polymer analogues.

Thus the search for other methods for synthesising ion exchangers based on modified mineral carriers is continuing.

2. The attachment of monomeric organic compounds by adsorption (structures II and III)

The adsorption of organic ionogenic compounds on the surface of a mineral carrier is undoubtedly the simplest method for synthesising the sorbents being considered. The earliest studies in this field (see for example Ref.71), however, revealed its main disadvantage, namely the low stability, due to the continuous elution of the deposited substance into the solution. This stimulated the development of methods for the covalent attachment of organic compounds to the surface.

Nevertheless, recent experience has shown that adsorption systems can be used successfully even in HPLC. The surface modifier is a compound which is firmly adsorbed on silica, for example tetraethylenepentamine,[72] or a compound which has a low solubility in the eluant, for example cetyltrimethylammonium bromide or n-hexadecylpyridinium chloride when working with aqueous eluants.[73] Silica with adsorbed tetraethylenepentamine has been used to separate carbohydrates and polyalcohols at pH 8–9; even under these conditions, it was necessary to add the modifier to the eluant to keep the column characteristics constant. Silica with adsorbed long-chain ammonium salts shows practically no change in its characteristics when used to separate mixtures of inorganic anions.[73]

An increase in the stability of adsorption-bonded systems can be achieved by using reversed-phase sorbents as the original carrier, for example silica specimens modified by octyl- or octadecylsilanes. The thin hydrophobic layer grafted to the surface ensures the strong retention of ionogenic substances containing long-chain alkyl groups: $C_nH_{2n+1}SO_3Na$,[74] $C_nH_{2n+1}OSO_3Na$,[74,75] $(C_nH_{2n+1})_4N^+Cl^-$,[74,75] and

$C_{16}H_{33}N(CH_3)_3^+Cl^-$.[76,77] This method is essentially the limiting case of ion-pair chromatography. The modified columns are made from organic materials. Aqueous solutions are mainly used as eluants in the chromatographic analysis. Under these conditions, high stability of the column operation is achieved; according to Ref.77, the exchange capacity remains unchanged during continuous operation for at least 80 d in the separation of mixtures of inorganic anions.

This method for obtaining sorbents is attractive chiefly because of the ease of variation of the nature and sorption characteristics of the ion exchangers based on the most readily available reversed-phase columns.

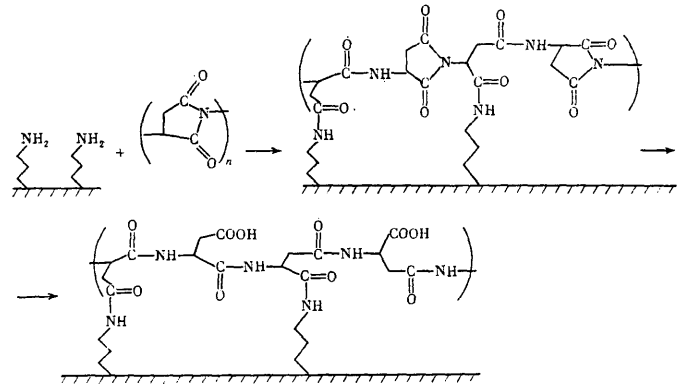
3. The attachment of polymers

The greatest variety of possible sorbent structures among the ion exchangers being considered is provided by mineral carriers with organic polymers attached to their surface. Initially, the interest in these materials was due to the possibility of their application as polymer fillers.[8,15,16,24,78–99] In recent years, these materials have been used increasingly as sorbents and catalyst carriers.[22,28,100–121]

The interest of research workers in materials of this class is due to the following potential advantages over mineral carriers with covalently attached monomeric organic compounds: 1) higher stability of action, resulting from the multi-point attachment of the polymeric modifier to the surface or from the more effective shielding of the surface; 2) the greater sorptive capacity, resulting from the increase in the proportion of the organic component; and 3) the simpler (in some cases) synthesis, which makes it possible to avoid the use of organosilicon modifiers.

Two main approaches are used in the production of these materials: modification of the surface by prepared polymers[22,100,104,112–121] and polymerisation of monomers on the surface.[24,28,41,78–99,101–103,105–111,122]

Modification by prepared polymers (structures IV–VI, IX, X). The simplest version of the modification is the adsorption of organic polymers on the surface of a mineral carrier to give so-called film or pellicular sorbents.[123] The best results are obtained using heterochain nitrogen-containing oligomers based on polyethyleneimine (PEI),[112–116] which are firmly adsorbed on the surface of hydroxyl-containing carriers. By changing the molecular mass of the oligomer used, it is possible to vary the thickness of the grafted layer over a wide range, beginning from the values characteristic of brush structures. For example, the use of branched PEI oligomers with a molecular mass of 600 gives layers with a thickness of 3–4 nm;[115] the best selectivity in the separation of oligonucleotides is shown by silica specimens with pore dimensions of 70–100 nm, modified by PEI with a molecular mass of 35 000.[121]



PEI attached by adsorption will obviously be transferred to the solution to some extent, particulary on treatment with acidic eluants. To increase the stability of action of these systems, Regnier and co-workers[112–115] proposed the cross-linking of the adsorbed oligomers using bifunctional and polyfunctional reagents: dibromoalkanes, epichlorohydrin, and cyanuryl chloride. The compounds most widely used for this purpose contain two or more epoxy-groups, which react with amines under mild conditions, and, when the epoxy-ring is opened, give additional alcohol groups which increase the hydrophilic nature of the sorbent. A similar approach was used in Ref.118, where adsorbed polyvinylpyrrolidone was cross-linked by the thermal decomposition of dicumyl peroxide or by using radiation.

When the adsorbed oligomers have been cross-linked, the particle of inorganic carrier is included in a "network" of organic polymer by so-called topological fixation; the components cannot be separated without complete breakdown of the sorbent. The sorbents with the greatest hydrolytic stability have been obtained by using titanium or aluminium oxides, or zirconated silica, as carrier: when these sorbents are kept at pH 14 for 24 h, only slight transfer of PEI to the solution is observed.[22]

Sorbents containing cross-linked PEI have the properties of weak anion exchangers, but they can easily be converted into strongly basic anion exchangers by quaternisation using methyl iodide[113] or into weakly acidic cation exchangers by reaction with halogenocarboxylic acids or with the anhydrides of dibasic carboxylic acids.[116,124]

To obtain film ion exchangers based on non-porous particles, the charged macro-particles are brought into contact with positively charged particles with colloidal dispersion. As a result of super-equivalent adsorption, the macro-particles acquire a charge opposite to the original charge. On these macro-particles it is possible in turn to deposit other micro-particles of opposite charge. Thus in Ref.104, particles of Amberlite XE-225 (a strongly basic polymeric anion exchanger) with dimensions of 100–500 nm were deposited from solution on glass particles with dimensions of 24–52 μm, followed by negatively charged particles of Ludox-AM with dimensions of 15 nm; these operations were repeated three times, to give an anion exchanger with a specific surface of 0.5 $m^2 g^{-1}$. Because of the low specific surface of these sorbents, their sorptive capacity is low and does not exceed $n \times 10$ μg-equiv g^{-1}, which is much lower than that of sorbents with a brush structure and, more particularly, the sorbents with adsorbed PEI described above.

To ensure stronger bonding of the oligomers to the carrier surface, in a number of cases the original carrier has been chemically modified using organosilicon compounds capable of forming covalent bonds with the functional groups of the oligomers.[116,119,120] Thus in Ref.116, PEI was attached using grafted carboxyl groups; in Ref.120, polyaspartic acid was attached to the surface of aminopropylsilica by the chemisorption and subsequent hydrolysis of polysuccinnimide.

Sorbents with an analogous structure are also obtained by modifying the carrier with polymers containing organosilicon anchor groups, for example polyethyleneimine containing $(CH_3O)_3Si(CH_2)_3$ groups[125] or a copolymer of 4-chloromethylstyrene and vinylmethyldichlorosilane.[117] The presence of active chlorobenzyl groups in the copolymer provides a method for synthesising a wide range of cation and anion exchangers. An advantage of this method of grafting is that the characteristics of the original polymer are usually well known.

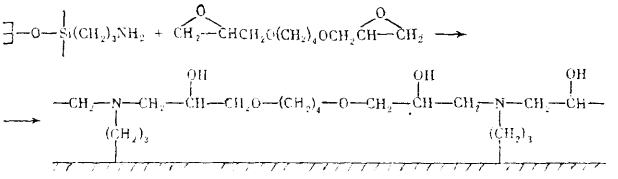
Polymerisation on the surface (structures IV, VII–IX, XI). The polymerisation of monomers on the surface of mineral materials is one of the most general methods of synthesising modified mineral carriers.[8,15,16] The simplest method involves polymerisation on the surface of non-modified carriers. Weakly acidic cation exchangers are

synthesised by polymerising acrylic acid[24,28,79,103,122] (in the polymerisation of methyl methacrylate[24,84,86,93] or acrylonitrile,[24] subsequent hydrolysis is necessary). Extensive synthetic possibilities are provided by the polymerisation of styrene;[100–103,122] sulphonation of the polymer layer on the surface gives sulphonic acid cation exchangers,[100–103, 122] and chloromethylation followed by amination gives strongly basic anion exchangers.[100,122] A promising monomer is chloromethylstyrene.[126–128] In some cases,[100–103,126–128] these vinyl monomers are copolymerised with divinylbenzene.

Various methods are used to initiate polymerisation: mechanochemical treatment,[80,81] ultraviolet irradiation,[90,129] and electrical discharge.[82] In most studies, polymerisation has been carried out using special initiators and using radiation. In the first case, the adsorption of the monomer on the carrier surface is accompanied by the adsorption of benzoyl peroxide,[24,100] t-butyl peroxide,[101] azobisisobutyronitrile,[28,127,128] or ammonium persulphate.[24] In the second case,[84–88,93] two methods are used: irradiation of the carrier with an adsorbed layer of monomer, or post-radiation grafting, where the carrier is subjected to the action of radiation and then treated with the monomer. The lifetime of the reaction centres on the surface may reach 20 d.[130]

All these cases give the homopolymer and a so-called non-extractable polymer, the proportion of which may reach 90–100%. For polymerisation under the influence of radical initiators or an electrical discharge, covalent bonds are not formed between the polymer and the carrier, and the modifying layer is held on the surface by adsorption forces or geometric factors. On mechanochemical treatment or the action of radiation or ultraviolet light on systems with adsorbed quinone,[90] radicals such as $\equiv Si-O^{\cdot}$,[15,16,80,90,93] which initiate polymerisation, may be formed on the carrier surface. In this case the polymer is joined to the surface by an $Si-O-C$ bond, which is not stable to hydrolysis and which is decomposed by the action of small quantities of moisture, so that it cannot be said that covalent bonds are formed between the polymer and the carrier surface.

An effective procedure which makes it possible to use milder polymerisation conditions in the surface layer and at the same time guarantees the formation of a strong carrier–polymer covalent bond involves the preliminary modification of the carrier by organosilicon compounds. The most widely used methods are those involving the attachment of vinyltrichlorosilane[91,93,105–109] and other vinyl derivatives[94,96] to the carrier surface. Treatment with γ-rays or radical initiators is then used to bring about the polymerisation of acrylic acid,[106,108,109] methyl methacrylate,[93,94] styrene,[94,96,105,107–109] or vinylpyridines[91] on the surface of the modified carrier. In a number of cases, cross-linking of the grafted polymer chains is brought about by carrying out the polymerisation in the presence of divinylbenzene.[105]



It is possible to attach to the surface not only vinyltrichlorosilane but also other organosilicon compounds capable of initiating radical polymerisation, in particular peroxides[23,92,97,131] and ozonides.[98] A method has also been described for attaching to the carrier surface compounds with the general formula $Cl_2(CH_3)Si(CH_2)_3X$, where $X = N(CH_3)_2$, $N(C_2H_5)_2$, and $OCOCCl_3$, with subsequent graft polymerisation of methyl methacrylate or styrene under the influence of visible light (λ = 400–500 nm) in the presence of manganese carbonyl,[95] fluorenone, or related organic compounds.[37]

A fundamental and as yet not fully resolved problem concerns the structure of the grafted layer in these materials. Analysis of data obtained by different authors indicates that only a small proportion of the silanol groups of the surface or grafted organosilicon compounds initiate the growth of a polymer chain. This leads to "islet" modification of the surface, and complete covering of the surface by the organic polymer requires a large quantity of the monomer, up to 3–6 effective monolayers (see for example Ref.84). In the initial stage of the polymerisation (at concentrations up to one third of an effective monolayer), linear macromolecules with a narrow molecular-mass distribution are formed; with increase in the degree of conversion there is an increase in the contribution of processes of chain transfer to the polymer, leading to branching of the macromolecules and marked broadening of the molecular-mass distribution.[85] This may lead to additional non-uniformity of the characteristics of the grafted layer.

The conformation of the grafted chains is determined by their chemical character, in particular their affinity for the surface hydroxyl groups of the carrier. Infrared spectroscopy has established that a large number of hydrogen bonds are formed between polymethyl methacrylate and an aerosil surface.[78,86] With a small quantity of deposited polymer, its molecules have a branched conformation, whereas at high concentrations they form a non-planar coil. Similar effects are observed in the polymerisation of vinylpyridines on an aerosil surface or of acrylic acid on an aminopropylaerosil.[79,88] The formation of hydrogen bonds between the functional groups of the polymer and the carrier leads to uniform covering of the surface and increases the strength of attachment of the polymer and the degree of shielding of the surface. It should be noted, however, that in systems with a strong adsorption interaction there is a sharp decrease in the rate of polymerisation.[79,88]

An increase in the strength of the bonding of the polymers to the carrier surface is achieved by copolymerising vinyl monomers with unsaturated organosilicon compounds containing reactive chorosilyl or ethoxysilyl groups, for example $(C_2H_5O)_3SiCH=CH_2$[99,105] and $(C_2H_5O)_2Si(CH_3)CH_2OCOC(CH_3)=CH_2$.[94] In Ref.99 it is stated that the grafted polymer obtained in this way cannot be separated from the carrier even by treating with HF; this is attributed to the many-point grafting of the polymer and the marked shielding of the carrier surface.

The last method of synthesis gives sorbents whose structures are identical to those of the specimens obtained by modifying the carrier surface with prepared polymers containing active organosilicon groups[117,125] (see above). A third method of obtaining sorbents of this kind involves the two-dimensional cross-linking of grafted monomeric organosilicon compounds. An example is provided by the cross-linking of grafted primary amines with diepoxides:[110]

After treatment in this way, the time of stable operation of the sorbent increases from several days to several months.

The data in the present section show that, on the average, mineral carriers modified by polymers have a higher stability to hydrolysis than sorbents with a brush structure. In a number of cases they can be synthesised without using organosilicon compounds. They are characterised by an increase in the exchange capacity to 2.5 mg-equiv g^{-1}. The capacity of ion exchangers based on organic polymers is generally much higher, but this difference is counterbalanced slightly by the large bulk density of the sorbents based on mineral carriers. Thus the exchange capacity of a sulphonic acid cation exchanger based on silica is 2.2 mg-equiv g^{-1}, which corresponds to 1 mg-equiv cm^{-3}; for Dowex 508 the corresponding quantities are 5 mg-equiv g^{-1} and 1.7 mg-equiv cm^{-3}.[108,109]

The disadvantages of the methods described, particularly those involving polymerisation on the surface, include the difficulty of controlling the course of the reaction and the unpredictable change in the structural characteristics of the sorbents; in many cases the specific surface decreases by a factor of 2.5–10, with almost the same decrease in the specific pore volume.[108,109] The mass-exchange characteristics of sorbents with thick polymeric modifier layers are close to those of organic ion exchangers, and are much inferior to those of sorbents with a brush structure; in the general case, this lowers the efficiency of chromatographic columns (see for example Ref.132). Nevertheless, the use of these sorbents is often justified even in HPLC, when the efficiency of separation is limited by another parameter of the process, for example the diffusion of the compounds being analysed in the chromatography of proteins.

4. Hydrolytic polycondensation of organosilcon compounds

The essential feature of the method being considered is the hydrolysis of trichloro- or trialkoxysilanes X_3SiR to give polysiloxanes. Since this gives a three-dimensional structure of $-Si-O-Si-O-$ bonds, these materials, despite the fact that they do not contain silicon dioxide, are in many respects analogous to modified silica specimens. If the hydrocarbon group R does not contain ionogenic functional groups, these are introduced into the prepared polysiloxane.

Ion exchangers are formed directly by the hydrolytic polycondensation of $Cl_3SiCH_2C_6H_4SO_3H$,[133] $Cl_3SiC_6H_4C_6H_4PCl_2$ (after oxidising the phosphonite group to phosphonate),[134], $Cl_3SiC_6H_4POCl_2$,[135] 1,1-dichloro-1-silalactones,[31,136] $Cl_3Si(CH_2)_nCOCl$ (n = 3,10),[31] $(C_2H_5O)_3Si(CH_2)_3NHCH_2CH_2NH_2$,[137] $[(C_2H_5O)_3Si(CH_2)_3]_2NCH_3$,[138] and $[(CH_3O)_3Si(CH_2)_3]_4N^+Cl^-$.[138] The exchange capacities of these sorbents are 2–6 mg-equiv g^{-1}. Convenient intermediate materials for synthesising ion exchangers are provided by the hydrolysis products of $X_3Si(CH_2)_nC_6H_5$ (X = Cl, C_2H_5O; n = 0–2),[139–142] Cl_3SiCH_2Cl,[143] $(C_2H_5O)_3SiCH_2SH$,[144] and $(CH_3O)_3Si(CH_2)_3SH$.[142]

Of all modified mineral carriers, ion exchangers based on polysiloxanes have the highest exchange capacity, only slightly lower than that of organic ion exchangers. This advantage, however, does not compensate the disadvantages associated with the fact that they do not contain a rigid silicon dioxide matrix. Polysiloxanes are less stable, and, like organic ion exchangers, undergo considerable swelling in various solvents, so that they are unsuitable for use in HPLC. The ionogenic groups of these ion exchangers differ considerably in their accessibility; the inner groups are inaccessible to large organic molecules, and this restricts the possibilities for the application of ion-exchange polysiloxanes in sorption and catalysis. Moreover, considerable difficulties are encountered in the preparation of polysiloxanes with required values of the specific surface, specific volume, and pore dimensions, whereas in other known methods of synthesis these parameters are easily varied by selecting an appropriate carrier.

The mechanical and mass-exchange characteristics of polysiloxanes can be improved by carrying out the simultaneous polycondensation of functional organosilicon compounds with tetraethoxysilane or polyethoxysiloxanes,[141,142,145,146] but the exchange capacity is lowered, and the synthesis is more complicated.

Hydrolytic polycondensation may provide a useful method for the synthesis of film ion exchangers.

III. Industrial ion exchangers based on modified mineral carriers

A number of firms in other countries now produce ion exchangers based on silica, chiefly for use in chromatography. The principal sorbents and the firms producing them are listed below (in most cases, in the sorbent names, the numbers denoting the particle size of the sorbent or the average pore diameter are omitted).

Sorbents for the HPLC of organic compounds

Weakly basic ion exchangers: Nucleosil NH_2, Nucleosil $N(CH_3)_2$, Polygosil NH_2, Polygosil $N(CH_3)_2$ (Macherey-Nagel, FRG–Switzerland); Zorbax NH_2 (Du Pont, USA); Bondapak NH_2 (Waters, USA); Aminopropyl-Daltosil 100, DEAE-Daltosil 100 (Serva, USA); DEAE 2SW Spherogel TSK-IEX (Beckman, USA); Lichrosphere 100 NH_2 (Merck, FRG); Vydac 601 SC (Separations Group, USA); Silasorb DEA (Lachema, Czechoslovakia).

Strongly basic anion exchangers. Nucleosil SB (Macherey-Nagel, FRG–Switzerland); Partisil 10 SAX (Whatman, UK); SAX Ultrasil (Beckman, USA); TEAB-Daltosil 100, TEAP-Si 100 (Serva, USA); Zorbax SAX, Zipax SAX (Du Pont, USA); Supelcosil LC-SAX (Supelco SA, Switzerland); Vydac 301 SC, Vydac 301 TPB (Separations Group, USA); Silasorb S (Lachema, Czechoslovakia).

Weakly acidic cation exchangers. Carboxymethyl-Daltosil 100, Carboxymethyl-Si60 (Serva, USA); CM 2SW Spherogel TSK-IEX (Beckman, USA).

Strongly acidic cation exchangers. Partisil SCX (Whatman, UK); Zorbax SCX, Zipax SCX (Du Pont, USA); Nucleosil SA (Macherey-Nagel, FRG–Switzerland); SCX Ultrasil (Beckman, USA); Vydac 401 SC, Vydac 401 TPB (Separations Group, USA); Supelcosil LC-SCX (Supelco SA, Switzerland); Sulfopropyl-Daltosil 100, Sulfopropyl-Si100 (Serva, USA).

Sorbents for the chromatography of biopolymers

Weakly basic anion exchangers: Ultropac TSK 545 DEAE (LKB, Sweden); SynChropak AX, SynChropak CATSEC, SynChroprep AX, SynChropak ASC (SynChrom, USA); Zetaprep DEAE (Molecular Separations Division, USA); Aminopropyl-Si100, DEAE-Si100 (Serva, USA); Nucleogen-DEAE (Macherey-Nagel, FRG–Switzerland); Spherogel TSK IEX 530 DEAE (Beckman, USA); TSK Gel IEX-545 DEAE SIL (Toyo Soda, Japan); Zorbax Bio-Series WAX-300 (Du Pont, USA); Shimadzu Shim-pack WAX1(2) (Shimadzu, Japan).

Strongly basic anion exchangers. SynChropak Q, SynChroprep Q, SynChropak QSC (SynChrom, USA); Zetaprep QAE (Molecular Separations Division, USA); Sep-Pak Accell QMA (Waters, USA); Zorbax Bio-Series SAX-300 (Du Pont, USA).

Weakly acidic cation exchangers. Ultropak TSK 535 CM (LKB, Sweden); SynChropak CM, SynChroprep CM, SynChropak CSC (SynChrom, USA); Zetaprep CM (Molecular Separations Division, USA); Carboxymethyl-Si300, Carboxypentyl-Si500 (Serva, USA); Sep-Pak Accell CM (Waters, USA); Spherogel TSK IEX 540 CM (Beckman, USA); Zorbax Bio-Series WCX-300 (Du Pont, USA); Shimadzu Shim-pack WCX-1 (Shimadzu, Japan).

Strongly acidic cation exchangers: Nucleosil SA Catecholamine (Macherey-Nagel, FRG–Switzerland); Zorbax Bio-Series SCX-300 (Du Pont, USA).

Sorbents for ion chromatography

Strongly basic anion exchangers: Partisil SAX (Whatman, UK); Vydac 302 SC (Separations Group, USA); Wescan Anion (Wescan Instruments, USA); Zipax SAX (Du Pont, USA); Supelcosil LC-IC (Supelco SA, Switzerland); Nucleosil Anion (Macherey-Nagel, FRG–Switzerland); R Sil An (Alltex Association, USA); TSK Gel IC-Anion SW (Toyo Soda, Japan).

Strongly acidic cation exchangers: Partisil SCX (Whatman, UK); Vydac CX (Separations Group, USA); Zipax SCX (Du Pont, USA).

Unfortunately, detailed information on the structures of most of these sorbents is not available either in the firms' literature or in the original papers; the methods of synthesis are not known, and in some cases it is not possible to say anything about the composition of the functional groups on the surface. It may be noted that the carrier most frequently employed is porous silica with an average pore diameter of 6–30 nm; sorbents for separating biopolymers have a large pore diameter, reaching 100 nm. In a number of cases (the sorbents Zipax, Vydac SC, Corasil, SynChropak ASC), the carriers are particles with a non-porous glass core and a porous external layer of silica with a thickness of about 1 μm.

Most of these sorbents consist of silica with chemically grafted monomeric organosilicon compounds. The weakly basic anion exchangers contain the groups $-NH_2$, $-N(CH_3)_2$, $-N(C_2H_5)_2$ (DEAE sorbents). The strongly basic anion exchangers contain different grafted tetra-alkylammonium salts. The weakly acid cation exchangers contain $-CH_2COOH$ groups (sorbents of the Carboxymethyl, CM series). In strongly acidic cation exchangers, attached aryl and alkyl sulphonic acids are used to equal extents. The synthesis of sorbents for the chromatography of biopolymers (in particular the sorbents of the DEAE and CM series) is often carried out with preliminary modification of the surface by a γ-glycidoxypropyltrialkoxysilane followed by the introduction of the required functional group.

Sorbents with polymers attached to the surface have appeared in recent years. Thus sorbents of the SynChropak series are obtained by modifying the surface with polyethyleneimine; the cation exchanger Zipax SCX contains a sulphonated layer of a fluorocarbon polymer on its surface.

The range of mineral carriers used is being extended. In particular, sorbents of the Zorbax Bio-Series are based on zirconated silica gel.

In the near future there should be an increase in the proportion of sorbents with deposited polymers and also sorbents based on mineral carriers with an increased stability to hydrolysis in alkaline media.

IV. Applications of ion exchangers based on modified mineral carriers

1. The concentration and separation of inorganic anions

One of the principal fields of application of ion exchangers based on organic polymers is the extraction from solution and separation of inorganic ions (see for example Ref.147). In recent years, however, the sorption of transition metal ions has been carried out increasingly using complexing sorbents,[148] which ensure high stability and selectivity of the binding of the metal ions. On this basis, research workers studying the synthesis of sorbents for metal ions immediately began to graft complex-forming groups on to the surface of silica, so that the number of publications on the applications of ion exchangers based on silica on this field is comparatively small (p.321 of Ref.9, and Refs.53–56, 64, and 149–165).

The most interesting results have been obtained on the sorption of noble metal ions. In strongly acidic media (2–4 M HCl), the quantitative sorption of rhodium(III) and iridium(IV) by aminosilica is observed,[157,162] and this makes it possible to separate these elements from other noble metals and a 10^4-fold excess of non-ferrous metals and iron(III). Anion exchangers based on silica can be used to separate gold from a large excess of non-ferrous metals[64,159] and silver from platinum and palladium.[153] Palladium(II), platinum(IV), osmium(VI, VIII), and ruthenium(IV) are sorbed by anion exchangers based on silica in the weakly acidic range;[157,160–162,164,165] the mechanism of sorption has not yet been established.

Sulphonic acid[151,154,155] and phosphonic acid[53–56] cation exchangers based on silica show an increased affinity for multiply-charged metal ions, in particular aluminium(III), scandium(III), zirconium(IV), and thorium(IV), so that these metals can be separated selectively from materials with complex compositions, for example alloy steels.

Silica with grafted ethylenediamine has proved effective for the anion-exchange binding of $Cr_2O_7^{2-}$, MnO_4^-, WO_4^{2-}, MoO_4^{2-}, AsO_4^{3-}, SeO_4^{2-}, and uranium(VI) as carbonate complexes (p.321 of Ref.9, and Refs.149, 150, and 152), so that it can be used to extract these anions from sea water.

In all the works cited it is pointed out that the main advantage of silica sorbents is the high rate of attainment of sorption equilibrium which makes it possible to work at high rates of flow of the solution being analysed through the column containing the sorbent (up to 100 ml min^{-1} cm^{-2}); this is particularly important in the extraction of ions from large volumes of dilute solutions. In most cases, quantitative desorption of the ions from the surface is achieved using small volumes of eluant, so that the concentration coefficient in a single "sorption–desorption" cycle is 10^2–10^3, which is appreciably greater than that for the organic-polymer analogues. The higher selectivity of sorbents based on silica is also noteworthy. The advantages of modified silicas include the possibility of determining sorbed ions on the surface by a wide range of physical methods: X-ray fluorescence,[9,37,38,149,150–152,156,157,162] luminescence,[151,158] and spectral methods.[151,166] This makes it possible to lower the detection limits of elements and to reduce the time taken for analysis.

2. High-pressure in chromatography

For a long time, high-performance liquid chromatogray did not find application in inorganic analysis, and the few published papers dealt chiefly with the separation of complexes of metals with organic ligands using reversed-phase methods (see the published reviews[167,168]). A powerful stimulus to work in this field was provided by the classical study of Small, Stevens, and Bauman,[169] who proposed the use of ion-exchange stationary phases combined with a conductometric detector. Subsequent studies (see the published monographs[170,171] and review[172]) fundamentaly altered existing views on many traditionaly difficult problems in inorganic analysis. Thus when ion chromatography is used, the time taken to analyse mixtures of the anions Cl^-, Br^-, I^-, NO_2^-, NO_3^-, and SO_4^{2-} and mixtures of the cations Li^+, Na^+, K^+, Rb^+, and Cs^+ or all the lanthanide elements at concentrations of 0.1–1 μg ml^{-1} is 5–20 min.

The most popular materials used in ion chromatogray are strongly basic anion exchangers (for the separation of anions) and sulphonic acid cation exchangers (for separating cations); the structure and

characteristics of the sorbents are varied over a wide range, depending on the eluant and the detection system.

When a conductometric detector is used, the eluant should have a low conductivity; the low concentration of the eluant makes it necessary to use specially synthesised sorbents with a low capacity (0.01–0.1 mmol g^{-1}), in which the ion exchange groups are concentrated chiefly on the outer surface of the granule.[170] In the analysis of anions by the so-called two-column version of ion chromatography with conductometric detection, weakly alkaline carbonate–bicarbonate solutions are used as eluants; under these conditions, silica sorbents are unstable, and it is necessary to use ion exchangers based on zirconated silica specimens or organic polymers.

When other methods of detection are used, for example spectrophotometric,[73–75,77,173–177] refractometric,[178–180] potentiometric (at a copper electrode),[181] emission (using an inductively bound plasma),[182] and atomic absorption[183] methods, the stability and capacity requirements to be satisfied by the sorbents are not so severe, so that it is possible to use the same ion exchangers as in the HPLC of organic compounds. In the ion chromatography of ions, extensive use is made of dynamically modified sorbents obtained by the adsorption of long-chain quaternary ammonium salts on silica[73] or reversed-phase sorbents.[74,75,77,173,174,184,185] An attractive feature is the possibility of easily varying the sorptive capacity of the ion exchangers, and the use of aqueous eluants ensures the high stability of these phases modified by adsorption.

The problems of the ion-chromatographic analysis of mixtures of alkali metal cations and various mixtures of the anions of inorganic acids have now been fully solved. Specific examples of the use of ion exchangers based on silica for these purposes can be found in the literature of the firms producing these materials, and in published monographs[170,171] and original papers.[73–75,77,132,173–180,184]

The efforts of research workers are now concentrated on the problems of analysing the alkaline earth and transition metals.[181,183,186–196] A number of complexing sorbents have been proposed for this purpose, in particular silica specimens with grafted 8-quinolinol,[195,196] crown ethers,[193] and related compounds,[194] but data in other papers indicate that the use of traditional cation exchangers makes it possible to achieve equal selectivity and efficiency of separation. The selectivity and retention are controlled by adding to the eluant complexing reagents such as hydroxyisobutyric,[190,191] citric,[181,189] and tartaric acids,[181,187,188] and ethylenediamine.[181] The ions are detected spectrophotometrically; for this purpose they are converted at the outlet from the analytical column into complexes with highly sensitive reagents such as PAR[183,187,188,191] or Arzenazo I.[190] It is possible in principle to use eluants to which the photometric reagent, for example Arsenazo III,[186] has been added beforehand; in this case the ion-exchange separation of the complexes of the metal ions with this reagent takes place. An interesting example is the use of EDTA solution as eluant; the metal ions being determined are converted into negatively charged complexes with EDTA, which are separated on a strongly basic anion exchanger followed by conductometric or spectrophotometric detection; an important feature is that the accompanying anions can be determined simultaneously.[192]

3. The chromatography of organic compounds

In the high-performance liquid chromatography of organic compounds, sorbents based on silica with grafted monomeric organosilicon compounds are mainly used. The most widely used substrates are organc acids, amines, and aminoacids. The dependence of the retention of the compounds being separated on the nature of the grafted ion-exchange group, the structure of the compounds being separated, and the composition of the eluant has been studied in detail. Thus the order of the elution of carboxylic acids coincides with the order of increase in their acidic dissociation constants.[108,197,198] The dependence of the retention of organic acids by a weakly basic anion exchanger on the acidity of the eluant is given by a curve with a maximum;[197] the retention on the ion exchangers is inversely proportional to the ionic strength of the eluant.[46,199]

The most extensive use of the HPLC of ionogenic organic compounds is in medicine and for the control of environmental pollution. A large number of studies[46,200–204] have been devoted to the determination of catecholamines—dopamine, noradrenalin, adrenalin, and dihydroxyphenylalanine—using a strongly acidic cation exchanger. Considerable attention is being paid to the determination, in blood and other biological materials, of various medicines and drugs—caffeine, aspirin,[45] morphine, cocaine, quinine,[199] codeine, heroin,[205] nicotine,[46] and penicillamine.[206] Data have been published on the use of ion exchangers based on silica to separate aminoacids,[204,207] carboxylic acids,[45,108,197,198,202,208–211] alkyl sulphonates,[212] aliphatic and aromatic amines,[202,213] pyridinium aldoximes,[214] and other pyridine derivatives.[46] In recent years, organic acids and other compounds have often been determined by ion chromatography with conductometric detection.[208,209,211,212]

An interesting feature is the use of strongly basic and weakly basic anion exchangers based on silica in the exclusion chromatography of cationic polymers, for example polyethyleneimines and polyvinylpyridines.[110,215,216] The use of fixed groups with the same charge on the carrier surface completely suppresses the desorption of the polymers.

4. The chromatography of biopolymers

Judging from the number of publications, the main field of application of ion exchangers based on mineral carriers is the chromatography of biopolymers. This is not surprising, since the role of biotechnology is steadily increasing, and the only acceptable method for analysing, separating, and purifying the complex mixtures in these processes is liquid chromatography, in particular ion-exchange chromatography, which is the most universal method for compounds of this class. Previously, the analysis and separation of biopolymers was carried out almost exclusively using sorbents based on polymers and soft gels, which show appreciable non-specific sorption. The high degree of swelling and low mechanical strength of wide-pore sorbents based on organic matrices, however, made them unsuitable for HPLC, so that attention was transferred to mineral sorbents. An advantage of these sorbents is that they are unaffected by biological action and withstand various forms of sterilisation.

Various aspects of the application of ion exchangers based on silica in the chromatography of biopolymers have been described in detail in various monographs[6,7,11] and reviews.[12,217–220] In the present review, therefore, only some of the most important features will be examined, and references will be given to various specific applications.

One of the basic requirements to be satisfied by sorbents for the chromatography of biopolymers is that the pore size of the sorbent should correspond to the dimensions of the molecules of the compounds being separated. Here it is necessary to take account of the fact that increase in the pore diameter of the sorbent leads to a decrease in its surface area and hence in the sorptive capacity and efficiency of the sorbent. A large number of studies have therefore been devoted to the optimisation of the porous structure of the sorbent to solve various specific problems (see for example Refs.52, 115, 121, 221, and 222).

A characteristic feature of proteins is their strong non-specific interaction with the surface of silica, which leads to their irreversible sorption and often to the loss of the biological activity of the compounds being separated.[223] It is therefore necessary to effectively shield the silica surface from reaction with proteins; this is achieved by modifying the surface beforehand by dipolar groups[27,52,70,224] or polyethyleneimine.[112–116,121,225] Moreover, protein molecules are capable of many-point ion-exchange bonding to the sorbent, so that to decrease the retention, sorbents with a low surface concentration of ion-exchange groups are used.[34,65–68,70,112]

The ion-exchange separation of biopolymers is most frequently carried out in a weakly alkaline medium, that is in the range of hydrolytic instability of silica sorbents. The chromatography of biopolymers is therefore often carried out using sorbents with adsorbed or grafted polymers[12,112–116,119–121,124,225–229] or sorbents based on zirconated silica specimens.[22,27,230]

The ion-exchange retention of proteins, viruses, and other biological adsorbates depends on many parameters, in particular the composition, acidity, and ionic strength of the eluant. Detailed experimental studies of these topics have been described.[226,227,230–233] The selection of the best conditions is assisted by data on the adsorption isotherms for proteins on ion exchangers[234] and the results of theoretical studies.[235,236] Thus a correlation has been established[235] between the retention of a protein and the number of charges involved in the adsorption–desorption process.

Ion exchangers based on silica are used in the chromatographic analysis of mixtures of basic proteins, α-chymotrypsin, cytochrome C, and lysozyme,[27,70,116,124,229,231,237] nucleosides,[45] nucleoside phosphates,[34,238] nucleic bases,[239] oligonucleotides,[66,67,69,113,221, 224,225,240–243] ribonucleic acid,[113,221,244] and DNA restriction fragments,[67,68,221,245–247] and to separate growth factors.[233,248,249]

Ion exchangers based on minerals are being more widely used for the preparative separation of biological compounds,[219,220,250,251] in particular interferon,[252] and also for their purification by chromatofocussing.[228,253]

5. Catalysis

Ion exchangers based on organic polymers, primarily sulphonic acid cation exchangers, are widely used in catalysis[147,254] in hydrolysis, hydration, esterification, alkylation, condensation, etc. The range of reactions catalysed is determined in practice only by the chemical nature of the ionogenic group, so that the replacement of an organic polymer by an inorganic matrix should not influence the catalytic properties. At the same time, it should be expected that ion exchangers based on mineral carriers will make it possible to carry out processes requiring a higher temperature or accompanied by strong exothermic effects leading to local superheating with consequent degradation of the catalyst.

The mesoporous structure of the carrier ensures that all the reaction centres are accessible, so that the specific activity (calculated for one centre) of ion exchangers based on mineral carriers should be much greater than that of organic polymer resins. In spite of the greater exchange capacity of organic ion exchangers, their activity calculated for unit mass or unit volume may be lower. This effect should be greatest for reactions involving large organic molecules.

The limit of the thermal stability of sulphonic acid cation exchangers based on silica and obtained by polycondensation is more than 100 K higher than that of the organic-polymer analogue Amberlite 15.[142] In the hydrothermal treatment of sulphonic acid cation exchangers, the greatest stability is shown by catalysts in which the silicon atom is joined to an aliphatic carbon atom.

Sulphonic acid cation exchangers based on silica have been used to catalyse the alkylation of alcohols by isobutylene to obtain alkyl t-butyl ethers (in particular methyl t-butyl ether)[255,256] and of phenol by dec-1-ene,[257] the dehydration of alcohols,[142] esterification,[142] and the gas-phase nitration of benzene by nitrogen dioxide.[142] Comparison of the activity of sulphonic acid cation exchangers based on silica with that of analogous cation exchangers based on organic polymers (KU-2, Amberlite 15, Lewatit SPC 108/H) showed that the former in many cases have a higher specific activity, calculated both for one centre and for unit mass or volume, in spite of the lower concentration of sulphonic acid groups.

Strongly basic silica anion exchangers with grafted optically active aminoalcohols and alkaloids are used to catalyse Michael asymmetric addition.[258,259] It was unexpectedly found that by varying the length of the chain joining the active centre to the carrier, and the accessibility of the silanol groups of the surface, it is possible to reverse the enantio-selectivity of the addition. This indicates that the carrier plays an active part in the formation of the intermediate substrate–catalyst complex.

A second method of using ion exchangers based on silica in catalysis is by the attachment of transition metal complexes. The heterogeneous metal-complex catalysts obtained in this way combine the high activity and selectivity of homogeneous metal-complex catalysts with the technology of traditional heterogeneous catalysts.[4,5] The metal complexes are usually attached by the coordination of ligands grafted to the carrier, but in a number of cases ion-exchange attachment is preferred. Examples include the attachment of chloro-complexes of platinum(II) and platinum(IV) to anion exchangers with grafted quaternary ammonium and phosphonium groups to obtain catalysts for the industrially important reaction of hydrosilylation of unsaturated compounds.[33,62] The ion-exchange attachment of platinum gives more stable catalysts than attachment by coordination (bonding through the phosphine group), and the catalyst can be used repeatedly without loss of activity. The selectivity of the formation of the β-isomer in the hydrosilylation reaches 100%. Unlike catalysts with a polymeric matrix, the silica carrier ensures the activity of all the platinum atoms.

Modified silica specimens can also be used to catalyse inter-phase transfer, as shown for the alkylation of phenol,[35] the synthesis of esters,[260] and halide exchange.[61,261] The catalytic properties of strongly basic phosphonium ion exchangers based on silica differ considerably from those of their polymer-based analogues and hexadecyltributylphosphonium bromide.[35,261]

Van der Waals radii and their application in chemistry

Yu V Zefirov, P M Zorkii
Lomonosov Moscow State University

ABSTRACT. Published systems of van der Waals radii (VR) have been examined and compared. The many ways of using VR in various branches of chemistry, in particular in crystal chemistry, stereochemistry, and X-ray diffraction (primarily to describe and interpret molecular conformations and crystal structures and to determine new structures) have been analysed. Particular attention has been paid to the detection of specific non-valence interactions (both inter- and intramolecular). Various structural-biological problems, in particular the production of 'incorrect' pairs of bases in DNA and the use of VR to explain the physicochemical properties of substances, have been examined. The properties of crystals determined by the effective volume, dimensions, and shape of the molecules, and the characteristic features of the structures of inclusion compounds, clathrates, and organic conductors, have been discussed. The use of VR to investigate the mechanism and predict the possibility of various chemical reactions has been described. The bibliography contains 173 references.

I. Introduction

Quantum-mechanical ideas play an exceptionally important role in present-day chemistry, yet the classical theory of the structure of molecules and classical stereochemistry, whose foundations were laid by Butlerov, Kekulé, Van't Hoff, Le Bel, and Werner, today still remain the basis of organic and coordination chemistry. In recent years they have been supplemented significantly by the quantitative geometric characteristics of molecular systems, based mainly on empirical generalisations of the results of studies by X-ray diffraction and other physical methods.

One such generalisation is the system of covalent radii, which makes it possible to estimate the lengths of valence bonds. However, as a consequence of the variety of valence states and the significant deviations from additivity, the use of covalent radii has been extremely limited. For practical purposes, tables of 'standard' bond lengths,[1] which together with 'standard' values of the valence angles make it possible to construct in a first approximation a rod-and-sphere model of a molecule, are more useful. Even these concepts are inadequate, however, since they do not make it possible to take account of non-valence intramolecular interactions and cannot be used to analyse the packing of molecules.

The need for a comprehensive discussion of the geometry of molecules and their packing made it necessary to develop the concept of van der Waals radii (VR), which is now widely used in various branches of chemistry. It might seem that with the present availability of such effective means of taking account of non-valence interactions as atom–atom potentials,[2,3] it would be possible to carry out a more rigorous and accurate quantitative analysis of the geometry of molecular systems. The universal nature, simplicity, and clarity of the VR concept, however, make it appropriate for use in preliminary qualitative estimates, and often for the final solution of many problems of practical importance.

II. Systems of van der Waals radii and the dispersion of intermolecular contacts

The first attempts to relate the distances between the atoms of neighbouring molecules in crystals to the corresponding radii of the atoms (or atomic groups)[4–6] included the first representations of large molecules as overlapping van der Waals spheres and of crystal structures as close-packed molecules in contact. Pauling[7] gave the first table of VR, consisting of the rounded values of the ionic radii. It was Kitaigorodskii,[8] however, who fully recognised the value of this approach for chemistry and molecular physics and who laid the foundations of the theory of the close-packing of molecules.

Table 1. Van der Waals atomic radii (Å) of the elements of organic compounds.

Element	Pauling, 1939 (Ref.7)	Kitaigorodskii, 1955 (Ref.8)	Kitaigorodskii, 1971 (Ref.9)	Bondi, 1964 (Ref.16)***	Zefirov and Zorkii, 1974 (Ref.11)
C	1.85*	1.72**	1.80	1.70	1.71
H	1.2	1.17	1.17	1.20	1.16
O	1.40	1.36	1.52	1.52	1.29
N	1.5	1.57	1.58	1.55	1.50
Cl	1.80	1.78	—	1.75	1.90
S	1.85	2.02	—	1.80	1.84 [15]

* Half the thickness of an aromatic molecule (in the third edition of his book,[7] Pauling changed this quantity to 1.70 Å, leaving the other quantities unchanged).

** The radius of the carbon atom in aromatic molecules; the radius of aliphatic carbon is given as 1.80 Å (in his next publication,[9] Kitaigorodskii adopted the universal value 1.80 Å).

*** Radii for atoms forming only single bonds (for aliphatic compounds in the case of hydrogen).

The VR values proposed by Kitaigorodskii[8] were extremely close to those of Pauling[7] (Table 1). Later Kitaigorodskii[9] modified his table slightly (in the present authors' opinion making it less satisfactory). A common disadvantage of these VR systems was that they were constructed from extremely limited structural data (sometimes the value of a VR was established from only one structure). Although the proposed VR values in many cases were close to the best values, the VR are in principle essentially statistical quantities, and should be determined by averaging over a large number of structures.

The starting point for the construction of a system of VR is essentially the basic postulate of the theory of the close-packing of molecules, according to which the molecules, bounded by the outer surface of intersecting van der Waals atomic spheres, touch one another in the crystal, that is they do not penetrate one another and are not suspended in a cavity. The problem is to select suitable VR values. Kitaigorodskii[8] showed that a satisfactory solution to this problem exists.

The quantities $\Delta r_{ij} = r_{ij} - (R_i + R_j)$, where R_i and R_j are the van der Waals radii, and i and j are the indices of atoms belonging to neighbouring molecules, will be used. If the VR are known, it is possible, for each pair of molecules, to find the smallest value of Δr_{ij}, that is $(\Delta r_{ij})_{\min}$. This postulate implies that the quantity $(\Delta r_{ij})_{\min}$ is never negative and is equal to zero for a certain number of molecule–molecule contacts, whose existence is sufficient to ensure a three-dimensional system of contacts (significant contacts) in the crystal.

In fact, the accuracy of this postulate is extremely low (the deviations exceed the uncertainty of the X-ray diffraction data by factors of 10–100). To make it more realistic, it is better to take for the significant contacts not the equality $\Delta r_{\min} = 0$ but the inequality $|\Delta r_{\min}| < \delta$, assuming that $\Delta r_{\min}$ may also be negative (that is that overlap of the van der Waals spheres is possible), but that the quantity δ is fairly small. Kitaigorodskii[8] assumed that the postulate applies if it is assumed that $\delta = 0.05 r_{ij}$. However, firstly some deviations are still observed even in this case, and, secondly, the objectively justified selection of a specific value of δ guaranteeing a correct description of a wide range of molecular packing is apparently in general impossible. A more fundamental analysis makes it necessary to adopt a statistical approach to VR with allowance for the dispersion of intermolecular contacts.

The dependence of the energy of interaction φ of two free atoms A and B on the distance r between them is given by a potential curve (Fig. 1*a*) with a minimum at the equilibrium distance r_0. If however the atoms A and B are in molecules, the 'contact' distance r_{AB} between them is less than r_0. This can be demonstrated by the hypothetical example shown in Fig. 1*b*. For simplicity, it is assumed that the atoms in the triatomic molecules being considered are identical; it will be assumed that the molecules can approach one another only by translation along a certain axis. If the energy of interaction of the molecules is regarded as the sum of the atom–atom potentials $\sum_{ij}\varphi_{ij}$, it follows that in the equilibrium position of the molecules, $r_{AB} < r_0$, since in the interaction of atoms which are not in direct contact, attraction predominates over repulsion, and with increase in the size of the molecules (Fig. 1*c*), the difference $r_0 - r_{AB}$ should increase. This difference naturally also depends on the orientation of the molecules.

Thus strictly speaking, the VR of an atom is in general not a physical constant. As a result of the rapid increase in the energy φ with decrease in r_{AB}, however, this distance rapidly reaches a quasi-limiting value. This in fact justifies the existence of tabulated values of R. It may be assumed, however, that shorter intermolecular contacts should be observed for large molecules.

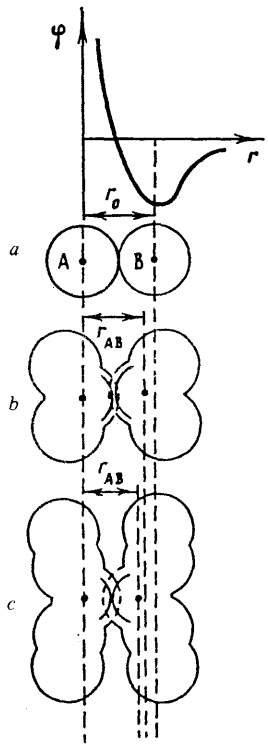

Figure 1. Dependence of the length of an atom–atom van der Waals contact on the composition and geometry of the molecule: *a*, interaction of free atoms A and B; *b*, interaction of atoms A and B in triatomic molecules; *c*, the same for penta-atomic molecules.

In fact, this tendency is masked by the individual characteristic features of the composition, shape, and packing of the molecules. The picture is much more complicated when the arrangement of not two but several molecules is considered. The tendency to adopt a packing ensuring the lowest energy of the crystal structure as a whole may lead to the appearance of local more closely packed and less closely packed regions, whose arrangement in space is specific for each specific crystal. The interatomic distances corresponding to the significant contacts of a given type A...B may differ considerably in different molecular crystals, but should be distributed within a certain range. For a specific structure, the VR give only the most probable (*a priori*) values of the intermolecular contacts.

Another important feature complicating the analysis of intermolecular contacts using VR is that the postulate formulated above assumes that the VR are additive, that is it is based on a combination rule according to which $\bar{r}_{AB} = (\bar{r}_{AB} + \bar{r}_{BB})/2 = R_A + R_B$, where $\bar{r}$ is the average length of the significant contact. Although at first sight this rule appears obvious, in fact it does not follow from any more general considerations. Moreover, the presence of effective charges on the atoms indicates that there will be deviations from additivity.

Good and Hope[10] examined possible combination rules for equilibrium distances, and gave preference to the equation $r_0(AB) = \sqrt{r_0(AA) \cdot r_0(BB)}$. When applied to intermolecular contacts, this corresponds to the expression $\bar{r}_{AB} = 2\sqrt{R_A R_B}$, which shows better agreement with experiment than the additivity usually assumed, but this is revealed only by a statistical analysis.[11]

Mean-statistical values of the VR of the elements of organic compounds were found[11] by treatment of X-ray diffraction data for 75 organic crystal structures without intermolecular hydrogen bonds. For each of these structures, significant contacts ensuring the existence of a three-dimensional framework of contacts were selected. The minimum number of such contacts is 4 when the molecules are in general positions, and 6 when they are at a centre of inversion. Even in the selection of the significant contacts it is necessary to specify some VR system. In a first approximation, the radii of Kitaigorodskii[8] were taken (except for the Cl atom, for which the value 1.86 Å [12] was used). Since the final (refined) VR values given in Table 1 were found to be fairly close to the original values, the significant contacts on the whole were apparently selected correctly.

Table 2, taken from the paper by Zefirov and Zorkii,[11] gives the values of $\bar{r}_{ij}$ for significant contacts of different types. The mean-statistical VR were selected to give best agreement between $\bar{r}_{ij}$ and $2\sqrt{R_i R_j}$; as already noted and as can be seen from Table 2, this is more effective than using the $R_i + R_j$ values. This last feature can apparently be interpreted as follows. If the atoms i and j are atoms of the same kind, then $R_i = R_j$ and $R_i + R_j = 2\sqrt{R_i R_j}$; if however they are atoms of different kinds, then $R_i + R_j > 2\sqrt{R_i R_j}$, that is according to statistical data when these atoms are in contact there is a tendency for the van der Waals spheres to overlap slightly. Since atoms of different kinds often have effective charges of opposite sign, their approach may be due to electrostatic attraction.

Table 2. Interatomic distances in the 'significant' intermolecular contacts, and comparison with the van der Waals radii.

Contact	$R_i + R_j$			$2\sqrt{R_i R_j}$	$\bar{r}_{ij}$	r_{ij} (min)	r_{ij} (max)	n *
	(Ref.8)	(Ref.9)	(Ref.11)	(Ref.11)				
C...C	3.44	3.60	3.42	3.42	3.41	3.32	3.53	31
H...H	2.34	2.34	2.31	2.31	2.31	2.04	2.58	58
C...H	2.89	2.97	2.87	2.81	2.81	2.57	3.12	160

N...H	2.74	2.75	2.66	2.63	2.64	2.53	2.84	51
Cl...H	2.95	—	3.06	2.96	2.96	2.88	3.03	26

* n is the number of contacts over which the averaging was carried out.

The similarity in the values of $\bar{r}_{ij}$ and $2\sqrt{R_i R_j}$ makes it possible to base the determination and application of VR on the condition $|(r_{ij} - 2\sqrt{R_i R_j})_{min}| \leqslant \delta$, where δ is sufficiently small. Bound by tradition, however, research workers more frequently use the classical and more obvious relationship $|r_{ij} - (R_i + R_j)| \leqslant \delta$, even when the radii proposed by Zefirov and Zorkii[11] are used. Strictly speaking, this is incorrect, but since the difference between $2\sqrt{R_i R_j}$ and $R_i + R_j$ is usually small, its does not lead to significant errors, and in the present review, in some cases, the authors of the works cited will be followed, and the intermolecular (or non-valence intramolecular) contacts will be compared with the sum of the VR, without this being specially pointed out.

For a correct understanding of the physical significance of the comparison of r_{ij} with $2\sqrt{R_i R_j}$ or with $R_i + R_j$, it is important to characterise the distribution of the values of r_{ij} corresponding to significant contacts of a definite type (that is to contacts between atoms of a definite type). For this purpose it is convenient to use the observed limiting values of r_{ij}(min) and r_{ij}(max), given in Table 2, and also the values of $\Delta_1 = \bar{r}_{ij} - r_{ij}$(min) and $\Delta_2 = r_{ij}$(max) $- \bar{r}_{ij}$. The values of Δ usually do not exceed 0.3 Å, or 0.15 Å for contacts not including H atoms. The values of $2\sqrt{R_i R_j}$ 'centre' fairly satisfactorily the range between r_{ij}(min) and r_{ij}(max), that is the distribution is close to normal. The values of $R_i + R_j$ for atoms of different kinds, however, are usually displaced considerably towards the upper limit.

The most familiar and most frequently used systems of VR are compared in Table 1.† As noted above, the most important VR obtained by Zefirov and Zorkii[11] are extremely close to those given by Kitaigorodskii,[8] except for the VR of the S and Cl atoms (in the last case the discrepancy is due to the fact that Kitaigorodskii[8] did not take account of the specific nature of the Cl...Cl contacts; see section III below). Subsequently, however, a much larger value was adopted[9] for the O atom, coinciding with that recommended by Bondi.[16] Bondi[16] used a statistical approach, but with extremely few data, and the final results were distorted by a number of significant errors.

Thus according to the original postulate of the theory of close-packing, significant contacts should be used to determine VR. This obvious feature was overlooked by Kitaigorodskii[9] and Bondi,[16] so that the VR of the O atom was too high. Thus when using Bolton's data[17] to examine the shortest interatomic distances between two neighbouring molecules of chloranil $C_6O_2Cl_4$, Bondi[16] used the 'contacts' O...O 3.26 Å and O...C 3.06 Å, without noticing that there is also an O...C distance of 2.85 Å (corresponding to a significant contact), which cannot be reconciled with the adopted value $R_0 = 1.52$ Å. A similar error was made by Kitaigorodskii[9] in the examination of the structure of alloxan $C_6H_2O_4$: he took as 'contacts' the O...O distances 2.94, 3.05, and 3.07 Å, which gave the average value $R_0 = 1.51$ Å, but the diagram given shows that this structure contains the significant contacts O...C 2.79 Å and O...H 2.38 Å and 2.47 Å, indicating that this VR value leads to unacceptable overlap of the van der Waals spheres.

A completely unreasonable statistical procedure, called 'revision of van der Waals atomic radii', was recently used by Nyburg and Faerman,[18] who determined VR using the Cambridge Structural Data Bank and determined all the shortest distances between atoms of the same kind in neighbouring molecules. The fact that many of them did not correspond to atom 'contacts' was completely ignored. A rational approach to the problem being discussed requires a correct analysis of the packing of the molecules in each of the structures being considered.

It is also important to emphasise the following significant feature. Contacts between atoms of the same kind are most convenient for determining VR. It is these contacts, however, which often show specific properties, making it impossible to obtain at this level a system of universal VR showing additivity (or satisfying the rule

† The mean-statistical VR of the F, Br, and I atoms[13,14] can be added to the data in Table 1.

$\bar{r}_{ij}$ (significant) $\simeq 2\sqrt{R_iR_j}$). Thus oxygen atoms, which (together with fluorine) have the highest electronegativity, usually carry an appreciable effective negative charge. It is for this reason, and also because of their relatively small size, that O atoms rarely form significant contacts with one another. An exception is provided by compounds rich in oxygen (for example containing a large number of nitro-groups). Even if a significant contact O...O is formed, however, it will generally be longer than twice the universal VR, because of the strong electrostatic repulsion. Special account can and must be taken of features of this kind (in particular, a special oxygen VR can be introduced just for O...O contacts), but the tabulated value of R_0, suitable for analysing ordinary contacts such as O...C, O...N, etc., obviously should not be derived from O...O distances.

For F...F contacts, in certain cases, another situation arises. Zefirov and Porai-Koshits[13] obtained the VR of fluorine by examining the significant contacts F...F in the crystals of compounds with the general formulae $(MF_5)_4$ and EF_6. This was possible, because in the molecules of these compounds the high negative charge on the F atoms is compensated by the 5 or 6 times larger positive charge on the M or E atoms, but in organofluorine compounds, the average F...F distances should be longer (greater than $2R_F$).

The contacts between other halogen atoms of the same kind (Γ...Γ) show another characteristic feature: here, a stronger exchange interaction is often superimposed on the purely van der Waals interaction. Contacts involving these interactions, described as specific interactions (see section III), are naturally unsuitable for determining VR. If this feature is not taken into account the VR obtained for the halogens are too low (as for example in data given by Kiraigorodskii[8] and Bondi[16]). Γ...Γ contacts can still be used to find the VR of halogens, however, if contacts with specific interactions are excluded. Zefirov and Porai-Koshits[14] determined the angular geometric characteristics corresponding to these contacts. This made it possible to exclude them from the set of distances examined and to obtain for the VR of the Cl, Br, and I atoms the values 1.90, 1.97, and 2.14 Å respectively. The value of R_{Cl} obtained by Zefirov and Porai-Koshits[14] coincided with that previously obtained by Zefirov and Zorkii[11] from an examination of the significant contacts between chlorine and other atoms.

III. The application of van der Waals radii in crystal chemistry, stereochemistry, and X-ray diffraction

Since they are based on X-ray diffraction data on the structure of crystals, VR are naturally used primarily to describe and interpret crystal structures, and also to determine new structures. When intermolecular interactions are considered, contacts of two types are examined: normal contacts corresponding to ordinary van der Waals interactions, and shortened contacts, where specific intermolecular interactions are revealed. A remarkable feature is that although they represent a geometric approach to the structure of a substance, VR can also be used to examine its energy, since they are used to obtain atom–atom potential functions, which now represent the most universal and effective means of calculating the energy of interaction of comparatively complex molecules. Although intermolecular contacts represent the source of data for compiling tables of van der Waals radii, one of their most important uses is in the analysis of the non-valence interactions within molecules and in the related discussion and prediction of molecular conformations.

1. Normal intermolecular contacts

Since a system of VR together with data on the dispersion of the lengths of the significant contacts reflects the usual picture of the packing of molecules in crystals, in the study of each new substance a comparison of the shortest intermolecular (atom–atom) distances with the sums of the VR or the quantities $2\sqrt{R_iR_j}$ usually makes it possible to establish the 'normal' character of the intermolecular interactions and confirms that the crystal does in fact consist of discrete molecules. Data on the shortest intermolecular distances (selected using VR) are often given as standard tables (see for example Ryabova and co-workers[19] and Romanenko and co-workers[20]).‡

For coordination compounds, the determination of the molecular character of a crystalline substance is often difficult, and the result is difficult to predict. An example is provided by the study[21] of a structure which was found to contain dimeric anions $[Cu_2(OCH_3)_2.\{2,6\text{-}(NO_2)_2C_6H_3O\}_4]^{2-}$, each joined by hydrogen bonds to two piperidinium cations $C_5H_{12}N^+$ forming the second coordination sphere of the complex. There are no contracted intermolecular contacts between these associates, so that the structure could be described as molecular.

The use of VR makes it possible to introduce the concept of molecular coordination number (MCN), which provides an extremely useful means of describing the structure of molecular crystals.[8,22] The distribution of the values of Δr_{min} (see section II) on a numerical axis usually appears approximately as shown in Fig. 2*a*, which gives the distribution of the Δr_{min} values for 3,3,'-bithienyl. Figures indicating the multiplicity of the given molecule–molecule contact are given above the vertical lines corresponding to the Δr_{min} values. A characteristic feature is the gap between the two values of Δr_{min} denoted μ and ν, where μ corresponds to the molecule with the largest Δr_{min} still in the coordination sphere, and ν corresponds to the molecule with the smallest Δr_{min} not included in the coordination sphere. The larger the gap between μ and ν, the more clearly defined the coordination sphere.§ Later,[23] this qualitative approach to the determination of the MCN was supplemented by the quantitative conditions: 1) $\nu - \mu \geqslant 0.6$ Å, and 2) -0.3 Å (or -0.15 Å) $\leqslant \mu \leqslant 1.0$ Å; this value in brackets corresponds to contacts not involving hydrogen atoms. In all 155 examples of the coordination environment of molecules examined,[23] it was possible, in the distribution of the Δr_{min} values, to select values of μ and ν satisfying the above conditions. At the same time, in 25% of cases, a picture similar to that shown in Fig. 2*b* was observed. Here, two appreciable gaps are observed in the sequence of Δr_{min} values, making it possible to distinguish a coordination sphere between the first and second spheres (a 'sesqui-sphere'). The MCN in these cases is written as a sum (for example 12 + 2). The quantitative criteria for the coordination 'sesqui-sphere' are: 1) $\nu_1 - \mu_1 \geqslant 0.3$ Å; 2) $\nu_2 - \mu_2 \geqslant 0.6$ Å; 3) $\mu_1 \geqslant -0.3$ (-0.15) Å; and 4) $\mu_2 \leqslant 1.0$ Å. Here it is assumed that $\nu_2 > \mu_2 \geqslant \nu_1 > \mu_1$.

---

‡ The advantages of a table of this kind over a table of distances shorter than some single value for contacts of all types are obvious; intermolecular distances selected without comparison with VR usually by themselves do not carry any valuable information.

§ The definition of MCN, previously introduced by Kitaigorodskii,[8] as the number of molecules having at least one contact with the molecule being considered does not make it possible to determine this quantity objectively.[22]

In homomolecular crystals, a continuous series of MCN from 9 to 18 has been observed. The most common values are 14 (about half of the structures) and 12 (about one third of the structures). An expanded form of notation for the MCN (in layers and in chains) has been proposed and analysed[24,25] for a more detailed characterisation of the coordination environment of molecules.

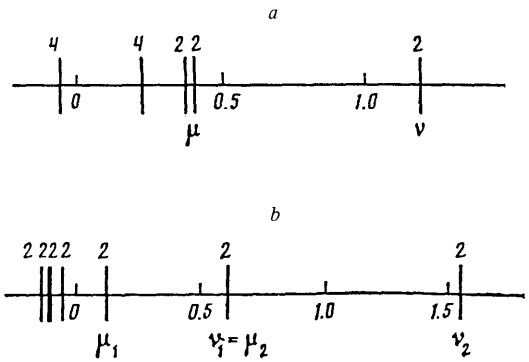

Figure 2. Diagrams illustrating the determination of the molecular coordination number (the values of Δr_{min} are shown on the numerical axis): *a*, structure of 3,3′-bithienyl; *b*, hypothetical structure with a coordination 'sesqui-sphere'.

In X-ray diffraction studies it is often pointed out that the intermolecular distances are greater than the ordinary values, and that this might indicate loosening of the packing. These conclusions are not sufficiently reliable, however, and are usually reached without taking account of the natural dispersion of the significant contacts.¶

On the other hand, the existence of anomalously short contacts indicates either that the X-ray diffraction data are unreliable or (when there is crystal-chemical justification) the existence of specific intermolecular interactions (see next section).

In some X-ray diffraction studies, VR are used to identify atoms. For example, in the determination of the structure of methylammonium hexachloroferrate(II) hydrate,[26] difficulties were encountered in identifying the nitrogen and carbon atoms, which give electron density maxima of similar height. The formation of a short intermolecular contact (2.76 Å) between an oxygen atom and one of the atoms difficult to identify indicated that this was a nitrogen atom, since this distance for the nitrogen and oxygen atoms, with allowance for their van der Waals radii, is normal, whereas it is too short for carbon and oxygen atoms.

The detection of unrealistic intermolecular contacts using VR plays an important part in the analysis of crystal structures with incomplete ordering. These structures are often described as a statistical sequence of molecules in which one of a number of possible positions of some atomic group is realised. For example, in an X-ray diffraction study[27] of the selenium derivative of biepoxycyclopentyl $C_{16}H_{16}O_4Se$ it was suggested that randomly distributed molecules with different angles of rotation of the phenyl groups coexist in the structure (the angle between two positions of the ring is close to 90°). It was shown,[28] however, that this model unavoidably leads to extremely short intermolecular contacts. A detailed analysis made it possible to construct a model of the structure consisting of enantiomorphic domains in which the molecules are packed in accordance with the usual VR values (the ways in which these domains are connected were also studied).

A domain structure was also proposed[29] for the crystals of 3-bromobicyclo[3.3.1]non-2-en-4-one, where random arrangement of the oxygen atoms leads to shortened O...O contacts with a length of 2.31 Å. Unrealistically short intermolecular Cl...Cl contacts (2.33 Å) were also noted[30] in the random structure of $Ni(p\text{-}H_2NC_6H_4OCH_3)_4(Cl_3CCOO)_2$. In the last two studies, however, the problem was not fully analysed, and a model which does not contradict the observed diffraction pattern and at the same time is consistent with crystal-chemical considerations has not yet been constructed.

The modelling of non-valence interactions by means of VR was an essential part of such outstanding and familiar studies as the determination of the structure of the α-helix of polypeptides[31] and the double helix of DNA.[32] At the present time also, the initial models of proteins and other biological materials are constructed using VR (these models are subsequently verified and refined by X-ray diffraction and NMR spectroscopy).

VR have recently been used[33] to solve structural-biological problems associated with the formation of 'incorrect' pairs of bases in DNA. In the transfer of inherited information, an exceptionally important role is played by the so-called 'Watson–Crick pairs' adenine–thymine (uracil) or guanine–cytosine. The use of mean-statistical VR values and allowance for the dispersion of van der Waals contacts showed that the nucleic acids of the incorrect pairs of bases in the usual tautomeric forms can be arranged in a double helix without producing shortened interatomic contacts or significant distortion of the sugar–phosphate core. It was found that the sugar–phosphate core is sufficiently flexible to allow the arrangement in a double helix of nucleotide pairs having dimensions approximately 2 Å larger (the inosine–adenine pair) and 2 Å smaller (the uracil–cytosine pair) than the canonical Watson–Crick pairs, and also pairs in which one base is displaced relative to the other by ~2 Å along a two-fold axis (the guanine–uracil pair).

The systems examined above contain only normal intermolecular contacts. This last feature is an experimental fact or is postulated on the basis of empirical generalisations, so that the requirement that the contacts be normal can be used to construct or correct structural models. At the same time, as already noted, shortened intermolecular contacts also arise regularly in certain systems; these systems are examined in the next section.

2. Shortened intermolecular contacts (SInterC)

The detection of anomalously short (shortened) contacts in crystal structures is of particular importance, since these contacts usually indicate the existence of specific intermolecular interactions which are appreciably stronger than ordinary van der Waals interactions and which have a significant influence on the structure and properties of molecular crystals. The most common example of specific interactions (SI) is the hydrogen bond. Metal–metal, halogen–halogen, sulphur–sulphur, and various other intermolecular SI are less well known. The detailed study of SInterC will undoubtedly lead to the detection of new types of SI which have not yet been studied.

¶ An exception is provided by crystals made up of very small molecules (containing a small number of atoms), studied at relatively high temperatures.

The term shortened intermolecular contacts is used to describe the distances r_{ij} between the atoms of different molecules if $r_{ij} < R_i + R_j - \delta$ or $r_{ij} < 2\sqrt{R_iR_j} - \delta$,[34] where δ is the overlap of the van der Waals spheres acceptable for a normal contact. Many workers discussing SInterC assume that $\delta \simeq 0$, which has no physical significance. As noted above, statistical analysis shows that it is appropriate to take $\delta = 0.15$ Å for contacts not involving hydrogen atoms, and $\delta = 0.30$ Å for contacts involving hydrogen atoms.

Contacts for which $2\sqrt{R_iR_j} - \delta < r_{ij} < 2\sqrt{R_iR_j}$ can be described as contacted. More or less contracted contacts are sometimes regarded as indicating van der Waals interactions of increased strength.[35] It should be borne in mind, however, that there is no direct relationship between the length of the shortest intermolecular contact in van der Waals interaction and the energy of interaction of the corresponding molecules. Thus contracted contacts cannot be regarded as a sign of specific intermolecular interactions.

The study of hydrogen bonds occupies a unique place in the investigation of SInterC. As data on hydrogen bonds have accumulated and become more detailed, a number of geometric criteria for the existence of an H-bond have been proposed.[36–39] All these criteria are based on an examination of the distances $r(X \ldots Y)$ or $d(H \ldots Y)$ in a system XH ... Y, although in fact the strength of a bond is also determined to a large extent by its linearity, that is by the angle X–H–Y.† The general idea is that the length of the contact between atoms involved in an H-bond is shorter than the distance between the same atoms joined by only van der Waals interaction. These criteria differ, however, in the use of different VR systems and different values of δ. The general trend has been that the criteria have been made more rigid as it has been found that in some cases they 'do not work'.

The criterion of Pimentel and McClellan,[36] the first to be proposed, is based on a comparison of the length of the contact X...Y with sum of the van der Waals radii of X and Y; δ is taken as zero. When it became possible to locate H atoms in X-ray diffraction studies, criteria based on the comparison of the lengths of the contacts H...Y with the sum of the VR of the H and Y atoms began to be used. These are the criteria of Hamilton and Ibers[37] ($d < R_H + R_Y$ or $d < R_H + R_Y - 0.2$ Å), Zefirov[38] ($d < 2\sqrt{R_HR_Y} - 0.35$ Å), and Rahim and Barman[39] ($d < r_{XH} + R_H + R_Y$).

The use of various criteria of this kind without introducing additional information, however, may lead to erroneous conclusions, particularly when the hydrogen atoms have not been located. It has been shown[40] by infrared spectroscopy that OH...O contacts are not H-bonds in the following crystals: citric acid[41] (O...O 2.84 Å), methyl-α-*D*-glucopyranose[42] (O...O 2.93 Å and H...O 2.19 Å), *L*-ascorbic acid[43] (O...O 2.93 Å and H...O 2.23 Å), and tartronic acid[44] (O...O 3.02 Å and H...O 2.23 Å). In all these cases, the use of the criteria of Pimentel and McClellan with the VR of Bondi,[16] $d(O \ldots O) < 3.04$ Å, Rahim and Barman, $d(O \ldots O) < 3.68$ Å, Hamilton and Ibers, $d(O \ldots H) < 2.6$ Å, and a modification of the latter, $d(O \ldots H) < 2.4$ Å would have led to errors, since according to these criteria, all the above contacts should correspond to an H-bond.

† For very large deviations from linearity, for example if $\angle XHY \leqslant 90°$, the concept of H-bond apparently loses significance.

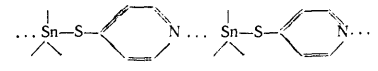
Strictly speaking, the existence and strength of an H-bond should be judged by energy calculations, for example by Poltev's method,[45,46] where account is taken of the angular dependence of the energy of the H-bond. The energy of approach (particularly when the value of the angle XHY is taken into account) unavoidably leads to the conclusion that there is no rigid boundary between the 'bond' and 'no bond' situations. This makes it obvious that any geometric criteria are arbitrary, although they may be useful for practical purposes. Moreover, the correct use of geometric parameters combined with VR is a most important (if not the principal) source of information on H-bonds. An important auxiliary role may be played by crystal-chemical (crystal-structural) considerations: the assumption that an H-bond is formed is often essential to establish the factors leading to a given mode of packing of the molecules.

The magnitude of the decrease in the length of a contact compared with the normal value, defined as $2\sqrt{R_iR_j}$ (or $R_i + R_j$) often makes it possible not only to detect an H-bond but also to deduce its strength. Thus a comparison of H-bonds of different types (NH...Cl and OH...O) from the differences $\Delta r_{HY} = r_{HY} - 2\sqrt{R_HR_Y}$, where the VR were taken from Zefirov and Zorkii,[11] showed that the structure of *trans*-chloro(*L*-prolinato-N,O)[(+)-α-methylbenzylamine-N]platinum(II) [47] contains pseudo-dimers of complexes formed by the stronger H-bonds NH...Cl; the pseudo-dimers are connected in layers by the weaker bonds OH...H.

Among the large number of H-bonds detected using VR, various types of bond which have been little studied are of particular interest. Thus an X-ray diffraction study[48] with location of the H atom has proved objectively that the crystal of (benzoylmethyl)-triphenylphosphonium bromide ($PhCOCH_2P^+Ph_3)Br^-$ contains H-bonds of the type CH...Br^-. The geometric parameters of this bond are: C...Br^- 3.457 Å, H...Br^- 2.26 Å, C–H 1.20 Å, angle $CHBr^-$ 172°. The distance H...Br is 0.41 Å shorter than the value of $2\sqrt{R_HR_{Br}} - 0.35$ Å, equal to 2.67 Å. In the crystal of (p-$CH_3OC_6H_4)_2Te(NSO_2C_6H_4CH_3$-$p$), one of the aromatic rings at the Te atom forms a short contact with the N atom (C_{16}...N 2.96 Å, H_{16}...N 2.25 Å, CHN 124°).[49] This contact is very short, so that it was assumed that the crystal contains a CH...N H-bond, analogous to the familiar CH... O bonds.

SInterC of the type Γ...Γ, where Γ = Cl, Br, I, are fairly frequently observed in crystal structures (fluorine does not form shortened contacts[13]). The greatest of the shortened contacts increases from chlorine to iodine. The significant contacts I...I show a practically continuous series of distances from twice the van der Waals radius to twice the covalent radius of iodine.[50] The production of Γ...Γ SInterC is attributed to the specific interactions between the halogen atoms, that is to the greater or lesser contribution of exchange forces.

The lower limits of the distances for the contacts C–Γ...Γ–C have been determined;[51] they are given effectively by the equation $r_{ij} = d - 0.15$ Å, where d is the length of the shortest contact in the structure of the corresponding halogen ($d = 3.28$ Å for Cl_2,[52] 3.32 Å for Br_2,[53] and 3.50 Å for I_2 [54]). Later, the 'upper limits' (r_{max}) of the distances r_{ij} for the specific interactions Γ...Γ in organic crystals were established.[14] The angular characteristic φ—the greater of the two angles C–Γ...Γ for each contact—was used. The data for 123 structures established that for $r_{ij} < r_{max}$, the angle $\varphi \geqslant 130°$, and that for $r_{ij} > r_{max}$, much smaller values of φ are also observed. On this basis, the value of r_{max} (3.65 Å for Cl, 3.79 Å for Br, and 4.14 Å for I) was taken as the 'upper limit' of the SI. A remarkable feature is that the relationship $r_{max} + 0.15$ Å $\simeq 2R_Γ$ is satisfied with a fairly high accuracy.



It is important to emphasise, however, that the concept of the 'upper limit' of specific interactions Γ...Γ is conditional. If $r_{ij} < r_{max}$, the interaction can be regarded as specific; if however $r_{ij} > r_{max}$, additional information is required to determine the nature of the interaction. The Γ...Γ atom–atom potentials taking account of the possible production of SI are unknown, but it is clear that with increase in the distance, the modulus of the energy of this bond decreases more smoothly than that of the covalent bond. In various crystals of organic halogen derivatives, the packing of the molecules is clearly determined by the tendency towards maximum approach of the Γ atoms. Thus the specific character of an interaction may be indicated (but not necessarily) by the characteristics of the arrangement of the molecules in the crystalline substance.

The use of VR combined with an energy calculation has shown how the successive introduction of F, Cl, Br, or I atoms into the molecule influences the packing of the molecules in the crystals of 1,5-dihalogenoanthraquinones $C_{14}H_6O_2\Gamma_2$.[55] All these crystals contain clearly defined molecular chains with similar structures. These chains resemble one another particularly closely in $C_{14}H_6O_2F_2$, $C_{14}H_6O_2Cl_2$, and $C_{14}H_6O_2Br_2$, but the ways in which they are superimposed in these structures differ considerably. When the structure is modified by the successive replacement of the H atoms in positions 1 and 5 of anthraquinone by halogen atoms, three factors are important: 1) the increase in the size of the atoms (the increase in their covalent and van der Waals radii), 2) the appearance (beginning at Cl) of SI, which to some extent may compensate the increase in the size of the atoms, and 3) the magnitude of the gap (or overlap) between the van der Waals spheres of the atoms belonging to neighbouring molecules. In particular, in anthraquinone the H atoms in positions 1 and 5 (or 4 and 8) in the chain do not give contacts close to the sum of the VR,‡ but the hydrogen atoms of neighbouring chains are in direct contact with them. The difference in the VR (ΔVR) of the F and H atoms is 0.24 Å; the difference in their covalent radii is ΔCR = 0.34 Å. Since SI are not characteristic of F atoms, their introduction into the anthraquinone molecule produces little change in the structure of the chains, but alters the way in which they are packed. The structure of $C_{14}H_6O_2F_2$ contains short contacts involving F atoms ($\Delta r_{ij} = r_{ij} - \Sigma VR = -0.12$ Å for F...H and 0.00 for F...C). Since ΔVR(Cl and F) = 0.50 Å and ΔCR(Cl and F) = 0.35 Å, the replacement of F atoms by Cl leads to a change in the packing.

In addition to Γ...Γ SInterC, S...S InterC are fairly frequently encountered in organic crystals. Thus Zefirov and Zorkii,[34] using published data,[56] reported 14 short S...S distances, seven of which were much shorter than twice the VR of the S atom, and apparently appeared as a result of SI between the sulphur atoms.

In crystals formed by molecules or ions containing metal atoms, SI and hence SInterC involving these atoms may be produced (for example metal...metal, metal...oxygen, etc. SI). Thus the packing of the molecules in the crystals indicates the existence of the specific interactions Cu...O in copper salicylideneiminate, and Cu...Cu in copper salicylidenemethyliminate.[57] It is difficult to discuss this question, however, since there are no reliable VR values for metal atoms. For example, the published VR of the mercury atom vary from 1.5 Å [8,58] to 1.9 Å or more,[59,60] although the VR of this atom have apparently been more extensively discussed than those of any other metal.

The question of the production of SI in a structure is sometimes important for establishing the formula of a substance. For example, the use of VR detected an Sn...N specific interaction in the structure of the triphenyltin derivative of 4-thiopyridine,[61] and from this it was concluded that in the crystal the compound is an organotin derivative of pyridinethiol, and not thiopyridine, and that its structure is described by the formula

and not

If only normal intermolecular contacts are observed in a molecular crystal, the recognition of molecular agglomerates (dimers, chains, layers) of physical significance using only VR usually cannot be carried out completely correctly; in this case an energy calculation is required.[62] When SI with energies much greater than the energy of ordinary van der Waals atom–atom interactions are present, however, the agglomerates are usually distinguished quite clearly, giving a physically justified description of the structure. Thus the structure of triphenylmethyl bromide[63] consists of dimers formed by Br...Br specific interactions; the crystals contain two types of dimer, with Br...Br distances of 3.181 Å§ ($\Delta r = -0.76$ Å) and 3.466 Å ($\Delta r = -0.47$ Å). The structure of zinc 7-methylthio-8-mercaptoquinolinate[64] contains a short contact S...S 3.29 Å ($\Delta r = -0.39$ Å); these contacts join the molecules in centrosymmetric dimers.

Infinite chains −O...Sn−N−C−O...Sn−N−C−O... parallel to the long axis of the acicular crystal were detected in the structure of triphenyltin isocyanate;[65] here, the Sn...O distance is 2.81 Å ($\Delta r \lesssim -0.5$ Å). The chains can be distinguished even more clearly in the above-mentioned structure of the triphenyltin derivative of 4-thiopyridine with Sn...N 2.62 Å [61] ($\Delta r \lesssim 0.9$ Å).

The packing of the BF_3 molecules in the crystal structure of boron trifluoride at −145 °C is extremely interesting.[66] As a result of the coordinative unsaturation of the boron atom, the planar-trigonal coordination is brought up to trigonal bipyramidal by the fluorine atoms of neighbouring molecules. The BF_5 trigonal bipyramids share vertices to form infinite layers in the crystal. The intermolecular B...F distances are 2.663–2.704 Å, which is appreciably smaller than the sum of the VR of the atoms F (1.40 Å)[13] and B (2.13 Å).[16]

3. *A priori* calculation of close packing

The determination of an optimum structure by theoretical calculation generally involves the search for arrangements of the molecules with minimum energy. In the absence of specific interactions, the tendency towards close packing models with a certain accuracy the tendency towards an energy minimum, so that the minimisation of the energy can be replaced by the search for close-packed arrangements.

‡ In the work cited,[55] the numerical data were replaced by analogous quantities calculated from refined[11,13,14] VR values.

§ This SInterC is the shortest known C−Br...Br−C contact, and almost reaches the lower limit of 3.17 Å found by Zefirov.[51]

Using VR, molecules can be represented as three-dimensional bodies, and crystal structures as the packing of these bodies. As noted above, representations of this kind first appeared in works by Sidgwick,[5] Albrecht and Corey,[6] and Pauling;[7] for Kitaigorodskii[8] they provided the starting point for the development of the theory of the close packing of molecules in crystals. This theory established not only the existence of a three-dimensional system of molecules 'in contact' but also the production of intermolecular contacts according to the 'projection into cavity' principle. Zorkii,[67] who refined the formulation of the basic postulates of the theory of the close packing of molecules, pointed out that not all molecule–molecule contacts are made according to this principle, but that each structure necessarily contains 'projection into cavity' combinations which act as 'catches' fixing the structure. The existence of 'projection into cavity' contacts by itself, however, does not ensure a high packing density.

When molecules are represented as three-dimensional bodies, the question of the possibility of predicting crystal structures as close-packed arrangements of these bodies arises. In general, for three-dimensional packing, this problem is extremely complex. For the two-dimensional packing of planar molecules, it has been solved by the method of flow trajectories,[62,68,69] which makes it possible to find graphically the close-packed arrangement of figures whose outer contour is formed by intersecting circles.

Specific calculations have been carried out[62] for Ni dimethylglyoximate (Ni-DMG) and Cu salicylidenemethyliminate (Cu-SMI), in whose crystals a unique situation is produced: the planes of the molecules coincide exactly with the planes of the 'layers',¶ so that even a two-dimensional analysis can be used to discuss the possibility of an *a priori* prediction of the structure.

For both substances, a series of minima was obtained on the curves giving the dependence of the quantity $1/k$, where k is the packing density coefficient, on the parameters of the structure. In both cases the actual packing of the molecules was found to be very close to 'incompressible', that is it corresponds approximately to certain minima on the $1/k$ curves, and the packing density coefficient cannot be increased by small translations and rotations. At the same time, these structures were not the most compact; they did not correspond to the deepest minima on the $1/k$ curves. This result can be seen particularly clearly for Cu-SMI, for which it was possible to construct a packing with $k = 0.91$, which is appreciably more compact than the packing with $k = 0.87$, close to the actual packing. Thus when discussing compact molecular packing, it is necessary to be careful when using terms such as 'close-packed' and 'closest-packed'.[8,9]

If the packing of molecules in the crystals were not only incompressible but also close-packed, this would mean that the values of $1/k$ and the energy of the structure not only changed in the same sense but also were proportional to one another. Such complete mutual correspondence between a formal geometric characteristic and a thermodynamic function can hardly be expected. The arrangement of molecules in a crystal is certainly determined not only by the compactness of the packing but also by the relative orientation of the multiple moments.

At the same time, calculations have shown that there are not many examples (15–20) of closest packing corresponding to structures close to the real structures of Ni-DMG and Cu-SMI. This means that it is possible to construct a comparatively small number of hypothetical structures and to select from them the most probable structure by making use of additional methods, for example by examining the optimum arrangement of the multipoles or by using experimental data on the lattice parameters.† For structures in which the analysis of the packing cannot be reduced to a two-dimensional calculation, however, this method is naturally unrealistic.

Considerable progess in the *a priori* prediction of molecular (mainly organic) crystal structures has been achieved by using atom–atom potential functions (AAPF).[2,3,71] A remarkable feature is that VR have also played an important role in the development of organic crystal chemistry (after the theory of close packing). The VR are used to specify the equilibrium distances r_0, which appear in the parameters of the AAPF (see Fig. 1). Here, a common error is made: the sum of the VR found from the crystal structures is taken as the equilibrium distance, without taking account of the 'compression' of the molecules in the crystal. An empirical relationship between these quantities, $r_0/\Sigma VR \simeq 1.16$, has been pointed out.[72]

4. The conformations of molecules

In the mechanical model of a molecule, its conformation is regarded as resulting from the valence and non-valence interactions of the atoms.[73] The lengths of the covalent bonds, fixed in a fairly narrow range, and their directed character are the universal stereochemical factors which practically always are of decisive importance. The part played by non-valence interactions is particularly clearly revealed in three cases: 1) for non-rigid molecules, for example molecules in which rotation about single bonds is possible; 2) when there is steric hindrance; and 3) when there are intramolecular SI (they are often called attractive interactions, in contrast to steric hindrance, where forces of repulsion are most important).

In the last two cases, shortened intramolecular contacts (SIntraC) arise, and although the nature of the shortening is completely different in this case, its geometric consequences are analogous, and are revealed in the deviation of the bond lengths and more particularly the valence angles from the ideal values (the deformation of valence angles involves a much smaller expenditure of energy than the compression or elongation of covalent bonds). The use of VR makes it possible to detect SIntraC, and to follow their influence on the conformation of molecules or to conclude that effects of this kind are not observed.

¶ The characteristic features of the crystal structures of Ni-DMG and CU-SMI are due to the specific intermolecular metal–metal bonds perpendicular to the 'layer'. The word 'layer' is here put in inverted commas, since in contrast to the usual practice the word is used in the purely geometric sense. The strongest intermolecular interactions in these crystals lead to the formation of chains (perpendicular to the 'layers'), but it is in the 'layers' being considered that the tendency towards close packing should be detected.

† The two-dimensional approach (the method of flow trajectories) has also proved extremely effective for the *a priori* prediction of the packing of the chains of $PdCl_2$ and $BeCl_2$ [12,70] (in the crystal, these chains are joined to one another only by van der Waals interaction). The high symmetry and the relatively simple form of the chains obtained by modelling using VR made it possible to calculate successfully the most compact incompressible packing; the actual structure of $PdCl_2$ was found to be the third most compact, and the actual structure of $BeCl_2$ to be the most compact.

If relatively mobile fragments of a molecule are not joined by SI and there is no steric hindrance between them, free internal rotation often arises.[74] This has a significant influence on the physicochemical properties of substances, as discussed below (see section IV).

A number of examples of the distortion of valence angles as a result of the overlap of the van der Waals spheres of valence-non-bonded atoms can be considered. In the radical-ion salt $[C_{14}H_8S_4]^+ \cdot [PtBr_5S(CH_3)_2]^-$,[75] the octahedral configuration of the Pt atom is distorted by the mutual repulsion of the atoms of the methyl groups and Br. In the cobalt complex of Vitamin PP, that is nicotinamide (NA), with the composition $[Co(NA)_2(H_2O)_4](CH_3COO)_2.2H_2O$,[76] the inequality of the exocyclic angles at the C atom of the heterocyclic ring joined to the C atom of the amide group (119.5° and 122.0°) is due to the difference in the VR of the N and O atoms of the amide group, and also to the repulsion between an H atom of the heterocyclic ring on the one hand and an H atom of the amide group on the other ($\Delta r = -0.36$ Å).

The VR values have a characteristic influence on the conformations of polyethylene and substituted polyethylene polymers. The van der Waals diameter of the H atom is 2.31 Å, and the identity period along a completely *trans*-carbon chain is 2.54 Å, so that the polyethylene molecules can (and do) have a planar zigzag conformation. This period of the *trans*-carbon chain, however, does not ensure sufficient space for other atoms replacing H atoms, and more particularly for groups of atoms. For example, the van der Waals diameter of the F atom is 0.26 Å larger than the identity period, so that in polytetrafluoroethylene, a planar zigzag conformation cannot be produced. In this case the crowding is reduced by slight bending of the chain to give a slightly twisted spiral.[77] Isotactic stereoregular hydrocarbon polymers with the general formula $-(CH_2-CHR)_n-$ have similar spiral conformations,[78] since even for R = CH_3 (VR $\simeq$ 2.0 Å), crowding of the chain does not allow the production of a planar conformation.

In a number of cases, VR can be used to explain the difference in the values of the dihedral angles in related compounds. Thus the decrease by 21.4° in the dihedral angle between the planes of the benzene rings of the phenothiazine unit in the molecule of 1,3-dinitro-10-phenylphenothiazine[79] compared with the corresponding angle in non-substituted phenothiazine, equal to 153.3°, makes it possible to avoid steric hindrance in the molecule of the derivative, since the hydrogen atoms of the N-phenyl substitute 'touch' the atoms of the lateral rings of the phenothiazine unit in the *peri*-positions. The distances are H...H 2.33 Å and H...N 2.61 Å, which are very close to the values $2R_H$ = 2.31 Å and $2\sqrt{R_H R_N}$ = 2.64 Å.[11] With increase in the dihedral angle, these contacts would be shortened. The presence of a shortened N...O contact (2.719 Å) explains the folded conformation of the arabinofuranose molecule.[80]

The use of VR makes it possible not only to explain various details of the conformations of molecules but also in many cases to reach other conclusions about their structure, primarily the possibility or impossibility of conjugation, the reasons for breakdown of planarity, etc. Measurements of the dipole moments and the molecular Kerr constants have been used to study the conformation of a number of triarylphosphine oxides $(XC_6H_4)_3PO$ and the dependence of the orientation of the aryl rings relative to the phosphoryl group on the nature of the substituents.[81] From the spatial arrangement of the *d* orbitals of phosphorus, it might have been assumed that the most favourable conditions for the conjugation of these orbitals with the aryl rings are created when the angle φ is equal to zero or 90°; here, φ is the angle of rotation of the aryl rings about the P–C bonds, and the zero value corresponds to the position of the rings in which their planes pass through the C_3 symmetry axis. A graphical analysis of three-dimensional models using the VR given by Zefirov and Zorkii[11] showed, however, that the conformations with an angle of φ equal to zero or 90° are impossible, because of the overlap of the van der Waals spheres of the *ortho*-hydrogen atoms of the aryl rings. Steric hindrance is absent only for values of φ in the range 30–60°. The values of φ calculated from the anisotropy of the polarisability were as follows:

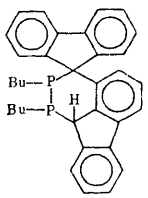
X	H	*p*-Cl	*p*-CH_3	*m*-Cl	*m*-CH_3
φ, °	55	65	60	49	52.

Assuming that the range of angles φ > 45° is more favourable than the range φ < 45°, the authors cited attributed the increase in φ when substituents are introduced into the *para*-position to the increase in the conjugation of the phosphoryl group with the aryl rings (for the *p*-chloro-derivative, slight steric hindrance predominates). In the opinion of the authors cited, the corresponding substituents in the *meta*-position lower the electrostatic repulsion, leading to a decrease in the angle φ.

A study[82] of the structure of dichlorobis(vinylbenzotriazole)-cobalt(II) showed that steric hindrance interferes with the π-conjugation of the vinyl groups with the benzotriazole rings: the terminal C atoms of the vinyl groups form extensively shortened (by 0.32 Å and 0.35 Å) contacts with the N atoms. Rotation of the free ends of the vinyl groups not towards the N atoms but in the opposite direction, however, would have led to even greater steric hindrance.

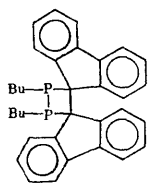
The rotation of the phenyl rings in the molecule of tricarbonyl-(1,4-diphenylbutadiene)iron $C_4H_4Ph_2Fe(CO)_3$ [83] is due to steric strain in the ligand (similar to that observed in biphenyl), as indicated by the shortening of the intramolecular non-valence distances C...C and C...H between the atoms of the phenyl rings and the butadiene system. In spite of the rotation of the phenyl groups relative to the plane of the butadiene system, however, these contractions remain fairly large: C...C 2.83–2.89 Å and C...H 2.55–2.65 Å. This strain in the ligand indicates[83] its tendency towards coplanarity and hence the presence of conjugation, which is apparently preserved despite the rotations indicated. The preservation of the planarity of a system in spite of a considerable number of contracted intramolecular contacts (compared with the sum of the VR), as for example in the cation of the salt $C_{18}H_{17}O_2^+ClO_4^-$,[84] ‡ indicates extensive delocalisation of the π-electrons.

Steric strains are sometimes reduced by their distribution among several neighbouring sites in a molecule. Thus the presence in the structure of di-(2,8-diphenylindolizin-3-yl)disulphide[85] of short intramolecular contacts S...C 3.330 Å and 3.342 Å (the sum of the VR of the S and C atoms is 3.55 Å) with the phenyl groups in positions 2 and 2′ leads to an increase in two triads of valence angles (on two triads of neighbouring carbon atoms) by 4–19° compared with the other exocyclic angles at these atoms.



In some cases, VR have made it possible to detect an increase in the length of valence bonds as a result of steric hindrance. This effect is particularly important, since it is most directly related to the stability of chemical compounds.

---



‡ In this structure the planarity of the system is preserved, despite a whole series of not only contracted but also shortened contacts, for example C...O 2.73 Å and 2.79 Å (Δr = –0.24 Å and –0.18 Å) and C...C 3.01 Å and 320 Å (Δr = –0.41 Å and –0.22 Å).

The presence of bulky substituents in the *ortho*-positions of a benzene ring influences the lengths of the bonds in the ring. Thus the presence of neighbouring phenyl and C_2F_5 groups in the molecule of 'fluoroterphenyl'[86] (shortest non-valence distances F...C 2.236 Å and 2.940 Å; length of the 'normal' van der Waals contact F...C 2.236 Å and 2.940 Å; length of the 'normal' van der Waals contact F...C 3.09 Å [13]) leads to an increase in the length of the corresponding C–C bond in the ring of 1.415 Å. Steric crowding is also responsible for the increase in the length of the C–C bond to 1.563 Å compared with 1.488–1.511 Å for the other three bonds of the type $C_{sp^2}-C_{sp^3}$ in the molecular of 2-*p*-anisidino-2,5-bis(trifluoromethyl)-3-perfluoroisobutenyl-5-monohydroperfluorohex-3-ene.[87] An even greater increase in the lengths of the bonds compared with the standard values is sometimes observed.

In the molecule of 1,2-di-t-butyl-1,2-diphosphorinane-(6,5,4-*l*,*m*)-fluorene-3-spiro-9′-fluorene[88]

extensively shortened intramolecular contacts are observed between the t-butyl groups and the phenyl rings of the fluorene fragments (C...C 3.286 Å, C...H 2.52 Å), and between the benzene rings of neighbouring fluorene fragments (C...C 3.298 Å), together with short P...C contacts (3.215 Å; sum of the VR of the P and C atoms 3.62 Å).[89] For this reason, all the P–C distances in the molecule are longer than the usual length of a single P–C(sp^3) bond, 1.85 Å;[89] here, the P–C bond length of 1.951 Å is one of the longest observed in structural studies of derivatives of three-coordinate phosphorus. Charnega and co-workers[88] also studied the molecule of fluorene-9-spiro-1-(3,4-di-t-butyl)-3,4-diphosphetane-2-spiro-9′-fluorene

which in addition to the contracted non-valence contact P...C of length 3.404 Å also contains contracts shorter than those in the previous case, C...C 3.297, 3.178, and 3.170 Å, and C...H 2.41 Å. In this molecule, the lengths of the P–C bonds in the ring are 1.904 Å and 1.911 Å, that is they are not elongated as extensively as in the previous molecule, but on the other hand, as a result of the repulsion of the fluorene groups, the bond between the spiro-carbon atoms is elongated considerably (to 1.626 Å). The central C–C bond in the molecule of 2,3-bis(trifluoromethyl)-2,3-bis(*p*-fluorophenyl)hexafluorobutane is elongated to an even greater extent (to 1.671 Å); in this case, in addition to the central bond, all the C–CF_3 bonds are also elongated (1.559–1.582 Å). In the opinion of the authors who studied this structure,[90] this increase in the length of the bonds in the 'central' unit of the molecule cannot be attributed entirely to steric hindrance.

Bonds of other types, for example P–S, may also be elongated by steric hindrance. In the molecule of 1,5-di(*p*-tolyl)-3,7-diphenyl-3,7-dithio-1,5-diaza-3,7-diphosphacyclo-octane,[91] the central fragment is the eight-membered $P_2N_2C_4$ ring. Both P atoms in the ring have the tetrahedral bond configuration characteristic of a four-coordinated phosphorus atom. The P–S bond lengths, 1.936 Å and 1.948 Å, are slightly longer than the standard value of 1.91 Å, due to the appreciable steric hindrance between the S atoms and the phenyl rings (the S...C distances are 3.11 Å, and the sum of the VR 3.55 Å).

In polynuclear coordination compounds, steric hindrance leads to an increase in the length of metal–metal bonds. Thus in the molecule of rhodium thioacetate $[Rh_2(CH_3COS)_4(CH_3CSOH)_2]$,[92] the Rh–Rh distance (2.55 Å) is much greater than the length of the Rh–Rh bond (2.3855 Å) in the analogous rhodium(II) acetate.[93] The VR of the sulphur atom (1.84 Å) is much larger than that of the oxygen atom (1.29 Å). As a result, the S...O distance in the thioacetate groups is 0.37 Å greater than the O...O distance in the acetate groups of the comparable complexes, and this, together with the electronic factor, leads to the difference in the Rh–Rh bond lengths indicated above.

Another example of the use of VR to analyse steric hindrance in molecules is given by Sadykov.[94] Here, an examination of shortened intramolecular non-valence contacts and increased valence angles gave the order of conformational strain in the molecules of matrine and its derivatives: allomatrine < sophoridine < matrine ≃ isosophoridine ≃ tetrahydroneosophoramine < *cis*-matrine.

A paper by Pasynskii and co-workers[95] gives an example of the use of VR to explain various characteristics of the conformations of molecules resulting from an attractive interaction. The use of VR in a study of the structure of $Cp_2Nb(CO)(\mu\text{-}CO)Mn(CO)_4$ detected an additional interaction between the clino-sandwich dicyclopentadienyl fragment and the pentacarbonylmanganese group. The bond between these structural fragments involves chiefly a direct Nb–Mn interaction; there is also an additional bond formed by a carbonyl group (μ-CO) acting as a bridge, and the corresponding distance Nb...C is 2.781 Å. This last value is much greater than the length of the Nb–C bond with the terminal CO group (2.06 Å), but is much shorter than the length of the van der Waals contact.

In conclusion it is useful to note that VR are very often used to reach important (and non-trivial) conclusions about the absence of any significant strain in a molecule being considered.

IV. The physicochemical properties of substances

1. The packing density coefficient. Properties determined by the effective volume, dimensions, and shape of molecules

In the absence of specific intermolecular interactions, the macroproperties of condensed phases are determined not by individual atom–atom contacts but by the integral characteristics of the molecular packing. One such characteristic, in particular, is the packing density coefficient (k). The values of k for the great majority of organic crystals lie in the range 0.65–0.77, and for substances with $k < 0.6$, a change to the vitreous state with decrease in temperature[9] or poor quality of the single crystals[96] are observed. Morphotropic jumps in homologous series are accompanied by an increase in the packing density. Substances with high packing density coefficients usually have high values of the density, viscosity, surface tension, heat of volatilisation, and melting point. An inverse dependence on k is shown by the compressibility of crystals with similar structure. Experiment has shown[9,97] that for benzene,

naphthalene, and anthracene, on going from the solid to the liquid phase, k decreases from values greater than 0.68 to 0.58, and the value in the gas does not exceed 0.5.§

Particularly compact arrangements result if the projections of a molecule fit closely into the cavities of neighbouring molecules. On the other hand, molecules with projections and cavities which do not correspond to one another are not suitable for the production of a compact arrangement. Loose molecular packing may also be due to other factors. For example, in substances containing a large number of fluorine atoms, on which appreciable negative charges are usually localised, a large number of intermolecular contacts F...F are unavoidably produced. In this case their length corresponds to the right-hand edge of the distribution curve (see section II). Thus in the crystals of perfluoro-3,3,6,6,4′,4′,4″,4″-octamethyl-1,2:4,5-dicyclobutenocyclohexa-1,4-diene ($C_{18}F_{28}$), the shortest F...F distances are 2.9–3.0 Å (VR of fluorine 1.40 Å [13]), and this explains[98] the unusually high volatility of this compound.

The analysis of intermolecular contacts is also used to interpret such properties as solubility. The low solubility of many molecular crystals is often attributed either to a high packing density or to the existence of SI. The existence of both is established using VR. Thus in the crystals of 3-carboxymethylthio-1,5-diphenylformazan,[99] the molecules are joined by H-bonds O–H...O of length 2.67 Å to form centrosymmetric dimers; between the planes of the dimers there are shortened contacts, apparently corresponding to stronger interactions, and this explains the low solubility. Similarly, the decrease in the solubility and the increase in the stability of the crystal structure of $Hg[C_9H_5(SCH_3)NS]_2$ and the isostructural zinc 7-methylthio-8-mercaptoquinolinate are attributed[59] to the existence of additional intermolecular interactions in their crystals. In fact, in this structure the molecules are connected to form dimers by a specific interaction S...S 3.35 Å (twice the VR of sulphur is 3.68 Å [15]).

A different situation is observed in the crystals of tetrakis(chloromethyl)adamantane.[100] Comparison of the intermolecular contacts with the corresponding sums of the VR showed that in this case the molecular packing is determined only by purely van der Waals forces, but at the same time it is highly compact, since the side groups occupy the spaces between the adamantane rings and ensure strong adhesion of the molecules. This adhesion, despite the absence of SI, explains the very low solubility and high melting point of the substance.

The shape of molecules, established using VR, is revealed particularly clearly in their ability to form solid solutions. Similarity in the shape and size of the replacing molecules and the molecules being replaced is a necessary and sufficient condition for the formation of substitutional solid solutions of organic compounds. Kitaigorodskii[101] proposed that the extent of this similarity be estimated using the geometric similarity coefficient ε, calculated as follows. The molecules, modelled using VR, must be superimposed to give the smallest extent of non-overlapping parts. If the overlap volume is v, and the volume of non-overlapping parts V, then $\varepsilon = 1 - V/v$. The molecules of A are soluble in a crystal of B if $\varepsilon > 0.8$ and there is no significant breakdown of the packing if a molecule of B is replaced in imagination by a molecule of A. An example is provided by the biphenyl–bipyridyl system. The molecules of these substances have very similar shapes, so that A dissolves in B, and B dissolves in A (a continuous series of solid solutions is not formed, however; the reason for this has been discussed [101]).

In addition to substitutional solid solutions, inter-block solid solutions also exist, where the dissolved molecules are localised on the surfaces of single-crystal blocks (in a mosaic crystal). Partial geometric correspondence between the molecules of the matrix and the impurity is sufficient for the formation of these solutions. Inter-block solid solutions have been used successfully[102] to produce new luminescent crystals. The matrices were naphthalene crystals, and the activating additives were anthranilic acid, methyl anthranilate, 1,4-diphenylbuta-1,3-diene, and 1,6-diphenylhexa-1,3,5-triene. Comparison of the projections of models of the additive molecules, constructed using VR, with the projection of a model of naphthalene showed that with decrease in the geometric similarity, the influence of the additives on the optical properties of napthalene decreases. Partial geometric correspondence is also a necessary condition for selecting a matrix for obtaining quasi-linear impurity spectra.[103]

To facilitate the calculation of the volume of molecules, Kitaigorodskii[8] proposed the use of the volume increments of the atoms (ΔV_i) and atomic groups. The value of ΔV_i for the atom being considered is calculated as the difference between the volume of the van der Waals sphere of this atom and the volumes of the spherical segments cut off on the given sphere by neighbouring valence-bonded atoms. The increments calculated in this way have been widely used[104–106] to calculate a whole series of important physical characteristics of polymers: density, volume expansion coefficient, vitrification temperature, temperature of the start of intensive thermal degradation, melting point, refractive index, coefficient of optical sensitivity to strain, bulk modulus of elasticity, etc. An important feature is that all these characteristics can be calculated even before synthesising the polymers, using only the chemical structure of the repeat unit. All the equations used in the calculations contain the volumes of the repeat units of the polymer $\sum_i \Delta V_i$. In particular, the density of an amorphous polymer is given approximately by the equation $d = km/\Sigma\Delta V_i$, where $k = 0.681$ (the average value of the packing density coefficient characteristic of polymers), and M the mass of the repeat unit. This calculation generally gives an accuracy of 0.001 g cm^{-3}. Similar calculations have been carried out by van Krevelen.[107]

This equation for the density shows that the value of d depends chiefly on the ratio of the volumes and mass of the atoms in the macromolecule. A unique element in this respect is fluorine, which has a small volume and a comparatively large atomic weight. Their ratio is much greater for fluorine than for any other monovalent substituent, and when fluorine is introduced into macromolecules it leads to a sharp increase in the density. A characteristic example is provided by Teflon (polytetrafluoroethylene).[108]

If the experimental value of the density is known, the packing density coefficient of the polymer can be calculated. This calculation made it possible to explain[109] the decrease in the softening temperature of copolymers of α,ω-dimethylacryloyloctaphenyltetrasilane with methyl methacrylate (MMA) with increase in the concentration of the former in the copolymers. At the same time the value of k decreases slightly, that is slight loosening of the molecular packing of the chains is observed, leading to a decrease in the softening temperature. Comparison of the calculated and experimental

§ Since there is no periodic structure in the liquid and the gas, the quantity being considered is the ratio of the total volume of the molecules modelled using VR to the total volume occupied by the given phase.

vitrification temperatures of network copolymers can sometimes be used to establish their structure. The structures of network copolymers based on MMA and diallyl *m*-carboranedicarboxylate were determined in this way.[110]

Another example of the successful use of VR to analyse the structure of condensed phases can be found in a paper by Abramzon and Goloudina,[111] who studied monolayers of surface-active substances at a liquid–gas interface. The authors cited tried to show that under certain conditions these layers have a crystalline structure. The property of the monolayer studied was the packing density, or more accurately the free volume corresponding to one molecule or hydrocarbon chain: $V_{free}^{m(c)} = V^{m(c)} - V_0^{m(c)}$, where $V^{m(c)}$ is the experimentally determined volume occupied by the molecule (or chain), and $V_0^{m(c)}$ the characteristic volume of the molecule (or chain), calculated using the VR of the H and C atoms and the methyl group given by Kitaigorodskii.[8] The authors cited analysed the contraction isotherms for condensed monolayers of aliphatic acids and higher alcohols by comparing the values of V_{free} for the packing of the hydrocarbon chains in the monolayer and the molecules of n-alkanes. The range of existence of solid layers was then determined, and it was shown that the phase transformations in the condensed layers of the substances examined are due to changes in the packing density of the hydrocarbon chains and are similar to the phase transformations in n-alkanes. This last feature provides evidence that the condensed monolayer has a crystal structure. A similar conclusion was reached in an electron diffraction study[112,113] of films of surface-active substances. Van der Waals radii have also been used to study the structure of aqueous solutions of a number of metal thiocyanates.[114]

Particle size plays an important role in transfer phenomena, and if the particles are polyatomic ions or molecules, VR can be used to study these phenomena. An example can be found in a paper by Lesnichaya,[115] where in a study of the electrical conductivity of molten guanidinium chloride $C(NH_2)_3Cl$, a comparison of the dimensions of the guanidinium ions obtained using VR with the dimensions of the chloride ion indicated that in this case an important part in ion transfer is played by mobile protons.

The use of VR (together with other parameters of the molecules) also makes it possible to explain and to estimate quantitatively the changes in the lattice parameters on intercalation, that is when molecules or ions are introduced into the spaces between the layer in layer single crystals. Thus on the intercalation of dichlorobenzene molecules into single crystals of $(C_{10}H_{21}NH_3)_2CdCl_4$, the distance between neighbouring layers increases by 3.65 Å, and for the intercalation of chloronaphthalene molecules the corresponding increase is 3.75 Å (the unit cell parameter *c* of the single crystal increases by 7.3 Å and 7.5 Å respectively).[116] These distances correlate well with the diameter of the chlorine atom (3.80 Å), particularly if account is taken of the possibility that chlorine atoms are situated in the cavities in the layers of the single crystal.¶ A similar change is observed in the parameter *c* of a single crystal of $(C_9H_{19}NH_3)_2PbI_4$ when hexane molecules are introduced (the distance between the layers increases by the thickness of the hexane molecule).[116] In insertion compounds of graphite with the composition $C_{24}K(C_6H_6)_x$, the benzene molecules are arranged at right angles to the graphite layers;[117] in this case, however, two limiting orientations are possible: one of the C–C bonds of the benzene ring may be arranged at right angles to or parallel to the layer. Comparison of the experimentally determined distance between the graphite layers and the dimensions of the benzene molecule, a model of which was constructed using VR, made it possible to give preference to the first version.

The system of VR makes it possible to describe clearly and fairly accurately the dimensions and shapes of the cavities and channels in various crystal structures, and also the dimensions and shapes of the molecules capable of entering these cavities and channels. This is related to questions of the permeability of molecular sieves and membranes, which are of primary importance for the understanding, prediction, and practical realisation of many chemical and biological processes (in particular, transport reactions).

Zeolite crystals contain more or less extensive cavities with windows formed by the connection of *n* silicon–oxygen tetrahedra. Taking the VR of oxygen as 1.4 Å, it is possible to calculate the dependence of the diameter of the window on *n*:[118]

n	4	5	6	8	10	12
D, Å	1.2	2.0	2.8	4.5	6.3	8.0.

The value of *D* determines the size of the atoms (ions) and molecules capable of entering the zeolite cavities.

A particularly fine geometric analysis is required in the study of inclusion compounds (clathrates). Thus the formation of these compounds is prevented not only when the dimensions of the species to be introduced are too large, but also when they are too small, since mobility of the particles in the cavities is energetically unfavourable. For example, α-dextrin (cyclohexaglucan), which contains channels with a diameter of ~6 Å, can accommodate molecules of benzene derivatives containing a smaller number of substituents which are not too large; β-dextrin (cyclopentaglucan), which contains channels with a diameter of 7.5 Å, forms inclusion compounds with naphthalene derivatives, but in γ-dextrin (cyclo-octaglucan), the cavities with diameter of 9–10 Å are too large for most ordinary organic substances, and they show little tendency to form inclusion compounds.[119] Similarly, the molecules of normal alkanes can be accommodated in the channels of urea, but cannot be held in the channels of thiourea, which have a larger cross-section and cannot be filled sufficiently fully by the thin chains of normal alkanes.[119]†

The use of VR is also extremely important in the study of the cavities in globular protein molecules. To study the mechanism of the penetration of the substrate to the active centres (haemo-groups) of the enzyme catalase, an attempt was made to find intramolecular cavities and channels in the enzyme.[121] The coordinates of the atoms were used to calculate the filling function of the space within the molecule. This function takes a constant value within a sphere of radius *R* round any of the atoms, and the value zero at other points (*R* is the sum of VR of the given atom and a water molecule). The van der Waals radii were assumed to have the following values: Cα 1.95, O 1.50, N 1.55, C 1.7, S 1.8, Fe 1.35, H_2O 1.4 Å. Several fairly large cavities were found; one of them consists of a bent channel which becomes broader when it meets the surface of the molecule, where its diameter reaches 8 Å; the other end of the channel extends towards the haeme group, and ends at a distance of 7 Å from it. This cavity apparently allows the substrate molecules to penetrate to the active centres of the enzyme.

¶ Dolzhenko and co-workers[116] considered only the thickness of the aromatic ring (3.42 Å), whereas the chlorine atoms obviously play a more important role.

† Later more detailed studies of the stability of compounds of urea with n-alkanes using VR have been published.[120]

Van der Waals radii are also used in the study of adsorption phenomena. Thus in a study of the mechanism of flotation using xanthates, the dimensions of the pentyl xanthate anion and the area (28 Å^2) occupied by this anion (arranged at right angles to the surface of the mineral particle) were found. These data established that at the initial concentrations of xanthate in the pulp usually employed in flotation, the quantity of sorbent attached to the surface of the mineral particles undergoing flotation in a number of cases is sufficient for the formation of 4–5 continuous monomolecular layers with close packing of the sorbent molecules.[122]

2. The rotation of atomic groups and molecules in crystals

The physicochemical properties of substances depend on the dynamics of the molecule, in particular on the rotation of individual groups or entire molecules. Crystals in which rotation of the molecules takes place differ considerably from ordinary crystals in a number of properties, primarily their plasticity.

The possibility that molecules rotate in a crystal can be estimated using VR. A classical example (one of the first) is provided by methane. Its crystals have a cubic face-centred cell with an edge of 6.35 Å. The shortest distance between the centres of the molecules is 4.49 Å, which is exactly equal to twice the quantity $r_{C-H} + R_H$ and indicates free rotation (without free rotation, the shortest distance between the centres of the molecules would be smaller, since according to the principle of close packing the van der Waals spheres of the H atoms should enter the cavities of neighbouring molecules). A similar calculation using VR was carried out[8] to prove the possibility of coordinated rotation of the molecules of methyl-, ethyl-, and propylmercury chlorides round one of the axes in the crystals. A particular case of the rotational-crystalline state is provided by the H-phase of n-alkanes, in which the molecules rotating about their long axis form a hexagonal arrangement corresponding to the close packing of cylinders.

Not only whole molecules, but also individual groups, may rotate in a crystal. Using the mean-statistical VR values of the atoms of fluorine and chlorine, Antipin and co-workers[123] found that in the structure of 2-trichlorophosphazo-2-trifluoromethylperfluoropropane $Cl_3P=N-C(CF_3)_3$ the trifluoromethyl groups mesh with one another like gears. This should restrict their movement mainly to twisting vibrations about the C–C bonds. An analysis of the non-valence contacts using VR made it possible to estimate the relative contributions of intramolecular and intermolecular forces to the barrier to the reorientation of these groups. The possibility of the rotation of other groups in molecules in crystals has been discussed, for example, in papers by Bokii and co-workers[124] and Gachegov and Soifer.[125]

In some systems, free rotation about a σ-bond is restricted by the approach of non-bonded substituents which would be impossible according to the corresponding VR values. In these cases the conformers are in fact isomers, and can be separated. Sometimes, steric hindrance to free rotation leads to the appearance of optical isomerism, and it becomes possible to separate the optical antipodes.

3. Organic conductors

In the case of isotropic metallic and ionic conductors, the conductivity is characterised by a fairly well studied three-dimensional band structure. Organic substances (charge-transfer complexes, radical-ion salts) usually show one-dimensional, or less frequently two-dimensional, conductivity, the interpretation of which requires an analysis of the molecular packing using VR. Various regular features of this conductivity, usually related to the stacked packing and the magnitude of the interplanar distance (the distance between the parallel planes of the molecules in contact), have been established.[126–128]

The one-dimensional character of the properties of most organic conductors is due to the characteristic features of their structures: the large planar molecules are arranged in stacks in such a way that the overlap of the electronic wavefunctions along the stacks is smaller by several powers of ten:[127] the conductivity electrons (π-electrons) move more readily along the stacks than between them.

The most familiar one-dimensional organic conductors are 7,7,8,8-tetracyanoquinodimethane (TCNQ) and its radical-ion salts, whose conductivity at room temperature reaches $10-10^2\ \Omega^{-1}\ cm^{-1}$. A characteristic feature of the crystal structures of these salts is the existence of a conducting system consisting of infinite stacks of TCNQ molecules, and the interplanar distance between the stacks is practically the same throughout the stack (3.22–3.26 Å) [126] and shorter than twice the VR of the carbon atom (3.42 Å). The increase in the interplanar distance TCNQ...TCNQ to 3.43 Å in the salt Pb^+TCNQ^- leads to a decrease in the conductivity to $10^{-2}\ \Omega^{-1}\ cm^{-1}$ (the other characteristics of the conducting quasi-one-dimensional structures are preserved).[129]

For other compounds with a quasi-one-dimensional electronic system, such as the radical-cation salts of tetrathiotetracene (TTT), tetraselenotetracene (TSeT), and tetrathiofulvalene (TTF), the condition for the production of high metallic conductivity is again the presence of conducting chains, that is regular radical-cation or radical-anion stacks with an interplanar distance which is the same throughout the stack and which is shorter than the ordinary van der Waals distance, and with neighbouring radicals superimposed in identical fashion. Important features for the stabilisation of the metallic state apparently include not only strong interactions within the conducting chain but also an additional strong interaction between the chains, as indicated by the contracted (compared with the sum of the corresponding VR) intermolecular contacts.[126]

Among the radical-cation salts of TTT and TSeT with a high conductivity ($10^3\ \Omega^{-1}\ cm^{-1}$ at room temperature), three complexes can be distinguished: $(TTT)_2I_3$, $(TSeT)_2Cl$, and $(TSeT)_2I$. In their crystal structures,[126] the shortest interplanar distances in the conducting stacks are 3.32, 3.37, and 3.40 Å respectively, whereas in the complexes of TTT these distances lie in the range 3.32–3.63 Å (twice the VR of sulphur is 3.68 Å), and in the TSeT complexes they lie in the range 3.37–3.53 Å (twice the VR of selenium is 4.00 Å [7]). Moreover, the structures of these three compounds contain extensively shortened intermolecular contacts: Se...Se 3.47 Å and 3.45 Å [in the stacks of $(TSeT)_2Cl$ and $(TSeT)_2I$ respectively] and S...S 3.38 Å [between the stacks in $(TTT)_2I_3$]. Similarly, in the regular radical-cation stacks of TTF in TTF–halogen complexes with different stoichiometry, the average interplanar distance (3.55 to 3.61 Å) is less than twice the VR of sulphur. The conductivity of almost all the complexes with non-stoichiometric compositions is $\sim 300-550\ \Omega^{-1}\ cm^{-1}$ at room temperature.[126]

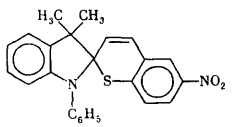
The discovery of the superconductivity of tetramethyltetraselenofulvalene hexafluorophosphate $(TMTSF)_2PF_6$,[130] and then of a whole series of related compounds $(TMTSF)_2A$, where A = ClO_4, AsF_6, SbF_6, etc.,[131,132] with superconducting transition temperature $T_c \simeq 1$ K, provided the starting point for a new stage in the study of organic conductors. These studies demonstrate the importance of VR in another field of the study of conductivity in organic conductors.

In the crystals of $(TMTSF)_2A$ the planar molecules form stacks extending along the *X* axis. For almost all pairs of Se atoms from neighbouring molecules along the *X* axis (within the stacks) and along the *Y* axis (between the stacks), the Se...Se distances (~ 3.9 Å)

are shorter than twice the VR of selenium. This suggests that the electrons can move fairly freely in the *XY* plane. This is confirmed by measurements of the anisotropy of the conductivity and the upper critical value of the magnetic field intensity.[128] The anions A are situated in the cavities formed by the packing of the zigzag conducting TMTSF chains. This quasi-one-dimensional metallic system is stabilised by pressure. If the VR of fluorine is taken as 1.4 Å, the diameter of the AsF_6 ion is close to 6.4 Å, and if the VR of oxygen is taken as 1.29 Å, the diameter of the ClO_4 ion is about 5.6 Å. The effect of the replacement of the AsF_6 ion in the $(TMTSF)_2AsF_6$ structure by the smaller ClO_4 ion is analogous to that of pressure; this 'chemical compression' gave the first organic superconductor at atmospheric pressure, $(TMTSF)_2ClO_4$.[131] The 'chemical compression' taking place when AsF_6 is replaced by PF_6 leads to equalisation of the lengths of the Se...Se contacts along the *X* and *Y* axes;[133] as a result, the difference in conductivity in these two directions is decreased. In the $(TMTSF)_2ClO_4$ crystals, the ratio of the dimensions of the cavities and the ClO_4 anions occupying them determines the types of ordering of the anions with decrease in temperature, and this has a significant influence on the change in properties.[127]

Superconductivity was later detected in a family of compounds, (BEDT-TTF)A. The molecule of BEDT-TTF (bis-ethylenedithiolotetrafulvalene) has eight S atoms in the conjugation chain. The change from TMTSF to BEDT-TTF made it possible to create organic conductors with even lower anisotropy. The crystalline salts of this family show a wide range of physical properties; they are capable of behaving as dielectrics, organic metals with a metal–dielectric transition, organic metals stable over a wide temperature range, and superconductors. In the investigation of the reasons for the difference in the conductivity of these substances, particular attention is paid to the intermolecular contacts S...S (of length ~3.7 Å or less) in and between the stacks.[134–139].

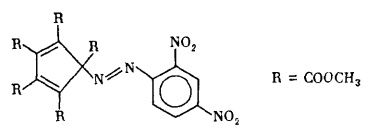
In the study of the conductivity of radical-ion salts, intermolecular (interionic) contacts S...S have been examined in other crystals, in particular in the structure of the tetraethylammonium salts of bis(1,3-dithiol-2-thione-4,5-dithiolato)gold(III).[140] Structures whose molecules contain both thio- and seleno-fulvalene rings, including the structure of bis-ethylenedithiodimethyldithiadiselenafulvalene tri-iodide,[141] in addition to S...S contacts, contain intermolecular Se...Se and S...Se contacts, close to the sums of the corresponding VR. Cation–anion contacts close to or shorter than the sums of the corresponding VR have also been analysed, for example S...I contacts with a length of 3.85 Å or less.[142]



V. Chemical reactions

The reactivity of a substance is often influenced by steric factors. In this connection, steric effects of the following types will be examined: 1) steric hindrance leading to the elongation of covalent bonds or to the distortion of valence angles, 2) the shielding or complete blocking of the active centre of a molecule, 3) steric factors determining the angle of nucleophilic of electrophilic attack, and other forms of the influence of steric factors on chemical processes.

The elongation of a covalent bond as a result of crowding in the molecule facilitates the rupture of this bond in a chemical reaction. Thus in the molecule of fluorene-9-spiro-1-(3,4-di-t-butyl)-3,4-diphosphetane-2-spiro-9'-fluorene[88] (see section III), the increase in the length of the bond between the spiro-atoms to 1.626 Å leads to a considerable decrease in its strength, and when the compound is brought into solution, the cyclic structure breaks down with the rupture of this bond, as confirmed by the EPR spectra.[143]



In the structure of 2,3-bis(trifluoromethyl)-2,3-bis(*p*-fluorophenyl)-hexafluorobutane,[90] the bonds in the central part of the molecule, in particular the central C–C bond (1.671 Å), are elongated considerably. Although in the opinion of the authors cited this cannot be due entirely to steric hindrance, the latter plays an important role, since the distances between the fluorine atoms of CF_3 groups in contact is 2.43–2.59 Å, which is much smaller than twice the VR of fluorine (2.80 Å). The authors cited[90] compared the properties of this compound with those of its analogue not containing F atoms (bicumyl), and noted the increased tendency of the fluoro-derivative to undergo dissociation to form radicals; for bicumyl this is not observed even at 200 °C. Similar easy rupture of an elongated single bond C–C 1.638 Å is also observed in the sterically crowded molecule of the thermally unstable 5,6-dibutyl-5,6-diphenyldecane (containing a number of short intramolecular contacts H...H of length 2.06–2.11 Å).[144]

Another example of a decrease in the strength of a bond elongated as a result of steric hindrance is provided by the molecule of 1'-phenyl-3',3'-dimethyl-6-nitrospiro(indoline-2,2'-[2H-1]-benzothiopyran).[145]

In this molecule, the length of the bond $C_{spiro}-S$ (1.866 Å) broken on photoexcitation is much greater than that of the corresponding bonds in six-membered heterocyclic compounds (1.80–1.83 Å [146]). The increase in length is due to the fact that the non-valence contact between the S atom of the benzothiopyran fragment and the C atom of one of the methyl groups of the indolene fragment (C...S 2.99 Å) according to Zefirov and Zorkii,[34] is 0.56 Å shorter than a normal S...C contact. In the opinion of the authors cited,[145] the photochemical properties of this molecule are explained by the vibrational mechanism of the rupture of the $C_{spiro}-S$ bond, which is elongated and weakened even in the ground state, and whose vibrations should be excited first.

Steric hindrance leading to the distortion of valence angles is also important, since under certain conditions it may initiate a chemical reaction at the corresponding site. An example is provided by an X-ray diffraction study[147] of 5-(2,4-dinitrophenylazo)-1,2,3,4,5-pentamethoxycarbonylcyclopentadiene.

As a result of steric hindrance (the shortest intramolecular distances C...N between valence-non-bonded atoms are 3.00 Å and 2.91 Å, whereas $2\sqrt{R_C R_N}$ = 3.20 Å), the valence angle CCN at the four-coordinate C atom is increased to 120°. The authors cited regard this feature as the factor responsible for the vigorous decomposition of the substance when heated to 100–110 °C. Moreover, the strain at this atom should facilitate the dissociation of the molecule in solution (at the C–N bond) to give an ion pair, whose recombination can take place at any of the carbon atoms of the cyclopentadiene ring.

The shielding of an active centre was dealt with by Bel'skii and co-workers,[148] who established by X-ray diffraction that in the molecule of 2,6-dicyano-3-trifluoromethyl-5-phenylaniline the distance between the H atom in position 4 of the aniline ring and one of the F atoms of a neighbouring trifluoromethyl group is 2.30 Å, and the distance from the H(4) atom to the nearest H atom of the phenyl substituent is 2.42 Å. Thus the hydrogen atom in position 4 is shielded by the trifluoromethyl and phenyl groups. As a result, electrophilic substitution cannot be carried out in position 4; in spite of numerous attempts, the authors cited could not obtain any 4-substituted aniline derivative of this type, whereas 3,5-dimethyl-2,6-dicyanoaniline readily undergoes electrophilic substitution.

It has been proposed[149] that the shielding of the metal atom in compounds MR_n can be estimated quantitatively using the solid angles, with vertices at the M atom, containing the inscribed R substituents, modelled by van der Waals spheres. The degree of shielding is characterised by the sum of these angles (the quantity Q), or more accurately by its approach to the total solid angle $4\pi \simeq 12.56$ rad. In the compounds $(R_3E)_2Hg$, where E = Si, Ge, Sn, the degree of shielding increases in the order R = Me, Ph, C_6F_5, which correlates with the decrease in reactivity, in particular the tendency to undergo oxidation. The fact that the value of Q is close to 4π indicates that the ligand environment of the metal is compact and hence stable. This explains, for example, the high thermal stability of $Ti(CH_2SiMe_3)_4$ and $V(CH_2SiMe_3)_4$, for which Q is 11.7 rad and 12.6 rad respectively, and the low stability of $TiMe_4$ (Q = 8.8 rad, decomposition temperature −40 °C) and $TiPh_4$ (Q = 9.3 rad, decomposition temperature −10 °C). It was suggested[149] that the value of Q can also be used to estimate the possible existence in principle of molecules of the type MR_n. A value in excess of 12.56 rad indicates steric strain, and a value which is much higher shows that the molecule cannot exist, for steric reasons. For example, in the hypothetical molecule $Ta(CH_2SiMe_3)_5$, the value of Q is 14.7 rad,[149] which is much greater than 4π. In fact, this compound has not yet been synthesised, despite repeated persistent attempts.[150] Another compound which has not been obtained is $(\pi\text{-Cp})_2CrCl_2$,[151] for which Q = 14.02 rad.

The VR of fluorine has been used[152] to illustrate that the ion NF_6^- cannot exist, in contrast to the PF_5 molecule and the PF_6^- ion. In the last two cases the overlap of the van der Waals spheres of the F atoms is extremely slight, whereas in the hypothetical NF_6^- ion it would be too great (summation of the covalent radii gives the distances P−F 1.74 Å and N−F 1.34 Å).

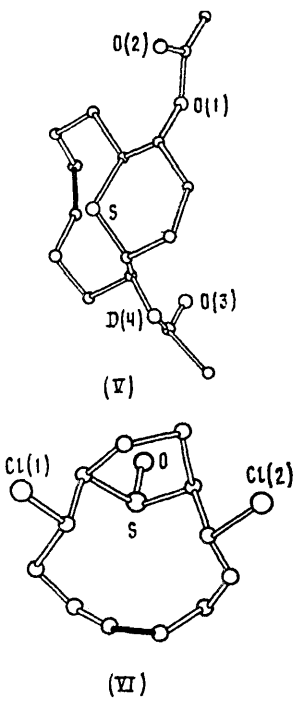
VR have also been used[153] for qualitative and quantitative estimates of the accessibility of the reaction centre in trityl ethers of sugars with the general formula Ph_3C-O-R, where R represents different sugars. A study of the spatial environment of the nucleophilic active centre—the ether oxygen atom—using Stuart–Briegleb models, based on X-ray diffraction data,[154,155] showed that in all the molecules studied the active centre is open only on the side of the vertex of the angle at the ether oxygen atom (the opposite side is completely shielded by one of the phenyl rings of the trityl group). Assuming that the glycosylating agent approaches the active centre chiefly along the bisector of the angle indicated on the side of its vertex, the authors cited[153] compared the degree of shielding of the ether oxygen atom in this direction in different molecules Ph_3C-O-R. For this purpose, three-dimensional models of the molecules were projected in the direction of the bisector of the $C-O-CPh_3$ angle. Analysis of the projections showed that in all cases the trityl group shields ~40% of the area of the active centre. In the molecule of 3-O-acetyl-4-O-trityl-1,2-O-[1-(*exo*-cyano)-ethylidene]-β–*L*-ramnopyranose, however, the active centre is shielded for the most part only by the trityl group (the shielding by H atoms is slight, and this shielding is easily removed by the conformational mobility). At the same time, in other molecules of this type, the active centre is more extensively shielded, both by the trityl group and by the O and C atoms of the sugar residue. To estimate quantitatively the degree of shielding of the active centre by the method proposed by Zakharov and co-workers,[149] three-dimensional models of the molecules were projected on a cylinder whose axis coincided with the bisector of the $C-O-CPh_3$ angle. According to the calculations, the above molecule allows practically free approach of the glycosylating agent to the active centre, whereas in the other cases, contact between the reagents is possible only for a definite relative orientation, so that the probability of effective collisions of the reacting molecules is lowered. This facilitates the competing reaction of isomerisation to give the glycosyl cation, which gives the 1,2-*cis*-bonded anomers.

An interesting example of the use of VR to analyse the chemical properties of molecules was described by Chernega and co-workers.[156] The sterically strained molecule of $(Me_3Si)_2N-P=N'-C_6H_2(t\text{-}Bu)_3$ (I) contains exclusively shortened contacts P...C (t-Bu) (3.26 Å and 3.37 Å; sum of the VR 3.60 Å [7]), and also a shortened Si...N contact (3.23 Å; sum of the VR 3.60 Å [7]). As a result the P=N′ (1.566 Å) is ~0.02 Å longer than the corresponding bonds P=N′ (1.544 Å and 1.545 Å) in the compounds $(Me_3Si)_2N-P=N'-SiMe_3$ (II) and $(Me_3Si, Me_3C)N-P=N'-CMe_3$ (III). Nevertheless, the reactivity of the first compound towards proton-donor reagents (alcohols, amines) is much lower than that of the last two compounds, and, moreover, compound I can be heated to 250 °C with no sign of dimerisation, in contrast to known λ^3-aminoiminophosphines, including compounds III and II, that is it has an exceptionally high thermal stability. This can be attributed to the fact that the atoms which elongate and weaken the P=N bond shield it at the same time. To investigate the magnitude of this shielding and how it changes when R′ = 2,4,6-$(t\text{-}Bu)_3C_6H_2$ is replaced by R″ = $SiMe_3$, the authors cited[156] used the program CRON [149] to calculate the projections of these substituents on a cylinder of unit radius with axis coinciding with the P=N′ bond. The calculations showed that the shielding of the P=N′ bond by R′ is ~1.5 times greater than that by R″. The greatest difference in the degree of shielding is observed in the region adjoining the P atom, that is on the side of the centre at which proton-donor reagent attack takes place. The sum Q of the solid angles with vertex at the P atom, calculated by the methods described,[149,157] is 4.4 rad for the substituent R′, and 2.4 rad for R″.

An analysis of the non-valence interatomic contacts has been used[158] to determine the angles of electrophilic and nucleophilic attack in reactions involving a divalent sulphur atom. The angular distribution of 169 S...X contacts smaller than the sum of the VR in organic, organometallic, and inorganic compounds of divalent sulphur (Y−S−Z) was studied. The authors cited suggested that when the attacking atom X is electrophilic, it approaches the S atom along a direction forming an angle of ~20° with the perpendicular to the Y−S−Z plane; if however, the X atom is nucleophilic, then with certain exceptions it approaches the S atom along the continuation of one of the valence bonds.

Another example of the influence of geometric characteristics, analysed using VR, on the chemical properties of molecules is provided by an X-ray structural study[159] of 2,10-diacetoxy-13-thia-bicyclo[7,3,1]-*cis*-tridec-5-ene sulphide and 2,9-dichloro-13-thia-bicyclo[8,2,1]-*cis*-tridec-5-ene sulphoxide (Fig. 3). In both molecules, the intramolecular distances between the S atom and the opposite C

atoms forming double bonds in the macrocyclic rings are only slightly greater than the value characteristic of the van der Waals contact C...S (3.55 Å), by 0.14 Å and 0.22 Å in the first case, and by 0.24 Å and 0.44 Å in the second. Moreover, in both cases the lone pairs of electrons of the S atoms are directed towards the C=C double bond. As a result of this conformation, the molecules being considered are 'prepared' for *trans*-annular transformations, which take place with these compounds under the influence of various reagents.



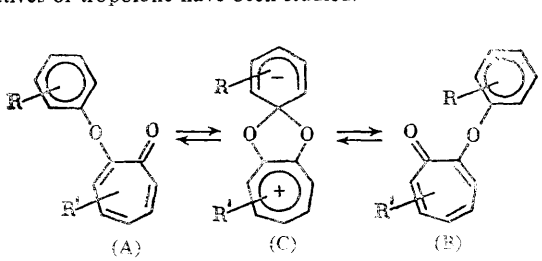


Figure 3. Conformations of the sulphide and sulphoxide molecules[159] (the double bonds are black).

In recent X-ray diffraction studies, the change in the geometry of molecules with similar compositions in an appropriately selected series of compounds is regarded as providing a model of the three-dimensional change in a molecule during a chemical reaction (mapping the course of chemical reactions). These studies have been described by Furmanova and Kompan.[160] The parameter used to follow the 'movement' of the system along the reaction path is often the distance between two atoms which initially are not bonded but which are joined by a valence bond as a result of the reaction.

In particular, the arylotropic rearrangements in O-nitroaryl derivatives of tropolone have been studied:[161,162]

By varying the number of positions of the substituents in the six- and seven-membered rings, a series of compounds was obtained, illustrating the course of the reaction (A) ⇄ (B), including the formation of the intermediate [the spiro-complex (C)]. In the molecule of S-(2′,4′,6′-trinitrophenyl)thiotropolone,[161] which has the *trans*-configuration, the torsional angle C(O)−C−S−C(Ar) (the angle φ) is 170°, the O...C(Ar) distance is greater than 4 Å, and the steric requirements for intramolecular *trans*-arylation are not satisfied. In O-(2′-nitro-4′-trifluoromethylsulphonylphenyl)-3,5,7-trimethyltropolone,[161] the aryl ring is rotated towards the carbonyl O atom (φ = 77°), and the distance O...C(Ar) 2.94 Å is practically equal to the normal van der Waals contact 2.97 Å, that is this structure is already prepared for the tautomeric transformation. The crystal of O-(2′,4′,6′-trinitrophenyl)tropolone,[161] contains two crystallographically independent molecules with similar geometric parameters; the O...C(Ar) distances in them (2.56 Å and 2.52 Å) are extensively shortened, indicating an attractive interaction between these atoms, that is the start of the formation of a new bond; the angle φ has the value 28.9° and 10.2° respectively. The O...C(Ar) distance is shortened to an even greater extent (to 2.45 Å) in the molecule of O-(2′,6′-dinitrophenyl)-3,5,7-trimethyltropolone,[162] where φ = 2°. The angle between the straight line O...C(Ar) and the plane of the aryl ring is 107.5°, and there is appreciable breakdown of the coplanarity of the covalent bonds at the C(Ar) atom, which is displaced from the plane of the atoms joined to it by 0.09 Å towards the carbonyl O atom. All this is characteristic of nucleophilic attack at an sp^2 carbon atom. Finally, the molecule of O-(2′,4′,6′-trinitrophenyl)-3,5,7-trimethyltropolone [162] has the structure of the spirocyclic intermediate of type (C) [in it, both O...C(Ar) distances are 1.47 Å].

Another example of the analysis of a reaction path using X-ray diffraction data is given by Sitkina and co-workers,[163] who regarded the molecule of 4-chlorophenylamino-3-acetoxy-1-methylindole-2-carboxaldehyde as a geometric model of the initial stage of the formation of the transition state of the inverse dark reaction of O → N transfer of the acyl group in O-acylated imines. In this molecule, the distance between the nucleophilic N atom and the migrating C atom is shortened to 3.02 Å (normal contact N...C 3.20 Å), indicating a weak attractive interaction.

Some of the above examples can be regarded as illustrating the influence of the three-dimensional structure of molecules, in particular the shielding of the reaction centres, on the rate of a chemical reaction.

The quantitative dependence of the reaction rate constant k on steric factors is given by the Taft equation[164] $\lg(k/k_0) = \Delta E_S(X)$, where $E_S(X)$ is a parameter characterising the steric effect of the substituent X. E_S is linearly dependent on the VR.[165] Subsequent studies[166] examined the parameter ν_X, the difference between the VR of the substituent X and the H atom: $\nu_X = R_X - R_H = R_X - 1.20$ Å. Using this parameter, the rate of esterification of substituted carboxylic acids by methanol or ethanol was described[167] by the modified Taft equation $\lg k = \psi\nu_X + h$, where ψ and h are empirical constants.

The changes in the reactivity of the chlorides of phosphoric and thiophosphoric acids $P(O)Cl_3$, $(RO)_nP(O)Cl_{3-n}$, and $(RO)_nP(S)Cl_{3-n}$, where n = 1, or 2, in the stepwise alcoholysis of aliphatic alcohols ROH (R = Me, Et, Pr, Iso-Pr, Bu, iso-But) have been analysed.[168] Assuming that the change in the reactivity of the reagents is due to steric factors, the authors cited took as a measure of the steric effects the values of ν given by Charton.[169] The relative reactivity in series with identical substituents in the two reagents is effectively described

by the equation $\lg k = av + b$, and in series with independent variation of the groups RO in the chlorides and R'O in the alcohols it is described by the equation

$$\lg k = av(\mathrm{OR}) + bv(\mathrm{OR}') + c,$$

where a, b, and c are constants.

The rate constants of bimolecular reactions have been calculated successfully[170] using the equation

$$k_{12} = \frac{(\sigma_1 + \sigma_2)^2}{4M^{1/2}} 0.1838 \cdot 10^{27} \exp(-B/T)T^{1/2}\left\{1 - \frac{C}{T}\left[1 + \frac{B}{T} - \frac{B^2}{T^2}\right]\right\},$$

where σ is the diameter of the species, calculated using the VR; M the reduced molecular mass $M_1M_2/(M_1 + M_2)$; and B and C are parameters calculated by the method described by Evdokimov.[170] The values of k were found (with a deviation of ~30% from the experimental values) over a wide temperature range up to 8000 K for the reactions

$$\mathrm{N} + \mathrm{O_2} = \mathrm{NO} + \mathrm{O},\ \mathrm{O} + \mathrm{O_3} = 2\mathrm{O_2},$$
$$\mathrm{Cl} + \mathrm{H_2} = \mathrm{HCl} + \mathrm{H},\ \mathrm{CO_2^{\cdot}} + \mathrm{N_2} = \mathrm{CO_2} + \mathrm{N_2^{\cdot}}$$

and other reactions. The results give correctly the temperature dependence of the rate constants.

VR are often used to determine the steric conditions under which solid-phase reactions of a particular type are possible. Thus in a study of the photo-isomerisation of naphthoquinone derivatives in the crystalline state[171] it was found that intramolecular transfer of the hydrogen atom takes place at distances comparable with the sum of the VR of the interacting atoms. According to data given by Shklover and co-workers,[172] solid-phase polymerisation in which a bond is formed between the atoms A and B of neighbouring molecules is possible if the distance R_{AB} does not exceed the quantity $(R_A + R_B + 0.5)$ Å.

An analysis of the intermolecular contacts in a hypothetical layer of molecules of 4,4'-diazidobiphenyl ($N_3-C_6H_4-C_6H_4-N_3$) (the structure of this layer was found by calculation using the method of flow trajectories and atom–atom potentials) made it possible to interpret the mechanism of the solid-phase polymerisation, accompanied by photolysis with the removal of two N_2 molecules and the formation of a nitrene radical.[173] The distance between the central N(1) atom of the azide group of one molecule and the N(2) atom joined to the aromatic ring of a neighbouring molecule is 3.0 Å, that is it is equal to the VR of the nitrogen atom. At the same time, the distance between N(2) and the nearest H atom of a neighbouring molecule (4.4 Å) is much greater than the length of the normal contact between these atoms (2.64 Å). This structure of the crystal should facilitate the reaction of the nitrene with the azide group of a neighbouring molecule and creates definite hindrance for the reaction with the removal of hydrogen; this is confirmed by analysis of the photolysis products.

Van der Waals radii have been known for more than 50 years. They first appeared in crystal chemistry, and have subsequently found extensive application in the most varied branches of physical chemistry, in particular in the study of the mechanism of chemical reactions. The present review is the first attempt to present this topic systematically, and it naturally does not deal with all methods (and all conceivable methods) of using this simple and extremely effective concept. The material presented, however, demonstrates the variety of chemical applications of van der Waals radii.

I. Introduction

The industrial production of enriched uranium is based on gas diffusion (GD).[1] In many countries, however, an intensive search is being carried out to find other methods of enrichment making it possible not only to lower the cost per separative work unit (kg S. W. U.) but also to decrease considerably the consumption of raw material and energy.[1–3] As alternatives to GD, methods based on the use of the centrifuge, lasers, effusion phenomena, a rotating plasma, and chemical isotopic exchange (CIE) are being examined.[2,3] Their theoretical principles and the possibility of their practical application have been examined in a number of reviews,[2–12] and there is an extensive patent literature. The greatest interest in CIE is being shown in Japan and France,[5,6] but published systematic reviews of this topic are inadequate. Some publications[3,5,12–18] deal only with individual aspects of the use of CIE to separate uranium isotopes, and ten years have passed since the publication of the review by Filippov and co-workers,[6] which deals most fully with this problem. In this period, many new and interesting publications have appeared, which not only develop the ideas presented in earlier work but also propose various fundamentally new approaches to the solution of the problem of separating uranium isotopes by chemical methods.

Of all the methods used to separate uranium isotopes, only CIE does not require the use of gaseous compounds or the atomic vapour of uranium. The regular features observed in the isotopic enrichment of uranium by CIE may be useful in the development of methods for separating the isotopes of heavy elements which for any reason do not form stable volatile compounds.

The aim of the present review is to analyse published data on the separation of uranium isotopes by chemical isotopic exchange and to compare promising methods for enriching uranium.

II. Theoretical principles of the separation of uranium isotopes by chemical isotopic exchange

In principle, chemical methods for separating isotopes may be based on kinetic or thermodynamic isotope effects arising in chemical transformations. In both cases the magnitude of the isotope effects is determined by the differences in the zero-point energies of the vibrations of the bonds in the isotopic molecules involved in the reactions.[1,19] Since the difference in the masses of the isotopic forms of molecules or ions is small, the interatomic distances and force constants of the bonds can with good accuracy be regarded as invariant.[19]

The CIE methods used at present are mainly based on thermodynamic isotope effects, since a single separation step is reversible. In this case the separation of isotopes can easily be made a multi-stage process by using counter-current separating systems. Moreover, the expenditure of energy in these processes is determined chiefly by the organisation of the phase reversal.[19]

In schemes for enriching uranium by CIE, the most widely encountered systems are those in which the isotopic exchange takes place between forms which do not react chemically and which are selectively distributed between two phases. The equilibrium constant of the isotopic exchange reaction (K) and hence the isotope separation coefficient (α) can be calculated by statistical thermodynamics.[1,19] In particular, for the heavy hydrogen isotopes, use is made of the approximate Bigeleisen–Mayer equation,[19] from which it follows that the values of $\ln\alpha$ are proportional to the square of the reciprocal of the mass of the isotope. Thus for CIE reactions in uranium compounds, very low values of α can be expected. The observed isotopic effects can be increased, however, by making use of complex processes in which the values of α for the elementary reactions act in the same direction and increase the overall effect. To determine the regular features of the change in the values of α in CIE processes, it has been proposed that isotopic exchange reactions be classified using three factors: the oxidation state of the element, the nature of the coordinated ligand, and the configuration of the coordination sphere.[20–22] The highest values of α should be achieved in systems in which the compounds being compared differ from one another to the greatest extent in terms of all three factors. The element in the

higher oxidation state should be combined with σ,π-donor ligands (N, O, F), and should form an unsaturated coordination sphere. For the element in the lower oxidation state, the coordinated ligands should have σ,π-donor and weak π-acceptor properties (Cl, Br, I, S, Se), and the coordination sphere should be close to saturation. Under real conditions, only a certain approximation to the optimum systems is possible, since the selection principles are contrary to the requirements for thermodynamic stability. Systems containing elements in different oxidation states are most promising, systems containing complexes with different configurations occupy second place, and systems differing only in the ligands are least promising.

A theoretical analysis of the values of α in isotopic fractionation in $U^{IV}-U^{VI}$ systems has been carried out.[23-26] The values of K have been calculated for the reactions:[23]

$$[^{235}U(H_2O)_8]^{4+} + [^{238}UO_2]^{2+} \rightleftarrows [^{238}U(H_2O)_8]^{4+} + [^{235}UO_2]^{2+},$$
$$^{235}U(H_2O)_4Cl_4 + [^{238}UO_2]^{2+} \rightleftarrows {}^{238}U(H_2O)_4Cl_4 + [^{235}UO_2]^{2+}.$$

At 20 °C, ^{235}U should be concentrated as UO_2^{2+} if the distances $U-H_2O$ in $[U(H_2O)_8]^{4+}$ and $U(H_2O)_4Cl_4$ are shorter than 2.26 Å and 2.30 Å respectively. X-Ray diffraction data indicate that these conditions are satisfied. The wavenumbers of the doubly degenerate (ν_2) and antisymmetric (ν_3) vibrations of the U−O bonds have been used to calculate the ratios of the reduced partition functions (RPF) of the UO_2^{2+} ion in its compounds with ClO_4^-, Cl^-, NO_3^-, and SO_4^{2-}.[24] The contribution of ν_3 to the RPF is 85% at 25 °C, and increases with increase in temperature. The equilibrium constants of the CIE reactions involving UO_2^{2+} are sensitive to changes in ν_2 resulting from complex formation. The separation coefficient for the isotopes ^{235}U and ^{238}U in U^{IV}–U^{VI} systems in the presence of cation exchangers is given by the expression[25,26]

$$\ln\alpha = \ln\alpha' + \ln[1 + (K-1)/(1+\bar{\rho})] + \ln[1 + (K^{-1}-1)/(1+\rho)], \quad (1)$$

where α' is the separation coefficient for the system containing only uranyl ions, K the equilibrium constant of the CIE reaction between U^{IV} and U^{VI} in solution, and ρ and $\bar{\rho}$ the molar ratios of U^{VI} and U^{IV} in solution and in the ion exchanger respectively.

It follows from Eqn. (1) that the influence of K on α is greater, the greater the difference between ρ and $\bar{\rho}$, that is the higher the selectivity of the sorption of the ionic forms of uranium. The concentration profiles of the elution curves, and equations relating the concentrations of the ith isotope to the position of the band in the column have been obtained, and the way in which the overall separation coefficient is related to the local values of α and the time taken to establish the steady state has been determined.[26,27]

To select the best method for separating uranium isotopes, it is also necessary to take account of economic factors. It has been suggested[5] that to be competitive, CIE methods must satisfy the following requirements:

1) the values of α should be not less than 10^{-3};

2) the chemical forms taking part in the exchange should be stable and should be distributed selectively between the phases;

3) the time for which uranium is involved in an elementary step should not exceed 1 min;

4) an effective means of phase reversal must be available.

The average consumption of energy should be about 5 eV per atom for reflux streams of high intensity.

III. The separation of uranium isotopes by ion exchange

1. Reactions involving U^{VI}

The results of experiments on the separation of uranium isotopes in a system formed by a uranyl salt solution and a sulphonic acid cation exchanger were published in 1954.[28] UO_2^{2+} was eluted through a column of Dowex 50 × 8 resin (50–100 mesh) in the Cu-form using a 5×10^{-3} M solution of $(NH_4)_2MgA$, where H_4A = EDTA. For a UO_2^{2+} band length of 28 cm and a migration distance of 90 cm, the specimen was enriched in the ^{235}U isotope from 4% to 5% at the front of the band. The isotopic fractionation took place as a result of the isotopic exchange reaction

$$[^{238}UO_2A]_s^{2-} + [^{235}UO_2]_r^{2+} \rightleftarrows [^{235}UO_2A]_s^{2-} + [^{238}UO_2]_r^{2+},$$

where the subscripts 's' and 'r' refer to the solution and resin phases respectively. In this system, phase reversal is described by the following equations:

$$[UO_2A]_s^{2-} + Cu_r^{2+} \rightarrow [UO_2]_r^{2+} + CuA^{2-} \text{ (sorption)}, \quad (2)$$
$$[UO_2]_r^{2+} + (NH_4)_2MgA \rightarrow [UO_2A]_s^{2-} \text{ (desorption)}. \quad (3)$$

Equilibria (2) and (3) are displaced to the right, so that both band fronts remain sharp during the elution, and no change in the band length takes place. This method of elution was called the Spedding method, after one of the authors.[28] In the process studied, the value of α for $^{235}U/^{238}U$ reached 1.002. It was later established[29] that in fact, $\alpha = 1.00006 \pm 0.00005$. The Spedding method has also been used to study isotopic replacement reactions in a cation exchanger–solution system using a column of length 1–2 m filled with Amberlite IR-120 or Dowex 50 × 8 resin in the H^+-form.[30] The sorption was carried out from $UO_2(NO_3)_2$, UO_2Cl_2, $UO_2(ClO_4)_2$, and $UO_2(SO_4)$ solutions. Solutions of ammonium acetate, citrate, and tartrate were used as eluants. The values of α obtained varied in the range 1.0001–1.0004. The values of α obtained using Dowex 50 × 8 resin were higher than those obtained using Amberlite IR-120.

Table 1. Isotopic enrichment in UO_2^{2+}–cation exchanger systems.[31-34]

Eluant	pH	Rate of elution, ml h^{-1}	Length of migration, cm	Rate of movement of the band, cm h^{-1}	$10^4\,\varepsilon$
Perchlorate	—	—	—	—	0.0±0.1
Chloride	7	9.5	197	1.85	0.25±0.1
Tricarballylate	—	—	—	—	0.66±0.1
Acetate	5	6.9	197	0.51	0.88±0.1
Glycollate	7	7.8	198	0.83	1.03±0.1
Lactate	7	7.0	203	0.80	1.42±0.15
Citrate	—	—	—	—	1.80±0.15
Malonate	7.5	6.3	200	1.4	2.18±0.2

Note. LS-6 cation exchanger (H^+-form, 100–200 mesh), 25 °C, column diameter 1 cm, eluant concentration 0.1 M; $\varepsilon = \alpha - 1$.

The Spedding method has been used to study the isotopic fractionation of uranium in a uranyl–cation exchanger system with elution by solutions of ammonium carboxylates or $NiCl_2$.[31-34] The results are given in Table 1. Enrichment in ^{235}U takes place at the

elution front, that is the carboxylate form of the uranyl complexes is enriched. The correlation between $\varepsilon = \alpha - 1$ and the wavenumbers ν_3 (cm^{-1}) of the antisymmetric vibrations of the UO_2^{2+} group in the complexes is given by the equation

$$\varepsilon = 4.62 \cdot 10^{-6}(960 - \nu_3),$$

where 960 cm^{-1} is the value of ν_3 in the resin phase. The data in Table 1 show good agreement with the results of a study[35] in which the eluant used for UO_2^{2+} sorbed on Dowex 50 resin was 0.07–0.22 M ammonium α-hydroxyisobutyrate solution (pH 2–6). The enrichment in ^{235}U took place in the solution phase, and the value of ε, $(1.9–0.6) \times 10^{-4}$, depended on the pH of the eluant.

The isotopic fractionation of uranium in UO_2^{2+}–cation exchanger systems with desorption by complex-forming reagents is also being studied in China.[36] It has been found[37] that the isotopic effects in UO_2^{2+}–anion exchanger systems are lower than those in cation-exchange chromatography.

Table 2. Isotopic fractionation of uranium in U^{IV}–cation exchanger systems.[38–41]

Eluant solution	Temperature, °C	Percentage cross-linking of resin	Length of column, m	Enrichment in $^{235}U^*$ relative to natural uranium, %
0.3 M NH_4Cl, HCl	30	10	12	4.9
0.45 M NH_4Cl, HCl	60	12	12	5.5
0.4 M NH_4Cl, HCl	—	15	12	6.2
0.15 M Na_2SO_4	40	20	10	3.3
0.2 M Na_2SO_4	30	16	10	2.9
0.2 M NaCl, 0.28 M HCl	—	20	8	2.8
0.2 M NaCl, 0.27 M HCl	—	10	5	1.4
0.28 M HCl	—	16	12	2.4
0.18 M H_2SO_4	35	16	10	2.0
1 M H_2SO_4	—	5	10	1.5
0.01 M NaF, 0.5 M H_2SO_4	—	—	4	1.1
Lactic acid 0.6 M	30	10	10	4.2
Sulphosalicylic acid 0.4 M	75	15	10	5.1
Citric acid				
0.1 M	60	12	10	4.6
0.5 M	—	—	4	0.8

*The enrichment takes place in the 'trailing' part of the elution curve.

2. Reactions involving U^{IV}

Japanese workers[38–41] have developed methods for separating uranium isotopes in U^{IV}–cation exchanger systems with elution by various complex-forming reagents (Table 2). Strongly acidic styrene–divinylbenzene cation exchange resins with different degrees of cross-linking have been used. In contrast to the systems containing UO_2^{2+}, with U^{IV} the enrichment in ^{235}U takes place in the resin phase, and the values of ε are lower for U^{IV} than for the uranyl ion. If U^{IV} is desorbed using pure H_2SO_4 solutions, marked spreading of the uranium zone is observed, so that solutions of $MgSO_4$ or an $H_2SO_4 + MgSO_4$ mixture have been proposed as eluants.[39,40] The value of ε when an $MgSO_4 + H_2SO_4$ mixture was used was 5×10^{-5}.[39]

In the elution of U^{IV} with solutions of citric,[41] malonic, and lactic[42] acids, the elementary separation coefficient decreases with increase in temperature. The values of ε are approximately the same for all three acids. The value for citric acid is 6×10^{-5} at 50°C.[41]

A method for separating uranium isotopes in a U^{IV}–anion exchanger system has been patented.[43] Uranium(IV) was sorbed on a chloromethylated or aminated styrene–divinylbenzene anion exchange resin from a solution containing NH_4HSO_4. The uranium was desorbed using an $NH_4HSO_4 + H_2SO_4$ mixture. In a column of length 10 m, enrichment in the ^{235}U isotope by 10% relative to the original concentration took place at the front of the elution curve.

Thus the single-stage separation coefficients of uranium isotopes in ion-exchange systems containing different ionic forms of the metal in the same oxidation state are too low for these systems to be used on the industrial scale. Recently, however, systems in which the enrichment coefficient ε reaches 10^{-3} have been found. Thus in the isotopic exchange reaction between U^{VI} extracted by a 0.1 M solution of the macrocyclic polyether dicyclohexyl-18-crown-6 in 1,2-dichloroethane and U^{VI} in an aqueous solution containing 3.1–3.9 M HCl, enrichment of the organic phase in the ^{235}U isotope was observed, and the calculated value of α was 1.002 ± 0.004.[44] In the corresponding system containing U^{IV}, enrichment of the organic phase in the light isotope was again observed, and the coefficient α was 1.001 ± 0.0003.[45] An interesting feature is that the separation coefficients for $^{235}U/^{238}U$ and $^{40}Ca/^{42}Ca$ in the systems containing the crown ether were found to be close to one another ($\alpha = 1.0010 \pm 0.0002$ for $^{40}Ca/^{42}Ca$).[46] The reasons for these high isotopic effects in the uranium systems are not yet clear.

IV. The isotopic fractionation of uranium in electron exchange processes

1. The U^{IV}–U^{III} system

The values of α can be increased considerably by using systems in which uranium is present in different oxidation states in the compounds undergoing exchange. The U^{IV}–U^{III} system has been proposed as one such system.[47–51] The different oxidation states are separated using ion exchange resins[47] or various extracting agents.[47–51]

In the ion exchange method, U^{IV} is sorbed from 8 M HCl solution, and U^{III} remains in the aqueous phase. When a cation exchanger is used, U^{III} is sorbed, and U^{IV} remains in the aqueous solution containing 0.25 M H_2SO_4. In both cases, U^{IV} is enriched in the ^{235}U isotope. The values obtained for α were 1.0024 and 1.0020 for the anion exchanger and the cation exchanger respectively. In practice, it is difficult to use ion exchangers, because of the instability of U^{III}.

It is recommended that in extraction systems, U^{IV} be transferred to the organic phase as its complexes with alkyl phosphates, phosphine oxides, phosphonates, or phosphinates. The organic diluents used are benzene, toluene, dodecane, or kerosene. The results of the experiments are given in Table 3. The isotopic fractionation involves the reaction

$$^{235}U^{III}_{aq} + {}^{238}U^{IV}_{org} \rightleftarrows {}^{235}U^{IV}_{org} + {}^{238}U^{III}_{aq}.$$

Since appreciable rearrangement of the structure of the species involved in the exchange is not required, this reaction is rapid, and its kinetic charactersitics are determined by the inter-phase transfer time. Irrespective of the extracting agent, the U^{IV} compound is enriched in the light isotope ^{235}U.

It is desirable that the separation of uranium isotopes in extraction systems be carried out by the counter-current method; the aqueous phase should contain 0.1–2.5 M UCl_3 and 4–9 M HCl, and the organic phase 0.1–1 M U^{IV}. To prevent the oxidation of U^{III}, the process must be carried out in a nitrogen atmosphere, and the reagents should be free from ions which catalyse the oxidation of U^{III}. It has also been suggested that reagents combining with oxygen should be introduced into the system.

It is recommended that phase reversal be carried out electrochemically.[51] Zinc amalgam (1.1–1.8% Zn) can be used as the cathode to reduce U^{IV} in the aqueous phase. The solution used for the electrolysis should contain 4–5 M $ZnCl_2$. Under these conditions, liberation of gas does not take place in the reduction of U^{IV}. The anode for oxidising U^{III} may consist of lead, lead amalgam, graphite, mercury, or tantalum; the best characteristics are shown by lead.

2. The CHEMEX process

In 1977 it was reported that an industrial method had been developed in France for obtaining uranium with a low degree of enrichment (up to 3.5% ^{235}U) from natural raw material by isotopic exchange in an extraction system (the CHEMEX process).[52] Later, various characteristics of this process were described in more detail.[18,53–56] The isotopic exchange between U^{IV} in the organic phase and U^{III} in the aqueous phase is carried out in plastic pulsation counter-current columns with a diameter of 1.2 m and a height of 30 m. Organophosphorus compounds are used as the extracting agents. The rate of the overall process is determined by the kinetics of inter-phase transfer. The kinetic charactersitics give an efficiency of up to 200 kg S. W. U. per year for a column volume of 1 m^3. The value of the single-stage separation coefficient reaches 1.0025. Phase reversal is achieved electrochemically in a cell with a graphite anode and a dropping mercury cathode. U^{IV} is reduced in the aqueous phase. The self-oxidation of U^{III} is prevented using a patented method.[50] The overall scheme of the CHEMEX process is shown in Fig. 1.

The cascade for the production from natural uranium of 250 000 kg S. W. U. per year of product with an enrichment of 3.5% in ^{235}U includes 20 identical extraction columns. The production of 50 tons of uranium with an enrichment of 3.5% requires 250 tons of natural uranium. 200 tons of depleted uranium (0.2% ^{235}U) are produced. The output is doubled by combining two identical cascades in a module (Fig. 2). The expected energy consumption is 300 kW per kg S. W. U.

The French Atomic Energy Commission proposes in 1990 to begin the construction of a plant with a capacity of 10^6 kg S. W. U. per year, consisting of two parallel modules and containing 80 exchange columns. The contruction will cost 25–30 million dollars. To develop the method, a model assembly was constructed in 1970, and in March 1985 a pilot plant consisting of a module with dimensions one tenth of those of the industrial assembly was brought into operation in Pierrelatte.[51] The main disadvantages of the method are in the loss of uranium in the technological cycle, and the low rate of the process, which requires the use of large-scale equipment and large quantities of uranium. The time required for the equilibrium state to be established is several months.

3. The $U^{IV}-U^{VI}$ system

a) The kinetics of electron transfer between U^{IV} and U^{VI}

In the development of the Manhattan project, it was established[58] that the equilibrium constant (K) of the exchange reaction

$$[^{238}UO_2]^{2+} + {}^{235}U\,(IV) \rightleftarrows [^{235}UO_2]^{2+} + {}^{238}U\,(IV) \qquad (4)$$

differs from 1 and is equal to 1.0012–1.0013. At that time, however, this reaction could not be used to obtain enriched uranium, because of the low values of the enrichment coefficient and the very long equilibration time.

Table 3. Separation of uranium isotopes by extraction in the $U^{IV}-U^{III}$ system.[50]

Extracting agent*	Diluent	Concentration of U^{IV} in the organic phase, M	Composition of the aqueous phase	Temperature, °C	Phase contact time, s	α
TBP	benzene	0.4	0.4 M U(III), 7 M HCl	21	15	1.0030
TBP (50%)	dodecane	0.2	0.2 M U(III), 7 M HCl	—	49—132	1.0026
TBP (40%)	kerosene	0.4	0.4 M U(III), 7 M HCl	21	15	1.0025
TBP (42%)	xylene	0.42	2.35 M U(III), 0.13 M U(IV), 1.55 M HCl	35	30	1.0028
TBP (50%)	toluene	0.42	0.4 M U(III), 8 M HCl	—	30	1.0026
n-Butyl di-isobutylphosphonate (40%)	dodecane	0.55	1 M U(III), ** 0.125 M U(IV), 4.6 M HCl	20	60	1.0025
TOPO (10%)	toluene	0.12	0.11 M U(III), 0.01 M U(IV), 5 M HCl	25	60	1.0024
Di-n-pentyl sulphoxide (2 M)	tetrachloroethane	0.44	0.43 M U(III), 0.16 M U(IV)	25	60	1.0020
Di-2-EHHP (30%)	toluene	0.08	0.08 M U(III), 4.5 M HCl, 6 M HBr	20	300	1.0020
Tri-2-methylbutyl phosphate	dodecane	0.67	0.7 M U(III), 8.2 M HCl	30	60	1.0027

*TBP = tributyl phosphate, TOPO = trioctylphosphine oxide, di-2-EHHP = di-2-ethylhexyl hydrogen phosphate.
**The given ratio between the organic and aqueous phases is 0.5.

The kinetics of the isotopic exchange reaction (4) in homogeneous solutions have been studied in considerable detail.[6] Only the main conclusions about the kinetics and mechanism of reaction (4) will be examined in the present review.

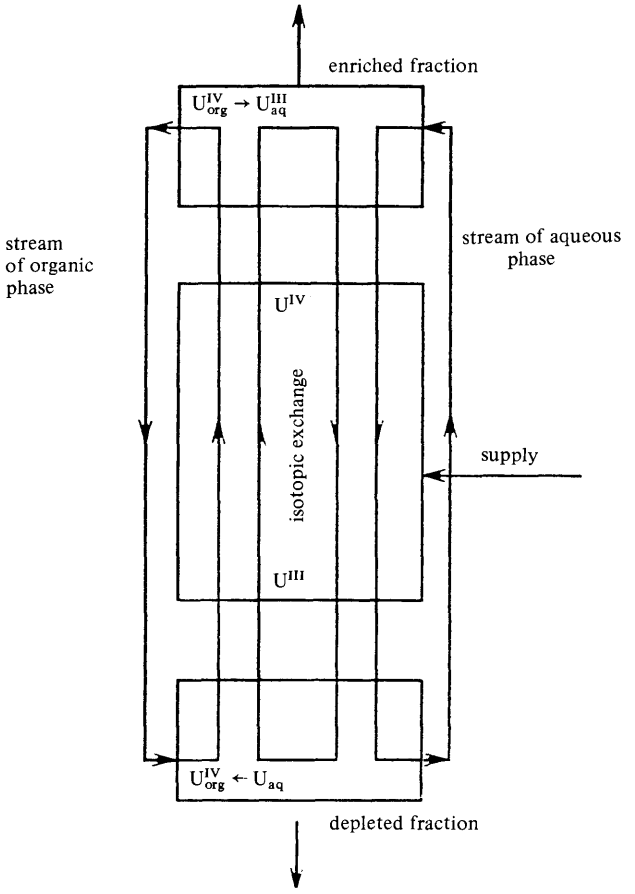

Figure 1. Diagram of the streams in the extraction column of the CHEMEX process.[18]

The order of the reaction between U^{IV} and U^{VI} with respect to the concentration of the reagents is usually fractional. In solutions with a relatively low acidity (2 M acid), its rate (R) is inversely proportional to the cube of the H^+ concentration. It has been suggested that in this acidity range the isotopic exchange mechanism includes the hydrolysis of U^{IV}. In hydrochloric acid solutions with an HCl concentration greater than 3 M, R increases with increase in the acid concentration. It has been suggested that under these conditions the exchange involves chloro-complexes of U^{IV} and U^{VI}. In H_2SO_4 and $(NH_4)_2C_2O_4$ solutions, isotopic exchange takes place between U^{IV} and U^{VI} sulphate and oxalate complexes respectively. In water–acetone and water–ethylene glycol mixtures, the orders of the reaction with respect to U^{IV}, U^{VI}, and H^+ show a complex dependence on the concentration of the organic solvent; the highest values of R are observed for a concentration of the organic component of 30–40%. The rate of reaction (4) increases considerably on ultraviolet irradiation of the solution.

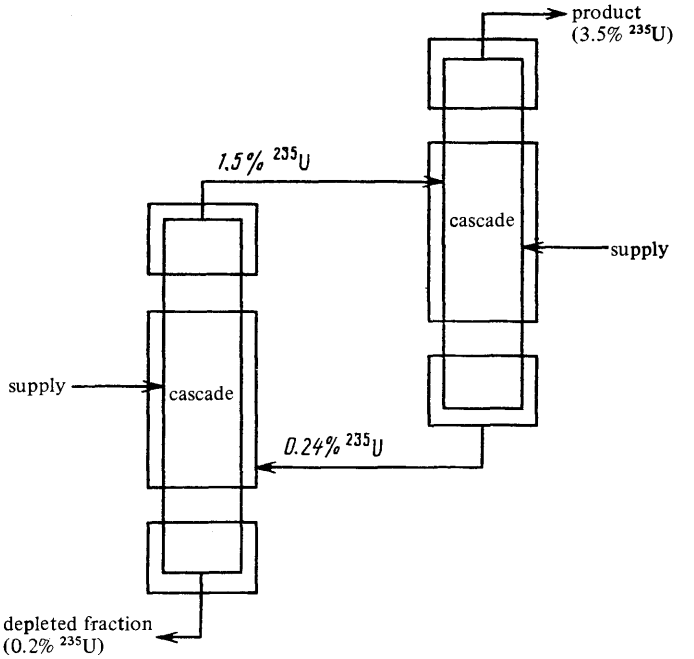

Figure 2. Industrial module of the CHEMEX process.[5]

Most authors consider that electron transfer between U^{IV} and U^{VI} involves the formation and subsequent disproportionation of U^{V}.[6]

Japanese workers studied the kinetics of isotopic exchange between U^{IV} and U^{VI} in the presence of Dowex 5 × 4 cation exchange resin[59] and Dowex 2 × 8 anion exchange resin.[60] The isotopic exchange process in the cation exchange resin involves two stages: exchange in the resin phase between U^{IV} and U^{VI}, and exchange between U^{IV} in the resin and U^{VI} in the solution. The rate of exchange in the resin phase is 10^3–10^4 times that of the corresponding reaction in the solution. The rate of exchange in the resin depends markedly on the acidity of the solution, but a corresponding relationship is not observed for the exchange in the solution. The apparent activation energies of these stages are 24.5 kJ mol^{-1} and 58.4 kJ mol^{-1} respectively.

The reaction in the anion exchange resin is described by the scheme:

$$\begin{aligned} &^{238}U(IV)_r + {}^{235}U(VI)_r \rightleftarrows {}^{235}U(IV)_r + {}^{238}U(VI)_r, \\ &^{238}U(IV)_s + {}^{235}U(IV)_r \rightleftarrows {}^{235}U(IV)_s + {}^{238}U(IV)_r, \\ &^{235}U(VI)_r + {}^{238}U(IV)_s \rightleftarrows {}^{235}U(IV)_s + {}^{238}U(VI)_r. \end{aligned} \quad (5)$$

The rate constant of reaction (5) at 30 °C is 7.3×10^{-4} litre mol^{-1} min^{-1}, which is much lower than the rate constant of the exchange in a homogeneous solution under analogous conditions. The explanation given for this phenomenon is that the concentration of acid in the resin phase is lower than that in the solution.[60] The activation

energy of reaction (5) is 96.2 kJ mol^{-1}, which is close to that in solution (101–105 kJ mol^{-1}). It has been suggested that the mechanisms of isotopic exchange in the solution and in the anion exchange resin are similar.

Isotopic exchange between U^{IV} and U^{VI} in systems containing AV-17-10P anion exchange resin in 6 M HCl solution, KU-8-2P cation exchange resin in 0.5 M HCl solution, and titanium phosphate in 0.7 M H_2SO_4 solution has been studied under static conditions.[61–63] In hydrochloric acid solutions at 25 °C in the absence of catalysts, practically no exchange takes place, but in the presence of titanium phosphate and sulphuric acid the rate of exchange is fairly high ($k = 1.5 \times 10^{-3}$ litre mol^{-1} s^{-1}). It is suggested that the limiting stage of the exchange is the reaction between U^{IV} sorbed on titanium phosphate and U^{VI} in the aqueous phase. In 6 M HCl solutions the rate of isotopic exchange increases considerably in the presence of Fe^{II} salts, but this effect is not observed in 0.5 M HCl solutions.

Table 4. Influence of catalysts on the rate of isotopic exchange in the $U^{IV}-U^{III}$ system.

Catalyst	Concentration of catalyst, M	Concentration of HCl, M	Temperature, °C	k, litre mol^{-1} min^{-1}	k/k_0^*	Refs.
$FeCl_2$	2.5	1	55	9.5	179	[65, 66]
	0.1	2	50	0.082	58	
$CuCl_2$	0.1	4	70	1.4	175	[68]
VCl_3	0.05	4	70	0.17	21	[68]
$CrCl_3$	0.1	4	70	0.01	1.25	[66—68]
p-Benzoquinone	0.05	1.7	90	2.0	1.2	[67]
Hydroquinone	0.1	4	90	0.53	4.8	[69]
Alloxan	0.1	2	50	0.37	65	[67, 69]
$VCl_3 + CrCl_3$	0.05+0.1	4	70	0.38	48	[66]

$FeCl_2$ + ethanol (40%)	1.0	4	55	42.4	820	[67, 69]

* k_0 is the exchange rate constant under corresponding conditions in the absence of a catalyst.

The rate of electron exchange between U^{IV} and U^{VI} can be increased considerably using various catalysts. Thus the reaction between U^{IV} sorbed by a cation exchange resin and U^{VI} in solution is catalysed by the nitrate ion.[64] Detailed studies have shown that the reaction is catalysed by various metal cations, for example Cu^{II}, In^{III}, Tl^{I}, Sn^{IV}, V^{III}, Nb^{V}, As^{III}, Cr^{III}, Mo^{V}, Mn^{II}, Pd^{II}, Hg^{II}, Sb^{III}, Bi^{III}, Zr^{IV}, Re^{V}, Ru^{III}, and Fe^{II},[65–67] and by various organic compounds, such as dicarboxylic or sulphonic acids, hydroxyacids, acids containing N,S-donor atoms and salts of these acids, furans,[68,69] derivatives of quinone and hydroquinone, catechols, and alloxans.[67,69] The concentration of catalyst varies in the range 0.05–3 M.[70] The use of a mixture of catalysts often gives a synergic effect, the magnitude of which depends markedly on the catalysts.[66,67] The catalystic systems are chosen so that the difference in the potentials for the U^{IV}/U^{VI} couple and the redox couple of the catalyst is 0–0.05 V.[67,71] The data in Table 4 show that in a number of cases the rate of the isotopic exchange between U^{IV} and U^{VI} can be increased by a factor of almost 1000. Since the mechanism of isotopic exchange in the $U^{IV}-U^{VI}$ system has not been reliably established, the nature of the action of the catalysts is not yet fully understood. Thus the search for the best catalytic systems is carried out mainly by trial and error.

b) Isotopic effects in the $U^{IV}-U^{VI}$ system

A method for separating uranium isotopes by CIE, in which equimolar quantities of the original U^{IV} and U^{VI} salts are mixed in the light at 25–75 °C and pH 1.5–1.9 has been described.[72] After 1 h, exchange is stopped by adding 3 M HCl solution. The oxidation states of uranium are separated by precipitating U^{IV} with a 5% excess of oxalic acid. In nine separation steps the ^{235}U concentration increases from 0.7052% to 0.7090%.

The exchange reaction was also carried out in 0.207 M H_2SO_4 for 20 h at 35 °C in the dark in a nitrogen atmosphere.[72] Uranium(IV) was precipitated using hydrofluoric acid. For the separation of ^{235}U and ^{238}U, $\alpha = 1.0013 \pm 0.0004$. Similar experiments were carried out in perchloric acid solutions,[74] where the value of α was 1.0012.

Isotope fractionation in the $U^{IV}-U^{VI}$ system in the presence of 0.05 M $CuBr_2$ as catalyst has been studied.[70] The experimental scheme is shown in Fig. 3. Dowex 50W × 4 was used as sorbent. After eight-fold repetition, the ^{235}U enrichment factor was 1.0042. It is suggested[73] that the value of α in the $U^{IV}-U^{VI}$ system is independent of the ligands coordinated to uranium.

Gonda and Kakihana[75] passed 0.05 M solutions of trioctylamine (TOA) or TBP in benzene, saturated with U^{IV} and U^{VI}, through ion-exchange columns with a length of 100 cm and a diameter of 1.2 cm, filled with Dowex 21K anion exchange resin, at a rate of 25 ml h^{-1}. In the system containing TBP, the solution at the outlet from the column was enriched in ^{235}U by a factor of 1.017 compared with the original solution. When TOA was used, the filtrate was depleted in the light isotope ($\alpha = 0.987$). Since in the system containing TBP the anion exchange resin sorbs mainly U^{VI}, in the TOA – U^{IV} system ^{235}U is apparently concentated as $[UO_2]^{2+}$.

When a solution containing 0.5 M H_2SO_4, 0.03 M NaF, and equimolar quantities of U^{IV} and U^{VI} was passed at a rate of 0.5 ml min^{-1} through a column of length 100 cm filled with a cation exchange resin, the resin sorbed mainly U^{IV}.[76] At the outlet from the column, the ^{235}U enrichment factor was 1.009. With increase in the rate of elution to 2 ml min^{-1}, the enrichment factor decreased to 1.000333.

In the counter-current method for separating the isotopes,[77] uranium(IV) sorbed by a strongly acidic cation exchanger moves downwards, and an aqueous solution of U^{VI} moves upwards. In the upper part of the column, U^{VI} slightly enriched in ^{235}U is removed, reduced to U^{IV}, and sorbed on the cation exchanger used in the second column. Uranium(IV) depleted in ^{235}U is removed from the lower part of the first column, oxidised to U^{VI}, and passed to the second column.

A slightly different counter-current method for separating uranium isotopes has been proposed.[78] In this method, the cation exchanger with U^{IV} sorbed on it again moves downwards, but an oxidising agent containing 1% H_2O_2 moves upwards. U^{IV} is oxidised to U^{VI}, desorbed from the resin, and moves upwards with the eluant. Uranium(VI) in the upper part of the column is enriched in the light isotope.

The isotopic fractionation of uranium in counter-current columns makes it possible to carry out a multi-stage process. In the U^{IV}–U^{VI} system, however, this cannot be achieved by using a stationary layer of ion exchanger. For example, Fujii and

co-workers[79] sorbed U^{VI} on a strongly basic macroporous ion exchanger placed in a column with a length of 100 cm and a diameter of 1 cm. Uranium was eluted with a solution containing 0.1–0.12 M $TiCl_3$ and 4–5 M HCl at a rate of elution in the range 3.75–12.3 ml h^{-1}. When the eluant comes in contact with the resin, U^{VI} is reduced to U^{IV}. Since U^{IV} is weakly sorbed by the anion exchanger under the conditions of the experiments, most of it is transferred to the aqueous phase and moves with the eluant. The movement of U^{IV} is accompanied by isotopic exchange between U^{IV} in the aqueous phase and U^{VI} in the exchanger phase. If the rate of attainment of isotopic equilibrium is sufficiently high, isotopic fractionation takes place repeatedly during the passage of the front,[70] as a result of which U^{IV} is enriched in the ^{235}U isotope in the tail of the elution curve. The values of ε obtained at 70 °C and 87 °C were 7.3×10^{-4} and 7.0×10^{-4} respectively. The number of theoretical plates in the experiments varied from 570 to 990, depending on the rate of elution and temperature.

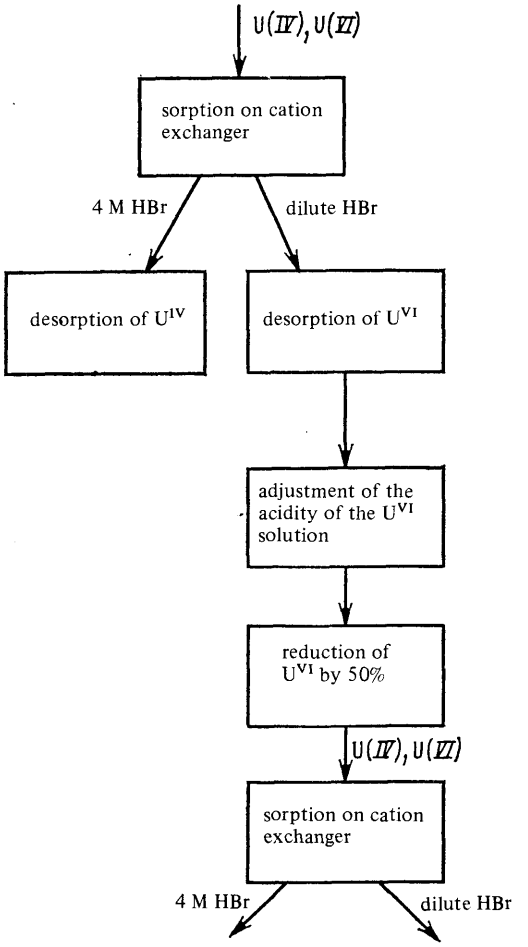

Figure 3. Diagram of the experiment to study isotopic effects in the $U^{IV}-U^{VI}$ system.[70]

Similar experiments were carried out with a cation exchanger in the U^{IV}-form.[64] 0.1 M $Fe(NO_3)_3$ solution was used as eluant. During the elution, U^{IV} was oxidised to U^{VI}, and was washed from the column. Enrichment in ^{235}U took place at the front of the elution curve.

Ponta and Calusaru[80] passed a solution of a U^{VI} salt through a column filled with a cation exchanger in the Ti^{III}-form. U^{VI} was reduced to U^{IV} and sorbed on the resin, and Ti^{III} was converted into TiO^{2+} and washed from the column. The observed isotopic effect is determined by the superposition of the relatively large isotopic effect of the electron exchange between U^{IV} in the resin and U^{VI} in the solution on the weaker isotopic effect of opposite sign due to the reduction of U^{VI} by Ti^{III}.

The methods of separation described above have proved unsuitable for industrial application, however. A method for separating uranium isotopes based on the continuous movement of a uranium zone along a column[81] filled with Dowex 50W-X8 cation exchange resin in the Ti^{III}-form was patented in 1972. When a solution of U^{VI} is passed through the column, the U^{VI} is reduced to U^{IV}, which is sorbed by the resin. As a result, a U^{IV} zone is produced in the upper part of the column. A solution of $FeCl_3$, which oxidises the sorbed uranium, is then passed through the column. The U^{VI} formed is transferred to the solution, and moves with the eluant to the boundary between the zones of uranium and the reducing agent Ti^{III}, where U^{VI} is again reduced to U^{IV} and sorbed by the cation exchanger. The uranium zone moves continuously along the column, and selective distribution of the uranium isotopes takes place at its boundaries as a result of isotopic exchange between U^{IV} from the resin and U^{VI} from the solution. Enrichment in ^{235}U takes place at the boundary between the zones of uranium and the reducing agent. The results of similar experiments carried out by other workers,[82–84] show good agreement with these data.[81]

The chromatographic separation of uranium isotopes according to the above scheme[81] has also been carried out using anion exchange resins.[85–88] In the experiments of Fukuda and co-workers,[88] the zone of uranium, present as anionic complexes of U^{VI}, moved along a column filled with a strongly basic anion exchanger in the Fe^{III}-form. A Ti^{III} solution was used as eluant. The HCl concentration lay in the range 9–4 M, and the temperature in the range 15–83 °C. $FeCl_2$ solution was used to catalyse the isotopic exchange. Enrichment in the light isotope took place in the 'trailing' part of the zone. The values of ε obtained at 30, 50, and 87 °C were 7.8×10^{-4}, 6.8×10^{-4}, and 7.0×10^{-4} respectively. Fe^{III}, Tl^{III}, Mo^{VI}, Sb^{V}, Cr^{VI}, Ce^{IV}, and Hg^{II} were proposed as oxidising agents, and Ti^{III}, V^{II}, V^{III}, Nb^{III}, Cr^{II}, and Cu^{I} as reducing agents.[89] The eluted mixture is treated with oxygen to regenerate the oxidising agent. The reducing agent is regenerated by hydrogen in the presence of catalysts (Pt, Ru, Rh, Pd, Os, or Ir).[89]

4. The ACE process

In 1972, the Japanese firm Asahi Chemical Industry began to develop an industrial method for obtaining uranium with a low degree of enrichment.[14] This method has been called the ACE process.[14] The method is based on isotopic exchange between U^{IV} and U^{VI}. Both cation exchangers and anion exchangers are used to separate the ionic forms of uranium. The firm has developed new highly effective resins giving the process improved kinetic characteristics, which make it economic.

A pilot plant for enriching uranium by CIE (one tenth of the size of the industrial assembly) was brought into operation in Japan in 1985.[90] The capacity of the assembly is 1–2 thousand kg S. W. U. per year. The cost of construction was about 15.8 million dollars.[91] The cascade consists of four columns with a height of 3 m and a diameter of 8 m (Fig. 4), filled with anion exchange resin. The sphericity and dimensions of the particles are varied along the length of the column.[92] Fe^{III} is used as oxidising agent, and Ti^{III} as eluant. The time required to establish the steady state to obtain uranium with an enrichment of 3% is 20–90 d, and the expenditure of energy is 105–180 kW.h per kg S. W. U.[93] To obtain uranium with an enrichment of 93%, the time taken to establish the steady state is 9–10 years.[13]

V. The separation of uranium isotopes in the UF_6-NOUF_6 system

Nugent[94] and Ogle[95] found that in the isotopic exchange between UF_6 and $NOUF_6$, relatively high isotopic fractionation of uranium takes place, and the light isotope is concentrated in the UF_6. Nugent[94] carried out the experiments in a column with a small diameter, filled with $NOUF_6$ in anhydrous HF. A solution of UF_6 in Freon-114, which is denser than the solution in the column, was dispersed in the upper part of the column. Isotopic exchange takes place as the drops fall. The value found for α was 1.0016. Similar results were obtained using the complexes $NOUF_7$ and NO_2UF_7 instead of $NOUF_6$. Ogle[95] used solutions of UF_6 in trichlorotrifluoroethane, dichlorotetrafluoroethane, or perfluorotributylamine. The data obtained by Ogle show good agreement with those obtained by Nugent.[94] A scheme for an assembly for separating uranium isotopes, based on the above method, has been proposed.[96] The values of α in the UF_6(gas)$-NOUF_6$(solid) system at 25 °C and 70 °C are 1.0016 and 1.0011 respectively.[73] The rate of exchange increases in the presence of HF. The main obstacle to the practical utilisation of the exchange between UF_6 and $NOUF_6$ is the high stability of $NOUF_6$ in anhydrous HF solutions towards oxidising agents.[94,98] The oxidation of $NOUF_6$ is necessary to organise phase reversal. F_2, ClF_3, ClF_5, BrF_3, and BrF_5 have been proposed as oxidising agents.[98] The problem of the repeated utilisation of NO has not yet been solved.[98] Moreover, the time taken to establish isotopic equilibrium is fairly long (~2 h), even in the presence of HF. These difficulties make it unlikely that an economic industrial method for separating uranium isotopes based on the reaction between UF_6 and $NOUF_6$ will be developed in the near future.

VI. Other methods

Many workers have used a combination of ion exchange and various electrochemical processes to increase isotopic effects. Thus a method in which isotopic exchange between U^{IV} and U^{VI} is combined with counter-current electromigration has been described.[99] After the electrochemical cell had operated for 1400 h, the ^{235}U concentration in the anode compartment increased by a factor of 1.0007. The method is uneconomic, compared with gas diffusion. Uranium isotopes have also been separated by electromigration using cation exchange membranes.[100] The authors cited suggested that the use of ion exchange membranes should increase the efficiency of isotopic fractionation, since the solvation of uranium ions in the membrane is less extensive than in solution, so that the differences in the masses of the isotope-containing forms should be greater for separation in the membrane. For the fractionation of ^{235}U and ^{238}U by this method α = 1.00006.

The theory of the separation of isotopes by electromigration in an ion exchanger–solution system has been developed, with allowance for the association of the ions and the formation of ion pairs, and also for isotopic exchange between ionic forms in solution and in the exchanger phase.[101]

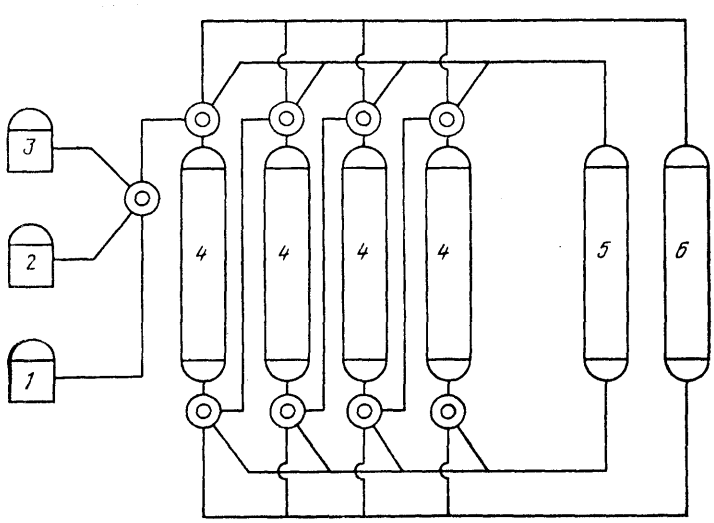

Figure 4. Diagram of the cascade of the ACE process:[2] *1*, vessel for depleted uranium; *2*, vessel for enriched uranium;, *3*, vessel for natural uranium; *4*, separating columns; *5,6*, columns for regenerating the oxidising agent and the reducing agent.

A combination of ion exchange and electrophoresis has been used.[102] Natural U^{IV} chloride was sorbed on the cation exchanger, and then eluted with a mixture of glycine and $CaCl_2$. A voltage was applied to the ends of the chromatographic column (current density 2–3 mA cm^{-2}); the cathode was situated in the upper part. The concentration of ^{235}U at the cathode after 3, 10, and 20 h was 0.736, 0.744, and 0.750 mol% respectively.

A cyclic process involving electro-adsorption and electro-desorption on porous electrodes having a highly developed surface and ion-exchange properties has been proposed for separating uranium isotopes.[103] The sorption–desorption cycles are synchronised with the periodic change in the direction of the flow of liquid, so that a concentration gradient is created along the column.

A kinetic isotopic effect has been detected in the sorption of $[UO_2]^{2+}$ on ion exchange resins under static conditions.[104,105] The sorbents used were the strongly acidic cation exchange resin Amberlite IR-120 in the H^+-form and the strongly basic anion exchange resin Amberlite IRA-400 and the weakly basic anion exchange resin Amberlite IRA-93 in the OH^-, Cl^-, or SO_4^{2-} forms. The ratio of the concentrations of ^{235}U and ^{238}U changed during the sorption. The time dependence of the separation coefficient α shows an extremal point, whose position depends on many factors. When the cation exchange resin was used, the maximum values of α were observed 2 min after contact with the solution, and with the anion exchange resins the smallest value of α was observed after 5–10 min. After passing the extremal point, the ratio $^{235}U/^{238}U$ returned to the original value. The values of α at the extremal points when Amberlite IR-120, IRA-93, and IRA-400 were used were 1.02, 1.03, and 0.99 respectively. The same authors patented similar methods for separating uranium isotopes, based on the kinetic isotopic effect in the sorption of $[UO_2]^{2+}$ on a carboxylic acid cation exchanger on an acrylic base[106] and on an anion exchanger consisting of a structured copolymer of glycyl methacrylate and amines.[107]

The values of α obtained in the works cited[104–107] are more than 10–100 times the uranium isotope enrichment coefficients in equilibrium processes with electron transfer. The nature of the observed phenomenon is not yet clear.

It has been found[108] that the rate of formation of uranyl hydroxide acetate as a result of the irradiation of $UO_2(CH_3COO)_2$ solution with visible light is different for ^{235}U and ^{238}U. The observed phenomenon was attributed to the magnetic isotope effect.

The lack of data on the magnitude and sign of this effect, however, does not make it possible to relate it directly to magnetic phenomena. Moreover, U^{VI} is reduced to U^{IV} when uranyl acetate solutions are irradiated with light. The authors cited[108] did not take account of this process. It follows from the theory of magnetic isotope effects[109] that their highest values are achieved when various conditions are observed. Firstly, the constants of the hyperfine interaction (HFI) with the magnetic nuclei of different isotopes in intermediate radical pairs should differ considerably from one another. Secondly, the HFI constants for one of the isotopes should have high values. Thirdly, the generation of triplet radical pairs is necessary, since their recombination is always preceded by a singlet–triplet interconversion, which leads to the most effective selection of the isotopes.

Until recently, there was lack of agreement on the electronic state of the excited uranyl group.[110] In particular, it was stated that as a consequence of strong spin–orbit coupling, the existence of a characteristic spin in the many-electron uranium atom was impossible. It has been shown,[111] however, that the application of an external magnetic field under certain conditions leads to a decrease in the yield of U^{IV} in the photoreduction of the uranyl group under the influence of N,N-diallyl-N,N-dimethylammonium chloride. The sign of the magnetic effect proves unambiguously the existence of a triplet state of the excited uranyl ion, which on photoreduction gives a triplet radical pair. Thus the appearance of magnetic isotope effects is probably possible in principle in the photoreduction of UO_2^{2+}. The search for specific systems in which these effects are greatest is obviously necessary.

VII. Comparison of the methods

According to the estimates of various specialists, even at the low rates of development of nuclear energy, the annual requirements of the capitalist countries for enriched uranium will be 30 million kg S. W. U. by 1990, and 60 million kg S. W. U. by the year 2000.[12] The production of enriched uranium will be increased both by modernising existing gas-diffusion (GD) plants and by introducing assemblies based on new principles. At the present time, three gas-diffusion plants are operating in the USA (Oak Ridge, Paducah, Portsmouth), and three in Western Europe, of which two are in France (Pierrelatte, Tricastin), and one in Britain (Capenhurst). The production of enriched uranium by GD in the EEC countries is controlled by the international organisation Eurodiff.

In 1970, Britain, West Germany, and the Netherlands established the firm Urenco to develop the ultracentrifuge (UC) method for separating uranium isotopes. In 1979, this firm began to operate two demonstration assemblies in Capenhurst (Britain) and Almelo (The Netherlands), which by 1987 had produced approximately 2 million kg S. W. U. of enriched uranium.[42] A pilot plant with an output of 75 000 kg S. W. U. per year using the UC method is operating in Nintyo-Toge, Japan. In 1985, the Japanese firm PNC began the construction of a similar plant with a planned output of 200 000 kg S. W. U. per year.[113] It is planned to provide 30% of Japan's requirements for enriched uranium from plants using the UC method.

In the USA, approximately 2.6 million dollars have been spent in the construction of a UC plant in Portsmouth.[114] It was planned to bring the first cascade of the plant with an output of 13.2 million kg S. W. U. per year into operation in 1988. The Department of Energy of the USA, however, decided to halt the development of the UC method.[114,115] A method based on the selective photo-ionisation of the atomic vapour of uranium under the influence of laser radiation (AVLIS) was chosen for industrial application in the nineteen-nineties.[115] The main advantages of the AVLIS method over UC is the lower capital expenditure and the lower cost of production per kg S. W. U., and also the greater flexibility for improvement of the method and a gradual increase in output.[115] The very high values of α (see Table 5) make it possible to use depleted uranium from GD plants as the starting material for the AVLIS process.[116] In the USA it is planned to begin in 1988 the construction of a plant using the AVLIS method with a planned output of 10 million kg S. W. U. per year.[115] A similar programme for separating plutonium isotopes is also being developed.[12] It is proposed to begin work on this in 1990. In 1984, 71.9 million dollars were spent on the development of this program. The AVLIS process is also being studied in France,[115] Japan,[117] and Britain.[118]

Representatives of Urenco state, however, that by the late nineteen-eighties the new generation of centrifuges will make it possible to achieve the same economic characteristics as the AVLIS process.[119]

Table 5. Comparison of methods for separating uranium isotopes.[2,5,7,116]

Method*	Level of development	α	Energy consumption, kW per kg S.W.U.	Capital expenditure, dollars per kg S.W.U.	Cost of product, dollars per kg S.W.U.
GD	principal method	1.003	2400—2500	250	95
UC	large-scale plants being brought into production	1.005	100—135	400	90
SJ	construction of large-scale plants being planned	1.015	3000—3600	350	125
SSJ	ditto	1.025	4000	—	—
AVLIS	demonstration assembly being constructed	~100**	50—150	60—70	25—30
MLIS	laboratory studies	2—4	235	—	—
CHEMEX	demonstration assembly in operation	1.002	300	325	60—65
ACE	ditto	1.001	105—180	—	—
PM	laboratory studies	1.1	330	—	—

*GD = gas diffusion, UC = ultracentrifuge, SJ = separating jet method, SSJ = supersonic jet method, AVLIS = selective laser photo-ionisation, MLIS = selective laser photo-dissociation, PM = plasma method; ** separation coefficient without allowance for losses 10^3-10^4.

In addition to AVLIS, the selective laser photo-dissociation of UF_6 vapour (the MLIS process) is also being developed. This method has certain advantages over AVLIS, since UF_6 is extremely volatile.[5] The MLIS process does not give such high values of α as the AVLIS process, however (see Table 5), so that it is necessary to increase the number of stages. The MLIS process is being studied in the Institute of Physical and Chemical Studies in Japan.[120] It is proposed to develop the MLIS method to the AVLIS level.

The separating jet (SJ) method has been developed in West Germany since the mid nineteen-fifties. In 1975, Brazil and West Germany agreed to construct a demonstration plant for enriching uranium by this method.[3] Table 5 shows that the SJ method is the most expensive of the alternative methods.

The supersonic jet (SSJ) method is being developed in the United Arab Republic, where a pilot plant with a planned output of about 300 thousand kg S.W.U. per year has been constructed. Insufficient technical information has been published on this process.

Attempts have been made to separate uranium isotopes in a strongly ionised rotating column of uranium plasma or in the plasma of a low-pressure arc with a hollow cathode (PM).[3] The details of the mechanism of the separation of the isotopes in the plasma are not yet clear, because of the complexity of its structure. The technical problems associated with the use of uranium compounds in a plasma have not been solved.

Comparison of different methods for separating uranium isotopes shows that the chief advantages of CIE methods are the simplicity of the equipment, the use of traditional technology and non-aggressive reagents, and the economic features.[3] Their disadvantages are the low values of α, the long times taken to establish equilibrium, and the complexity of the methods for phase reversal. The developers of the CHEMEX and ACE processes, however, have managed to overcome the difficulties and to develop competitive methods for enriching uranium (see Table 5). The CHEMEX process gives the cost of 1 kg S.W.U. at the level of 60% of the cost of 1 kg S.W.U. in the Eurodiff plants.[115] An advantage of the ACE process over the CHEMEX process is the simplicity of phase reversal, since the latter process requires the use of additional equipment to carry out the redox reactions (electrolyser, etc.).[90] Table 5 shows that the energy used in the ACE process is much lower than that in the CHEMEX process. At the same time, the value of ε for the CHEMEX process is twice that for the ACE process.

Because of these disadvantages, it cannot be said that CIE methods occupy a leading place in the technology of uranium enrichment. These simple and economic methods may prove useful, however, in countries where the requirements for uranium with a low degree of enrichment are low and where there is no need to develop a large-tonnage capital-intensive technology such as GD or UC. Moreover, CIE methods may possibly find application when combined with other promising methods such as laser methods in the early stages of the production of uranium with a low degree of enrichment, when it is necessary to process very large volumes of the starting material.

The possibilities provided by chemical methods for separating uranium isotopes have not been exhausted. In particular, much can still be achieved using processes based on kinetic isotopic effects.

The vapour phase heterogeneous-catalytic hydrogenation of carbonyl compounds and carbon monoxide

N V Pavlenko
Pisarzhevskii Institute of Physical Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. A systematic account is given of data on the mechanisms and kinetics of processes involving the vapour phase hydrogenation of carbonyl compounds and carbon monoxide to hydrocarbon on transition metals. The activity and selectivity series in relation to the reduction of the carbonyl group and CO are determined mainly by the energies of the bonds formed by the compounds hydrogenated and hydrogen with the metal. The bond energy depends in its turn both on the chemical nature of the metal and on the degree of its dispersion. The role of the geometrical factor, which influences the concentration of the active centres, is also examined.

Rules for the selection of catalysts for the hydrogenation of carbonyl compounds and CO on transition metals have been formulated on the basis of the relations discovered between the physicochemical and catalytic properties.

The bibliography includes 110 references.

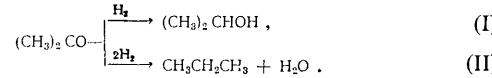
I. Introduction

Processes involving the heterogeneous-catalytic hydrogenation of carbonyl compounds (aldehydes, ketones, etc.) include a large number of reactions of practical interest, especially when it is possible to achieve them at low temperatures and atmospheric pressure. At the same time, these reactions have been little investigated and only recently has there been a greater interest in them.

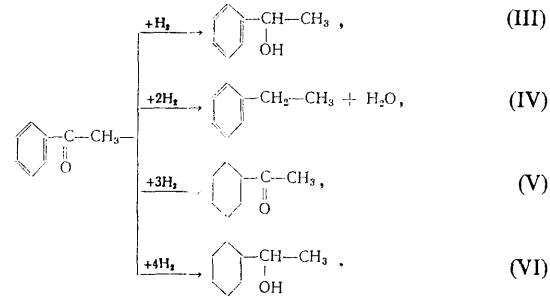
Carbon monoxide may be regarded as the simplest representative of carbonyl compounds and syntheses based on it make it possible to obtain a large number of products of practical value.



Despite the large variety of the hydrogenation reactions of carbonyl compounds, they have many features in common, whose discovery should promote the development of theoretical principles for the prediction and selection of catalysts.

The present review will consider mainly studies carried out in recent years on the mechanisms, kinetics, and catalyst selection rules for processes involving the gas-phase hydrogenation of carbonyl compounds as well as CO to hydrocarbons. The liquid-phase hydrogenation of aldehydes, ketones, and unsaturated oxo-compounds in solutions at an elevated pressure has been described in detail in other reviews and monographs.[1–4]

II. Thermodynamics of processes involving the hydrogenation of carbonyl compounds and carbon monoxide



Depending on the reaction conditions and the catalyst used, the hydrogenation of carbonyl compounds can result in the formation of alcohols, hydrocarbons, and also reduction products with retention of the carbonyl group.

The reduction of acetone in the presence of metal catalysts takes place mainly with formation of isopropyl alcohol and propane:[5]

(I)
(II)

The interaction of acetophenone with hydrogen leads to a more complex composition of the product, because in this case there is a possibility of both the hydrogenation of the aromatic rings and of the complete or partial reduction of the carbonyl group:[5]

(III)
(IV)
(V)
(VI)

The standard Gibbs free energies ΔG_r° of the hydrogenation of acetone (in the range 300–450 K) and acetophenone (at 300–600 K) and the corresponding equilibrium constants K_e, found at a pressure

of 0.1 MPa, are listed in Table 1. Evidently in the temperature range from 300 to 600 K the equilibrium constants of reactions (II) and (IV) are several orders of magnitude higher than the K_{ei} of reactions (I) and (III). Consequently at the above temperatures the complete reduction of acetone to propane and of acetophenone to ethylbenzene is thermodynamically more favourable.

The similarity of the K_{ei} for reactions (I) and (III) and also for reactions (II) and (IV) indicates a comparatively small influence of the nature of the substituent at the carbonyl group on the thermodynamic probability of its reduction. The hydrogenation of the aromatic ring of acetophenone is easier than the reduction of the carbonyl group.

With increase in temperature (in the range 300–600 K), the equilibrium constants of the reactions involving the reduction of the carbonyl group and the hydrogenation of the aromatic ring of acetophenone diminish. Analysis of the constants K_{ei} shows that, in the experimental temperature range, reactions (II) and (IV)–(VI) are almost irreversible in contrast to reactions (I) and (III). An increase in the overall pressure of the systems to 1–10 MPa makes it possible to raise the equilibrium yield of isopropyl alcohol and methylphenylmethanol to 75–100 mol %.[5]

A thermodynamic analysis of the principal acetone hydrocondensation reactions involving the formation of higher (C_6-C_9) alcohols, ketones, and hydrocarbons and oxygen-containing compounds from CO and H_2 has been considered.[7,8] The temperature dependence of the equilibrium constants of the reactions involving the formation of methane and its homologues, i.e.

$$CO+3H_2=CH_4+H_2O, \qquad \text{(VII)}$$

$$nCO+(2n+1)H_2=C_nH_{2n+2}+nH_2O \ (n\geqslant 2), \qquad \text{(VIII)}$$

from the synthesis gas is presented in Table 2.[8] Evidently, with increase in temperature, the thermodynamic probability of the synthesis of methane homologues falls. However, it remains high for all hydrocarbons (up to ~700 K). The differences between the thermodynamic probabilities of the formation of hydrocarbons of different types are unimportant, since the process selectivity is determined by kinetic and not thermodynamic factors. The available data[8] make it possible to calculate the equilibrium compositions of products with a specified number of carbon atoms in the molecule.

Table 2. Temperature dependence of the equilibrium constants of the CO + H_2 reactions.[8]

Hydrocarbon formed	$\lg K_e$			
	300 K	500 K	700 K	900 K
CH_4	24.7	10.1	3.6	—0.1

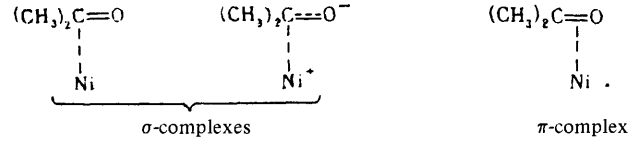
III. Characteristics of the adsorption of reactants on the surfaces of metal catalysts



1. Adsorption of carbonyl compounds

The structure and nature of the surface species formed in the adsorption of carbonyl compounds on metal catalysts have been investigated mainly by IR spectroscopy. It has been found[9] that at 298 K acetone on the iron surface forms the π-complex $(CH_3)_2C{=}O$ (Fe). At the same time, the spectrum contains absorption bands characterising the alkoxy-groups $(CH_3)_2CO-Fe$. On nickel and cobalt, extensive decomposition of the acetone molecule to carbon monoxide has been observed. The presence in the IR spectra of

Table 1. Temperature dependence of the standard Gibbs free energies (in kJ mol^{-1}) and equilibrium constants (in kPa^{-1}) in reactions (I)–(VI).[5]

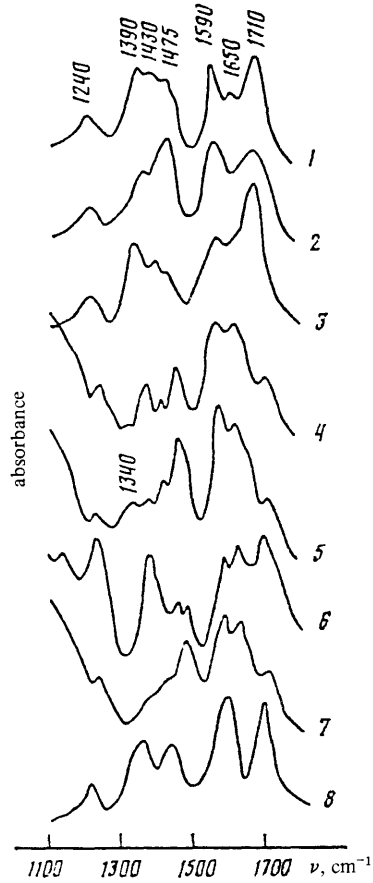
absorption bands in the range 1570–1700 cm^{-1} indicates the presence of π-complexes on the nickel and cobalt surfaces. In a study of the adsorption of acetone and of its deuteriated derivatives on Ni/SiO_2 in the temperature range 298–473 K, Young and Sheppard[10] suggested the possibility of forming two types of complexes between nickel and the ketone:

The adsorption of acetone on the 5% Ru/Al_2O_3 catalysts, differing in the content of preadsorbed hydrogen, has been investigated by IR spectroscopy. The authors[11] believe that, regardless of the presence or absence of H_2 on the ruthenium surface, acetone is hydrogenated on platinum group metals[12] via the formation of only alkoxy-groups and that π-complexes are not produced.



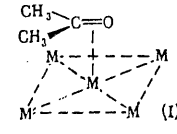


Figure 1. IR spectra of acetone adsorbed on deposited metals: *1*, Fe; *2*, Co; *3*, Ni; *4*, Ru; *5*, Rh; *6* Ir; *7*, Pt; *8*, Cu.

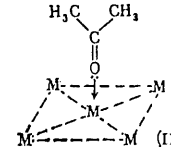
The IR spectra of acetone adsorbed on deposited transition metals, obtained under conditions close to those in the catalytic reaction (I), are presented in Fig. 1.[13–15] Acetone is hardly adsorbed on the surface of the Pd/Al_2O_3 catalyst—the corresponding absorption band could not be detected in the IR spectrum. The observed shift ($\Delta\nu \simeq 20$ cm^{-1}) of the maximum of the band corresponding to the vibration of the carbonyl group [$\nu(CO) = 1740$ cm^{-1}] has been explained by the presence of a weak chemisorption bond between the CO groups of acetone and the OH groups on the γ-Al_2O_3 surface, which corresponds to the formation of complexes with the $(CH_3)_2C=O...H-O-Al\langle^{O-}_{O-}$ hydrogen bond.[16] A new absorption band in the range 1590–1605 cm^{-1} appears in the spectrum of acetone adsorbed on metal catalysts. In addition, an absorption band in the range 1640–1650 cm^{-1} has been detected after adsorption on Fe, Ru, Rh, Ir, and Pt. When $(CH_3)_2CO$ is adsorbed on deposited transition metals (M), there is a possibility of the formation of a donor–acceptor complex when π-electrons are transferred from the ketone molecule to the unoccupied *d* orbitals of the metal or a dative interaction may take place, in which the *d* electrons of the metal are localised in the antibonding π* orbitals of the carbonyl group.[17]

The direction of the shift of the electron density in the adsorption complex depends on the ratio of the electronegativities of the metal atom and the ketone molecule. The electronegativity of the $(CH_3)_2CO$ molecule is determined by the electronegativities of the carbon and oxygen atoms of the carbonyl groups, which are respectively 2.55 and 3.44 on the Pauling scale.[18] The electronegativities of metals on this scale decrease in the sequence

$$\mathrm{Pt}(2.28),\ \mathrm{Ru}(2.28) > \mathrm{Ir}(2.2),\ \mathrm{Rh}(2.2) > \mathrm{Ni}(1.91) > \mathrm{Cu}(1.90) > \mathrm{Co}(1.88) > \mathrm{Fe}(1.8). \qquad \text{(IX)}$$



Taking into account the greater electronegativity of the acetone molecule compared with that of the metal atoms, it has been suggested[13–15] that in the system considered the dative interaction predominates over the donor–acceptor interaction, so that the appearance of the absorption band in the range 1590–1605 cm^{-1} characterises the formation of a planarly oriented π-complex (I) on the surfaces of the catalysts investigated:

(I).

The energy of the dative interaction increases with decrease in the electronegativity of metals, so that acetone should be adsorbed most strongly on the catalyst located at the end of the series (IX), which agrees with experimental data.[13]

In conformity with the work of Blyholder and co-workers,[9,19] the absorption band in the range 1640–1650 cm^{-1} has been assigned[13,15] to the formation of a donor–acceptor complex:

(II)

in which the molecular orbital of the CO group overlaps the unoccupied *d* orbital of the metal.

The conclusions concerning the structure of the adsorption complexes were confirmed by our quantum-chemical calculations on the interaction of acetone with Ni and Cu clusters, carried out by

the INDO method.[20] It follows from the results that the formation of a "parallel" π-complex (I) with an acetone molecule is more likely for the Cu cluster, whereas for the Ni cluster the probabilities of the formation of the complexes (I) and (II) are approximately the same. Regardless of the nature of the metal (Ni, Cu), the loosening of the C=O bond in the π-complex (I) is greater than in the donor–acceptor complex (II). This permits the conclusion that the π-complex (I) is the most probable intermediate in the catalytic hydrogenation of acetone.

Acetone and other carbonyl compounds form type (II) complexes with the surface of simple and mixed oxides used as carriers for metal catalysts, while hydrogen-bonded complexes are produced on coordination to surface OH groups.[16,39,40] The adsorption of acetone on the surfaces of oxides may be accompanied by aldol and crotonic condensations, whose mechanisms (for γ-Al_2O_3) were investigated in our previous studies.[16,41]

2. The adsorption of carbon monoxide

The experimental and calculated data for the adsorption of CO on transition metals has been described systematically in monographs[21–24] and reviews.[25–28] Depending on the nature of the metal and the adsorption conditions, the CO molecule initially forms a weak one-electron bond, which is rapidly converted into stronger bonds: a linear bond with one metal atom and a bridge bond with two or more M atoms:[26]

$$M + CO \rightleftarrows M^- \ldots CO^+ \rightleftarrows M{-}C{\equiv}O \overset{M}{\rightleftarrows} \begin{matrix} M \\ M \end{matrix}\!\!>\!C{=}O. \qquad (X)$$

Quantum-chemical calculations[29] on the interaction of CO with iron, cobalt, nickel, and copper atoms with formation of the linear form of the M–CO bond have shown that the M–C bond strength diminishes in the sequence Fe > Co, Ni > Cu, whilst the energy of the M–O bond increases in the sequence Ni < Co < Cu < Fe. The calculated data agree well with the IR spectroscopic results,[30,31] on the basis of which it has been concluded that there is a dative bond between the above metals and the CO molecule involving the formation of the π-complex (the alkoxy-complex is hardly formed). The following sequence based on decreasing M–C bond strengths has been established for platinum group metals on the basis of absorption spectra:[32–34]

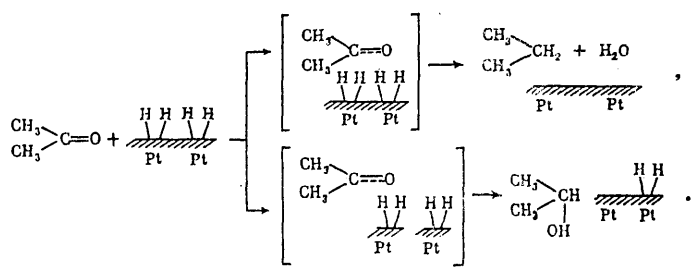
$$Ir > Ru > Pt > Rh > Pd.$$

According to quantum-chemical calculations,[35] the average M–CO bond energy diminishes with increase in electronegativity in series (IX), while the strength of the C–O bond in the adsorbed molecule increases, so that the presence of metals with the lowest electronegativity (Fe, Co) should promote to the greatest extent the rupture of the CO bond and the formation of hydrocarbons via the reaction between CO and H_2. This conclusion has been confirmed by numerous experimental data.[36–38]

The adsorption of CO on simple and mixed oxides of non-transition metals results in the formation of carboxylate and carbonate structures of different types.[22,24]

3. The adsorption of hydrogen

The adsorption properties of massive and dispersed metal catalysts in relation to hydrogen have been investigated in fair detail.[2,22,23,25,42] Analysis of the available and experimental calculated data shows that the dissociative form of the adsorption of H_2 predominates on Group VIII metals; on copper, hydrogen is adsorbed in the form of molecules,[43] whilst on ruthenium both molecular[15] and dissociative[23] forms of adsorption of H_2 are observed (depending on the adsorption conditions and the degree of dispersion of the metal).



IV. The mechanism and kinetics of the hydrogenation of ketones and CO

1. Hydrogenation of acetone

When reaction (I) was carried out on sputtered metal films, it was shown[44] that the rate of the process r is independent of the partial pressure of acetone P_A, depends in a complex manner on the partial pressure of hydrogen P_{H_2}, and is inhibited as the concentration of the reaction product (isopropyl alcohol) increases. The kinetic equation $r = kP_A^{1.2}P_{H_2}^{1.5}$, where k is the reaction rate constant, has been proposed[45] for the reaction on Raney nickel.

The kinetic orders of reaction (I) have been determined[46,47] and a kinetic equation, describing the process on an inhomogeneous surface in the region of reversibility, has been devised in addition.[47] It has been suggested[44,47] that the rate of the reaction is determined by the stage involving the surface interaction of the adsorbed acetone molecules with the hydrogen atoms or molecules.

The following parallel mechanism of the hydrogenation of acetone to propane and alcohol on a diatomic active centre of the catalyst has been proposed[48] in the case of platinum black:

The kinetics of the vapour-phase hydrogenation of acetone on massive nickel, cobalt, copper, and their alloys have been studied in detail by Avetisov and Gel'bshtein and co-workers.[49–52] It has been shown[49] that the rate of reaction increases appreciably with increase in P_A, depends to a lesser extent on P_{H_2}, and is inhibited by the isopropyl alcohol formed. The observed reaction orders with respect to the components are variable and depend on their concentrations and temperature. It has been suggested[49] that hydrogen atoms adsorbed on nickel in the H^+-form enter into the reaction and that the rate of this process is limited by the surface interaction of the adsorbed ketone molecules and H atoms. It has been assumed[49] that acetone and hydrogen are adsorbed on different active centres of the catalyst surface. The non-planar acetone molecules do not then occupy all the adsorption centres on the metal surface even when the latter is fully saturated. On these grounds, it has been postulated[49] that hydrogen atoms are adsorbed on the metal surface in the gaps between the ketone molecules. An adsorption mechanism of reaction (I) has been put forward on the basis of kinetic data and the corresponding equation, which describes satisfactorily the experimental relations, has been derived.[49]

The kinetic relations and the reaction mechanism characteristic of the reactions on nickel are retained on the cobalt catalyst and nickel–cobalt alloys containing between zero and approximately 50 at.% of cobalt.[52]

It has been established[50] that, in the presence of massive copper, the rate of reaction hardly depends on P_A, increases with increasing P_{H_2}, and diminishes with increasing partial pressure of isopropyl alcohol P_{al}. On the basis of the results of studies[53,54] in which it had been shown that at temperatures below 573 K hydrogen is not adsorbed on copper, Babkova et al.[50] examined different versions of the impact (with respect to H_2) mechanism of the hydrogenation of acetone.

The hypothesis[50] that the hydrogenation of acetone on copper can be described with the aid of the mechanism proposed by Twigg[55] for the hydrogenation of ethylene on nickel as applied by Temkin[56] to the hydrogenation of ethylene on a palladium membrane is interesting. This mechanism can be represented schematically as follows:

Scheme 1

1) $(CH_3)_2CO + Z \rightleftarrows Z(CH_3)_2CO$,
2) $Z(CH_3)_2CO + Z_1 + H_2 \rightleftarrows Z(CH_3)_2COH + Z_1H$,
3) $Z(CH_3)_2COH + Z_1H \rightarrow Z(CH_3)_2CHOH + Z_1$,
4) $Z(CH_3)_2CHOH \rightleftarrows (CH_3)_2CHOH + Z$,

where Z and Z_1 are adsorption centres on the catalyst surface.

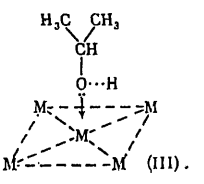
Hydrogen from the gas phase interacts with an adsorbed acetone molecule (on the adsorption centre Z), which results in the formation of a partly hydrogenated form of acetone and a hydrogen atom adsorbed on a free centre (Z_1) on the copper surface. The ability of copper to adsorb atomic hydrogen has been reliably established.[57] On the basis of the scheme described above, equations describing the experimental data in the experimental temperature and reactant concentration ranges have been proposed.[50]

The similarity of the kinetics of the acetone hydrogenation reaction catalysed by nickel and nickel–copper alloys with a copper content up to 60 at.% suggested[51] that the mechanism proposed[50] for the hydrogenation of acetone on the nickel catalyst is valid also for the nickel–copper alloy having the composition indicated above. For a higher copper content in the alloy (> 60 at.%), acetone is hydrogenated in conformity with Twigg's mechanism describing the reaction on the copper catalyst.

The kinetics of the reversible hydrogenation of acetone on the nickel catalyst have been investigated.[47,58] The hydrogenation reaction proceeds via two pathways: the adsorbed ketone molecule reacts with adsorbed hydrogen atoms and a partly hydrogenated acetone molecule reacts either with gas-phase hydrogen or with a second adsorbed hydrogen atom. The dehydrogenation of isopropyl alcohol includes a stage in which the gas-phase alcohol interacts with the dissociatively adsorbed hydrogen.[47,58]

The kinetics of the hydrogenation of acetone in a differential flow reactor at 423 K in the presence of Cu, Pt, Pd, and Rh deposited on kieselguhr have been studied.[59] 29 kinetic equations, corresponding to the Langmuir–Hinshelwood mechanism, have been analysed by the ECV method. The activity of the platinum group metal diminishes in the following sequence according to the reaction rate constants (k expressed in mol/h kg of catalyst): Pt > Rh > Pd. The activities of the catalysts investigated lie in the following sequence in terms of the initial rate of hydrogenation: Cu > Rh > Pt > Pd. The series presented must be regarded as arbitrary, since the concentrations of the metals deposited on kieselguhr were different and the specific surfaces of the metals were therefore also different. Furthermore, at temperatures above 737 K it is essential to take into account the reversibility of the acetone hydrogenation reaction,[5] which was not done in the above study.[59]

The experimental relations obtained in the presence of the copper catalyst were described[59] by a kinetic model according to which the molecularly adsorbed hydrogen reacts with a dissociatively adsorbed acetone molecule, but the authors do not explain what they mean by the dissociative adsorption of acetone on copper and what is the mechanism of this process. The kinetic equations proposed[59] for the description of the processes occurring on platinum group metals (Pt, Rh, Pd) are consistent with the mechanism according to which the rate is determined by the interaction between the adsorbed hydrogen and acetone molecules. However, these conclusions conflict with numerous literature data, according to which the atomic form of the adsorption of hydrogen predominates on the surface of platinum metals.



We carried out a systematic study of the vapour-phase hydrogenation of acetone on deposited and massive transition metals.[13–15,60–65] Detailed investigation of the kinetics of reaction (I) at different temperatures showed that the following picture is observed in all cases: the rate of the process increases with increasing concentrations of the reactants, reaching saturation. The reaction product (isopropyl alcohol) does not inhibit the hydrogenation of acetone on all catalysts other than the copper and ruthenium catalysts, where a decrease in rate with increase in P_{Al} was observed.[14,15]

The study of the mechanism and kinetics of the reverse reaction—the dehydrogenation of isopropyl alcohol on the Pt/Al_2O_3 catalyst, i.e.

$$(CH_3)_2CHOH \rightarrow (CH_3)_2CO + H_2, \qquad \text{(XI)}$$

demonstrated the following features: with increase in P_{Al} and for low values of P_{H_2}, the rate of reaction (XI) increases, reaching saturation. In the presence of an excess of hydrogen, the order of the reaction with respect to the alcohol increases, approaching unity. The reaction products (acetone and hydrogen) then inhibit reaction (XI).

These results made it possible, in the first place, to account for the influence of the alcohol concentration on the kinetics of reaction (I). The character of this influence depends significantly on the degree of coverage of the metal surface by hydrogen θ_H, which affects the adsorption of isopropyl alcohol on the metal surface. The isopropyl alcohol molecule, which has no unsaturated bonds, is adsorbed (perpendicularly) on the metal surface as a result of the dissociation of the OH group. This leads to the formation of the alkoxy-structure[64]

(III).

In the joint adsorption of $(CH_3)_2CHOH$ and H_2 molecules, competition is observed:[64] the atomically adsorbed hydrogen prevents the dissociation of the OH group of the isopropyl alcohol molecule and the adsorption of the latter on the metal. This is manifested clearly in the dehydrogenation of isopropyl alcohol, where an increase in P_{H_2} in the reaction mixture leads to the inhibition of reaction (XI) and an increase in the reaction order with respect to the alcohol.

The following mechanism for the reversible addition of hydrogen to the carbonyl group has been proposed[64,65] on the basis of the entire set of adsorption and kinetic data obtained:

Scheme 2

1) $H_2 + 2Z_H = 2Z_HH$,
2) $(CH_3)_2CO + Z_A = Z_A(CH_3)_2CO$,
3) $Z_A(CH_3)_2CO + Z_HH \rightleftarrows Z_A(CH_3)_2COH + Z_H$,
4) $Z_A(CH_3)_2COH + Z_HH \rightleftarrows Z_H(CH_3)_2CHOH + Z_A$,
5) $Z_H(CH_3)_2CHOH = (CH_3)_2CHOH + Z_H$,

where Z_A and Z_H are the centres for the adsorption of acetone and hydrogen respectively.

The equilibrium adsorption of the initial reactants takes place in the first two stages: acetone forms the π-complex (I) on the polyatomic centre Z_A, while the dissociative adsorption of hydrogen takes place on single M-centres Z_H.

Our data make it possible to justify and specify in detail the physical significance of the active centres (Z_A and Z_H) postulated by Babkova et al.[49]

The study of the IR spectra of the acetone adsorbed on metals[13–15] (Fig. 1) led to the conclusion that at the temperatures of the catalytic reaction (~330–370 K) the ketone molecule is oriented "parallel" to the metal plane [the complex (I)]. For this orientation, acetone is adsorbed only on specific groups of M atoms with a suitable geometry (of the type of Balandin's multiplets). The fraction λ of such complex centres Z_A is small, so that acetone hardly affects the adsorption of H_2 on single centres Z_H (on the rest of the surface), whose fraction is close to unity. Since the transition state (the rate-limiting stage of the process) is formed on a pair of centres $Z_A + Z_H$, the number of active centres (n_a) for the catalytic reaction should be small. The quantity n_a enters into the expression for the pre-exponential factor k_L^0 in the expression for the rate constant for the rate-limiting stage:[66]

$$k_L^0 = \kappa(k_BT/h)n_a \exp(\Delta S_L^*/R),$$

where k_BT/h is the frequency factor, κ the transmission coefficient, usually equal to unity, ΔS^*_L the entropy of activation, and R the gas constant. Since ΔS^*_L for stages of the type $A_{ads} + B_{ads} = C_{ads}$ is usually small in absolute magnitude,[67] we have $k_L^0 \simeq (k_BT/h)_a$, so that an increase in k_L^0 with decrease in the degree of dispersion of the metal, up to a certain limit corresponding to the $(n_a)_{max}$, is to be expected. This corresponds to a situation such that the probability of the existence of the complex groups Z_A on the planes of the microcrystals increases as the metal particles grow (with This corresponds to a situation such that the probability of the existence of the complex groups Z_A on the planes of the microcrystals increases as the metal particles grow (with increase in $\bar{d}$) and the fraction of the active surface also increases, reaching saturation, whereupon the fraction of the planar M atoms becomes virtually unity. Fig. 2 confirms this, catalysts of different chemical composition, characterised by different activation energies E_L, fitting on a single straight line. Comparison of the experimental maximum values of $k_L^0 \simeq 10^6$ (Table 3) with the "normal" value $k_L^0 = 10^7$–10^8 mol m^{-2} × s^{-1}, corresponding to $\gamma = 1$, shows that the fraction of the working surface λ is only a few per cent even on large crystals.

The ideas described are also confirmed by the results of a study[68] in which it has been established that the adsorption of acetone and hydrogen in the presence of the Pt/Al_2O_3 catalyst with different degrees of dispersion takes place without competition. The activity of the catalyst increases with increase in the size of the Pt system from 5 to 20 nm and then remains constant.

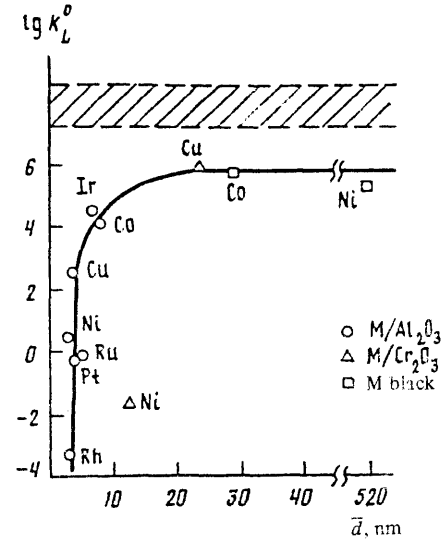


Figure 2. Dependence of the pre-exponential factor of the rate constant for the rate-limiting stage on the hydrogenation of acetone on the degree of dispersion of the metal. The dashed lines represent the values of k_L^0 corresponding to the entire working surface ($\lambda = 1$) for $\Delta S_L^* \simeq 0$–20 J mol^{-1} K^{-1}.

**Calculated for 337 K.

***The data of Stoddart and Kemball[44] are quoted.

It follows from the competing adsorption of hydrogen and isopropyl alcohol that these substances are bound to the same centres (Z_H) and that the alcohol forms the complex (III). The equilibrium desorption of the product takes place in stage 5. Stages 3 and 4 are reversible but non-equilibrium. At low temperatures stage 3 is slowest.[64]

The observed rate of reaction of acetone under stationary conditions is

$$r = r_3 - r_{-3} = r_4 - r_{-4}, \quad (1)$$

where $\gamma \pm i$ are the rates of the stages in the forward and reverse directions. When account is taken of Eqn. (1), the overall kinetic equation for the reversible hydrogenation of acetone, corresponding to Scheme 2, is

$$r = r_3 - r_{-3} = k_3 \frac{b_A P_A}{1 + b_A P_A + l} \frac{\sqrt{b_{H_2} P_{H_2}}}{1 + \sqrt{b_{H_2} P_{H_2}} + b_a P_a} - k_{-3} \frac{l}{1 + b_A P_A + l} \frac{1}{1 + \sqrt{b_{H_2} P_{H_2}} + b_a P_a}, \quad (2)$$

in which $k_{\pm i}$ are the rate constants for the stages in the forward and reverse directions and b_A, b_{H_2}, and b_a are the adsorption coefficients of acetone, hydrogen, and the alcohol respectively, and

$$l = (k_3 b_A P_A + k_{-4} b_a P_a)/(k_4 \sqrt{b_{H_2} P_{H_2}} + k_{-3}).$$

The quantity l represents the "degree of reversibility of the reaction"[64,65] and is equal to the fraction of the centres Z_A occupied by the same hydrogenated form of acetone. Eqn. (2) agrees quantitatively with experimental data for the kinetics of reaction (I) in both the forward and reverse directions: the inhibiting effect of hydrogen on the adsorption of the alcohol is then clearly manifested.[64]

Under conditions remote from equilibrium (at low temperatures where $l \to 0$), acetone is hydrogenated by the mechanism presented in Scheme 3:

Scheme 3

1) $H_2 + 2Z_H = 2Z_HH$,
2) $(CH_3)_2CO + Z_A = Z_A(CH_3)_2CO$,
3) $Z_A(CH_3)_2CO + Z_HH \rightarrow Z_A(CH_3)_2COH + Z_H$,
4) $Z_A(CH_3)_2COH + Z_HH \xrightarrow{fast} Z_H(CH_3)_2CHOH + Z_A$,
5) $Z_H(CH_3)_2CHOH \xrightarrow{fast} (CH_3)_2CHCH + Z_H$.

In this case Eqn. (2) assumes a simpler form[13,15] (the term characterising the reverse reaction is missing) and describes satisfactorily the kinetic data for the forward process in the presence of all the catalysts investigated (Table 3) with the exception of copper and ruthenium. When the copper and ruthenium catalysts are used, account must be taken of the observed inhibition of reaction (I) by the isopropyl alcohol formed and of the involvement in the reaction of the hydrogen adsorbed in the molecular form, which we have established by the programmed thermal desorption method.[15,43] Scheme 3 must therefore be modified somewhat:

Scheme 4

1) $H_2 + Z_H = Z_HH_2$,
2) $(CH_3)_2CO + Z_A = Z_A(CH_3)_2CO$,
3) $Z_A(CH_3)_2CO + Z_HH_2 \rightleftarrows Z_H(CH_3)_2CHOH$,
4) $Z_H(CH_3)_2CHOH = (CH_3)_2CHOH + Z_H$.

Here too the rate-limiting stage is the interaction of the adsorbed starting materials, while in the remaining stages equilibrium is established. The kinetic equation

$$r = k_3 \frac{b_A P_A}{1 + b_A P_A} \frac{b_{H_2} P_{H_2}}{1 + b_{H_2} P_{H_2} + b_a P_a},$$

which describes satisfactorily the experimental data for the Cu and Ru catalysts,[14,15] corresponds to this mechanism (Scheme 4).

The study of the individual stages of the mechanism of the hydrogenation of acetone on transition metals has shown[65] that, if the reactive π-complex (I) is formed on adsorption of the ketone, then partial reduction of the complex leads only to isopropyl alcohol. When acetone is adsorbed as the donor–acceptor complex (II), the carbonyl group of the ketone is fully reduced with elimination of the oxygen atom. Bearing in mind that acetone and other ketones are weak Lewis bases, we achieve such alteration in the form of adsorption and in the mode of reaction[69] by using bifunctional catalysts containing, apart from the transition metals, also strong Lewis acid centres L to which the oxygen of the carbonyl group is bound via the unshared electron pair. Hydrogen is activated on the metal. We propose[70] the following two pathway mechanism (Scheme 5) of the complete reduction of the carbonyl group of acetone [reaction (II)]:

Scheme 5

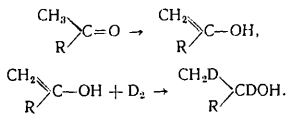
1) $H_2 + 2Z_H = 2Z_HH$,
2) $(CH_3)_2CO + Z_L = Z_L(CH_3)_2CO$,
3) $Z_L(CH_3)_2CO + Z_HH = Z_L(CH_3)_2COH + Z_H$,
4) $Z_L(CH_3)_2COH + Z_HH = Z_L(CH_3)_2CHOH + Z_H$,
5) $Z_L(CH_3)_2CHOH = (CH_3)_2CHOH + Z_L$,
6) $Z_L(CH_3)_2COH + Z_HH \rightarrow Z_LC_3H_6 + H_2O + Z_H$,
7) $Z_LC_3H_6 + Z_HH \rightarrow Z_LC_3H_7 \xrightarrow{Z_HH} C_3H_8 + Z_L + 2Z_H$.

Equilibrium is established in stages 1–5 which determine the rate of formation of isopropyl alcohol. Stage 3 is common to the synthesis of the alcohol and the hydrocarbon. The rate of the total hydrogenation of acetone is limited by Stage 6, in which the addition of a H atom to the adsorbed semihydrogenated form of the acetone is accompanied by dehydration and the formation of adsorbed propene $Z_LC_3H_6$ in the form of a π-allyl complex,[71] which is then rapidly hydrogenated to propane in a single stage.

The following kinetic equation corresponds to Scheme 5:

$$r = k_6 \frac{K_3 b_A P_A \sqrt{b_{H_2} P_{H_2}}}{1 + b_A P_A \left(1 + K_3 \sqrt{b_{H_2} P_{H_2}}\right) b_a P_a} \frac{\sqrt{b_{H_2} P_{H_2}}}{1 + \sqrt{b_{H_2} P_{H_2}}}, \quad (3)$$

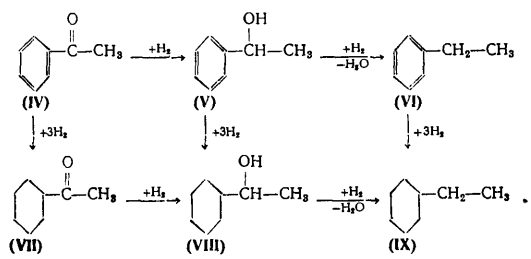
where k_6 is the rate constant for the rate-limiting stage and K_3 the equilibrium constant for the third stage. Eqn. (3) describes satisfactorily[70] the experimental and kinetic data for the complete hydrogenation of acetone in the presence of the bifunctional catalyst.



As a result, the kinetic and thermodynamic characteristics of the different stages in the mechanisms of the acetone hydrogenation reactions occurring via Schemes 2–5 were calculated from experimental data for the catalysts listed in Table 3: the rate constants, the adsorption coefficients, the activation energies, the heats (q_i) and entropies (ΔS_i^0) of adsorption, and the pre-exponential factors of the rate constants. Analysis of the data obtained yielded new arguments in support of the proposed mechanisms and made it possible to find relations between the physicochemical and catalytic properties of the substances which can be used in the selection and improvement of catalysts for the hydrogenation of carbonyl compounds. These relations will be examined below.

The mechanism of the hydrogenation of acetone and other ketones has been investigated with the aid of deuterium–hydrogen

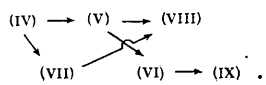
exchange.[2,72–74] In order to describe the interaction of deuterium with carbonyl compounds, two limiting mechanisms are usually employed:[2,72] the "ketone" and "enol" mechanisms. According to the ketone mechanism, deuterium adds directly to the carbonyl group:



The "enol" mechanism presupposes the preliminary enolisation of the ketone and the subsequent addition of deuterium to the C=C bond:

According to data[73,74] obtained in the study of the interaction of deuterium with alicyclic ketones in the presence of a prefused iron catalyst (in the temperature range from 323 to 483 K), the relative contributions of the "ketone" and "enol" mechanisms are in the proportions 1 : 1.5.

2. Hydrogenation of acetophenone



The hydrogenation of acetophenone is a complex process whose detailed mechanism has not been investigated:

Schemes for the conversion of acetophenone in the presence of nickel, platinum, and palladium have been proposed by Balandin and co-workers[75] on the basis of calculations of the adsorption energies of the index groups. On nickel, the hydrogenation process takes place in accordance with the following scheme:

For the palladium catalyst, the scheme remains the same but, as a consequence of the greater difference between the adsorption energies of the CO group and the aromatic rings, the addition of hydrogen to the ring on palladium is fairly difficult. On platinum as well as on nickel and palladium, the keto-group is most readily hydrogenated. At the same time, the reactivity of the aromatic rings in the presence of the platinum catalyst becomes higher than that of the alcoholic group, which was not observed[75] on nickel and palladium. It has therefore been suggested[75] that the hydrogenation of acetophenone proceeds according to the scheme

In terms of activity in the acetophenone hydrogenation reaction, the metals considered can be arranged in the following sequence: Ni > Pd > Pt. The hydrogenolysis on the metals indicated should proceed with much difficulty.[75]

In the hydrogenation of acetophenone on industrial catalysts (Cu–Cr–Ba; Ni–Ti–Al), it has been shown[76] that the copper–chromium–barium specimen is more selective in relation to the formation of methylphenylmethanol, while the nickel–titanium–aluminium specimen is more active in relation to the overall conversion of acetophenone. In the presence of the catalysts indicated, the process proceeds via the consecutive scheme (IV) → (V) → (VI). An empirical kinetic equation has been obtained and a mathematical model has been proposed for the process.[76]

3. Hydrogenation of aliphatic and cyclic ketones

The kinetics of the hydrogenation of aliphatic and alicyclic ketones in the presence of a premelted iron catalyst are described by the power equation[77]

$$r = kP_{\text{k}}P_{\text{H}_2}^{0.5}. \qquad (4)$$

The following mechanism, presupposing the adsorption of the reactants on the same centres (Z) of the iron catalyst, has been put forward on the basis of kinetic data for the hydrogenation of 2-octanone:[78]

Scheme 6

1) $H_2 + 2Z = 2ZH$,
2) $R^1COR^2 + Z = ZR^1COR^2$
3) $ZR^1COR^2 + ZH \rightarrow ZR^1C(OH)R^2$,
4) $ZR^1C(OH)R^2 + ZH = ZR^1CH(OH)R^2$,
5) $ZR^1CH(OH)R^2 = R^1CH(OH)R^2 + Z$.

The rate of the process is limited by the addition of the first hydrogen atom to the adsorbed ketone molecule; equilibrium is established in the remaining stages. Eqn. (4) has been used[77] to optimise the hydrogenation of alicyclic ketones (C_5, C_6) formed in the synthesis of alcohols by the oxidation of higher paraffins.

In order to optimise the phenol hydrogenation process in the manufacture of caprolactam, the kinetics of the addition of hydrogen to phenol and cyclohexanone molecules have been studied.[79] The following mechanism has been proposed for the reversible hydrogenation of cyclohexanone to cyclohexanol on nickel catalysts on the basis of kinetic measurements:[80]

Scheme 7

1) $H_2 + 2Z_H = 2Z_HH$,
2) $C_6H_{10}O + Z_c = Z_cC_6H_{10}O$,
3) $Z_cC_6H_{10}O + 2Z_HH \rightleftarrows Z_cC_6H_{11}OH + 2Z_H$,
4) $Z_cC_6H_{11}OH = C_6H_{11}OH + Z_c$,

where Z_c and Z_H are the centres for the adsorption of the ketone and hydrogen respectively. It is assumed that the two hydrogen atoms add simultaneously to the adsorbed ketone molecule. Cyclohexanone and hydrogen are adsorbed on different centres (Z_c and Z_H), of the catalyst, whose surface is regarded as effectively uniform. The kinetic equation proposed on the basis of this mechanism (Scheme 7) describes satisfactorily the experimental relations. These relations served as the basis of the mathematical model used to optimise the synthesis of cyclohexanol.[81]

The mechanisms of the hydrogenation of aliphatic and cyclic ketones (Schemes 6 and 7) are in general similar to the mechanism of the incomplete hydrogenation of acetone (Scheme 2), which we have established, while the kinetic equation (2), which we proposed for the description of the experimental relations obtained in the hydrogenation of acetone, is applicable also to the description of the

kinetics of the hydrogenation of 2-octanone established by Glebov et al.[78]

4. Hydrogenation of carbon monoxide

Numerous studies have been devoted to the hydrogenation of CO on metals, which leads mainly to the formation of methane and higher hydrocarbons.[36–38, 82–85] The proposed mechanisms[86–88] refer solely to the conversion of CO into methane and do not take into account the simultaneous formation of methane homologues. The mechanism of the formation of methane homologues has stages in common with the mechanism of the synthesis of methane itself and these common stages affect the rate of formation of CH_4.

The study of reactions (VII) and (VIII) on deposited metallic catalysts of different types (Table 4) enabled us to put forward[89–92] the following CO hydrogenation mechanism:

Scheme 8

1) $H_2 + 2Z = 2ZH$,
2) $CO + Z = ZCO$,
3) $ZCO + ZH = ZCOH + Z$,
4) $ZCOH + ZH \rightarrow ZX_0 + Z$,
5) $ZX_0 + ZH \rightarrow ZX_0' \xrightarrow{ZH} CH_4 + H_2O + Z$,
6) $ZX_0 + ZCO \rightarrow ZX_1 + Z$,
6') $ZX_1 + ZH \rightarrow ZX_1' \xrightarrow{ZH} C_2H_6 + H_2O + Z$,
7) $ZX_1 + ZCO \rightarrow ZX_2 + Z \ldots$,

where the adsorbed AX_0 species is the common intermediate in the formation of all the products. Its interaction with ZH affords methane (chain termination), while the reaction of ZX_0 with a carbon-containing species leads to a new adsorbed species ZX_1,, leading to the synthesis of higher hydrocarbons (chain propagation).

Table 4. Specific catalytic activities and selectivities of metal catalysts in the hydrogenation of CO.

Cu/Al_2O_3	3.4	inactive	—

Note. Mixture composition: P_{CO} = 20 kPa, P_{H_2} = 50 kPa.

*Calculated for 548 K.

The first four stages in Scheme 8 determine the activity of the catalyst and the others determine its selectivity. It is assumed that adsorption equilibrium is established in stages 1–3, while the rate of the overall process is then determined by stage 4. The way in which ZCOH interacts with ZH, via the intermediate formation of the "enolic" form of formaldehyde ZCOH or via the formation of the surface carbide ZC with liberation of water, is immaterial for the process kinetics.

The question of the composition and structure of the carbon-containing species interacting with ZX_i is obscure. The IR spectra obtained under the conditions of the catalysis[84] usually manifest only the absorption bands of the adsorbed CO molecules which form complexes with the deposited metals [see Eqn. (X)]. Consequently, the surface concentrations of other carbon-containing intermediate compounds can be regarded as negligible.

The kinetic equation for the overall conversion of CO (in conformity with Scheme 8) can be written in the form

$$r = r_4 = k_4 \frac{K_3 b_{CO} P_{CO} b_{H_2} P_{H_2}}{\left[1 + b_{CO} P_{CO} + \sqrt{b_{H_2} P_{H_2}}(1 + K_3 b_{CO} P_{CO})\right]^2}, \quad (5)$$

where k_4 is the rate constant for the rate-limiting stage 4, K_3 the equilibrium constant for stage 3, and $b_i P_i$ are the products of the adsorption coefficients and the partial pressures of the reactants. Eqn. (5) describes quantitatively the experimental relations for all the catalysts which we have investigated and agrees with the kinetic results obtained in other studies.[86,87,93] The heats of adsorption q_{CO} of CO on metals, agreeing with the values of q_{CO} found by other procedures,[23] were calculated from the temperature variation of b_{CO}.[90,91]

The following expression for the process selectivity with respect to methane S_{CH_4} can be written on the basis of Scheme 8:[89,91,92]

$$S_{CH_4} = r_5/(r_5 + r_6) = [1 + (k_6 b_{CO} P_{CO}/k_5 \sqrt{b_{H_2} P_{H_2}})]^{-1}, \quad (6)$$

where r_i and k_i are the rates of stages 5 and 6 and the corresponding rate constants.

The selectivity with respect to higher hydrocarbons S_{C_n} is $1-S_{CH_4}$. Consequently

$$S_{C_n} = \frac{k_6 b_{CO} P_{CO}/k_5 \sqrt{b_{H_2} P_{H_2}}}{1 + (k_6 b_{CO} P_{CO}/k_5 \sqrt{b_{H_2} P_{H_2}})}. \quad (7)$$

Eqns. (6) and (7) lead to kinetic equations describing the processes involving the hydrogenation of CO to methane and higher hydrocarbons (the Fischer-Tropsch synthesis):

$$r_{CH_4} = rS_{CH_4}, \quad r_{C_n} = rS_{C_n}. \quad (8)$$

These expressions describe the experimental data satisfactorily.[89,91]

The rate of formation of individual hydrocarbons can be calculated from Eqn. (8) and the Schultz–Flory equation:[84]

$$c_n = n(1-\alpha)^2\alpha^{n-1}, \quad (9)$$

where c_n is the concentration of the hydrocarbon in which the number of carbon atoms is n. The coefficient α, which is usually found empirically from the proportions of the products,[84] is the probability of the formation of the higher hydrocarbon, i.e. the ratio of the rate of chain propagation (r_p) to the sum of the rates of chain propagation and termination (r_t):

$$\alpha = r_p/(r_p + r_t) = r_6/(r_6 + r_5). \quad (10)$$

The physical significance of the coefficient α follows from Eqn. (10). It consists in the fact that $\alpha = S_{C_n}$ in Eqn. (9):

$$\alpha = [1 + \beta(\sqrt{P_{H_2}}/P_{CO})]^{-1}, \quad (11)$$

where

$$\beta = k_5 \sqrt{b_{H_2}}/k_6 b_{CO}.$$

Thus the mechanism proposed for the hydrogenation of CO (Scheme 8) and the corresponding kinetic equation (5) make it possible to elucidate the significance of the coefficient α in terms of the rate (equilibrium) constants for the elementary stages.

V. The rules for the selection of ketone hydrogenation catalysts

1. Catalytic activity

The available data on the empirical selection of catalysts for the hydrogenation of carbonyl compounds are presented in a model review.[1] The mechanisms which we have established for the acetone hydrogenation reactions permit an approach to a rational selection and improvement of catalysts for the selective hydrogenation of carbonyl compounds.

It can be seen from the data in Table 3 that the specific catalytic activity r [the rate of reaction (I)] decreases in the sequence

$$\begin{aligned} &Pt/Al_2O_3 > Cu/Cr_2O_3 > Ni\ black > Ni/Cr_2O_3 > \\ &> Ir/Al_2O_3 > Rh/Al_2O_3 > Ni/Al_2O_3 > Ru/Al_2O_3 > \\ &> Cu/Al_2O_3 > Co/Al_2O_3 > Co\ black \gg Fe/Al_2O_3, Pd/Al_2O_3, Cu\ black. \end{aligned} \quad (XII)$$

The last three members of this series did not exhibit an activity in reaction (I); the causes of this have already been examined.[13,14]

The series (XII) agrees qualitatively with the activity series of metallic films found by Stoddart and Kemball:[44]

$$Pt > Ni > Fe,\ W > Pd > Au. \quad (XIII)$$

However, it is essential to note that the following problem arises when the metal activity series in low-temperature hydrogenation (and similar processes) are compared and interpreted. During these processes, there is no appreciable influence of the reaction medium on the catalyst, levelling out the differences between specimens of the same chemical composition but with different degrees of dispersion, as happens, for example, in many oxidation reactions[67] occurring at higher temperatures. The smaller the crystal size, the higher the coordinative unsaturation of the surface M centres and the greater their affinity for the reactants. This is indicated, in particular, by the increase in the heat of adsorption of acetone q_A with decrease in the average metal particle size $\bar{d}$ (Fig. 3). The latter agrees with the results of numerous quantum-chemical calculations,[94] showing that, on passing from small clusters to large crystals, the metal–metal cohesion bond is strengthened and the metal–adsorbate adhesion bond is weakened, saturation being attained in the region of approximately 10–20 nm. Relations of this kind are apparently characteristic of low-temperature "structure-sensitive" (in Boudart's terminology[95]) hydrogenation processes and other reactions.

With increase in the heat of adsorption of acetone, q_A, the adsorption entropy falls—the thermodynamic compensation effect occurs:[15,62] the higher the heat of adsorption, the more negative the entropy (ΔS^0_H) (the smaller the mobility of the adsorbed species). However, even in the presence of such an effect, the influence of the degree of dispersion of the metal on the acetone adsorption coefficient b_A is considerable (it vanishes only on passing to large crystals). The position of the metal in the activity series therefore depends both on its chemical nature and on the degree of its dispersion.

For "structure-sensitive" reactions such as the hydrogenation of the carbonyl group of ketones, the role of the degree of the dispersion of the metal may not be manifested solely in its influence on the energy of the bonds between the reactants and the surface. The probability of the multipoint adsorption of complex molecules of the compound hydrogenated and of the activated complexes may depend on the dimensions of the microcrystal (Fig. 2). Furthermore, account must be taken of the influence of the chemical nature of the crarier on the activity both as a consequence of the interaction of the metal with the carrier and of the activation of the substrate on the sections of the carrier adjoining the metal. The ability of the hydrogen adsorbed on the metal to migrate to neighbouring sections of the oxide carrier is well known.[96] This can explain the finding that the Cu/Cr_2O_3 catalyst, which has approximately the same adsorption coefficients b_A and b_{H_2} as Cu/Al_2O_3, is characterised by a significantly greater (by a factor of 40–50) rate constant k_L for the rate-limiting stage (Table 3).

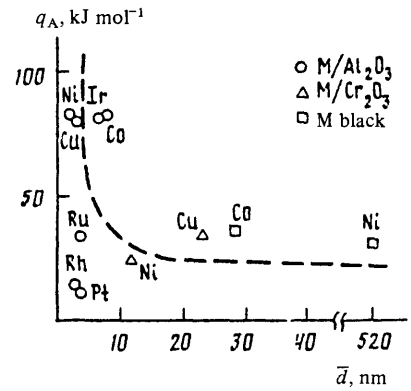

Figure 3. Dependence of the heat of adsorption of acetone on the degree of dispersion of the metal.

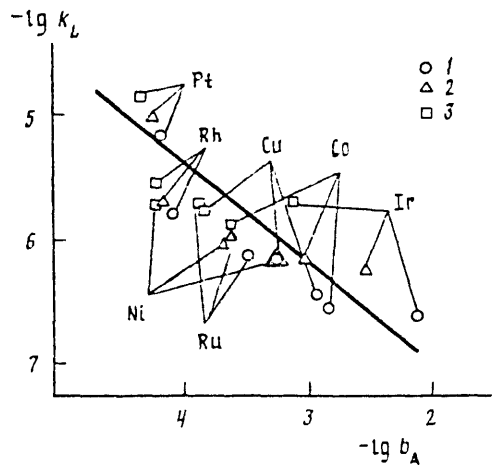

Figure 4. Dependence of the rate constant for the rate-limiting stage of the hydrogenation of acetone on the adsorption coefficient of acetone at different temperatures (K): *1*, 337; *2*, 348; *3*, 364.

In the case of metals deposited on the same carrier (γ-Al_2O_3) and having approximately the same degrees of dispersion ($\bar{d} \simeq 3$–7 nm), the specific catalytic activity r diminishes in the sequence

$$Pt > Ir > Rh > Ni > Ru > Cu > Co \gg Fe,\ Pd\ . \quad (XIV)$$

This series can be naturally interpreted on the basis of the mechanism proposed for the hydrogenation of acetone (Scheme 2). The bonds formed by the ketone and H_2 with the surface are ruptured in the rate-determining stage 3. One should therefore expect a decrease in the rate constant for the rate-limiting stage with increasing strength of the reactant–metal adsorption bond. Fig. 4 shows that k_L does indeed diminish with increase in b_A. b_A diminishes steadily, in its turn, with increase in the electronegativity of the metal χ_M (Fig. 5). This can be explained by the dominant role of the dative interaction in the formation of the adsorption π-complex (I): with increase in χ_M, the energy of this interaction falls, since the ability of the metal to give up electrons to the ketone molecule being adsorbed decreases.

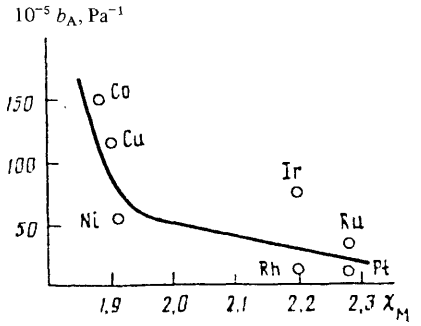

Figure 5. Relation between the adsorption coefficients of acetone (337 K) for metals deposited on Al_2O_3 and the Pauling electronegativities of the metals.

The fact that $\lg k_L$ is correlated satisfactorily solely with the strength of the acetone bond can be explained in the following manner. We formulate the Brønsted–Temkin equation for k_L:

$$k_L = gK_L^{\alpha}, \qquad (12)$$

where g and α are constants and k_L is the equilibrium constant for stage 3 (Scheme 2). In its turn, $K_L = b_{AH}K/b_A\sqrt{b}_{H_2}$ [b_{AH} is the adsorption coefficient of the semihydrogenated form $(CH_3)_2COH$ and K is the equilibrium constant, independent of the catalyst, of the gas-phase reaction $(CH_3)_2CO + 0.5H_2 = (CH_3)_2COH$]. Since the M–H bond is ruptured in stage 3 (Scheme 2) and the analogous M–C σ-bond is formed in the intermediate compound $(CH_3)_2C(M)–OH$, one can assume that the ratio $b_{AH}/\sqrt{b}_{H_2}$ changes little on passing from one metal to another. Therefore $K_L \simeq (\text{const.})b_A^{-1}$, so that

$$k_L = g\,(\text{const})\,b_A^{-\alpha} = (\text{const}')\,b_A^{-\alpha}. \qquad (13)$$

The transfer coefficient α can be found from the slope of the linear plot of $\lg k_L = f(\lg b_A)$ (Fig. 4). It proved to be 0.7, which is close to the typical value $\alpha = 0.5$.

In comparing the rates of the overall reaction (I) on different metals, one should use the kinetic equation (2), which can be put in the form $r = k\theta_A\theta_H$ (θ_A is the degree of surface coverage by acetone). Since saturation of the active centres Z_H by hydrogen ($\theta_H \simeq 1$) was attained in most cases for the conditions selected (Table 3), it follows that $r = k_L\theta_A$.

Consider the dependence of r on the heat of adsorption of acetone q_A. By differentiating $\ln r$ with respect to q_A and setting the derivative $d \ln r/dq_A$ equal to zero, we find [taking into account Eqn. (13)] the condition for the optimum $(\theta_A)_{opt} = 1 - \alpha$. This means that the highest rate of hydrogenation is attained for a degree of saturation at the centres Z_A by acetone equal to $1 - \alpha$. The optimum adsorption coefficient of acetone corresponds to this:

$$(b_A)_{opt} = [(\theta_A)_{opt}/(1 - (\theta_A)_{opt})]\,P_A^{-1} = [(1 - \alpha)/\alpha]\,P_A^{-1}.$$

The calculated quantity $(b_A)_{opt} = 4.3 \times 10^{-5}$ Pa^{-1} is close to the experimental value b_A for Pt (6×10^{-5} Pa^{-1} at 364 K), which explains why Pt occupies the first place in the series (XIV). For acetone–metal bond energies exceeding the optimum value, the activity should fall and, when $q_A < (q_A)_{opt}$ the activity should increase with increasing q_A, which is in fact observed in practice (Fig. 6).

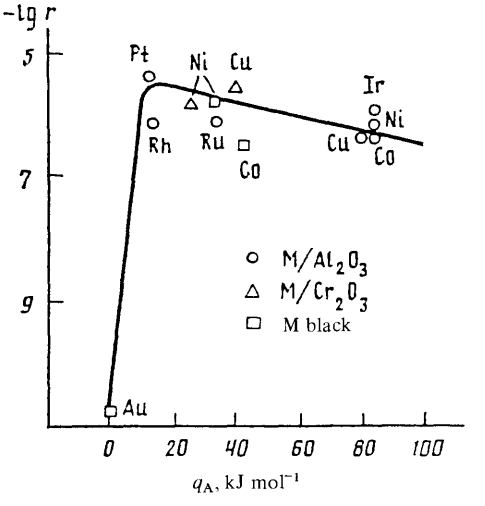

Figure 6. Dependence of the catalytic activities of metals in the hydrogenation of acetone at 364 K on the heat of adsorption of the ketone.

When cyclopentanone is hydrogenated on metallic films[97] the following metal activity series holds: Pt > Pd > Rh > W > Ni. It is in general similar to the sequences (XII) and (XIV) (with the exception of the position of Pd), which justifies the hypothesis that the rules established for the hydrogenation of acetone are fairly typical for the reactions of compounds of this class.

2. Selectivity

Together with hydrogenation reactions of type (I), the complete reduction of ketones with formation of the corresponding hydrocarbons [reaction (II)] can take place on metal catalysts. This process is analogous to the synthesis of methane from CO and H_2.

In the hydrogenation of acetone in the temperature range from 300 to 370 K on deposited metal, the formation of propane was observed[15] in the initial period of the reaction only on platinum (the selectivity with respect to C_3H_8 was 100%) and on iridium. In the latter case, propane and isopropyl alcohol were detected in the reaction products.

In catalysis on metallic films,[44] the activity of the metals in reaction (II) diminishes in the sequence

$$Pt > W > Ni > Fe \gg Pd, Au, \qquad (XV)$$

which resembles the activity series (XIV) in relation to the overall acetone hydrogenation process.

In order to interpret the selectivity with respect to C_3H_8, it is sufficient to supplement Scheme 3 by a complex stage involving further interaction of the adsorbed alcohol with the adsorbed H atoms:

$$6)\ Z_H(CH_3)_2CHOH + Z_HH \rightarrow (I) \xrightarrow[fast]{Z_HH} C_3H_8 + H_2O + 3Z_H,$$

where (I) is an intermediate compound.

Thus the selectivity with respect to the hydrocarbon is

$$S_{C_3H_8} = k_6\theta_H/(k_6\theta_H + k_5).$$

At fairly high pressures P_{H_2}, where $\theta_H \simeq 1$, we obtain

$$S_{C_3H_8} = [1 + (k_5/k_6)]^{-1}.$$

The constants k_5 and k_6 depend equally on the bond energy between the alcohol molecule and the surface, so that the ratio k_5/k_6 does not depend on this energy. At the same time, the constant k_5 is also independent of the M–H bond energy, whereas k_6 increases as this bond is weakened. Consequently the selectivity with respect to propane is given by

$$S_{C_3H_8} = [1 + \exp(\alpha q_{H_2}/2RT)\ (\text{const})]^{-1}. \qquad (20)$$

According to Eqn. (20), one should expect the formation of hydrocarbons in the hydrogenation of ketones on metals which bind hydrogen least strongly. Among the deposited catalysts tested in the acetone hydrogenation reaction, such metals are Pt, Ir, and Cu. The formation of propane on Pt and Ir only shows that an obligatory condition is also the involvement in stage 6 of atomic hydrogen (hydrogen is adsorbed on Cu in the form of molecules[43]).

The activity r of transition metals in relation to the overall acetone hydrogenation process diminishes with increase in the heat of adsorption of the ketone q_A (Fig. 6). Comparison of the values of q_A with known[23] values of q_{H_2} shows that q_A and q_{H_2} vary in general in parallel. The activity of the metal r therefore falls with increasing q_{H_2}. Since $S_{C_3H_8}$ also diminishes with increasing q_{H_2} according to Eqn. (20), one should expect a similarity between the overall metal activity series and the activity series in relation to reaction (II), which is in fact observed [cf the series (XIV) and (XV)].

The extensive hydrogenation of ketones is promoted by the presence of atomic hydrogen weakly bound to the metal surface. On passing from a deposited metal to a metal film, the strength of the M–H bond should diminish as a consequence of the increase in the size of the metal crystals. This can also be used to account for the finding that, in the case of metallic films, the formation of propane could be detected on a greater number of metals than on deposited catalysts having a high degree of dispersion.

It follows from Eqn. (20) that, with increase in temperature, the selectivity with respect to the hydrocarbon should increase, which is also in agreement with experimental data.[44]

VI. The rules for the selection of carbon monoxide hydrogenation catalysts

1. Catalytic activity

Data for the specific catalytic activities of a large number of transition metals in relation to the overall conversion of CO have been obtained in a number of studies.[86–88] The activities of metals deposited on Al_2O_3, measured at atmospheric pressure and 548 K,[86] decrease in the sequence

$$Ru > Fe > Ni > Co > Rh > Pd > Pt > Ir. \qquad (XVI)$$

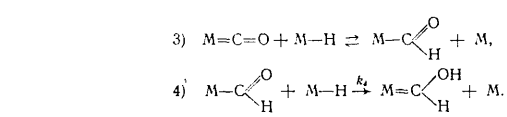
The activity series for metals deposited on SiO_2 is somewhat different:[88]

$$Co > Fe > Ru > Ni > Rh > Ir,\ Pt > Pd > Cu. \qquad (XVII)$$

The data which we have obtained[98] for the specific catalytic activities of metal catalysts in relation to the hydrogenation of CO and also for their selectivities with respect to CH_4 are presented in Table 4. It is seen that at 548 K the activities of the metals deposited on γ-Al_2O_3 and having approximately the same degrees of dispersion ($\sim$2–7 nm) decrease in the sequence

$$Ru > Rh > Co > Ni > Pt > r > Pd \gg Fe, Cu. \qquad (XVIII)$$

In general the series (XVI)–(XVIII) are similar: among group VIII metals, the metals of the iron and ruthenium subgroups are the most active, while platinum, palladium, and iridium are least active. Activity series, analogous to the series (XVIII), established at atmospheric and elevated pressures have been described.[82,99]



The catalytic activities of deposited cobalt catalysts in the Fischer–Tropsch synthesis at 540 K diminish in the following sequence of carriers:

$$SiO_2 > TiO_2 > ZrO_2 > BeO > Cr_2O_3 > Al_2O_3 > MgO \gg WO_3. \qquad (XIX)$$

At the same temperature, the activities of deposited nickel catalysts diminish in the sequence of carriers

$$ZrO_2 > TiO_2 > BeO > MgO > Al_2O_3 > SiO_2 > Cr_2O_3 \gg WO_3. \qquad (XX)$$

The variation of the activities of the metals in the sequence (XVIII) can be explained on the basis of the CO hydrogenation mechanism (Scheme 8). For this purpose, we specify in a more concrete form the chemistry of stages 3 and 4. If one begins with the assumption that the key intermediate compound ZX_O represents the adsorbed "enolic" form of formaldehyde,[82] the stages indicated can be formulated as follows:

At low temperatures, at which the activity series (XVIII) has been attained, the degree of surface coverage by CO molecules (θ_{CO}) is close to unity. Eqn. (5) then assumes the form

$$r = k_4 K_3 b_{H_2} P_{H_2} (b_{CO} P_{CO})^{-1}. \quad (14)$$

We shall consider the dependence of the constant of this equation on the heats of the stages, assuming that the entropy terms are approximately constant in a series of isotypical catalysts. It is also evident that

$$b_{CO}^{-1} \propto \exp(-q_{CO}/RT), \quad (15)$$

$$b_{H_2} \propto \exp(q_{H_2}/RT). \quad (16)$$

Since the M–H bond is ruptured and the M=C bond is partly ruptured, in stage 3, it follows that

$$K_3 \propto \exp(-q_{CO}/2RT - q_{H_2}/2RT). \quad (17)$$

We have the following expression for the equilibrium constant for stage 4:

$$K_4 \propto \exp(q_{CO}/2RT - q_{H_2}/2RT),$$

On the basis of the Brønsted–Temkin relation, we formulate the following expression for the rate constant for this stage:

$$k_4 \propto \exp(\alpha q_{CO}/2RT - \alpha q_{H_2}/2RT) \quad (18)$$

where α is the transfer coefficient, usually equal to 0.5.

On substituting Eqns. (15)–(18) in Eqn. (14) and taking into account the fact that the comparison is carried out at a constant P_i, we obtain (for $\alpha = 0.5$)

$$\ln r \propto -1.25(q_{CO}/RT) + 0.25(q_{H_2}/RT).$$

Since the absolute value of the numerical coefficient of q_{CO} is much greater than that of q_{H_2} and in addition $q_{CO} > q_{H_2}$,[23,42] one can write

$$\ln r \cong -1.25(q_{CO}/RT) + \text{const}, \quad (19)$$

i.e. the catalytic activity should decrease with increase in the heat of adsorption CO, which is confirmed qualitatively by the data in Fig. 7.

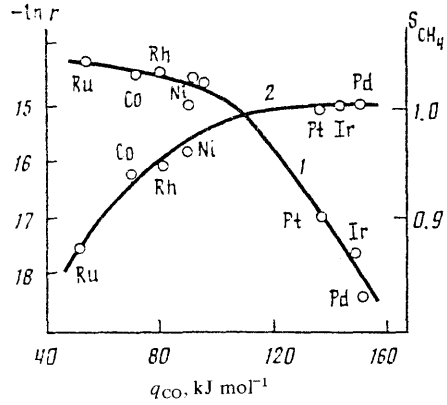


Figure 7. Dependence of the catalytic activities of metals (curve *1*) in the hydrogenation of CO and of their selectivities with respect to methane (curve *2*) on the heat of adsorption of CO.

In its turn, q_{CO} depends on the average metal particle size d: the smaller d, the greater q_{CO}. Evidently the influence of carriers [see the series (XIX) and (XX)] on the activity of a given metal is manifested primarily by a change in the degree of dispersion of the deposited metal M, on which depends the heat of adsorption of CO. With increase in $\bar{d}$, r initially rises, since this entails a decrease in q_{CO}, reaching a maximum in the presence of Co/SiO_2 ($\bar{d}$ = 38 nm) and Ni/ZrO_2 ($\bar{d}$ = 97 nm) (Table 5), but on further increase in $\bar{d}$, the M–CO bond is apparently weakened so much that r decreases in the presence of Co/TiO_2 ($\bar{d}$ = 46 nm) and Co/WO_3 ($\bar{d}$ = 60 nm). The same also applies to nickel catalysts: on Ni/TiO_2 ($\bar{d}$ = 103 nm) and Ni/WO_3 ($\bar{d}$ = 181 nm), r decreases. A similar dependence of the activity of the metal on the degree of dispersion was observed by Boudart and McDonald[68] and Kuznetsov et al.[100] Furthermore, the yield of oxygen-containing compounds (mainly ethanol) increased with increase in the degree of dispersion of cobalt deposited on the same carrier.[100]

The coefficient α in the Schultz–Flory equation also diminishes with increasing degree of dispersion of the metal. If account is taken of Eqn. (7) and the fact that q_{CO} increases as $\bar{d}$ diminishes, the dependences of r and α on $\bar{d}$ described above become analogous to the dependences of r and S_{C_n} on q_{CO} obtained whilst varying the chemical nature of the metal (Fig. 7).

2. Selectivity

It is seen from the data in Table 4 that the selectivity in the hydrogenation of CO to methane diminishes (and that with respect to higher hydrocarbons increases) in the following sequence of metal catalysts:

$$Pd,\ Ir > Pt > Ni > Rh > Co > Ru. \quad (XXI)$$

The selectivity with respect to higher hydrocarbons S_{C_n} of the CO catalyst diminishes in the sequence of carriers

$$ZrO_2 > MgO > BeO > Al_2O_3,\ Cr_2O_3 > SiO_2 > TiO_2 > WO_3 \quad (XXII)$$

and that of the nickel catalyst diminishes in the sequence

$$ZrO_2 > Al_2O_3 > Cr_2O_3 > MgO > BeO,\ SiO_2 > TiO_2 > WO_3. \quad (XXIII)$$

Comparison of the series (XVIII) with (XXI) shows that there is an antiparallel relation between the activity and the selectivity with respect to methane S_{CH_4}: the higher r, the smaller S_{CH_4} (Fig. 8). It has been shown in a study[92] where this empirical relation was noted for the selectivity with respect to CH_4 can be put in the form $S_{CH_4} = (1 + \eta)^{-1}$, where $\eta = r_6/r_5$ is the ratio of the rates of stages 6 and 5 in the CO hydrogenation mechanism (Scheme 8). Bearing in mind that, on passing from one metal to another, the changes in η are associated mainly with the changes in the rate constants (k_6 and k_5) for the stages indicated and the formation of ZX_0' and ZX_1 does not involve the appearance of new bonds with the catalyst (H which adds to the adsorbed species of CO is inserted in the M–C bond), we obtain[92,98]

$$S_{CH_4} = [1 + \text{const}' \cdot \exp(-\alpha q_{CO}/RT)]^{-1} \quad (21)$$

(it is assumed that the changes in q_{CO} predominate over the changes in q_{H_2}). It follows from Eqn. (21) that the selectivity with respect to CH_4 should increase (whilst that with respect to higher hydrocarbons should diminish) with increase in q_{CO}, which is in fact

actually observed (Fig. 7). Simultaneous solution of Eqns. (19) and (21) leads (after the elimination of q_{CO} from them) to the expression[92,98]

$$S_{CH_4} = (1 + Br^c)^{-1} \quad (22)$$

(B and c are constants). Eqn. (22) explains the observed antiparallel variation of the activity S_{CH_4} (Fig. 8). Furthermore, it follows from Eqn. (22) (in conformity with experimental data) that $S_{CH_4} \to 1$ when $r \to 0$ and $S_{CH_4} \to 0$ when $r \to \infty$.

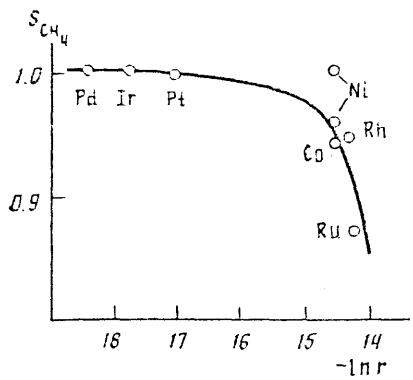

Figure 8. Relation between the activities and selectivities of metals in the CO hydrogenation reaction.

The relations examined refer to the case where the normal Schultz–Flory distribution holds and when the carrier of the metal can be regarded as inert.

For the same metal deposited on different carriers [see the series (XXII) and (XXIII)], the changes in q_{CO} are due to different degrees of dispersion of the metal, so that according to Eqn. (21) a dependence of S_{C_n} on $\bar{d}$ is also to be expected, which has in fact been observed for both cobalt and nickel catalysts (Table 5). However, the changes in S_{C_n} are not induced solely by changes in the degree of dispersion of the metal and hence by the different values of q_{CO}. In each group of catalysts, deposited on different carriers (Table 5), it is possible to differentiate M/L specimens (L is the carrier) having virtually the same degrees of dispersion and hence the same heats of adsorption q_{CO}. At the same time, the selectivities S_{C_n} of such catalysts differ by 24–34%, which means that the subsequent reactions of the intermediate ZX_0 take place with a direct involvement of the carrier particles (apparently at the metal–carrier interface[101]).

In conformity with the mechanism of the hydrogenation of CO (Scheme 8) it has been suggested that the hydrocarbon chain grows via the interaction of the adsorption complex of ZCHOH (ZX_0) with ZCO. Under these conditions, the complex ZCHOH can be partly bound to the carrier (Lewis acid) as a result of the interaction of the unshared electron pair of the oxygen atom with the carrier cation (M_1^{n+}):

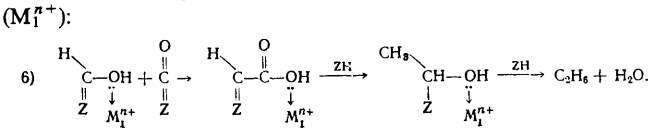

Table 5. Specific catalytic activities and selectivities of deposited metal catalysts in the hydrogenation of CO.

Carrier	$\bar{d}$ for metal, nm	$10^7 r^*$, mol m^{-2} s^{-1}	Selectivity w.r.t. higher hydrocarbon S_{C_n}, %
CO catalyst			
SiO_2	38	52	26

SiO_2	6	3.2	36
Cr_2O_3	12	1.9	44
WO_3	181	<1	0

Note. Mixture composition: P_{CO} = 20 kPa, P_{H_2} = 50 kPa.

* Obtained at 540 K.

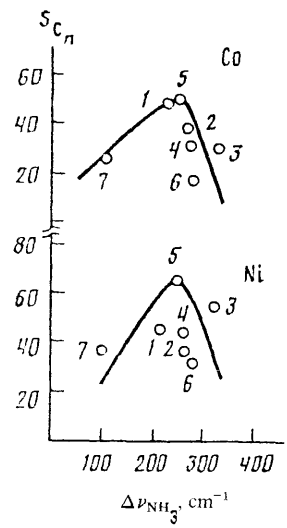

Figure 9. Dependence of the selectivities of deposited Ni and Co catalysts on the acidity of the carriers; carrier: *1*, MgO; *2*, BeO; *3*, Al_2O_3; *4*, Cr_2O_3; *5*, ZrO_2; *6*, TiO_2; *7*, SiO_2.

Then the rate of stage 6 and hence S_{C_n} should depend on the acidity of the carrier. Experimental data have shown that such a relation does indeed exist (Fig. 9): with increase in acidity [with increase in the vibration frequency of the ammonia adsorbed on $(M_1^{n+})_x O_y$ 102], the selectivity with respect to higher hydrocarbons also increases, reaching a maximum for M/ZrO_2. Further increase in the acidity of the carrier diminishes S_{C_n}, the catalyst deposited on carriers with the maximum acidity (M/WO_3) exhibiting 100% selectivity with respect to CH_4. The existence of the optimum acidity can be explained by the fact that, when the bond between the

complex ZCHOH and M_l^{n+} is both too strong and too weak, the probability of the hydrocondensation process is reduced.

In this case the following relation can be written for the selectivity of the Fischer–Tropsch synthesis:

$$S_{C_n} = S_{C_n}(q_{CO}) + S_{C_n}(q_L),$$

where $S_{C_n}(q_{CO})$ is the contribution to the selectivity determined solely by the heat of adsorption of CO and $S_{C_n}(q_L)$ is the contribution to selectivity which depends on the energy of the acid–base interaction.

VII. Hydrogenation of aldehydes

The hydrogenation of saturated aldehydes is of practical importance for the preparation of primary alcohols, mainly 1-propanol, 1-butanol, isobutyl alcohol, and certain higher alcohols:

$$R{-}CHO + H_2 = R{-}CH_2OH. \qquad \text{(XXIV)}$$

Reaction (XXIV) is the concluding stage of the preparation of alcohols by oxo synthesis from alkenes, CO, and H_2. The hydrogenation reaction is carried out as a rule on the catalyst (CO/kieselguhr) used for oxo synthesis. In addition, the Ni–Cu–Cr[103] and Cu–Zn–Al catalysts (synthesis of methanol from CO and H_2),[104] the Ni–Cr and Cu–Cr catalysts,[105] as well as mixed catalysts based on platinum metals[106] are used for the hydrogenation of aldehydes. The detailed mechanism of reaction (XXIV) has not been investigated.

VIII. Conclusion

Certain generalisations, necessary for the rational selection of catalysts and the prediction of the catalytic activity of substances in the hydrogenation of different carbonyl compounds and CO may be based on the data described in this review for the mechanisms and kinetics of such reactions. The activity and selectivity of metal catalysts depend significantly on the energy of the bond (q_R) between the molecule hydrogenated, R, and the catalyst. While the general character of the variation of the catalytic activity with the metal–R bond strength is similar, the optimum values of q_R depend significantly on the nature of the molecule hydrogenated: $(q_{CO})_{opt} \gg (q_{ketone})_{opt}$. As a result of this, an antiparallel variation of the activities of transition metals as a function of their positions in the Periodic Table is observed for the ketone and CO hydrogenation reactions.[107]

The quantity q_R may be varied by altering either the chemical nature of the metal or the degree of its dispersion. The size of the crystals can be regulated in its turn by introducing various additives[107] or by varying the conditions in the reduction of metal oxides.[61]

Consequently, for "structure-sensitive" hydrogenation reactions of carbonyl compounds and CO, where the differences between the adsorption and catalytic activities are not abolished under the influence of the reaction medium, the unequal degrees of dispersion of the metal have just as strong an influence on the catalytic properties as the chemical nature of the metal. Another factor determining the activity and selectivity of the deposited metals may be the variation of q_{CO} under the influence of the "strong metal–carrier interaction" (SMCI).[108,109] The SMCI effect is manifested as a rule for small values of $\bar{d}$ (< 2 nm[109]) and when the carrier cations M_l^{n+} are able to undergo a change in the oxidation state.

The selectivity of the hydrogenation of carbonyl compounds depends to a large extent on the form of the adsorption of the molecule hydrogenated, which is in its turn determined by the chemical composition of the catalyst. Thus, when the "planar" π-complex (I) is formed, acetone is hydrogenated only as far as isopropyl alcohol, while the transition to the "perpendicular" alkoxy-structure (II) promotes the complete reduction of ketones to hydrocarbons.[69]

The CO molecule is also adsorbed in different forms depending on the nature of the catalyst. On transition metals, where carbon monoxide can form bridged and linear structures [see reaction (X)], the carbon–oxygen bond is weakened as a consequence of the predominance of the dative bond.[110] The main CO hydrogenation products on transition metals are therefore hydrocarbons. Among transition metal (Ni, Cu, Zn, Cr) oxides, the preferential formation of oxygen-containing compounds is observed. This reaction pathway is determined by the formation of the CO–M_xO_y donor–acceptor bond. In this case, the C–O bond is seen to be strengthened and the M–C bond is weakened.[110]

The general features of the selective heterogeneous-catalytic hydrogenation reactions of carbonyl compounds and CO listed above will help in the future to achieve a general treatment of new experimental results concerning particular reactions and alternative bases for the specific rational choice of selective catalysts for these processes.

I. Introduction

This review is devoted to the consideration of the methods of synthesis and chemical properties of nitrocyano-compounds in which the nitro- and cyano-groups are linked to a common carbon atom. Compounds of this type have found application as biologically active substances,[1-3] as initiators of chain polymerisation reactions,[4] as inhibitors of the thermooxidative ageing of polymers,[5] as components of energy absorbing compositions,[6-8] and also as intermediates for their preparation.[9-12]

α-Nitrocyano-compounds are widely used in organic synthesis. The presence in their molecules of several reaction centres makes it possible to involve these compounds in numerous reactions leading to a wide assortment of polyfunctional aliphatic and heterocyclic products. Many reactions proceed in a non-trivial manner under these conditions, which is associated with the specific features of the mutual influence of the functional groups and the ability of the reaction intermediates to enter into secondary intramolecular processes.

α-Nitronitriles have been used to investigate the inductive and resonance effects of substituents[13-18] and the electronic and steric structures of carbanions.[19-24]

The chemical properties of nitriles and nitro-compounds have been described in detail in monographs and reviews,[25-28] while the methods of synthesis and chemical reactions of α-nitronitriles have been described in a fragmentary manner in only one book.[27]

II. Methods of synthesis

1. Methods of synthesis of α-nitrocyanoalkanes

The first member of the series—nitroacetonitrile—has been synthesised by the dehydration of metazonic acid.[29-35] Its homologues have been obtained by the oxidation[36,37] and photolysis[39] of α-nitrosocyanoalkanes, by the oxidation of α-hydroxyaminocyanoalkanes,[38] by the pyrolysis of 1,1-azobis-1,1-dicyanoalkanes,[40] and by the reaction of α-bromocyanoalkanes with $NaNO_2$.[41,42]

The methods of synthesis of α-nitrocyanoalkanes involving the nitration of nitriles or the cyanation of salts of nitroso-compounds are general in character. The nitration of nitriles by acid nitrating agents cannot be stopped, with rare exceptions,[43] at the stage involving the formation of mononitrocyanoalkanes. One nitro-group can be introduced by carrying out the reaction under alkaline conditions:[44,45]

$$RCH_2CN \xrightarrow[t\text{-}C_4H_9OK]{C_5H_{11}ONO_2} R{-}C^{\ominus}(CN)(NO_2)\,K^{\oplus},$$

$R = C_2H_5$, n-C_4H_9, C_6H_5,

$$NCCH_2(CH_2)_nCH_2CN \xrightarrow[t\text{-}C_4H_9OK]{C_5H_{11}ONO_2} K^{\oplus}{}^{\ominus}C(CN)(NO_2){-}(CH_2)_n{-}C^{\ominus}(CN)(NO_2)K^{\oplus},$$

$n = 2$–4, 6.

α-Nitrocyanoalkanes have been synthesised in 60–80% yields by the oxidative cyanation of salts of secondary nitroalkanes and nitrocycloalkanes.[46,47] A one-electron redox mechanism has been proposed:[47]

$$R^1R^2C^{\ominus}{-}NO_2 \xrightarrow[{}^{\ominus}CN]{K_3Fe(CN)_6} NC{-}C(R^1)(R^2){-}NO_2,$$

$R^1 = CH_3$, $R^2 = CH_3$, C_2H_5, n-C_5H_{11}; $R^1R^2 = -(CH_2)_n-$.

The preparation of functional derivatives of nitroacetonitrile containing aminocarbonyl,[48-51] alkoxycarbonyl,[51] and acyl[52] groups has been described.

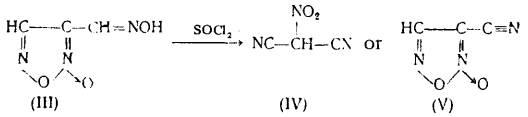
2. Methods of synthesis of α-polynitrocyanoalkanes

The interaction of cyanoacetic acid and its derivatives (amide, esters, nitrile, as well as their mono- and di-nitro-derivatives) with the nitrating mixture leads to the formation of trinitroacetonitrile (I).[53,54] However, the nitration of methyl cyanoacetate affords methyl dinitrocyanoacetate (II):[55]

$$R{-}C(X^1)(X^2){-}C{\equiv}N \xrightarrow[H_2SO_4]{HNO_3} (O_2N)_3CCN,$$

(I)

X^1, $X^2 = H$, NO_2,
$R = COOH$, $CONH_2$, $C{\equiv}N$.

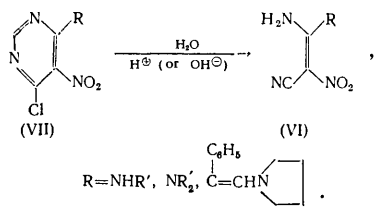


$$CH_3OCOCH_2C{\equiv}N \xrightarrow[H_2SO_4]{HNO_3} CH_3OCOC(NO_2)(NO_2){-}C{\equiv}N.$$

(II)

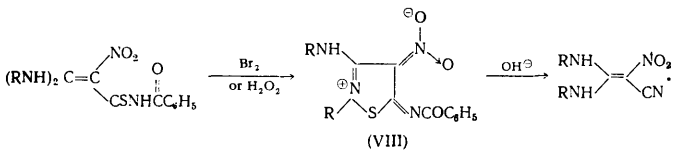
The nitration of α-hydroxyiminonitriles is a more general method of synthesis of αα-dinitrocyanoalkanes.[4,55-57] The cyanation of the silver salt of trinitromethane by iodocyanogen, leading to trinitroacetonitrile, can serve as an example of another approach to the synthesis of α-polynitrocyanoalkanes.[58]

3. Methods of synthesis of α-polycyanonitroalkanes



The dehydration of furoxanealdoxime (III), to which the structure of nitrocyanoacetaldoxime was erroneously attributed previously,[59] gives rise to dicyanonitromethane (IV) or to the cyanofuroxane (V).[51] The ammonium, potassium, and silver salts of compound (IV) have been obtained:[59,60]

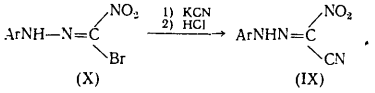
(III) (IV) (V)



4. Methods of synthesis of α-nitronitriles whose functional groups are linked to an sp^2-hybridised carbon atom

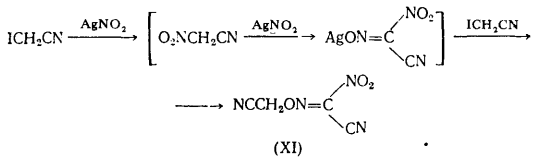
The simplest representative of α-nitrocyanoalkenes, namely α-nitroacrylonitrile, is unstable,[61] but many of its β-substituted derivatives are stable. 1-Amino- and 1,1-diamino-2-nitro-2-cyanoalkenes (VI) are formed in the degradative hydrolysis of chloronitropyrimidines (VII) under acid[62–64] or alkaline[65] conditions:

(VII) (VI)



The alkaline hydrolysis of derivatives of isothiazoline (VIII), obtained by oxidising nitroketen aminals, also leads to 1,1-diamino-2-nitro-2-cyanoethylenes:[66]

(VIII)



Methods have been developed for the preparation of 1-amino-2-nitro-2-cyanoethylenes by the interaction of 3-chloro-4-nitroisothiazole[67] and 5-methyl-4-nitroisooxazole[68] with amines.

The cyanation of the arylhydrazones of bromonitroformaldehyde (X) constitutes a general method of synthesis of the arylhydraxones of cyanonitroformaldehyde (IX):[2,69]

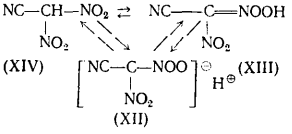
(X) (IX)

The interaction of iodoacetonitrile with $AgNO_2$ leads to a derivative of cyanonitroformaldoxime (XI):[70]

(XI)

III. Properties

1. The structure and acid–base properties of α-nitrocyanoalkanes



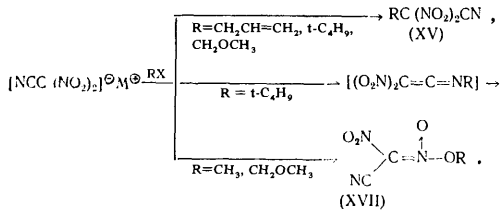
α-Nitronitriles containing hydrogen atoms in the α-position relative to the nitro- and cyano-groups are strong CH acids and are able to form salts with metals or organic bases. The thermodynamic stability of the α-nitrocyanoalkane anions is due to the strong-*I* effects of nitro- and cyano-groups (the Taft σ* constants are 3.9 and 3.6 respectively[71]) and also by the ability of the latter to participate in the delocalisation of the charge of the carbanion (mesomeric effect). The pK_a for certain α-nitrocyanoalkanes are listed in Table 1.

Table 1. The pK_a values for α-nitrocyanoalkanes in water.[72]

Compound	pK_a	T, °C
$NCCH_2NO_2$	4.86	27
$NCCH(C_6H_5)NO_2$	0.29	20
$NCCH(CO_2CH_3)NO_2$	−5.20	20
$NCCH(NO_2)_2$	−6.22	20

The dinitroacetonitrile anion has an almost planar structure, which follows from the results of X-ray diffraction analysis of its potassium, rubidium, and caesium salts.[22–24] Its C ≡ N bond length (1.20 Å) exceeds the C≡N bond length in cyanoalkanes (1.14–1.16 Å), while the C–C(N) bond is shorter (1.36 Å) than the usual C–C single bond (1.43 Å), which indicates the involvement of the nitrile group in conjugation. This conclusion has been confirmed by the results of IR spectroscopic[22] and ^{14}N NMR[19,20] studies on the dinitroacetonitrile anion.

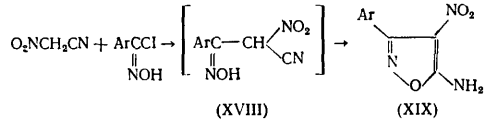
It has been established by IR and UV spectroscopic methods that dinitroacetonitrile can exist in solutions in three tautomeric forms: as the ion pair (XII) (in water and polar organic solvents),[73] as the thermally labile *aci*-form (XIII) (in 100% H_2SO_4 or anhydrous dichloroethane),[74] and as the "true" dinitro-compound (XIV):



(XIV) (XII) (XIII)

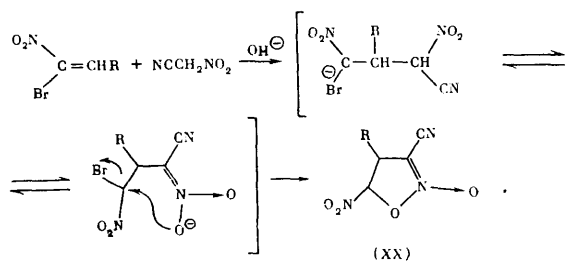
The structures of the α-nitronitriles whose nitro- and cyano-groups are linked to an sp^2-hybridised carbon atom have not been investigated.

2. Reactions of α-nitronitriles with electrophiles



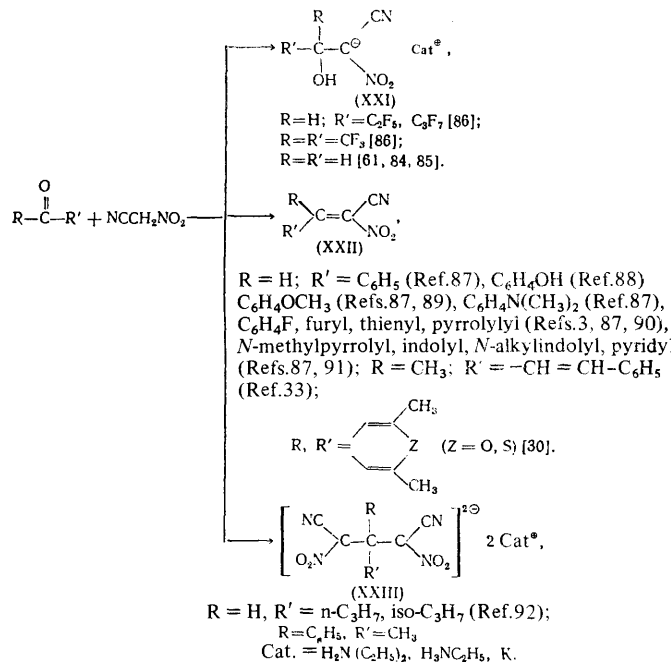
(a) Alkylation of α-nitrocyanoalkanes. The interaction of the silver salt of dinitrocyanomethane with alkylhalides can take place at the carbon atom linked to the nitro- and cyano-groups (*C*-alkylation), at the nitrogen atom of the nitrile group (*N*-alkylation), and at the oxygen atom of the nitro-group (*O*-alkylation) depending on the

nature of the alkylating agent. The reaction products are dinitrocyanoalkanes (XV), dinitrocarboxamides (XVI), and nitronic esters (XVII)[75,76,134] respectively:



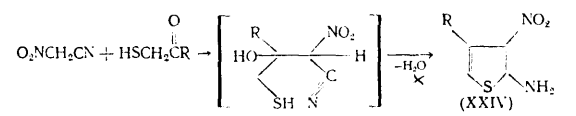
The interaction of the silver salt of phenylnitroacetonitrile with trityl chloride leads only to the *O*-alkylation product.[77] The formation of nitronic esters is observed in the alkylation of α-nitrocyanoalkanes by diazomethane.[78–80] Nitronates with a low stability can enter into further interactions under the reaction conditions.[81]

The interaction of nitroacetonitrile with Mannich bases[33,61] or with arylchloroximes[52] affords the *C*-substitution products. In the latter case the product of the cyclisation of the intermediate (XVIII)—5-amino-3-aryl-4-nitroisoxazole (XIX)—was isolated:



The ability of the nitrile group to enter into intramolecular condensation reactions under mild conditions is a characteristic property of α-nitronitriles, which distinguishes them from other types of cyano-compounds and makes it possible to construct on their basis various heterocyclic systems (see below).

(b) Reactions of α-nitrocyanoalkanes with alkenes containing activated double bonds. The α-nitrocyanoalkanes containing a mobile hydrogen atom in the α-position relative to the nitro- and cyano-groups are able to add to compounds containing the C = C double bond activated by strong electron-accepting substituents. The reactions of dinitroacetonitrile with methyl acrylate, acrylamide, acrolein, butenone, methylenebisacrylamide, and *NN'N''*-triacryloylperhydro-*s*-triazine lead to the formation of the corresponding Michael adducts.[76] The process does not require base catalysis owing to the high acidity of dinitroacetonitrile. The reaction of nitroacetonitrile with vinyl ketones can afford products of the addition to both the C = C double bond and to the carbonyl group.[82] The interaction of the sodium salt of nitroacetonitrile with 1-bromo-1-nitroalkenes results in the formation of 4-alkyl(aryl)-3-cyano-5-nitroisoxazolines (XX) in accordance with the following scheme:[83]



(c) Reactions of α-nitrocyanoalkanes with compounds containing C = O or C = N bonds. The interaction of nitroacetonitrile with aldehydes leads as a rule to three types of products: the salts of 1-nitro-1-cyano-2-hydroxyalkanes (XXI), 1-nitro-1-cyanoalkenes (XXII), and the salts of the dinitriles of substituted 2,4-dinitroglutaric acids (XXIII). The reaction can be stopped at the stage involving the formation of compound (XXI) by using formaldehyde,[61,84,85] perfluoroaldehydes, and perfluoroketones[86] as carbonyl components. The products of the reaction of nitroacetonitrile with aromatic and heteroaromatic aldehydes are unsaturated compounds (XXII).[6,61,87–91] When nitroacetonitrile interacts with aliphatic aldehydes, the salts (XXII) formed initially combine with a second nitroacetonitrile molecule and are converted into salts of dinitrodinitriles (XXIII).[61,92]

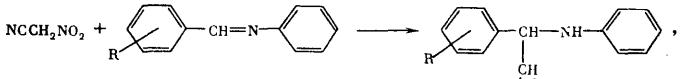
The reaction of nitroacetonitrile with ketones also leads to the formation of compounds (XXII) and (XXIII). The first possibility obtains in the case of benzylideneacetone,[33] 2,6-dimethyl-γ-pyrone, and 2,6-dimethyl-γ-thiapyrone[30] and the second arises in the reactions of nitroacetonitrile with acetophenone and cyclohexanone:[33]

The interaction of nitroacetonitrile with α-mercaptoketones is accompanied by intramolecular condensation and derivatives of 1-amino-2-nitrothiophen (XXIV) are formed:[9]

The product of the reaction of dinitroacetonitrile with formaldehyde is 2,2-dinitro-2-cyanoethanol.[76]

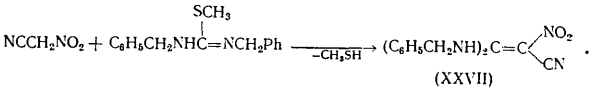
The reactions of α-nitrocyanoalkanes with carbonyl compounds require as a rule base[33,86,88,89,92] or acid[91] catalysis. Certain reactions take place readily also in the absence of catalysts.[31,76]

Nitroacetonitrile enters into three-component reactions with formaldehyde–amine and alkyl orthoformate–amine systems. In the former case, the process proceeds like the Mannich reaction and leads to the formation of 2-amino-1-nitro-1-cyanoalkanes[33] while in



the latter derivatives of 2-amino-1-nitro-1-cyanoethylene (XXV) are prodduced:[93,94]

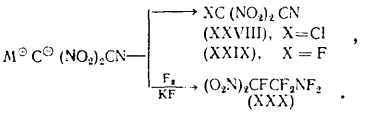
$$NCCH_2NO_2 + CH(OR)_3 + ArNH_2 \rightarrow \begin{matrix} O_2N \\ NC \end{matrix}\!\!>\!C{=}CH{-}NH{-}Ar,$$



$Ar = C_6H_5$, p-ClC_6H_4, p-$CH_3C_6H_4$. (XXV)

The addition of α-nitrocyanoalkanes to C = N double bonds has been little investigated. The interaction of nitroacetonitrile with benzylideneaniline and its derivatives is completed by the formation of the adducts (XXVI).[33] The product of the reaction of nitroacetonitrile with *NN'*-dibenzyl-*S*-methylisothiourea is 1,1-di(benzylamino)-2-nitro-2-cyanoethylene (XXVII):[34]

$NCCH_2NO_2$ + (R-substituted) $CH{=}N$ — $\rightarrow$ (R-substituted) $CH{-}NH$ — $CH(CN)(NO_2)$,

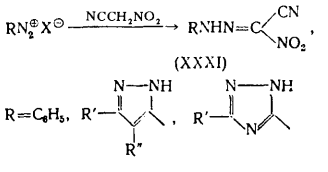


R = H, *o*-Cl, *p*-Cl. (XXVI)

$$NCCH_2NO_2 + C_6H_5CH_2NHC(SCH_3){=}NCH_2Ph \xrightarrow[-CH_3SH]{} (C_6H_5CH_2NH)_2C{=}C(NO_2)(CN).$$

(XXVII)

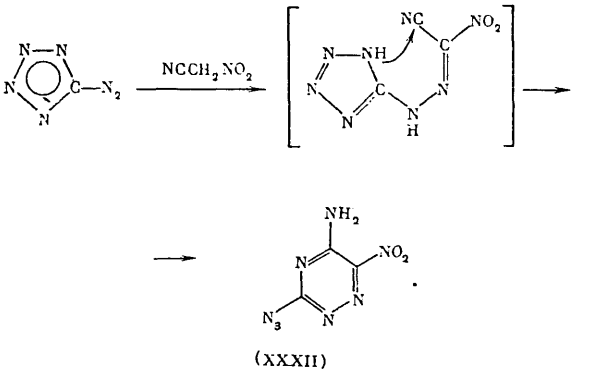
(d) Reactions of α-nitrocyanoalkanes leading to the formation of a carbon–heteroatom bond. The salts of α-nitro-[29,44,45] and α-dinitrocyanoalkanes[53] are readily brominated with formation of α-bromo-derivatives. The product of the interaction of the sodium salt of dinitroacetonitrile with Cl_2 is chlorodinitrocyanomethane(XXVIII).[53] Chlorine fluorosulphonate[95] and the $HCl-H_2O_2$ system[53] have also been used as chlorinating agents for the synthesis of compound (XXVIII). Fluorination of salts of dinitroacetonitrile by elemental fluorine in an aqueous medium[96] and in the CaF_2-Ni system[97] leads to the formation of fluorodinitroacetonitrile (XXIX). In the presence of KF, the nitrile (XXIX) formed initially combines with two molecules of F_2 at the C = N double bond, affording 2-difluoroamino-1,1-dinitrotrifluoroethane (XXX):[97]



$M^{\oplus}C^{\ominus}(NO_2)_2CN$ — $\rightarrow XC(NO_2)_2CN$ (XXVIII), X=Cl (XXIX), X = F; $\xrightarrow[KF]{F_2} (O_2N)_2CFCF_2NF_2$ (XXX).

The reaction of the sodium salt of dinitroacetonitrile with perchloryl fluoride does not permit the synthesis of compound (XXIX),[98] but fluorination of the potassium salt of ethyl nitrocyanoacetate by this fluorinating agent affords ethyl fluoronitrocyanoacetate.[99]

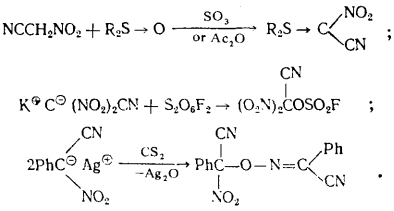
Dinitroacetonitrile is smoothly nitrated by fuming HNO_3 and sulphuric acid–nitric acid mixtures to trinitroacetonitrile.[53] The reaction is described by a third-order kinetic equation, which includes the concentrations of dinitroacetonitrile, HNO_3, and the water or H_2SO_4 present in the system.[100]



The interaction of nitroacetonitrile with aromatic[29] and heteroaromatic[32] diazonium salts leads to the formation of the corresponding hydrazones of nitrocyanoformaldehyde (XXXI):

$RN_2^{\oplus}X^{\ominus} \xrightarrow{NCCH_2NO_2} RNHN{=}C(CN)(NO_2)$, (XXXI)

R=C_6H_5, R'= , R'=



In the case of diazotetrazole, the process cannot be stopped at the hydrazone formation stage; the hydrazone is converted under the reaction conditions into 5-amino-3-azido-1,2,4-triazine (XXXII), which cannot be obtained in other ways:[101]

(XXXII)

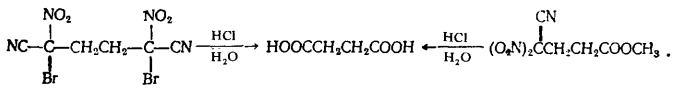
In contrast to nitroacetonitrile, dinitroacetonitrile reacts with aromatic diazo-compounds to form only arenediazonium salts containing the anion $(O_2N)_2\bar{C}CN$.[102]

In a number of instances, the reactions of α-nitrocyanoalkanes with electrophiles lead to the formation of a bond between the carbon atom and the atoms of Group VI elements. The formation of the ylide C ← S bond is observed in the interaction of nitroacetonitrile and its salts with dialkyl sulphoxides[103,104] [Eqn. (1)]. The formation of the C–O bond accompanies the reactions of the potassium salt of dinitroacetonitrile with peroxysulphuryl difluoride[105] [Eqn. (2)] and of the silver salt of α-nitrophenylacetonitrile with CS_2[106,107] [Eqn. (3)]:

$$NCCH_2NO_2 + R_2S \rightarrow O \xrightarrow[or\ Ac_2O]{SO_3} R_2S \rightarrow C(NO_2)(CN); \quad (1)$$

$$K^{\oplus}C^{\ominus}(NO_2)_2CN + S_2O_6F_2 \rightarrow (O_2N)_2C(CN)OSO_2F; \quad (2)$$

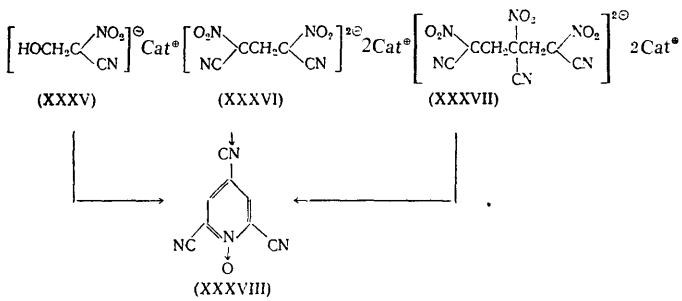
$$2PhC^{\ominus}(CN)(NO_2)Ag^{\oplus} \xrightarrow[-Ag_2O]{CS_2} PhC(CN)(NO_2)-O-N{=}C(Ph)(CN). \quad (3)$$



3. Reactions of α-nitronitriles with nucleophiles

(a) Reactions of α-nitrocyanoalkanes with nucleophiles accompanied by the elimination of functional groups. α-Nitrocyanoalkanes exhibit dual reactivity in relation to nucleophiles. The attack by a nucleophile on the carbon atom of the nitrile group leads to the formation of adducts. The attack on the carbon atom linked to the nitro- and cyano-group is accompanied by the elimination of one of them.

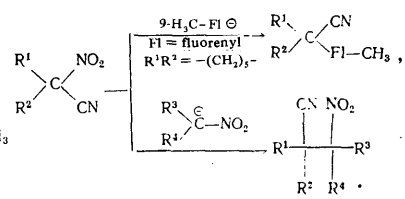
The mode of elimination depends on the nature of the nucleophile and the structure of the α-nitrocyanoalkane. Thus, treatment of trinitroacetonitrile[53] or fluorodinitroacetonitrile[98] with the OH^- anion, which has a high oxidation potential, results in the nitrile group being split off. However, the reactions of trinitroacetonitrile with reductants (H_2S, $Br^{\ominus}$) lead to the elimination of the nitro-group.[53,54]



Treatment of alkyl derivatives of nitro- and dinitro-acetonitrile is accompanied in all cases by decyanation and the formation of the salts of the corresponding nitroalkanes.[45,56,76] Under fairly severe conditions (heating with aqueous alkali), the salts of α-nitrocyanoalkanes also undergo decyanation on treatment with nucleophiles.[44,57]

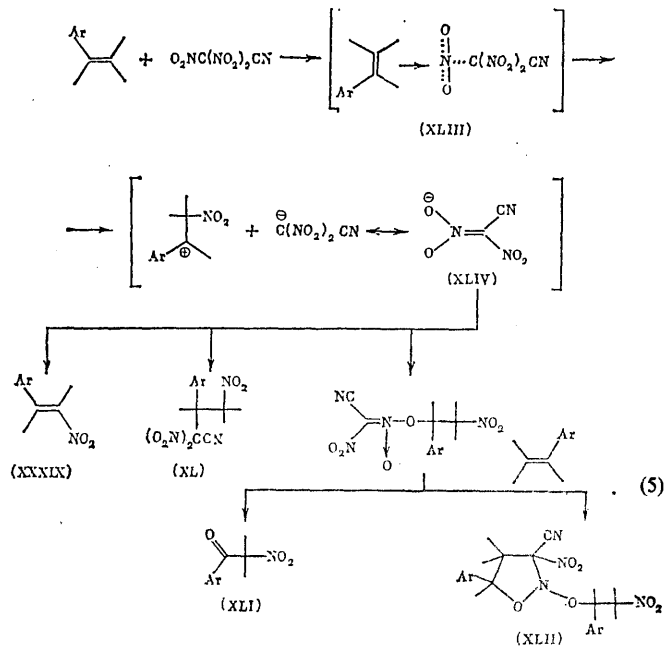
The elimination of functional groups is observed in the reactions of α-nitrocyanoalkanes with aqueous acids. The product of the reactions of compounds (XXXIII) and (XXXIV) with HCl is succinic acid;[45,76]

(XXXIII) (XXXIV)



The acid hydrolysis of the salts (XXXV)–(XXXVII) proceeds with retention of the cyano-groups and the formation of 2,4,6-tricyanopyridine *N*-oxide (XXXVIII):[61,84,85]

(XXXV) (XXXVI) (XXXVII) (XXXVIII)

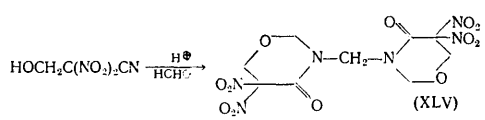


The cyano-groups are retained also in the reactions involving the "degradative alkylation" of dialkyl derivatives of nitroacetonitrile by the 9-methylfluorenyl anion[108] or salts of nitroalkanes,[109–111] leading to the formation of highly branched cyano-compounds [Eqn. (4)]:

R^1, R^2	R^3, R^4
$-(CH_2)_4-$	CH_3, CH_3
CH_3, CH_3	CH_3, CH_3
CH_3, CH_3	$-(CH_2)_5-$
CH_3, CH_3	CH_3, $CH_2CH_2COOCH_3$

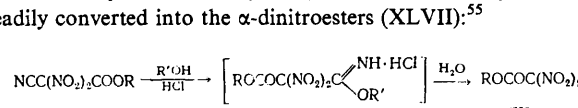
(4)

The reaction of trinitroacetonitrile with arylalkenes, which behave in this case as nucleophiles, is accompanied by denitration. The reaction may result in the formation of a whole series of products: conjugated nitroalkenes (XXXIX), 1-cyano-1,1,3-trinitroalkanes (XL), α-nitroketones (XLI), and 2-(β-nitroalkoxy)-3-cyano-3-nitroisoxazolidines (XLII).[112–115] A reaction mechanism has been proposed,[113,115] including the formation of a charge-transfer complex (XLIII) and an ion pair (XLIV), which is stabilised either by splitting off H^+ from the cation or by the *C*- or *O*-alkylation of the dinitroacetonitrile anion [Eqn. (5)]:



(XLIII) (XLIV) (XXXIX) (XL) (XLI) (XLII)

(5)

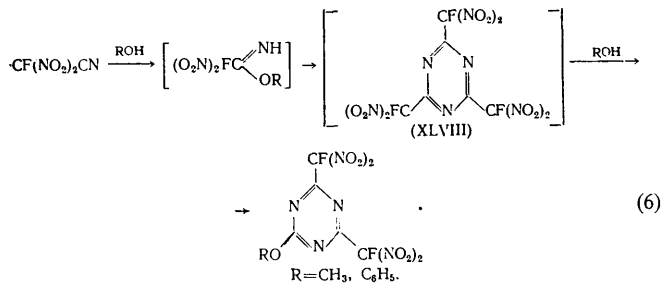


(b) Reactions of α-nitrocyanoalkanes with nucleophiles accompanied by addition to the C ≡ N bond. The nitrile group in α-nitrocyanoalkanes is activated by the neighbouring nitro-group and readily combines with nucleophiles: water, alcohols, amines, and chlorine fluorosulphate.

The hydrolysis of α-nitrocyanoalkanes can be stopped at the stage involving the formation of amides of carboxylic α-nitroacids on treatment with HCl in inert organic solvents[96,116] or when the reaction is carried out in 85–99% H_2SO_4.[99,117] The hydrolysis of 2,2-dinitro-2-cyanoethanol in the presence of formaldehyde is accompanied by condensation reactions and leads to the formation of the bicyclic methylenebisamide (XLV):[76]

(XLV)

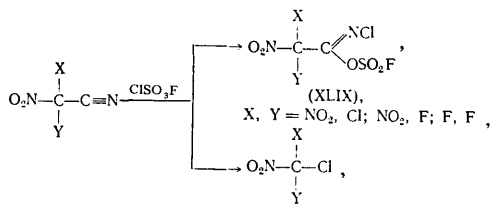
The products of the reactions of α-nitrocyanoalkanes with alcohols in the presence of HCl are iminoester hydrochlorides (the Pinner reactions).[55,118] In the case of dinitrocyanoacetates, the imonoester hydrochlorides (XLVI) have a low stability and are readily converted into the α-dinitroesters (XLVII):[55]



(XLVI) (XLVII)

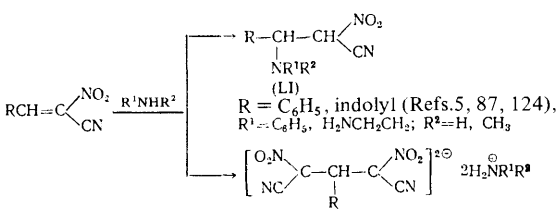
R = CH_3, C_2H_5, n-C_4H_9, C_6H_{11}, CH_2CH_2Br, $CH_2CH_2ONO_2$.

Fluorodinitroacetonitrile combines with alcohols in the presence of basic catalysts [CH_3ONa, $N(C_2H_5)_3$][97] or without a catalyst,[98] affording the free iminoesters. The iminoester formation stage apparently includes the cyclotrimerisation of fluorodinitroacetonitrile to 1,3,5-triazine derivatives (XLVIII) in the presence of alcohols



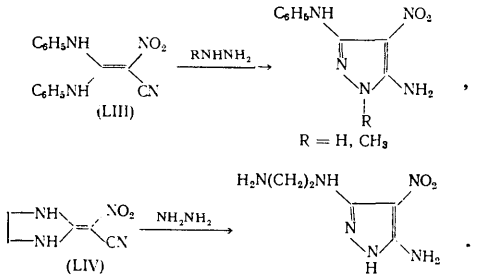
under a pressure of 8–10 kbar in accordance with reaction (6):[119]

(6)



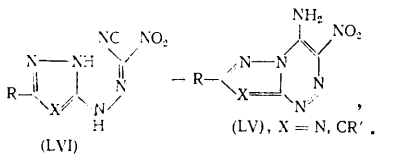
The interaction of α-nitrocyanoalkanes with amines usually leads to the formation of amidines.[97,120] In a number of cases, amidines are capable of undergoing further interactions (hydrolysis,[10] cyclisation[121]) under the reaction conditions. The addition of hydroxylamine to nitroacetonitrile results in the formation of the amidoxime of nitroacetic acid.[29]

Chlorine fluorosulphate adds to the C≡N bond of chlorodinitro-, fluorodinitro-, and difluoronitro-acetonitriles, affording chloroimino-fluorosulphonylesters (XLIX).[95,122] However, the reaction with ethyl dinitrocyanoacetate leads not to the adduct but to the product (L) of the substitution of the nitrile group by chlorine:[95]



(L), X = NO_2, Y = $CO_2C_2H_5$.

(c) Reactions of α-nitronitriles whose functional groups are linked to an sp^2-hybridised carbon atom with nucleophiles. α-Nitrocyanoalkenes can combine with nucleophiles in the β-position. The interaction of 1-aryl- and 1-heteroaryl-2-nitro-2-cyanoethylenes with amines affords two types of products depending on the basicity of the amines: 1-amino-2-nitro-2-cyanoethylenes (LI) and the salts of the dinitriles of 3-substituted 2,4-dinitro-glutaric acids (LII). The less basic aromatic amines (pK_b = 9.0–9.5) form the adducts (LI),[5,87,124] while alkylamines (pK_b = 3.0–4.8) (with the exception of ethylenediamine) afford the salts (LII):[87–89,123,126,128]

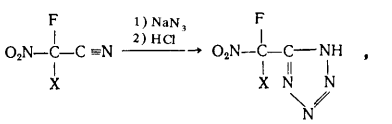


R = C_6H_5 (Refs.87, 123), thienyl (Refs.125, 126, 128), C_6H_4OH (Ref.88), $C_6H_4OCH_3$ (Ref.89), C_6H_4F (Ref.3), furyl (Ref.127);
R, R^1 = H, alkyl, cycloalkyl.

In a number of instances, the addition of nucleophiles to derivatives of 1-nitro-1-cyanoethylene may be accompanied by intramolecular condensation involving the nitrile group. Thus the reaction of nitrocyanoketen aminals (LIII) and (LIV) with hydrazine leads to polyfunctional compounds of the pyrazole series:[129]

R = H, CH_3

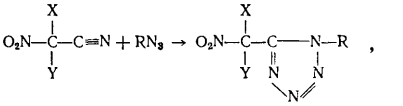
Cyclisation with formation of condensed derivatives of 1,2,4-triazine (LV) is observed in the case of pyrazolyl- and triazolyl-hydrazones of cyanonitroformaldehyde (LVI).[32] One of the nitrogen atoms of the heterocycle plays the role of the nucleophile attacking the carbon atom of the nitrile group under these conditions:



(LV), X = N, CR′.

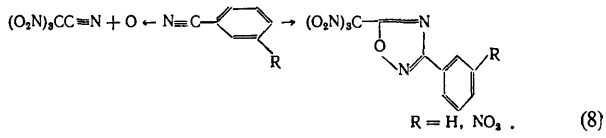
4. Cycloaddition reactions of α-nitronitriles

α-Nitrocyanoalkanes are capable of entering into 1,3-dipolar cycloaddition reactions. The dipolarophile activity of the nitrile group in these compounds exceeds the activity of the majority of aliphatic nitriles owing to the presence in their composition of the electron-accepting nitro-groups.



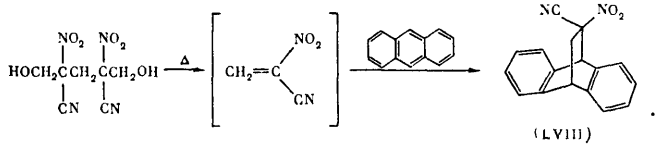
Fluorodinitro-, and difluoronitro-acetonitriles readily combine with NaN_3, forming the corresponding tetrazole derivatives (LVII):[130,131]

(LVII), X = F, NO_2.



Sodium azide adds also to the salts of α-nitrocyanoalkanes, but the reaction requires much more severe conditions.[132]

The reactions of α-nitrocyanoalkanes with organic azides lead as a rule to the formation of 1,5-disubstituted tetrazole derivatives. The reaction conditions depend on the steric structure of the azide. Whereas methyl azide adds to fluoridinitro- and difluoronitro-acetonitrile even at room temperature,[130] the cycloaddition of the sterically more hindered n-hexyl and trimethylsilyl azides occurs only after heating for many hours at 60–70 °C[131] [Eqn. (7)]:



X = Y = F; R = CH_3;
X = NO_2, Y = F; R = CH_3, n-C_6H_{13}, Si $(CH_3)_3$;
X = Y = NO_2; R = Si $(CH_3)_3$. (7)

The reaction of trinitroacetonitrile with aromatic nitrile oxides, leading to the trinitromethyl derivatives of 1,2,4-oxadiazole in high yields[133] [Eqn. (8)], takes place under mild conditions:

(8)

α-Nitrocyanoalkenes can enter into the Diels–Alder reaction. 1-Nitro-1-cyanoethylene, generated *in situ* from the dinitrile of 2,4-di(hydroxymethyl)-2,4-dinitroglutaric acid, combines with anthracene to form the adduct (LVIII):[61]

(LVIII)

IV. Applications of α-nitronitriles

Many α-nitronitriles whose functional groups are linked to an sp^2-hybridised carbon atom exhibit biological activity. Thus 2-(nitrocyanomethylene)-1,3-dithiacyclobutane exhibits a fungicidal activity.[1] The arylhydrazones of cyanonitroformaldehyde possess insecticidal and fungicidal activities.[2]

The bis-2,2-dichlorodiethylammonium salt of 2,4-dinitro-3-phenylglutaronitrile exhibits an antitumour activity[32] and a number of nitronitrile salts are inhibitors of the thermooxidative ageing of polymers.[5]

The potassium, sodium, and barium salts of dinitroacetonitrile have been recommended as regulators of the rate of combustion of rocket fuels.[6,7]

α-Dinitrocyanoacetates have been proposed as additives to explosive and combustible mixtures, as initiators of chain polymerisation reactions, and as reagents for the determination of OH and NH_2 groups.[4]

Epoxy-αα-dinitrocyanoalkanes have been patented at monomers for the synthesis of high-energy polymeric binders.[8] Trinitro- and fluorodinitro-acetonitriles can be used as intermediates for the preparation of mixtures of trinitromethyl- and fluorodinitromethyltetrazoles—components of solid rocket fuels.[11,12]

Advances in the chemistry of isochroman

E A Markaryan, A G Samodurova
Mndzhoyan Institute of Fine Organic Chemistry, Academy of Sciences of the Armenian SSR, Erevan

ABSTRACT. Data on the synthesis and chemical and biological properties of isochroman and its derivatives dating from 1923 (the start of research into this field) until 1985 inclusive are examined and described systematically.

The bibliography includes 235 references.

I. Introduction

The synthesis of the oxygen-containing heterocyclic isochroman {3,4-dihydro-1*H*-benzo[*c*]pyran} system has been known for a long time but intensive research undertaken to investigate the chemistry of this heterocycle and to seek biologically active compounds (BAC) in the isochroman series date back to the 1970s. The increasing number of publications and patent data during the last 10–15 years indicate the undoubted value of the isochroman ring as the structural basis of a large number of BAC.

The isochroman ring enters into the composition of many substances of natural origin: compounds obtained by the cultivation of micro-organisms,[1] the antibiotic isochroman quinone,[2,3] various metabolites,[4–15] compounds isolated from Oidiodendron rhodogenum,[16] and other substances of plant origin.[17–23] Some of the compounds indicated[1] are of practical value (for example, in the treatment of ulcers and oedemas).

Isochroman derivatives are structural analogues of biogenic amines and derivatives of tetrahydroisoquinoline. In particular, 1-alkylaminoisochromans can be regarded as cyclic analogues of arylalkanolamines incorporating the phenylethylamine fragment in a rigidly fixed structure, which is of definite interest, since it can promote a more specific interaction with a bioreceptor.[24] The analogy between the isochroman and tetrahydroisoquinoline derivatives is determined not only by their structures but also by their interconversions. A series of studies devoted to the conversion of tetrahydroisoquinoline derivatives into isochroman derivatives[25–32] and conversely [33–34] have been published.

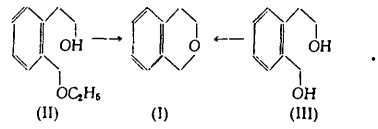
Isochroman derivatives, in particular isochromanones, serve in their turn as synthons in the synthesis of nitrogen-containing bicyclic and polycyclic compounds: galanthamine,[35] phthalazones,[36] yohimbine and its derivatives,[37,38] the seleno-analogue of yohimbine,[39] heterocyclic steroids,[40,41] and other compounds.[42–44] Furthermore, isochroman derivatives can be used also for the synthesis of iridoids,[45] analogues of prostaglandin,[46] indole derivatives,[47] tricyclic systems,[48] and dibenzotropolone.[49] Compounds resembling the last one, especially its derivatives involving the carbonyl group, have a pronounced biological activity, which is accounted for by their structural relation with a natural alkaloid–colchicine.

Despite the very considerable interest in isochroman derivatives, they have been scarcely surveyed in the literature (with the exception of a brief review[50]).

The present review surveys the methods of synthesis and the chemical and biological properties of isochroman and its derivative, mainly of synthetic origin, with different positions of the substituents in the benzene and dihydropyran rings. It does not include isochromanone derivatives, which, in view of the extensive nature of the data available, can be the subject of a separate review.

II. Methods of synthesis of isochroman and its derivatives

There are many features in common between the methods of synthesis of isochroman and its derivatives, but, depending on the position of the substituents and the need to employ different starting materials, there are also specific features in the synthetic approach. It is therefore useful to subdivide isochroman derivatives into the following groups: (a) with substituents in the dihydropyran ring; (b) with substituents in the aromatic ring; (c) with substituents in both the dihydropyran and benzene rings.



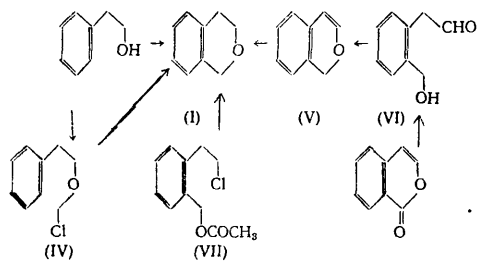
1. Methods of synthesis of isochroman

Isochroman (I) was first synthesised in 1923[51] by heating 2-(2-ethoxymethylphenyl)ethanol (II) with a fourfold excess of fuming hydrobromic acid for 32 h at 100 °C. The homoxylylene dibromide formed simultaneously can be converted into compound (I) by heating with water or a dilute solution of potassium carbamate. The initial alcohol (II) can be obtained by a multistage synthesis. This method is merely of historical interest.

One of the ways of obtaining isochroman involves the cyclisation of 2-(2-hyroxymethylphenyl)ethanol (III), which was obtained from homophthalic anhydride.[52,53] Cyclisation at 45 °C in the presence of potassium bisulphate[52] or on treatment with a mixture of hydrobromic and acetic acids[53] leads to isochroman in 50% yield. In the second case, homoxylylene dibromide is formed together with isochroman.

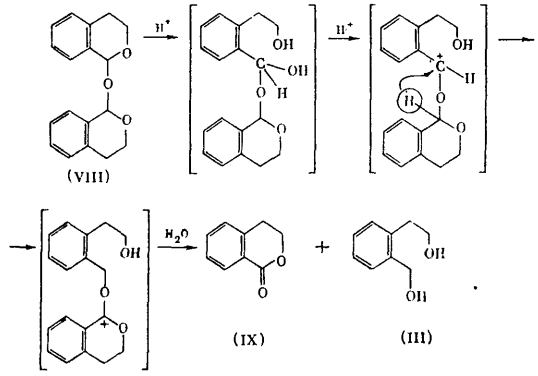
The most effective method, which ensures an almost quantitative yield of compound (I), involves the direct distillation of the diol (III) at 70 °C and a pressure of 3 mmHg in the presence of catalytic amounts of concentrated sulphuric acid.[54] Isochroman has been synthesised in

80% yield by the reaction of 2-phenylethanol with formaldehyde in the presence of concentrated sulphuric acid:[55]



Methods of synthesis of compound (I) based on the chlorometallation of 2-phenylethanol with subsequent cyclisation were developed subsequently. Such a method was first described in 1935.[56,57] Treatment of 2-phenylethanol with paraformaldehyde and hydrogen chloride results in the formation of the chloromethyl derivative, which is then converted into isochroman in 50% yield on treatment with inorganic acids, preferably at 100 °C. Compound (I) with m.p. +3 °C was thus obtained. In 1954, the method was improved and the yield of isochroman reached 90%.[58] The intermediate chlorometallation product was cyclised in this case when the temperature of the reaction mixture rose spontaneously to 45–50 °C without the addition of concentrated hydrochloric acid. Consequently the decrease in the cyclisation temperature leads to an appreciable increase in the yield of compound (I).

Up to 1956, it was assumed that the chlorometallation of 2-phenylethanol results in the formation of 2-(2-chloromethylphenyl)ethanol which subsequently cyclises to isochroman. However, detailed study of the chemistry of this reaction showed[59] that the first stage of the reaction involves the formation of chloromethyl 2-phenylethyl ether (IV), which then cyclises to isochroman. By carrying out the reaction in the temperature range –5–0 °C, it is possible to isolate the intermediate (IV) in 76% yield. The cyclisation product (isochroman) was obtained in 67% yield by heating the ether (IV) with hydrochloric acid at 20–40 °C. The yield of compound (I) increases appreciably (by 30%) when the intermediate (IV) is refluxed in carbon disulphide in the presence of aluminium trichloride.[59] The ether (IV) has been cyclised[60,61] in the presence of alkali or without it, a high yield of compound (I) being ensured in both cases (the yield is 10% higher in the former case than in the latter).

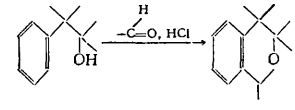


From the standpoint of increasing the yield (to 95%), the synthesis of isochroman from 2-phenylethanol and formaldehyde in the presence of a mixture of hydrochloric acid and phosphorus trichloride also merits attention.[62]

The preparation of isochroman by hydrogenating isochromen (V) in acetic acid in the presence of 10% palladium on charcoal has been described.[63] Isochromen was synthesised from isocoumarin via the hydroxyaldehyde (VI).

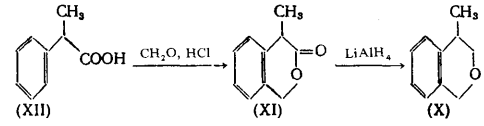
Isochroman can be obtained in 70% yield from the acetyl derivative (VII) by treatment with alcoholic alkali:[64]

Isochroman has been isolated after cleaving di-1-isochromanyl ether (VIII) in the presence of sulphuric acid.[65] The ether then disproportionates to the diol (III) and 1-isochromanone (IX):



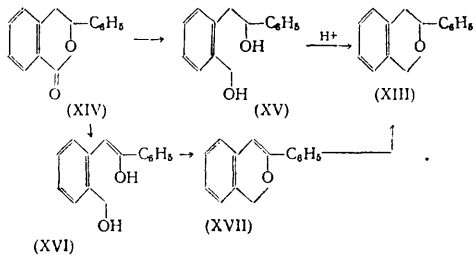
2-(2-Hydroxymethylphenyl)ethanol formed under the reaction conditions readily cyclises to isochroman.

Thus the most effective procedures for the synthesis of isochroman are the methods[58,62] involving the cyclisation of chloromethyl 2-phenylethyl ether in the temperature range 45–50 °C.



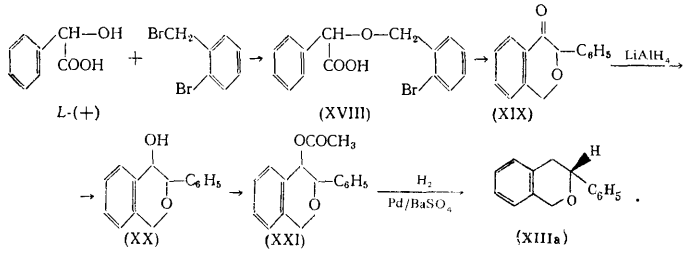
2. Derivatives of isochromans with substituents in the dihydropyran ring

There are several methods of synthesis of isochroman derivatives containing one or several substituents in the 1-, 3-, and 4-positions. One of them is the chloroalkylation of 2-phenylalkanol, analogous to the chloromethylation described in the previous Section:

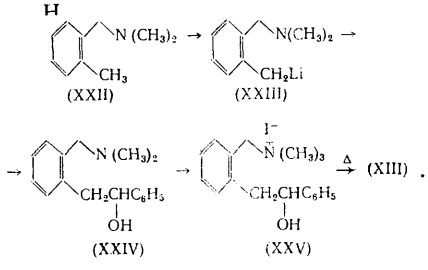


However, chloroalkylation and even more so chloroarylalkylation take place with low yields. 1-Methylisochroman and 1-phenylisochroman have been obtained in this way in 50% yield in the former case and in a yield as low as 7% in the latter case.[60,66]

3-Methylisochroman,[59,67–70] 3-ethyl- and 3-benzyl-isochromans,[68] 4-methylisochroman,[57,67,68] 4-nitroisochroman,[57] and 4,4-dimethylisochroman[71] have been synthesised by the chloromethylation of chain-substituted 2-phenylethanols. 4-Methylisochroman (X) has also been obtained by reducing 4-methyl-3-isochromanone (XI).[66] The latter is formed when hydratropic acid (XII) is chloromethylated:

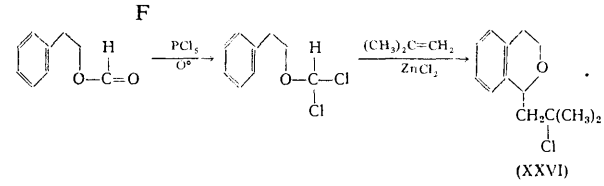


3-Phenylisochromanone (XIII) has been synthesised from 3-phenylisocoumarin (XIV).[52] The reduction of the latter with lithium aluminium hydride (LAH) afforded 2-(2-hydroxymethylphenyl)-1-phenylethanol (XV), which cyclises to compound (XIII) in an acid medium. The reduction of 3-phenylisocoumarin by LAH has been studied in greater detail by a series of investigators. Thus,



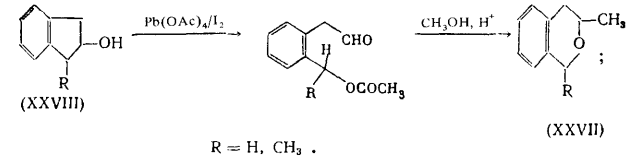
together with the main product, another readily oxidisable compound—the enediol (XVI)—has been obtained.[72] By reducing compound (XIV) at 0 °C, it was possible to isolate compound (XVI) as the main product in 86% yield. The enediol (XVI) cyclises on distillation with formation of 3-phenylisochromen (XVII), which is reduced to compound (XIII) in ethyl acetate by hydrogen in the presence of palladium on charcoal:

A stereoselective synthesis of (*R*)-(+)-3-phenylisochroman (XIIIa) has been achieved with the aid of consecutive reactions: the condensation of L-(+)-mandelic acid with *o*-bromobenzyl bromide; the cyclisation of the carboxyether (XVIII) formed in the presence of butyl-lithium to 3-phenyl-4-isochromanone (XIX); the reduction of the latter with LAH to the corresponding alcohol (XX); the conversion of the alcohol into the acetyl derivative (XXI); the hydrogenation of compound (XXI) to compound (XIIIa):[74]



The synthesis of 3-phenylisochroman from dimethyl(*o*-methylbenzyl)amine (XXII) is unusual:[72]

By treating compound (XXII) with n-butyl-lithium, it is possible to obtain the lithio-derivative (XXIII), whose condensation with benzaldehyde affords the aminoalcohol (XXIV). 3-Phenylisochroman is then obtained via a stage involving the formation of the methiodide (XXV) and its subsequent decomposition by heating. 1,3-Diphenyl- and 3,3-diphenyl-isochroman have been obtained similarly.[72] 1,3-Diphenylisochroman has been synthesised by reducing 2,3-diphenylindene ozonide with sodium tetrahydroborate in trifluoroacetic acid.[75] 1,3-Diphenylisochroman has also been isolated as a side product in the reaction of benzaldehyde with benzylmagnesium chloride.[76]

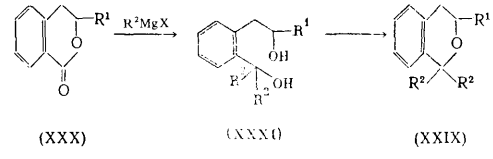


1-Methoxy-4,4-dimethyl-1,3-diphenylisochroman has been obtained by UV irradiation 2-(2-methyl-1-phenylpropenyl)benzophenone in methanol.[77]

It is of interest to note the synthesis of 1-β-chloroisobutylisochroman (XXVI) in accordance with the scheme[78]

The same compound can be obtained from 1-chloroisochroman and isobutene in the presence of a Friedel–Crafts catalyst.[79]

Substituted isochromans (XXVII) have been synthesised from indan derivatives (XXVIII) in accordance with the scheme[80]

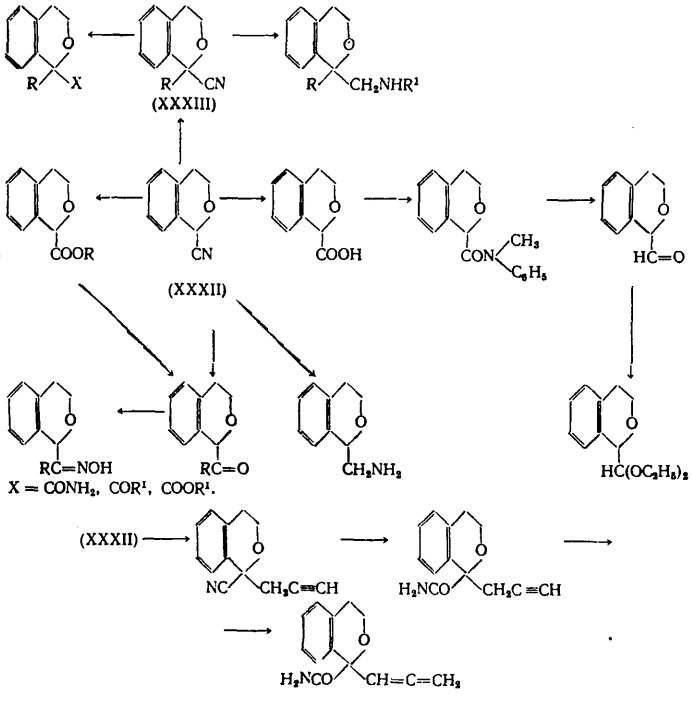


The cyclisation of allyl *o*-bromobenzyl ether on treatment with triethylamine in the presence of palladium acetate and tri-*o*-tolylphosphine leads to a mixture of isomeric derivatives of 2-benzopyran. One of them is 4-methyleneisochroman (XXI).[81]

The photochemical oxidation of 1,1-dimethylindene in methanol results in the formation, together with other products, of 3-hydroxy-1-methoxy-4,4-dimethylisochroman.[82]

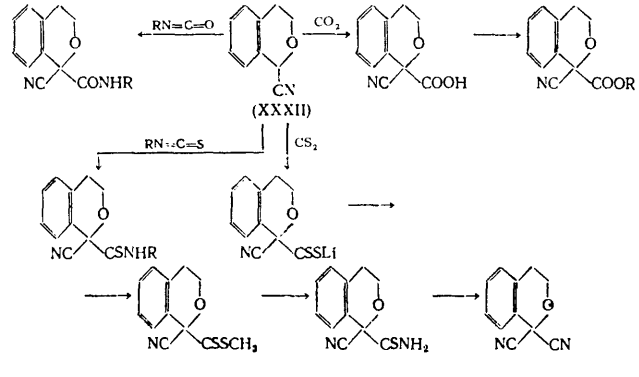
The cyclisation of an *o*-polyene-substituted β-phenylethanol in the presence of a Lewis acid, leading to an isochroman derivative with a tetracyclic substituent in the 1-position, has been described.[83] It is notable that the compound cyclised was obtained by multistage synthesis.

Yet another unusual method of synthesis of isochroman derivatives involves the cyclisation of *o*-mercuriobenzyl alcohols with conjugated or non-conjugated dienes in the presence of a palladium catalyst.[84]



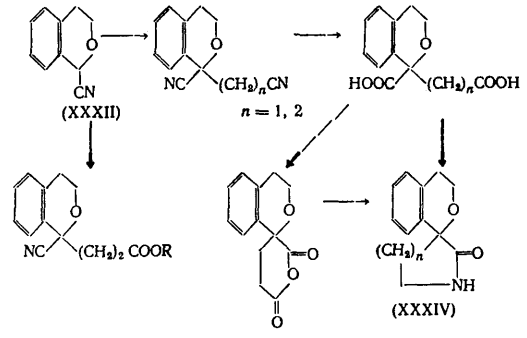
1,1-Disubstituted and 1,1,3-trisubstituted isochroman derivatives (XXIX) have been obtained from substituted 1-isochromanones (dihydroisocoumarins) (XXX).[59,66] Treatment of the lactones (XXX) with a fourfold excess of a Grignard reagent afforded the diols (XXXI). The latter cyclise to the final compounds (XXIX) at 100 °C in the presence of an equimolar amount of phosphoric acid:

The methods of synthesis of 1-monosubstituted and 1,1-disubstituted isochroman derivatives based on the reactivity of the methylene group in the 1-position in isochroman are of great practical value (Scheme 1). Thus 1-halogenoisochromans have been obtained by halogenating isochroman. On reaction with copper cyanide[58] or mercury cyanide,[85] they form 1-cyanoisochroman (XXXII). The latter has been converted into various 1-substituted isochromans: ketones,[85,86] aldehydes,[87] oximes,[24,86] an amine,[24,88,89] a carboxylic acid,[85,88] esters,[86,89] etc. (Scheme 1).



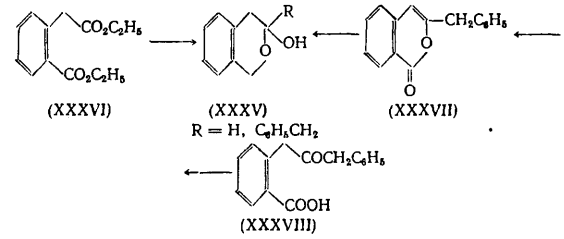
In the presence of strong bases (sodium amide or hydride, organosodium compounds), 1-cyanosiochroman (XXXII) was converted, on treatment with various halides, into a wide variety of 1,1-disubstituted isochromans (XXXIII) by virtue of the high reactivity of the hydrogen in the α-position relative to the nitrile group.[85,90–95] The isochromans (XXXIII) were then subjected to numerous transformations indicated in Scheme 1.

Scheme 1



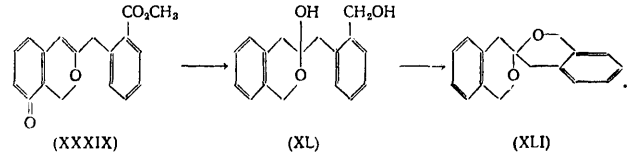
The dithioester, carboxy-, nitrile, and thiocarbamide groups have been introduced in the 1-position of 1-cyanoisochroman in the presence of phenyl-lithium (Scheme 2).[96,97] As in the previous case, certain reactions involving the final compounds obtained were carried out.[96,97]

Scheme 2



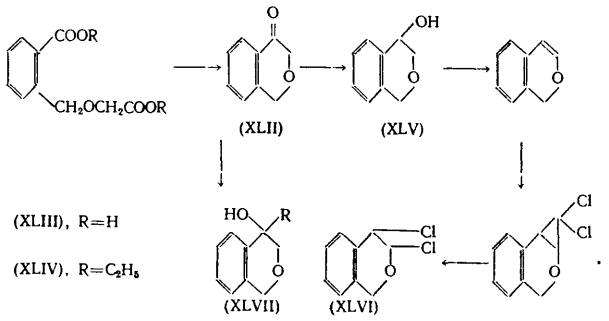
The cyanoethylation of 1-cyanoisochroman has also been achieved.[98,99] It has been shown that condensation takes place best in the presence of tetraethylammonium hydroxide.[99] The series of reactions of the bifunctional isochromans obtained leads to the spirocyclic product (XXXIV, n = 2)[98,99] (Scheme 3). Compounds (XXXIV, n = 1) have been obtained similarly.[91]

Scheme 3



Thus syntheses based on 1-cyanoisochroman lead to extensive possibilities for the preparation of a wide range of varied 1,1-disubstituted isochroman derivatives.

Apart from the compounds with functional-group substituents described above, hydroxyisochromans are also of interest. 3-Hydroxyisochroman (XXXV, R = H) has been synthesised by reducing diethyl homophthalate (XXXVI) with three equivalents of di-isobutylaluminium hydride.[100] 3-Benzyl-3-hydroxyisochroman (XXXV, R = $C_6H_5CH_2$) has been obtained by reducing 3-benzylisocoumarin (XXXVII) with LAH.[73] The isocoumarin (XXXVII) was synthesised by the intramolecular condensation of benzyl 2-carboxybenzyl ketone (XXXVIII) in the presence of acetyl chloride:



3-Hydroxy-3-(2-hydroxymethylbenzyl)isochroman (XL) has been obtained by reducing 3-(2-methoxycarbonylbenzyl)isocoumarin (XXXIX) with LAH.[101] On treatment with perchloric or sulphuric acid, compound (XL) is converted into the spiroketal (XLI):

The reduction of derivatives of 3,4-dihydroisocoumarin with sodium tetrahydroborate in the presence of boran trifluoride (hydroboration) leads to the elimination of the carbonyl group from the 1-position.[102]

The starting material for the synthesis of 4-hydroxy-derivatives is 4-isochromanone (XLII), obtained in 40% yield both by the Perkin reaction from (2-carboxyphenyl)methoxyacetic acid (XLIII) and via the Dieckman reaction from ethyl (2-ethoxycarbonylphenyl)-methoxyacetate (XLIV). 4-Hydroxyisochroman (XLV) has been obtained by the reduction of the ketone (XLII) with LAH[103,104] and was further converted into dichlorohomoisochroman (XLVI). The

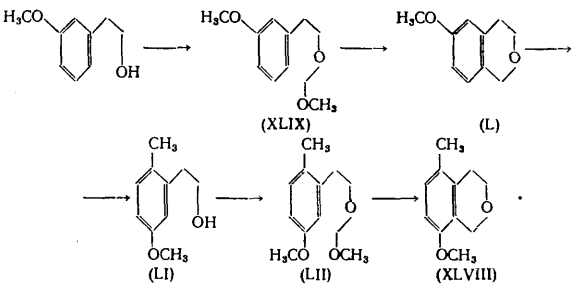
same ketone has been converted into a 4-hydroxy-4-R-substituted isochroman (XLVII) by reaction with a Grignard reagent:[105]

The reaction of DL-glyceraldehyde with benzene in the presence of liquid hydrogen fluoride is of interest. The interaction results in the formation of 1-(1,2-dihydroxyethyl)-3-hydroxymethyl-4-phenylisochroman.[106]

1,1,3,3,4,4-Hexachloroisochroman has been synthesised by treating 3,3,4,4-tetrachloroisocoumarin with phosphorus pentachloride.[107] The isocoumarin derivative was obtained by the reaction of homophthalic acid with the same chlorinating agent.

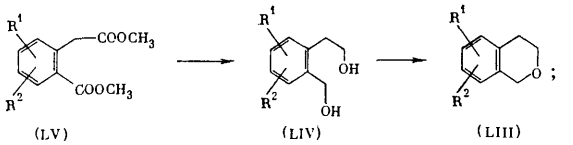
Thus the most convenient method of synthesis of isochroman derivatives with various substituents in the dihydropyran ring is the chloroalkylation of 2-phenylethanol and its derivatives substituted in the ethyl group. This method makes it possible to introduce substituents into the 1-, 3-, and 4-positions in any combination, usually with satisfactory yields of the substituted isochromans, with the exception of the 1-substituted derivatives. Synthesis based on 1-cyanoisochroman merits attention for the latter.

3. Derivatives of isochroman with substituents in the aromatic ring



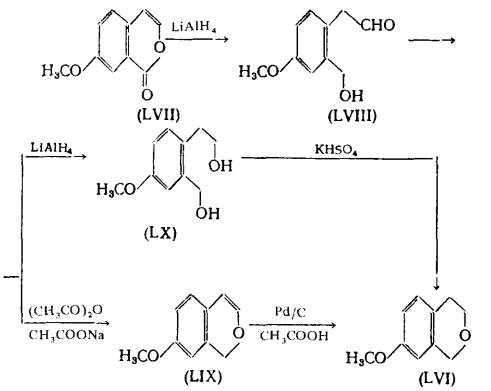
Compounds with substituents in the aromatic ring can be obtained by the chloromethylation reaction using arylethanols:[59,67,108,109]

R = 7-CH_3, 5,8-$(CH_3)_2$, 5,6-benzo, 6,7-$(OCH_3)_2$



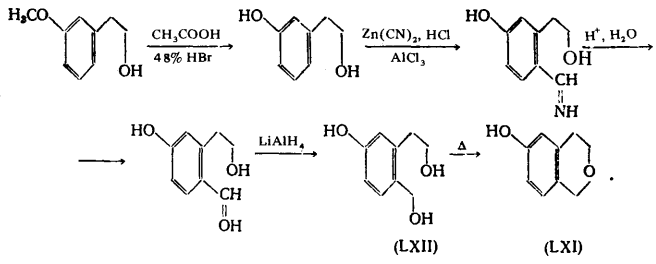
When hydrogen chloride is passed for a long time and also in the presence of an excess of formaldehyde, the chloromethyl group also enters in the *para*-position in the benzene ring relative to the chloromethoxyethyl substituent. 7-Chloromethyl- and 7-chloromethyl-5-methyl-isochromans were obtained respectively in this manner in the synthesis of isochroman and its 5-methyl derivative.[56,110] Various derivatives—the nitrile, the amide, and esters—have been synthesised by further reactions of 7-chloromethylisochroman.[110]

A method has been developed for the synthesis of 5,8-disubstituted derivatives of isochroman (XLVIII).[111] 2-(3-Methoxyphenyl)ethyl methoxymethyl ether (XLIX) has been synthesised by a Williamson reaction. The ether cyclises to 6-methoxyisochroman (L) in the presence of toluene-*p*-sulphonic acid and the isochroman is converted further into 8-methoxy-5-methylisochroman (XLVIII). The methyl group is introduced into the 5-position as a result of consecutive reactions: the degradative reduction of 6-methoxyisochroman in the presence of aluminium hydride, the condensation of 2-(5-methoxy-2-methylphenyl)ethanol (LI) with chloromethyl methyl ether, and the cyclisation of 2-(5-methoxyphenyl-2-methyl)ethyl methoxymethyl ether (LII):



Thus an unusual feature of this method consists in the fact that the methyl group can be introduced into the 5-position in combination with various substituents in the 8-position in the isochroman ring.

A series of methoxy-derivatives of isochroman (LIII) have been synthesised by cyclising the arylethanols (LIV) on treatment with phosphorus pentoxide or potassium bisulphate.[112–116] The arylglycols (LIV) have been synthesised by reducing the diesters (LV):

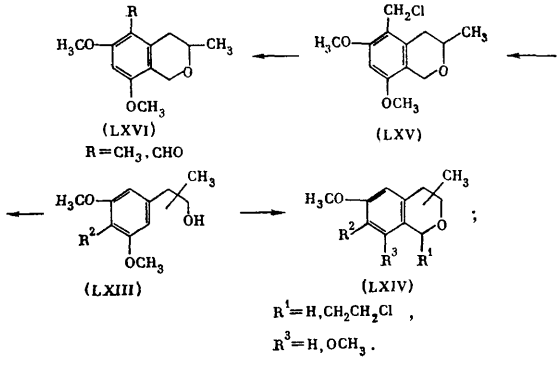


R^1=H, 5-OCH_3; 6-OCH_3;
R^2=H, 6-OCH_3, 7-CH_3, 7-OCH_3, 7-$OCH_2C_6H_5$; R^1R^2=6,7-OCH_2O.

7-Methoxyisochroman (LVI) has also been obtained as in the scheme[117]

(2-Hydroxymethyl-4-methoxyphenyl)acetaldehyde (LVIII) has been obtained by reducing 7-methoxyisocoumarin (LVII) with LAH. The acetaldehyde was converted into 7-methoxyisochroman (LVI) via two pathways: dehydration to 6-methoxyisochromene (LIX) and the catalytic hydrogenation of the latter or its reduction to the diol (LX) and then dehydration with ring closure. Both versions of the synthesis are of interest from the standpoint of the isolation of the intermediates (LVIII) and (LIX). On the other hand, in order to obtain the target product, it might be possible to reduce 7-methoxyisocoumarin immediately to the diol (LX) with its subsequent dehydration.

The hydroxy-derivative—6-hydroxyisochroman (LXI)—has been synthesised via the diol (LVII) using the Gatterman formulation:[118]

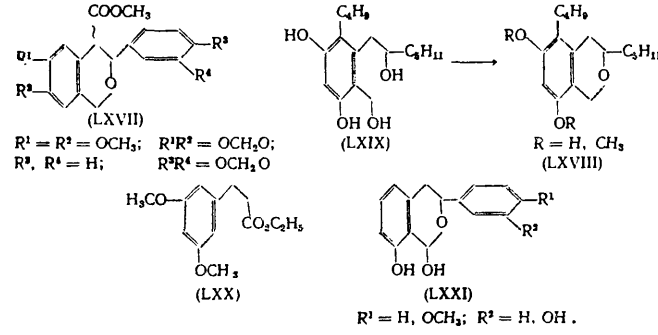


The above methods of synthesis of methoxy- and hydroxy-derivatives reduce mainly to the preparation of the substituted diols (LIV), (LX), and (LXII) with their subsequent cyclisation, described above for the synthesis of the unsubstituted derivative.

4. Derivatives of isochroman with substituents in the aromatic and dihydropyran rings

In order to obtain isochroman derivatives with substituents in both rings, the same cyclisation reactions are used as for the synthesis of the previous structures and sometimes the problem reduces to the preparation of the corresponding initial arylalkanols.

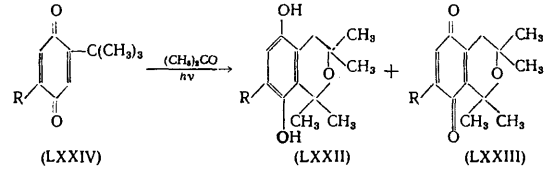
6,7,8-Trimethoxy-3-methyl- and 6,8-dimethoxy-3-methyl-isochromans (LXIV) have been obtained by the chloromethylation of 2-(3,4,5-trimethoxyphenyl)-1-methyl- and 2-(3,5-dimethoxyphenyl)-1-methyl-ethanols (LXIII).[119,120] Compound (LXIV) was synthesised in a low yield because of partial polymerisation of the phenol-formaldehyde type. A higher yield is obtained in the chloro-methylation of the arylalkanol (LXIII, $R^2 = H$) by monochloromethyl methyl ether in the presence of zinc chloride. The chloromethyl derivative (LXV) is formed for a specific ratio of the ether and zinc chloride and is subsequently converted into compound (LXVI):



2-(3,4-Dimethoxyphenyl)-2-methylethanol has been condensed with chloroacetal in the presence of boron trifluoride to form 1-(2-chloroethyl)-6,7-dimethoxy-4-methylisochroman (LXIV, R^1 = CH_2CH_2Cl, R^2 = OCH_3, R^3 = H) and its stereochemistry has been investigated.[121]

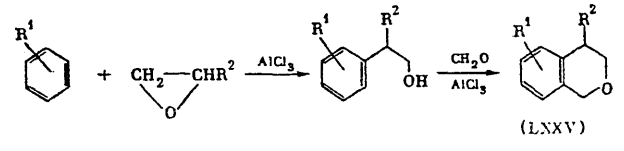
The diastereoisomeric isochromans (LXVII) have been obtained from the methyl esters of *erythro-* and *threo*-2,3-diaryl-3-hydroxy-propionic acids and formaldehyde in methanol in the presence of sulphuric acids.[122]

The method of synthesis of (±)-5-butyl-6,8-dihydroxy-3-pentylisochromans (LXVIII) is based on the cyclisation of compound (LXIX). The latter has been obtained by multistage synthesis from ethyl β-(3,5-dimethoxyphenyl)propionate (LXX).[123]



8-Hydroxy-4,4,7-trimethyl-1,3-diphenylisochroman has been obtained by the stepwise aromatisation of 4a-chloro-4,4,7-trimethyl-1,3-diphenyl-4a,5,6,7,8,8a-hexahydroisochroman-8-one. The latter was synthesised by condensing limonenone with benzaldehyde.[124,125] 8-Hydroxy-4,5,6,7-tetramethylisochroman has been obtained by reducing sclerin—8-hydroxy-4,5,6,7-tetramethylchroman-1,3-dione:[10]

Among hydroxy-derivatives, 3-aryl-1,8-dihydroxyisochromans (LXXI), obtained by reducing 8-hydroxyisocoumarins by complex hydrides, are also known.[126]

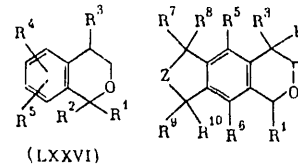


4-Hydroxyisochromans have been obtained from 4-isochromanone derivatives both by reduction[127] and by the Reformatskii reaction.[128]

The formation of the isochroman derivatives (LXII) and (LXIII) in the photolysis of the quinone (LXIV) in acetone[129] (other compounds are obtained as well) is of interest from the chemical standpoint:

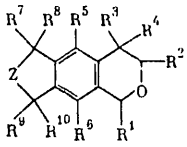
The methods of synthesis of isochroman derivatives based on the cyclisation of *o*-alkenylbenzyl alcohols[130,131] and the catalytic reduction of indene ozonides[132] are distinguished by unusual features.

One of the common methods of synthesis of isochroman derivatives (LXXV) with substituents in the aromatic and dihydropyran rings involves the condensation of an arylalkanol with formaldehyde in the presence of aluminium chloride.[133,134] Arylalkanols can be synthesised in different ways. Thus they have been obtained[133,134] by the reaction of arenes with epoxyalkanes in the presence of aluminium chloride. Compounds (LXXV) have also been obtained by hydroxymethylation and cyclisation in the presence of a mixture of hydrochloric acid and phosphorus trichloride:[62]



A number of investigators[135–141] have synthesised 1,1,6,7-tetrasubstituted isochromans (LXXVI) by condensing an arylethanol with carbonyl compounds (ketones, aldehydes or their acetals,

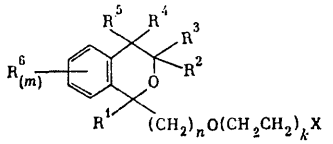
ketoacids). A solution of 3% trichloroacetic acid, toluene-*p*-sulphonic acid, and hydrogen chloride has been used as the initial catalyst.



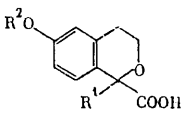
A similar condensation has been used to synthesise 1-substituted and 1,4-disubstituted isochroman derivatives (LXXVI) with different positions of substituents in the aromatic ring (including also condensed fragments in the 6,7-positions) in the presence of polyphosphoric acid or toluene-*p*-sulphonic acid.[142–145] It is notable that the above condensation yielded tricyclic isochromans (LXXVII) which can be used in the perfume industry.[146–149] The similar compounds (LXXVIII), obtained by the reaction of isochroman derivatives with dichloroalkanes in the presence of aluminium chloride,[150] have the same properties. 1-Alkoxyalkylisochromans (LXXIX) and (LXXX), with a wide variety of substituents in different positions in both the aromatic and dihydropyran ring, are also known.[151–153] The above compounds are intermediates in the synthesis of hypotensive and psychotropic preparations.

A series of isochroman derivatives (LXXXI)–(LXXXIII) have been obtained by condensing the corresponding arylalkanols with ketones or ketoacids.[154–157]

The hydrogenolysis of wood results in the formation of 1-ethyl-6-hydroxy-4-(4-hydroxy-3-methoxybenzyl)-7-methoxyisochroman.[158,159] Catalytic reduction of the *Chrysodin* metabolite yielded 3-hexyl-6,8-dihydroxy-7-methylisochroman:[160]

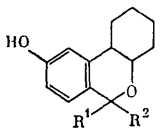


(LXXVI)



(LXXVII), $R^1=R^2=R^3=R^5=R^6=H$; R^4, R^7-R^{10} = Alk; $Z=CHR^{11}$, $R^{11}=H, CH_3$;

(LXXVIII), R^1-R^{10} = Alk; $Z=CH_2, CHCH_3, (CH_2)_2, CH_2CHCH_3$.



(LXXIX), X = OH;

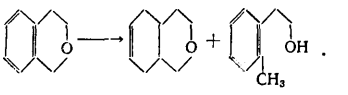
(LXXX), X = Cl.

(LXXXI), R^1, R^2 = Alk;

(LXXXII), R^1 = Alk; R^2 = H.

(LXXXIII)

R^1, R^2 = Alk, Ar, alkoxycarbonyl; $R^1 + R^2$ = carbocycle.

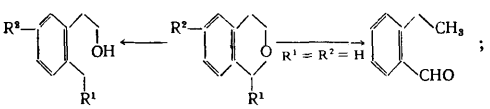


Thus isochroman derivatives with substituents in both the aromatic and dihydropyran rings can be obtained by the cyclocondensation of arylalkanols with various carbonyl compounds in the presence of both protic acids and Lewis acids. The variation of the substituents in the 1-position depends on the type of the carbonyl-containing component. It is notable that preference should be given to methods based on the application of polyphosphoric or toluene-*p*-sulphonic acid. When aluminium chloride is used as the catalyst, it is essential to take certain precautions, since the decomposition of the complexes formed is accompanied by the vigorous evolution of hydrogen chloride.

III. Chemical properties of isochroman and its derivatives

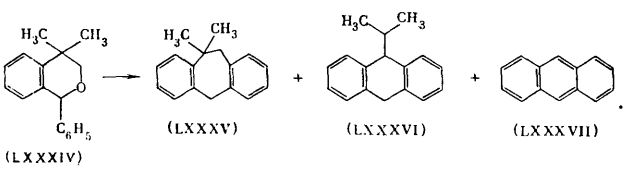
1. Hydrogenation

The catalytic hydrogenation of isochroman and its derivatives can involve hydrogenolysis accompanied by the opening of the cyclic ether as well as the reduction of the benzene ring. It is notable that the hydrogenolysis of isochroman derivatives is of practical value, especially in the perfume industry.[161–164]



In the catalytic hydrogenation of isochroman in the presence of the Raney nickel catalyst at 200 °C and a pressure of 150 atm, the hydrogenolysis product 2-(2-tolyl)-ethanol was isolated in addition to the normal reduction product—tetrahydroisochroman:[58]

Other fractions have been isolated after distillation through a column as a result of a similar reaction but at normal pressure: (1) *cis*- and *trans*-1,2-dimethylcyclohexanes, 1,2-dimethylbenzene, and 2-ethyl-1-methylbenzene; (2) *trans*-hexahydroisochroman; (3) *cis*-hexahydroisochroman; (4) an unidentified high-boiling fraction.[165]

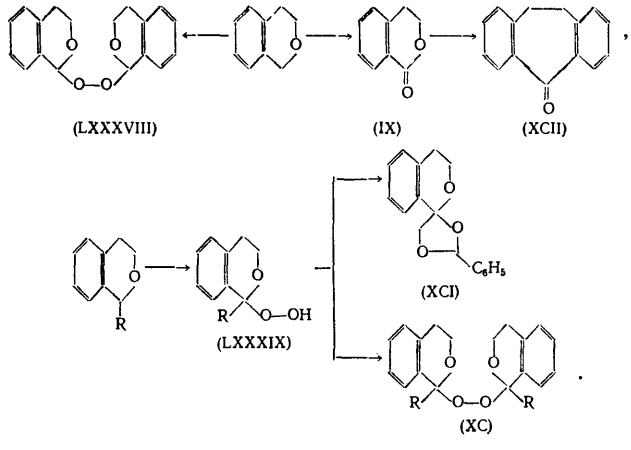


It is of interest that the tetrahydro- and hexahydro-derivatives of isochroman are obtained by special methods, involving the Dieckmann, Robinson, etc. cyclocondensation reactions, and not by the hydrogenation of the corresponding isochromans.[166–168]

Treatment of isochroman with hydrogen in the presence of Raney nickel at room temperature for 10 min affords a rearrangement product—2-ethylbenzaldehyde.[58] The catalytic reduction of 1-alkyl- or 1-aryl-isochromans in the presence of the Raney nickel catalyst at 200 °C and a pressure of 200 atm leads to ring opening with formation of 2-arylethanols.[58] The reduction of the benzene ring is not then observed. The substituent in the 1-position evidently increases the resistance of the aromatic ring to hydrogenation. Reduction with the opening of the dihydropyran ring occurs when 6-methoxyisochroman interacts with aluminium hydride:[111]

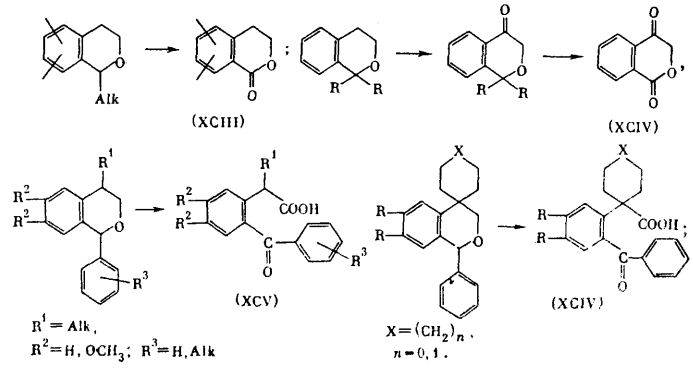
R^1 = H, Alk, Ar; R^2 = H, OCH_3.

The reduction of 4,4-dimethyl-1-phenylisochroman (LXXXIV) by hydriodic acid in the presence of red phosphorus is of interest from the chemical point of view.[169] The reaction results in a rearrangement with the opening of the heterocycle, which leads to the formation of three tricyclic compounds—10,10-dimethyl-10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene (LXXXV), 9-isopropyl-9,10-dihydroanthracene (LXXXVI), and anthracene (LXXXVII):



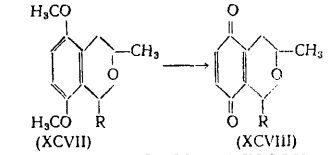
(LXXXIV) (LXXXV) (LXXXVI) (LXXXVII)

2. Oxidation



When isochroman is allowed to stand in air for several days at room temperature, the crystalline 1-isochromanyl peroxide (LXXXVIII) is formed, decomposing at 78 °C (2 mmHg).[52] It is possible to isolate the diastereoisomers of the peroxide (the *meso*-isomer and the racemate) from isochroman by allowing it to stand in the light for a month.[170] When isochroman and its 1-substituted derivative are oxidised by atmospheric oxygen at room temperature and under UV irradiation, the corresponding hydroperoxides (LXXXIX) are formed.[61,170] On treatment with dilute inorganic acids, the latter are readily converted into the symmetrical peroxides (XC). On interaction with benzaldehyde in the presence of potassium hydroxide, the hydroperoxide (LXXXIX, R = CH_3) affords 2-phenylspiro[1,3-dioxolan-4,1′-isochroman] (XCI).

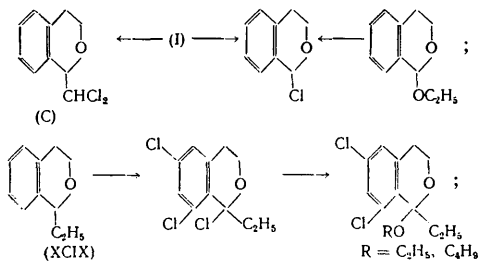
The oxidation of isochroman by nitric acid leads to 1-isochromanone (3,4-dihydroisocoumarin).[66,171] It is of interest to note the formation of the tricyclic system 10,11-dihydro-5*H*-dibenzo[*a*,*d*]-cyclopentan-5-one (XCII) from the latter when it is involved in a Friedel–Crafts reaction in the presence of aluminium chloride in benzene:[171]



D1

Isochroman and its derivatives with the substituents in both the aromatic and dihydropyran rings have been oxidised by chromium trioxide, selenium dioxide, hydrogen peroxide, pyridinium chlorochromate, and sodium hypochlorite.[58,59,67,112–114,172–177] It has been shown that the oxidation takes place in the 1-position with formation of the dihydroisocoumarins (XCIII). On the other hand, if the 1-position is occupied by two alkyl substituents, then the oxidation takes place in the 4-position and more prolonged oxidation leads to the ketolactone (XCIV).[172] It is of interest to note the influence of allyl groups in the 1-position in isochroman on the oxidation process. In this case the reaction is accompanied by the opening of the dihydropyran ring and leads to (2-benzoylphenyl)acetic acid (XCV, $R^2 = R^3 = H$)[172] and its derivatives (XCV, $R^2 = OCH_3$, R^3 = Alk)[178] or (XCVI):[179]

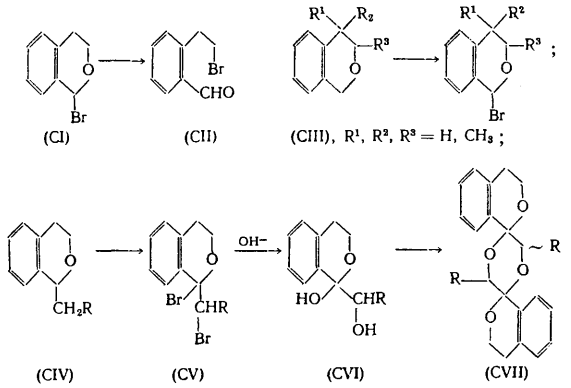
The anodic oxidation of isochroman in the presence of *N*-hydroxyphthalimide is also directed to the 1-position.[180] The electrochemical oxidation of 6,7-dimethoxy-1-(3,4-dimethoxybenzyl)isochroman leads to a tetracyclic system containing in its structure the oxidised isochroman ring and to 1-(2-hydroxy-4,5-dimethoxybenzyl)-6,7-dimethoxyisochroman (oxidation of the aryl component of the side chain).[181] The oxidation of isochroman under UV irradiation in the presence of iron(III) chloride in the acetone–water mixture is notable. This entails the formation of 9% of 3,4-dihydroisocoumarin and 23% of β-(*o*-carboxyphenyl)ethanol.[182] The oxidative demethylation of 5,8-dimethoxyisochromans (XCVII) by silver oxide leads to the formation of the quinonoid structure (XCVIII):[138]



Thus the oxidation of isochroman and its derivatives is directed mainly to the 1-position. In addition, in certain cases the oxidation is accompanied, like the reduction, by the opening of the dihydropyran ring.

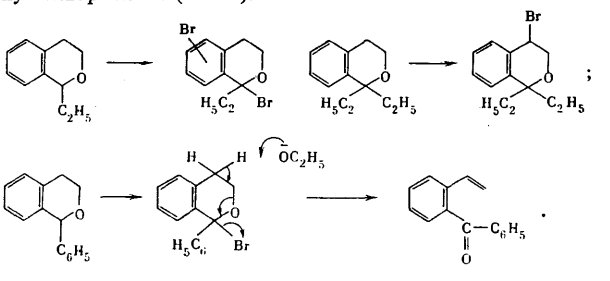
3. Halogenation

Both molecular halogens and bromosuccinimide are used for the halogenation of isochroman and its derivatives. It has been established that the halogenation proceeds preferentially in the 1-position, since this is most reactive. 1-Chloroisochroman was first obtained by chlorinating isochroman at −5 °C.[58] The same product has been synthesised in 60–80% yield by the reaction of 1-ethoxyisochroman with acetyl chloride.[60,61,183] The chlorination of 1-ethylisochroman (XCIX) at 0 °C is directed to the 1-, 6-, and 8-positions in the isochroman ring.[66,84] On treatment with an alkoxide, only the chlorine atom in the 1-position is substituted by the alkoxy-group.



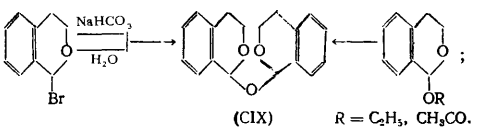
Isochroman is capable of being converted into 1-dichloromethylisochroman (C) on treatment with chloroform in an alkaline

medium in the presence of benzyltriethylammonium chloride by combining with dichlorocarbene:[87]

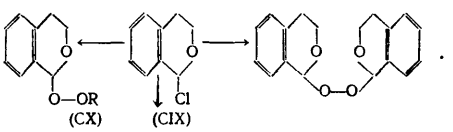


1-Bromoisochroman (CI) has been obtained by brominating isochroman in benzene or carbon tetrachloride under UV irradiation.[58,60,61,71,89] As a cyclic analogue of α-halogenoethers, this bromo-derivative rearranges to its structural isomer *o*-(β-bromoethyl)benzaldehyde (CII)[60,185] as a result of its high reactivity.[184] Isochromans substituted in the 3- or 4-position [compounds (CIII)] are also brominated in the 1-position under the same conditions.[70,71,90]

The bromination of 1-alkyl- and 1-benzyl-isochromans (CIV) does not stop at the stage involving the formation of the monobromo-derivative but leads to products of the substitution of the side chain, for example, the dibromo-derivatives (CV). The latter have been converted into the diols (CVI), which cyclise to the *cis,trans*-isomeric spirocyclic derivatives (CVII) in an acid medium:[61]

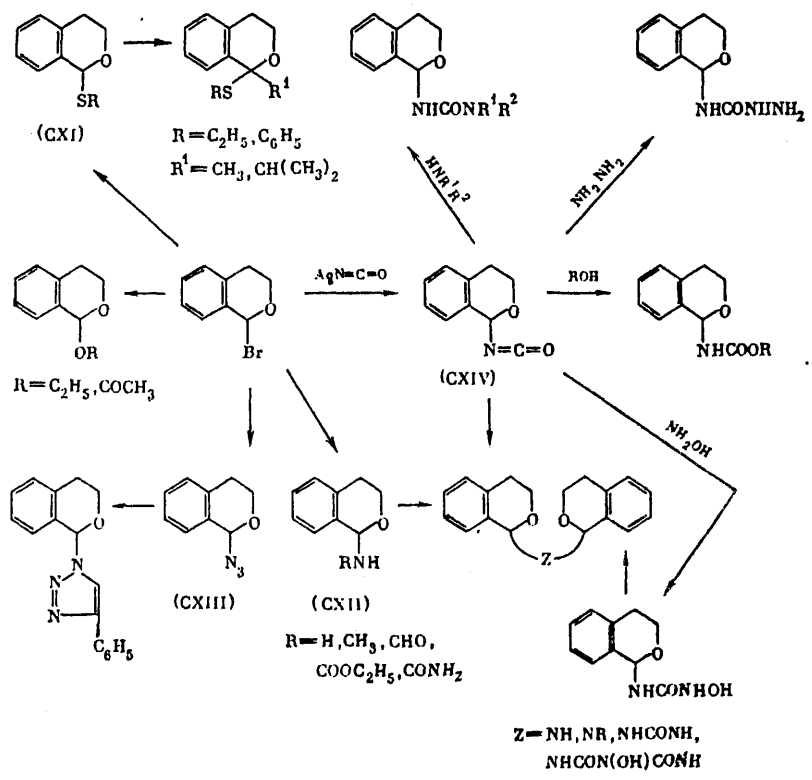


The bromination of isochroman and its 1-substituted-derivatives by *N*-bromosuccinimide has been investigated. It has been shown that, whereas isochroman is converted into 1-bromoisochroman,[58,84] its 1-ethyl derivative is brominated both in the 1-position and in the aromatic ring.[84] Furthermore, if the 1-position in isochroman is occupied by two alkyl groups, then bromination takes place in the 4-position.[84] The bromination of 1-phenylisochroman by *N*-bromosuccinimide in the presence of sodium ethoxide leads to 2-vinylbenzophenone (CVIII):[68]



4. Certain substitution reactions of isochroman derivatives

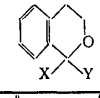
Although 1-chloro- and 1-bromo-isochromans rearrange under certain conditions to structural isomers,[60] nevertheless, they are of special interest from the standpoint of their conversion into a wide variety of isochroman derivatives. Thus, when 1-bromoisochroman is treated with a solution of sodium bicarbonate or simply with water, di-1-isochromanyl ether (CIX) is obtained.[60] The latter is also formed from 1-ethoxy- or 1-acetoxy-isochroman in quantitative yield when they are allowed to stand in air:[40]

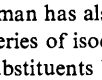


On treatment with water, 1-chloroisochroman behaves similarly to 1-bromoisochroman, forming di-1-isochromanyl ether.[58] 1-Chloroisochroman has been condensed with hydroperoxides with formation of the corresponding peroxides (CX) (yield 80–85%).[183] 1-Isochromanyl peroxide is obtained by treating 1-chloroisochroman with 30% hydrogen peroxide.[186] 1-Isochromanyl hydroperoxide is formed on treatment with 5.3% hydrogen peroxide:

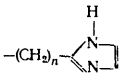
The reactions of 1-halogenoisochromans with cyanide are described in Section II. We shall only note the formation of 1-cyano-4,4-R_2-substituted isochromans from the corresponding 1-bromo-4,4-R_2 derivatives and mercury(II) cyanide.[90] Compounds having different substituents in the 1-position have been synthesised in satisfactory yields by the reaction of a Grignard reagent and 1-halogenoisochroman as well as its 4,4-disubstituted derivatives.[58,60,61,66,165] Such 1-substituted isochroman derivatives are obtained in low yields on chloroalkylation of phenylalkanols. 1-Ethoxy- and 1-acetoxy-isochromans have been obtained by the reaction of 1-bromoisochroman with sodium ethoxide and potassium acetate.[58] 1-Acetoxyisochroman has been converted into 1-cyanoisochroman on treatment with trimethylsilyl cyanide in the presence of a Lewis acid.[187] 1-Ethoxyisochroman can be obtained also by treating 1-bromoisochroman with ethanol.[60] 1-Alkylthioisochromans (CXI) have also been obtained by an analogous procedure. They were then converted into 1,1-disubstituted isochromans.[188]

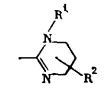
Scheme 4

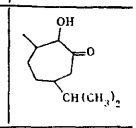


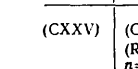


A series of nitrogen-containing compounds has been obtained from 1-bromoisochroman. Thus treatment of the latter with amines, aminoalcohols, amides, sodium azide, and silver isocyanate yielded the corresponding derivatives (CXII)–(XCIV).[189,190] These compounds were subjected to a series of transformations, which are illustrated in Scheme 4.









Isochroman derivatives containing substituents such as the alkoxy-, acyl-, acyloxy-, etc. groups in the 1-position are also capable of undergoing nucleophilic substitution reactions. The interaction of 1-ethoxyisochroman with sodium bisulphite, acetic anhydride,[60] aromatic and aliphatic alcohols,[191] nitrogen-containing compounds–amides, thioamides, sulphonamides, urea, thiourea,[192] and amines (aromatic, aliphatic, heterocyclic),[30,192] as well as benzoxazoline-2-thione has been achieved.[193] The final reaction products (CXVa–d), (CXVI), and (CXVIIa–c) are presented in Scheme 5.[33,191–193] It is notable that the reaction of 1-ethoxyisochroman with alcohols and amines takes place in different ways depending on their structure (type).

1-Ethoxyisochroman has also been used as the starting material for the synthesis of a series of isochroman derivatives (CXVIII) with functional group substituents by reaction with compounds having active methylene groups: diethyl malonate, α-tetralone, acetylacetone, malononitrile, and acetoacetic ester.[191,194] It is notable that the isochroman derivatives [CXVIII, XY = $(COOC_2H_5)_2$ or CHXY = 2-oxocyclohexyl] are converted into naphthalene or anthracene derivatives in the presence of alkali metal alkoxides.[194]

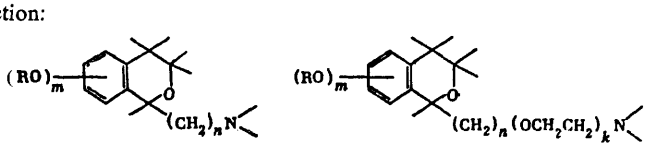
IV. Biological activity of isochroman derivatives

Isochroman derivatives containing amino-groups in the dihydropyran ring have been most thoroughly investigated from the pharmacological point of view, since these compounds are in fact "rigidly fixed" analogues of arylalkylamines. They are all characterised by a broad spectrum of biological activity: antidepressant, diuretic, psychotropic, antiinflammatory, vasodilating, etc..

The study of the influence of 1-methylaminoisochromans (CXIX) [compounds (CXIX)–(CXXXI) are presented in Table 1] on the cardiovascular system[24] showed that compound (CXIX, R = H) exhibits a hypertensive activity. The corresponding *N*-methyl analogue (CXIX, R = CH_3) possesses considerable adrenoblocking properties, while 1-*N*-ethylamino- and 1-*N*-isopropylaminomethylisochromans (CXIX, R = C_2H_5 or iso-C_3H_7) possess a weak hypotensive activity. According to the results of some workers who have investigated the effect of phenylethylamines on adrenoreceptors, the replacement of the hydrogen at the nitrogen atom in 2-phenylethylamines by higher alkyl groups leads to a transition from adrenomimetic to adrenolytic properties. Although the analogous isochroman derivatives exhibit a weak activity, they give rise to the same pattern. On the other hand, the replacement of the hydrogen atom at the nitrogen atom of 1-aminomethylisochroman by arylalkyl groups as well as the introduction of an additional methylene group between the nitrogen atom and the isochroman ring lead to compounds (CXX), which possess some sympatholytic and adrenolytic activity and exert an effect on the central nervous system (CNS).[195] This activity persists also in 1-aminoalkylisochromans (CXXI) containing an alkyl substituent at the carbon atom linked to the isochroman ring.[196] Many compounds (CXXII) in which two 1-aminomethylisochroman fragments or a 1-aminomethylisochroman fragment and another basic residue are separated by different numbers of methylene groups have been synthesised.[197,198] It has been established that they all exhibit cholinolytic activity, while compounds (CXXII, n = 8) exert a pronounced blocking action on sympathetic nerve fibres and adrenoreceptors.[198] 1-Piperidino- and 1-piperazinoisochromans (CXXIII) have antihistamine properties.[199,200]



It is of interest to note that the simultaneous introduction of the phenyl and aminopropyl groups in the 1-position, as in compounds (CXXIV), leads to substances with a pronounced adrenomimetic effect, which can be used in psychotherapy, particularly in the treatment of endogenic depression.[200–202] The pharmacological properties also of other 1,1-disubstituted isochromans derivatives have been investigated. Thus 1-cyano-1-morpholinomethylisochroman [CXXV, $NR_2 = N(CH_2)_4O$, $n = 1$] exhibits a spasmolytic activity, while 1-cyano-1-(2-diethylaminoethyl)- and 1-cyano1-(2-piperidinoethyl)-isochromans [CXXV, $NR_2 = N(C_2H_5)_2$ or $N(CH_2)_5$, $n = 2$] exhibit an anti-cough effect whilst lacking spasmolytic activity.[94] In a dose of 2 mg kg^{-1}, the latter compound showed the same effect as the familiar drug Silomat in a dose of 5 mg kg^{-1}.[89] The diamino-derivative, namely 1-(β-diethylaminoethyl)-1-[*N*-(β-methylcrotonyl)amino-methyl]isochroman (CXXVI), is a muscle relaxant.[89]

1-Acetyl-1-(2-diethylaminoethyl)isochroman (CXXVII) exhibits a spasmolytic activity of the papaverine type and on an isolated intestine manifests an activity equal to that of papaverine in strength.[89]

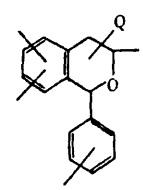
The isochroman derivatives (CXXVIII), having nitrogen-containing cyclic fragments (imidazolylalkyl, tetrahydropyrimidyl) in the 1-position, are pesticides in large doses, while in small doses they exhibit a depressing effect on the CNS.[185] These compounds eliminate the convulsions induced by an electric shock more effectively than does hexobarbital and are corazole antagonists. They also show a local anti-inflammatory effect in the carrageenin oedema. Biological activity has also been discovered in a series of spiro-derivatives of isochroman. Spirooxazineisochromans (CXXIX) exhibit a psychotropic activity,[203] while 1-methyl-2,5-dioxopyrrolidine-3-spiro-1′-isochroman (CXXX) manifests a pronounced anti-inflammatory effect.[91]

In order to investigate the antitumour properties of 1-isochromanyl hydroperoxide, the latter was synthesised but did not exhibit a pronounced activity.[204] A compound of the isochroman series, namely 3-(1-isochromanyl)-6-isopropyltropolone (CXXXI),[205] showing an appreciable antitumour activity is known.[206] The introduction of substituents of different kinds (aryl, heteroaryl) in the 1-position in isochroman lowers appreciably the above activity.[207]

Further expansion of the research into biologically active isochroman derivatives has consisted in the simultaneous introduction of the amino-fragment in the 1-position and of hydroxy- or different alkoxy-groups in the aromatic ring of isochroman. Thus numerous 1-(aminoalkyl) derivatives of isochroman (CXXXII) have been patented.[141,208–217] Alkyl, arylalkyl, and heteroaryl groups are used as substituents at the nitrogen atom. In particular, many compounds containing substituted piperazine fragments have been described. The biological activity spectrum is extremely broad: anti-depressant, anticonvulsive, hypotensive, anti-inflammatory, analgesic, vasodilating, myorelaxing, anticoagulation, and other activities. Compounds (CXXXIII) are also of interest;[218,219] the presence of the poly(ethylene oxide) chain in them did not affect the selectivity of their action:

(CXXXII) (CXXXIII)

$m, n, k = 1–3$.

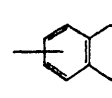


The biological properties of the isochroman derivatives (CXXXIV) and (CXXXV) containing a basic fragment in the 3- and 4-positions have also been investigated. Among them, 1-arylisochromans (CXXXIV) with the aminoalkylene chain in the 3-position, for example, can be used in the treatment of disturbances of the activity of the CNS: in particular, they exhibit anticonvulsant, anti-depressant, and appetite-depressant activities.[220,221] The most active compound—3-(*N*-methylaminomethyl)- and 3-(*NN*-dimethyl-aminomethyl)-1-phenylisochromans—exhibit a more pronounced activity than the familiar appetite depressant (d)-amphetamine. Furthermore, they are free from the disadvantages of the latter—the excitation of the CNS.[222] The introduction of a fluorine atom both in the aromatic ring of isochroman and in the phenyl group in the 1-position does not alter the activity. It is notable that the study of the pharmacodynamics of 3-aminomethyl-7-fluoro-1-phenylisochroman established that, in contrast to the anorexigenic preparations, this compound does not increase the pulmonary blood pressure.[223]

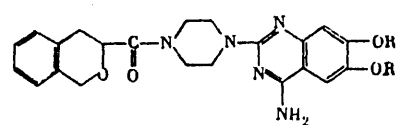
Isochroman derivatives (CXXXVI) containing simultaneously aryl and aminoalkyl substituents in the 3-position are known; in contrast to compounds (CXXXIV) and (CXXXV), they are effective drugs for the treatment of cardiovascular diseases (they exhibit hypotensive and diuretic activities).[224,225] Isochroman derivatives having the structure (CXXXVII) also possess hypotensive properties.[226] 1-Methyl- and 1-phenyl-isochromans with dialkylamino- or piperazinyl groups in the 4-position manifest antihistamine properties.[227] Piperidine-4-spiro-4′-isochromans (CXXXVIII) exhibit the same type of activity.[228] It is of interest that compounds (CXXXIX), which also contain the piperidine ring but the latter is linked to the isochroman ring by a C–C bond, manifest anti-allergic properties.[229,230]

N-Substituted piperidine-4-spiro-3′-isochromans (CXL) possess hypotensive and anti-depressant activities.[231]

Among semisynthetic cephalosporins, a substance with an isochromanyl residue exhibiting a bactericidal activity has been discovered.[232]

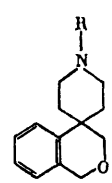


Among more complex structures (tri- and tetra-cyclic), dibenzopyran and morphine-like substances, possessing antipyretic, analgesic, and anti-inflammatory properties, are known.[233,234] Acids of the isochroman series also exhibit anti-inflammatory and antibacterial activities.[140,235]



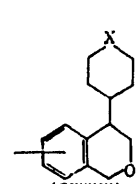
(CXXXIV), (CXXXV)

(CXXXIV): $Q = 3-$ or $4-(CH_2)_nNAlk_2$,

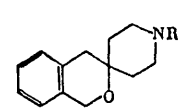


(CXXXV): $Q = 3-CHCH_2NR_2$ (CH_3)

(CXXXVI)



(CXXXVII), R = Alk



(CXXXVIII)

R = CH_3, $(CH_2)_nC_6H_5$; $n = 1,2$

(CXXXIX)

X = $CR^1R^2NR^1_2$; R^1, R^2 = H, Alk, ArAlk

(CXL)

R = H, $CH_2C_6H_5$, $COOC_2H_5$

Summarising, one should note that it is as yet too early to reach conclusions about the relation between the structure and activity of isochroman compounds, but the existence of a large number of substances with different biological activities suggests that deliberate search for preparations among individual groups of isochroman derivatives is desirable. The availability of the starting materials and the existence of methods of synthesis make it possible to use on a wide scale a series of isochroman derivatives as synthons for the preparation of biologically active substances.

Thermal decomposition and photodecomposition of biscyclopentadienyl complexes of titanium, vanadium, and their analogues

V P Mar'in, L I Vyshinskaya, G A Razuvaev (deceased)
Institute of Chemistry at the Lobachevskii Gorky State University

ABSTRACT. Data on the reactions involving the thermal decomposition and photodecomposition of the biscyclopentadienyl compounds Cp_2MR_n (M = Ti, Zr, Hf, V, or Nb) are surveyed. The pathways leading to the formation of RH as well as the rearrangement of the biscyclopentadienyl structure in the thermal and photochemical reactions are discussed. Processes involving hydrogen exchange and the exchange of the cyclopentadienyl rings are examined.

The bibliography includes 92 references.

I. Introduction

Studies on the thermal decomposition of organometallic compounds (OMC) were published almost simultaneously with studies on their synthesis, but initially this was associated with the investigation of the theoretical aspects of the stability of the metal–carbon bond. Subsequently such investigations became of practical interest in relation to questions of analysis and, mainly, the preparation of metallic and inorganic coatings by the thermal decomposition of the corresponding OMC. Monographs[1,2] have been devoted to general problems of the study of the mechanism of the thermal decomposition of OMC and their practical use for the preparation of coatings.

Compounds of two types are most numerous among OMC of the titanium and vanadium subgroups: covalent, i.e. σ-alkyl or σ-aryl compounds, and sandwich-covalent compounds, i.e. π-cyclopentadienyl-σ-alkyl(aryl) complexes. The principal features of the thermal decomposition of the covalent derivatives have been examined in another review.[3]

The first studies on the thermal and photolytic decomposition of the sandwich-covalent compounds Cp_2TiR_2 (R = CH_3 or C_6H_5) were published at the end of the 1960's. These investigations established that the decomposition of Cp_2TiR_2 in solutions entails the homolytic cleavage of two Ti–R σ-bonds accompanied by the intermediate formation of paramagnetic trivalent titanium compounds, which has been demonstrated by EPR. When the reaction is carried out in CCl_4, the radicals formed react with metallic mercury. The interesting fact that the decomposition of Cp_2TiR_2 initiated the radical polymerisation of methacrylate, styrene, and vinyl chloride has been noted in addition. These studies have been surveyed.[4]

Various aspects of the thermal decomposition of the complexes Cp_2MR_n have been investigated in recent years. As the chemistry of the so called 'titanocene' developed, processes involving the cyclopentadienyl ligands, leading to a rearrangement of the initial biscyclopentadienyl structure of the compound, were examined. Such a rearrangement, inducing an increase in the coordinative unsaturation of the complex, leads to new applications of these compounds in processes involving the activation of the C–H bonds of hydrocarbons and the fixation of mercury or nitrogen, and also in organic synthesis.

Simultaneously with the investigation of the thermal decomposition of titanium subgroup compounds, studies were performed on the thermal decomposition of sandwich-covalent compounds of trivalent vanadium: Cp_2VR (R = CH_3 or C_6H_5). These studies demonstrated a sharp difference between the mechanisms of the decomposition of the reactions of the titanium and vanadium derivatives.

The first attempts at the synthesis of tetravalent vanadium compounds Cp_2VR_2 were unsuccessful, which helped to strengthen the concept that these derivatives are highly labile. However, in 1966 the compounds Cp_2VR_2 (R = CH_3, C_2H_5, or $C_6H_5CH_2$) were obtained and somewhat later their decomposition was also studied. The results made it possible to compare the decomposition reactions of titanium and vanadium compounds having the general formula Cp_2MR_2.

This review surveys the results of the thermal and photolytic decomposition of the sandwich-covalent compounds of titanium, vanadium, and their analogues having the general formula Cp_2MR_n as a function of the nature of the σ-substituents and the transition metals.

II. Thermal decomposition of titanium subgroup compounds

1. Thermal stability and decomposition products

The thermal stability of the majority of the compounds Cp_2MR_2 (M = Ti, Zr, or Hf) has been characterised by differential thermal analysis (DTA).[5–10] It has been established on the basis of DTA data that the compounds Cp_2TiR_2 (R = CH_3 or Ar) decompose exothermically in the temperature range from 80° to 160 °C. Among the compounds indicated, the methyl derivative, which decomposes appreciably even at room temperature, has the lowest thermal stability. The differences between the thermal stabilities of the aryl derivatives are insignificant. However, the increased stability of compounds containing methyl groups in the meta-position in the benzene ring compared with $Cp_2Ti(C_6H_5)_2$ is notable. This is probably caused by the steric effects of such ligands, which proved significant in the formation of the dehydrobenzene complex under the decomposition conditions.[6,7]

A kinetic study of the thermal decomposition of Cp_2TiR_2 [R = C_6H_5, $C_6H_5CH_2$, *m*-$CH_3C_6H_4$, *p*-$CH_3C_6H_4$, or 3,4-$(CH_3)_2C_6H_3$] showed that the decomposition process is described by a first order equation. The calculated activation energy for the decomposition reaction is in the range 16–30 kcal mol^{-1} and decreases with decrease in the decomposition temperature of the compound Cp_2TiR_2. Depending on R, the decomposition temperature decreases in the following sequence:[8]

$$3,4\text{-}(CH_3)_2C_6H_3 > m\text{-}CH_3C_6H_4 > p\text{-}CH_3C_6H_4 > C_6H_5 > CH_2C_6H_5.$$

In the series of isotypical compounds Cp_2MR_2 (M = Ti, Zr, or Hf), the thermal stability rises from titanium to hafnium. Among all the compounds considered, $Cp_2Hf(CH_3)_2$ is the most stable (it decomposes above 250 °C).[9,10]

An increase in the stability of the biscyclopentadienyl compound on substitution of the hydrogen atoms by deuterium in the σ-substituents at the metal atom has been noted.[7,10] A similar substitution of hydrogen atoms by deuterium in the cyclopentadienyl rings does not increase significantly the thermal stability of the compounds. This fact shows that the rate-limiting stage of the decomposition process involves the rupture of the M–R bond or the abstraction of a hydrogen (deuterium) atom from the σ-linked group.

It has also been shown that the stability of the sandwich-covalent compound increases as the hydrogen atoms in the cyclopentadienyl rings are replaced by methyl groups.[11]

When the biscyclopentadienyl derivatives Cp_2MR_2 (M = Ti, Zr, or Hf; R = alkyl or aryl) are heated *in vacuo* or in hydrocarbon solvents at the decomposition temperatures, the M–R σ-bond is cleaved with liberation of 1.4–1.9 mol of RH (Table 1).[6,7,9,10] The dimerisation products are almost absent for all the compounds. The decomposition process can be formally represented by the scheme

$$(C_5H_5)_2MR_2 \rightarrow C_{10}H_8M + 2RH.$$

The decomposition of Cp_2MR_2 results in the formation of a residue, which has the approximate empirical formula $C_{10}H_8M$ according to analytical data. The IR spectra of this residue and its alcoholysis indicate the presence in it of η^5-Cp ligands.[6,7,9] The metal-containing residues formed on decomposition of Cp_2MR_2 (M = Ti, Zr, or Hf) react differently with hydrogen chloride. Thus Cp_2TiCl_2 is not formed when the titanium-containing residue is treated with HCl, treatment of the zirconium-containing residue with HCl affords a small amount of Cp_2ZrCl_2, while treatment of the hafnium-containing residue with HCl produces a yield of Cp_2HfCl_2 of 0.7 mol per mole of the initial compound. The different yields of the metallocene dichlorides in these reactions indicate differences between the compositions of the metal-contianing thermal decomposition products formed.[10]

Table 1. Thermal decomposition of the compounds Cp_2MR_2.

Compound	Decomposition conditions	Yield of RH after decomposition of Cp_2MR_2, mol mol^{-1}	Yield of products resulting from treatment of solid residue from decomposition of Cp_2MR_2 with HCl, mol mol^{-1}		Refs.

2. Pathways leading to formation of RH

One of the important questions arising in the study of the thermal decomposition of Cp_2MR_2 is that of the source of hydrogen atoms for the formation of RH. The cyclopentadienyl rings, the σ-linked group, or the solvent can serve as sources of this kind. In order to answer this question, studies have been made using deuterium-labelled compounds. Deuterium was introduced either into the Cp rings or into the R groups, or deuteriated solvents were used.

Table 2. Thermal decomposition of deuteriated methyl derivatives of titanium subgroup metals *in vacuo*.

Compound	Decomposition conditions		Isotopic composition of methane, %					Refs.
	T, °C	*t*, min	CH_4	CH_3D	CH_2D_2	CHD_3	CD_4	
$Cp_2Ti(CH_3)_2\text{-}d_{10}$	90	30	54.0	41.0	4.1	0.9	—	[6]
$Cp_2Zr(CH_3)_2\text{-}d_{10}$	230	15	17.2	56.3	15.7	7.8	3.0	[9]
$Cp_2Hf(CH_3)_2\text{-}d_{10}$	290	30	48.7	33.4	14.2	2.9	0.8	[10]
$Cp_2Hf(CD_3)_2 + Cp_2Hf(CD_3)_2\text{-}d_{10}$ (1:1)	290	30	33.0	56.8	10.2	—	—	[10]

The thermal decomposition of $Cp_2M(CH_3)_2\text{-}d_{10}$ without a solvent involves the liberation of mainly CH_4, CH_3D, and CH_2D_2 (Table 2). The decomposition of the phenyl derivatives $Cp_2M(C_6H_5)_2\text{-}d_{10}$ under the same conditions affords C_6H_6, C_6H_5D, and $C_6H_4D_2$ (Table 3).

These data demonstrate unambiguously that in the decomposition of the titanium subgroup compounds there are two competing pathways leading to the formation of RH—both with participation of the hydrogen of the Cp rings and with participation of the hydrogen of the neighbouring group R.

Table 3. Thermal decomposition of deuteriated phenyl derivatives of titanium subgroup metals *in vacuo*.

Compound	Decomposition conditions		Isotopic composition of benzene, %							Refs.

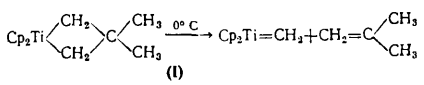
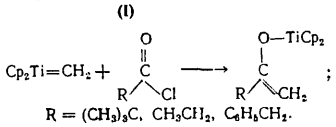
$Cp_2Hf(C_6H_5)_2$-d_{10}	200	30	85.0	15.0	—	—	—	—	—	[10]



When hydrogen atoms are abstracted from the group R by an intramolecular pathway, intermediate complexes containing dehydrogenated groups R coordinated to the metal are formed:

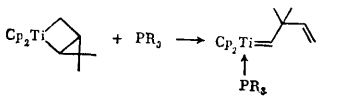
$$Cp_2MR_2 \rightarrow RH + Cp_2M(R_{-H}). \quad (1)$$

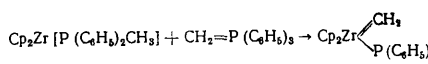


These complexes can decompose in their turn with liberation of RH as a result of the abstraction of hydrogen from the Cp or C_5H_4 groups via the reactions

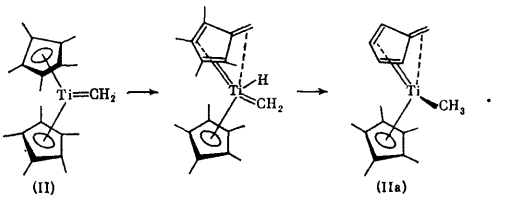
$$Cp_2M(R_{-H}) \begin{cases} \rightarrow Cp(C_5H_3)M + RH \\ \rightarrow (C_5H_4)_2M + RH. \end{cases} \quad (2)$$

α-Elimination via reaction (1) from the methyl derivatives leads to the formation of carbene complexes of the type $Cp_2M=CH_2$ (I). The structural parameters of the complex (I) and the related carbene complexes have been calculated theoretically.[12] The Tebbe reagent $Cp_2Ti=CH_2AlCl(CH_3)_2$ is an example of compounds in which the methylene fragment has been stabilised by coordination to the metal. This complex participates in metathetical processes and is used to synthesise titanacyclobutanes[13–16] and other metallacycles.[17] The methylene complex (I), which is formed on decomposition of titanacyclobutanes, produces two stable titanium enolates in the presence of acid chlorides:[18,19]



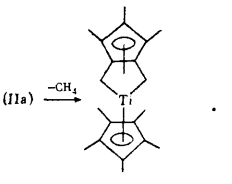


(I)



R = $(CH_3)_3C$, CH_3CH_2, $C_6H_5CH_2$.

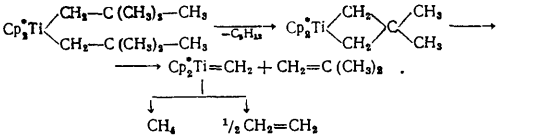
The carbene complexes of titanocene and zirconocene can be stabilised by phosphines:[20,21]



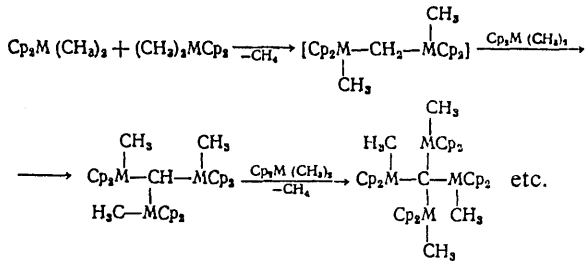
The thermal decomposition of the pentamethylcyclopentadienyl derivative $Cp^*_2Ti(CH_3)_2$ [$Cp^* = C_5(CH_3)_5$] involves the formation of the methylene complex $Cp^*_2Ti=CH_2$ (II) similar to compound (I). The methylene complex (II) is stabilised by the transfer of a hydrogen atom from a ring methyl group to the metal and then to the methylene group, which results in the formation of the complex (IIa):[22]

(II) (IIa)

Further heating of the complex (IIa) leads to the abstraction of a second methyl group from the metal atom, a methyl group of the cyclopentadienyl ring serving as a hydrogen donor in this process:[23]

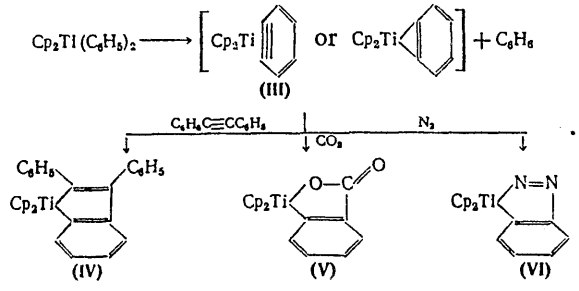


The thermal decomposition of Cp^*_2 leads to the same results:[23]



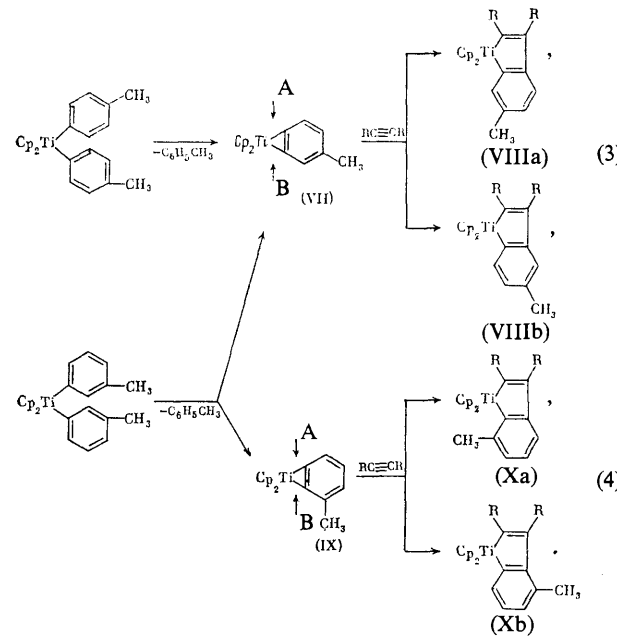
The synthesis of the ethylene complex $Cp^*_2Ti(CH_2=CH_2)$, which readily reacts with methylenecyclopropane forming the titanocyclopentane ring, has been described.[24]

γ-Elimination resulting in the formation of a metallacycle takes place in the thermal decomposition of $Cp^*_2Ti[CH_2C(CH_3)_3]_2$ in addition to the α-elimination, which leads to the liberation of neopentane and the formation of the carbene complex $Cp^*_2Ti=CH\text{–}C(CH_3)_3$ (main process). The cleavage of the bond in the metallacycle affords the carbene complex (II) and isobutene. The complex (II) generates methane as a result of the abstraction by the carbene of a hydrogen atom from the cyclopentadienyl rings or from the solvent. Ethylene is evolved on dimerisation of two carbene molecules. The unsubstituted norcarane has been detected among the decomposition products of $Cp^*_2Ti[CH_2C(CH_3)_3]_2$ in cyclohexane, which confirms the existence of compound (II):[25]



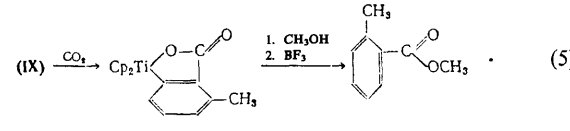
A similar γ-elimination process with formation of metallacycles takes place in the decomposition of the thorium complex $Cp^*_2Th.[CH_2Si(CH_3)_3]_2$.[26]

It has been suggested that the abstraction of hydrogen from the σ-linked ligand in the methyl derivatives $Cp_2M(CH_3)_2$ (M = Ti, Zr, or Hf) takes place also intermolecularly:



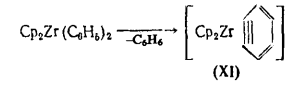
This pathway leading to the formation of RH has been confirmed by the hydrolysis of the decomposition products of $Cp_2M(CH_3)_2$ by deuteriated water. The evolution of CH_2D_2, CHD_3, and CD_4 indicates the presence of the [M–CH_2–M], [M–$\underset{\displaystyle M}{\overset{|}{C}}$H–M], and [C(M)]$_4$ groups in the decomposition products.[27]

The decomposition of the phenyl derivatives $Cp_2M(C_6H_5)_2$ via reaction (1) leads to the formation of benzene (as a result of the abstraction of the *ortho*-hydrogen atom from the neighbouring phenyl group) and of the intermediate complex (III). This decomposition mechanism has been confirmed in relation to the decomposition of $Cp_2Ti(C_6H_5)_2$ in the presence of tolane, CO_2 (80–90 °C), and N_2 (80–130 °C, 100 atm). In all three cases, the decomposition of $Cp_2Ti(C_6H_5)_2$ affords the intermediate complex (III), which then reacts with the above molecules, giving rise to the stable complexes (IV) and (V) and the unstable complex (VI) respectively:[28,29]



The thermal decomposition of the aryl derivatives of titanocene leads to the formation of similar intermediate complexes of titanium with substituted benzene rings, whose reactivity is determined by steric factors. The thermolysis of $Cp_2Ti(p\text{-}CH_3C_6H_4)_2$ [reaction (3)] proceeds via the formation of the intermediate complex (VII), which can react with the acetylenes RC≡CR (R = CH_3, CF_3, or C_6H_5), from the A or B side, producing the benzotitanoles (VIIIa) and (VIIIb) in approximately equal amounts:[30]

(3)

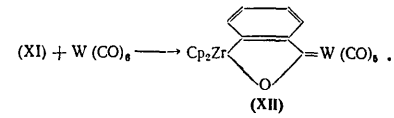


(4)

In the thermal decomposition of $Cp_2Ti(m\text{-}CH_3C_6H_4)_2$ [reaction (4)] there is in principle a possibility of the formation of the intermediate complexes (VII) and (IX). There is no doubt that the steric influence of the methyl group in the *meta*-position in the benzene ring makes the formation of the complex (IX) less preferred than that of the complex (VII). If the decomposition of $Cp_2Ti(m\text{-}CH_3C_6H_4)_2$ were accompanied by the formation of the intermediate (IX), then attack by the acetylene would be possible only from the A side, which would lead to the complex (Xa) but not (Xb).[30] However, this reaction pathway has been completely disproved[31] because, after carboxylation and alcoholysis, the orthoesters, which should have been formed via reaction (5), are absent from the products, and only the *para*- and *meta*-derivatives of benzoic acid esters are present in proportions of 1 : 3:

(5)

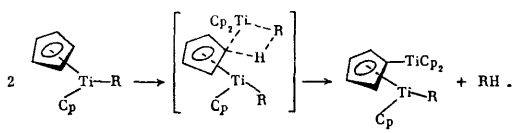
It has been shown[32–36] that, when $Cp_2Zr(C_6H_5)_2$ or its derivatives are heated (70–90 °C), the intermediate complex (XI) is formed:



Similar complexes also serve as intermediates in the isomerisation reactions of the compound Cp_2ZrAr_2 and in the reaction with the solvent–benzene.[32]

The complex (XI) reacts with alkenes, affording high yields of zirconaindans.[33,34] The interaction of the complex (XI) with *cis*- and *trans*-stilbenes is stereospecific and gives rise to the formation of *cis*- and *trans* 2,3-diphenyl-1-zirconaindans respectively.[33] It has been shown that alkylzirconaindans decompose above 100 °C in saturated hydrocarbons with formation of phenylalkanes. It has been suggested that the decomposition proceeds via a stage involving

the formation of a phenylene complex via the transfer of a hydrogen atom from the aromatic ring to the metal. The thermolysis of 3-butylzirconaindan in the presence of an excess of norbornene entails the displacement of hexene and the formation of a zirconaindan complex containing the norbornane ring.[34]



The reaction of the complex (XI) with $W(CO)_6$ yielded the carbene complex (XII):[35]

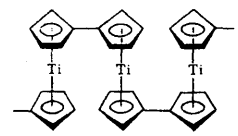
(XII)

The interaction of the complex (XI) with $CH_2 = P(C_6H_5)_3$ leads to the ylide $Cp_2Zr(C_6H_5)[CH = P(C_6H_5)_3]$.[36]

The cyclopentadienyl ligands together with the σ-linked groups R can serve as a source of hydrogen atoms in the formation of RH. The direct abstraction of hydrogen atoms by the group R from the Cp ring requires a high activation energy. Such a reaction proceeds more readily via an intermolecular pathway, in which the Cp ring is metallated by titanium, as suggested for the decomposition of trivalent titanium derivatives:[5]

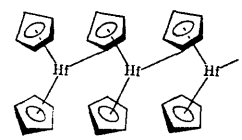
However, it is more likely that hydrogen is abstracted from the Cp ring via the preliminary transfer of hydrogen to the metal. Such transfer was observed when the compounds Cp_2MR_2 (M = Ti, Zr, or Nb; R = Cl or CH_3) were treated with different reductants. Similar processes involving the transfer of hydrogen atoms to the metal occur also in the thermal decomposition of the derivatives Cp_2MR_2 (M = Ti, Zr, or Hf). One of the facts confirming such transfer is the isotopic composition of the hydrogen evolved on hydrolysis of the thermal decomposition products of Cp_2MR_2 (Table 4). When the products of the thermal decomposition of Cp_2MR_2-d_{10} are treated with HCl/H_2O, HD is formed preferentially, while treatment with DCl/D_2O leads to the preferential formation of D_2. The formation of HD in the former case and of D_2 in the latter shows that the decomposition products contain deuterium atoms which have been transferred from the Cp ligands to the metal.[10,27]

Table 4. Hydrolysis of the products of the thermal decomposition of Cp_2ZrR_2-d_{10}.[27]



Initial compound	Agent	Isotopic composition of hydrogen
$Cp_2Zr(CH_3)_2$-d_{10}	HCl/H_2O	$H_2/HD/D_2 = 1/1.3/0.1$
	D_2O/DCl	$HD/D_2 = 1/5$
$Cp_2Zr(C_6H_5)_2$-d_{10}	HCl/H_2O	$H_2/HD/D_2 = 1/1.4/0.1$

The transfer of hydrogen to the metal takes place particularly readily after the abstraction of one group R and the liberation of a coordination site on the metal. The dehydrogenation of the cyclopentadienyl ring by the group R on formation of RH can proceed via the elimination of RH with participation of a hydrogen atom which has been transferred to the metal from the Cp ring:



$$Cp_2MR \rightarrow Cp\,(C_5H_4)\,M\,(H)\,R \rightarrow Cp\,(C_5H_4)\,M + RH,$$
$$Cp_2MR_{-H} \rightarrow Cp\,(C_5H_4)\,M\,(H)\,R_{-H} \rightarrow Cp\,(C_5H_4)\,MR \rightarrow (C_5H_4)_2M + RH.$$

The donation of hydrogen atoms by the cyclopentadienyl ring for the formation of RH should lead to a rearrangement of the initial biscyclopentadienyl structure. The dimeric hydride forms of 'titanocene', having different structures, are known to react differently with HCl. Thus the 'titanocene' $[(\eta^5\text{-Cp})_2Ti_2(\eta^5\text{:}\eta^5\text{-}C_{10}H_8)]H_2$, having the fulvalene structure, does not afford Cp_2TiCl_2 on reaction with HCl.[37,28] However, the 'titanocene' containing the $\eta^5\text{:}\eta^1$-Cp ligands reacts with HCl to form Cp_2TiCl_2.[39]

These data permit the hypothesis that dimeric or polymeric chains with $\eta^5\text{:}\eta^5$-fulvalene ligands exist in the products of the thermal decomposition of the biscyclopentadienyl derivatives of titanium by analogy with the fulvalene form of 'titanocene':

A structure similar to the 'titanocene' with the $\eta^5\text{:}\eta^1$-cyclopentadienyl ligands is achieved in the products of the thermal decomposition of the hafnium derivatives:

The effect of the treatment of the product of the thermal decomposition of Cp_2HfR_2-d_{10} with HCl, which results in the formation (in 70% yield) of hafnocene dichloride whose isotopic composition is described predominantly by the formula Cp_2HfCl_2-d_{10}-d_7, serves as indirect proof of the existence of this structure in the hafnium products.[10] The existence of the Cp_2HfCl_2-d_9 and -d_{10} isotopic forms indicates the presence of ligands (C_5D_4) bound to the metal. The d_9 form corresponds to the $(C_5D_4)(C_5D_5)Hf$ fragments, while the d_8 form corresponds to the $(C_5D_4)_2Hf$ fragments in the decomposition products.

Thus the elimination of RH with participation of the hydrogen atoms of the Cp rings leads to a rearrangement of the initial biscyclopentadienyl structure, whose character is determined by the nature of the central atom.

3. The hydrogen exchange in the thermal decomposition of Cp_2MR_2

There exist a series of experimental data obtained in the thermal decomposition of deuteriated biscyclopentadienyl compounds of titanium, zirconium, and hafnium, which indicate the occurrence of hydrogen exchange between the groups Cp and R. The following must be included among them:

(1) The change in the isotopic composition of methane in the thermal decomposition of methyl derivatives of titanium and hafnium [it has been established that, with increase in the degree of decomposition of the compounds (after an increase in temperature and in the reaction time), the fraction of methane containing hydrogen derived from the Cp ring is found to increase[10,40,41]].

(2) The formation of protium-containing methane (CD_3H, CD_2H_2, and CH_3D) on treatment of the products of the thermal decomposition of $Cp_2M(CD_3)_2$ and deuterium-containing methane (CD_4, CD_3H, CDH_3) with DCl and on treatment of the products of the thermal decomposition of $Cp_2M(CH_3)_2$–d_{10} with HCl.[10]

(3) A clear-cut demonstration of the occurrence of hydrogen exchange has been obtained by detecting deuterium in the Cp rings in the Cp_2HfCl_2 formed on treatment of the $Cp_2Hf(CD_3)_2$ decomposition products with HCl:[10]

Isotopic forms of Cp ligands	d_0	d_1	d_2	d_3	d_4
Contents of these forms, %	85.3	12.3	1.5	0.7	0.2.

The hydrogen exchange between the Cp and R groups should entail two reactions—the reversible transfer of hydrogen from the methyl group to the metal [reaction (6)] and rapid exchange of hydride hydrogen and the hydrogen in the Cp or C_5H_4 ligands [reaction (7)]:

$$\rangle M{-}CH_3 \rightleftarrows \rangle M\langle^{CH_2}_{H}\,, \qquad (6)$$

$$Cp\,(C_5H_4)\,MH \rightleftarrows Cp\,(C_5H_5)\,M. \qquad (7)$$

The exchange is facilitated after the abstraction of one σ-linked group as a result of the liberation of a coordination site at the metal. The rate of exchange via reactions (6) and (7) must exceed the rate of elimination of the second methyl group. This in fact explains the finding that, on decomposition of $Cp_2M(CH_3)_2$, the fraction of methane containing hydrogen from the Cp rings increases with increasing reaction time. After the treatment of the $Cp_2Hf(CD_3)_2$ thermal decomposition products with HCl, Cp_2HfCl_2–d_1–d_4 compounds were isolated. These data indicate the presence in the decomposition products of the $(C_5H_5)(C_5H_3D)Hf$, $(C_5H_3D)_2Hf$, and other fragments containing one or several deuterium atoms. The dominant content of Cp_2HfCl_2-d_1 shows that the exchange involves only one ring.[10]

The transfer of the hydrogen atom from the ring to the metal takes place also via an intermolecular pathway. This is demonstrated by the composition of Cp_2MR_2 (M = Ti or Zr) in the presence of Cp_2V-d_{10}, in which there is H–D exchange between the hydride atoms of Cp_2MR_2 and vanadocene. The product of the thermal decomposition of Cp_2MR_2 also participates in the H–D exchange reaction with vanadocene. It has been shown that there exists a mobile equilibrium in which the hydrogen atoms of the Cp ligands in the initial compounds, the hydride hydrogen atoms, and the deuterium in the C_5D_5 ligands of vanadocene participate.[27]

The complexes $[Cp(C_5H_4)NbH]_2$ and Cp_2TaH_3 are known to be active catalysts of the H–D exchange in the D_2–C_6H_6 system.[42] It was found that the hydride complexes formed in the decomposition of the compounds Cp_2MR_2 are active in the hydrogen exchange of the hydrocarbons. Thus it has been established that hydrogen exchange takes place between C_6H_6 and D_2 under the conditions of the thermal decomposition of $Cp_2Ti(CH_3)_2$.[43] The thermal decomposition of $Cp_2Zr(C_6H_5)_2$-d_{10} in the presence of methane affords deuterium-containing methane. When the product of the thermal decomposition of $Cp_2Zr(CH_3)_2$-d_{10} is heated with C_2H_6, deuterium-containing propene and propane are produced (Table 5).[27] Deuteriomethane has been detected in the decomposition of $Cp_2Hf(CH_3)_2$ in C_6D_6.[10] It has been suggested that hydrogen exchange takes place under the thermal decomposition conditions between the hydride atoms of the cyclopentadienyl complex and the hydrogen atoms of the hydrocarbon.[10,27] The exchange proceeds via a stage involving the formation of σ-alkyl (or σ-aryl) intermediate transition metal complex:[44]

$$L_2M{-}H + R'D \longrightarrow \left[\begin{array}{c} R' \\ | \\ L_2M{-}D \\ | \\ R \end{array}\right] \longrightarrow L_2M{-}D + R'H\,;$$

L = Cp, C_5H_4.

Table 5. Thermal decomposition of Cp_2MR_2 in the presence of hydrocarbons (according to the results of Razuvaev and co-workers[10,27]).

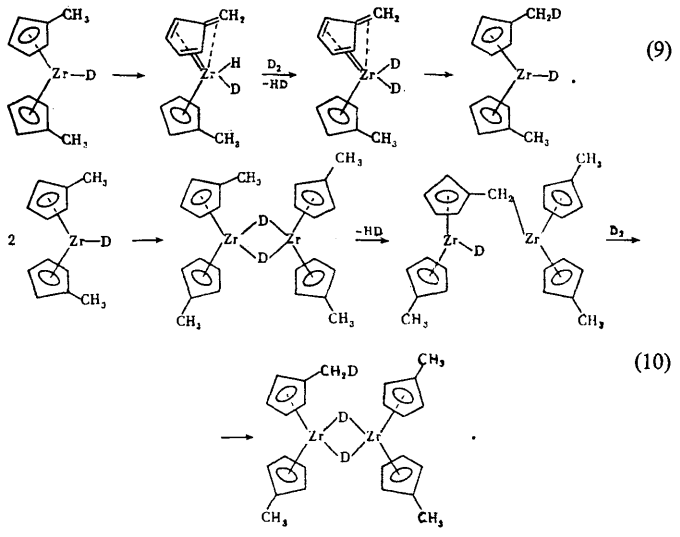
System	Reaction conditions		Isotopic composition of hydrocarbons, %
	T, °C	t, min	
$Cp_2Zr(C_6H_5)_2$-d_{10} + CH_4	160	45	CH_4 96.0 CH_3D 4.0
Products of thermal decomposition of $Cp_2Zr(CH_3)_2$-d_{10} + C_3H_6	200	60	C_3H_8 17.5 C_3H_6 86.3 C_3H_7D 39.5 C_3H_5D 13.7 $C_3H_6D_2$ 26.7 $C_3H_5D_3$ 16.3
$Cp_2Hf(CH_3)_2$ + C_6D_6	200	180	CH_4 95.1 CH_3D 4.9

Thus the thermal decomposition of biscyclopentadienyl compounds is accompanied by the hydrogen exchange between the hydrogen atoms of the Cp rings, the hydride atoms, the hydrogen atoms of the σ-linked group, and the hydrogen atoms of the hydrocarbon in the presence of which the decomposition takes place:

$$H_{Cp} \rightleftharpoons H_M \rightleftharpoons H_R\,, \qquad H_M \rightleftharpoons H_{ext}$$

If a compound containing an alkyl substituent in the cyclopentadienyl ring undergoes thermal decomposition, then the hydrogen exchange involves also the atoms in the alkyl group. Thus it has been shown on the basis of ^1H NMR and EPR data as well as the results of isotope analysis that H–D exchange takes place between the hydrogen atoms of the methyl groups and molecular deuterium in the thermolysis or photolysis of $[(C_5H_4CH_3)_2ZrH_2]_2$ in a D_2 atmosphere.[45]

It has been established that hydrogen is eliminated in the first stage with formation of a trivalent zirconium derivative:



$$[(C_5H_4CH_3)_2ZrH_2]_2 \longrightarrow 2\,(C_5H_4CH_3)_2ZrH + H_2.$$

Next D_2 exchanges with hydride atoms. Such exchange can proceed via a four-centre transition state:

$$\rangle ZrH + D_2 \rightarrow \rangle Zr\langle^{H.}_{D.}\!:D \rightarrow \rangle Zr{-}D + HD. \qquad (8)$$

It has been suggested that the exchange of hydride hydrogen with the hydrogen atoms of the alkyl group takes place intramolecularly with formation of zirconium-fulvene derivatives [reaction (9)] or via

an intermolecular pathway [reaction (10)]:

(9)

(10)

If the methyl group in the cyclopentadienyl ligand is replaced by the bulky silyl group SiR_3, then hydrogen exchange proceeds only via reaction (8) without involving the cyclopentadienyl rings of the hydride complex.[45]

4. The participation of the solvent in the decomposition of Cp_2MR_2

Comparison of the products of the thermal decomposition of Cp_2MR_2 without a solvent and in solutions in hydrocarbons (benzene, toluene) shows that the decomposition processes are similar.[6,10] Two pathways leading to the formation of RH are observed in both cases—with participation of the hydrogen atoms of the Cp rings and with participation of σ-linked groups. In the thermal decomposition of deuteriated Cp_2MR_2, both in solutions and in the solid state, the isotopic composition of RH is approximately the same. In most studies on the thermal decomposition of Cp_2MR_2 in deuterium-containing hydrocarbon solvents, it has been noted that the solvents do not participate in the RH formation process.[7,40] The small amounts of RD detected in this case may indicate the occurrence of hydrogen exchange between the solvent and RH.

The participation of oxygen-containing solvents in the decomposition of the complexes Cp_2MR_2 has been established and has been confirmed by the isolation of RD [for example, in the decomposition of Cp_2MR_2 in THF-d_8 or $(C_2D_5)_2O$ [7,40]] and also by the change in the isotopic composition of RH on passing from hydrocarbon solvents to ethers in the thermal decomposition of deuteriated compounds.[10] Solvents such as tetrahydrofuran (THF) and diethyl ether readily form adducts with various transition metal compounds. It has been established that the ligand bound in the complex is an additional donor of hydrogen in the formation of RH.

The products of the thermal decomposition of Cp_2MR_2 in chlorine-containing solvents such as CCl_4 and $CHCl_3$ differ from the decomposition products in hydrocarbons (Table 6). The thermal decomposition of Cp_2MR_2 in $CHCl_3$ and CCl_4 affords a high yield of RCl and Cp_2MCl_2 together with RH.[10,46]

Experimental data show that the thermal decomposition of Cp_2MR_2 in chlorine-containing solvents includes the stage involving the decomposition proper of the compounds (both in the decomposition without a solvent and in hydrocarbon solvents) and the stages involving the interaction of the chlorine-containing solvent with the initial compound or with its thermal decomposition product. It has been suggested that, together with the radical pathway, there exists a carbene decomposition pathway. The relative contributions of these pathways depend on the nature of the metal. The contribution of the carbene pathway is insignificant for M = Ti or Zr, increasing somewhat for M = Hf.[10,46]

Table 6. Thermal decomposition of Cp_2MR_2 in chlorine-containing solvents.

Compound	Decomposition conditions			Decomposition products, mol/mol of starting material				Refs.
	solvent	T, °C	t, h	RH	RCl	Cp_2MCl_2	$(CCl_3)_2$	
$Cp_2Ti(CH_3)_2$	$CHCl_3$	70	24	1.90	Нет	0.80	not determined	[4]
$Cp_2Ti(C_6H_5)_2$	$CHCl_3$	70	24	1.80	»	0.81	»	[4]
	CCl_4	80	20	1.20	0.60	0.24; 0.68 $CpTiCl_3$	nil	[7]
$Cp_2Zr(CH_3)_2$	$CHCl_3$	150	100	1.90	0.05	0.80	»	[46]
	CCl_4	150	100	1.30	0.65	0.72	»	[46]
$Cp_2Zr(C_4H_5)_2$	$CHCl_3$	150	100	1.20	0.62	0.73	»	[46]
	CCl_4	150	100	1.30	0.60	0.65	»	[46]
$Cp_2Hf(C_6H_5)_2$	CCl_4	150	8	0.72	0.22	0.81	0.41; 0.39 $(CHCl_3)$	[10]

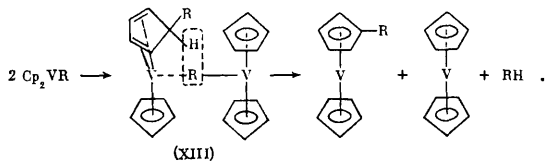
III. Thermal decomposition of vanadium compounds

1. Thermal stability and decomposition products

The thermal stability of the biscyclopentadienyl compounds of trivalent vanadium Cp_2VR [R = CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, n-C_5H_{11}, or $CH_2C(CH_3)_3$] is determined by the nature of the σ-substituent.[47] Cp_2VCH_3 is the most stable. The presence of β-hydrogen atoms in the alkyl chain reduces sharply the stability of the compounds as a consequence of the ease of the elimination reaction with participation of these atoms.

In the series of tetravalent vanadium compounds Cp_2VR_2 (R = CH_3, C_2H_5, or $CH_2C_6H_5$), the benzyl derivative has the lowest stability, the half-life in toluene at 20 °C being 30 min. The highest thermal stability is shown by $Cp_2V(CH_3)_2$. This compound is thermally stable at room temperature for a long time. According to DTA data, the decomposition of the complex $Cp_2V(CH_3)_2$ is observed above 122 °C with an exothermic heat change,[48,49] In terms of its thermal stability, $Cp_2V(CH_3)_2$ resembles the monosubstituted derivative Cp_2VCH_3. The substitution of a methyl group in $Cp_2V(CH_3)_2$ by chlorine reduces sharply the stability of the compound. The mixed derivative $Cp_2V(CH_3)Cl$ begins to decompose at 87 °C (according to DTA data).[50]

The thermal decomposition of Cp_2VR (R = CH_3 or Ar), $Cp_2V(CH_3)Cl$, and $Cp_2V(CH_3)_2$ without a solvent and in solutions in hydrocarbons or THF leads to the elimination of approximately 0.5 mol of RH per σ-linked group. The principal vanadium-containing decomposition products of these compounds are biscyclopentadienyl compounds, whose yield is 0.6–0.8 mol per mole of the initial compound. The composition of the decomposition product has been established mass-spectrometrically. The decomposition products of Cp_2VR and Cp_2VR_2 are mixtures of vanadocene and its substituted derivatives $Cp(C_5H_4R)V$ and $(C_5H_4R)_2V$. [49,51] The decomposition of $Cp_2V(CH_3)Cl$ results in the formation of Cp_2VCl and its methyl derivatives.[50]

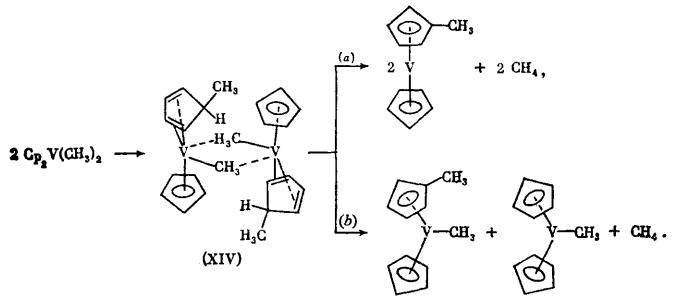


The migration of the bulky organoelemental group to the cyclopentadienyl ring has been demonstrated in the thermal decomposition of the biorganoelemental compound $Cp_2VGe(C_2H_5)_3$. The compound $Cp[C_5H_4Ge(C_5H_5)_3]V$ was isolated and characterised as a result of the reaction.[52]

2. Thermal decomposition pathways

Comparison of the compositions of the products of the thermal decomposition of the biscyclopentadienyl compounds of titanium and vanadium demonstrates a sharp difference between the decomposition pathways. In the decomposition of the vanadium compounds, the cleavage of the metal–carbon σ-bond takes place with retention of the sandwich structure, some of the σ-linked groups passing to the Cp ring.

In the thermal decomposition of vanadium compounds containing deuterium in the cyclopentadienyl rings, mainly RD and the vanadocenes $(C_5D_5)_2V$, $(RC_5D_4)(C_5D_5)V$, and $(RC_5D_4)_2V$ are formed.[49] The preferential involvement of the Cp rings as donors of hydrogen atoms in the formation of RH as well as the high yield of vanadocene and its substituted derivatives show that the formation of RH and the migration of the group R to the Cp ring are components of a single process.



It has been suggested[49,52] that the decomposition of Cp_2VR is preceded by an intermolecular interaction leading to the dinuclear complex (XIII) with the η^4-alkyl(aryl)cyclopentadienyl ligand. The main pathway in the reaction of the complex (XIII) involves the elimination of RH, vanadocene, and its substituted derivative:

(XIII)

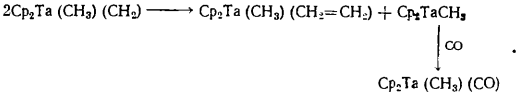
The isolation of small amounts of CpR indicates the occurrence of a side reaction of the complex (XIII) via a pathway involving the rupture of the V–η^4-CpR bond.

The decomposition of $Cp_2V(CH_3)_2$ is preceded by the formation of the dinuclear complex (XIV), which then decomposes via two pathways:[49]

(XIV) (XVa) (XVb)

The σ-derivatives formed via pathway (*b*) are unstable under the reaction conditions and decompose in accordance with the scheme presented above.

The formation of intermediate dinuclear complexes between the initial compounds and the vanadocene produced has also been postulated in the decomposition of Cp_2VR_n. This is indicated by the evolution of deuteriomethane in the thermolysis of an equimolar mixture of $Cp_2V(CH_3)_n$ + $Cp_2Vd\text{-}d_{10}$ and of products containing methyl groups in the deuteriated cyclopentadienyl ring.[49] The formation of di- and poly-methylvanadocenes in the thermolysis of $Cp_2V(CH_3)_n$ (n = 1,2) can be explained by the existence of the dinuclear complexes.



IV. Thermal decomposition of niobium and tantalum compounds

The thermal decomposition of the biscyclopentadienyl compounds of niobium and tantalum has been investigated for only a few examples. The compounds Cp_2NbR_2 (R = CH_3 or C_6H_5) decompose at temperatures close to those of the decomposition of compounds of the type Cp_2TiR_2.[53] The decomposition of Cp_2NbR_2 leads to the elimination of the σ–linked groups in the form of RH (1.3–1.8 mol). Treatment of the solid residue from the decomposition with HCl affords up to 10% of Cp_2NbCl_2.[53,54] The above products indicate the similarity of the thermal decomposition reactions of the niobium compounds and compounds of the titanium subgroup but not the vanadium subgroup elements.

The formation of C_6D_5H alone in the decomposition of $Cp_2Nb.(C_6D_5)_2$ shows that the cyclopentadienyl rings are the source of hydrogen atoms for the formation of RH. The abstraction of hydrogen from the Cp ring takes place mainly intramolecularly. This is indicated by the thermolysis of an equimolar mixture of $Cp_2Nb(C_6H_5)_2$ and $Cp_2Nb(C_6D_5)_2\text{-}d_{10}$. In contrast to the titanium analogue, the compound $Cp_2Nb(C_6H_5)_2$ does not react with tolane. This fact confirms that the decomposition of the niobium derivative does not involve the elimination of hydrogen from neighbouring phenyl groups and that a complex similar to the complex (III) is not formed.

Unfortunately there are as yet no experimental data indicating the pathway followed in the abstraction of hydrogen atoms from the cyclopentadienyl ring and in the elimination of RH. However, the existence of niobium hydride derivatives of the type $[Cp(C_5H_4)NbH]_2$ as well as the ease of the conversion of 'niobocene' into the hydride complex[55] show that in the case of titanium compounds too RH can be eliminated with participation of hydride hydrogen.

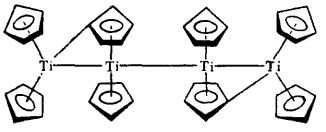
There are several examples of thermal decomposition reactions of tantalum and niobium complexes occurring with retention of the biscyclopentadienyl structure of the compounds. Thus it has been shown that the methyl complex of tantalum $Cp_2Ta(CH_3)(CH_2)$ decomposes slowly at room temperature via the mechanism

When $Cp_2Nb(C_2H_5)(C_2H_4)$ is heated, ethylene is readily split off. Subsequent β-elimination leads to the formation of $Cp_2Nb.(C_2H_4)H$.[56]

V. Photolytic decomposition of titanium and vanadium subgroup compounds

The photolytic decomposition of biscyclopentadienyl compounds of the titanium and vanadium subgroups differs from the thermal reactions already examined. EPR study of the photolysis of the methyl derivatives of titanium, zirconium, and hafnium $Cp_2M(CH_3)_2$

has led to the conclusion that the main stage of the photolysis is the homolytic cleavage of the M–CH_3 σ-bond with formation of intermediate compounds of the trivalent metal, which reacts both via the pathway involving the homolytic dissociation of a second M–CH_3 bond and via the pathway involving the intramolecular elimination of methane:[57–59]



$$Cp_2M(CH_3)_2 \xrightarrow{h\nu} Cp_2MCH_3 + {}^{\cdot}CH_3 ,$$

$$\downarrow \qquad\qquad \downarrow$$

$$\text{«}Cp_2M\text{»} + {}^{\cdot}CH_3 \qquad\qquad Cp(C_6H_4)M + CH_4 .$$

This course of the process has been confirmed by the isotopic composition of the methane evolved in the photolysis of $Cp_2Ti(CD_3)_2$ in C_6H_6 ($CD_3H : CD_4 = 2.5 : 1$).[60]

The photolysis of $Cp_2M(CH_3)_2$ (M = Ti or V) results in the formation of black pyrophoric oligomeric or polymeric products containing both cyclopentadienyl rings and C_5H_4 fragments. The so called 'titanocene', obtained in the photolysis of $Cp_2Ti(CH_3)_2$, has been most thoroughly investigated. Its treatment with gaseous HCl results in the formation of Cp_2TiCl_2 as the main product. In addition, $CpTiCl_3$ and $(C_5H_4Cl)_2TiCl$ were isolated. Its reaction with Br_2 affords predominantly $CpTiBr_3$ and Cp_2TiBr. Small amounts of $Cp(C_5H_4Br)_2TiBr$ and $Cp(C_5H_4Br)TiBr_2$ were obtained. On the basis of these data, it has been suggested that the 'titanocene' formed in the photolysis has the following structure:[61]

The photolysis of $Cp_2Ti(CH_3)_2$ initiates the free-radical polymerisation of methyl methacrylate. The low-valence complex (XVI) is formed in the first stage of the polymerisation reaction (via a cryptoradical mechanism or via the preliminary transfer of hydrogen from the Cp ring to the metal). In the presence of methyl methacrylate (MMA), the complex (VI) generates a radical:

$$Cp_2Ti(CH_3)_2 \xrightarrow{-CH_4} \underset{\textbf{(XVI)}}{Cp(C_5H_4)TiCH_3} \xrightarrow{MMA} Cp(C_5H_4)Ti + CH_3\dot{M}MA \xrightarrow{n\ MMA} \text{polymer} .$$

The polymer obtained in the photolysis of $Cp_2Ti(^{14}CH_3)_2$ in MMA contains on average about one ^{14}C atom per chain. It has also been established that the tritium atoms in the cyclopentadienyl rings of $Cp_2Ti(CH_3)_2$-t_{10} enter into the composition of the polymer formed as a result of the photolysis.[62]

In contrast to $Cp_2Ti(CH_3)_2$, biphenyl is formed in the photolysis of the phenyl analogue in benzene in an amount of 1.2 mol per mole of the initial compound.[63] This finding clearly demonstrates that the solvent participates in the formation of biphenyl. The photolysis of $Cp_2Ti(C_6H_5)_2$ in C_6D_6 yielded 46% of C_6H_5–C_6H_5 and 54% of Ph–Ph-d_5. The photolysis of $Cp_2Ti(p\text{-}CH_3C_6H_4)_2$ in benzene resulted in the formation of toluene (0.11 mol), 4-methylbiphenyl (0.11 mol), and 4,4-dimethylbiphenyl (0.36 mol) together with the 'titanocene'. Under analogous conditions, toluene (0.35 mol), 3-methylbiphenyl (0.35 mol), and 3,3-dimethylbiphenyl (0.21 mol) were obtained in the photolysis of $Cp_2Ti(m\text{-}CH_3C_6H_4)_2$. The data presented show that there are two completing pathways in the photolytic decomposition of aryltitanium compounds:

$$Cp_2TiAr_2 \begin{cases} \xrightarrow{h\nu} \text{«}Cp_2Ti\text{»} + 2Ar^{\cdot} \begin{cases} \xrightarrow{\text{H donor}} Ar{-}H , \\ \xrightarrow[-H]{C_6H_6} Ar{-}C_6H_5 , \end{cases} \\ \xrightarrow{h\nu} \text{«}Cp_2Ti\text{»} + Ar{-}Ar . \end{cases}$$

The first pathway involves the homolytic cleavage of the Ti–Ar σ-bond and the generation of Ar radicals, which can abstract a hydrogen atom from the solvent or from the Cp ring or can enter into a homolytic substitution reaction with the solvent—benzene. The second pathway involves the reductive elimination reaction which leads to the formation of biaryls.[63]

In contrast to the titanium analogues, in the photolysis of diarylzirconocenes, the contribution of the reductive elimination reaction increases. This is confirmed by the high yield of 4,4-dimethylbiphenyl formed in the photolysis of $Cp_2Zr(p\text{-}CH_3C_6H_4)_2$ in benzene.[64]

The intermediate aryne complexes are not formed in the photolysis of titanium and zirconium compounds via the abstraction of an *ortho*-hydrogen atom from the aryl ligand, which is indicated by the absence of isomeric biphenyls among the reaction products.[64]

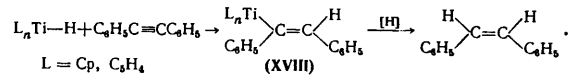
The study of the photolysis of the aryl derivatives Cp_2ZrAr_2 (Ar = C_6H_5 or $C_6H_5CH_2$) by the EPR method demonstrated the presence of a stage involving the homolytic cleavage of the Zr–Ar bond, as in the decomposition of the methyl derivatives. The compounds Cp_2ZrAr formed in this stage have been detected as complexes with phosphines.[65]

The photolysis of $Cp_2Ti(CH_3)_2$ and Cp_2TiAr_2 in the presence of CO leads to the formation of $Cp_2Ti(CO)_2$ in 50–60% yield.[63,66] The carbonyl groups in the complex $Cp_2Ti(CO)_2$ are capable of being exchanged for the molecules of gaseous carbon monoxide in hexane [reaction (11)].[67] The photolysis of $Cp_2Ti(CO)_2$ in the presence of an excess of PF_3 affords $Cp_2Ti(PF_3)_2$ [reaction (12)].

$Cp_2Ti(CO)PR_3$ is formed in the photolytic or thermal reaction of $Cp_2Ti(CO)_2$ with PR_3 (R = C_2H_5 or C_6H_5) in hydrocarbon solvents [reaction (13)]:[67]

$$Cp_2TiR_2 \xrightarrow{h\nu,\ CO} Cp_2Ti(CO)_2 \begin{cases} \underset{\longleftarrow}{\xrightarrow{h\nu,\ C^{18}O}} Cp_2Ti(CO)C^{18}O \underset{\longleftarrow}{\xrightarrow[-CO]{C^{18}O}} Cp_2Ti(C^{18}O)_2 , & (11) \\ \underset{\longleftarrow}{\xrightarrow{h\nu,\ PF_3}} Cp_2Ti(CO)PF_3 \underset{\longleftarrow}{\xrightarrow[-CO]{PF_3}} Cp_2Ti(PF_3)_2 , & (12) \\ \underset{\longleftarrow}{\xrightarrow{h\nu \text{ or } \Delta,\ PR_3}} Cp_2Ti(CO)PR_3 . & (13) \end{cases}$$

The photolysis of $Cp_2M(CH_3)_2$ and Cp_2MAr_2 (M = Ti or Zr) in the presence of diphenylacetylene leads to the metallacycles (XVII):[63,66,68]



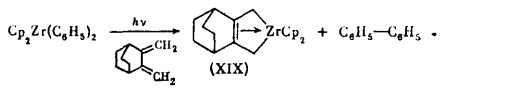
$$Cp_2MR_2 \xrightarrow[C_6H_5C\equiv CC_6H_5]{h\nu} Cp_2M(C_6H_5)_4$$

(XVII)

A similar complex can be obtained by the reaction of Cp_2TiCl_2 with metallic magnesium and tolane.[68,70] In both cases an unstable metlalocene is formed in the first stage and then reacts with an alkyne, which leads to the complex (XVII).

The photolysis of titanium and zirconium compounds differs from the thermal reaction, which leads to the formation of 1,1-bis-(cyclopentadienyl)-2,3-diphenylbenzotitanole or the analogous zirconole via an intermediate aryne complex.

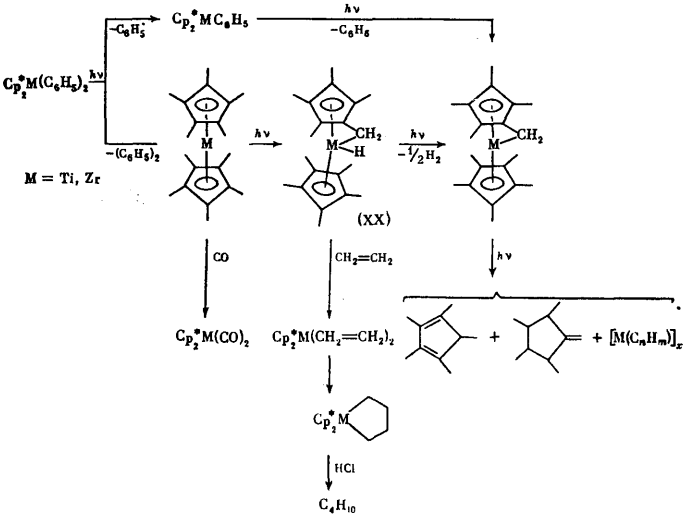
Apart from compound (XVII), organic products such as diacetylenes and *cis*- and *trans*-stilbenes are formed in the photolysis of Cp_2TiAr_2 in the presence of diphenylacetylenes. Stilbenes are also formed in the photolysis of $Cp_2Ti(CH_3)_2$ in the presence of diphenylacetylene but in a lower yield. The formation of the reduction products, namely *cis*- and *trans*-stilbenes, indicates the presence of hydride intermediates in the photolysis process, which can be formed via the transfer of a hydrogen atom from the Cp ring to the metal:



The first stage of the process involves the insertion of acetylene into the M–H bond with formation of the intermediate σ-complex (XVIII), which affords stilbene in the presence of a hydrogen donor.[63]

The stable complex $Cp_2Zr(\eta^4\text{-}trans\text{-}CH_2=CHCH=CH_2)$ is formed in the photolysis of $Cp_2Zr(C_6H_5)_2$ in the presence of *trans*-butadiene. It can also be obtained by reducing Cp_2ZrCl_2 with lithium in the presence of butadiene:[71]

When a solution of $Cp_2Zr(\eta^4\text{-}trans\text{-}CH_2\text{–}CHCH=CH_2)$ is irradiated or heated in C_6D_6, an equilibrium is established between the isomeric *trans*- and *cis*-forms of the diene complexes of zirconocene.[71]



The photolysis of $Cp_2Zr(C_6H_5)_2$ in toluene in the presence of 2,3-bis(methylene)bi-cyclo[2.2.2]octane leads to the complex (XIX) in 65% yield:[72]

The photolysis of $Cp_2^*M(C_6H_5)_2$ (M = Ti or Zr)[73] as well as the unsubstituted derivatives proceeds via two main pathways: reductive elimination and homolysis. The isotopic composition of the biphenyl formed in the photolysis of $Cp_2^*M(C_6H_5)_2$ (M = Ti or Zr) in C_6D_6 established that the contribution by the reductive elimination is 97% for M = Ti and 25% for M = Zr.

The reductive elimination reaction of $Cp_2^*M(C_6H_5)_2$ leads to the unstable permethylmetallocene, which is converted into compound (XX) via the abstraction of hydrogen from the ring methyl group. Oligomeric metal-containing products as well as 2,3,4,5-tetramethylfulvene and pentamethylcyclopentadiene are formed ultimately.

A dicarbonylmetallocene is formed in the photolysis of the permethyl derivative in the presence of CO, as in the case of the unsubstituted compounds. The metallacycle is produced in the presence of ethylene (35 atm, –20 °C). The homolytic cleavage of the M–C_6H_5 σ-bond takes place to a slight extent even at low temperatures. The phenyl radicals formed have been detected by EPR as adducts with spin-trapping agents:

Comparison of the results of the photolysis of the permethyltitanocene derivatives and the unsubstituted compounds demonstrates an appreciable increase in the contribution of their reductive elimination with introduction of methyl substituents into the Cp ring. Such a change in the relative contributions of the photolytic pathways is due both to the steric influence of the bulky methyl group and to the absence from the rings of mobile hydrogen atoms capable of functioning as hydrogen donors in the homolytic decomposition. For the zirconium derivative, in which the central atom has a larger atomic radius compared with the titanium complex, the steric effect of the ligands is less significant.[73]

The photolysis of $Cp_2V(CH_3)_n$ (n = 1,2) and $Cp_2Nb(CH_3)_2$ in hydrocarbon solvents leads to the cleavage of the metal–carbon σ-bond. The main gaseous product is methane. Studies carried out with deuterium-containing compounds as well as C_6D_6 have shown that the source of hydrogen for the formation of methane may be the cyclopentadienyl rings, methyl groups, and solvents. As a result of the photolysis, the biscyclopentadienyl structure breaks down, which is indicated by the absence of vanadocene from the photolysis products.[74]

The photolysis of $Cp_2V(CH_3)_n$ (n = 1,2) and $Cp_2Nb(CH_3)_2$ in pentane in the presence of CO affords low yields of the carbonyl complexes $CpV(CO)_4$ and $CpNb(CH_3)(CO)$ respectively.[74]

VI. Exchange of cyclopentadienyl ligands

Under the conditions of photolysis in solution in toluene, the dichlorides of the biscyclopentadienyl derivatives of titanium, zirconium, and hafnium are capable of exchanging the cyclopentadienyl ligands:[75–77]

$$d_{10}\text{-}Cp_2MCl_2 + Cp_2MCl_2 \rightleftarrows 2Cp(d_5\text{-}Cp)MCl_2.$$

This process is not only photolytic but also thermal, its rate increasing with temperature.

The thermal exchange of the cyclopentadienyl ligands occurs also in the $Cp_2V\text{-}d_{10}\text{–}Cp_2M$ system:[78]

$$d_{10}\text{-}Cp_2V + Cp_2M \rightleftarrows d_5\text{-}CpVCp + d_5\text{-}CpMCp + d_{10}\text{-}Cp_2M + Cp_2V;$$
M = V, Cr, Mn.

The rate of this exchange depends on the nature of the metal in Cp_2M and increases in the sequence V < Cr < Mn.

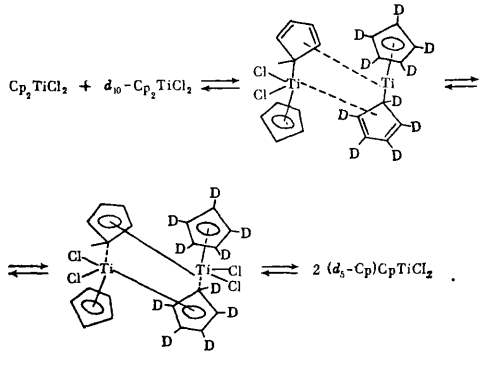
The exchange of the cyclopentadienyl ligands can take place between metallocenes in different oxidation states. Thus the occurrence of the exchange in the Cp_2VCl–$(C_5H_4CH_3)_2VCl_2$, Cp_2V–$(C_5H_4CH_3)_2VCl_2$, and Cp_2V–$(C_5H_4CH_3)_2VCl$ systems has been demonstrated. The rate of exchange increases significantly on heating to 70 °C.[75]

Several mechanisms which can account for the exchange of the Cp ligands in metallocenes have been proposed.[75,78] In particular, a certain amount of ionic character of the bonds in the metallocenes Cp_2M (M = V, Cr, or Mn), manifested in the reactions with iron chloride and also in the rapid exchange with LiC_5D_5, indicates the possibility that the exchange reaction may proceed via an ionic pathway:

$$Cp_2M \rightleftarrows C_5H_5^- + CpM^+,$$

$$C_5H_5^- + d_{10}\text{-}Cp_2M \rightleftarrows d_5\text{-}CpMCp + C_5D_5^- .$$

The rate-determining stage of the exchange in the postulated mechanism is the dissociation into ions, whose rate is directly proportional to the amount of ionic character of the molecules. Comparison of the rates of exchange shows that the exchange process involving compounds with a more pronounced ionic character of the bonds is faster. Thus, in the systems Cp_2M-d_{10}–Cp_2M (M = V, Cr, or Mn), a faster exchange is observed in the case of manganocene, for which the ionic character of the bonding of the Cp ligands is more clearly manifested.



A radical pathway is possible for the photolytic ligand exchange:

$$(C_5H_5)_2V \rightleftarrows C_5H_5^{\cdot} + C_5H_5V^{\cdot},$$

$$C_5H_5^{\cdot} + (C_5D_5)_2V \rightleftarrows (C_5H_5)(C_5D_5)V + C_5D_5^{\cdot} .$$

The radical exchange of the Cp rings in Cp_2MCl_2 has been confirmed by experiments on the photolysis of Cp_2TiCl_2 by the EPR method, where the Cp radical was detected in the form of adducts with spin trapping agents.[76,80]

Together with the radical mechanism of the exchange, there exists an intermolecular bridge mechanism, which presupposes a change in the character of the bonding of the cyclopentadienyl ring during the exchange process:[77,79]

The exchange of the cyclopentadienyl ligands may be accompanied by the thermolysis of the compounds Cp_2MR_2. Such a process has been noted, for example, in the decomposition of the compounds $Cp_2V(CH_3)_n$.[49]

VII. Thermal decomposition with rupture of metal–cyclopentadienyl ring bonds

The thermal cleavage of the $(\eta^5\text{-}C_5H_5)$–M bonds occurs under more severe conditions than those leading to dissociation of the metal–carbon bond. The thermolysis of mixed sandwich-covalent titanium and vanadium derivatives takes place in the temperature range 100–200 °C. The contribution by the reactions involving the dissociation of the $M\text{–}C_5H_5$ bonds is then insignificant. The strength of this bond has also been measured thermochemically.[81] The average $M\text{–}C_5H_5$ dissociation energies in different titanium, zirconium, and vanadium compounds are in the range 63–88 kcal mol^{-1}.

The $M\text{–}C_5H_5$ bond dissociation energies of metallocenes of the 3*d* series have been estimated thermodynamically.[82] Similarly calculations have shown that dissociation in accordance with the equation

$$Cp_2M \rightarrow 2C_5H_5^{\cdot} + M \qquad (14)$$

is possible for vanadocene only at temperatures above 830 °C ($\Delta G < 0$). In a real experiment, the thermal decomposition of metlalocenes occurs at a lower temperature (350–450 °C) and not via pathway (14) alone.

The study of the kinetics of the thermal decomposition of metallocenes Cp_2M (M = V, Cr, or Mn) made it possible to establish the following catalytic series:

$$Cp_2V > Cp_2Cr > Cp_2Mn.$$

The thermal stability diminishes in parallel with the decrease in the $M\text{–}C_5H_5$ bond strength.[83]

The thermal stability of bis(cyclopentadienyl)metal dichlorides Cp_2MCl_2 (M = Ti, Zr, or Hf) also depends on the nature of the central atom and increases in the sequence

$$Cp_2TiCl_2 < Cp_2ZrCl_2 < Cp_2HfCl_2.$$

The thermal decomposition of vanadocene has been examined in greatest detail.[84] The pyrolysis of Cp_2V in a static system (450–510 °C) takes place mainly with evolution of hydrogen and cyclopentadiene. Apart from the products indicated, methane, benzene, and naphthalene are formed in the pyrolysis of vanadocene. The composition of the volatile products depends on temperature and the duration of heating. Thus at low temperatures and for short heating, the formation of an appreciable amount of cyclopentadiene is observed. With increase in temperature and heating time, the yield of C_5H_6 falls and the main volatile products of the total pyrolysis of vanadocene are hydrogen and methane. In the pyrolysis of Cp_2V in a flow system (800–900 °C), considerable amounts of acetylene and ethylene are formed in addition to the products indicated.

The data presented show that the dehydrogenation of the cyclopentadienyl and the dissociation of a C–C bond are observed in the decomposition of vanadocene together with the metal–cyclopentadienyl bond cleavage reaction. The latter can occur via radical or molecular pathways. The radical pathway is more probable when the pyrolysis is carried out at low pressures and in the bulk of the reactor. In this case, the homolysis of the bond leads to the formation of the cyclopentadienyl radical, which abstracts a hydrogen atom from the initial molecule with the consequent evolution of C_5H_6.

In the decomposition via the molecular pathway, cyclopentadiene is formed intra- or inter-molecularly with participation of the Cp ligand and the hydrogen atom which had been transferred to the metal from another Cp group beforehand:

$$Cp_2V \rightarrow Cp(C_5H_4)VH \rightarrow C_5H_6 + (C_5H_4)V.$$

The elimination of hydrogen takes place either by the direct dissociation of a ring C–H bond or via the splitting off of a hydride atom:

$$Cp_2V \rightarrow Cp(C_5H_4)VH \rightarrow H_2 + (C_5H_4)_2V.$$

The final products of such reactions are polymeric species containing the metal and the dehydrogenated rings.

Analogous reactions occur also in the decomposition of the dichlorides Cp_2MCl_2 (M = Ti, Zr, or Hf). As a result of the presence of a strong M–Cl bond in these compounds, the main reaction in the range 400–800 °C is the dehydrogenation of a cyclopentadienyl ring with evolution of hydrogen.[6,85]

It is notable that the higher rate of dehydrogenation and dissociation of the C–C ring bond compared with the rate of the reaction involving dissociation of the M–Cp bond virtually precludes the segregation of the pure metal under the conditions of the thermal decomposition of the compounds indicated. This is confirmed by thermochemical data. The calculated thermodynamic functions (ΔG, ΔH, ΔS) for the most probable reactions show that the reaction leading to the formation of a carbide is most probable for Cp_2MCl_2.[82,86] Indeed, the carbides of the corresponding metals are formed in the high-temperature (900 °C) decomposition of Cp_2MCl_2 (M = Ti or Zr) in a hydrogen atmosphere. Titanium carbides are also formed in the high temperature decomposition of the sandwich-covalent compounds Cp_2TiR_2 (R = CH_2 or C_6H_5).[85]

- - - o0o - - -

Analysis of the results of studies of the thermal and photochemical reactions of the sandwich-covlent derivatives of titanium and vanadium subgroup metals permitted the conclusion that the π-cyclopentadienyl ligands play an appreciable role in the splitting of the metal–carbon σ-bond. The processes occurring in the thermal and photochemical reactions can be regarded as model processes in the study of reduction or catalytic reactions with participation of these compounds.

During the preparation of the manuscript for the press, studies were published on the intermolecular activation of the C–H bonds of the substituents in the cyclopentadienyl rings in the thermolysis of the compounds $(C_5H_4R)_2Zr(C_6H_5)_2$ [R = $C(CH_3)_2C_6H_5$],[87] $(C_5H_3R_2)_2M(CH_3)_2$ (R = t-C_4H_9, M = Ti or Zr),[88] and $Cp^*_2Zr(C_6H_5)_2$.[89] It has been established that such activation of the C–H bonds of the alkyl groups of the Cp rings can occur as a result of low-temperature reactions of decamethylmetallocenes[90,91] and on dissociative ionisation of $(C_5H_4Alk)_2ZrCl_2$.[92]

Aza analogues of organic and inorganic oxygen compounds of selenium

N Ya Derkach (deceased), E S Levchenko
Institute of Organic Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. In this review information is presented on the methods of synthesis and physical and chemical properties of the aza analogues of selenoxides, selenones, derivatives of seleninic and selenous acids, and selenium dioxide—compounds which formally contain selenium–nitrogen double bonds.

The bibliography includes 56 references.

I. Introduction

For organic and organoelemental chemistry the last 20–30 years have been characterised by a rapid growth of studies into the chemistry of aza analogues of organic and inorganic oxygen compounds of elements in Groups V and VI of the Periodic Table, formed by the formal replacement of oxygen atoms in the E = O or $E(=O)_2$ group (E = P, As, Sb, Bi, S, Se, Te by an imino group (=NR). Compounds that contain E = NR, E(O) = NR, or $E(=NR)_2$ groups are of interest because they often have properties which are not typical of their oxygen analogues. Moreover, the variation in character of the radical on the imide nitrogen atom within each separate class of compounds leads not only to a wide structural diversity but also to a considerable variation in properties. Especially marked progress has been made in the chemistry of imido compounds of phosphorus and sulphur. At the present time there exist the extensive separate branches of organophosphorus and organosulphur chemistry, which have undoubtedly stimulated research into the chemistry of imido compounds of other elements, in particular, selenium.

The first examples of imido compounds of selenium—*N*-arylsulphonylselenimides—were obtained in 1962, but more intensive and systematic studies in this field were started in the 1970's.

Aza analogues of selenoxides, selenones, seleninic and selenous acid derivatives, and selenium dioxide are known at the present time. There is still no standard nomenclature for these classes of selenium compounds. In the present review we shall follow the nomenclature accepted for the analogous sulphur compounds which appear to us to correspond most closely to the IUPAC rules:

$R^1R^2Se = NR$—selenimides,
$R^1R^2Se(O) = NR$—selenoximides,
$R^1Se(=NR)Hal$—arene-*N*-R-imidoseleninyl halides,
$Hal_2Se = NR$—*N*-R-imidoselenous dihalides
N-R-imidoselenyl halides,
$RN = Se = NR^1$—selenium diimide derivatives,
RN = Se = O—selenylamines.

II. Selenimides

Among the aza analogues of selenoxides—*N*-R-selenimides—*N*-arylsulphonyl- and *N*-carbacyl-selenimides $R^1R^2Se = NR$ [R = SO_2R^3 (I), COR^3 (II)] are known at the present time. The methods of synthesis of *N*-R-selenimides and thier sulphur analogues, the corresponding *N*-R-sulphimides,[1] as a rule are similar, but there are also considerable differences between them.

A general and most simple method for the synthesis of *N*-arylsulphonylselenimides (I) is the oxidative imination of selenides with *N*-sodium-*N*-chloramides of arenesulphonic acids:[2–6]

$$R^1R^2Se + ArSO_2NNaCl \rightarrow R^1R^2Se{=}NSO_2Ar + NaCl, \quad (I)$$

R^1, R^2 = Alk, Ar, $ArCH_2$.

The reaction occurs in acetonitrile,[6] dimethylformamide,[3,5] a mixture of acetonitrile and methanol,[3] and methanol,[4] generally at 20 °C and using anhydrous arenesulphonic acid *N*-sodium-*N*-chloramides.

Selenimides (I) are also obtained by the successive treatment of selenides with t-butyl hypochlorite and *N*-sodium arenesulphonamides at –25 to –40 °C in acetonitrile or chloroform[7,8] or at 20 °C in carbon tetrachloride:[9]

$$R^1R^2Se \xrightarrow[2)\ ArSO_2NHNa]{1)\ t\text{-}BuOCl} (I) + NaCl + t\text{-}BuOH.$$

An analogous reaction is used to obtain *N*-R-sulphimides.[10] It has been proposed that a t-butoxychlorosulphurane is formed as an intermediate in this process. Treatment of diaryl or aryl alkyl selenides with t-butyl hypochlorite gives t-butoxychloroselenanes, which have been isolated and characterised:[9,11]

$$R^1R^2Se + t\text{-}BuOCl \underset{150°C}{\overset{20°C}{\rightleftarrows}} R^1R^2Se(OBu\text{-}t)Cl. \quad (III)$$

Compounds (III) are colourless crystalline products, soluble in organic solvents (benzene, chloroform, methylene chloride, 1,2-dichloroethane), and on heating to 130–140 °C in a vacuum they sublime but at atmospheric pressure at 150 °C decompose to the initial selenides and t-butyl hypochlorite. The Se–Cl bond in compounds (III) is covalent; their specific electrical conductivity in dichloroethane is virtually the same as the electrical conductivity of the solvent.[9] Compound (III), $R^1 = R^2$ = Ph, is hardly hydrolysed at all after the prolonged action of water at 20 °C, but on boiling for 2–3 h it decomposes to form a mixture of diphenyl selenoxide and

diphenylselenium dichloride (the latter is formed by the reaction of diphenyl selenoxide and hydrogen chloride):

$$Ph_2Se(OBu\text{-}t)Cl \xrightarrow[-t\text{-}BuOH]{H_2O} [Ph_2SeO + HCl] \rightarrow$$
$$\rightarrow {}^1/_2\, Ph_2SeCl_2 + {}^1/_2\, Ph_2SeO + {}^1/_2\, H_2O.$$

If hydrogen chloride is removed from the reaction mixture (by prolonged standing in a vacuum desiccator above caustic potash), only diphenyl selenoxide is obtained.[9]

Compound (III), $R^1 = R^2 = Ph$, is also formed by reaction of diphenylselenium dichloride with t-butyl hypochlorite, but this reaction is reversible and is displaced towards formation of the selenane only by removal of chlorine from the reaction mixture:[9]

$$Ph_2SeCl_2 + t\text{-}BuOCl \underset{0^\circ C}{\overset{60^\circ C}{\rightleftharpoons}} (III) + Cl_2.$$

Alkoxychloroselenanes (III) are also formed by the reaction of R^1R^2-selenium dichlorides with alkoxides in a molar ratio of 1 : 1.[12] When compounds (III) are treated with the sodium derivative of benzenesulphonamide or benzamide, the corresponding *N*-R-selenimides (I) and (II) are obtained:[9]

$$(III) + RNHNa \xrightarrow{20\ ^\circ C,\ CCl_4} \underset{(I),\ (II)}{Ph_2Se = NR} + t\text{-}BuOH,$$
$$R = PhSO_2\ (I),\ PhC(O)\ (II).$$

However, in order to prepare compounds (I) or (II) it is not necessary to isolate compounds (III) since the reaction can be carried out in one stage as shown below.

The following relatively simple and general method for the synthesis of *N*-R-selenimides (I) and (II) is the reaction of selenoxides with sulphonamides and carboxamides:[5,7,13–15]

$$R^1R^2SeO + RNH_2 \rightarrow \underset{(I),\ (II)}{R^1R^2Se{=}NR} + H_2O.$$

The reaction conditions are dependent on the nature of the amides and the substituents on the selenium atom. Dibenzyl selenoxide and methyl aryl selenoxides react with arenesulphonamides and trifluoroacetamide in chloroform, acetonitrile, or benzene on heating[5,7,13,15] or even at 20 °C when water is removed.[7,14] Acetamide or chloroacetamide do not react under these conditions. When diphenyl selenoxide is refluxed with *p*-nitrobenzamide, the corresponding *N*-*p*-nitrobenzoylselenimide is formed in low yield.[13] The reaction of diaryl selenoxide with benzamide or trichloroacetamide was carried out in the presence of acetic anhydride.[15]

When diphenyl selenoxide is heated with aromatic amines in the presence of dehydrating media, and also when diphenylselenium dichloride is reacted with aromatic amines in the presence of triethylamine, diphenyl selenide and the corresponding azobenzenes are formed.[16]

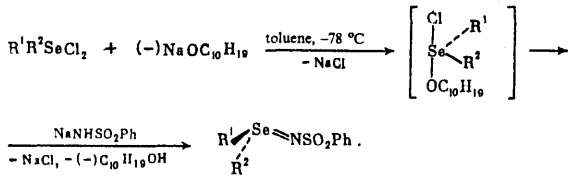
N-Arylsulphonylselenimides (I) are readily obtained by the reaction of diaryl selenoxides with bis(arylsulphonyl)diimides of sulphur or selenium[17] and also with aldimines:[18]

$$Ar_2SeO \xrightarrow[-Ar^2CHO]{\overset{(ArSO_2N{=})_2E,\ (E=S,\ Se)}{-EO_2}\quad \overset{}{Ar^1SO_2N{=}CHAr^2}} Ar_2Se{=}NSO_2Ar.$$

Arene-*N*-arylsulphonylimidoseleninyl chlorides react with styrene to form *Se*-aryl-*Se*-styryl-*N*-arylsulphonylselenimides:[19]

$$ArSe(=NSO_2Ar^1)Cl + CH_2{=}CHPh \rightarrow Ar(PhCH{=}CH)Se(=NSO_2Ar^1).$$

Se-Methyl-*Se*-aryl-*N*-phenylsulphonylselenimides are obtained by reaction of methylarylselenium dichloride with *Te*,*Te*-diaryl-*N*-phenylsulphonyltellurimides:[20]

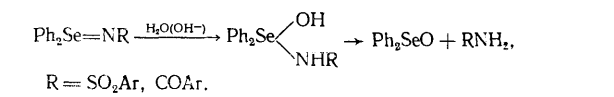


$$Ar_2Te{=}NSO_2Ph + CH_3(Ar^1)SeCl_2 \xrightarrow{benzene}$$
$$\rightarrow CH_3(Ar^1)Se{=}NSO_2Ph + Ar_2TeCl_2.$$

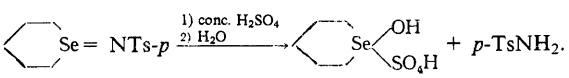
Selenimides (I) and (II) are relatively stable, colourless crystalline compounds. According to the data of X-ray diffraction analysis of compounds $PH_2Se = NSO_2Ph$[21] and $Ph_2Se = NSO_2C_6H_4CH_3$-*p*,[22] the length of the selenium–nitrogen bond (1.82 and 1.787 Å) is greater than the calculated length of a selenium–nitrogen double bond (1.628 Å) and also a single selenium–nitrogen with a high degree of double bond character, for example, in $Ph_3P = NSeCl_3$ (1.680 Å) and $(Ph_3P = N)_2SeCl_2$ (1.725 Å[22]), whereas the sulphur (VI)–nitrogen bond (1.60 Å[21] and 1.598 Å[22]) is shorter than a single bond (1.69 Å[22]).

From the results of X-ray diffraction analysis and the IR spectra of compounds (I) and (II) (using ^{15}N isotope exchange) the following bands were attributed to ν(Se = N): 550–590 cm^{-1},[5] 572 cm^{-1},[22] 675 cm^{-1};[23] and for ν(S(VI)–N): 930–950 cm^{-1},[5,22,23] [in two studies[14,24] ν(Se = N) in compounds (I) was assigned to the regions at 890 cm^{-1} [14] and 930–950 cm^{-1},[24] while ν(S(VI–N) was assigned to 672–677 cm^{-1}.[24] The results of these studies provide the basis for the proposal that the loss of double bond character of the Se = N bond and the considerable double bond characer of S(VI)–N in compounds (I) are due to the high contribution of resonance structures with a positive charge on the selenium atom:[5,21–24]

$$Ph_2Se{=}NSO_2Ar \longleftrightarrow Ph_2\overset{+}{S}e{-}\overline{N}SO_2Ar \longleftrightarrow Ph_2\overset{+}{S}e{-}N{=}S\begin{matrix}O^-\\ \\ O\end{matrix}$$
$$\qquad\qquad\qquad

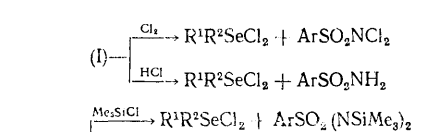


enrichment of one of the stereoisomers occurs at the stage where a compound of tetracoordinate selenium is formed:[12]

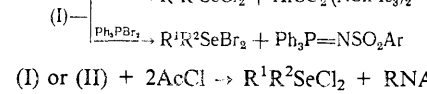


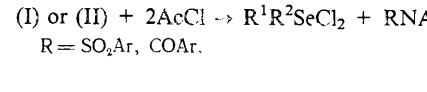
Asymmetric induction also occurs on reaction of asymmetric selenoxides with (+)- or (−)-10-camphorsulphonamides[14,18] and also with (+)- or (−)-camphorsulphonylbenzaldimine.[18]

The covalent radius of selenium (1.16 Å) is higher than the covalent radius of sulphur (1.02 Å), and the length of the Se = N bond (1.787–1.82 Å)[21,22] is greater than the length of the S = N bond (1.628–1.638 Å),[1] which is due to the greater degree of polarisation of the selenium-nitrogen bond. This is also confirmed by comparing the PMR spectra of selenimides and sulphimides with coresponding structures. The signal from the α-protons in the PMR spectra of selenimides occurs at higher field than in the corresponding sulphimides.[5]

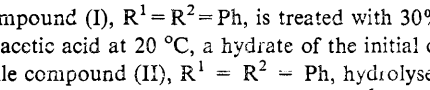


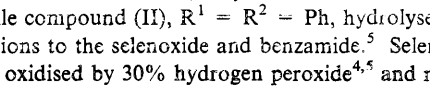
The difference in the length of E = N bonds (E = S, Se) and their degree of polarity also affect the relative reactivity of selenimides and sulphimides. In contrast to *N*-arylsulphonylsulphimides,[1] selenimides (I) are much less stable towards hydrolysis. Compounds (I) and (II) are unchanged on treatment with dilute acids and bases at 20 °C, but on heating or on treatment with concentrated alkali in alcohol they are rapidly hydrolysed to the corresponding selenoxide and arenesulphonamide.[3,4] The formation of an intermediate hydrated structure has been proposed when hydrolysis occurs or in the preparation of selenimides from selenoxides and amides.[5,6]



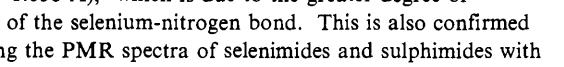


A compound with a selenurane structure was obtained by reaction of *N*-tosyl-*Se*,*Se*-pentamethyleneselenimide with sulphuric acid (−50 °C) followed by hydrolysis:[5]





The Se = N bond in selenimides is very readily cleaved on treatment with chlorine, hydrogen chloride,[4] acetyl chloride, trimethylchlorosilane, or triphenylphosphine dibromide:[25]

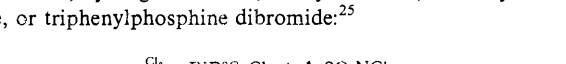


When compound (I), $R^1 = R^2 = Ph$, is treated with 30% hydrogen peroxide in acetic acid at 20 °C, a hydrate of the initial compound is formed, while compound (II), $R^1 = R^2 = Ph$, hydrolyses under these conditions to the selenoxide and benzamide.[5] Selenimides (I) and (II) are oxidised by 30% hydrogen peroxide[4,5] and nitrogen dioxide[4] at 20 °C or with an aqueous solution of potassium permanganate on boiling[5] to the corresponding selenones and amides:

When selenimides (I) are reacted with triphenylphosphine, the corresponding selenide and triphenylphosphine imide are formed in quantitative yield:[5]

Selenimides (II) decompose on heating to selenides and isocyanates[5]

In a study of the kinetics of thermolysis of selenimides and sulphimides $Ph_2Se=NCOPh$ and $Ph_2S = NCOPh$ it was established that the former decomposes 300 times faster than the latter, with the entropies of activation for these reactions being similar. This is undoubtedly due to the weaker selenium–nitrogen bond.[5]



III. Selenoximides

At the present time only *Se*,*Se*-diaryl-*N*-arylsulphonylselenoximides (IV) are known among amido derivaties of hexavalent selenium. Compounds (IV) are obtained by the reaction of diaryl selenones with *N*-sulphonylarenesulphonamides,[4,26] and also with *N*,*N*′-diarylsulphonyldiimides of selenium or sulphur:[17]

It should be noted that sulphones do not react with *N*-sulphonylarenesulphonamides.

In the IR spectra of compounds (IV), ν(Se = N) occurs in the region 930–910 cm^{-1}. It was concluded from the fine structure of the UV spectra that the fragment >Se(O)(=NSO_2−) has a rigid structure which interacts weakly with the π-system of the aromatic rings.[27]

Compounds (IV) remain unchanged on prolonged standing in air, they are stable to water at 100 °C, and are not affected by acids and bases at 20 °C. However, on prolonged heating with a 2 N solution of caustic soda they are hydrolysed to diaryl selenones and arenesulphonamides.

When treated with dry hydrogen chloride compounds (IV) decompose to form diarylselenium dichlorides, arenesulphonamides, chlorine, and water.

In contrast to selenimides (I), selenoximides (IV) do not react with elemental chlorine.[26]

IV. Arene-*N*-R-imidoseleninyl chlorides

The main method for the synthesis of arene-*N*-R-imidoseleninyl chlorides (V) is the oxidative imination of areneselenenyl chlorides or selenol derivatives with *N*-halo compounds. Compounds (V) are very readily formed by reaction of *Se*-trimethylsilyl- or *Se*-benzoylselenols with *N,N*-dichloramides of arenesulphonic acids, carboxylic, carbon, or phosphoric acids.[19,28-30] The reactions occur very readily, and trimethylchlorosilane or benzoyl chloride are easily extracted from the reaction mixture:

$$ArSeSiMe_3 + RNCl_2 \xrightarrow[-15\text{ to }5\ ^\circ C]{CCl_4} \underset{(V)}{ArSe(=NR)Cl} + Me_3SiCl,$$

$$R = SO_2Ar,\ COAr\ \ COOC_2H_5,\ (AlkO)_2P(O).$$

$$p\text{-}BrC_6H_4SeCOPh + PhSO_2NCl_2 \rightarrow p\text{-}BrC_6H_4Se(=NSO_2Ph)Cl + PhCOCl.$$

Arene-*N*-arylsulphonylimidoseleninyl chlorides are also formed by reaction of areneselenenyl chlorides with *N*-sodium-*N*-chloramides of arenesulphonic acids:[19]

$$ArSeCl + PhSO_2NNaCl \xrightarrow[10-20^\circ C]{CCl_4} (V) + NaCl.$$

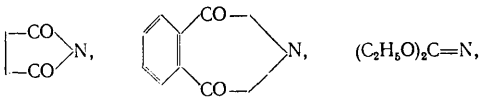
When areneselenenyl chlorides are reacted with *N,N*-dichloramides of sulphonic and carboxylic acids, arylselenium trichlorides are formed together with chlorides (V):[19,29]

$$2ArSeCl + RNCl_2 \rightarrow (V) + ArSeCl_3,$$
$$R = SO_2Ar^1,\ COAr^1.$$

Diselenides also readily react with *N,N*-dichloramides to form chlorides (V) and areneselenenyl chlorides:[19,29]

$$ArSeSeAr + RNCl_2 \rightarrow (V) + ArSeCl.$$

Most likely when ArSeX reacts with *N,N*-dichloramides compounds of tetracoordinate selenium are first formed, undergoing subsequent conversion to form chlorides (V):



$$ArSeX + RNClZ \longrightarrow \left[\begin{array}{c} Cl \\ | \\ ArSe-X \\ | \\ R-N-Z \end{array}\right] \longrightarrow (V) + XZ,$$

$X = SiMe_3$, COR, SeR, Cl; $Z = Cl$, Na.

This is confirmed by studying the reactions of areneselenenyl chlorides with *N*-chlorimides and *N*-monochloramides of carboxylic acids, and with t-butyl hypochlorite, etc.

When areneselenenyl chlorides are reacted with *N*-chlorimides, fairly stable compounds of tetracoordinate selenium (VI) are obtained:[31]

$$ArSeCl + R_2NCl \rightarrow Ar(R_2N)SeCl_2,$$

$R_2N =$  , $(C_2H_5O)_2C{=}N$,

$PhC(OAlk){=}N$, $Ph_2C{=}N$ etc.

Compounds of tetracoordinate selenium (VII) and (VIII) are formed by reaction of areneselenenyl chlorides with carboxylic acid *N*-monochloramides[32,33] or with 6-butyl hypochlorite:[11,34]

$$ArSeCl + RCONHCl \rightarrow \underset{(VII)}{Ar(RCONH)SeCl_2},$$

$$ArSeCl + t\text{-}BuOCl \rightarrow \underset{(VIII)}{Ar(t\text{-}BuO)SeCl_2}.$$

Arene-*N*-R-imidoseleninyl chlorides (V) are very readily obtained when arylselenium trichlorides are treated with bis(trimethylsilyl)-amides of sulphonic or carboxylic acids[29] or by heating arylselenenium trichlorides with *N,N*-dichloramides.[29] However, the latter reaction is reversible and chlorides (V) are only obtained when chlorine is removed from the reaction mixture.

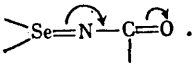
$$ArSeCl_3 \begin{cases} \xrightarrow{RN(SiMe_3)_2} (V) + 2Me_3SiCl \\ \xrightarrow{RNCl_2,\ \Delta} (V) + Cl_2 \end{cases}$$

$R = SO_2Ph$, COPh.

When *N*-chlorohexamethyldisilazane is reacted with areneselenenyl chloride and arylselenium trichloride in the ratio 1 : 1 : 1, compounds which apparently have the structure of arene-*N*-[aryl(dichloro)-seleno]imidoseleninyl chlorides (IX) are formed.[35] The above-mentioned reactions of areneseleninyl chlorides with *N*-chlorimides and areneselenium trichlorides with bis(trimethylsilyl)amides provided the basis for the following proposed reaction scheme:

$$ArSeCl + ClN(SiMe_3)_2 \rightarrow [Ar(Cl_2)SeN(SiMe_3)_2] \rightarrow$$
$$\xrightarrow[-2Me_3SiCl]{ArSeCl_3} \underset{(IX)}{ArSe(Cl_2)N{=}Se(Cl)Ar}.$$

The formation of isomeric chlorides (IX) as a result of the following reaction acts as confirmation of this scheme and the structure of the compounds formed.



$$p\text{-}ClC_6H_4SeCl + ClN(SiMe_3)_2 \rightarrow [p\text{-}ClC_6H_4Se(Cl_2)N(SiMe_3)_2] \rightarrow$$
$$\xrightarrow{+PhSeCl_3} \underset{(IXa)}{p\text{-}ClC_6H_4Se(Cl_2)N{=}Se(Cl)Ph};$$

$$PhSeCl + ClN(SiMe_3)_2 \rightarrow [PhSe(Cl_2)N(SiMe_3)_2] \rightarrow$$
$$\xrightarrow{p\text{-}ClC_6H_4SeCl_3} \underset{(IXb)}{PhSe(Cl_2)N{=}Se(Cl)C_6H_4Cl\text{-}p}.$$

Compounds (IX) are also obtained by reaction of *N*-chlorohexamethyldisiliazane with benzeneselenenyl chloride or phenylselenium trichloride but in lower yield. The reactions are evidently more complex in these cases.[35]

N-R-Imidoseleninyl chlorides (V) and (IX) are colourless or pale yellow crystalline compounds, readily soluble in chloroform, dichloroethane, and acetonitrile; on standing in the absence of moisture they decompose after 3–5 days.[19,28,29,35]

In the IR spectra of *N*-arylsulphonylimidoseleninyl chlorides (V), $R = SO_2Ar$, $\nu(Se{=}N)$ apparently occurs in the region 910–950 cm^{-1},[24,27] while for *N*-aroylimidoseleninyl chlorides (V), R = COAr, it is in the region 845–870 cm^{-1}.[29] The shift to longer wavelength is evidently due to delocalisation of the π-electrons in the system

Chlorides (V) and (IX) are readily hydrolysed to seleninic acids and amides:[19,28,29,35]

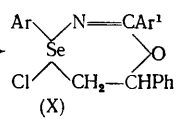
$$(V) + 2H_2O \rightarrow ArSeOOH + RNH_2 + HCl,$$
$$(IX) + 4H_2O \rightarrow 2ArSeOOH + NH_4Cl + 2HCl.$$

When treated with dry hydrogen chloride or chlorine, compounds (V) and (IX) undergo cleavage of the Se = N bond to form arylselenium trichlorides and amides or *N,N*-dichloramides:[19,29,35]

$$(V) \begin{cases} \xrightarrow{2HCl} ArSeCl_3 + RNH_2 \\ \xrightarrow{2Cl_2} ArSeCl_3 + RNCl_2, \end{cases}$$

$$(IX)\begin{cases}\xrightarrow{4HCl} 2ArSeCl_3 + NH_4Cl\\ \xrightarrow{3Cl_2} 2ArSeCl_3 + [NCl_3]\end{cases}.$$

Chlorides (V) react with secondary amines to form the corresponding *N*-R-imidoseleninic acid amides, which are colourless crystalline or liquid, compounds that are very readily hydrolysed by atmospheric moisture and slowly decompose on standing when moisture is excluded:[19,29]



$$(V)\xrightarrow[-R_2NH.HCl\ \text{or}\ R_2NSiMe_3\ -Me_3SiCl]{2R_2NH} ArSe(=NR^1)NR_2$$

$R^1 = SO_2Ar,\ COAr;\ R_2N = (C_2H_5)_2N,$  .

Arene-*N*-arylsulphonylimidoseleninyl chlorides react with styrene to form a mixture of compounds from which *Se*-aryl-*Se*-styryl-*N*-arylsulphonylselenimides are isolated in about 50% yield:[19]

$$ArSe(=NSO_2Ar^1)Cl + PhCH{=}CH_2 \xrightarrow[-HCl]{20^\circ C} ArSe(=NSO_2Ar^1)CH{=}CHPh.$$

Arene-*N*-aroylimidoseleninyl chlorides react with styrene by a [2 + 4]-cycloaddition to form 1 : 1 adducts, which apparently have the structure of 5,6-dihydro-4-selena-1,3-oxazines (X):[29]

$$ArSe(=NCOAr^1)Cl + PhCH{=}CH_2 \rightarrow$$ 
(X)

Compounds (X) are colourless crystalline compounds, difficultly soluble in most organic solvents. In their IR spectra $\nu(C = N)$ is present at 1580 cm^{-1} and $\nu(Se-N)$ at 589 cm^{-1}, and there is no absorption in the region 840–870 cm^{-1} that is characteristic of the Se = N bond in the initial chlorides. The electrical conductivity of saturated solutions of compounds (X) in dichloroethane or methanol is higher than the electrical conductivity of the solvent by a factor of 10 or 100 respectively, which is an indication of the contribution from an ionic structure.[29]

V. *N*-R-imidoselenous dihalides

The first examples of this class of compounds—*N*-arylsulphonylimidoselenyl chlorides—were obtained in 1967 by reaction of selenium with arenesulphonic acid *N*,*N*-dichloramides.[36] It was subsequently established that oxidative imination of selenium has a wide range of application. Selenium reacts in a similar manner with the *N*,*N*-dichloramides of sulphonic and benzoic acids, and with dialkyl *N*,*N*-dichlorophosphoramidate, *N*,*N*-dichlorourethane, *N*,*N*-dichloroalkylamines, and *N*,*N*-dichloroaminopentafluorosulphur to form the corresponding *N*-R-imidoselenyl chlorides (XI):[37–41]

$$Se + RNCl_2 \xrightarrow[20^\circ C]{CH_2Cl_2\ \text{or}\ CCl_4} RN{=}SeCl_2, \quad (XI)$$

$R = SO_2Ar,\ COAr,\ C_2H_5OCO,\ (AlkO)_2PO,\ Me_2C(CN),$
$(CH_2)_5(CN),\ R_F,\ F_5S.$

In inert solvents (methylene dichloride, carbon tetrachloride, dichloroethane, etc.) the reactions generally take place at 20 °C or with slight evolution of heat.

Sulphur, as a rule, reacts with *N*,*N*-dichloramides and *N*,*N*-dichloramines in a similar manner.[42] However, it should be noted that there are some differences between the oxidative imination of sulphur and selenium. Imination of sulphur is assisted when catalysts are present (iodine, tetraalkylammonium salts, etc.).[42] In most cases selenium reacts with *N*,*N*-dichloro compounds more readily than sulphur and the reaction is unaffected by catalysts. When sulphur is reacted with sulphinic acid *N*,*N*-dichloramides, the corresponding *N*-R-imidothionyl chlorides or sulphur diimide derivatives are formed depending on the ratio of reactants and the reaction conditions.[42] When selenium reacts with these reagents only *N*-R-imidoselenyl chlorides are obtained regardless of the ratio.[37]

It was established that *N*-perfluoroalkylimidoselenyl chlorides are also formed by reaction of *N*,*N*-dichloroperfluoroalkylamines with selenium monochloride:[39,40]

$$RNCl_2 + Se_2Cl_2 \xrightarrow[-50^\circ C]{CCl_3F} (XI) + SeCl_4,$$
$$R = CF_3,\ C_2F_5.$$

It has been reported that *N*-R-imidothionyl chlorides $Cl_2 = SNCOR$, R = Ar, Alk, are obtained by reaction of sulphur with carboxylic acid *N*-monochloramides.[42] Selenium also very readily reacts with carboxylic acid *N*-monochloramides, but in this case derivatives of orthoselenous acid—bis(R-carbacylamido)selenium dichlorides (XII)—are formed:[31–33]

$$2RCONHCl + Se \rightarrow (RCONH)_2SeCl_2, \quad (XII)$$
$$R = Ar,\ Alk.$$

When selenium is reacted with *N*,*N*-dichloroperfluoroaryl- or *N*,*N*-dichlorotetrafluoropyridyl-4-amines, the corresponding azo compounds and selenium tetrachloride are formed:[39]

$$Se + 2RNCl_2 \rightarrow RN{=}NR + SeCl_4,$$
$$R = C_6F_5,\ p\text{-}CF_3C_6F_4,\ 4\text{-}C_5F_4N.$$

The reaction schemes for the oxidative imination of both selenium and sulphur have not yet been established. It has been proposed that sulphur or selenium on reacting with *N*,*N*-dichloro compounds by a radical or ionic mechanism form the intermediates RN(Cl)ECl, which, depending on the nature of R (the state of the E–Cl bond), undergo conversions by three different routes—to form *N*-R-imidothionyl chlorides (*N*-R-imidoselenyl chlorides), azo compounds, or derivatives of sulphur diimides (the latter conversion is not typical for selenium):[39]

$$RNCl_2 + E \rightarrow [RN(Cl)ECl]\begin{cases}\xrightarrow{E=S,\ Se} RN{=}ECl_2\\ \xrightarrow{-ECl_2} [RN{:}] \rightarrow {}^1/_2RN{=}NR\\ \xrightarrow{E=S,\ -Cl_2} [RN{=}S] \rightarrow {}^1/_2RN{=}S{=}NR + {}^1/_2S_8\end{cases}$$

N-R-Imidoselenyl chlorides and fluorides are very readily formed by the reaction of selenium tetrachloride or tetrafluoride with *N*,*N*-bis-(trimethylsilyl)amides:[43,44]

$$RN(SiMe_3)_2 + SeHal_4 \rightarrow RN{=}SeHal_2 + 2Me_3SiHal,$$
$$R = MeSO_2,\ PhSO_2,\ PhCO;\quad Hal = Cl,\ F.$$

N-Pentafluorotelluroimidoselenyl fluoride is obtained by reaction of selenium tetrafluoride with *N*-trimethylsilylpentafluorotellur-amine:[44]

$$F_5TeNHSiMe_3 + SeF_4 \rightarrow F_5TeN{=}SeF_2 + Me_3SiF + HF.$$

On heating pentafluorotelluramine with selenium tetrachloride, *N*-pentafluorotelluroimidoselenyl chloride is formed:[44]

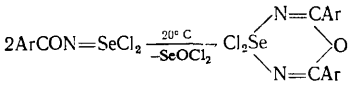
$$F_5TeNH_2 + SeCl_4 \xrightarrow{CH_2Cl_2,\ \Delta} F_5TeN{=}SeCl_2 + 2HCl.$$

Selenium tetrachloride reacts on heating with *N,N*-dichlorobenzenesulphonamide to form *N*-phenylsulphonylimidoselenyl chloride:

$$PhSO_2NCl_2 + SeCl_4 \rightarrow PhSO_2N{=}SeCl_2 + 2Cl_2.$$
(XI)

However, this reaction is reversible and goes to the right only when chlorine is removed from the reaction mixture.[37]

N-R-Imidoselenyl chlorides and fluorides are colourless or pale yellow crystalline compounds with low stability. Their stability improves when the electronegativity of the radical R is increased. Out of the compounds of this class that are known at the present time the most stable are *N*-pentafluorotelluroimidoselenyl chlorides[44] and *N*-arylsulphonylimidoselenyl chlorides.[36,37] *N*-Perfluoroalkylimidoselenyl chlorides start to decompose immediately after preparation or distillation according to the scheme:[41]



$$6R_FN{=}SeCl_2 \rightarrow 3R_FN{=}NR_F + 2SeCl_4 + 2Se_2Cl_2.$$

It is very likely that *N*-perfluoroarylimidoselenyl chlorides cannot be obtained because of their extremely low stability and not because there is a different pathway for the reaction between selenium and *N,N*-dichloroperfluoroarylamines.[39]

N-Pentafluorothioimidoselenyl chloride undergoes the following conversions even at room temperature:[40,41]

$$2F_5SN{=}SeCl_2 \xrightarrow{20^\circ C} 2F_3S{\equiv}N + SeCl_4 + SeF_4.$$

N-Aroylimidoselenyl chlorides slowly decompose at 20 °C with the elimination of selenyl chloride and giving compounds which apparently have the structure of 4-dichloro-4,1,3,5-selenaoxadiazines:

In the IR spectra of imidoselenyl chlorides (XI) the absorption due to ν(Se = N) varies over a quite broad region (Table 1). The lowest value of ν(Se = N) is that in *N*-aroylimidoselenyl chlorides; ν(C = O) (1600 cm^{-1}) is also decreased in these compounds at the same time, which is probably due to delocalisation of electron density in the group[38]

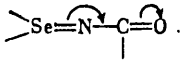


Table 1. Frequencies of the stretching vibrations of the Se = N bond in the IR spectra of *N*-R-imidoselenyl chlorides.

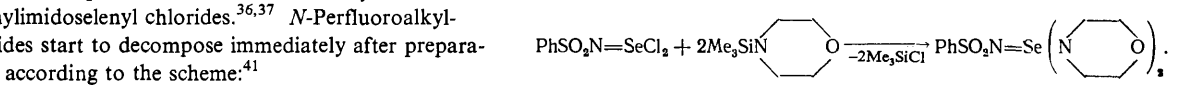
R	ν (Se=N)·см⁻¹	Refs.	R	ν (Se=N), см⁻¹	Refs.
F_5S	1045	[40]	C_2F_5	933	[41]
F_5Te	965	[44]	$(CH_3)_3C$	960	[37]
$ArSO_2$	980—975	[24, 37]	$(CH_2)_4C(CN)$	950	[37]
CF_3	962	[41]	ArCO	765—750	[38]



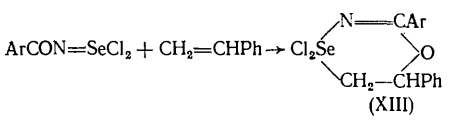
Compounds (XI) are very reactive. They are hydrolysed even by moist air to form amides and amines, selenous acid, and hydrogen chloride.[37] Acidolysis of *N*-phenylsulphonylimidoselenyl chlorides with formic acid results in the formation of benzenesulphonamide and selenyl chloride:[37]

$$PhSO_2N{=}SeCl_2 + 2HCOOH \rightarrow PhSO_2NH_2 + SeOCl_2 + 2CO.$$

Compounds (XI) very readily undergo cleavage of the Se = N bond when treated with hydrogen chloride or chlorine:[37,38]

$$(XI) \begin{cases} \xrightarrow{2HCl} RNH_2 + SeCl_4 \\ \xrightarrow{2Cl_2} RNCl_2 + SeCl_4 \end{cases}$$
R = $ArSO_2$, ArCO, Alk.

When *N*-phenylsulphonylimidoselenyl chloride is reacted with *N*-trimethylsilylmorpholine, the dimorpholide of *N*-phenylsulphonylimidoselenous acid is obtained:[37]



When compounds (XI) are reacted with *N,N*-bis(trimethylsilyl)-amides, selenium diimide derivatives are formed,[38,45] (see below).

N-R-Imidoselenyl chlorides react very readily with unsaturated compounds. The course of the reaction depends on the nature of the acyl residue. For example, *N*-phenylsulphonylimidoselenyl chloride reacts with styrene in the ratio 1 : 2 to form *Se,Se*-[bis(2-chloro-2-phenylethyl)]-*N*-phenylsulphonylselenimide:[37]

$$PhSO_2N{=}SeCl_2 + 2PhCH{=}CH_2 \rightarrow PhSO_2N{=}Se(CH_2CHClPh)_2.$$

N-Aroylimidoselenyl chlorides react with ethylenic hydrocarbons in the ratio 1 : 1 by a [4 + 2]-cycloaddition mechanism to form 4,4-dichloro-5,6-dihydro-4,1,3-selenaoxazines (XIII):[38,46]

(XIII)

Compounds (XIII) are colourless crystalline compounds which are difficultly soluble in most organic solvents. When compound (XIII), Ar = COPh, is treated with methanol, (2-phenyl-2-benzoyloxyethyl)-(methoxyl)selenium dichloride is obtained:[38]

$$(XIII) + MeOH \rightarrow PhC(O)OCH(Ph)CH_2Se(OMe)Cl_2.$$

For other properties of compounds (XIII), see below.

VI. Aza analogues of selenium dioxide

Out of the aza analogues of oxygen compounds of sulphur, the nitrogen analogues of sulphur dioxide—thionylamines and thionylamides RN = S = O and sulphur diimide derivatives RN = S = NR—have attracted particular attention. The high reactivity and preparative availability of these classes of compounds have offered considerable potential for their use in organic synthesis, which is suggested by the large number of publications, review articles, and monographs (see bibliograph of Bussas et al.[47]). This has undoubtedly stimulated interest in the aza analogues of selenium dioxide—derivatives of selenium diimide and selenylamines or selenylamides.

1. Selenium diimide deriatives

One of the main methods of synthesising symmetrical deriatives of selenium diimide (XIV) is the reaction of selenium tetrafluoride or tetrachloride with bis(trimethylsilyl)amides of sulphonic or carboxylic acids:[43,45,48–50]

$$SeHal_4 + 2RN(SiMe_3)_2 \xrightarrow[-4Me_3SiHal]{15-20^\circ C} RN{=}Se{=}NR, \quad (XIV)$$
$$R = ArSO_2,\ ArCO,\ AlkCO;\quad Hal = Cl,\ F.$$

Symmetric and asymmetric derivatives of selenium diimide are obtained by the reaction of hexamethyldisilylamides with *N*-acylimidoselenyl chlorides or fluorides[43,45,49]

$$RN{=}SeHal_2 + R^1N(SiMe_3)_2 \xrightarrow[-2Me_3SiHal]{\text{ether, } 0-20\ ^\circ C} RN{=}Se{=}NR^1,$$
$$R = ArSO_2,\ PhCO,\quad R^1 = ArSO_2,\ ArCO,\ AlkCO;$$
$$Hal = Cl,\ F.$$

Selenium bis(sulphonyl)diimides are unexpectedly obtained by reaction of *N*,*N*-bis(trimethylsilyl)amides with selenyl fluoride or chloride.[43,51] By analogy with the reaction of thionyl chloride[47] formation of the corresponding *N*-R-selenylamides RN = Se = O would be expected.[47] However, only selenium diimide derivatives are formed as a result of this reaction, whatever the ratio of reactants:

$$SeOHal_2 + RN(SiMe_3)_2 \xrightarrow{-Me_3SiHal} [RN{=}Se{=}O] \xrightarrow[-(Me_3Si)_2O]{RN(SiMe_3)_2} (XIV),$$
$$R = PhSO_2,\ MeSO_2,\ CF_3CO,\ CF_3SO_2;\quad Hal = Cl,\ F.$$

When *N*-phenylsulphonylimidoselenyl fluoride is reacted with hexamethyldisiloxane, selenium bis(phenylsulphonyl)diimide is obtained in place of the expected *N*-selenylbenzenesulphonamide. It has been proposed that in this reaction, as in the previous one, *N*-selenylamides are formed as intermediates:[43]

$$PhSO_2N{=}SeF_2 + (Me_3Si)_2O \xrightarrow{-2Me_3SiF} [PhSO_2N{=}Se{=}O] \xrightarrow[-SeOF_2]{PhSO_2N{=}SeF_2} (PhSO_2N{=})_2Se.$$

Selenium *N*,*N*-bis(trimethylsilyl)diimide is obtained by reaction of Li hexamethyldisilazane with selenyl chloride:[51]

$$2(Me_3Si)_2NLi + SeOCl_2 \rightarrow (Me_3SiN{=})_2Se + Me_3SiCl + LiCl.$$

Reaction of selenium tetrachloride with t-butylamine gives selenium bis(t-butyl)diimide:[52,53]

$$SeCl_4 + 6\ t\text{-}BuNH_2 \xrightarrow[-4\ t\text{-}BuNH_2HCl]{\text{ether, } 25\ ^\circ C} (t\text{-}BuN{=})_2Se.$$

Selenium diimide derivatives (XIX) are light yellow crystalline compounds that are fairly readily soluble in methylene dichloride and dichloroethane. They have low thermal stability—at 20 °C they can be kept for 2–3 days in the absence of moisture while on heating they rapidly decompose.[18,43,45,48–52] Selenium bis(t-butyl)diimide is a liquid which decomposes at room temperature to form *N*,*N*′-di(t-butyl)-2,4,5-triselena-1,3-diazolidine, which a yellow crystalline product:[52]

$$3(t\text{-}BuN{=})_2Se \xrightarrow[-(t\text{-}BuN{=})_2]{} \begin{array}{c} Se \\ /\ \backslash \\ t\text{-}Bu-N \quad N-Bu\text{-}t. \\ |\quad\ | \\ Se-Se \end{array}$$

Selenium bis(trifluoromethylseleno)diimide is stable only up to 80 °C. Above that temperature the compound decomposes:[51]

$$(F_3CSeN{=})_2Se \rightarrow CF_3SeSeCF_3 + Se + N_2.$$

Selenium bis(trimethylsilyl)diimide decomposes even at −48 °C. The structure of this compound has been demonstrated from its chemical reactions.[51]

In the IR spectra of selenium diimide derivatives, the intense absorption bands in the region 1000–900 cm^{-1} are due to the Se=N bond frequencies.[45,49] In the IR spectrum of selenium bis(t-butyl)-diimide two absorption bands at 998 cm^{-1} (*as*) and 650 cm^{-1} (*s*) have been attributed to stretching vibrations of the Se = N bond.[52] In the PMR spectrum of this compound (in $CDCl_3$ in the presence of shift reagents) at −30 °C there are two signals (δ 1.38 and 1.40) which coalesce at 5 °C. On the basis of this it was proposed that at low temperature selenium bis(t-butyl)diimide has a (*Z*/*E*)-configuration:[52]

$$\begin{array}{c} Bu\text{-}t \\ / \\ N{=}Se{=}N \\ | \\ t\text{-}Bu \end{array} .$$

Selenium diimide derivatives (XIV) are very reactive compounds. They are readily hydrolysed by atmospheric moisture to the corresponding amides or amines and selenous acid.[45,49] When treated with dry hydrogen chloride selenium diimides undergo cleavage of the Se = N bond to form the corresponding amides and selenium tetrachloride:[45]

$$(PhSO_2N{=})_2Se + 4HCl \rightarrow 2PhSO_2NH_2 + SeCl_4.$$

The reaction of selenium bis(arylsulphonyl)diimide with chlorine occurs in two stages. Firstly, when the reagents are reacted in the ratio 1 : 2, *N*,*N*-dichlorobenzenesulphonamide and *N*-phenylsulphonylimidoselenyl chloride are obtained, the latter decomposing on further treatment with chlorine to give *N*,*N*-dichlorobenzenesulphonamide and selenium tetrachloride:[45]

$$(PhSO_2N{=})_2Se \xrightarrow{2Cl_2} PhSO_2NCl_2 + PhSO_2N{=}SeCl_2 \xrightarrow[-SeCl_4]{2Cl_2} PhSO_2NCl_2.$$

Selenium bis(arylsulphonyl)diimides react with compounds containing an X=O group (aldehydes, dimethylformamide, diphenyl selenoxide, triphenylphosphine oxide, etc.) to form compounds with an X = NSO_2Ar group:[17]

$$(PhSO_2N{=})_2Se + 2X{=}O \rightarrow 2X{=}NSO_2Ph + SeO_2,$$
$$X = ArCH,\ Me_2NCH,\ Me_2S,\ Ph_2S,\ Ph_2Se,$$
$$Ph_3P,\ Ph_2Se(=O),\ (C_2H_5)_2NC_6H_4N.$$

Selenium bis(benzoyl)diimide (XIV), R = PhCO, reacts with dimethyl sulphoxide in a similar manner:[17]

$$(PhCON{=})_2Se + 2Me_2SO \rightarrow 2Me_2S{=}NCOPh + SeO_2.$$

Selenium bis(benzoyl)diimide does not react with aromatic aldehydes. However, in the presence of benzamide reaction occurs very readily and *N*,*N*′-dibenzoylamidals are formed.[17] Apparently in this case selenium bis(benzoyl)diimide acts as a dehydrating agent in the reaction between benzamide and aldehyde, and the rate of this reaction, which is a source of benzamide, is much higher than the rate of reaction between the selenium diimide and aldehydes. The overall equation for the reaction is as follows:

$$2ArCHO + 2PhCONH_2 + (PhCON)_2Se \rightarrow 2ArCH(NHCOPh)_2 + SeO_2.$$

Selenium bis(phenylsulphonyl)diimide initially reacts with triphenylphosphine to give a 1 : 1 adduct, which on treatment with a further mole of triphenylphosphine forms triphenylphosphine selenide and a compound which probably has the structure of *N,N'*-bis(phenylsulphonyl)-*N*-triphenylphosphoniohydrazinate:[17]

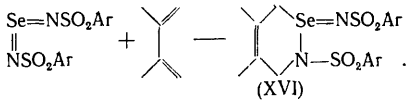
$$(PhSO_2N{=})_2Se + Ph_3P \rightarrow [PhSO_2N{-}Se{-}\overline{N}SO_2Ph] \rightarrow \underset{\overset{|}{{}^+PPh_3}}{} \xrightarrow[-Ph_3PSe]{Ph_3P} PhSO_2N{-}\overline{N}SO_2Ph.$$
$$\underset{\overset{|}{{}^+PPh_3}}{}$$

Triphenylphosphine oxide, benzonitrile, and selenium are formed from selenium bis(benzene)diimide on reacting with triphenylphosphine:[17]

$$(PhCON{=})_2Se + 2Ph_3P \rightarrow 2Ph_3PO + 2PhCN + Se.$$

Reaction of selenium bis(trimethylsilyl)diimide with benzenesulphonyl chloride gives the corresponding bis(phenylsulphonyl)diimide:[51]

$$(Me_3SiN{=})_2Se + PhSO_2Cl \rightarrow (PhSO_2N{=})_2Se + 2Me_3SiCl.$$



Selenium diimide derivatives react very readily with unsaturated compounds. The course of the reaction depends on the structure of the initial reagents. Disubstituted selenium diimides that contain just one acyl group on the nitrogen atom react with unsaturated compounds (styrene, cyclohexene, 1,1-diphenylethylene, etc.) by a [4 + 2]-cycloaddition mechanism to form 4-imino-5,6-dihydro-4,1,3-selenaoxazines, which are colourless crystalline compounds.[46,49] In particular, when selenium *N*-benzoyl-*N'*-phenylsulphonyldiimide is reacted with styrene, 4-phenylsulphonylimino-5,6-dihydro-2,6-diphenyl-4,1,3-selenaoxazine (XV) is formed, being identical to the compound obtained by reaction of compound (XIII), Ar = Ph, with bis(trimethylsilyl)benzenesulphonamide (see Section V):

$$\left.\begin{array}{l} PhSO_2N{=}Se{=}NCOPh + CH_2{=}CHPh \\ (XIII) + PhSO_2N(SiMe_3)_2 \end{array}\right\} \rightarrow PhSO_2N{=}Se \underset{CH_2{-}CHPh}{\overset{N{=}CPh}{\diagdown\!\!\diagup O}} \quad (XV)$$

On hydrolysis of both compound (XIII) and compound (XV) the same 2-phenyl-2-benzoyloxyethaneseleninic acid is obtained:[38,49]

$$\left.\begin{array}{l} (XIII) \xrightarrow[-HCl,\ -NH_4Cl]{3H_2O} \\ (XV) \xrightarrow[-PhSO_2NH_2,\ -NH_3]{3H_2O} \end{array}\right\} \rightarrow PhC(O)OCH(Ph)CH_2SeOOH.$$

Selenium bis(arylsulphonyl)diimide reacts with hydrocarbon dienes by a [2 + 4]-cycloaddition mechanism to form 1 : 1 adducts, which apparently have the structure of 3,6-dihydro-1-arylsulphonyl-2-arylsulphonylimino-2,1-selenazines (XVI):[50]

(XVI)

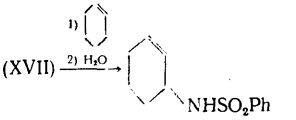
Compounds (XVI) are colourless crystalline compounds, stable on standing at 20 °C when moisture is excluded.

In 1976 Sharpless et al.[53,54] reported the synthesis of selenium *N,N'*-ditosyldiimide by reaction of chloramine-T with selenium or selenium tetrachloride with *p*-toluenesulphonamide. In fact, chloramine-T and chloramine-B readily react with selenium in methylene dichloride or dichloroethane in the ratio 2 : 1. However, the compounds formed in this process differ in composition and physical and chemical properties from the coresponding selenium bis(arylsulphonyl)diimides described above.[45,49,50] The compounds obtained from chloramine-B or chloramine-T and selenium by the method of Sharpless[53,54] are colourless, finely crystalline compounds with quite a sharp melting point. In contrast to the corresponding selenium bis(arylsulphonyl)diimides, they are insoluble in methylene dichloride, dichloroethane, and other organic solvents. On the basis of this it was proposed that when chloramine-B or chloramine-T react with selenium, the *N,N'*-disodium salts of bis(arylsulphonylamido)selenium dichloride (XVII) are formed:[50]

$$Se + 2ArSO_2NNaCl \rightarrow \underset{(XVII)}{[ArSO_2N(Na)]_2SeCl_2},$$
$$Ar = Ph,\ p\text{-}MeC_6H_4.$$

Indirect evidence for the structure of the "Sharpless products" is given by the reaction of selenium with carboxylic acid monochloramides, resulting in the formation of bis(aroylamino)selenium dichlorides (XII) (see Section V).[32,33]

When selenium tetrachloride is reacted with arenesulphonamides in the presence of triethylamine in dichloroethane (see the study of Sharpless[53]) selenium bis(arylsulphonyl)diimide is also possibly obtained. In fact, on mixing the reactants an orange-yellow colour characteristic of selenium diimides immediately appears. However, after 5–10 min the reaction mixture darkens and selenium separates out almost quantitatively. It was established by independent experiments that when triethylamine hydrochloride is added to selenium bis(arylsulphonyl)diimide in dichloroethane, the reaction mixture darkens after 1–3 min, selenium separates out, and a mixture of oily products of indeterminate structure is formed. It cannot be ruled out that selenium bis(arylsulphonyl)diimide forms a bis(triethylammonium) salt, which then decomposes:[50]



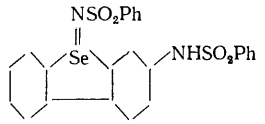
$$(ArSO_2N{=})_2Se + 2Et_3N{\cdot}HCl \rightarrow (ArSO_2NH{\cdot}Et_3N)_2SeCl_2.$$

This proposal is indirectly supported by the reaction of triethylamine hydrochloride with selenium bis(benzoyl)diimide, which results in the formation of bis(benzoylamino)selenium dichloride (XII) (see Section V):

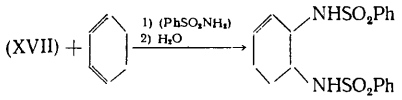
$$(PhCON{=})_2Se + 2Et_3N{\cdot}HCl \rightarrow \underset{(XII)}{(PhCONH)_2SeCl_2} + 2Et_3N.$$

Compound (XII) has been isolated and identified; but if it is not immediately isolated from the reaction mixture, the latter gradually darkens (after 10–15 min) and selenium separates out.[50]

A difference between the properties of selenium diimide derivatives and "Sharpless products" is also revealed in reactions with unsaturated compounds. When (XVII) is reacted with olefins, products derived from allylic amidation[50] are obtained (cf. the studies of Sharpless[53,54]), for example:



Selenium bis(arylsulphonyl)diimide also react with olefins, but the course of the reaction depends on the nature of the olefin. When α-methylstyrene is reacted with selenium bis(phenylsulphonyl)-



diimide, as also with compound (XVII), 2-phenyl-3-phenylsulphonylaminopropene is obtained[50] (cf. Sharpless[53,55]):

$$(PhSO_2N{=})_2Se \text{ or } (XVII) \xrightarrow[2)\ H_2O]{1)\ PhC(Me){=}CH_2} PhC(CH_2NHSO_2Ph){=}CH_2.$$

However, these compounds react in different ways with cyclohexene. Compound (XVII) gives *N*-benzenesulphonamido-2-cyclohexene, while from the products of the reaction between selenium bis(phenylsulphonyl)diimide and cyclohexene a product is isolated, which apparently has the structure of 1-phenylsulphonylamino-9-phenylsulphonylimino-9-selenaperhydrofluorene:[50]

When compounds (XVII) are reacted with cyclohexadiene in the presence of sulphonamide followed by hydrolysis, 1,2-bis(phenylsulphonylamino)-3-cyclohexene (XVIII) (cf. Sharpless[54]):

(XVIII)

When the products (XVI) of the reaction between disubstituted selenium diimides and hydrocarbon dienes were hydrolysed (Sharpless et al. suggested that these compounds were intermediates), it was not possible to obtain arylsulphonamidation compounds of the type (XVIII).[50]

2. Selenylamines

There is very little information about N = R-selenylamines and N = R-selenylamides. It was reported in 1932 that when aromatic amines are reacted with selenyl chloride, *N*-selenylarylamines (XIX) are formed:[56]

$$3ArNH_2 + SeOCl_2 \xrightarrow[-2ArNH_2\cdot HCl]{} ArN{=}Se{=}O, \quad (XIX)$$

$Ar = Ph,\ o\text{-}MeC_6H_4.$

Compounds (XIX) are orange-yellow oils which can be distilled under vacuum and decompose when heated at atmospheric pressure. On heating with aniline in the presence of zinc chloride, compounds (XIX) give difficultly soluble, dark green pigments containing selenium.

Reaction of t-butylamine with selenyl chloride gives *N*-t-butylselenylamine, which is a brown liquid that is extremely susceptible to hydrolysis:

$$3\ t\text{-}BuNH_2 + SeOCl_2 \xrightarrow[-2\,t\text{-}BuNH_2HCl]{\text{ether},\ -10\ ^\circ C} t\text{-}BuNSeO.$$

When traces of moisture are present the product is converted to a colourless crystalline compound with mp 145 °C, which apparently has the structure of a selenous acid amide $t\text{-}BuNH_2.SeO_2$.[52] The NMR spectrum of t-butylselenylamine confirms the presence of t-butyl groups. In the IR spectrum of this compound the intense absorption and at 1110 cm^{-1} has been attributed to ν_{as}(NSeO) and the band at 625 cm^{-1} to ν_s(NSeO).[52]

As was indicated above, attempts to obtain *N*-selenylamide derivatives RNSeO, where R = $ArSO_2$, $AlkSO_2$, PhCO, AlkCO, Me_3Si, were not successful.[43,49] Evidently these compounds are extremely unstable and undergo further conversions.

The influence of electric fields on the chemisorption and catalytic properties of semiconductor catalysts

E P Mikheeva
Institute of Catalysis, Siberian Division of the USSR Academy of Sciences, Novosibirsk

ABSTRACT. Studies of the influence of electric fields on the chemisorption and catalytic properties of semiconductor catalysts, carried out in order to test the principal postulates of the electronic theory of catalysis, are examined. It is shown that, because of the high density of the surface states, the possibility of the electronic control of the surfaces of polycrystalline catalysts by the field effect method is extremely limited. Possible ways of regulating the chemisorption and catalytic activities of solid catalysts with the aid of an external electric field are discussed: (1) the change in the concentration of polar molecules in strong inhomogeneous local fields near the surface; (2) the activation of surface compounds by "hot" electrons; (3) the modification of the defective structure when the concentration of cations in the surface layers of oxide catalysts is altered; (4) surface doping of film catalysts by alkali metals from the dielectric support during their electrolytic deposition.

Introduction

In chemical thermodynamics the external electric field is considered, like pressure and temperature, as an additional thermodynamic parameter influencing the rate and equilibrium constants for a chemical reaction. The principal aspect of the utilisation of electric fields in catalysis is at the junction between catalysis and electrochemistry and has been the subject of a special branch of chemistry—electrocatalysis. The need to solve practical problems—the creation of highly effective hydrogen and oxygen electrodes, the search for low-temperature hydrocarbon oxidation catalysts, the intensification of various reactions involved in the electrosynthesis of organic and inorganic compounds, and also the additional possibilities for the investigation of the mechanism of catalysis by electrochemical methods—have stimulated a large number of studies in the field of electrocatalysis, the principal results of which have been surveyed in a series of reviews[1–4] and monographs.[5,6]

Very strong fields are used in the study of surfaces by the autoelectronic and autoionic microscopic methods. These methods make it possible to obtain an image of the surface and the use of an atomic probe or a mass spectrometer also permits the study of the chemical composition of the surface and of a wide variety of reactions occurring in extremely strong electric fields at the tip of the emitter. The field-stimulated surface reactions have been analysed in a series of reviews.[7–10]

Finally, as the electronic ideas have developed, yet another aspect of catalysis has arisen—the employment of the field effect method in the study of the chemisorption and catalytic properties of semiconductors.

The idea that free carriers are involved in chemisorption and catalytic properties appeared in connection with the experimental observation of the dependence of the electrophysical parameters of semiconductors (electrical conductivity, electron work function, and the Hall constant) on the gaseous and environment. The theoretical foundations of the electronic theory of catalysis were laid in the studies of Vol'kenshtein [Wolkenstein],[11] Hauffe,[12] German,[13] and other workers. The use of quantum-statistical methods for the description of surface phenomena made it possible to discover the role of the Fermi level as a "collective" factor influencing the chemisorption and catalytic properties of semiconductors. Hence follows directly the possibility of regulating the activity of catalysts via external influences such as the introduction of heterovalent additives[14–16] and the application of an external electric field, which shifts the position of the Fermi level on the semiconductor surface.

The change in the chemisorption and catalytic properties of semiconductors following the application of an external electric field was predicted theoretically by Vol'kenshtein as early as 1955.[17] The electroadsorption effect was first observed experimentally in a study[18] where an increase in the hydrogen and carbon monoxide pressure was noted when a positive potential was applied to a germanium film specimen. At the present time the influence of the field on chemisorption and catalytic properties has been observed also in other studies. In view of the fundamental importance of these results for the confirmation of the electronic theory of catalysis, they have been described in many monographs and review articles devoted to the physical chemistry of the surfaces of semiconductors.[11,19–21]

In semiconductor physics, the field effect method has been given a theoretical justification. It has found technical applications in connection with the use of sufficiently perfect single crystals with the lowest concentration of surface states at the semiconductor–dielectric interface. However, the majority of the adsorption and catalytic studies in which the field effect method was applied have been carried out on polycrystalline specimens with a high concentration of surface states, which exceeds by several orders of magnitude the

density of the field-induced charge. Under such conditions, it is impossible to expect any appreciable shift of the position of the Fermi level or a change in the charge state of the catalytic reactive centres. In most studies, qualitative results concerning the effect of the field on adsorption and catalysis were presented without a comparison of the orders of magnitude of the observed effect with the concentration of the field-induced charge and the possible shift of the surface potential. It is striking that, despite the entire wide variety of the condenser designs and conditions (temperature, pressure, electric field strength, material of the dielectric) used, different secondary influences by the field on the heterogeneous catalytic system were as a rule not taken into account.

The aim of the present review is a critical examinaion of the results of studies of the chemisorption and catalytic properties of semiconductors by the field effect method with allowance for the physicochemical phenomena arising in systems when an external field is applied and the discussion of the possible mechanisms of the observed effects and the ways in which the electric field influences the adsorption and catalytic processes.

Henceforth the terms "electroadsorption" and "electrocatalysis" will be understood to imply the influence of an external field on the chemisorption and catalytic processes regardless of the mechanism involved in the action of that field. The electric field strength used in the field effect method is determined by the breakdown strength of the dielectric and does not exceed 3×10^8 V m^{-1}, but, owing to the roughness of the relief, near the surface the field strength may greatly exceed the average value calculated from the geometry of the condenser. We shall therefore consider briefly below the mechanisms of the influence of a very strong field on a heterogeneous gas–solid catalytic system.

II. The possible mechanisms of the influence of a very strong electric field ($>10^8$ V m^{-1}) on a heterogeneous gas–solid catalytic system

The electroadsorption and electrocatalytic effect in a gas-solid system may be determined both by the change in the state of the gas and solid molecules in the external field and by the influence of the field on their interaction. The effect of the field on a heterogeneous catalytic system is based on the following physical phenomena.

1. The change in the potential energy of the electrons of the atoms, molecules, and ions formed in the autoionisation process in a very strong external field (5×10^9–5×10^{10} V m^{-1}).
2. The formation of a system of dipoles oriented by the field.
3. The change in the electron work function of the solid as a consequence of the influence of the field on the electrostatic image forces.
4. The appearance of a mechanical stress, directed at right angles to the surface of the solid, when the electric field is applied.

We shall consider the mechanisms of the influence of the field on adsorption and catalysis determined by these phenomena.

The possibility of altering the properties of a heterogeneous catalytic system under the influence of very strong fields ($>5 \times 10^9$ V m^{-1}), comparable to intraatomic fields, is not open to doubt. Quantum-mechanical calculation performed for a series of gas molecules have shown[22,23] that, for $E > 5 \times 10^9$ V m^{-1}, the electron density is redistributed and this is accompanied by a change in the effective charges on atoms, in the bond lengths and angles, and in the ionisation potentials and electron affinities and hence by a change in the reactivity of the molecules. A simple diatomic adsorbate–support model in an external electric field has been calculated[24] by the LCAO method. An effect of the field on the bond energy, the equilibrium position, and the vibration frequencies of the adsorbate has been observed for $E > 10^9$ V m^{-1}. The energies of the bonds formed on chemisorption of the H_2O and CO molecules on NaCl and MgO(001) have been given[25] as a function of the adsorbate–support distance in the presence of an external field. It has been shown that the field alters not only the electrostatic but also the exchange energy of the interaction of the adsorbed molecules with the surface of ionic crystals.

In the strong electric field ($\sim 10^{10}$ V m^{-1}) arising at the tip of the ion emitter, atoms and molecules are ionised due to the quantum-mechanical tunnel electron transfer through the barrier generated by the field and the image forces in the metal.[8–10,26] The change in the form of the potential curve for the ion near the surface of the solid when an external $\sim 10^{10}$ V m^{-1} field is applied can lead (depending on the sign of the field) either to the stabilisation of the surface ionic structures or to the desorption of the ion by the field. Analysis of the chemical composition of the surface by the method involving the desorption of ions by the field using a time of flight atomic probe or an ionic field mass spectrometer have made it possible to observe various reactions occurring in the presence of strong electric fields. The following types of reactions have been quoted in a review.[9]

(a) Proton or cation exchange in the ionisation of gas molecules near the surface.

(b) The formation of complex ions on interaction of various gases with metallic emitters.

(c) The decomposition of molecules into fragments under the influence of the field.

(d) The ion–molecule reactions which can be initiated by radicals, radical-ions, or molecules in ionised states.

The study of the elementary processes occurring under the influence of very strong fields is of definite interest also for catalysis in the absence of an external field, because fields with $E \simeq 10^9$ V m^{-1}, generated by the ionic lattice of the solid, are then present over the surface of catalysts.[27]

For $E < 5 \times 10^9$ V m^{-1}, where the changes in the quantum-mechanical parameters of the molecules under the influence of the field become insignificant, the influence of the field on the adsorption and catalytic processes can be determined by polarisation effects. On polarisation in an external electric field, molecules with a dipole moment μ and a polarisability α receive an additional energy $\mathscr{E} = \mu E + {}^1/_2 \alpha E^2$, which results in their preferential orientation in space in the direction of the field, which cannot fail to affect the energy of the bond between the adsorbed species and the catalyst surface.

The dependence of the coverage of the tungsten tip of an [field ion] emission microscope by oxygen and alkali metal atoms on the field strength near the tip has been investigated.[28–30] The state of the surface before and after adsorption and also the change in the degree of adsorption under the influence of fields of different polarity were characterised by the electron work function of the tip determined from the Fowler–Nordheim relation between the emission current and the applied potential. It was observed that the degree of surface coverage by metal atoms under the influence of a field having a positive polarity increases and that under the influence of a field with a negative polarity diminishes. In relation to oxygen, the electron adsorption effect has the opposite sign—additional adsorption of oxygen on the tungsten tip is observed when a field with a negative polarity is applied. The results

obtained make it possible to represent the metal and oxygen atoms adsorbed in a charged form as dipoles with effective dipole moments μ^* and polarisabilities α^*, the heat of adsorption of which changes in the presence of the field E by an amount $\Delta q = \mu^* E + {}^1/_2 \alpha^* E^2$. With increase in the degree of coverage and hence with decrease in the proportion of the charged form of the chemisorbed species, the influence of the field on the chemisorption weakens and the effective values of μ^* and α^* diminish in the general case.

The changes in the state of the gas phase after the application of an external field can also be described by means of a thermodynamic approach[31] taking into account the influence of polarisation and spatial orientation processes on the entropy and the internal and free energies of the reactants and products of the chemical reaction and hence on its rate and equilibrium constants. The change in free energy per unit volume of the dielectric after the application of a field E is $\Delta \mathscr{F} = {}^1/_2 \varepsilon_0 \varepsilon_D E^2$. If the dielectric constants ε_D of the reactants and products are not the same, there is a possibility of a shift of the thermodynamic equilibrium in the system. According to the data of Block and Moentack,[32] the change in the equilibrium constant K as a function of the electric field strength E is determined by the relation

$$\partial \ln K / \partial E = \Delta M / kT,$$

where ΔM is the difference between the field energies of all the species in the field E before and after the reaction:

$$\Delta M = \left[\sum \mu_p - \sum \mu_r\right] E + {}^1/_2 \left[\sum \alpha_p - \sum \alpha_r\right] E^2.$$

(The subscripts r and p refer to the reactants and products of the reaction respectively).

The change in the reaction rate constant as a result of the decrease in the entropy of the dipolar molecules in the gas phase or in the adsorption layer, caused by the freezing of the rotational degrees of freedom in the electric field, has been estimated.[33] For a limited rotational freedom of the activated complex, this increases the reaction rate constant in the field $E = 9 \times 10^9$ V m^{-1} by a factor of 10^2–10^4. Evidently the polarisation effect can have an appreciable influence on the thermodynamic state of the gas phase and on the rate of chemical processes in a field $E > 10^9$ V m^{-1}, where the field energies of the species exceed kT. For example, $\mathscr{E} \simeq kT$ for a water molecule with $\mu = 1.8$ D and $\alpha = 1.46$ Å when $E = 3 \times 10^9$ V m^{-1}. When $E < 10^8$ V m^{-1}, the polarisation effects may be neglected.

Another thermodynamic parameter which changes in the presence of an inhomogeneous electric field is the pressure exerted by a gaseous dielectric on the surface of the solid catalyst. In the space near the electrode, the polarised gas molecules are acted upon by the force

$$\mathscr{F} = (\mu + \alpha E)\, dE/dr,$$

which is proportional to the electric field strength gradient dE/dr and which varies as the density of the flux of species incident per unit area per unit time and of the momentum given up by the molecules to the solid.[7] The multilayer adsorption of water vapour ($\sim$100 monomolecular layers) on a tungsten tip has been observed[34] at high electric field strengths ($E > 10^9$ V m^{-1}) and a low vapour pressure ($p_{H_2O} = 10^{-3}$ Pa) in the chamber of an ion emitter. The condensation of water vapour under such conditions can be explained by the increase in the pressure p_{H_2O} by several orders of magnitude near the tip as a result of the force acting on the dipolar H_2O molecules in the field direction. The sharp increase in surface coverage of a germanium cathode by oxygen in a field with the autoionic sign whose strength exceeds 1.39×10^{10} V m^{-1} has been noted.[35] The authors attribute this threshold effect to the possibility that the oxygen molecule may overcome the activation barrier in adsorption on a germanium tip as a result of the energy aquired in the inhomogeneous electric field. The increase in the surface coverage of the catalyst by the reactants under the influence of the electric field can alter the kinetics and mechanism of the catalytic process.

The external electric field can act both on the local properties of the solid catalyst and on the electron work function as a consequence of the Schottky effect. The decrease in the electric image forces in the presence of the external field reduces the overall electron work function by an amount $\Delta\chi = e^{3/2} E^{1/2}$ and is observed from the increase in the thermal electron and autoelectron emission currents and also from the increase in the degree of surface ionisation.[36] The surface ionisation and ion adsorption and desorption processes induced by the field can influence the rate of homogeneous-heterogeneous catalytic reactions. As an example, one may quote the decomposition of ammonia on the Pt–Rh–Pd catalyst in an electric field.[37] When a negative potential was applied to the catalyst, an increase in the rate of decomposition of NH_3 by a factor of 1.5–2 was observed with a simultaneous decrease in temperature and the conductivity of the specimen. The mechanism of the action of the field was attributed by the authors to the field-induced desorption of the negatively charged species, which accelerates the gas-phase processes. The field thereby prevents the species recombination processes on the surface, as a result of which the temperature on the catalyst surface decreases.

The changes $\Delta\chi$ become appreciable for fields with $E > 10^8$ V m^{-1} and should have a significant influence on the rates of reactions in which the electronic transitions between the solid and the surface species constitute the rate-limiting stage of the reaction. The study of the dependence of the activation energy for the decomposition of formic acid and of the rate of the latter on the electron work function of the catalyst, altered by an external electric field, has been undertaken.[38] A silver wire 2.5×10^{-5} m in diameter, serving as the internal electrode of a cylindrical condenser, was used as the catalyst. The changes in the electron work function $\Delta\chi$ after the application of the field were detected reliably by measuring the autoelectron emission currents. In conformity with earlier results,[39] it was assumed that the catalytic decomposition of formic acid should be accelerated by a field with a positive polarity of the silver catalyst and should be inhibited by one with a negative polarity. However, experiments showed that an irreversible decrease in the rate of reaction takes place in both cases. The authors explained this result by an increase in the roughness of the catalyst surface and a change in its structure when the reaction takes place in the presence of the field.

The mechanism of the change in the structure of the catalyst surface in an external field is apparently complex, but, when $E > 10^9$ V m^{-1}, the mechanical stress $\sigma_E = {}^1/_{8\pi} \varepsilon_0 E^2$, arising under the influence of mechanical forces and directed at right angles to the electrode surface, plays an important role. In fields with $E = (3$–$5) \times 10^9$ V m^{-1}, whereupon the energy imparted by the field to the gas molecules is comparable to kT, the mechanical stress $\sigma_E = 10^6$–10^7 Pa can induce the plastic deformation of the surface layers of the solid.[40]

Thus, despite the wide variety of the mechanisms of the action of fields with $E > 10^9$ V m^{-1} on the catalytic system (the rearrangement of the molecular and surface structures, the change in the energy of the bond between the adsorbate and the surface, the dependence of the rate and equilibrium constants for a chemical reaction on the field, the increase in the gas pressure near the catalyst-electrode, and the influence of the field on the electronic transitions between the solid and the adsorbed species, and the desorption of ions by the field), the possibility of using very strong fields in catalytic studies is limited as a consequence of the degradation of the catalyst surface by the field.

III. The influence of the electric field on the chemisorption and catalytic processes occurring on semiconductor catalysts

1. The mechanism of the influence of the electric field on chemisorption and catalysis from the standpoint of the electronic theory

In the case of a semiconductor catalyst, the influence of the field on chemisorption and catalytic processes can be associated with the shift of the position of the Fermi level on the semiconductor surface when an additional surface charge is induced by the field. This possibility has been examined in the electronic theory of catalysis.[11,41,42] According to the electronic theory,[11] the gas molecules are adsorbed on the surface of the semiconductor catalyst in neutral and charged forms, between which transitions are possible. The probability that a species exists in the charged or neutral state and also the degree of surface coverage of the adsorbent under the conditions of thermodynamic equilibrium, when adsorption equilibrium between the gas phase and the surface and the electronic equilibrium between the bands and the surface state have been attained, is determined by the position of the Fermi level at the surface of the semiconductor catalyst.[11] The species chemisorbed in the donor, acceptor, and neutral forms differ in their reactivities. The Fermi level, by determining the concentration of the active form, is thus a regulator of the rate of the catalytic reaction. The rate of reaction may depend on the position of the Fermi level also in the case where the intermediate surface compounds are formed with participation of the conductivity electrons of the solid.[43] Hence follows the possibility of a change in the adsorption capacity and catalytic activity of the semiconductor catalyst after the application of an external field, which alters the concentration of the free carriers in the surface region of the semiconductor and hence the level of the chemical potential of the electrons.

The relative changes in the chemisorption capacity and catalytic activity induced by the electric field are defined by the following relations according to the data of Baru and Vol'kenshtein:[42]

$$\Delta N/N_0 = (N - N_0)/N_0 = \eta_0^{\mp} \{\exp[\mp (V_s - V_{s0})] - 1\}, \quad (1)$$

$$\Delta g/g_0 = (g - g_0)/g = \exp[\mp (V_s - V_{s0})] - 1, \quad (2)$$

where N and N_0 are the total numbers of species of the given kind chemisorbed on a unit surface under the conditions of equilibrium in the gas phase when the field is applied and in its absence, $\eta_0^{\mp} = N_0^{\mp}/N_0$ is the relative content of the charged form on the surface for $E = 0$, g and g_0 are the rates of reaction when the field is applied and in its absence, and $V_s - V_{s0}$ is the change in the surface potential (in units of kT) equal to the shift of the position of the Fermi level on the surface of the specimen following the application of the field; $(V_s - V_{s0}) > 0$ corresponds to an increase in the electron work function after the induction of a positive charge in the semiconductor and $(V_s - V_{s0}) < 0$ corresponds to its decrease after the introduction of a negative charge into the semiconductor.

It follows from Eqns. (1) and (2) that the field inducing a negative charge in the semiconductor and shifting the level of the chemical potential on the specimen surface upwards relative to the edge of the band increases the degree of adsorption of acceptors (and also accelerates the acceptor reaction) and diminishes the degree of adsorption of donors (inhibits the donor reaction). The field inducing a positive charge in the semiconductor acts in the opposite way. The form of the functional dependence of $\Delta N/N_0$ and $\Delta g/g_0$ on $V_s - V_{s0}$ shows that the positive effect increases with increase in the displacement of the surface potential, while the negative effect is expressed by the asymptotic approach of $\Delta N/N_0$ to $\eta_0^{\mp}$ and of $\Delta g/g_0$ to -1. Consequently the electrodesorption effect is limited by the relative contribution of the charged form of chemisorption before the application of the field.

2. The change in the bending of the bands of on the surfaces of semiconductors under the influence of an external electric field

The conclusion arising from the electronic theory that the chemisorption and catalytic activities of semiconductors can be regulated by an electric field has been tested experimentally. The change in the concentration of free carriers in the surface region of the semiconductor catalyst was achieved by applying a potential difference to a condenser one of the plates of which consisted of the semiconductor investigated. The wide variety of condenser designs employed is striking (Fig. 1) A plane-parallel condenser has been used in a number of studies[44–49] (Figs. 1*a*, 1*c*, and 1*e*), while the role of the dielectric plate was assumed by a vacuum (gas) or a mica plate. The principal deficiency of condensers having this design is the presence of a field in the gas phase at the surface of the adsorbate, which requires special precautions to avoid their discharge and the ionisation of the gas.

A condenser design free from this disadvantage has been proposed[18] (Figs. 1*b* and 1*f*). A thin film specimen, whose thickness d is smaller than the Debye shielding length L, is sputtered onto a support which serves simultaneously as the dielectric plate of the condenser; a metallic electrode is deposited on the other side of the support. Condensers having this design have been used in a number of studies[18,50–71] and it has been shown[72] that, when the condition $d < L$ holds, the application of the field should alter the position of the Fermi level and the degree of filling of the surface states by electrons not only from the inner side of the film but also from its outer side directed towards the gas phase.

Cylindrical condensers with a gap above the catalyst surface have been used to investigate the influence of the field on chemisorption and catalytic processes at elevated temperatures and pressures (from 2×10^3 to 10^5 Pa)[73–77] (Figs. 1*g* and 1*h*). In order to avoid discharge processes in the gas phase and the electrical breakdown of the dielectric, the field strength between the condenser plates was kept at a value not exceeding 10^6 V m^{-1} and the charge induced in the semiconductor was $e\Delta n_v \leqslant 5 \times 10^{13}$ el. charge m^{-2}. In a number of studies,[44–46,50–54] electroadsorption has been investigated at room temperature and low adsorbate pressures (0.5 Pa), which made it possible to increase the field strength to 2×10^7–2×10^8 V m^{-1} and the induced charge to 10^{15}–10^{16} el. charge m^{-2}.

A quantitative comparison of the experimental results for the influence of the field on chemisorption and catalytic processes with theoretical data derived from Eqns. (1) and (2) of the electronic theory is possible, provided that the dependence of the shift of the surface potential (V_s–V_{s0}) on the electric field strength E is known. The dependence of V_s on E cannot be obtained purely theoretically from the solution of the Poisson equation because a large part of the charge induced by the field is captured by the surface state of the semiconductor and the shift of the surface potential is much smaller than the theoretically possible value. The field effect method has been developed in detail for germanium and silicon single crystals.[78–80] This method makes it possible to calculate from the experimental field effect curve the bending of the bands on the surface and the charge captured by the surface state as a function of the field-induced charge.

Most of the studies of the influence of the field on chemisorption and catalytic processes have been carried out on polycrystalline semiconductor specimens, an exact calculation of the electrophysical parameters of the surface of which as a function of the electric field strength is impossible. The relation obtained by Many et al.[80] has been used by Deren and Mania[75] to estimate the order of magnitude of the bending of the bands after the application of the field:

$$V_s - V_{s0} = eLE \tag{4}$$

where L is the Debye shielding length:

$$L = (\varepsilon_0 \varepsilon_n kT/2\pi e^2 n_0)^{1/2}, \tag{5}$$

where ε_n and ε are the dielectric constants of the semiconductor and the dielectric, n_0 is the concentration of free carriers in the semiconductor, and e is the charge of the electron. The field strength in the semiconductor E_n is linked to the field strength in the dielectric E by the electrostatic relation

$$E_n = (\varepsilon/\varepsilon_n) E. \tag{6}$$

One should bear in mind that such a shift of the surface potential is established in the first instant after the field has been switched on and then, as the charge is captured by surface states, the quantity V_s–V_{s0} can decrease appreciably. Virtually all the semiconductors investigated are characterised by a high density of surface states.

On a germanium single crystal, the density of fast and slow states is 10^{16} m^{-2}, but increases after the adsorption of water, *p*-benzoquinone, and diphenylamine vapours to 10^{18} m^{-2} and above.[81,82] On epitaxial PbS films, the concentration of slow states *in vacuo* is 10^{17} m^{-2}.[83] Evidently the density of surface states on polycrystalline specimens should be even higher. The shift of the Fermi level on the outer side of the film after the application of an electric field to its reverse side has been determined by the conductimetric and the contact potential difference methods in a study[57] carried out on polycrystalline TiO_2 films deposited on mica supports (the condenser illustrated in Fig. 1*b*). It was shown that a thin film of reduced TiO_2 (~500 A) provides an almost complete shield against the field and the change in the contact potential difference is much lower than the theoretical value, which indicates a transfer of a considerable proportion of the induced charge to the surface states.

A large proportion of studies of the influence of the field on the chemisorption and catalytic properties of semiconductors have been carried out on polycrystalline zinc oxide specimens.[48,50,51,66–68,76] The field effect on ZnO single crystals and polycrystalline film specimens *in vacuo* has been observed by a number of workers.[84–91] Estimating the mobility of the field effect with different initial conductivities of the specimen, Heiland[85] calculated the density of surface states per unit energy range in the vicinity of the Fermi level: $S_{EF} = 10^{18}$ m^{-2} eV^{-1}. Later S_{EF} was regarded[92,93] as the "effective" density of capture centres taking into account the fact that a proportion of the states undergoing charge transfer after the application of an electric field or on illumination exist not on the surface but in the region of the space charge. The nature of the capture centres for the free carriers is apparently immaterial for the estimation of the shift of the Fermi level following the application of the external field. Bearing in mind that the field-induced charge $e\Delta n_V$ is equal to the sum of the charges $e\Delta n_{ss} + e\Delta n_c$ ($e\Delta n_{ss}$ and $e\Delta n_c$ are respectively the density of the charge transferred to the capture centres and the charge participating in the conduction by the

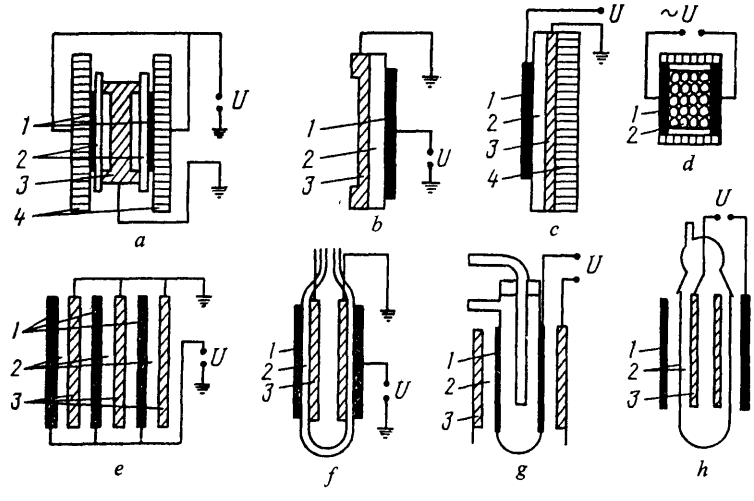

Figure 1. Design of the condensers used in the study of the influence of an external electric field on the chemisorption and catalytic properties of semiconductors: *1*, field electrodes; *2*, layers of dielectric; *3*, test specimens; *4*, support or holder.

specimen) and that we have $e\Delta n_c \ll e\Delta n_{ss}$ so that $e\Delta n_V \simeq e\Delta n_{ss}$, it is possible to estimate the shift of the Fermi level provided that the density of states S_{EF}, per unit energy range, is known:

$$V_s - V_{s0} = \Delta n_V / S_{EF}. \quad (7)$$

Henceforth, in order to discriminate between the mechanisms of the effect of the field on the chemisorption and catalytic properties of polycrystalline semiconductors, the observed effects will be compared with the changes in the surface potential $V_s - V_{s0}$ (possible for the field strengths E and the concentrations of the field induced charge $e\Delta n_v$ employed) calculated with the aid of Eqns. (4) and (7).

3. The electroadsorption of gases on semiconductor adsorbents

(a) The electroadsorption of oxygen and methanol and water vapours on a germanium single crystal

The classical field effect method[78–80] has been used to investigate the influence of the field on the adsorption of oxygen and methanol and water vapours on a germanium single crystal.[44–46] It is noteworthy that the surface properties of germanium, studied by many investigators,[21,78–80] are by no means described by the simple ideal crystal model with a local level of the adsorbed molecule, which has served as the basis of Vol'kenshtein's electronic theory. On a "real", i.e. oxidised, surface of the germanium single crystal[78] one observes a high concentration of fast and slow states of adsorption or biographical origin. By virtue of the cooperative character of the local fields, the curves for the charge capture by both fast and slow surface states, which depend on the surface potential, are monotonic.

In the adsorption of different molecules, the local surface levels are not manifested, but the energy spectrum shifts smoothly towards an increase in the concentration of slow surface states. Kiselev[94–97] proposed a donor–acceptor mechanism of the charging of the surface in adsorption, which is based on the idea that the adsorbed molecules interact with "defective" surface atoms. When an adsorption complex is formed, the electrophysical parameters of the defect change, as a result of which it is converted into a hole or electron capture centre and the localisation of the charge influences in its turn the character and strength of the bond. The chemisorption of the charged form alters the bending of the bands on the semiconductor surface, which entails a redistribution of the charge between the levels of the chemisorbed species and the levels of the biographical defects. The redistribution of the charge between the fast and slow surface states of biographical and adsorption origin and the continuous character of the energy spectrum complicate the observation and interpretation of the electroadsorption effect.

Since the surface of the germanium single crystal (2×10^{-4} m^2) is small, manometric adsorption measurements were not performed and the electroadsorption effect was estimated from the sign and magnitude of the change in the surface charge after the adsorption of the gas in the presence of the field.[44–46] The condenser illustrated in Fig. 1*a* was used in these studies. It is striking that the electroadsorption depended on the method used for the preliminary treatment of the surface of the germanium single crystal. By varying the etching conditions, two types of surface were obtained. For the same geometry of the condenser, gas pressure, and electric field strength, the electroadsorption of oxygen was observed on a type II surface but was absent on a type I surface. On the other hand, methanol vapour was adsorbed in the presence of the field only on the type I surface. This must be regarded as proof that the electroadsorption of gases is not associated with the discharge in the gas phase but is determined by phenomena occurring on the surface of germanium in the presence of the field.

The influence of a field with negative polarisation, which increases the number of electrons on the surface, on the adsorption of O_2 was observed on incompletely oxidised type II germanium specimens with a high density of slow acceptor states (there were no slow donor states on these specimens). After the field had been switched off in an oxygen atmosphere, the steady relaxation of the reverse electron transition to the bulk of germanium from the slow acceptor states, which are apparently centres for the adsorption of O_2, increased (compared with a vacuum). This induced an increase in the negative surface charge (Fig. 2). An increase in the positive surface charge has been detected on type I specimens, having the structure of the "real" surface and a high density of slow donor states, in the adsorption of methanol vapour under conditions involving the application of a field with positive polarity to the specimen.

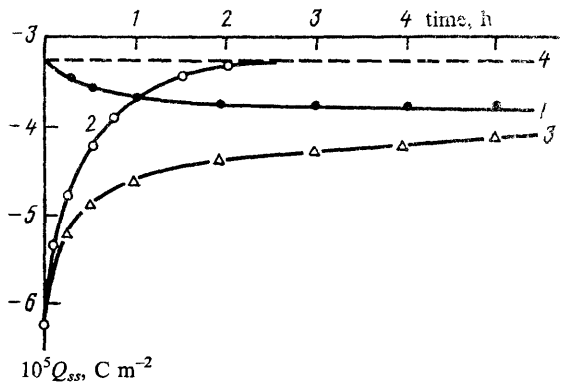

Figure 2. Relaxation of the surface charge: *1*, in the adsorption of O_2; *2*, when the field is switched off *in vacuo*; *3*, when the field is switched off in an oxygen atmosphere; *4*, the charge on the surface conditioned *in vacuo*.

A quantitative comparison of the change in the positive charge of the surface with the shift of the Fermi level has been carried out[46] in relation to the electroadsorption of water vapour using a pulse method, which is free of the disadvantages of the field effect method at a constant potential such as the inconstancy of the shift of the Fermi level as a function of time, the filling of surface states of non-adsorption origin, and appreciable changes in the surface potential of the opposite sign when the field is switched off. The amplitude, duration, and Q-factor of the pulses were chosen so that the switching on of the pulse field *in vacuo* did not change the surface charge of the specimen heated at 450 K. When a pulsed field with a positive polarity is applied to germanium in the presence of water vapour, the positive surface charge accumulates, the accumulation effect increasing with increase in the amplitude of the pulses. In a pulsed field with the opposite polarity, a decrease in the positive surface charge was observed with a tendency towards saturation as the amplitude of the pulses rose.

The experimental dependence of the change in the positive surface charge ΔQ_V in the adsorption of water vapour on germanium in a field with a positive polarity applied to the specimen (measured after the completion of the rapid relaxation process) on the change in the bending of the bands (V_s–V_{s0}) is described by the relation[46]

$$\Delta Q_V = \text{const} \cdot \exp(V_s - V_{s0}). \quad (8)$$

The results of the study of the electroadsorption of water and methanol vapours on germanium have been examined by Kiselev[94–96] from the standpoint of the donor–acceptor model. According to these data,[94,95] the CH_3OH and H_2O vapours are adsorbed on an oxidised germanium surface via a coordination mechanism in the vicinity of surface defects, which serve as capture centres for holes from the bulk of the semiconductor. The localisation of a hole near a coordinated water molecule should result in the unshared electron pair being pulled even further to the adsorption centre and in an increase in bond strength. A field increasing the concentration of holes on the semiconductor surface should promote the adsorption of water molecules, while a field with the opposite polarity should induce their desorption.[94–97] In later studies,[98,99] the accumulation of the positive surface charge was explained by the protonation of H_2O. According to Kiselev and co-workers,[98,99] the localisation of a hole in a slow state increases the effective dipole of the adsorbed complex, increases the amount of ionic character of the bond, and decreases the activation energy for the heterolytic dissociation of H_2O. These processes can be regulated by altering the electronic state of the surface with the aid of an external electric field. The number of protonated water molecules increases exponentially with increase in the shift of the surface potential (V_s–V_{s0}) in the presence of the field.

(b) The electroadsorption of O_2 on polycrystalline ZnO films

The influence of field on the adsorption of oxygen has been investigated on β-HgS films[47] and polycrystalline ZnO specimens.[48,50,51,56] A condenser with a mica plate, illustrated in Fig. 1*c*, where the maximum field strength was 10^7 V m^{-1}, has been used.[47] In order to observe the effect, measurements were made of the resistances of the specimens in the adsorption of O_2 with the field applied to the specimen. The adsorption of oxygen ($p_{O_2} = 5 \times 10^{-1}$ Pa) was accompanied by an increase in the resistance of the β-HgS film exhibiting *n*-type conductivity. When a field increasing the concentration of electrons in the semiconductor was subsequently switched on, the resistance of the specimen σ fell and, after it had been switched off, the resistance acquired a value appreciably exceeding σ before the application of the field. This result has been explained[47] by the transition from the neutral form of chemisorption to the charged form as a consequence of the additional capture of electrons by centres with chemisorbed oxygen.

The additional increase in the resistance of the specimens after the adsorption of oxygen with the field applied to the specimen has been observed by Hoenig and Lane[48] and Constantinescu et al.[56] Hoenig and Lane[48] used a condenser with an air gap (Fig. 1*c*), low field strengths $E_{max} = 5.6 \times 10^5$ V m^{-1}, and an induced charge concentration $E\Delta n_V = 2 \times 10^{13}$ el. charge m^{-2}. Under these conditions, the shift of the Fermi level, estimated according to Eqn.(7), is $\sim 2 \times 10^{-5}$ eV and the influence of the collective factor on the adsorption of gases may be disregarded because it is insignificant.

The fact that the additional increase in the resistance of the ZnO film in the presence of oxygen occurred following the application of a field with a negative polarity to the semiconductor is also striking (Fig. 3*a*). This result is an argument against the discharge mechanism of the electroadsorption of oxygen, since in a discharge negative charging of the surface is attained after the application of a positive potential to the specimen. However, the data obtained by the field effect method on ZnO single crystals and polycrystalline specimens (with the exception of one study[100] carried out on a ZnO single crystal freshly cleaved in an ultrahigh vacuum at low temperatures) indicate the absence of surface conductivity of the inversion type; the negative charge induced by the electric field increases the conductivity of the specimen by an amount $\Delta\sigma_V$. It has been shown[88] that in an oxygen atmosphere the quantity $\Delta\sigma_V$

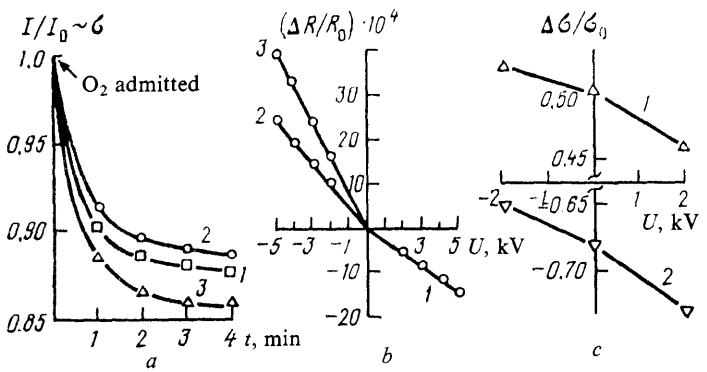

Figure 3. The influence of the field on the adsorption of oxygen and hydrogen on polycrystalline ZnO films. *a*, Variation of the conductivity of the specimen in a stream of the N_2 + O_2 mixture: *1*, in the absence of the field; *2*, on application of a field having the – sign to the specimen; *3*, on application of a field having the + sign to the specimen; *b*, The relative changes in resistance $\Delta R/R_0$ as a function of the applied potential: *1*, on application of a field having the – sign to the specimen (the changes $\Delta R/R_0$ *in vacuo* and in a O_2 atmosphere are the same); *2*, on application of a field having the + sign to the specimen *in vacuo*; *3*, ditto in a O_2 atmosphere ($p_{O_2} = 1.3 \times 10^2$ Pa); *c*, the relative changes in the conductivity of the film $\Delta\sigma/\sigma_0$ in the adsorption of hydrogen (curve *1*) and oxygen (curve *2*) atoms as a function of the magnitude and sign of the potential applied to the field electrode ($p_{O_2} = p_{H_2} = 1.33$ Pa).

diminishes (whilst retaining the positive sign) as a result of the additional capture of electrons by the oxygen-generated acceptor traps. The increase in the resistance of the ZnO films when a negative-polarity field is applied to the semiconductor is apparently associated with some kind of additional mechanism of capture of free carriers by the adsorbed oxygen.

The field effect is usually considered in the literature from the standpoint of the breakdown of the electronic equilibrium between the surface and the bulk of the semiconductor when a transverse electric field is applied. However, under conditions where a field acts on defective structures such as those of polycrystalline oxide films, there is apparently a shift of not only the electronic but also of the electronic-ionic equilibrium in the surface region of the semiconductor. In particular, on reduced ZnO films with a high concentration of interstitial Zn^+ ions, there is a possibility of the relaxation polarisation of the specimen under the influence of the external field penetrating the specimen over a distance equal to the Debye shielding length. The characteristic features of the variation of the electrical conductivity of ZnO following the adsorption of oxygen have been explained by the migration of the interstitial zinc in the region of the space charge.[101] In another study,[102] this phenomenon was regarded as an additional mechanism for the discharge of a surface subjected to the action of a corona discharge. The relaxation polarisation of ZnO following the application of a positive potential to the field electrode of the condenser (Fig. 1*c*) should lead to the diffusion of Zn^+ into the bulk of the specimen and of electrons to the ZnO surface. The increase in the resistance of the film observed in electroadsorption of O_2 can be explained by the capture of these electrons by the chemisorbed oxygen.[48]

The relaxation polarisation of the film in an external field apparently determines the mechanism of the electroadsorption of O_2, which has been observed[56] from the additional increase in the resistance of the ZnO film in a O_2 atmosphere following the application of a positive-polarity field to the specimen (Fig. 3*b*), which seemingly conflicts with the ideas of the electronic theory of adsorption. ZnO films with a thickness of (3–5) $\times$ 10^4 nm, comparable to the Debye shielding length, and the condenser illustrated in Fig. 1*f* were used in the above study. The authors suggest that oxygen is adsorbed mainly on the outer side of the film adjoining the gas phase and explain the observed effect by a change in the potential within the Zn film as a result of the accumulation of electrons at the oxide film–gas interface. The mechanism of such electron accumulation is apparently associated with the migration of mobile interstitial zinc ions Zn^+ to the glass–semiconductor interface when a negative potential is applied to the field electrode.

A somewhat different result was obtained on ZnO films 5×10^3 nm thick, sputtered onto a mica support (the condenser illustrated in Fig. 1*b* was used) under conditions where there was no field over the semiconductor surface.[50] The character of the change in the film resistance agrees with the electronic theory of adsorption: the negative-polarity field applied to the semiconductor increases the concentration of negatively charged adsorbed oxygen atoms and reduces the degree of adsorption of positively charged hydrogen atoms (Fig. 3*c*), the relative increase in the concentration of the charged forms of the chemisorbed species amounting to 7–9%. In the study of Ryl'tsev et al.,[50] the electroadsorption effects were investigated at the field-induced charge concentrations $e\Delta n_V$ = 1.6×10^{16} el. charge m^{-2}, which are the maximum possible in the field effect method, whereas in other investigations[48,56] these concentrations were lower by 2–3 orders of magnitude. The shift of the Fermi level, estimated with the aid of Eqn. (7), is $\sim 1.6 \times 10^{-2}$ eV and the values of ΔN^- observed by Ryl'tsev et al.[50] do not exceed those calculated by Eqn. (1).

Consequently the influence of the field on adsorption processes, investigated by Ryl'tsev et al.,[50] is probably due to the "collective" factor. The discrepancy between the results obtained in the above studies[50,56] can be accounted for bearing in mind that Ryl'tsev et al.[50] used several times thinner films, which were "transparent" to the gas, on which adsorption occurred not only on the outer side but also over the entire surface of crystallites, including the space charge region modified by the external field. Furthermore, relaxation polarisation should influence to a lesser extent the results obtained by Ryl'tsev et al.[50] because they used films characterised by a narrow space charge region whose specific resistance was lower by 2–3 orders of magnitude than that of the films used by Constantinescu et al.[56]

The adsorption of atomic hydrogen and oxygen on ZnO[50] and TiO_2 [51] films deposited on quartz supports and subjected to a thermal field treatment has also been investigated. Despite the sevenfold enrichment of the TiO_2 specimen in electrons, the effects observed[51] were small: the rate of adsorption of oxygen atoms increased by 15% and the rate of adsorption of hydrogen atoms diminished by 25%. The authors explained the appreciable change in the conductivity of the semiconductor films after they have been acted upon by a field with a strength of 5×10^6 V m^{-1} at 500–650 K by the electret state of the quartz support. However, according to Kovalenko's data,[103] quartz does not possess the properties of a very effective electret, its surface charge amounting to 5×10^{14} el. charge m^{-2}, which cannot ensure a change in the resistance of the oxide films by an order of magnitude. The type of spectroscopic composition of the quartz was not indicated in the above studies[50,51] and no data were given concerning the electret charging and discharging processes, which precludes a definite conclusion about the mechanism of the action of the field on the electrical conductivity and chemisorption properties of the films.

(c) The desorption of gases by the field using a metal–dielectric–semiconductor system

One of the difficulties in the interpretation of the electroadsorption effects observed from the change in the resistance of the specimen as a result of the action of the field in a gas atmosphere is associated with the impossibility of separating the charges captured by the adsorbed molecules and by the "slow" surface states of non-adsorption origin, whose electrophysical parameters change as a result of adsorption. Studies in which electroadsorption was observed directly by the manometric method are therefore of great interest.[18,52–54] The shift of the adsorption equilibrium after the application of the field was first investigated on polycrystalline *p*-type germanium films $\sim 10^3$ nm thick.[18,52] The condenser illustrated in Fig. 1*b*, with the maximum values E_{max} = 7×10^7 V m^{-1} and $e\Delta n_V = 4 \times 10^{15}$ el. charge m^{-2}, was used in the investigation. The desorption of H_2, CO, and hydrocarbons was observed after the application of a positive-polarity field to the germanium film; the amount of desorbed gas corresponds to thousandths of a monolayer. The application of a field having the opposite sign did not result in the observation of the electrodesorption effect. The authors explain the results[18,52] by a change in the occupancy by electrons of the adsorption centres located on the outer side of the film, directed towards the gas phase, when the field is applied to the inner side. Theoretically this is possible if the film thickness d is smaller than the Debye shielding length L;[72]

according to the authors,[18,52] this conditions holds for $d \simeq 10^3$ nm. The electrophysical parameters of the germanium films used were not indicated in the above studies,[18,52] but according to other data[104,105] thin ($< 10^4$ nm) germanium films have *p*-type conductivity and a high concentration of free carriers [$n_p = (6\text{–}8) \times 10^{24}$ m^{-3}] regardless of the type of conductivity of the single crystal used for the sputtering, which is due[105] to the high density of surface acceptor states. However, in this case $L = 10^2$ nm according to Eqn. (5) and the condition $d < L$ cannot be fulfilled.

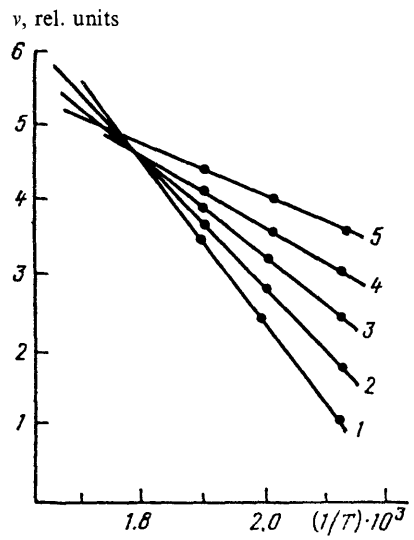

Figure 4. The Arrhenius relations for the rate of decomposition of formic acid at different currents flowing through the Ni–Al_2O_3–Au structure; *i*(A): *1*, 0; *2*, 0.25; *3*, 0.5; *4*, 1.0; *5*, 1.5.

The influence of the field on the desorption of gases as well as catalytic reactions has also been observed in other systems metal–dielectric–thin film involving a semiconductor or a metallic catalyst, but this happened after the application of a field of only one sign, namely one with a positive polarity, to the catalyst.[53–55,106] An appreciable increase in the steady-state rate of decomposition of formic acid and ammonia and also a change in the selectivity of the oxidation of propene on a gold film deposited on a nickel disc with an intervening Al_2O_3 layer has been observed[55] after the application of a negative potential to the nickel disc which performed the role of a field electrode (the condenser illustrated in Fig. 1*b* was used). For different currents flowing through the metal–oxide–metal (MOM) structure, a compensation effect was observed: with increase in temperature, the influence of the field on the rate of decomposition of formic acid was weakened (Fig. 4). The authors[55] explain these results by a change in the rates of the elementary processes in the interaction of the surface compounds with the stream of "hot" electrons arising in the MOM and MDS (metal–dielectric–semiconductor) structures when the electron gas in the dielectric is heated by a strong electric field.[107]

Various mechanisms for the scattering of the kinetic energy of electrons by the surface of the solid and the species adsorbed on it have been detected by the spectroscopy of the characteristic losses of low energy electrons (EELS).[108] The possibility of the vibrational excitation of the molecules adsorbed on the surface of a solid in processes involving the capture of free carriers by deep electron traps has been demonstrated.[109] The resonance adsorption of the excess kinetic energy of the "hot" electrons during scattering by surface states of adsorption origin can apparently be accompanied by both desorption and by the appearance of chemically active species. After the electrodesorption of H_2 and switching off the field at room temperature, the sorption of oxygen and the evolution of methane on germanium films were observed, which may be associated with the activation of the surface hydrocarbon compounds. Unfortunately the leakage currents in the condenser and their dependence on the electric field strength were not indicated in the above studies,[18,52] which makes it difficult to discuss the mechanism of the effect of the field.

(d) Gravimetric study of the influence of the field on the adsorption of oxygen and methanol on a silver catalyst

In order to test the proposed electronic mechanism of the oxidation of methanol, the influence of the field on the adsorption of oxygen and methanol on a silver catalyst coated by an oxide film was investigated gravimetrically[73] at $T = 723$ K and $P = 10^5$ Pa. A result discouraging from the standpoint of the electronic theory was obtained—oxygen was adsorbed for both negative and positive polarity of the external field on the catalyst. A similar result had been obtained earlier[48] on ZnO films using a plane-parallel condenser (Fig. 1*c*). When a field increasing the concentration of electrons in the semiconductor was switched on, the gas pressure in the system fell, which indicated additional adsorption of O_2. When a field with the opposite polarity was switched on, increasing the concentration of holes in the semiconductor, the desorption of oxygen was observed initially at low field strengths, changing subsequently to the adsorption of O_2 with increase in field strength. These results indicate that vacuum insulation conditions are maintained for the mica-free condensers used by Hoenig and Lane,[48] since the occurrence of a gas discharge should have been accompanied only by an increase in pressure.

The fact that the concentration of oxygen adsorbed due to the effect of the field (N-N_0) exceeds by several orders of magnitude the concentration of the induced charge $e\Delta n_V$ is striking.[48,73] The quantity N-N_0 calculated[48] from the change in pressure is 10^{17} molecules m^{-2}, whereas $e\Delta n_V = 10^{13}$ el. charge m^{-2}. The adsorption of oxygen under the influence of fields of both polarities has been explained[72] by the polarisation of non-polar O_2 molecules and the attraction of the induced dipoles to the surface of the cylindrical electrode. An electrostatic mechanism of the field effect on adsorption can also be proposed to account for the results of Hoenig and Lane[48] bearing in mind that the strength of the inhomogeneous electric field near the catalyst greatly exceeds the value calculated from the geometry of the condenser because of the roughness of the surface and is defined by the relation $E = U/Ar$,[9] where U is the external potential difference and r is the radius of individual crystallites or surface rugosities. For $U = 500$V and $r = 10^3$ nm, the energy imparted by the field to the polarised O_2 molecules exceeds their average kinetic energy in the absence of the field. As a result of this, the gas pressure in the inhomogeneous field over the catalyst surface and the degree of coverage of the latter by the adsorbate increase when an external potential is applied.

In the case of polar methanol molecules, the electroadsorption effect has different signs for different polarities of the external field in contrast to oxygen.[73] In a negative-polarity field on a silver catalyst, the degree of coverage by adsorbed methanol increases by 50%, while in a positive-polarity field it diminishes by approximately the same amount. Bearing in mind the clear discrepancy between the low field-induced charges ($e\Delta n_V = 10^{12}$ el. charge m^{-2}) and the large electroadsorption effect, the electroadsorption of methanol, like that of oxygen, must be explained by the electrostatic attraction of the dipolar alcohol molecules to the surface of the charged catalyst and not by the influence of the electronic factor. The orientation of the methanol molecules with the positive end towards the surface (the "hydrogen" orientation) apparently promotes the formation of various surface compounds of methanol, which have been detected by IR spectroscopy.[110] The increase in the partial pressure of the molecules with the "hydrogen" orientation both as a consequence of the dipolar polarisation and the attraction of the dipoles in the inhomogeneous field explains the increase in the amount of adsorbed gas in the presence of a negative-polarity field on a silver catalyst.

4. The influence of the field on catalytic reactions

Examination of the experimental data for the influence of the field on the adsorption of O_2, H_2, and methanol and water vapours on semiconductor adsorbents has shown that in some cases the observed effects can be explained by a shift of the Fermi level and a change in the concentration of free carriers under the influence of the external electric field, while in others they can be explained by secondary effects such as the relaxation polarisation of the solid and the polarisation of the gas in the vicinity of the catalyst surface. A secondary process of this kind must be taken into account also in the interpretation of the results obtained in the study of the influence of the field on the reactions occurring on semiconductors.

a) Dehydrogenation of ethanol on ZnO and the oxidation of methanol on a silver catalyst

In the study of catalytic reactions in the presence of an external field, cylindrical condensers with an air gap and a low field strength E between the plates are most often used. An exception is the study of Ivankiv et al.,[49] where a plane-parallel condenser with a mica plate, illustrated in Fig. 1*c*, permitting the attainment of $E_{max} = 3.5 \times 10^7$ V m^{-1} and $E\Delta n_V = 10^{15}$ el. charge m^{-2}, was used to investigate the influence of the field on the dehydrogenation of ethanol. The study was performed at 523 K on pressed and polished discs prepared from ZnO + 1% CuO powder. Copper oxide is apparently added to achieve a satisfactory conductivity and catalytic activity of the specimens. When a positive-polarity field was switched on, the rate of dehydrogenation of ethanol increased on the catalyst and the yield of aldehyde rose, while for a negative polarity the rate of reaction fell. The authors attribute these effects to a change in the concentration of the electron and hole gas on the surface of the semiconductor when a transverse electric field is applied. The results obtained agree with the idea that electron-accepting surface centres participate in the alcohol dehydrogenation reaction.[111] It is noteworthy that the curve relating the electrocatalytic effects to the electric field strength obtained in the above study[49] reaches a plateau (saturation) at $E = 1.5 \times 10^7$ V m^{-1} and does not change when E is increased to 3×10^7 V m^{-1}. The insignificant leakage currents (3×10^{14} electrons s^{-1}) when the rate of the catalytic reaction in the presence of the field changes (2×10^{17} molecules s^{-1}) is also evidence against a discharge mechanism of the electrocatalytic effect.

The influence of the field on the selectivity of the oxidation of methanol on a silver catalyst covered by an oxide film has been observed[74] at $T = 750$ K and very low concentrations of the field-induced charge ($e\Delta n_V = 10^{12}$ el. charge m^{-2} is smaller by three orders of magnitude than in the study of Ivankiv et al.[49]). A condenser with a cooled field electrode, illustrated in Fig. 1*g*, was used.[74] When a negative-polarity field was switched on, the yield of formaldehyde on the catalyst increased by 7–8%, while in the presence of a positive-polarity field the yield of formaldehyde fell but that of CO_2—the product of the total oxidation of CH_3OH—increased (Fig. 5). The authors explain the observed effect by a change in the concentration of free carriers on the catalyst surface. However, bearing in mind the very low concentration of the induced carriers and the results for the influence of the field on the adsorption of O_2 and CH_3OH, it would probably be more reasonable to attribute the observed electrocatalytic effects to the different reactivities of the surface compounds formed in the adsorption of methanol, with the "hydrogen" and "oxygen" types of orientation, in the partial and total methanol oxidation reactions.

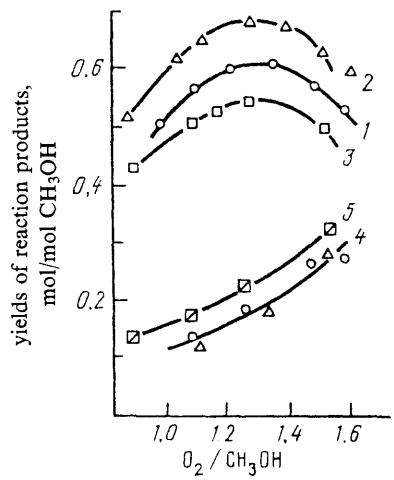

Figure 5. Dependence of the yield of methanol oxidation products on the electric potential applied to the catalyst: *1*, the yield of formaldehyde in the absence of the field; *2*, ditto on application of a field having the – sign to the specimen; *3*, ditto for a field with a + sign applied to the specimens; *4*, the yield of CO_2 in the absence of the field and on application of a field having the + sign to the specimen; *5*, ditto with the – sign of the field applied to the specimen.

(b) The oxidation of CO on NiO, ZnO, and Cu_2O

When different metal oxide films, grown on the surface of a foil by oxidation in oxygen at elevated temperatures were used, a change in the rate of oxidation of CO to CO_2 was observed in the presence of an external electric field.[75–77] In these studies, the external potential was applied between the field electrode and the metallic foil, which ensured the uniformity of the distribution of the potential along the oxide film (the design of the condenser is shown in Fig. 1*h*).

An increase in the rate of oxidation of CO by a factor of 1.5–2 and a decrease in the activation energy for the reaction by 0.21 eV after a positive-polarity field had been applied to the catalyst were observed[75] on nickel oxide obtained by heating nickel foil at 1300 °C in a stream of oxygen. A quantitative comparison of the relative changes in the rate of reaction $\Delta g/g_0$ as a function of the electric field strength, according to Eqns. (2) and (4), has been carried out.[75] Expressing the effective shielding length in terms of a series of semiconductor characteristics of NiO, the authors found that the experimental data agreed quantitatively with the theoretical relation between $\Delta g/g_0$ and E. However, it becomes clear from the comparison of the data presented[75] that the electric field strength in the vacuum gap near the catalyst surface was used as the value of E, whereas Eqn. (4) has been obtained for the electric field strength in the semiconductor at the interface with the vacuum E_n. The quantities E_n and E are linked by the relation $E_n = E/\varepsilon_n$, where ε_n is the dielectric constant of the semiconductor. Bearing in mind that $\varepsilon_{NiO} = 10$ for the field strength $E_{max} = 10^6$ V m^{-1} and $L = 3 \times 10^3$ nm employed,[73] we obtain from Eqn. (4) $V_s V_{s0} = 3 \times 10^{-3}$ eV. The experimentally observed increase in the rate of reaction by a factor of 1.5–2 as well as the decrease in the activation energy for the reaction after the application of the field by 0.21 eV do not correspond to the maximum possible shift of the surface potential, which could also be much smaller as a consequence of the transfer of the charge to surface states.

Deren and Mania[76] studied the influence of the field on the rate of oxidation of CO to CO_2 on the oxide coating of a zinc foil under the conditions of an electrode working in a non-stationary regime, whose activity gradually fell with time. After the application of a positive potential to the field electrode, a sharp increase in the rate of reaction was observed initially, but after several minutes it fell to the value corresponding to the rate of oxidation in the absence of the field. A field with the opposite polarity induces a temporary decrease in the activity of ZnO. These results led to the conclusion that there exists a limiting acceptor stage in the oxidation of CO to CO_2. The increase and then the decrease in the rate of oxidation of CO after the application of a negative-polarity field to the catalyst to values corresponding to a zero external potential is evidence against the discharge mechanism of the electrocatalytic effect. The authors explain the observed time variation by the transfer of the induced electrons to slow surface states.

The electrocatalytic effect occurs also when Cu_2O is used as the catalyst.[77] In order to elucidate the mechanism of the field effect on the catalytic activity of Cu_2O, a study was made of the possibility of the structural modification of the Cu_2O film during its growth on a copper plate at 1050 °C in the presence of a 10^6 V m^{-1} field. When a positive potential was applied to the copper plate, the layer of the Cu_2O scale acquired an increased resistance, in contrast to the copper(I) oxide formed in the absence of the field, which is associated, according to the authors,[77] with the formation of an interstitial solid solution of the excess copper ions. When a field with the opposite polarity was applied, layers of Cu_2O with an excess of oxygen, exhibiting a reduced resistance, were formed. The influence of the field on the oxidation of copper also affects the interplanar spacings in the specimens and the thickness of the oxide films. The copper(I) oxide obtained in the absence and presence of the field exhibited different catalytic properties. The Cu_2O films formed on application of a negative potential to the specimen had an increased activity in the oxidation of CO to CO_2 compared with the films oxidised with application of a positive potential. This difference increased when the reaction was carried out in the presence of a field having the same sign as that used in the formation of the film.

Thus the authors have shown that the enrichment or depletion of the oxide surface in the metal cations under the influence of the electric field may be the cause of the modification of its catalytic activity. A similar change in the defective structure of the surface may occur on NiO and ZnO specimens as a result of the migration of the cations into the region of the space charge modified by the external field. The movement of Ni^{2+} in NiO as well as that of the interstitial zinc in ZnO under conditions where the surface potential is modified by the adsorbed oxygen has been considered.[101,112] It is noteworthy that, when NiO and ZnO films were used as the catalysts, the acceleration of the oxidation of CO to CO_2 was observed for different signs of the external potential: after the application of a positive-polarity field to NiO on a foil and after the application of a negative-polarity field to ZnO. A catalytic study of oxides was carried out in the low-temperature region (180–400 °C), where the CO oxidation reaction probably has an associative mechanism.[113] According to the data of Sokolovskii et al.,[114] the decomposition of surface carbonates on ZnO proceeds with participation of the O_2^- radical-anions. The sharp rise in the catalytic activity of ZnO for a negative potential on the specimen can apparently be explained by the additional adsorption of oxygen in a charged form, which is observed (as described in the previous Section) when the field-induced charge is transferred to the surface adsorption states and also as a consequence of the relaxation polarisation of the oxide in the region of the space charge. According to Gravel',[115] the rate-limiting stage of the oxidation of CO on the NiO catalyst is the interaction of CO_3^- with the adsorbed carbon monoxide. The enrichment of the surface layers of nickel oxide in the Ni^{2+} and Ni^{3+} cations promotes the formation of carbonyl complexes and an increase in the catalytic activity of NiO.

(c) The reversible chemical modification of ZnO, TiO_2, and Pt/TiO_2 film catalysts by the electric field

A series of studies[58–71] have been devoted to the mechanism of the effect of the field on the adsorption and catalytic properties of thin ZnO, TiO_2, and Pt/TiO_2 films deposited on the inner surface of a Pyrex reactor (see the condenser illustrated in Fig. 1*f*). The influence of the field on the rate of decomposition of isopropyl alcohol,[58] the oxidation of CO by NO and O_2,[60] the decomposition of NO[60] and water vapour,[61] and the adsorption of O_2,[59,62] H_2,[61] and CO[62] has been observed. The results have been explained from the standpoint of the electronic theory of catalysis with participation of charged intermediate compounds in the catalytic processes.

In order to test the mechanisms of the field effect, the above reactions were reproduced in a quartz reactor (Fig. 1*f*) and also in experiments using a plane-parallel condenser with a mica plate as the dielectric (Fig. 1*b*). For comparable field-induced charges, the changes in the conductivity of the film ($\Delta\sigma_V$) deposited on mica did not exceed several per cent of the initial conductivity of the specimen, the shift of the Fermi level was less than $0.1kT$, and the influence of the field on the adsorption of oxygen and on the rate of oxidation of CO and of the decomposition of NO were not observed.[57]

In a glass reactor at temperatures in the range 130–160 °C, changes in the conductivity of the ZnO, TiO_2, and Pt/TiO_2 films, which were anomalously high for the field effect method, were obtained for a positive potential applied to the field electrode. For

an initial specific conductance $\sigma_0 = 10^{-11}$–10^{-10} Ω, referred to a unit surface of the specimen, the relative changes $\Delta\sigma_V/\sigma_0$ reached 10^4–10^5 and the activation energy for electrical conduction fell from 0.7–0.9 to 0.1–0.2 eV.[67] The ZnO, Pt/TiO_2, and TiO_2 films retained a low resistance state for several tens of hours after the field had been switched off, exhibiting at the same time a "memory effect" with respect to the action of the field on chemisorption and catalytic processes. However, their transition to the low resistance state was reversible. The application of a negative potential to the field electrode as well as heating to a high temperature resulted in the return of the resistance of the films and of their chemisorption and catalytic properties to the initial values. The results of the measurements of the condenser charging and discharge currents under conditions of the application of fields with the opposite polarity and thermally stimulated depolarisation, also confirming the reversibility of the change in the state of the film catalyst after thermal field treatment, have provided a basis for explaining the observed effects in terms of the relaxation polarisation of the Pyrex glass, which has the properties of a thermoelectret.[63] The thermoelectrisation of the dielectric[116] may be caused both by the formation of dipoles and by the separation of charges in the electret during the migration of current carriers (for example, Na^+ ions in Pyrex glass).

In order to elucidate the possibility of the transfer of sodium from the support to the semiconductor film, the electron diffraction and oxygen absorption methods as well as the method involving the titration of the absorbed oxygen with carbon monoxide were used. It was shown that the passage of a charge through the condenser is accompanied by the electrolytic migration of sodium from the dielectric glass support and its deposition on the surface of a semiconductor film as a finely dispersed metallic phase.[64–66] Thus the earlier results for the influence of the field on adsorption and catalysis can be explained by the surface doping of the oxide films with sodium. The adsorption of oxygen with application of a positive potential to the field electrode takes place as a consequence of the interaction of oxygen with sodium accompanied by the formation of the compounds NaO_2, Na_2O_2, and Na_2O. When sodium superoxide and peroxide are heated, they decompose with evolution of oxygen, the maxima in the thermal desorption spectrum being observed at 370 and 520 K.[65] The decrease in the adsorption capacity of the oxidised TiO_2 film relative to hydrogen after the preliminary application of a positive-polarity field to the field electrode[61] can be explained by the blocking of the hydrogen adsorption centres by sodium atoms.[117] The cause of the evolution of hydrogen when water vapour is admitted into the system after the latter had been exposed to the field is evident:[71] hydrogen is displaced from H_2O by sodium, which binds strongly to the oxygen of the water molecule.

The increase in the rate of absorption of a stoichiometric mixture of O_2 and CO and the simultaneous inhibition of the CO oxidation reaction on ZnO films on application of the field[68] can be explained by the interaction of CO and CO_2 with sodium oxides and the formation of Na_2CO_3. The blocking of part of the ZnO surface by these compounds reduces the steady-state rate of oxidation of CO by a factor of 2–3, while the activation energy and the reaction orders remain unaltered. At the same time, the electrophysical parameters of the ZnO film working under stationary conditions differ greatly from the initial values after the application of the field as a result of the interaction of part of the sodium with the oxygen of the crystal lattice (the activation energy for electrical conduction diminishes from 0.65 to 0.17 eV). Hence it is concluded that the concentration of the conductivity electrons is not the parameter controlling the rate of oxidation of CO on ZnO films.

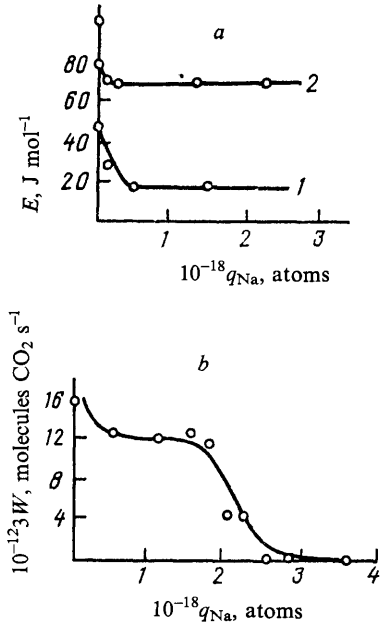

Figure 6. Dependence of the activation energy for electrical conduction in the Pt/TiO_2 film on the amount of Na introduced (*a*) and dependence of the rate of oxidation of CO on the Pt/TiO_2 film (~4 wt.% Pt) on the amount of electrodeposited Na (*b*): *1*, *in vacuo*; *2*, in the presence of the $2CO + O_2$ stoichiometric mixture ($p_{2CO+O_2} = 0.72$ Pa).

In order to elucidate the role of the contact fields between the active phase and the carrier in chemisorption and catalytic processes, the effect of the field on a deposited Pt/TiO_2 catalyst was investigated.[69,70] The transfer of sodium from the support to the surface of the Pt/TiO_2 film is accompanied, as in the case of TiO_2, by a sharp decrease in the activation energy for the electrical conduction of the film at low levels of doping. The activation energy does not change on further increase in the concentration of the added sodium (Fig. 6*a*, curves *1* and *2*). The change in the catalytic properties of the Pt/TiO_2 system on doping with sodium is not correlated with the change in the activation energy for electrical conduction (Fig. 6*b*) and is observed at higher concentrations of added sodium where, according to the conditions in the preparation of the sodium-modified deposited platinum catalyst, the chemical interaction between sodium and platinum becomes possible.[70] This permits the conclusion that the position of the Fermi level in the carrier and the associated contact phenomena at the metal–semiconductor interface do not play an appreciable role in the catalytic process on platinum.

When quartz is used as the dielectric, a similar pattern in the variation of the electrical conductivity and in the catalytic and chemisorption properties of TiO_2 film is observed, but with the

electric field applied at a higher temperature (~530 K) than for Pyrex (430 K), this being associated with the reduced sodium content in quartz.[71]

It is of interest to note that, when a field with a positive polarity is applied to the field electrode during the oxidation of CO to CO_2 on ZnO and Pt/TiO_2 films, the catalysts are not poisoned irreversibly by compounds formed by sodium with O_2, CO, CO_2, and Pt. For standard conditioning at 750 K, these compounds decompose with evolution of CO and CO_2 to the gas phase and the sodium oxide particles remaining on the surface react chemically with the glass, fusing with the latter, as a result of which the catalytic activity of the film returns to its initial value (before the application of the field). The reversible character of the interaction of sodium with the oxides ZnO, TiO_2, and Pt/TiO_2 makes it possible to return the catalytic and adsorption characteristics of these catalysts to the initial values by applying a field with the reverse polarity. This makes it possible to use an external electric field to regulate the rates of catalytic processes in which metallic sodium exhibits a satisfactory activity or is a promoting additive.

At elevated temperatures (from 670 to 720 K), glass begins to play the role of a solid electrolyte and the metal–glass–conducting catalyst film system, in which the metal is exposed to air and the catalyst is placed in the gas investigated, constitutes an electrochemical cell. As a result of adsorption and absorption processes on the metal, glass, and the catalyst, electrode potentials arise between the gas electrodes. They depend on the nature of the catalyst and the gas investigated.[118,119]

The influence of polarisation on the rates of catalytic hydrogen oxidation and ammonia synthesis reactions has been investigated.[120,121]

(d) The influence of an alternating field on the oxidation of CO on NiO and the hydrogenation of ethylene on ZnO

It has been suggested[122] that an alternating external field be used as the basis of a method for the investigation and regulation of heterogeneous catalytic reactions on semiconductors. The possibility of the adsorption of gas molecules for one polarity of the alternating field and of their desorption for the other as a function of the donor–acceptor properties of the gas has been considered.[122] The author[122] called this phenomenon alternosorption. The use of an alternating field makes it possible to control the time during which the species are present on the catalyst surface. Whilst studying the dependence of the rate of reaction on the frequency of the external field, it is possible to determine the optimum time for the elementary step in the oxidation-reduction catalytic process.

The influence of a sinusoidal 2.2×10^6 V m^{-1} external field on the rate of oxidation of CO to CO_2 has been investigated at 123 °C.[123] Nickel discs coated by a layer of NiO 10^3 nm thick, separated from one another by ceramic plates, were used as the catalyst. In the frequency range from 50 to 300 Hz, the rate of oxidation of CO increases severalfold and passes through a maximum located between 100 and 200 Hz. Hence it was concluded that the time during which the adsorbed species are present on the catalyst surface is between 5 and 10 ms.

The influence of the alternating electric field was investigated in greater detail in the hydrogenation of ethylene on a ZnO specimen.[124] A polycrystalline zinc oxide powder was placed between two field electrodes to which an alternating potential was applied (see the condenser illustrated in Fig. 1*d*). When a 1.2×10^5 V m^{-1} sinusoidal potential was switched on in the temperature range from 60° to 146 °C, a change in the reaction orders with respect to hydrogen and ethylene and a decrease in the activation energy from 71 to 48 kJ mol^{-1} were observed. The authors were unable to establish the mechanism of the action of the field, but noted that it may be associated with induction heating or a discharge, because the rate of reaction decreased in the presence of the field.

This study is of interest because of the methodological approach to the selection of the condenser design. A design was selected which does not require specially prepared film catalyst specimens and ohmic terminals on them, the longitudinal alternating field being applied directly to the polycrystalline powdered semiconductor, (Fig. 1*d*). The polycrystalline specimens consisted of a multiplicity of crystallites loosely adjoining one another and having a large number of contacts. The equivalent electric circuit of such specimens consists of a combination of a series of active resistances and capacitances. A theoretical model of the barrier conductivity of polycrystalline films taking into account the change in the filling of the surface states at the boundary between the crystallites, when the height of the barrier was altered by application of an external electric field, was examined.[125] The application of an alternating field to the polycrystalline semiconductor entails an alternation of the charges of the contact capacitances accompanied by the filling and emptying of the surface traps located in the boundary regions of the crystallites.

According to the donor–acceptor mechanism of adsorption and charging, the role of the effective electron and hole traps on the surface of the semiconductor is assumed by electron-accepting and electron-donating centres forming surface complexes with the molecules adsorbed on them. The participation of the main centres and also of the ion pair, consisting of a coordinatively unsaturated cation and an oxygen ion, in the activation of adsorbed ethylene and hydrogen during the hydrogenation of the former was examined by Minachev et al.[126] Apparently the mechanism of the influence of the alternating field on the kinetics of the hydrogenation of ethylene is determined by the change in the filling of these centres by free carriers.

IV. Conclusion

This review has examined studies in which changes were observed in the concentration of the charged form of the chemisorbed species, in the coverage of the surface by the adsorbent, and in the rates of catalytic reactions on application of an electric field at right angles to the surface of the catalyst using various methods: conductimetric, field effect, gravimetric, volumetric, and mass-spectrometric analysis of the gas.

Various designs of the condensers, in which the field strength and hence the charge induced in the semiconductors varied within wide limits (from 10^{12} to 10^{16} el. charge m^{-2}), were used for this purpose. The estimates of the change in the surface potential following the application of the field, obtained in the present review, show that even at the highest concentration of the induced charge, amounting to 10^{16} el. charge m^{-2}, the quantity $V_s - V_{s0}$ on polycrystalline specimens does not exceed tenths of kT. In almost all the studies of the influence of the field on catalytic reactions, the induced charge $e\Delta n_V = 10^{12}$–10^{13} el. charge m^{-2} and the corresponding shifts of the surface potential are negligible ($\ll kT$). Thus, owing to the high density of the surface states, the possibilities of the field effect method for discovering the role of the collective factor in semiconductor catalysis are extremely limited.

The authors explained the results obtained in terms of a change in the filling of the active surface centres by free carriers. Under conditions where almost all the field-induced charge passes to the surface states and the shift of the Fermi level is negligible, the changes in the local properties of the surface under the influence of the captured charge carriers come to the fore. In Vol'kenshtein's theory, the electrons and holes on the semiconductor surface play the role of free valences; their direct involvement in the formation of a bond converts the adsorbed molecules into radicals with an increased reactivity. In the donor–acceptor model of adsorption and charging,[21] the more probable and general case of the deformation of the adsorbed complex in the Coulombic field of the captured charge carrier is considered. This increases the amount of ionic character of the bond and the probability of the dissociation of the molecule. It has been shown[109] that the capture of free carriers by adsorbed states is accompanied by the evolution of the excess energy, which is dissipated in the vibrational modes of the adsorbed molecules, which can also stimulate their dissociation or desorption.

Various secondary effects, i.e. effects not associated directly with a change in the concentration of the free carriers, introduce some uncertainty into the interpretation of the results for the influence of the field on adsorption and catalysis. Essentially, only the change in the chemisorption and catalytic properties of semiconductors following the application of the electric field has been established in the majority of studies, while the question of the mechanism of the action of the field remained open. In the review much attention has therefore been devoted to the most probable mechanisms of chemisorption and catalysis in the presence of the field for the given catalytic systems and associated with the occurrence of a series of physicochemical processes, among which the influence of the relaxation polarisation of the dielectric and of the surface layers of the semiconductor must be specially emphasised.

It is suggested in the electronic theory of catalysis that the field effect method can shift the Fermi level and can alter the concentration of electrons and holes on the semiconductor surface without changing the chemical composition of the catalyst. This point of view is in general incorrect because the application of an external field to defective structures such as polycrystalline semiconductor films and dielectric supports at elevated temperatures (>400 K) is accompanied by the migration of weakly attached ions through space and the establishment of a new electronic–ionic equilibrium. The defective structure and the chemical composition of the catalyst surface are modified as a consequence of this.

It has been established[64–66] that the surface doping of film catalysts with sodium atoms deposited electrolytically from a sodium-containing glass support having the ionic type of conductivity can be achieved with the aid of an external field. The alkali metals sodium and potassium on a carrier exhibit a satisfactory catalytic activity,[127,128] but they are of even greater interest as promoting additives to deposited metallic catalysts.[129,130]

Electrodeposited sodium is introduced onto the surface in the atomic form and exists on it in a finely dispersed metallic state.[65,66] It is of interest to investigate in reducing media the catalytic activity of finely dispersed metallic sodium and of the intermetallic compounds formed when sodium interacts with the active metallic phases of the deposited catalyst. Bearing in mind that, as a consequence of the reversibility of the interaction of sodium with oxides, its surface content can be varied smoothly in either direction and that the amount of electrodeposited metal can be easily evaluated coulometrically, the doping method proposed[64–71] must be recognised as a convenient procedure for the preparation of model film catalysts. The use of other metal-containing glasses makes it possible to extend the class of metallic doping additives.

A series of other physicochemical phenomena, which are apparently responsible for the mechanisms and may be used to regulate adsorption and catalytic processes, have been considered in this review. They include the following.

1. The change in the concentration of polar molecules with a definite type of orientation in strong inhomogeneous local fields near the catalyst surface. The inhomogeneous fields arising as a result of the greater curvature and roughness of the catalyst surface relief may alter both the rate and the selectivity of the catalytic process.

2. The involvement in the catalytic processes of the "hot" electrons arising when a current flows in MOM and MDS structures. As a result of the excess kinetic energy of the "hot" electrons, there is a possibility of the activation of the reactants chemisorbed on the catalyst or of the desorption of the reaction products and hence of the acceleration of the catalytic reaction.

3. The change in the chemical composition of the surface layers of the catalyst in an external electric field. The modification of the defective structure as a result of the increase or decrease in the concentration of cations near the catalyst surface alters the probability of the formation of different surface compounds and can be used in the study of the mechanisms of catalytic processes.

The study of the influence of an alternating field on catalytic reactions is promising. When an alternating field is employed, there is no need to assemble a special condenser, since there are many contact capacitances in the polycrystalline specimen itself at the boundary between the crystallites. When a sinusoidal potential is switched on, the contact capacitances undergo alternating changes in charge and there is a multiplicity of steps involving the capture of free carriers by the surface states arising in the interaction of the adsorbed molecules with the electron-accepting and electron-donating centres on the semiconductor surface, which may entail the deformation of the intramolecular bonds and a change in the reactivity of the adsorbed molecules. Additional physicochemical methods (IR spectroscopy, thermal desorption) can be used to investigate the adsorption and catalytic processes occurring in the presence of an alternating field.

In conclusion one must say that, although the prediction of the electronic theory that the field effect method would prove promising in the study of the elctronic factor in catalysis has not come true, nevertheless an external electric field can be used effectively for the regulation of the chemisorption and catalytic activities of semiconductor catalysts. The different physicochemical processes occurring when an electric field is switched on may stimulate adsorption and catalytic reactions.

Catalytic decomposition of organic and organoelemental peroxides in the presence of electron donors and electron acceptors

N V Yablokova, Yu A Aleksandrov
Scientific-Research Institute of Chemistry, Lobachevskii Gor'kii State University

ABSTRACT. The main characteristics (the kinetics and mechanism) of the radical decomposition of organic and organoelemental peroxides in the presence of active electron-donor and electron-acceptor components in alkanes and polymerising media are discussed. The decisive role of the formation of complexes of peroxides with active catalytic components and olefins in these processes is shown. The formation of triple complexes of monomer–Lewis acid–olefin plays an important part in the initiation of radical polymerisation. Examples of the practical application of the initiating systems peroxide–electron donor and peroxide–electron acceptor are given.

I. Introduction

During the last 15–20 years research into radical polymerisation has undergone a real transformation; new ideas and possibilities have appeared, adding fresh impetus to this well-known process.[1–4]

One of the current and future trends is radical-complex polymerisation using chemical activation agents that participate in radical polymerisation.[4–11] Radical-complex polymerisation in essence consists of the directed change in reactivity of monomers and growing radicals that participate in chain propagation by using complexing agents (Lewis acids, proton acids), which results in catalytic acceleration (or selective inhibition) of this stage of the radical chain process.

In 1957 it was found[5] that the rate and degree of radical polymerisation of acrylonitrile (AN) increased in the presence of small quantities of LiCl. The increase in rate of the reaction was attributed to the interaction of the nitrile group in the AN monomer and radical with LiCl. It was recorded in subsequent studies[6–12] that there was an increase in the rate of radical homo- and co-polymerisation of the vinyl monomers methyl methacrylate (MMA) and AN in the presence of inorganic salts (LiCl, $MgCl_2$, $ZnCl_2$, $AlCl_3$, $AlBr_3$, $SnCl_4$) that are capable of forming coordinate complexes with functional groups (C=O and C≡N) in the reacting monomers and radicals.

Another trend of research is to improve the polymerisation processes by means of the chemical action of effective initiators on the fundamental initiation stage.[1,2] This idea consists of the possibility of controlling the reactivity of the initiator through its specific interaction with active donor or acceptor components which accelerate the radical decomposition of the initiator and cause it to be effective over a required range of temperature. Olefins, amines, phosphates, phosphites, sulphides, and other compounds have been used as electron donors while Lewis acids, PCl_3, and SO_2Cl_2 have been used as electron acceptors. The formation of complexes between peroxides and electron donors or electron acceptors leads to a change in the electronic configuration of the peroxide and hence its capacity to generate radicals.[13–16]

II. Effect of electron donors on the decomposition of peroxides and initiation of radical polymerisation

Binary donor–acceptor systems which have an organic peroxide as one of the components have attracted the attention of research workers for a long time because of the possibility of using them as effective initiators of radical polymerisation.[17–22] A necessary condition for such a system to function is its ability to generate radicals within the required range of temperature at a rate desirable for the process. A sufficient condition is high activity of the radicals formed, capable of initiating a radical process. It has been shown by various methods[13–16,19,20] that at the primary stage a complex is formed with charge transfer between the components of the donor–acceptor system.

A general mechanism for the radical initiation of polymerisation of different monomers by the system organic peroxide–amine (A) with low degrees of conversion[18] may be given by the following scheme:

$$P \rightleftarrows [R^{\cdot}\,R^{\cdot}] \rightarrow 2R^{\cdot},$$

$$P + A \rightleftarrows [P...A] - \begin{cases} \longrightarrow [R^{\cdot}...A] + R^{\cdot} \\ \longrightarrow \text{heterolysis} \end{cases}$$

$$[R^{\cdot}...A] - \begin{cases} \longrightarrow R^{\cdot} + A \\ \xrightarrow{M} RMA^{\cdot} \\ \xrightarrow{H} RH + A^{\cdot} \end{cases}$$

$$R^{\cdot} + M \rightarrow RM^{\cdot},$$

M – monomer

The formation of complexes between amines and peroxides was demonstrated by UV, IR and NMR spectroscopy in the same study.[18] From a quantitative study of the effect of acids and bases on the kinetics of the decomposition reactions of peroxide in the presence of amines in different media it was proposed that a complex

of amine–peroxide–solvent was formed. Amines (aminoacids) have a considerable effect on the kinetics of radical polymerisation of vinyl monomers, namely, on the rate of initiation and the ratio of chain growth constant to chain termination constant ($k_g/k_t^{1/2}$). When aromatic amines interact with organic peroxides the primary reaction in the initiation system peroxide–amine is formation of a complex between the components.[20–22] The complexing agent activates the peroxide molecule and assists the generation of radicals at a high rate within the required range of temperature. A primary complex was detected in benzoyl peroxide–aromatic amine systems at 243–253 K. The formation of benzoate free radicals was established by means of EPR using a spin trap (phenyl t-butyl nitrone).

The presence of a heteroelement in organoelemental peroxides of composition $R_{n-1}EOOR'$ makes them have a greater tendency to coordinate compared with organic peroxides. Their conversion routes in an inert solvent or polymer systems are much more complex than for organic peroxides. Reactions (1)–(7) are possible conversion routes for organoelemental peroxides in radical polymerisation processes:

$$R_{n-1}EOOR' \rightarrow R_{n-1}EO^{\cdot} + {}^{\cdot}OR', \quad (1)$$

$$R_{n-1}EOOR' \rightarrow R_{n-2}E(OR)OR', \quad (2)$$

$$R_{n-1}EOOR' \rightarrow R_{n-1}EOH + R'_{-H}O, \quad (3)$$

$$R_{n-1}EOOR' \rightarrow [R_{n-2}E{=}O] + R'OH \text{ (if one of } R = H), \quad (4)$$

$$R_{n-1}EOOR' + SH \rightarrow R'OH + [\overline{R_{n-1}EO^{\cdot}S^{\cdot}}] \quad (5)$$

$$\downarrow \qquad\qquad \downarrow$$

$$R_{n-1}EOS \qquad R_{n-1}EO^{\cdot} + S^{\cdot}$$

$$R_{n-1}EOOR' + D \rightleftarrows [R_{n-1}EOOR'.D] \rightarrow [R_{n-1}EO^{\cdot}.D] + {}^{\cdot}OR', \quad (6)$$

$$R_{n-1}EOOR' + R''E' \rightarrow R''_{n-1}E'OR' + [\overline{R_{n-1}EO^{\cdot}\ {}^{\cdot}R''}] \quad (7)$$

$$\downarrow \qquad\qquad \downarrow$$

$$R_{n-1}EOR'' \qquad R_{n-1}EO^{\cdot} + {}^{\cdot}R''$$

SH – solvent, D – donor.

Reaction (1) is the homolytic decomposition of peroxide to radicals that are responsible for initiating radical processes. An actual polymerisation or vulcanisation system is a complex multi-component mixture in which the peroxide can participate not only at the stages of initiation and chain growth but also in side reactions. For example, reactions of spontaneous non-radical conversion of peroxides[23–25] [reactions (2)–(4)] are in a number of cases fundamental for organoelemental peroxides, and the initiator then has little effect on radical polymerisation.

Reactions (5)–(7) are processes for generating radicals in bimolecular reactions with the solvent,[26] donor electrons,[13,14] or organoelemental compounds[27–30] when the latter are present in the reaction system.

During polymerisation of MMA, butyl methacrylate (BMA), or styrene, some complexing agents—electron donors—can produce a substantial change in initiating activity of organoelemental peroxides, accelerate radical polymerisation or copolymerisation, and also have an effect on the composition of the copolymer.[31–33] The activation effect on the decomposition of organoelemental peroxides in olefins is due to the formation of a donor–acceptor complex of olefin–organoelemental peroxide, which decomposes to radicals at a higher rate than does pure peroxide in an inert solvent.

$$R_{n-1}EOOR' + \rangle C{=}C\langle \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \left[\rangle C{=}C\langle \cdots R_{n-1}EOOR' \right] \xrightarrow{k_2} \left[\rangle C{=}C\langle \cdots R_{n-1}EO^{\cdot} \right] + R'O^{\cdot}$$

Organosilicon peroxides $R_{4-n}Si(OOBu\text{-}t)_n$, where n = 1–4, R = Me, CH_2 = CH, form similar complexes with acrylic monomers. Coordination occurs between the unshared electron pair of the carbonyl oxygen in the monomer an the vacant *d* orbital of silicon in the peroxide.

The formation of a complex of $Me_3SiOOBu\text{-}t$ with MMA and BMA in hexane and benzene in the temperature range 193–293 K was demonstrated by ^1H NMR spectroscopy from the change in chemical shifts of the protons of the MeO groups in MMA or the *cis*-protons of the $CH_2{=}C$ group in the monomers on changing the concentration of peroxide.[15] By measuring the chemical shifts of the protons it was possible to determine the equilibrium constants and enthalpies (ΔH) of complex formation. The displacement of the proton signals downfield is an indication that the monomers act as electron donors in the complex.

It should be noted that even t-butyl peroxide (TBP) forms a complex with MMA or BMA.[34] Measurements were made by monitoring the variation in the difference between the chemical shifts of the *cis*- and *trans*-olefinic protons in MMA (internal chemical shift ν). The concentration of TBP was varied at a fixed concentration of MMA. Addition of peroxide caused a decrease in ν in MMA by a value of Δ. The latter is dependent on the concentration of peroxide (C_n):[35]

$$\frac{1}{\Delta} = \frac{1}{K\Delta_c}\frac{1}{C_n} + \frac{1}{\Delta_c},$$

where K is the equilibrium constant for formation of complex, Δ_C is the chemical shift of complex.

It was possible to determine complexes of TBP and $Me_3SiOOBu\text{-}t$ with MMA and BMA at temperatures below 253 K.[15,34] The equilibrium constants for formation of these complexes are small, and for the MMA–TBP complex they vary from 0.22 to 0.1 over the temperature range 193–253 K while for the MMA–$Me_3SiOOBu\text{-}t$ complex the variation is 1.3 to 0.25 over the temperature range 213–253 K. The values of δH for these complexes are equal to 6.0 ± 0.3 and 23 ± 3 kJ mol^{-1} respectively. Hence organosilicon peroxides form stronger complexes with monomers than do organic peroxides, which is due to the presence in the organosilicon peroxides of an active acceptor site on the silicon atom (vacant *d* orbital).

The complexing agent activates organoelemental peroxides (the peroxide band is weakened), and the rate constant for decomposition of the peroxide bonded to the monomer in the complex is increased. For example, $Me_3SiOOBu\text{-}t$ decomposes in nonane at 373 K with a rate constant (k) equal to 2×10^{-9} s^{-1} (calculated from published data[36]), whereas in BMA the value of k increases by a factor of 1000 and has a value of 2.4×10^{-6} s^{-1}.[37] The energy of activation of the decomposition processes on changing from nonane to BMA falls from 159 to 75 kJ mol^{-1}. A similar pattern occurs for all organoelemental peroxides of the series $Me_{4-n}Si(OOBu\text{-}t)_n$ on changing from an inert solvent to a polymerisable olefin (MMA, BMA).

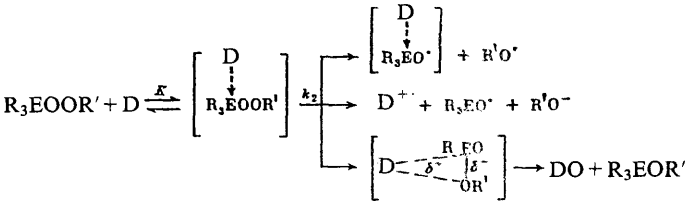
The formation of a donor–acceptor complex of monomer with an organoelemental peroxide is responsible for the increase in rate of decomposition of the peroxide and hence an increase in the rate of initiation of polymerisation. In one study[15] the rate of polymerisation of different vinyl monomers initiated by organosilicon peroxides is given. As the number of peroxide groups in organosilicon initiator molecule increases, the rate of polymerisation of the vinyl monomers MMA, BMA and styrene increases disproportionately to the number of peroxide groups, which is an indication of the different reactivity of the latter in the $Me_{4-n}Si(OOBu\text{-}t)_n$ molecule.

The polymerisation of vinyl monomers initiated by organosilicon peroxides is a radical process since its rate is proportional to the concentration of initiator to the power 0.5, and when the stable radical 2,2,6,6-tetramethyl-1-piperidinoxyl [$C_0 = 1-6 \times 10^{-5}$ mol litre^{-1}] is introduced into the polymer system, inhibition that is typical for a radical process occurs, the magnitude of the induction period being proportional to the concentration of the inhibitor.

Thus, organosilicon peroxides that generate radicals in an inert solvent at 423–473 K, owing to the formation of a complex with monomer, are capable of initiating radical polymerisation within the temperature range 353–373 K.

The ability of organoelemental peroxides to form complexes with olefins, as shown above, led to the assumption that they had a potential effect on the composition of copolymers during copolymerisation.[15,16] It was shown that the relative reactivities of monomers vary when copolymerisation is carried out in the presence of organosilicon peroxides. This could be accounted for by the formation of complexes of silicon peroxides not only with monomers but also with the growing radicals, while the latter effect is probably more important because of the small quantity of peroxide in the reaction system.

Table 1. Stability constants and enthalpies of formation for 1 : 1 R_3EOOR'·ligand complexes at 298 K.[32]



Peroxide	Ligand	$-\Delta H$, kJ mol^{-1}	K^*
$Si(OOBu\text{-}t)_4$	C_5H_5N	29.06	1.96
$Et_3(SnOOBu\text{-}t)$	C_6H_{12}	6.99	0.054
	$Ph_2C{=}CH_2$	11.40	0.055
	$PhCH{=}CH_2$	10.80	0.052

$Et_3SnOOCMe_2Ph$	C_5H_5N	21.5	0.88

*Solution with concentration 1 mol litre^{-1} chosen as the standard state.

It is not only the monomer itself that is capable of activating organic peroxides or organoelemental peroxides to form donor–acceptor complexes with them but other electron donors (amines, ethers, phosphates, sulphides) can also accelerate the decomposition of peroxides and increase the proportion of homolytic cleavage of the peroxide bond. In a number of studies[14,16,31–34,38–45] kinetic and activation parameters are given for the decomposition of organic peroxides and organoelemental peroxides of silicon, germanium, and tin in the presence of various donors (D). It was established by kinetic, thermochemical, and ^{1}H NMR spectroscopic methods[31,32,38–45] that the primary stage of the decomposition of peroxides in the presence of D is formation of a complex between peroxide and D [reaction (6)]. This stage was detected by means of calorimetry at 298 K [31,32] and also kinetically at the decomposition temperatures of the peroxides[38–43] and the values of K and ΔH of the peroxide–donor complexes were determined (Tables 1 and 2). The degree of charge transfer in the complexes $Si(OOBu\text{-}t)_4-C_5H_5N$ and $Et_3SnOOBu\text{-}t-C_5H_5N$ is 0.2 and 0.1 respectively.

In order to determine which of the atoms (E or O) is coordinated to D, ^{1}H NMR spectroscopy was used to study the change in chemical shifts of the protons of the Me_3C and Me_3Sn groups in the peroxide $Me_3SnOOBu\text{-}t$ in the presence of D.[45] For comparison the chemical shifts of the protons in TBP were determined in relation to the composition of the solution.[45] Gorbatov et al.[45] were able to maintain from the results obtained that coordination of D occurs on the tin heteroatom. From the nature of the change in the chemical shift in the system peroxide–chloroform (electron acceptor) it may be concluded that the latter forms a complex with both $Me_3SnOOBu\text{-}t$ and TBP, and the coordination occurs on the peroxide bond, more precisely, on the oxygen atom of the peroxide bond that has highest electron density.[46]

At the rate-limiting stage of the decomposition of the complex between peroxides and donors, either displacement of electron density along a system of σ-bonds (olefins, ethers, phosphates) or with transfer of an electron (amines, sulphides, phosphites), which assists homolysis of the peroxide, or the transfer of two electrons in a heterolytic S_N2 process (sulphides, phosphites) occurs:

If the equilibrium constant K is small, the proportion of peroxide decomposing outside the complex with rate constant k_1 may be significant:

$$R_3EOOR' \xrightarrow{k_1} R_3EO^{\cdot} + R'O^{\cdot}.$$

if [D] ≫ [organoelemental peroxide], the experimentally determined rate constant for decomposition of organoelemental peroxide (k_{exp}) is calculated from the equation:

$$k_{exp} = \frac{k_1 + k_2K[D]}{1 + K[D]},$$

where k_2 is the decomposition constant for the peroxide–donor complex. The values of k_1, k_2, K, and ΔH for certain complexes are given in Table 2.

If follows from an analysis of these results that the proportion of the peroxides bonded to the complex is small and depends on the nature of the peroxide and the basicity of the ligand. Organosilicon peroxides that have a lower capacity for complex formation mainly decompose outside the complex. Organotin monoperoxides and organosilicon polyperoxides, which have greater acceptor properties relative to D, decompose in the presence of D both in the form of a complex ($k_2 \gg k_1$) and without it.

Table 2. Values of k_1, k_2, and K for peroxide–donor complexes.

III. Effect of electron acceptors on the decomposition of peroxides in alkanes and polymerising media

1. Reactions of organoelemental compounds with peroxides

The published data[28–30,47–51] on the reaction of organoelemental compounds with peroxides indicate that the systems organoelemental compound–organic peroxide and organoelemental compound–organoelemental peroxide have potential use as radical sources. The tendency to associate and form complexes is a characteristic feature of organoelemental compounds of lithium, magnesium, cadmium, etc. Therefore in reactions of organoelemental compounds of Groups I and II with peroxides the role of coordination interactions of the organoelemental reagent is displayed particularly clearly. A peroxide-base affects the organoelemental compound in several ways: it decreases the degree of association of the initial compound, increases the polarity of the C–E bond, and probably assists the transfer of an electron from the C–E bond to the peroxide bond.[52] As a result of this a radical pathway is the main one for the reaction of organoelemental compounds of Groups I and II with peroxides and a scheme for the process including coordination and association of the reactants may be represented in the following way:[28]

$$(R_nE)_x + R'OOR'' \rightleftarrows [(R_nE)_y \cdot R'OOR''] \rightleftarrows [(R_n\overset{e}{\overbrace{}}E)_y \cdot R'O\overset{e}{\overbrace{}}OR''] \rightarrow$$
$$\rightarrow \begin{bmatrix} R^{\cdot} & R_{n-1}E^{+} \\ R'O^{\cdot} & R''O^{-} \end{bmatrix} (R_nE)_{y-1} \rightarrow (\overline{R^{\cdot}\ \ OR'})\,(R_nE)_{y-1} + R''OER_{n-1}$$
$$\downarrow \qquad\qquad \downarrow$$
$$(R_nE)_{y-1} + R^{\cdot} + {}^{\cdot}OR' \qquad ROR' + (R_nE)_{y-1}\ .$$

This scheme is based on a single-electron transfer (SET) mechanism, which has been demonstrated by chemically induced polarisation of nuclei. However, the detection of radicals using this method does not provide a basis for the assumption that the whole process is radical since the effect of chemical induced polarisation of nuclei can occur even when the contribution of a radical route is small.

Not all reactions of organoelemental compounds or organoelemental peroxides can be expected to occur by a common mechanism since organoelemental compounds differ according to their degree of association in the initial state, the polarity of the E–C bond, and their ability to coordinate with electron donors. The probability that a SET mechanism will occur should increase as the ionic character of the E–C bond increases.[49]

The suggestion that the reactions of alkyl peroxides with alkyls of Group III elements are radical in character was put forward about 30 years ago.[53,54] The proof of this was subsequently obtained,[55] when it was shown that Et_3B reacts with $EtOOBEt_2$ in benzene in the absence of oxygen to form ethane, ethylene, butene, ethylbenzene, etc. It was also established that this system induces the radical polymerisation of MMA.

Quite recently when R_3Al (R = Alk, Ar) was reacted with t-$BuOOER_3$ (E = C, Si, Ge, Sn) it was possible by means of a spin trap (2-methyl-2-nitrosopropane) to detect the radicals $R^{\cdot}$ and $R_3EO^{\cdot}$,[56,57] the existence of which had previously been postulated.[58–60]

At the present time it is taken as proven that the primary reaction in the interaction of peroxides with organoelemental compounds of Groups I–III is complex formation:[61–63]

$$R_nE + R'OOR'' \rightleftarrows [R_nE \cdot R'OOR'']. \qquad (I)$$

In a number of cases these complexes have been isolated and characterised. For example, the formation of complexes between alkyllithium and organic peroxides was established kinetically.[61] The existence of the complexes n-$Bu_3B.Me_3COOCMe_3$ and n-$Bu_3B.Me_3SiOOCMe_3$ in hexane at −196 °C was demonstrated by electronic emission spectroscopy.[46,64] It was established that the alkylborane is coordinated with the oxygen atom of the Me_3CO residue.

The question then arises as to which mechanism is followed in the conversion of the complex formed and which factors are responsible for it generating radicals? How is the energy that is necessary for the homolysis of the E–C and O–O bonds, and also possibly the C–O bond, redistributed in it?

Alyasov et al.[29] considered that $Alk_3B.t\text{-}BuOOEr_3$ (E = C, Si, Be) complexes do not generate radicals in the absence of radical acceptors (solvent, monomer, halocarbon). In the absence of radical traps, radicals may possibly still be formed but they are destroyed in the solvent cage and the escape of free radicals into the main volume is negligible. Probably a radical acceptor in the reaction system is "built on" to complex (I) in such a way that in the activated state an energetically and sterically favourable structure occurs, in which all three components—peroxide, organoelemental compound, and radical acceptor stabilising the radical particles formed—are "excited". For example, it was proposed[58–60] that in the reaction of Alk_3Al with benzoyl peroxide (BP) in a polymerising medium a complex with monomer (M) is first formed—$Alk_3Al.M$ (this naturally occurs since $[M] \gg [Alk_3Al]$ and $[M] \ll [BP]$). Subsequently BP interacts with the complex formed according to the reaction

$$[Alk_3Al.M] + BP \rightleftarrows [BP.Alk_3Al.M] \rightleftarrows$$
$$Alk_2AlOC(O)Ph + Alk^{\cdot} + PhC(O)OM^{\cdot}.$$

Organoelemental compounds of Group IV (R_4E) as a rule react with peroxides at the decomposition temperatures of the latter. The peroxides constitute the source of primary radicals and tetralkyl derivatives of silicon, germanium, and tin are hydrogen donors.[47,48]

$$R_4E + R'O^{\cdot} \rightarrow R'OH + R_3ER^{\cdot}_H.$$

The subsequent fate of the radicals is determined by the nature of E. Organosilicon radicals readily dimerise, germanium-containing radicals both dimerise and undergo disproportionation, while for tin-containing radicals dimerisation is not typical. The main reaction of the latter is cleavage of their Sn–C bond:[48]

$$R_3Sn{-}CH_2\dot{C}H_2 \rightarrow R_3Sn^{\cdot} + C_2H_4.$$

Thus, organoelemental compounds of Group IV react with peroxides as a rule according to a homolytic mechanism. Firstly, homolysis of the peroxide occurs on the O—O bond, then there is a homolytic S_N2 reaction of the resulting radicals with the organoelemental compound. If the peroxide decomposes by several parallel reactions (homolysis, heterolysis, or intramolecularly), its reaction with Group IV organoelemental compounds is complicated.

It is not possible to determine unequivocally the mechanism for decomposition of a peroxide coordinated with an organoelemental compound in complex (I). It may be either a redox process involving a single-electron transfer of an S_N2 reaction of the radical generated from the peroxide with the organoelemental compound or an intramolecular reaction or a heterolytic S_N2 process. The ratio of radical to non-radical pathways is to date difficult to determine in each individual case.

For example, the formation of radicals may be due to the transfer of an electron

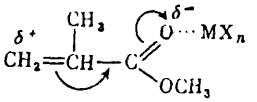
$$[R_nE \cdot R'OOR'] \xrightarrow{e} \begin{bmatrix} R^{\cdot} & {}^{+}ER_{n-1} \\ R'O^{\cdot} & {}^{-}OR'' \end{bmatrix} \begin{cases} \longrightarrow ROR' + R_{n-1}EOR'' \\ \longrightarrow R^{\cdot} + R'O^{\cdot} + R_{n-1}EOR'' \end{cases}$$

However, this complex can be converted via different activated states by two routes—homolytic and heterolytic:

$$[R_nE \cdot R'OOR'] \begin{cases} \longrightarrow \left[\begin{matrix} R^{-} & {}^{+}ER_{n-1} \\ R'O^{+} & {}^{-}OR'' \end{matrix}\right]^{\neq} \rightarrow ROR' + R''OER_{n-1} \\ \longrightarrow \left[\begin{matrix} R^{\cdot} & {}^{+}ER_{n-1} \\ R'O^{\cdot} & {}^{-}OR'' \end{matrix}\right]^{\neq} \rightarrow R^{\cdot} + R'O^{\cdot} + R''OER_{n-1} \end{cases}$$

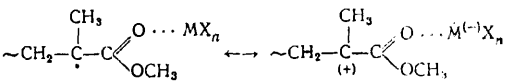
Several other variants of the decomposition of the complex can be proposed (a cryptoradical process, concerted homolytic cleavage, etc.), but it is not possible at the present time to come to any definite conclusion about the mechanism of the reaction.[50]

The system organoelemental compound—peroxide generates free radicals at quite low temperatures and can serve as an effective initiator for the polymerisation of vinyl monomers.[58–60,65–72]



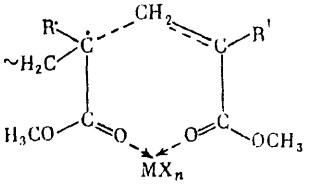
Information about the efficiency of initiation obtained by various methods provides an insight into what proportion of radicals leaves the solvent cage and is of use in radical chain polymerisation. But this method cannot be used to determine the proportion of cryptoradical processes occurring within the solvent cage.

2. Reactions of Lewis acids with peroxides



Polymerisation of acrylic monomers that is initiated by organoelemental compounds is accelerated by the addition of Lewis acids [$ZnCl_2$, $SnCl_4$, $SbCl_3$, $SbCl_5$, $TiCl_4$, R_nSiCl_{4-n} (n = 1–4), R_3SnCl, R_2SnCl_2 (R = Me, Et, n-Pr, n-Bu)] or compounds such as PCl_3 and SO_2Cl_2. Lewis acids have an effect on the fundamental stages of polymerisation and in particular on initiation and chain propagation. In the presence of Lewis acids as well as PCl_3 and SO_2Cl_2 the rate of polymerisation of acrylic monomers increases, the energy of activation of the process being reduced.[15,73–76]

Definite ideas about the mechanisms that are responsible for the change in rate and the initiation constants in radical polymerisation in the presence of the system organic(organoelemental) peroxide—Lewis acid can be put forward by studying the nature of the interaction between Lewis acids and monomers and peroxides.



According to published results[77–80] Lewis acids (MX_n) form complexes with acrylic monomers. The composition and structure of double complexes, for example, between MMA and acids such as $AlCl_3$, $AlBr_3$, $ZnCl_2$, $AlEt_3Cl$, $SnCl_4$, were studied by IR,[79,80] UV,[78] and NMR [81,82] spectroscopy. It was shown that complexes are formed as a result of an interaction between the complexing agent and the carbonyl group of the monomer. The strength of these complexes is such that it can be determined from the magnitude of the shift of the IR absorption bands due to stretching vibrations of the carbonyl group or from the displacement of the band due to a $\pi-\pi^*$ transition in the UV region.[78] It follows from UV spectroscopic data[78] that the formation of a complex between MMA and $ZnCl_2$, for example, leads to an increase in conjugation energy in the monomer.

It was shown by EPR [80] that a complex is formed between polymethyl methacrylate (PMMA) radicals and Lewis acids, which leads to a change in properties of these radicals. Zubov et al.[80] represent the state of the radical bonded in a complex as a resonance hybrid of two structures—radical and polar:

A Lewis acid bonded in a complex with the monomer or growing radical does not act as an inert substituent but as a "complementary particle involved in the formation of an intermediate complex at the growth stage".[4]

3. Formation of triple complexes in polymerising media

In the triple system monomer—Lewis acid—organic(organoelemental) peroxide several reactions for complex formation can take place. If the monomer is MMA and the Lewis acid is $SnCl_4$, these reactions may be represented in the following manner:[34]

$$MMA + SnCl_4 \rightleftarrows [MMA - SnCl_4], \quad (8)$$

$$[MMA - SnCl_4] + MMA \rightleftarrows [MMA_2 - SnCl_4], \quad (9)$$

$$MMA + P \rightleftarrows [MMA - P], \quad (10)$$

$$P + SnCl_4 \rightleftarrows [PSnCl_4], \quad (11)$$

$$P + [MMA - SnCl_4] \rightleftarrows [P - SnCl_4 - MMA], \quad (12)$$

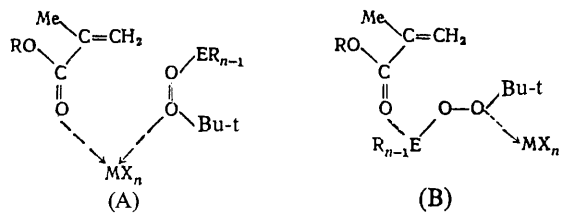
$$MMA + P - SnCl_4] \rightleftarrows [P - SnCl_4 - MMA]. \quad (13)$$

A molecule of organoelemental peroxide has two coordination sites—donor (O—O) and acceptor (E). According to our studies[36] complexes of different chlorides of silicon and tin having the structure R_nECl_{4-n} (E = Si, Sn, R = Alk, n = 1–4) with organoelemental peroxides have the composition 1 : 1 or 1 : 2. ^1H NMR studies on the formation of a complex between $Me_3SnOOCMe_3$ and pyridine,[45] $CHCl_3$,[83] Bu_2SnCl_2, and $SiCl_4$ [84] and the results obtained on the dependence of the change in chemical shift of the protons from the Me_3Sn and Me_3C groups on the mole fraction of the second component showed that pyridine acts as an electron donor towards the peroxide and it coordinates with the tin atom. On the other hand the tin and silicon halides, like chloroform, act as

electron acceptors and they coordinate with the peroxide bond (probably with the oxygen atom of the Me_3CO residue, which has a higher electron density).[46]

The equilibrium constants for formation of complexes between $Me_3SiOOCMe_2Ph$ and Me_3SiCl and Me_2SiCl_2 were found to be equal to 5.6 ± 0.9 and 8.3 ± 1.1 at 443 and 423 K respectively.[84]

The coordinating capacity of Lewis acids such as $SnCl_4$ or $SiCl_4$ is usually not exhausted by the addition of a single molecule of peroxide or monomer. Hence the logical conclusion is that in the presence of electron donors the process of complex formation, as depicted by equations (8), (10), and (11), can go further and result in the formation of a triple complex in which a double complex acts as an electron pair acceptor [equations (9), (12), (13)].



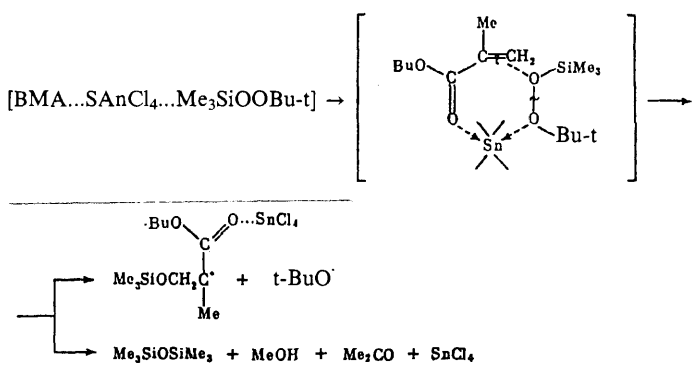
Three-component $nV\pi$-complexes that contain two monomers and a Lewis acid have been detected experimentally by IR, UV, and NMR spectroscopy.[81,82,85–88] Triple $nV\pi$-complexes of MMA–$ZnCl_2$–styrene, AN–$ZnCl_2$–styrene, methacrylonitrile-(MAN)–$ZnCl_2$–1-hexene, and MAN–$ZnCl_2$–styrene have been detected by UV spectroscopy from an analysis of the charge-transfer band in the long wavelength region of the spectrum.[85–87] Equilibrium constants and enthalpies of complex formation were calculated for some complexes. For example, the equilibrium constants for formation of an MMA–$SnCl_4$–styrene complex is equal to 0.24 and 0.67 at 298 and 233 K respectively.[86] The limiting shifts of protons in individual $nV\pi$-complexes were determined from ^{1}H NMR spectroscopic data.[82] From a quantitative analysis of the shifts and their correlation with the values calculated according to the Hückel method and the ionisation potentials of the molecules it was possible to determine the structure and possible conformations of triple complexes.

Using the known literature data on double and triple complexes that occur in the presence of Lewis acids,[4,78–88] we have developed a scheme for "including" the Lewis acid in the initiation stage of radical polymerisation involving an organoelemental peroxide.[15,34] According to this scheme double complexes are first formed. The addition of the third component to the double complex creates an energetically and sterically favourable situation for the formation of an activated complex in the initiation of radical polymerisation.

The triple systems MMA–$SnCl_4$–TBP, MMA–$SnCl_4$–$Me_3SiOOBu$-t, MMA–PCl_3–TBP, MMA–PCl_3–TBP, MMA–PCl_3–$Me_3SiOOBu$-t, and BMA–PCl_3–$Me_3SiOOBu$-t were studied using ^{1}H NMR spectroscopy in nonane in the temperature range 228–283 H by following the variation in the difference between the chemical shifts of the *cis*- and *trans*-olefinic protons of MMA or BMA (internal chemical shift ν).[34,89] The magnitude of ν depends on the structure of the monomer molecule and the distribution of electron density in it and is therefore sensitive to complex formation. Other factors (the presence of an inert solvent, temperature, concentration) have only a slight effect on it. The study of triple complexes was preceded by a study of double ones: olefin–peroxide, peroxide–Lewis acid, olefin–Lewis acid (Table 3).[34,89]

The internal chemical shift of MMA or BMA increases when $SnCl_4$ or PCl_3 is added. When the third component—an organic or organoelemental peroxide—is introduced, ν decreases. The observed chemical shift in the triple system is an average of the shifts from all the resonance forms. The values of the chemical shifts of the free monomer (MMA or BMA) and that bonded in a complex as well as the equilibrium constants for formation of double complexes served as the initial data for the calculation of the parameters of triple complexes. As a result, the formation constants of the triple complexes were obtained (Table 3).

On the basis of the strength of donor–acceptor bonds in double complexes, the most likely structure of the triple complex is that of (A), in which the relatively strong bond of monomer with Lewis acid is preserved.



On the other hand, since we found that the formation of a complex between peroxide and monomer was possible,[34,89] structure B, in which the donor properties of the peroxide are strengthened by the supply of electron density from the monomer, cannot be completely ruled out. This type of complex (B) is probable for the system MMA(BMA)–peroxide–PCl_3.

Table 3. Parameters of complex formation in double and triple systems at 253 K.

System	K*	$-\Delta H$, kJ mol^{-1}	Refs.
MMA–PCl_3	0.17±0.02	7.5±0.5	[89]
$Me_3SiOOBu$-t–PCl_3	7±3	26±9	[89]
$Me_3SiOOBu$-t–MMA	0.23±0.02	23±4	[89]
TBP–MMA	0.1±0.04	6.0±0.3	[34]
MMA–$SnCl_4$	15±2	—	[90]
MMA_2–$SnCl_4$	3±0.3	—	[90]
MMA–PCl_3–$Me_3SiOOBu$-t	34 3	29±4	[89]
MMA–$SnCl_4$–TBP	2.7—8.7	8±4	[34]

*Solution with concentration 1 mol litre^{-1} chosen as the standard state.

We believe that in a triple complex the peroxide is activated and decomposes by both a homolytic and a heterolytic mechanism at a higher rate. For example, in the triple system BMA–$SnCl_4$–$Me_3SiOOBu$-t the scheme for "including" the peroxide and $SnCl_4$ in the initiation of polymerisation of BMA may be represented in the following manner:

When the concentration of Lewis acid is increased, the rate of the parallel reaction of non-radical decomposition of the peroxide also rises. This can be assessed from the quantitative yield of $Me_3SiOSiMe_3$ that is obtained twenty four hours after mixing stoichiometric quantities of $Me_3SiOOBu$-t and $SnCl_4$ in nonane at 298 K.[15] This apparently causes the decrease in the rate of polymerisation of BMA at relatively high concentrations of $SnCl_4$.

Thus these reactions relate to the slowest and most energy-consuming stage of radical polymerisation—the initiation stage. The main role of electron donors and acceptors as catalytic components is to form complexes with the initiator, which results in activation of the latter.

IV. Use of organoelemental peroxides for the initiation of radical polymerisation and vulcanisation

The increased production of polymeric materials and the improvement of their quality are due to the development of new, highly effective initiating compositions that can affect the physico-mechanical and performance characteristics of polymeric materials. The compositions organoelemental(organic) peroxide–electron donor or organoelemental(organic) peroxide–electron acceptor are promising initiating systems. The use of organoelemental peroxides for the initiation of polymerisation or vulcanisation as well as for promoting adhesion in the system polymer–substrate has been covered in sufficient detail in two reviews.[91,92] Here we shall only dwell on certain aspects of the use of organoelemental peroxides that have recently undergone development.

MCl_n–t-BuOOH systems, where M = Al, Sn, Ge, In, P, have a high initiating capacity. MMA, styrene, vinyl chloride, and other monomers are polymerised in their presence over a wide range of temperature at high rates and with high degrees of conversion.[93–103] Polymeric materials that are obtained using Lewis acid–peroxide systems have improved physicomechanical properties, are readily processed to sheet products and fibres, can be vulcanised, and in a number of cases have a stereoregular structure.

A large amount of data has been obtained on the initiating activity of boron alkyl–organoelemental peroxide systems, which is dependent on the nature of the boronalkyl substituent, the structure of the peroxide reagent, and the monomer.[30,104–108] The initiating activity of peroxides changes according to the series:

$$Ph_4SbOOBu\text{-t} > Et_3SnOOBu\text{-t} > Et_3GeOOBu\text{-t} > > Me_3SiOOBu\text{-t} \gg TBP.$$

The high rates for generating free radicals in reactions of alkyls of elements with organoelemental peroxides are due, in our opinion, to their ability to form complexes with each other and with monomer. Energetically and sterically favourable conditions are created in a complex for decomposition of the peroxide to radicals and for reaction of the resulting radicals with the monomer.

In the initiation of polymerisation by polyfunctional peroxides such as $R_{4-n}Si(OOCMe_3)_n$, where n = 2–4, R = Me, CH_2 = CH, it is possible to obtain macroperoxysilanes.[109,110] This opens up the possibility for synthesising block copolymers of different monomers during radical polymerisation. For example, macroinitiators obtained by polymerisation of BMA and styrene up to a degree of conversion of 20% were used to initiate the secondary polymerisation of BMA and the synthesis of block copolymers.[110] The high degree of polymerisation initiated by macroperoxysilanes is characterised by the absence of the gel effect, and the addition of Lewis acids (such as $SnCl_4$) activates the decomposition of macromolecular initiators in the same way as their low-molecular analogues.

In the formation of block copolymers the initiation of polymerisation of a second monomer is possible. In particular, active polystyrene containing from 6 to 9 peroxide groups per macromolecule was used as a macroinitiator for the polymerisation of BMA.[110] Samples of polystyrene with peroxide groups in the macromolecule were prepared as a 10% solution in BMA. The block copolymer obtained (97–98%) was separated from the homopolymer by selective extraction and analysed by IR spectroscopy. It transpired that the block copolymer was enriched with BMA units. The main feature of this method for obtaining block copolymers is the virtual absence of homopolymer of the monomer being polymerised.[110]

Thus, by using multifunctional peroxysilanes it is possible to obtain block copolymers without significant inclusion of homopolymer during radical polymerisation. This method can also be applied to other monomers that are capable of radical polymerisation.

It is known that the properties of polymeric composite materials can be improved by chemical modification of the surface of the filler with compounds that act simultaneously as initiator and binder. Silicon polyperoxides are such compounds. Several methods for obtaining peroxidised fillers have been reported.[111–114] We have developed a method for obtaining modified granular fillers (Aerosil, TiO_2, Al_2O_3) by treating them with organosilicon polyperoxides in a volatile organic solvent.[115]

The grafting of an initiator to the surface of a filler results in an increase in the rate of thermal decomposition of the peroxide attached to the surface compared to the decomposition of a similar compound in the liquid phase. The reason for this lies in the specific orientation of the molecule of peroxide in the surface layer and the coordination interaction of peroxide oxygen with the surface groups or atoms, resulting in a weakening of the peroxide bond. It has been shown by chemical and electron-microscope methods that grafting of silicon peroxides to the surface of Aerosil, TiO_2, or Al_2O_3 creates on the surface of the filler chemically bonded reaction sites that can initiate the polymerisation of monomers and chemically graft the polymer matrix to the filler.[116] Homolytic decomposition of the peroxide attached to the surface of the filler results in the formation of two radicals, one of which is chemically bonded to the surface and initiates the formation of the graft polymer and the other is freed into space and either undergoes further decomposition or initiates a homopolymerisation reaction.

The polymerisation of styrene on the surface of a filler modified with silicon polyperoxide can be used to obtain a composite in which up to 30% of the polymer is grafted to the surface of the filler.[15] The formation of a grafted product takes place not only when the peroxide is initially attached to the surface but also when silicon polyperoxide is introduced in a pure state into the system of filler–monomer.[115] This indicates that silicon polyperoxide dissolved in monomer can be grafted on to the surface during polymerisation and achieves a polymer graft to approximately the same extent as in the case of the initial attachment of this peroxide to the surface of the filler.

The highest rate of graft polymerisation and the maximum yield of graft polymer are attained when vinyltri(t-butylperoxy)silane is used as the modifier. Grafting to the filler occurs via the peroxide groups, while grafting to the polymer is via the peroxide and vinyl residues.[115]

A study of the properties of polystyrene samples filled with Aerosil or Al_2O_3 the surface of which was modified with organosilicon peroxides showed that the composite polystyrene had improved impact strength and good rigidity.[115]

It was recommended that organoelemental peroxides should be used to cure rubbers, primarily organosilicon rubbers.[117–120]

A promising method for modifying synthetic materials is the introduction of peroxidate groups into an oligomer chain. When the oligomeric peroxides are heated, macroradicals are generated and they recombine to form three-dimensional structures without the additional introduction of a vulcanising agent.[121]

We have synthesised previously unreported peroxyoligoorganosilazanes that can be used to cross-link organosilicon compounds.[122]

Heat-cured compounds have been widely used in various branches of the Soviet economy, but dicumyl peroxide (DCP) is mainly used as a curing initiator, and has a number of operating problems connected with its use. The process takes place in two stages, and at the second stage a toxic volatile product—acetophenone, which has an unpleasant acrid smell—is liberated. Organosilicon peroxides such as $RSi(OOBu\text{-}t)_3$, where R = Me, CH_2 = CH, are free from such disadvantages.

A comparative study of the characteristics of vulcanisation of methylvinylphenylsiloxane oligomers in the presence of DCP and $RSi(OOBu\text{-}t)_3$ organosilicon peroxides showed that curing with the silicon peroxides starts 10–20 °C below that with DCP, and the products formed by decomposition of the organosilicon peroxides are considerably less toxic than acetophenone.

Moreover, the products formed in the presence of $RSi(OOBu\text{-}t)_3$ have higher strength and elasticity. This establishes a promising future for the chemical activation of peroxides aimed at reducing the vulcanisation temperature.

- - - o 0 o - - -

Thus, at the present time it can be taken as reliably established that electron-donor and electron-acceptor compounds (activators) catalyse the decomposition reactions of organic and organoelemental peroxides, including those that decompose to radicals during radical polymerisation of olefinic monomers. The effect of the activators is due to the specific interaction of the components making up activator–peroxide–monomer systems and the formation of mixed double and triple complexes with a fractional contribution differing according to the nature of the activator, peroxide, and monomer.

Electron donors form a complex with peroxide by interaction of *p* (or π) electrons with vacant *d* orbitals in the heteroatom of peroxide. Complex formation weakens the peroxide bond. The rate constant for decomposition of a donor–peroxide complex has a value which is several orders higher than the decomposition constant of pure peroxide in an inert medium.

In the system monomer–peroxide–Lewis acid, together with double complexes of monomer–Lewis acid, monomer–peroxide, and peroxide–Lewis acid, labile triple complexes of monomer–Lewis acid–peroxide are formed, in which both the monomer and peroxide have a coordinate bond with the metal atom at the same time.

From the results obtained it is possible to account for the behaviour of organic and organoelemental peroxides in actual polymerising systems and to predict the main pathways for conversion of initiators in them. The latter is useful for resolving specific problems in developing required initiating systems for the preparation of polymeric materials with given properties.

Fluorine-containing organic derivatives of polyvalent halogens

I I Maletina, V V Orda, L M Yagupol'skii
Institute of Organic Chemistry, Academy of Sciences of the Ukrainian SSR, Kiev

ABSTRACT. The methods of synthesis and properties of fluorine-containing organic derivatives of polyvalent iodine, bromine, and chlorine are examined.

The bibliography includes 162 references.

Contents

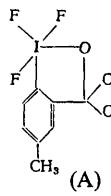
I. Introduction 544
II. Derivatives of trivalent halogens 544
III. Derivatives of pentavalent halogens 551
IV. The electronic nature of substituents containing polyvalent iodine 555

I. Introduction

Organic derivatives of polyvalent iodine were first obtained by Willgerodt in 1886. The methods of synthesis and properties of compounds containing iodine in the trivalent and pentavalent states have been described in a monograph[1] and in reviews.[2–4] Subsequent reviews were devoted to separate types of polyvalent iodine compounds—iodonium salts and ylides,[5,6] diacyloxyiodoarenes.[7] Iodonium ylides and the applications of polyvalent iodine compounds in organic syntheses have been considered in greatest detail in Koser's[8] and Varvoglis's[9] reviews respectively.

There have been no reviews devoted to fluorine-containing derivatives of polyvalent iodine. Nevertheless certain types of compounds have been synthesised solely as a result of the introduction of fluorine atoms into the molecule.

The chemistry of fluorine-containing organic derivatives of polyvalent iodine is developing vigorously. They are finding increasingly extensive application as selective oxidants, alkylating and fluorinating agents, and physiologically active substances.



Certain fluorine-containing organic derivatives of bromine and chlorine have been synthesised in recent years.

This review deals with data on fluorine-containing organic compounds with a carbon–polyvalent-bond published up to 1987. There exist the following types of polyvalent iodine compounds of this sort.

1. Compounds of trivalent iodine in which the iodine atom is linked to one carbon atom. These include iodosylperfluoroalkanes R_FIO, difluoroiodoarenes $ArIF_2$ and difluoroiodoperfluoroalkanes R_FIF_2, bis(trifluoroacetoxy)iodoarenes $ArI(OCOCF_3)_2$ and bis(trifluoroacetoxy)iodoperfluoroalkanes $R_FI(OCOCF_3)_2$, dimethoxyiodotrifluoromethane $CF_3I(OCH_3)_2$, and also μ-oxo-compounds, in which the iodine atoms are linked by an oxygen bridge, namely $ArI(OCOCF_3)-O-I(OCOCF_3)Ar$. Iminoiodoarenes, for example, $ArI=NSO_2CF_3$, belong to the same type.

2. Compounds of trivalent iodine containing an iodine atom linked to two carbon atoms. These include arylperfluoroalkyl- and aryl-αα-dihydropolyfluoroalkyliodonium salts, for example, $C_6H_5\overset{+}{I}\,C_3F_7BF_4^-$, and also iodonium ylides of the type $ArI=C(SO_2F)_2$.

3. Compounds of pentavalent iodine in which the iodine atom is linked to one carbon atom. These include iodylperfluoroalkanes R_FIO_2, difluoroiodylarenes $ArIOF_2$, and difluoroiodylperfluoroalkanes R_FIOF_2, tetrafluoroiodoarenes $ArIF_4$ and tetrafluoroiodoperfluoroalkanes R_FIF_4, tetrakis(perfluoroacyloxy)iodoarenes $ArI(OCOR_F)_4$, and bis(perfluoroacyloxy)iodylarenes $ArI(O)(OCOR)_2$. Trifluoroperiodinane (A) and bis(imino)iodoarenes (B) can also be included in this type:

(A)

(B)

4. Compounds with pentavalent iodine in which the iodine atom is linked to two carbon atoms. These include diphenyliodosyl salts, for example, $(C_6H_5)_2IF_2$ and $(C_6H_5)_2I(O)OCOCF_3$.

There are few available literature data on the fluorine-containing organic derivatives of polyvalent bromine and chlorine. The compounds R_FBRF_2, $RFBr(OCOCF_3)_2$, and R_FClF_2 have been synthesised. The available information about the synthesis of $C_6F_5Cl(F)-Cl(F)C_6F_5$ is hardly reliable.

II. Derivatives of trivalent halogen

1. Methods of synthesis

(a) Iodosyl compounds

Until recently, only aromatic iodosyl compounds ArIO were known, their stability being caused apparently by the conjugation of the positively charged iodine atom with the aromatic ring. The methods of synthesis of iodosylarenes have been described in reviews.[1–4] The most convenient of them is based on the alkaline hydrolysis of diacetoxyiodoarenes.[10]

The first representative of aliphatic iodosylperfluoro-compounds—iodosylperfluoropropane—was obtained by the hydrolysis of bis(trifluoroacetoxy)perfluoropropane in the presence of sodium bicarbonate.[11] Iodosylpentafluorobenzene was synthesised similarly:[11,12]

$$R_FI(OCOCF_3)_2 \xrightarrow{H_2,\,NaHCO_3} R_FIO, \quad R_F = C_3F_7,\ C_6F_5.$$

Contrary to the assertion[13] that iodosyl compounds are not formed when perfluoroalkyl iodides are treated with ozone, iodosyltrifluoromethane was obtained by this procedure:[14]

$$CF_3I + O_3 \xrightarrow[CCl_3F,\,-78\text{–}40\,^\circ C]{} CF_3IO + O_2.$$

The same compound is formed when difluoroiodotrifluoromethane in acetonitrile is treated with finely dispersed silica:[14]

$$2CF_3IF_2 + SiO_2 \xrightarrow[-40\text{–}0\,^\circ C]{} 2CF_3IO + SiF_4.$$

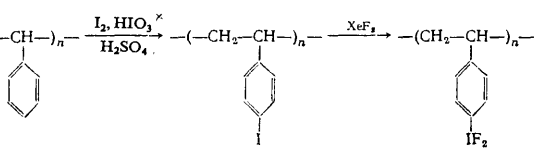
The relative stability of iodosylperfluoroalkanes is associated with the electron-accepting influence of the perfluoroalkyl group.

(b) Difluoroiodo-, difluorobromo-, and difluorochloro-compounds

The first representatives of difluoroiodo-compounds—difluoroiodoarenes—were obtained by treating iodosylarenes with 40% hydrofluoric acid.[2,4] It has also been suggested[15] that difluoroiodoarenes be obtained by the exchange of the chlorine atoms in dichloroiodoarenes with the fluorine in hydrofluoric acid in the presence of yellow mercury oxide:

$$ArICl_2 + HgO + 2HF \rightarrow ArIF_2 + H_2O + HgCl_2.$$

An important disadvantage of these methods is the presence in the reaction mixture of water, which hinders the isolation and purification of the readily hydrolysing difluoroiodoarenes. The method of synthesis of difluoroiodoarenes by treating iodosyl compounds or bis(trifluoroacetoxy)iodo-derivatives with sulphur tetrafluoride is free from this disadvantage. Apart from difluoroiodoarenes, readily removed gases—thionyl fluoride and trifluoroacetyl fluoride—are formed under these conditions:[11]



$$ArIO + SF_4 \rightarrow ArIF_2 + SOF_2,$$
$$C_6F_5I(OCOCF_3)_2 + SF_4 \rightarrow C_6F_5IF_2 + 2SOF_2 + 2CF_3COF.$$

The first representative of heterocyclic difluoroiodo-derivatives—3-difluoroiodopyridine—was also obtained by this method.[11]

Xenon difluoride can be used to synthesise difluoroiodo-compounds:[16]

$$ArI + XeF_2 \xrightarrow[20\text{–}60\,^\circ C]{} ArIF_2 + Xe.$$

Various difluoroiodoarenes[17,18] as well as polymeric difluoroiodoarene—the product of the iodination and subsequent fluorination with xenon difluoride the so called "popcorn" (cross-linked styrene–divinylbenzene copolymer)[19,20]—have been obtained with the aid of xenon difluoride:

Studies in which conditions were found for the selective fluorination of various iodoarenes by elemental fluorine have been published comparatively recently:[21,22]

$$ArI + F_2 \xrightarrow[CCl_2F,\,-100\,^\circ C]{} ArIF_2.$$

Fluorine is diluted with nitrogen in proportions of 1:20. It is then possible to avoid the fluorination of the aromatic ring even in those cases where it contains electron-donating substituents. The compound $C_6F_5IF_2$ had been obtained earlier by this procedure.[23]

The first difluoroiodoperfluoroalkane—difluoroiodotrifluoromethane—was synthesised by treating trifluoromethyl iodide with fluorine:[24]

$$CF_3I + F_2 \rightarrow CF_3IF_2$$

Subsequently various difluoroiodoperfluoroalkanes were obtained by treating the corresponding perfluoroalkyl iodides with strong fluorinating agents—elemental fluorine,[13,25,26] chlorine trifluoride, and bromine trifluoride or pentafluoride.[13] The compound $SF_5(CF_2)_2IF_2$ was also obtained with the aid of chlorine trifluoride.[27]

Difluoroiodoperfluoroalkanes[11] and difluoroiodo-αα-dihydropolyfluoroalkanes[28] are formed readily when the corresponding bis(trifluoroacetoxy)iodo-derivatives are treated with sulphur tetrafluoride.

The low-temperature fluorination of methyl iodide with elemental fluorine leads to difluoroiodotrifluoromethane.[29]

Difluoroiodoalkanes could not be obtained with the aid of elemental fluorine or strong fluorinating agents, since the C–I bond is ruptured under these conditions. Alkyl iodides cannot be oxidised to bis(trifluoroacetoxy)iodo-derivatives for the same reason. It has been found that difluoroiodomethane is formed in a quantitative yield when xenon difluoride reacts with an excess of methyl iodide:[30–32]

$$CH_3I + XeF_2 \xrightarrow[20\,^\circ C]{} CH_3IF_2 + Xe.$$

The product has been characterised only by ^1H and ^{19}F NMR spectra.

Difluoroiodoethane has been obtained from ethyl iodide using a very mild fluorinating agent—$CsSO_4F$.[33]

The formation of difluorobromoarenes in the oxidation of bromoarenes with xenon difluorides[34] and in the synthesis of diarylbromonium salts by condensing arenes with BrF_3 [35] has been detected by the ^{19}F NMR method.

The synthesis of difluorobromopentafluorobenzene by the reaction of C_6F_5Br with elemental fluorine at 128 °C was described later.[36,37] $C_6F_5BrF_2$ was isolated by preparative chromatography. However, the authors believe[38,39] that the product of the reaction of elemental fluorine with C_6F_5Br is not $C_6F_5BrF_2$. They obtained $C_6F_5BrF_2$ by substituting a fluorine atom in BrF_3 by the pentafluorophenyl residue and confirmed its formation by studying the ^{19}F NMR, IR, and mass spectra and also by means of chemical reactions:

$$C_6F_5SiF_3 + BrF_3 \rightarrow C_6F_5BrF_2 + SiF_4.$$

The formation of $C_6H_5ClF_2$ on interaction with C_6F_5Cl with elemental fluorine has been described.[40,41] It has been suggested that $C_6H_5Cl(F)-Cl(F)C_6F_5$ is formed as a side product in this reaction. A study has been devoted to the synthesis of this compound and the demonstration of its structure.[42] We believe that the existence of this compound is doubtful.

(c) Bis(trifluoroacetoxy)iodo- and bis(trifluoroacetoxy)bromo-compounds

The first representative of compounds of this kind—bis(trifluoroacetoxy)iodobenzene—was obtained by treating dichloroiodobenzene with silver trifluoroacetate or by treating iodosylbenzene with trifluoroacetic acid:[43]

$$C_6H_5ICl_2 + 2AgOCOCF_3 \rightarrow C_6H_5I(OCOCF_3)_2 + 2AgCl,$$
$$C_6H_5IO + 2CF_3COOH \rightarrow C_6H_5I(OCOCF_3)_2 + H_2O.$$

A method of synthesis of this compound from diacetoxyiodobenzene by the exchange reaction with trifluoroacetic acid at 60 °C was later proposed:[44,45]

$$C_6H_5I(OCOCH_3)_2 + 2CF_3COOH \rightarrow C_6H_5I(OCOCF_3)_2 + 2CH_3COOH.$$

Bis(trifluoroacetoxy)iodopentafluorobenzene was synthesised by oxidising iodopentafluorobenzene with nitric acid in the presence of trifluoroacetic anhydride[12] or trifluoroperacetic acid.[23]

In order to obtain bis(trifluoroacetoxy)iodoarenes containing in the benzene ring not unduly strong electron-donating and electron-accepting substituents, a method has been developed for the direct introduction of the $I(OCOCF_3)_2$ group into the aromatic ring by treatment with iodine tris(trifluoroacetate)[12,23] in trifluoroacetic acid:[46]

$$ArH + I(OCOCF_3)_3 \xrightarrow[-CF_3COOH]{} ArI(OCOCF_3)_2,$$

$$Ar = C_6H_5,\ 2,5\text{-}(CH_3)_2C_6H_3,\ 4\text{-}CH_3C_6H_4,\ 4\text{-}ClC_6H_4,\ 3\text{-}CF_3C_6H_4.$$

It was found that only the *meta*-isomer is formed from trifluoromethylbenzene, a mixture of 38% of the *ortho*-isomer and 62% of the *para*-isomer is formed from toluene, and a mixture of 6% of the *ortho*-isomer and 94% of the *para*-isomer is formed from chlorobenzene. Such composition of the isomers indicates an electrophilic mechanism of the reaction.

In the synthesis of bis(trifluoroacetoxy)iodoarenes from iodosylarenes, it is best to use trifluoroacetic anhydride instead of the acid itself. The reaction takes place with a quantitative yield:[46,47]

$$ArIO + (CF_3CO)_2O \xrightarrow[CH_2Cl_2]{-20 \text{ to } -30\,^\circ C} ArI(OCOCF_3)_2,$$

$$Ar = C_6H_5,\ 4\text{-}CH_3C_6H_4,\ 3\text{-}FC_6H_4,\ 4\text{-}FC_6H_4,\ 4\text{-}ClC_6H_4,\ 3\text{-}CF_3C_6H_4.$$

The last two methods are not applicable to the synthesis of bis(trifluoroacetoxy)iodoarenes containing strong electron-accepting substituents. In this case, the iodoarene was oxidised with fuming nitric acid in the presence of trifluoroacetic anhydride:[48]

$$XC_6H_4I + 2HNO_3 + 2(CF_3CO)_2O \rightarrow XC_6H_4I(OCOCF_3)_2 + 2NO_2 + 2CF_3COOH,$$

$$X = 3\text{-}CF_3,\ 3\text{-}NO_2,\ 4\text{-}NO_2.$$

The reaction takes place quantitatively.

The first representative of trivalent bromine carboxylates—bis(trifluoroacetoxy)bromopentafluorobenzene—was synthesised by the reaction of difluorobromopentafluorobenzene with trifluoroacetic anhydride at 0 °C in Freon 11.[39]

Until recently, saturated aliphatic di(acyloxy)iodo-compounds were unknown. The attempts to oxidise iodoalkanes to iodosyl compounds or their derivatives were unsuccessful, since this involves the dissociation of the C–I bond.

The first compounds of this type—bis(trifluoroacetoxy)iodoperfluoroalkanes and bis(trifluoroacetoxy)iodo-αα-dihydropolyfluoroalkanes—were obtained by oxidising perfluoro- and αα-dihydropolyfluoro-alkyl iodides with trifluoroperacetic acid in chloroform or trifluoroacetic acid:[11,28,49]

$$R_FI \xrightarrow[CF_3COOH]{CF_3CO_3H} R_FI(OCOCF_3)_2.$$

The reaction is general in character. The only exception is iodotrifluoromethane, which could not be oxidised by trifluoroperacetic acid. A mixture of another oxidant (nitric acid) with trifluoroacetic anhydride decomposes CF_3I, which results in the formation of iodine tris(fluoroacetate) in a quantitative yield.

Bis(trifluoroacetoxy)iodotrifluoromethane was synthesised by substituting the fluorine atoms by trifluoroacetoxy-groups in the reaction of difluoroiodotrifluoromethane with an excess of trifluoroacetic anhydride at −40 °C.[50] $CF_3IF(OCOCF_3)$ is formed as an intermediate:

$$CF_3IF_2 \xrightarrow[-CF_3COF]{(CF_3CO)_2O} CF_3IF(OCOCF_3) \xrightarrow[-CF_3COF]{(CF_3CO)_2O} CF_3I(OCOCF_3)_2.$$

Bis(trifluoroacetoxy)iodotrifluoromethane can be obtained also by treating iodosyltrifluoromethane with an excess of trifluoroacetic anhydride:[50]

$$CF_3IO + (CF_3CO)_2O \xrightarrow[-30\,^\circ C]{} CF_3I(OCOCF_3)_2.$$

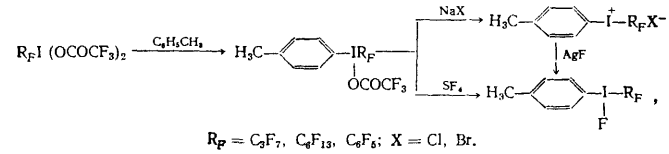
(d) Fluorine-containing trivalent iodine ylides and iminoiodoarenes

Iminoiodoarenes were first obtained by the reaction of diacetoxyiodoarenes with toluene-*p*-sulphonamide in methanol in the presence of KOH.[51] Under the same conditions, trifluoroacetyliminoiodobenzene $PhI{=}NCOCF_3$ is formed from trifluoroacetamide and $PhI(OCOCH_3)_2$.[52] Compounds containing the $I{=}NSO_2CF_3$ groups could not be obtained by this method. A method consisting in the reaction of difluoroiodoarenes with *NN*-bis(trimethylsilyl)trifluoromethanesulphonamide has been developed for the synthesis of trifluoromethanesulphonyliminoiodoarenes.[53] Benzenesulphonyliminoiodoarenes have been obtained from *NN*-bis(trimethylsilyl)-benzenesulphonamide:[47,54]

$$XC_6H_4IF_2 + RSO_2N(SiMe_3)_2 \xrightarrow[-Me_3SiF]{} XC_6H_4I{=}NSO_2R,$$

$$R = CF_3,\ X = H,\ 3\text{-}F,\ 4\text{-}F;\quad R = C_6H_5,\ X = H,\ 4\text{-}CH_3,\ 3\text{-}F,\ 4\text{-}F.$$

$C_6F_5I{=}NSO_2C_6H_5$ was obtained similarly.



Aryliodonium di(fluorosulphonyl)methylides have been synthesised by the reaction of diacetoxyiodoarenes with methanedisulphonyl fluoride:[47,55]

$$XC_6H_4I(OCOCH_3)_2 + H_2C(SO_2F)_2 \xrightarrow[CH_2Cl_2,\ 20\,^\circ C]{} XC_6H_4I{=}C(SO_2F)_2,$$

$$X = H,\ 3\text{-}F,\ 4\text{-}F,\ 3\text{-}NO_2.$$

(e) Arylperfluoroalkyliodonium salts

These compounds were first obtained in 1971 [49] by condensing bis(trifluoroacetoxy)iodoperfluoroalkanes with benzene and toluene in trifluoroacetic acid. On treatment with sodium chloride or bromide in an aqueous acetone solution, the trifluoroacetates obtained are converted into chlorides and bromides. Arylperfluoroalkyliodonium fluorides are formed from trifluoroacetates on treatment with sulphur tetrafluoride or from chlorides by the exchange reaction with silver fluoride:

$$R_F = C_3F_7,\ C_6F_{13},\ C_6F_5;\ X = Cl,\ Br.$$

In order to increase the stability and reactivity of arylperfluoroalkyl iodonium salts, iodonium salts with the non-nucleophilic anion BF_4^- have been synthesised by the reaction of difluoroiodoperfluoroalkanes with benzene in the presence of BF_3:[56]

$$R_FIF_2 + BF_3 \xrightarrow{CH_2Cl_2,\ -60\,^\circ C} R_F\overset{+}{I}FBF_4^- \xrightarrow[-HF]{C_6H_6} C_6H_5\overset{+}{I}R_FBF_4^-,$$

$$R_F = C_3F_7,\ C_6F_{13}.$$

Arylperfluoroalkyliodonium salts with the trifluoromethanesulphonate (triflate) anion have been synthesised.[57] The condensation of bis(trifluoroacetoxy)iodoperfluoroalkanes with benzene or fluorobenzene was carried out in Freon 113 or in trifluoroacetic acid at

0 °C in the presence of trifluoromethanesulphonic, sulphuric, or fluorosulphonic acid:

$$R_FI(OCOCF_3)_2 \xrightarrow[XSO_3H]{ArH} ArI(OSO_2R)R_F,$$

$R_F = C_nF_{2n+1}$, $n = 2-10$; Ar = C_6H_5, 4-FC_6H_4; X = CF_3, OH, F.

Diiodonium salts—αω-bis(aryliodonium)perfluoroalkanes—with the BF_4^- [58] and $OSO_2CF_3^-$ [59] anions as well as aryl-1,1-dihydropolyfluoroalkyliodonium salts with the methylene group at the iodine atom and with the anions Br^-,[28] BF_4^-,[60] and $OSO_2SF_3^-$ [61] have also been obtained by these methods. Having replaced trifluoromethanesulphonic acid by the polymeric sulphonic acid Nafion-H in the synthesis of arylperfluoroalkyliodonium salts, an iodonium salt with a polymeric anion was obtained.[62] The synthesis of arylperfluoroalkyliodonium triflates has been surveyed.[63]

2. The properties of fluorine-containing organic compounds of trivalent iodine

(a) Iodosyl compounds

Iodosylarenes are yellowish or greenish solid substances with a characteristic smell. Their stability is low, they explode on fusion, and they disproportionate on standing:[4]

$$2ArIO \rightarrow ArI + ArIO_2.$$

Aromatic iodosyl compounds are insoluble in organic solvents and are sparingly soluble in water. On the basis of Mössbauer spectra[64] and comparison of IR and Raman spectra,[65] it has been suggested that the iodine atom in the iodosylbenzene crystals are coordinated in a T-fashion with oxygen atoms and are located in the same plane as the latter. It has been postulated that iodosylbenzene is not a polymer but a cyclic oligomer.[65]

Iodosylarenes behave as the anhydrides of the hypothetic dibasic acids $ArI(OH)_2$. They are amphoteric and form salts with a low stability after the addition of acids or bases:[4]

$$ArIO + H_3O^+ \rightleftarrows ArI^+OH + H_2O,$$
$$ArIO + OH^- \rightleftarrows ArIO_2H^-.$$

Iodosyltrifluoromethane is a colourless crystalline and very unstable substance. It can be stored in the dark at a low temperature. It decomposes with liberation of iodine at 20 °C and on rapid heating in a sealed capillary at 45 °C. When it is dissolved in methanol, the methoxide $CF_3I(OCH_3)_2$ is formed.[14]

Iodosylperfluoropropane is a more stable compound (decomposition temperature 70 °C). It does not change in air at 20 °C but decomposes gradually in the light.[11]

(b) Difluoroiodo- and difluorobromo-compounds.

Difluoroiodoarenes are colourless or yellowish crystalline substances readily hydrolysed by atmospheric moisture to iodosylarenes,[11] which corrode glass vessels on standing. They are soluble in methylene chloride, chloroform, and benzene. Solutions of difluoroiodotoluene in chloroform can be stored in glass vessels for 2–3 days.[4] The chemical shifts of the fluorine atoms in the IF_2 group in the ^{19}F NMR spectrum are presented in Table 1. The ^1H NMR and Raman spectra of these compounds have been published.[22]

The difluoroiodo-derivatives of pentafluorobenzene, perfluoro-n-alkanes, and αα-dihydropolyfluoroalkanes, obtained by the reaction of the corresponding bis(trifluoroacetoxy)iodo-compounds with sulphur tetrafluoride,[11,28] are low melting colourless crystalline substances or liquids, readily soluble in polar organic solvents. On heating above the melting point, they do not decompose and can be

Table 1. The chemical shifts of the fluorine atoms of iodine- and fluorine-containing substituents (δ_F, p.p.m.) relative to CCl_3F in benzene and perfluorocarbon derivatives.

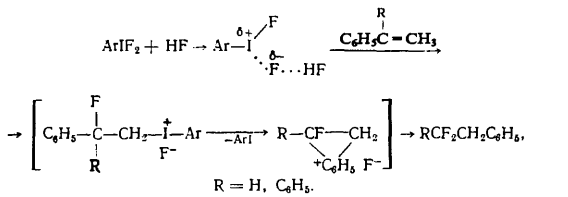
*** Recalculated relative to CCl_3F.

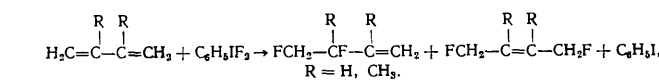


vacuum distilled. There are literature data showing that the above compounds, synthesised by other methods,[13,23,26] decompose at temperatures above 0 °C. This can probably be accounted for by the presence of impurities. The chemical shifts of the fluorine atoms of the IF_2 group in the ^{19}F NMR spectra of different difluoroiodoperfluoroalkanes are presented in Table 1 and the vibrational spectra of CF_2IF_2 have also been published.[66]

On hydrolysis of difluoroperfluoroalkanes, definite products could not be isolated. It has been suggested[13] that hydrolysis results in the formation of iodonium salts of the type $(R_F)_2\overset{+}{I}X^-$, where $X = OH^-$, IO_3^-, I^-, or F^-.

The fluorine atoms of the IF_2 group in difluoroiodotrifluoromethane can be replaced by trifluoroacetoxy-groups on treatment with an excess of trifluoroacetic anhydride,[50] while treatment with an excess of nitrogen pentoxide results in their substitution by nitrato-groups.[67] Difluoroiodotrifluoromethane forms 1:1 adducts with acetonitrile, pyridine, and quinoline. The stability of these complexes increases with increase in the electron-donating capacity of the base.[25]

Difluorobromopentafluorobenzene is a colourless crystalline substance melting at 35–36 °C and not decomposing up to 85 °C.[39]



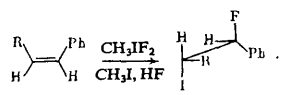
Difluoroiodoarenes and difluoroiodoalkanes are used as mild and selective fluorinating agents. The interaction of difluoroiodoarenes with 1,1-diphenylethylene,[68,69] or styrene[15] affords geminal difluoro-compounds and not 1,2-difluoro-derivatives, as was erroneously stated by Bockemüller.[68] Their formation can be explained by a rearrangement of the intermediate benzenium cation. The process is catalysed by HF:[15,18]

Rearrangements of the same type have been observed also in the fluorination with difluoroiodoarenes of 1-(3-chlorophenyl)-1-phenyl- or 1-(4-methoxyphenyl)-1-phenylethylene and also 1-phenylcyclo-pentene or 1-phenylcyclohexene.[18]

The interaction of difluoroiodoarenes with norbornene[18] results in the formation of a mixture of three products, while the reaction with norbornadiene[70] gives rise to a mixture of four products, whose proportions depend on the substituent in the benzene ring of the difluoroiodoarene.

The fluoroination of 1,3-dienes with difluoroiodobenzene[71] affords a mixture of 1,2- and 1,4-adducts in proportions of approximately 1:2:

The use of aromatic difluoroiodo-derivatives as fluorinating agents was complicated by the fact that the reaction results in the formation of iodoarenes which hinder the isolation of the fluorination products. This difficulty was eliminated by employing a polymeric difluoroiodo-derivative.[19,20,72] It was found that its interaction with phenylalkenes and norbornene yields the same products as in the reaction with difluoroiodoarenes.



An interesting method of isolating the iodoarenes from the reaction mixture has been described.[73] 4-Difluoroiodophenylacetic acid has been proposed as a fluorinating agent. 4-Iodophenylacetic acid, formed as a result of the reaction of the fluorinating agent with substituted 1,1-diphenylethylenes, can be readily washed out with a solution of sodium carbonate.

Difluoroiodoarenes are also used to convert silylated enolic ethers into α-fluoroketones.[74]

Difluoroiodobenzene also proved to be a convenient agent for the oxidative fluorination of aromatic derivatives of trivalent antimony:[75]

As already mentioned above, difluoroiodomethane was not isolated in a pure form. However, its solutions in an excess of methyl iodide in the presence of hydrogen fluoride were made to react with phenylalkenes[76–78] and phenylalkynes.[79] It was found that this entails the addition of iodine and fluorine atoms (the elements of IF) to the double bond, which is not accompanied by a rearrangement and takes place stereoselectively in accordance with the Markovnikov rule and leads to 1-fluoro-2-iodo-derivatives:

1,2- and 1,4-dihydronaphthalenes react similarly.[80] 1-Fluoro-2-iodo-1,1-diphenylethane is obtained when 1,1-diphenylethylene is treated with $C_2H_5IF_2$.[33]

(c) Bis(trifluoroacetoxy)iodo- and bis(trifluoroacetoxy)bromo-compounds

Bis(trifluoroacetoxy)iodoarenes are colourless crystalline substances melting with decomposition at 100–150 °C, soluble in methylene chloride, chloroform, benzene, and ether, and insoluble in pentane. In solutions and during storage they decompose slowly, the decomposition being much faster on heating. Electron-donating substituents in the benzene ring reduce their stability during storage, while electron-accepting substituents increase the resistance to hydrolysis.

On hydrolysis with water, aromatic bis(trifluoroacetoxy)iodo-compounds are converted into μ-oxo-compounds:[43]

Alkaline hydrolysis yields iodosylarenes. A μ-oxo-compound is formed from bis(trifluoroacetoxy)iodobenzene on heating to 70 °C or on interaction with iodosylbenzene:[43]

μ-Oxo-compounds can be obtained by treating iodosylbenzene with a stoichiometric amount of the corresponding acid.[81] The properties, spectroscopic characteristics, and crystal structures of various μ-oxo-compounds have been examined in detail.[81]

Bis(trifluoroacetoxy)iodoarenes are reduced by sodium or potassium iodide in an acid medium to the corresponding iodo-derivatives.[46,82]

μ-Oxodiphenyldiiodosylbis(trifluoromethanesulphonate) $C_6H_5I(OSO_2CF_3)-O-I-(OSO_2CF_3)C_6H_5$, obtained by treating diacetoxyiodobenzene in chloroform with trifluoromethanesulphonic

acid[83] or by treating iodosylbenzene in methylene chloride with the anhydride of trifluoromethanesulphonic acid,[84] is a yellow substance, sparingly soluble in organic solvents, having m.p. 119–121 °C.[83]

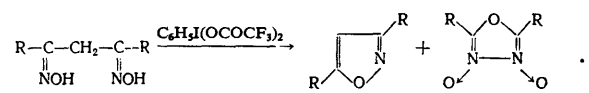
Bis(trifluoroacetoxy)iodoperfluoroalkanes and bis(trifluoroacetoxy)iodo-αα-dihydropolyfluoroalkanes are colourless crystalline substances readily soluble in polar organic solvents. They can be stored for a long time in Teflon vessels without access of moisture. Derivatives of perfluoroalkanes are more stable than those of αα-dihydropolyfluoroalkenes.[28,49] The replacement of the aromatic groups by the more electron-accepting polyfluoro- or perfluoroalkyl group increases the tendency of bis(trifluoroacetate) to hydrolyse.[49]

In contrast to bis(trifluoroacetoxy)iodoperfluoroalkanes, bis(trifluoroacetoxy)iodo-αα-dihydropolyfluoroalkanes are converted into *meso*-oxo-compounds on treatment with water and not into iodosyl compounds.[28]

The μ-oxo-derivatives of αα-dihydropolyfluoroalkanes are colourless crystalline substances which have higher melting points and are less soluble in organic solvents than the corresponding bis(trifluoroacetoxy)iodo-derivatives. A characteristic feature of *meso*-oxo-compounds is their solubility in water (it diminishes with increase in the length of the carbon chain of the polyfluorinated group).

The hydrolysis of bis(trifluoroacetoxy)iodo-αα-dihydropolyfluoroalkanes with a 5% solution of sodium bicarbonate leads to extremely unstable iodosyl compounds, which decompose with liberation of iodine.[28]

The thermal decomposition of bis(trifluoroacetoxy)iodotrifluoromethane takes place in accordance with the scheme[50]



$$CF_3I(OCOCF_3)_2 \xrightarrow[-(CF_3CO)_2O]{} CF_3IO \rightarrow CF_3I + CF_3IO_2.$$

At low temperatures the reaction stops at the iodosyltrifluoromethane formation stage.

Bis(trifluoroacetoxy)bromopentafluorobenzene $C_6F_5Br(OCOCF_3)_2$ is a pale-yellow substance melting with decomposition at 54 °C. Its ^{19}F NMR, IR, and mass spectra have been published.[39] Diacetoxyiodoarenes are widely used in organic synthesis[7,9] as oxidants, acetoxylating agents, and reagents for the synthesis of iodonium salts. Bis(trifluoroacetoxy)iodoarenes are stronger oxidants and electrophiles than diacetoxyiodoarenes. The explanation is that the trifluoroacetoxy-group exhibits a greater electron-accepting inductive effect than the acetoxy-group ($\sigma_{I(OCOCH_3)} = 0.27$; $\sigma_{I(COCF_3)} = 0.65$ [85]) and a larger positive charge is concentrated on the iodine atom in bis(trifluoroacetoxy)-iodoarenes.

Bis(trifluoroacetoxy)iodoarenes have found applications in oxidation, trifluoroacetoxylation, and halogenation reactions and in the synthesis of other compounds of trivalent iodines. Bis(trifluoroacetoxy)iodobenzene is used in various dehydrogenation reactions under mild conditions. Hydrazo-compounds are converted with its aid into azo-compounds, thiophenols are converted into disulphides, hydroquinones are converted into quinones, 1,2-dioximes are converted into furoxanes, *N*-substituted hydroxylamines are converted into nitroso-compounds, and primary and secondary alcohols are converted into aldehydes and ketones.[45]

The previously unavailable furoxano[3,4-b]quinoxolines were obtained with the aid of bis(trifluoroacetoxy)iodobenzene.[9,86] 1,3-Dioximes form a mixture of isoxazoles and 1,3,4-oxadiazole 3,4-dioxides in this reaction:[7]

trans-2-Unsaturated 2,4-dioximes are oxidised to mixtures of 3a,6a-dihydroxazolo[5,4-*d*]isoxazoles and pyridazine 1,2-dioxides.[87,88]

Bis(trifluoroacetoxy)iodobenzene converts acid amides into amines (the Hofmann rearrangement) under mild conditions:[89–91]

$$R-\overset{\overset{O}{\|}}{C}-NH_2 + C_6H_5I(OCOCF_3)_2 + H_2O \rightarrow$$
$$\rightarrow R\overset{+}{N}H_3CF_3COO^- + CF_3COOH + C_6H_5I + CO_2.$$

The same reaction is used to cleave peptides with terminal COOH groups, which makes it possible to determine the aminoacid sequence[92] and also to synthesise L-2,3-diaminopropionic acid—a constituent of a polypeptide antibiotic.[93]

Arylacetylenes have been oxidised to α-diketones[94] and benzaldehydes have been oxidised to benzoic acids[95] with the aid of bis(trifluoroacetoxy)iodobenzene. It has been used in the synthesis of morphines as an agent effecting oxidative cyclisation.[96]

The oxidative cleavage of dibenzyl ethers[97] and the ring opening in oxirans (leading to hydroxyaldehydes and hydroxyketones after the hydrolysis of the trifluoroacetate[98]) and arylcyclopropanes[99–101] also belong to the class of trifluoroacetoxylation reactions.

Reactions involving the oxidative substitution of a halogen, namely iodine, in alkyl halides[102,103] lead to trifluoroacetate esters, for example:

$$n\text{-}C_7H_{15}I + C_6H_5I(OCOCF_3)_2 \rightarrow n\text{-}C_7H_{15}OCOCF_3.$$

Bis(trifluoroacetoxy)iodobenzene introduces two trifluoroacetoxy-groups into alkene molecules in a high yield, the bisesters obtained being readily hydrolysed to glycols.[9] In the interaction of bis(trifluoroacetoxy)iodobenzene with aryldiazomethanes and aryl diazoethanes, the main products are the trifluoroacetate esters $ArCH_2OCOCF_3$ or $ArCH(CH_3)OCOCF_3$.[9] The trifluoroacetoxylation reaction has been used to synthesise codeine.[104]

The phenomenon of competitive binding of superweak anions has been extended to the reactions involving the coupled addition of aryliodoso-salts to the C=C double bond in the interaction of hex-1-ene or cyclohexene with bis(trifluoroacetoxy)iodobenzene in the presence of lithium perchlorate or triflate, which leads to the formation of bistriflates or bisperchlorates of hexane-1,2-diol or cyclohexane-1,2-diol:[105,106]

$$C_4H_9CH=CH_2 + C_6H_5I(OCOCF_3)_2 + LiOZ \rightarrow C_4H_9CH(OZ)-CH_2OZ,$$
$$Z = SO_2CF_3,\ ClO_3.$$

The bistriflates and bisperchlorates of hexane-1,2-diols are also formed when hex-1-ene or cyclohexene are treated with *meso*-oxodiphenyldiiodosobis(trifluoromethanesulphonate) or the corresponding perchlorate.[83] Subsequently this reaction was extended also to butadiene.[84]

The reactions involving halogenation with a mixture of bis(trifluoroacetoxy)iodobenzene with halogens are of considerable interest. It has been shown[107] that the bis(trifluoroacetoxy)-iodobenzene/iodine system is an extremely effective agent for the iodination of aromatic compounds. Iodine has been introduced by this method into a series of alkyl- and halogeno-benzenes, various polynuclear aromatic hydrocarbons, certain heterocyclic compounds,[107,108] *o*- and *m*-carbaboranes,[109] and also arylcyclopropanes.[110]

The halogenation of various aromatic compounds by mixtures of $C_6H_5I(OCOCF_3)_2$ with the halogens and also with boron and aluminium halides has been described.[111,112] A powerful halogenating agent—trifluoroacetyl hypohalite—is apparently generated in all these reactions, for example:

$$PhI(OCOCF_3)_2 + I_2 \rightarrow PhI + 2CF_3COOI,$$
$$PhI(OCOCF_3)_2 + AlCl_3 \rightarrow PhI + CF_3COOAlCl_2 + CF_3COOCl.$$

Bis(trifluoroacetoxy)iodobenzene has also been used to synthesise other trivalent iodine compounds, for example, phenyl-2-thienyliodonium trifluoroacetate.[113] The first representative of trivalent iodine compounds containing two I–N bonds, namely diphthalimidoiodobenzene, was obtained by the reaction of bis(trifluoroacetoxy)iodobenzene with potassium phthalimide.[114] It was found that similar compounds are also formed from other cyclic imides.[115]

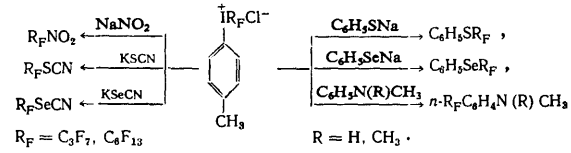
Nitrophenyliodonium phenoxides have been obtained by the reaction of bis(trifluoroacetoxy)iodobenzene with nitrophenols.[116]

(d) Fluorine-containing trivalent iodine ylides and iminoiodoarenes

Acyliminoiodoarenes are crystalline substances melting with decomposition at 100–130 °C. Triphenylmethanesulphonylimino- and trifluoroacetylimino-iodoarenes are readily hydrolysed by atmospheric moisture, while benzenesulphonyl- and toluene-*p*-sulphonyl-iminoiodoarenes are converted into idosylarenes only on alkaline hydrolysis. In the IR spectra of these compounds, the characteristic vibrations of the SO_2 group are displaced towards shorter wavelengths compared with the corresponding sulphonamides.[51–54]

Acyliminoiodoarenes can be used in transylidation reactions. For example, the reaction of tosyliminoiodobenzene with thioanisole, dimethyl sulphoxide, and triphenylphosphine yields the corresponding iminosulphuranes and iminophosphoranes.[51] On catalysis by iron- or manganese-porphyrins, the compounds PhI=NR (R = tosyl or $COCF_3$) react with alkenes, forming *N*-substituted aziridines.[52]

Aryliodonium di(fluorosulphonyl)methylides are colourless or slightly yellowish crystalline substances which melt with decomposition at 160–170 °C,[47,55] dissolve in polar organic solvents, and do not dissolve in pentane.



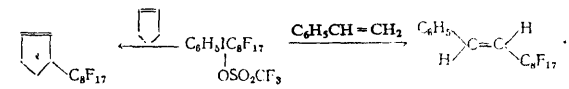
(e) Arylperfluoroalkyliodonium salts

Arylperfluoroalkyliodonium trifluoroacetates and halides are colourless crystalline substances soluble in benzene, methylene chloride, acetone, and acetonitrile. They are lower melting substances and are less stable on storage than diaryliodonium salts.[49] The low melting point can apparently be explained by the more covalent character of the bond between the iodine atom and the acid residue than in diaryliodonium salts, while their low stability is due to the intramolecular interaction of the nucleophilic anion with the onium centre.

Iodonium salts containing the BF_4^- anion are colourless crystalline substances melting with decomposition at 150–160 °C.[56] The salts containing the $OSO_2CF_3^-$ anion (the "FITS reagents")[63] melt with decomposition at lower temperatures (120–130 °C).

Arylperfluoroalkyliodonium tetrafluoroborates and triflates are stable substances which do not decompose on storage or on exposure to atmospheric moisture.

An important property of arylperfluoroalkyliodonium salts is their ability to transfer the perfluoroalkyl group to various nucleophiles. This was first demonstrated for perfluoro-n-alkyl-*p*-tolyliodonium chlorides:[117]



When (perfluoroalkyl)phenyliodonium tetrafluoroborates are used under the same conditions, the yields of the products of the perfluoroalkylation of sodium *p*-nitrothiophenoxide, monomethylaniline, and dimethylaniline are much higher than in the case where chlorides are used and are nearly quantitative according to GLC data.[56]

The "cationic" perfluoroalkylation reactions with the aid of FITS reagents have been extended to various carbanions,[118,119] aromatic compounds,[120] thiols,[121] phenols,[120,122] and unsaturated compounds.[123–126] The latter react with arylperfluoroalkyliodonium triflates in various ways depending on the substrate and the reaction conditions. Ethylene and other alkenes give rise to adducts in the presence of bases:[123]

$$ArI(OSO_2CF_3)-R_F + H_2C=CH_2 \xrightarrow[Na_2CO_3]{Nu^-} R_F-CH_2-CH_2-Nu,$$
$$Nu^- = HCOO^-,\ HO^-,\ CH_3O^-,\ Cl^-.$$

Alka-1,3-dienes afford exclusively 1,4-adducts.[123]

When the reaction with alkenes is carried out under other conditions, for example, in methylene chloride with added pyridine, products resulting from substitution at the vinyl or allyl carbon atom are obtained:[123]

If the reactions of iodonium triflate salts with alkenes are performed in the presence of oxygen, the perfluoroalkylation is accompanied by oxidation; perfluoroalkylated ketones are formed from alkenes, esters are formed from enol ethers, and unsaturated aldehydes and ketones are formed from dienes.[124]

The interaction of arylperfluoroalkyliodonium triflates with the trimethylsilyl ethers of enols affords high yields of α-perfluoroalkylketones, for example:

$$CH_3C(OSiMe_3)=CH_2 \xrightarrow{PhIC_6F_{17}OSO_2CF_3} \underset{88\%}{CH_3COCH_2C_6F_{17}}.$$

Depending on the reaction conditions, products resulting from substitution, addition, or oxidation are formed in the reactions with various alkynes.[126]

The alkylating effect of iodonium salts in which the perfluoroalkyl group is separated from the iodine atom by the methylene group, namely aryl-1,1-dihydropolyfluoroalkyliodonium tetrafluoroborates[60] and triflates,[61] has been investigated[60,127–129] and it has been shown that these salts are stronger alkylating agents than their perfluoroalkyl analogues, apparently as a consequence of the facilitation of the heterolysis of the $I-CH_2R_F$ bond compared with $I-CF_2R_F$.

The differences between the reactivities of iodonium salts with perfluoroalkyl and 1,1-dihydropolyfluoroalkyl groups are manifested in their interaction with nitrogen-containing compounds. Whereas

arylperfluoroalkyliodonium salts do not alkylate pyridine, aryl-1,1-dihydropolyfluoroalkyliodonium salts alkylate tertiary amines, including pyridine and other heterocyclic nitrogen-containing bases[60,127] with formation of quaternary salts. Aniline, *N*-ethylaniline, and β-phenylethylamine are polyfluoroalkylated only at the nitrogen atom,[60,127] while in the case of *NN*-dimethylaniline, a mixture of a quaternary salt and the product of polyfluoroalkylation in the *para*-position in the aromatic ring is obtained.[60]

The dialkylation of aniline has been achieved in a high yield with the aid of phenyl-1,1-dihydrotrifluoroethyliodonium triflate in the presence of a sterically hindered substituted pyridine:[127]

$$C_6H_5NH_2 \xrightarrow{C_6H_5\overset{+}{I}CH_2CF_3\overline{O}SO_2CF_3,\ 20\,^\circ C} C_6H_5N(CH_2CF_3)_2.$$
94%

The reaction with the trimethylsilyl ethers of enols in the presence of KF results in the formation of β-perfluoroalkylcarbonyl compounds in a satisfactory yield:[129]

$$PhI(OSO_2CF_3)CH_2R_F + PhC(OSiMe_3)=CH_2 \xrightarrow[CH_2Cl_2,\ 20\,^\circ C]{KF} PhCOCH_2CH_2R_F + PhI.$$

Aryl-(1,1-dihydropolyfluoroalkyl)iodonium triflates undergo dehydrofluorination on treatment with bases, forming aryl-(1-*H*-perfluoroalk-1-enyl)iodonium triflates:[128]

$$PhI(OSO_2CF_3)CH_2CF_2R_F \xrightarrow{NaH} PhI(OSO_2CF_3)CH=CFR_F \qquad R = CF_3,\ C_2F_5,\ C_6F_{13}.$$

On treatment with *O*-nucleophiles, a fluorine atom at the double bond is substituted, while on treatment with *S*-nucleophiles these compounds react as polyfluoroalkenylating agents:[128]

$$PhI(OSO_2CF_3)CH=CFCF_3 \xrightarrow{PhO^-} PhI(OPh)CH=CFCF_3 \xrightarrow{ArS^-} CF_3CF=CHSAr + CF_3C(SAr)=CHSAr$$
$$Ar = p\text{-}(CH_3)_3CC_6H_4.$$

The tetrafluoroborates of αω-bis(aryliodonium)perfluoroalkanes $C_6H_5\overset{+}{I}(CF_2CF_2)_n\overset{+}{I}C_6H_5.2BF_4^-$ (n = 2, 3) exhibit a high anti-cholinesterase activity.[130]

III. Derivatives of pentavalent halogens

1. Methods of synthesis

The starting materials for the synthesis of fluorine-containing aromatic derivatives of pentavalent iodine are iodylarenes. The methods of their synthesis and their properties are therefore briefly described below. Among the perfluoroalkyl derivatives of pentavalent iodine, tetrafluoroiodoperfluoroalkanes are most readily available.

(a) Iodyl compounds

Iodylarenes were obtained almost 100 years ago.[131] The following are the most convenient methods of their synthesis; the disproportionation of iodosylarenes with steam distillation of the iodoarenes formed,[132] the oxidation of dichloroiodoarenes with sodium hypochlorite,[133] and the oxidation of iodoarenes with 40% peracetic acid.[134] Iodylpentafluorobenzene has been obtained by the disproportionation of iodosylpentafluorobenzene.[135]

A modification of the iodosylarene disproportionation method for the preparation of iodylarenes containing strong electron-accepting substituents in the benzene ring has been proposed. It consists in the steam distillation of bis(trifluoroacetoxy)iodoarenes which are more readily available in this instance. This results in the hydrolysis and disproportionation of the iodosylarenes formed.[48]

$$2XC_6H_4I(OCOCF_3)_2 \xrightarrow{H_2O} 2XC_6H_4IO \rightarrow XC_6H_4IO_2 + XC_6H_4I,$$
X=3-CF_3, 3-NO_2, 4-NO_2.

Iodylarenes, including those with electron-accepting ring substituents, are formed in 45–50% yield when iodoarenes are oxidised with potassium bromate in sulphuric acid.[136] The method is attractive because of its simplicity and safety.

The first representative of aliphatic iodyl compounds, namely iodyltrifluoromethane, has been obtained as a result of the prolonged reaction of CF_3IF_4 with finely dispersed silica in CCl_3F at 0 °C.[14]

(b) Difluoroiodyl compounds

Difluoroiodylarenes have been obtained by dissolving iodylarenes in hot 40% hydrofluoric acid:[3,137]

$$XC_6H_4IO_2 + 2HF \rightarrow XC_6H_4IOF_2 + H_2O,$$
X=H, 2-CH_3, 3-CH_3, 4-CH_3, 4-Br.

$C_6F_5IOF_2$ has been synthesised similarly.[135]

Among aliphatic difluoroiodyl compounds, only difluoroiodyltrifluoromethane CF_3IOF_2 is known. It is formed when difluoroiodotrifluoromethane is ozonised or when tetrafluoroiodotrifluoromethane reacts with finely dispersed silica.[14]

(c) Tetrafluoroiodo- and tetrafluorobromo-compounds

Tetrafluoroiodoarenes are obtained in a quantitative yield by heating iodylarenes with sulphur tetrafluoride.[138,139] Difluoroiodylarenes react similarly, their use being safer, since they are less explosive than iodylarenes:[140]

$$XC_6H_4IO_2 \xrightarrow{SF_4} XC_6H_4IF_4 \xleftarrow{SF_4} XC_6H_4IOF_2,$$
X=H, 4-CH_3, 3-F, 4-F.

The above methods are applicable only to the synthesis of the tetrafluoroiodoarenes which contain weak electron-donating or weak electron-accepting substituents in the benzene ring. The attempts to obtain tetrafluoroiodoarenes with strong electron-donating or strong electron-accepting substituents by this method have been unsuccessful.[140]

Tetrafluoroiodopentafluorobenzene has been obtained by treating iodopentafluorobenzene with chlorine trifluoride.[141,142] *p*-$F_4IC_6F_4IF_4$ is formed similarly from *p*-diiodotetrafluorobenzene.[142] $C_6F_5IF_4$ has also been synthesised by treating difluoroiodopentafluorobenzene with xenon difluoride.[16] This compound can be obtained by the reaction of IF_5 with the stoichiometric amount of $Si(C_6F_5)_4$:[143,144]

$$4IF_5 + Si(C_6F_5)_4 + 2Py \xrightarrow[CH_3CN]{80^\circ C} 4C_6F_5IF_4 + SiF_4 \cdot 2Py.$$

IF_5 reacts much more readily with aryltrifluorosilanes:[144]

$$ArSiF_3 + IF_5 \xrightarrow[CH_3CN]{35^\circ C,\ Py} ArIF_4 + SiF_4 \cdot 2Py,$$
Ar=C_6H_5, 4-$CH_3C_6H_4$, 4-FC_6H_4, C_6F_5.

The reaction involving pentafluorophenyltrifluorosilane takes place at 20 °C in the absence of pyridine.

According to Obaleye and [illegible] tetrafluorobromopentafluorobenzene has been obtained [illegible] reaction of pentafluorobromobenzene with elementa[illegible]ine at 128 °C.

Ttrafluoroiodoperfluoroalkanes are obtained by the reaction of iodoperfluoroalkanes with elemental fluorine,[13,26] chlorine trifluoride,[27,141,145] and bromine trifluoride or pentafluoride at low temperatures in inert solvents. CF_3IF_4,[141,145] $C_2F_5IF_4$, $C_4F_9IF_4$, $C_{10}F_{21}IF_4$,[13] as well as derivatives of 1,2-diiodotetrafluoroethane $F_4ICF_2CF_2IF_4$ [26] and tetrafluoroiodoperfluoroalkylsulphur pentafluoride $F_5S(CF_2)_nIF_4$ (n = 2, 4) [27] have now been described.

The first representatives of perfluoroalkyl derivatives of pentavalent bromine, namely tetrafluorobromoperfluoro-n-propane[146] and tetrafluorobromoperfluoro-n-hexane[147] have been obtained by fluorinating the corresponding perfluoroalkyl bromides with elemental fluorine at 0 °C.

(d) Tetrakis(perfluoroacyloxy)iodo-compounds

Tetrakis(trifluoroacetoxy)iodoarenes have been obtained in quantitative yields by treating iodylarenes with trifluoroacetic anhydride:[48]

$$XC_6H_4IO_2 + 2(CF_3CO)_2O \xrightarrow{[CF_3COOH]} XC_6H_4I(OCOCF_3)_4,$$
$$X=H,\ 4\text{-}CH_3,\ 4\text{-}Cl,\ 3\text{-}F,\ 4\text{-}F,\ 3\text{-}CF_3,\ 3\text{-}NO_2,\ 4\text{-}NO_2.$$

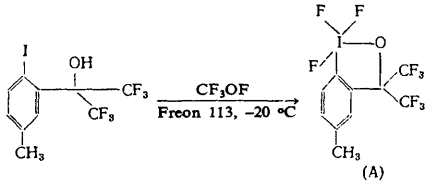
Tetrakis(perfluorobutyryloxy)iodoarenes have been obtained similarly by reaction with perfluorobutyric anhydride.[48] The reaction of iodylarenes with the anhydride of a weaker acid (acetic) affords diacetoxyiodylarenes.[48]

The reactions are carried out at 20 °C using a large excess of the anhydride, which is then regenerated. Electron-donating substituents accelerate the reaction, while electron-accepting substituents retard it somewhat. The addition of small amounts of the corresponding acid catalyses the process.

Tetrafluoroiodobenzene reacts similarly to iodylbenzene:[48]

$$C_6H_5IF_4 + (R_FCO)_2O \rightarrow C_6H_5I(OCOR_F)_4 + R_FCOF,$$
$$R_F=CF_3,\ C_3F_7.$$

(e) Diacyloxyiodyl compounds



Bis(trifluoroacetoxy)iodylarenes have been obtained in quantitative yields by treating iodylarenes with trifluoroacetic acid:[148]

$$XC_6H_4IO_2 + CF_3COOH \rightarrow XC_6H_4I(OCOCF_3)_2 + H_2O,$$
$$\text{(O above I)}$$
$$X=H,\ 4\text{-}CH_3,\ 3\text{-}F,\ 4\text{-}F,\ 3\text{-}CF_3,\ 4\text{-}NO_2.$$

Diacetoxy- and bis(perfluorobutyryloxy)-iodylarenes have been synthesised similarly using an excess of acetic and perfluorobutyric acids. Small amounts of the anhydride of the corresponding acid are added to bind the water in reversible reactions. The stronger the acid, the faster the dissolution of the iodylarenes.

(f) Trifluoroperiodinanes

Trifluoroperiodinane (A) is a compound containing a pentavalent iodine atom in the ring linked to alkoxy- and aryl ligands. It has been obtained by oxidising with trifluoromethyl hypofluorite an iodoarene containing in the *ortho*-position relative to the iodine atom a tertiary carbinol residue:[149,150]

(A)

The *gem*-analogue of trifluoroperiodinane (A) has been synthesised by a procedure similar to that used for compound (A) itself.[150]

(g) Diiminoiodoarenes

Bis(sulphonylimino)iodoarenes have been obtained by the reaction of tetrafluoroiodoarenes with *NN*-bis(trimethylsilyl)derivatives of trifluoromethanesulphonamide[53] and benzene sulphonamide:[47,54]

$$XC_6H_4IF_4 + 2RSO_2N(SiMe_3)_2 \xrightarrow{\text{ether, 20 °C}} XC_6H_4I(NSO_2R)_2 + 4Me_3SiF,$$
$$R=CF_3,\ X=H,\ 3\text{-}F,\ 4\text{-}F;\ R=C_6H_5,\ X=H,\ 4\text{-}CH_3,\ 3\text{-}F,\ 4\text{-}F.$$

Instead of tetrafluoroiodoarenes, it is possible to use also tetrakis(trifluoroacetoxy)iodoarenes for the synthesis of bis(benzenesulphonylimino)iodoarenes.[54]

(h) Diaryliodosyl salts

Diphenyliodosyl hydroxide has been obtained by the self-condensation of iodylbenzene in the presence of alkali. It forms compounds with carbonic and acetic acids. They have been described as hydrogen-bonded cyclic complexes.[151]

A series of diaryliodosyl salts were subsequently obtained in accordance with the following scheme:[152]

$$ArIO_2 \xrightarrow{HO^-} Ar_2I(O)OH \xrightarrow{RCOOH} Ar_2I(O)OCOR \xrightarrow{X^-} Ar_2\overset{+}{I}(O)\ X^-,$$
$$R=CH_3,\ CF_3;\ X^-=F^-,\ Cl^-,\ Br^-,\ IO_3^-.$$

The interaction of diaryliodosyl trifluoroacetates with sulphur tetrafluoride at low temperatures leads to diaryldifluoroiodosyl trifluoroacetates.[153] On heating to 60 °C, the trifluoroacetate anion is also substituted by a fluoride ion and diphenyldifluoroiodosyl fluoride is formed:[153]

$$(XC_6H_4)_2\overset{+}{I}{=}O \xrightarrow[-10\text{–}0\,^\circ C]{SF_4} (XC_6H_4)_2\overset{+}{I}F_2\ \overline{O}COCF_3 \xrightarrow[60\,^\circ C]{SF_4} (XC_6H_4)_2\overset{+}{I}F_2\ F^-,$$
$$X=H,\ 4\text{-}F.$$

2. The properties of fluorine-containing organic compounds of pentavalent iodine

(a) Iodyl compounds

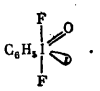
Iodylarenes are colourless crystalline substances, which explode on heating above 200 °C or on impact with liberation of iodine. They are insoluble in the majority of organic solvents and are sparingly soluble in sulpholane, dimethyl sulphoxides, and water. They are usually crystallised from water.

The structure of the solid iodylarenes has been investigated by X-ray diffraction and nuclear quadrupole resonance using *p*-chloroiodylbenzene as an example.[154] It has been shown that the iodylarene molecule is non-planar and asymmetric in the crystalline state and the IO_2 group is perpendicular to the plane of the aromatic ring. The I—O bond lengths (1.60 and 1.65 Å) are smaller than the sum of the covalent radii of oxygen and iodine (2.00 Å), which indicates a partial double bond character.[4] The effective charge on the iodine atom has been estimated from the NQR spectra. It is close to +1.7 |e|.[54] The data presented make it possible to attribute to iodylarenes the following structure:

which is similar to the structure of nitrobenzene except that the nitro-group is located in the plane of the aromatic ring.

This hypothesis has been confirmed by data obtained by comparing the IR and Raman spectra of iodylbenzene.[65] The I–O stretching vibrations in iodylbenzene occur at higher frequencies than in iodobenzene, so that the I–O distance in iodylbenzene is shorter. The Mössbauer spectra of $C_6H_5IO_2$ have been described.[64] According to the literature,[64] the O–I–O angle in the iodylbenzene molecule is close to 95 °C.

The chemical properties of iodylarenes have been little investigated. They are known to exhibit amphoteric behaviour—they react with strong acids, forming salts, and dissolve in alkalies with formation of unstable anions, which decompose on acidification.[4] Conductiometric determination of the pK_a of iodylbenzene yielded 10.4.[151]



The interaction of iodylarenes with the anhydrides of carboxylic perfluoroacids and with carboxylic acids, leading to the formation of tetrakis(perfluoroacyloxy)iodoarenes[48] and diacyloxyiodylarenes,[148] proceeds via a stage involving the formation of a salt of the type $ArI^{+}(O)OH\overline{O}COR$.

The study of the chemical properties of iodylarenes is hindered by their insolubility in the usual organic solvents. The preparation of 4-t-butyliodylbenzene, soluble in hot benzene, chlorobenzene, and nitrobenzene and the study of the oxidation by this compound of alkenes, acetylenes, phenanthrene, anthracene, and tetralin have been described. The corresponding carbonyl compounds are obtained in 50–75% yield and the 4-t-butyliodobenzene dissolved can be regenerated.

Iodyltrifluoromethane is a colourless crystalline substance, stable in air, which decomposes at 50 °C with liberation of iodine. CF_3IO_2 is insoluble in CCl_3F and acetonitrile but is readily soluble in methanol, probably as a result of the formation of methoxides of the type $CF_3I(O)(OCH_3)_2$ or $CF_3I(OCH_3)_4$.[14] The IR and ^{19}F NMR spectra of iodyltrifluoromethane have been published.[14]

(b) Difluoroiodyl compounds

Difluoroiodylarenes are colourless crystalline substances, which are hydrolysed by atmospheric moisture with formation of iodylarene and hydrogen fluorides. Like iodylarenes, they are sparingly soluble in organic solvents and explode on heating above 200 °C. The following structure has been proposed for difluoroiodylbenzene on the basis of a comparison of the IR and Raman spectra:[65]

Difluoroiodyltrifluoromethane is a colourless crystalline substance which sublimes at −10 °C (0.01 mmHg). It is very readily hydrolysed by atmospheric moisture and readily dissolves in CCl_3F and acetonitrile.[14] Difluoroiodyltrifluoromethane reacts with alcohols, acids, and acid anhydrides, the fluorine atoms being substituted. All these reactions are reversible, for example:[156]

$$CF_3IOF_2 + ROH \rightleftarrows CF_3IOF(OR) + HF,$$
$$CF_3IOF(OR) + ROH \rightleftarrows CF_3IO(OR)_2 + HF.$$

When an attempt is made to isolate such compounds, they decompose. The reactions could therefore be investigated by NMR.[156]

Difluoroiodyltrifluoromethane reacts with Lewis acids (BF_3, AsF_5, and SbF_5). This probably entails the initial formation of a complex which then decomposes, being converted into tetrafluoromethane and the compounds $IO[BF_4]$, $IO[AsF_6]$, $IO[SbF_6]$, or $IO[Sb_2F_{11}]$.[157]

(c) Tetrafluoroiodo- and tetrafluorobromo-compounds

Tetrafluoroiodoarenes are colourless crystalline substances which melt without decomposition at 80–100 °C and are readily soluble in ether, benzene, and methylene chloride and less so in hexane. They are hydrolysed by atmospheric moisture to iodylarenes, they corrode glass vessels, and on heating or prolonged storage they react with quartz. On storage in platinum or Teflon vessels in the absence of moisture, they are stable.[138,140]

The ^{19}F NMR spectra of tetrafluoroiodobenzene contain one signal—an asymmetric singlet. The fluorine atoms of tetrafluoroiodobenzene are equivalent and its molecule apparently has the form of a tetragonal pyramid with fluorine atoms at the base, the iodine atom in the centre, and the phenyl residue at the apex.[138]

Tetrafluoroiodobenzene is thermally stable; it hardly changes on heating to 250 °C and decomposes at an appreciable rate only at about 300 °C.[140] On photolysis of tetrafluoroiodobenzene, atomic fluorine is evolved, which has been demonstrated by photolysing $C_6H_5IF_4$ in deuteriated benzene with subsequent mass-spectrometric analysis of the reaction products.[158]

Tetrafluoroiodobenzene is less reactive than iodine pentafluoride. In contrast to the latter, it dissolves in benzene without appreciable interaction. On dissolution in primary alcohols, a vigorous reaction takes place, leading to aldehydes (as a result of charring, the yields are 20%), iodobenzene, and hydrogen fluoride. Tetrafluoroiodobenzene dissolves in t-butyl alcohol in the cold without interaction, whilst at 30–35 °C it interacts with formation of t-butyl fluorides. Acids and their lithium salts are converted into acid anhydrides and fluorides respectively on heating with tetrafluoroiodobenzene.[140] Tetrafluoroiodobenzene fluorinates triphenylphosphine to trifluorotriphenylphosphorane, being reduced at the same time to difluoroiodo- or iodo-benzene depending on the reactant ratio employed:[138]

$$C_6H_5IF_4 + 2(C_6H_5)_3P \rightarrow C_6H_5I + 2(C_6H_5)_3PF_2.$$

Tetrafluorobromopentafluorobenzene is a colourless liquid which fumes in air. It oxidises 0.1 M KI solution and does not decolorise 0.1 M $KMnO_4$ solution.[36]

Tetrafluoroiodoperfluoroalkanes are colourless crystalline substances which are hydrolysed by atmospheric moisture and decompose at 20–60 °C. They are soluble in CCl_3F, IF_5, dioxane, and acetonitrile. The stability of the compounds R_FIF_4 increases with increase in the length of the carbon chain in the perfluoroalkyl group.[145]

On hydrolysis of tetrafluoroiodoperfluoroalkanes with water[13] or KOH in ethanol,[145] iodylperfluoroalkanes are not formed. The author suggests[13] that the iodonium salts $(R_F)_2\overset{+}{I}X^-$ are formed, but these have not been isolated in a pure form.

CF_3IF_4 decomposes in accordance with the following scheme:[145]

$$CF_3I + IF_5 \xleftarrow{[IF]} CF_3IF_4 \rightarrow CF_4 + IF_3 \rightarrow IF + IF_5$$
$$\downarrow$$
$$I_2 + IF_5$$

In the reaction with methoxytrimethylsilane, the fluorine atoms are substituted in succession by methoxy-groups:[145]

$$CF_3IF_4 + (CH_3)_3SiOMe \rightarrow CF_3IF_3(OMe) + (CH_3)_3SiF.$$

Similar substitution products are obtained also in the interaction with alcohols, acids, and anhydrides:[156]

$$CF_3IF_4 + n\,ROH \rightleftarrows CF_3IF_{4-n}(OR)_n + n\,HF.$$

Tetrafluorobromoperfluoropropane[146] and tetrafluorobromoperfluoroheptane[147] are colourless liquids. They are capable of oxidising four equivalents of KI, for example:

$$n\text{-}C_7F_{15}BrF_4 + 4KI \rightarrow n\text{-}C_7F_{15}Br + 2I_2 + 4KF.$$

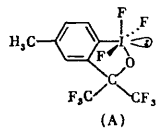
(d) Tetrakis(perfluoroacyloxy)iodo-compounds

Tetrakis(perfluoroacyloxy)iodoarenes are colourless crystalline substances melting with decomposition. They are readily hydrolysed by atmospheric moisture and are unstable during storage. Electron-donating substituents in the benzene ring diminish the stability of these compounds during storage, while electron-accepting substituents diminish their resistance to hydrolysis. Tetrakis(perfluoroacyloxy)-iodoarenes are readily soluble in organic solvents but their stability in solutions is low.[48]

The IR spectrum of tetrakis(trifluoroacetoxy)iodobenzene differs from the IR spectrum of iodylbenzene by the presence of an intense band at 500 cm^{-1} and two bands at 735 and 783 cm^{-1} instead of four bands at 700–800 cm^{-1} in the spectrum of iodylbenzene. The ^{19}F NMR spectrum of $C_6H_5I(OCOCF_3)_4$ has a single signal—a symmetrical singlet. This compound apparently has a structure similar to that of tetrafluoroiodobenzene.[48]

Tetrakis(trifluoroacetoxy)iodobenzene is a fairly powerful oxidant; it oxidises *m*-nitrobenzyl alcohol to the corresponding aldehyde in 3 h at 20 °C in 80% yield,[159] while bis(trifluoroacetoxy)iodobenzene oxidises benzyl alcohol to benzaldehyde in 4 h at 80 °C in 50% yield.[45]

(e) Diacyloxyiodylarenes



Diacyloxyiodylarenes are colourless crystalline substances melting with decomposition at higher temperatures than the corresponding tetrakis(perfluoroacyloxy)iodoarenes. They dissolve less readily in organic solvents and are more stable during storage and in hydrolysis. The IR spectra of the compounds $ArI(OCOR)_2$ are similar to the IR spectrum of $C_6H_5IOF_2$.[148]

Diacetoxyiodylbenzene has been used as an oxygen donor in the hydroxylation of steroids catalysed by cytochrome P-450.[160]

(f) Trifluoroperiodinanes

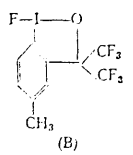
Trifluoroperiodinanes are colourless crystalline substances melting with decomposition. Trifluoroperiodinanes (A) (decomposition temperature 191–193 °C) can remain for a time in air without appreciable hydrolysis. The addition of water to this compound at 25 °C does not lead to reaction for several days. When trifluoroperiodinane is treated with an aqueous KOH solution, an iodyl derivative is probably obtained.[150] The *gem*-dimethyl analogue of trifluoroperiodinane (decomposition temperature 123–124 °C) hydrolyses faster than compound (A). In the presence of atmospheric moisture, the hydrolysis takes place over 4 h at 25 °C. The hydrolysis products have not been identified.[150] The *gem*-dimethyl analogue is also less stable during storage. It decomposes in 7 days at 25 °C and in 2–3 weeks at –20 °C.

Judging from the ^{19}F NMR spectra of perfluoroiodinanes, the fluorine atoms of the IF_3 group in these compounds are non-equivalent. An octahedral structure has been proposed for compound (A) (the sixth ligand is an electron pair):[150]

(A)

The doublet in the ^{19}F NMR spectrum of compound (A) at $\delta = -13.20$ ($J = 116$ Hz) is due to two equivalent fluorine atoms, while the triplet at $\delta = -41.57$ ($J = 116$ Hz) is due to a single fluorine atom. Other investigators[145] arrived at a similar conclusion concerning the structure of the compound $CF_3IF_3(OCH_3)$. The ^{19}F NMR spectrum of its IF_3 group consists of a doublet at $\delta = -7.0$ ($J = 113$ Hz) and a triplet at $\delta = -46.5$ ($J = 113$ Hz).

Trifluoroperiodinane decomposes slowly in acetonitrile and the solution corrodes glass in the presence of atmospheric moisture. On treatment of compound (A) with three or more equivalents of chlorotrimethylsilane, chloroiodinane, fluorotrimethylsilane, and chlorine are formed. When trifluoroperiodinane is irradiated with UV light in the presence of toluene or anisole at 50 °C, it remains unchanged.[150]



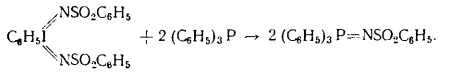
Trifluoroperiodinane reacts rapidly with phenylmagnesium bromide in accordance with the scheme

$$(A) + C_6H_5MgBr \xrightarrow{\text{ether}} \underset{90\%}{C_6H_5F}.$$

The interaction of trifluoroperiodinane with primary and secondary amines containing an α-hydrogen atom and subsequent hydrolysis afford a satisfactory yield of the corresponding carbonyl compounds.[150] In the reaction with t-butylamine, azoisobutane is formed. Trifluoroperiodinane does not react with tertiary amines.[150]

The interaction of trifluoroperiodinane with primary and secondary alcohols gives rise to aldehydes and ketones respectively.[150]

In all cases, trifluoroperiodinane is reduced as a result of the reaction to fluoroiodinane (B):



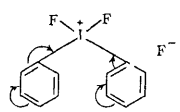
(B)

In contrast to trifluoroperiodinane, its *gem*-dimethyl analogue does not oxidise benzyl- and isopropyl-amines to the corresponding carbonyl compounds, but the reactions with alcohols proceeds with satisfactory yields.[150]

(g) Diiminoiodoarenes

Bis(trifluoromethanesulphonylimino)- [53] and bis(benzene-sulphonylimino)-iodoarenes[54] are colourless or slightly yellowish crystalline substances, melting with decomposition at 100–130 °C, and are sparingly soluble in organic solvents. They are readily hydrolysed by atmospheric moisture to iodoarenes. The absorption due to the characteristic vibrations of the O_2 group are displaced in the IR spectra of these compounds towards lower frequencies compared with trifluoromethanesulphonamide and benzenesulphonamide.[53,54]

The diimino-derivatives of pentavalent iodine can be used in transylidation reactions. For example, the reaction of bis(benzenesulphonylimino)iodobenzene with triphenylphosphine afforded a high yield of *N*-benzenesulphonyltriphenylphosphine imine:[54]

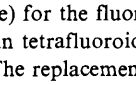


(h) Diaryliodosyl salts

Dioaryliodosyl bromides, chlorides, fluorides, and trifluoroacetates[52] are involatile and infusible crystalline substances which decompose explosively at 160–200 °C. They are readily converted into the corresponding iodonium salts on treatment with iodine, sodium bisulphite, and hydrogen peroxide.[152]

The diaryliodosyl difluoride salts are colourless crystalline substances soluble in methylene chloride, nitromethane, and acetonitrile and insoluble in ether, benzene, and hydrocarbons. In a moist atmosphere, they readily hydrolyse to diaryliodosyl salts.

The ^{19}F NMR spectra of diphenyliodosyl difluorides consist of two signals: $\delta[(C_6H_5)_2\overset{+}{I}F_2] = 22.62$ p.p.m. and $\delta(CF_3COO^-) = -13.13$ p.p.m. for the trifluoroacetate in CH_2Cl_2; $\delta[(C_6H_5)_2\overset{+}{I}F_2] = -24.5$ p.p.m. and $\delta(F^-) = 89.25$ p.p.m. (relative to trifluoromethylbenzene) for the fluoride in nitromethane.[153] As mentioned above,[138] in tetrafluoroiodobenzene all the fluorine atoms are equivalent. The replacement of one fluorine atom in tetrafluoroiodobenzene by the phenyl group led to a compound with non-equivalent fluorine atoms. The presence of two phenyl groups in the diphenyliodosyl trifluoride molecule apparently facilitates the polarisation of the I–F bond and stabilises the ionic structure $(C_6H_5)_2\overset{+}{I}F_2F^-$:[153]



IV. The electronic nature of substituents containing polyvalent iodine

The electronic nature of substituents containing an iodine atom in the trivalent and pentavalent states has been studied systematically.[47] The investigation of the ^{19}F NMR spectra of *meta*- and *para*-fluorobenzenes demonstrated a change in the character of the electronic influence of the substituent on the benzene ring in the series iodine–iodosyl group–iodyl group and on substitution of the oxygen atoms of the iodosyl and iodyl groups by fluorine and chlorine atoms and by acetoxy-, trifluoroacetoxy-, benzenesulphonylimino-, trifluoromethanesulphonylimino-, and bis(fluorosulphonyl)methylide groups. The chemical shifts of the fluorine atoms in the iodine-containing substituent (δ_F, p.p.m.) relative to CCl_3F are presented in Table 1.

The chemical shifts of the fluorine atoms in the *meta*- and *para*-derivatives of fluorobenzene relative to fluorobenzene have been measured in methylene chloride. Taft's $\delta-\sigma$ correlation equations have been used to calculate the inductive constants σ_I and the conjugation constants σ_R of the substituent.[161] The σ constants of substituents containing polyvalent iodine are listed in Table 2. The table shows that substituents containing polyvalent iodine interact with the aromatic ring mainly via the inductive mechanisms. The high values of the constants σ_I are probably caused by the high polarity of the bonds between the iodine atom and fluorine, chlorine, oxygen, and nitrogen atoms.

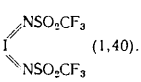


Table 2. The chemical shifts δ of the fluorine atoms in the *meta*- and *para*-derivatives of fluorobenzene relative to fluorobenzene and the σ constants of the iodine-containing substituents.[47]

Substituent	δ_m	δ_p	σ_I	σ_R	σ_m	σ_p
I	2.60	−1.25	0.45	−0.13	0.38	0.32
I=O	3.40	5.10	0.56	0.06	0.59	0.62
$I(OCOCH_3)_2$	5.45	7.13	0.85	0.06	0.88	0.91
IF_2	6.29	5.12	0.97	−0.04	0.95	0.93
$I(OCOCF_3)_2$	6.48	7.98	1.0	0.05	1.03	1.05
$I{=}NSO_2C_6H_5$	6.76	7.54	1.04	0.03	1.05	1.07
ICl_2	7.72	8.46	1.17	0.03	1.18	1.20
$I{=}NSO_2CF_3$	8.18	11.46	1.24	0.11	1.30	1.35
$I{=}C(SO_2F)_2$	8.30	9.14	1.25	0.03	1.26	1.28
$\overset{+}{I}C_6H_5BF_4^-$	8.88	9.85	1.34	0.03	1.35	1.37
IO_2	4.10	7.09	0.66	0.10	0.71	0.76
$I(OCOCF_3)_2$ ‖ O	6.55	8.42	1.01	0.06	1.04	1.07
IF_4	6.87	10.86	1.05	0.14	1.12	1.19
$I(OCOCF_3)_4$	7.46	8.43	1.14	0.03	1.15	1.17
	7.50	8.40	1.14	0.03	1.15	1.17
	8.44	12.33	1.27	0.13	1.33	1.40

The replacement of the oxygen atom in the I=O group by fluorine and chlorine atoms and by trifluoroacetoxy- or benzenesulphonylimino-groups increases appreciably the σ_I constants, while in the case of the trifluoromethanesulphonylimino- or bis(fluorosulphonyl)methylide groups the increase is by a factor greater than two.

It is of interest that the ICl_2 group is more electron-accepting than IF_2, which can be explained by the greater contribution of the polar structure $\overset{+}{I}X^-$ (X = halogen) in the dichloroiodo-derivatives compared with the difluoroiodo-derivatives.

The accumulation of fluorine atoms and the $OCOCF_3$ groups at the iodine atom [the IF_4 and $I(OCOCF_3)_4$ substituents] increases somewhat the inductive effect. In compounds with a pentavalent tricoordinate iodine atom, the difference between the σ_I constants of the trivalent and pentavalent iodine analogues diminishes with increase in the electron-accepting capacity of the second group introduced at the iodine atom (the transition from $NSO_2C_6H_5$ to NSO_2CF_3). The I–N bond in $ArI{=}NSO_2CF_3$ is apparently polarised so much that the introduction of a second NSO_2CF_3 group increases the positive charge on the iodine atom to only a slight extent. This is confirmed by the finding that, on complete charge separation in diaryliodonium tetrafluoroborates, the σ_p constant of the substituent $\overset{+}{I}C_6H_5BF_4$ (1.37) is very close to the σ_p constants of the groups $I{=}NSO_2CF_3$ (1.35) and

(1,40).

It is notable that the inductive effect of the ylide groups having the I–N and I–C bonds [I=NSO_2CF_3 and I=$C(SO_2F)_2$] is very large and almost the same (σ_I = 1.24 and 1.25 respectively), which indicates a high degree of polarisation in the ylide bond in both types of compound.

The effects of the conjugation of the iodine-containing groups are insignificant. All the iodine-containing substituents investigated, except IF_2, are characterised by small positive conjugation constants.

The thermal gas-phase synthesis of heterocyclic compounds with one or several silicon atoms in the ring

E A Chernyshev, N G Komalenkova
State Institute of the Chemistry and Technology of Organoelemental Compounds, Moscow

ABSTRACT. The results of studies on the synthesis of organosilicon heterocyclic compounds under the influence of high temperatures in a flow system at atmospheric pressure and in a high vacuum are surveyed. The preparative possibilities of the gas-phase thermal method for the synthesis of new or previously difficult to obtain mono-, bi-, and poly-cyclic compounds with one or several silicon atoms in the ring are examined. The principal aspects of the thermal heterocyclisation processes are described.

Attention is concentrated on the synthesis of heterocycles with functional group substituents at the silicon atom as well as high-temperature reactions with participation of unstable intermediates: silylenes, sila-alkenes, and siladienes.

The bibliography includes 130 references.

I. Introduction

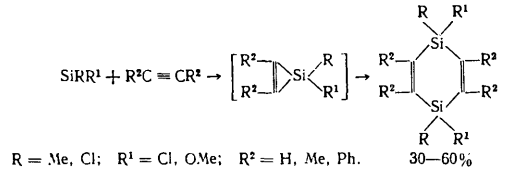
The chemistry of heterocyclic compounds of silicon constitutes at the present time an independent branch of organosilicon chemistry. The number of publications devoted to the method of synthesis and the study of the structure and properties of organosilicon heterocyclic compounds has been steadily increasing. The interest in these compounds is associated both with their practical applications (biological activity, thermal stability, etc.) and with theoretical aspects due to the appearance of new properties in the compounds after the introduction of a silicon atom into the carbon ring and their different behaviour in chemical reactions compared with acyclic organosilicon compounds.

One of the simplest and most effective methods of synthesis of many classes of organosilicon heterocyclic systems, previously impossible to obtain, is the gas-phase thermal method, which consists in the interaction of various silicon-containing and organic compounds at temperatures in the range 300–700 °C in a flow system (the reactor consists of a hollow quartz or metallic tube). It is simple as regards apparatus and in most cases is distinguished by a high selectivity.

The present review is devoted to the discussion of the synthetic possibilities of this method and includes studies published up to the middle of 1987.

Extensive experimental data have now accumulated, which makes it possible to discover the principal fundamental aspects of the high-temperature synthesis of silicon heterocycles. These are primarily the intramolecular thermal cyclisation of organosilicon compounds containing structural fragments necessary for cyclisation in the presence of thermally labile bonds as well as bonds exhibiting an increased reactivity as a consequence of steric interaction with bulky substituents in the α-position in naphthalene and in the *o*-position in benzene or biphenyl. Another aspect vigorously developing recently has been the thermal synthesis of silicon heterocycles with participation of unstable species and compounds: silylenes, sila-alkenes, and siladienes. The sources from which these highly reactive intermediates can be generated in the gas phase as well as acceptors—systems capable of trapping them with formation of thermally stable compounds—have been found. The use of hexachlorodisilane and higher perchloropolysilanes as sources of dichlorosilylene have made it possible to extend greatly the preparative possibilities of the pyrolytic cyclisation method. The high reactivity of the thermally generated dichlorosilylene and the appreciable selectivity of its interaction with specific chemical bonds have made it possible to synthesise specifically various classes of heterocycles with one or several silicon atoms in the ring, whose preparation by other methods was difficult or impossible.

Interesting communications concerning the thermal method for the generation of unstable silicon intermediates in extremely short time intervals (vacuum flash pyrolysis) have appeared comparatively recently. The latest review of these studies was published in 1985.[1] The detection of these species and the study of their properties are mainly of theoretical interest. Nevertheless, despite the increased complexity of the apparatus required for their synthesis, in many cases, the high-temperature reactions of these intermediates can be considered also on the preparative scale—for the synthesis of silicon-containing heterocyclic systems.

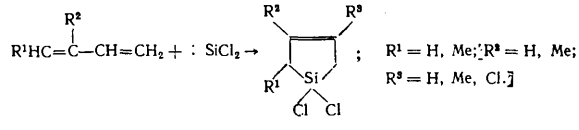


II. Monocyclic compounds

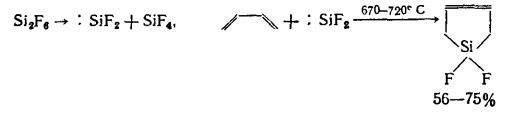
1. Synthesis with participation of silylenes

(a) The addition of silylenes to multiple bonds

The interactions of silylenes with unsaturated compounds must be regarded as some of their most characteristic reactions. Such reactions are of great preparative interest for the synthesis of silicon-containing heterocyclic systems. The most active silylene "trapping agents" are alkynes and conjugated dienes. The most convenient and fairly general method of synthesis of silylenes is the thermolysis of various disilanes. Thus the gas-phase reaction of

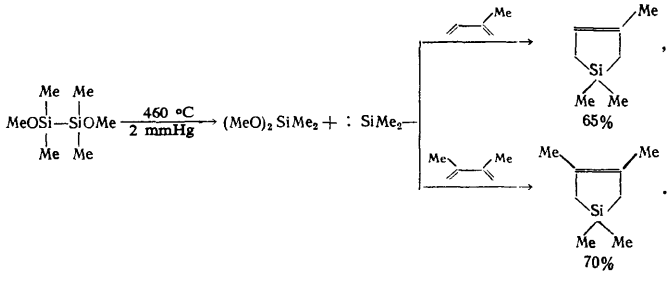


tetrachlorodimethyl-, tetramethoxydimethyl-, and hexachlorodisilanes with acetylene and its derivatives is widely used for the synthesis of disilacyclohexa-2,5-dienes with functional group substituents at the silicon atom:[2–8]



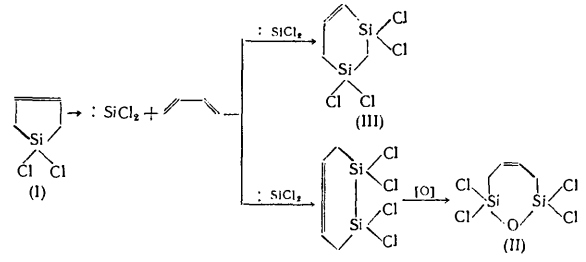
R = Me, Cl; R^1 = Cl, OMe; R^2 = H, Me, Ph. 30—60%

A report of the synthesis of 1,1,4,4-tetramethoxy-1,4-disilacyclohexa-2,5-diene in the copyrolysis of hexamethoxydisilane with acetylene (temperature 370 °C, yield of heterocycle 56%) appeared in 1985.[9] An excellent source from which dimethoxysilylene can be generated, namely hexamethoxydisilane, was proposed in that study. Evidently, the primary step in the thermal interaction is the addition of the corresponding silylene to the triple bond of the alkyne with formation of a silacyclopropene derivative and its subsequent reaction.[2,3,8,10,11]



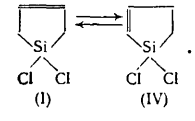
The thermal generation of $:SiCl_2$ from hexachlorodisilane has led to effective ways of synthesising the simplest unsaturated organosilicon heterocycles—derivatives of silacyclopent-3-ene—from conjugated dienes:[2,3,7,8,12–14]

The yields of the heterocycles are almost quantitative (90–95%). A report has recently appeared[15] of the synthesis of 1,1-difluoro-1-silacyclopent-3-ene by the gas-phase pyrolysis of hexafluorodisilane in an excess of buta-1,3-diene:



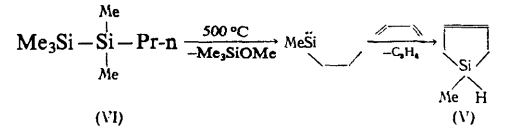
By carrying out the process in a flow system with a reactant contact time of 0.01–0.2 s, it has been possible to capture the highly reactive monomeric $:SiF_2$. The reactions involving the addition of dimethylsilylene, generated thermally from 1,2-dimethoxytetramethyldisilane, to acyclic 1,3-dienes both at atmospheric pressure[10,16] and *in vacuo*[17] also take place readily in the gas phase, for example:

The authors[17] suggest the concerted 1,2-addition of dimethylsilylene to substituted buta-1,3-dienes with subsequent opening of the vinylsilacyclopropane ring.



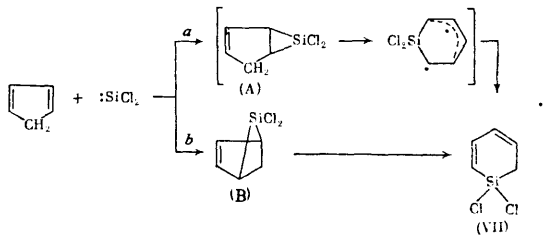
On the other hand, the evidence obtained[2,8,18–20] for the retrodiene thermal decomposition of 1,1-dichloro-1-silacyclopent-3-ene justifies the assumption that the gas-phase interaction of $:SiCl_2$ with buta-1,3-dienes formally corresponds to the Diels–Alder reaction and therefore proceeds via the concerted 1,4-cycloaddition mechanisms.

The ability of 1,1-dichloro-1-silacyclopenta-3-ene (I) to generate $:SiCl_2$ has been used for the preparative high-temperature synthesis of new heterocycles with two silicon atoms in the ring: 1,1,3,3-tetrachloro-1,3-disila-2-oxacyclohept-5-ene (II) and 1,1,3,3-tetrachloro-1,3-disilacyclohex-4-ene (III):[2,8,21]



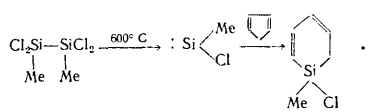
In the pyrolysis of the heterocycle (I) (680 °C), the yields of compounds (II) and (III) and 25 and 45% respectively. When the temperature is reduced, the yields of these compounds diminish and amount to only 7 and 3% at 500 °C. The heterocycle with the Si—Si bond is evidently unstable and is converted into compound (II) under the conditions of the pyrolysis.

A detailed study of the thermal reactions of the heterocycle (I) showed that it is also capable of isomerising to 1,1-dichloro-1-silacyclopent-2-ene (IV) and that this reaction is reversible:[12,22,23]



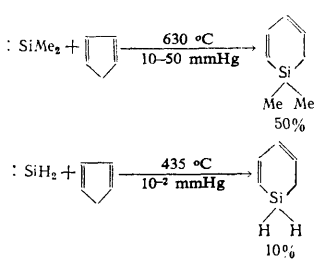
A method has been proposed for the synthesis of compound (IV) by passing its more readily available isomer (I) repeatedly (5–6 times) through a quartz flow reactor at 540 °C.[22]

The generation of dimethylsilylene by the vacuum flash pyrolysis (750 °C, 1 mmHg) of 1,1-dimethyl-1-silacyclopent-3-ene has been reported.[24,25] The isomeric 1-silacyclopent-2-ene is also formed under these conditions. The same workers proposed a new source of $:SiMe_2$ in pyrolytic cyclisation reactions—dimethyl(*cis*-prop-1-enyl)-vinylsilane.[25] The synthesis of the 1-silacyclopent-3-ene hydride derivative (V) via methylpropylsilylene, generated from the disilane (VI), merits special attention:[26]



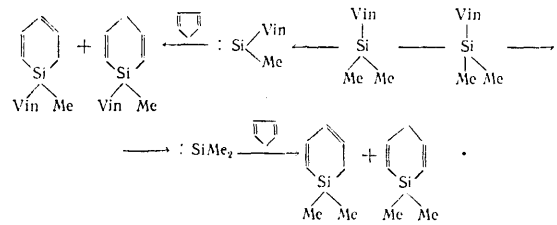
A new aspect of the chemistry of silylenes is the study of their reactions involving addition to cyclic conjugated systems with formation of previously inaccessible monocyclic silicon compounds. Such a reaction was carried out in the thermal interaction of hexachlorodisilane with cyclopentadiene.[2,3,7,13,14,27] The copyrolysis of hexachlorodisilane with cyclopentadiene or its dimer at 500 °C led

to the formation of 1,1-dichloro-1-silacyclohexa-2,4-diene as the main product (yield up to 50%):

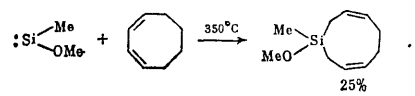


It is notable that the preparation of this compound by other methods is difficult, since these are multistage syntheses leading to low yields of compound (VII) with an admixture of isomers which are difficult to separate.[28] It is possible to put forward two alternative schemes for the expansion of the ring in the five-membered cyclic diene: by adding to it dichlorosilylene in the 1,2-positions (pathway *a*) or in the 1,4-positions (pathway *b*). The first version provides for the formation of the silacyclopropane intermediate (A), which then rearranges to the final reaction product via a biradical. A similar biradical mechanism has been proposed for the thermal rearrangement of the hydrocarbon analogue[29] and also in the study of the gas-phase interaction of dimethylsilylene with cyclopentadiene.[30] However, one cannot rule out also the possibility of the 1,4-cycloaddition of $:SiCl_2$ to cyclopentadiene, which has a fixed cisoid conformation. A fairly pronounced strain in the four-membered ring of the intermediate bicyclic compound (B) is created, as a result of which it can rearrange to the final product—1,1-dichlorosilacyclohexa-2,4-diene. The possibility of the thermal generation of dichlorosilylene in the pyrolysis of compound (VII), demonstrated by the method of "chemical trapping agents",[31] and also the mass-spectrometric study of the pathways leading to the decomposition of this compound[32] confirm to some extent the pathway *b*.

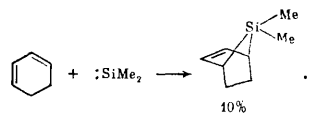
The method described in a number of studies[2,3,7,13,14,27] has been frequently reproduced.[30,33] The preparative possibilities of the method proposed have been greatly expanded by employing both a series of different sources of silylenes as well as certain other organic cyclic compounds with a diene group. 1-Chloro-1-methyl-1-silacyclohexa-2,4-diene has been synthesised in this way:



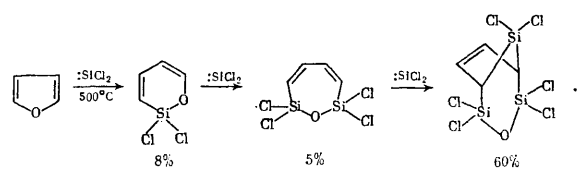
A similar reaction has also been carried out *in vacuo* (650 °C, 10^{-2} mmHg).[35] The interaction of dimethylsilylene and the unsubstituted silylene, generated from the corresponding disilanes, with cyclopentadiene led to the formation of silacyclohexadienes with methyl or hydride substituents at the silicon atom:[30]



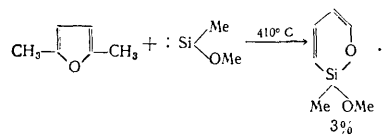
In all cases, except the last, the formation of small amounts of the corresponding derivatives of silacyclohexa-2,5-diene has been noted.



The copyrolysis of 1,1,2,2-tetramethyl-1,2-divinyldisilane $(Me_2VinSi)_2$ with cyclopentadiene has been investigated[35] (650 °C, 10^{-2} mmHg). Four cyclic compounds in approximately equal amounts were detected in the reaction products; non-selective decomposition of the organic disilane via two schemes has been proposed:

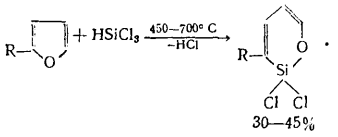


Methoxymethylsilylene adds to cycloocta-1,3-diene with formation of a non-conjugated cyclic diene:[36]

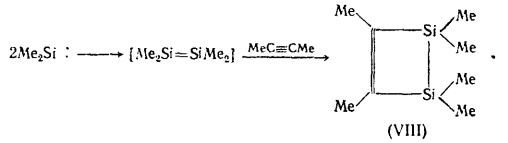


On the other hand, the expansion of the ring of the organic diene is not observed in the interaction of dimethylsilylene with cyclohexa-1,3-diene; only a bicyclic compound is formed in a low yield:[30]

The interaction of dichlorosilylene with furan takes place in a more complex manner. An oxygen-containing analogue of silacyclohexa-2,4-diene, namely 1,1-dichloro-2-oxa-1-silacyclohexa-3,5-diene, was isolated from the reaction mixture in a very low yield.[2,3,7,13,14] The principal product of this reaction is a bicyclic compound with three dichlorosilylene fragments:

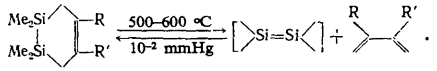


The pyrolytic interaction of methoxymethylsilylene with 2,5-dimethylfuran also does not lead to the specific formation of the six-membered diene system with the Si—O fragment. The yield of the heterocycle does not exceed 3%:[37]



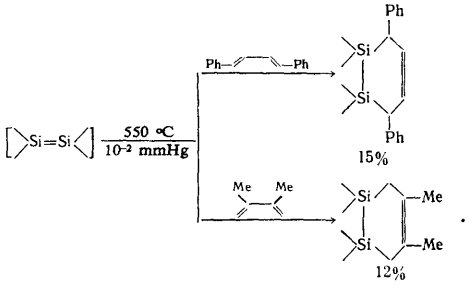
Heterocycles of a similar type are formed in much higher yields in the pyrolytic interaction of furan and its α-substituted derivatives with trichlorosilane. The method proposed makes it possible to obtain derivatives of 2-oxa-1-silacyclohexa-3,5-diene with functional

group substituents at the silicon atom from readily available reactants:[8,38–40]

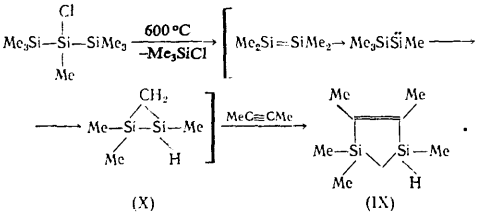


(b) Disilenes. The isomerisation of disilenes to silylsilylenes

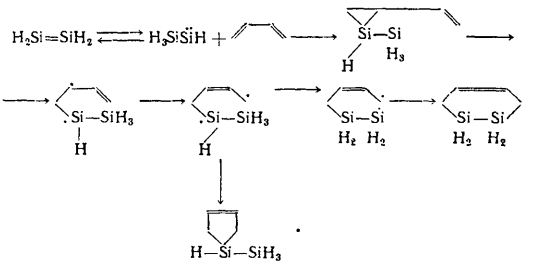
In a study of the gas-phase reaction of dimethylsilylene, generated from dimethoxy-tetramethyldisilane, with dimethylacetylene in 1973, a new heterocyclic compound was isolated—permethyldisilacyclobutene (VIII):[41]



Several schemes for the formation of compound (VIII) have been proposed; one of them involves a stage in which :$SiMe_2$ dimerises to disilene—an unstable intermediate with π-bonded silicon atoms.[10,11] Reaction involving the [6 → 4 + 2]cyclo-elimination of tetramethyldisilene in the extensive gas-phase vacuum pyrolysis of 1,2-disilacyclohex-4-ene has been proposed recently:[42]

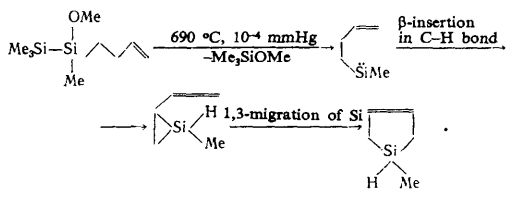


R, R′ = H, Me.

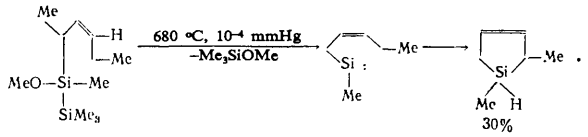


The pyrolysis of this compound in the presence of "trapping agents" made it possible to extend the set of heterocycles with the structure indicated above:

A novel method of synthesis of unsaturated heterocyclic systems with one or two silicon atoms in the ring involving disilenes has been described.[10,11,43,44] The proposed schemes for the preparation of these heterocycles reflect a specific property of disilenes—their ability to isomerise to silylsilylenes during pyrolysis. Thus 1,1,2,3,4-pentamethyl-1,3-disilacyclopentene (IX) has been synthesied by the cothermolysis of various sources of tetramethyldisilene, namely 7,7,8,8-tetramethyl-1-phenyl-2,3-benzo-7,8-disilabicyclo[2.2.2]octa-2,5-diene[10,11] and 2-chloroheptamethyltrisilane,[43] in the presence of dimethylacetylene in 25–28% yield. The authors regard the heterocycle (IX) as the formal product of the insertion of an alkyne in the Si–Si bond of the intermediate disilacyclopropane (X). The isomerisation of tetramethyldisilene to methyl(trimethylsilyl)silylene is postulated under these conditions:[43]

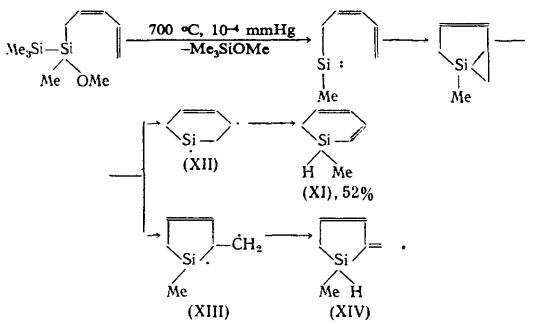


Heterocyclic compounds with endocyclic and exocyclic Si–Si bonds have been obtained in proportions of 1 : 1 by the thermal interaction of butadiene with trisilane, which is apparently capable of generating during pyrolysis not only :SiH_2 but also the product of its recombination with subsequent isomerisation to silylsilylene:[44]

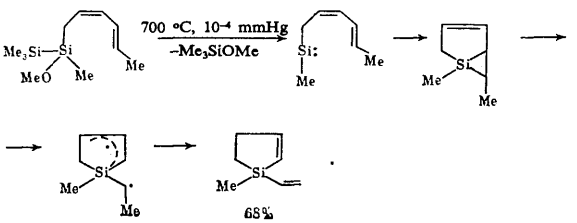


(c) Intramolecular reactions of silylenes

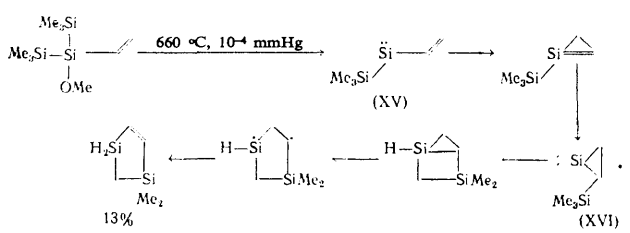
A new apsect of the high-temperature chemistry of organic silylenes, associated with the study of their intramolecular reactions, has begun to develop in the last few years. A method has been proposed for the intramolecular trapping of silylenes, the idea of which consists in the fact that the role of the chemical trapping agent is assumed by the very source from which the silylene is generated. In order to limit the contribution of intermolecular reactions and secondary processes in the generation of such silylenes, they are investigated in a high vacuum. Some of the reactions of this kind can be regarded as methods of synthesis of unsaturated silicon-containing heterocyclic structures. Thus it has been established[45] that 3-butenylmethylsilylene, thermally generated from 1-(3-butenyl)-1-methoxytetramethyldisilane, cyclises to 1-methyl-1-silacyclopent-3-ene in 56% yield:



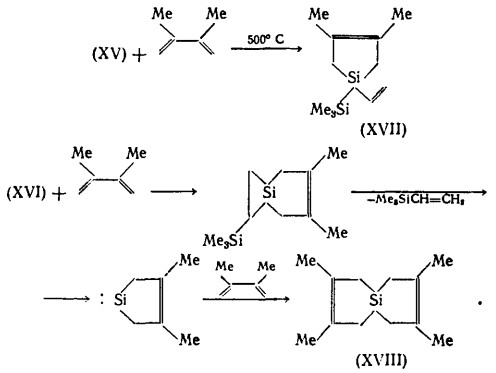
The same heterocycle has been obtained in a satisfactory yield also from another source of 3-butenylmethylsilylene—butenyldichloromethylsilane in its interaction with alkali metal atoms (K/Na) in the gas phase (flow system, temperature 300–340 °C, pressure



10^{-1} mmHg, K/Na = 7/1).[46] The intramolecular reaction of another alkenylsilane, namely methyl-4-(2-pentenyl)silylene, leads to the formation of 1,2-dimethyl-1-silacyclopent-3-ene:[45]

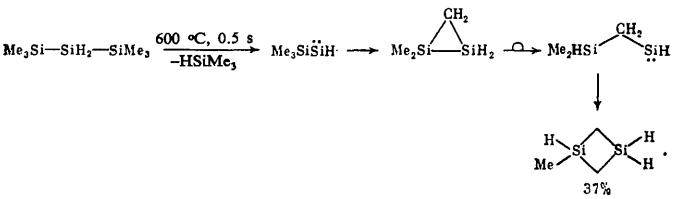


A six-membered heterocycle with a diene group—1-methyl-1-silacyclohexa-2,4-diene (XI)—is the main product of the intramolecular reactions of methyl-5-(penta-1,3-dienyl)silylene.[45] The latter undergoes intramolecular π-addition to the terminal double bond with the subsequent formation of the biradicals (XII) and (XIII), whose further reactions lead to the final products (XI) and (XIV). 2-Methylene-1-methylsilacyclopentene (XIV) has been isolated in 13% yield:

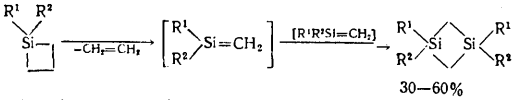


The pyrolysis of the methyl-substituted hexadienyldisilane can be regarded as a thermal method of synthesis of 1-methyl-1-vinyl-1-silacyclopent-2-ene:[45]

A very interesting vinylsilylene intramolecular rearrangement has been observed in the vacuum pyrolysis of 2-methoxy-2-vinylhexamethyltrisilane.[47] The hypothesis of the possible existence of silacyclopropanylidene as an intermediate was proposed for the first time and a scheme for the preparation of 1,1-dimethyl-1,3-disilacyclopent-4-ene with its participation was put forward:



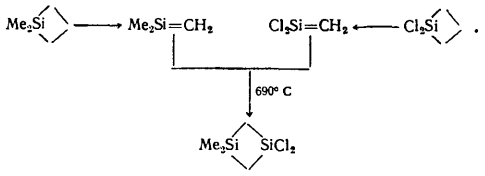
The existence of the intermediates (XV) and (XVI) has been confirmed by the reaction of the initial trisilane with dimethylbutadiene, whereupon also the new heterocyclic systems (XVII) and (XVIII) were obtained:



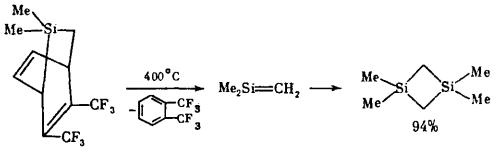
With increase in the excess of dimethylbutadiene, the yield of the spiro-product (XVIII) also increases. It amounts to 20 and 44% for the diene:trisilane ratios of 3:1 and 8:1 respectively. The yield of the heterocycle (XVII) does not exceed 8% in both cases.

An interesting new intramolecular thermal rearrangement of α-silylsilylenes, discovered recently[48] in the pyrolysis of 1,1,1,3,3,3-hexamethyltrisilane, can be regarded as a method of synthesis of 1-methyl-1,3-disilacyclobutane:

2. Synthesis with participation of silaalkenes



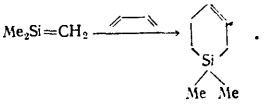
Systematic study of the processes involved in the pyrolysis of monosilacyclobutanes with various substituents at the silicon atom has led to the discovery of an interesting highly selective thermal [4 → 2 + 2]cycloelimination reaction, which proceeds with formation of disilacyclobutanes.[49–51] A unimolecular mechanism of the decomposition of the initial cyclic sila-compounds to ethylene and an unstable intermediate with an unsaturated bond at the silicon atom—silaalkene (silene)—was established. Stabilisation of the silaalkene by cyclodimerisation leads to the formation of disilacyclobutanes:[51–53]



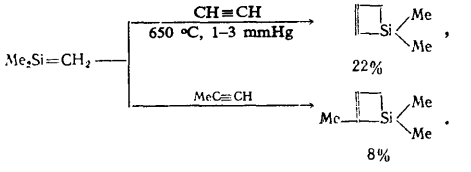
$R^1 = R^2$ = Me, Cl; R^1 = Me, R^2 = Cl; R^1 = Me, R^2 = CH=CH$_2$.

The reaction takes place in an inert gas atmosphere or at reduced pressure in flow reactors (a hollow tube or a tube filled with a heat exchanger) or in static reactors (quartz bulb). In the general case, the pyrolysis of monosilacyclobutanes is a relatively simple and convenient method of synthesis of 1,3-disilacyclobutanes, especially those whose synthesis by other methods is difficult. In the chemistry of organosilicon compounds, this method has been frequently used for preparative purposes, for example, for the synthesis of tetrachloro-1,3-disilacyclobutanes[50,51] and also its

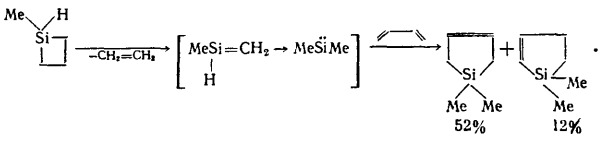
derivatives with mixed substituents at the silicon atom,[54] which are difficult to obtain:



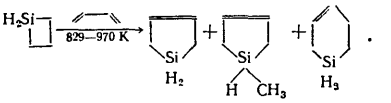
Another highly selective method for the synthesis of tetramethyl-1,3-disilacyclobutane, in which dimethylsilene is generated by the pyrolysis of 7,7-dimethyl-2,3-bis(trifluoromethyl)-7-silabicyclo-[2.2.2]octa-2,5-diene, has been proposed:[55]



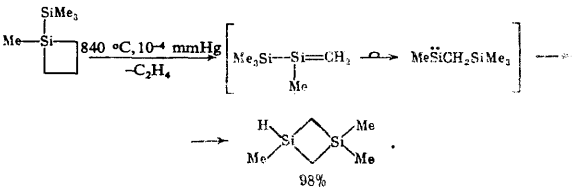
A high yield of the target product was obtained only on thermolysis of the initial compound in a stream of cyclohexane. In the absence of the carrier gas, the yield of the heterocycle was only 4%.



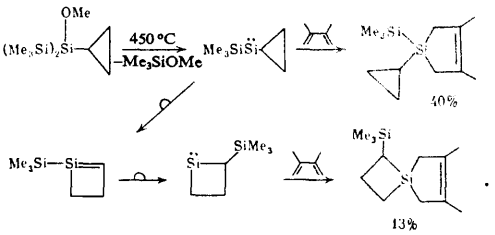
The application of the chemical trapping agent method made it possible to use the properties of silaalkenes as excellent dienophiles for the synthesis of silicon-containing unsaturated heterocycles. The pyrolysis of dimethylsilacyclobutane in the presence of a threefold excess of butadiene afforded 1,1-dimethyl-1-silacyclohex-3-ene in 65% yield. Under these reaction conditions, the formation of tetramethyldisilacyclobutane was fully suppressed:[51]



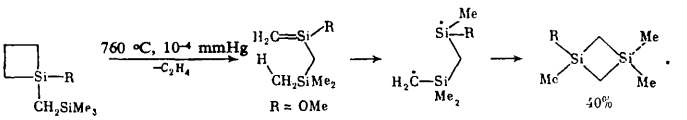
When the same source was used to generate the dimethylsilaalkene, the derivatives of silacyclobutene were isolated in the reaction with alkynes:[56]



Yet another reaction of silaalkenes, namely their thermally induced isomerisation to silylenes, proved extremely useful as regards synthesis. Thus a study of the copyrolysis of 1-methyl-1-silacyclobutane with butadiene established that the main reaction product is 1,1-dimethylsilacyclopentene (a mixture of isomers), which enabled the authors to propose a scheme for their formation via the isomerisation of intermediates:[57,58]

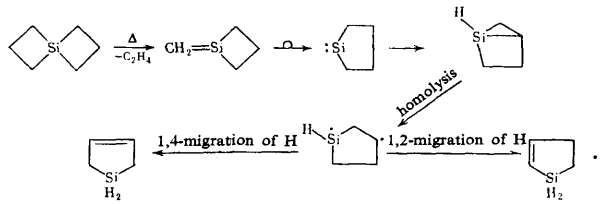


In a study of the pyrolysis of silacyclobutane in the presence of a chemical "trapping agent" for the intermediates in a high vacuum flow system, three heterocyclic compounds were identified—the products of the reactions of silylene, methylsilylene, and silaalkene with butadiene:[59]



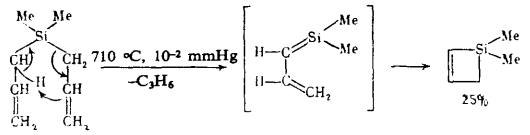
The quantitative formation of 1,1,3-trimethyl-1,3-disilacyclobutane from 1-methyl-1-(trimethylsilyl)-1-silacyclobutane under the conditions of vacuum pulse pyrolysis can also be treated as a process proceeding via the silene–silylene rearrangement:[60]

It is striking that the copyrolysis of 2-cyclopropyl-2-methoxyhexamethyltrisilane in the presence of a sixfold excess of 2,3-dimethylbutadiene led to the main reaction product (a substituted silacyclopentene) via the usual "silylene" scheme. On the other hand, the authors attribute the formation of the spiro-product to a complex silylene–silene–silylene rearrangement illustrated schematically below:[61]



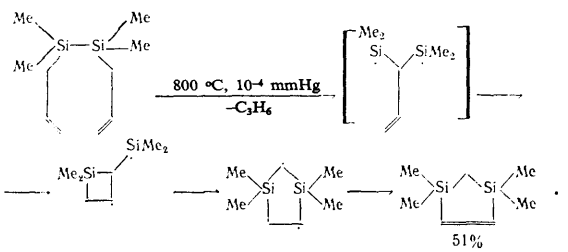
Yet another new rearrangement of silene has been recently proposed[62] in relation to the thermal reactions of certain silyl derivatives of silacyclobutane.[62] Methyl-substituted 1,3-disilacyclobutanes with the methoxy-group at the silicon atom have been obtained on the basis of this rearrangement:

The process is concluded by the ejection of ethylene from the initial compound with formation of an intermediate silene, the subsequent 1,5-shift of a hydrogen atom in it, and subsequent recombination of the 1,4-radical.

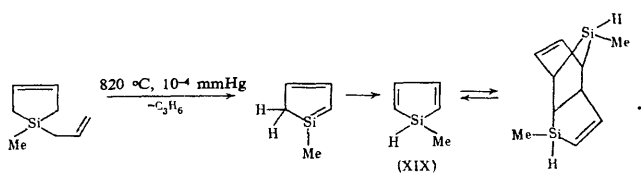


The thermal decomposition *in vacuo* of silaspiro[3,3]heptane is also of theoretical interest.[62,63] The principal products of this reaction are 1-silacyclopentenes. It may be that the primary stage of the process is the formation of a silacyclic silene with its

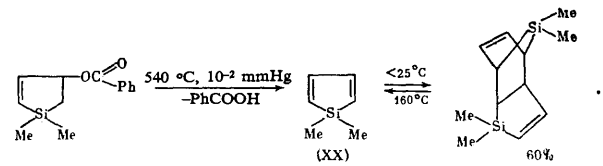
subsequent rearrangement to a silylene, whose further reactions are presented in the scheme below:



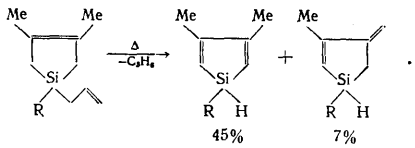
3. Synthesis with participation of siladienes



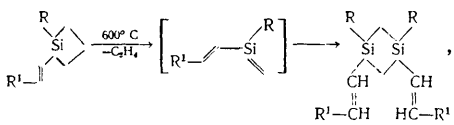
A simple single-stage method of synthesis of 1,1-dimethyl-1-silacyclobutene under the conditions of the vacuum pyrolysis of diallyldimethylsilane was proposed in 1978.[64] The authors put forward a novel scheme for the formation of the heterocycle involving the generation of an unstable compound with an unsaturated bond involving the silicon atom and a diene group (1-silabuta-1,3-diene) in the retroene elimination of propene from the initial compound with subsequent cyclisation of the intermediate:



Later a similar scheme was widely used[65–69] in novel syntheses of silicon-containing heterocycles, including monocyclic compounds.[65–67] Thus the pyrolysis of 1,2-diallyl-1,1,2,2-tetramethyl-1,2-disilane yielded 1,1,3,3-tetramethyl-1,3-disilacyclopentene:[65]

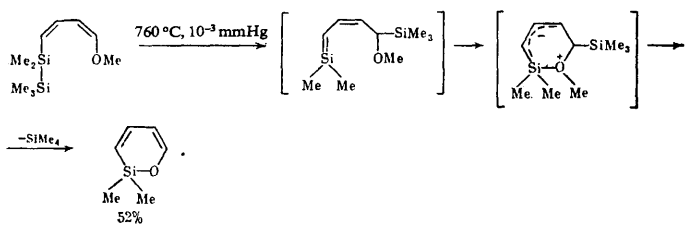


A pathway leading to the synthesis of methyl-1-silacyclopenta-2,4-diene (XIX) in the vacuum pyrolysis of 1-allyl-1-methyl-1-silacyclopent-3-ene has been put forward:[66,67]

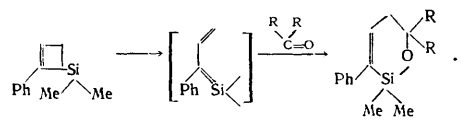


The heterocycle (XIX) was not isolated in a pure form, but its dimer was obtained in 74% yield. The thermolysis of the dimer at 150 °C leads to the formation of compound (XIX), which produces an adduct with maleic anhydride. 1,1-Dimethyl-1-silacyclopentadiene (XX) was synthesised by the vacuum pyrolysis of 4-benzoyloxy-1,1-dimethyl-1-silacyclopent-2-ene:[70]

In the absence of a trapping agent, compound (XX) dimerises at room temperature but can be regenerated on thermolysis of the dimer. In 1986 a group of French investigators[71] succeeded in obtaining the first stable *C*-methyl-substituted 1-silacyclopentadiene containing a Si–H bond:



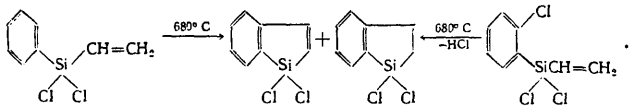
Examples of the thermal transformations of certain silacyclobutanes vinyl-substituted at the silicon atom, proceeding via a hetero-1,3-diene with formation of divinyldisilacyclobutanes, are also known:[72]



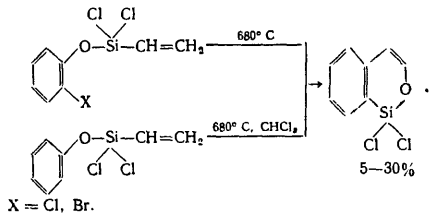
R = Me, R¹ = H; R = Me, R¹ = Ph; R = R¹ = Me; R = Ph, R¹ = H.

The thermal synthesis of certain oxygen-containing silicon heterocycles with participation of siladienes also proved to be possible. An interesting version of the synthesis of 2,2-dimethyl-1-oxa-2-silacyclohexadiene has been described.[73] The scheme for the vacuum pyrolysis of the pentamethyldisilane derivative of buta-1,3-diene includes the generation of a sildadiene intermediate with subsequent elimination of tetramethylsilane:

The copyrolysis of 1,1-dimethyl-2-phenyl-1-silacyclobut-2-ene with acetone or formaldehyde in the gas phase also leads to the formation of heterocycles with the Si–O fragment.[74] The authors suggest the intermediate formation of the siladiene intermediate (XXI):

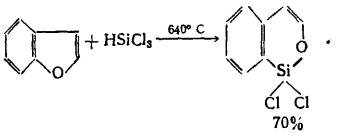


R = Me, 38%; R = H, 35%.



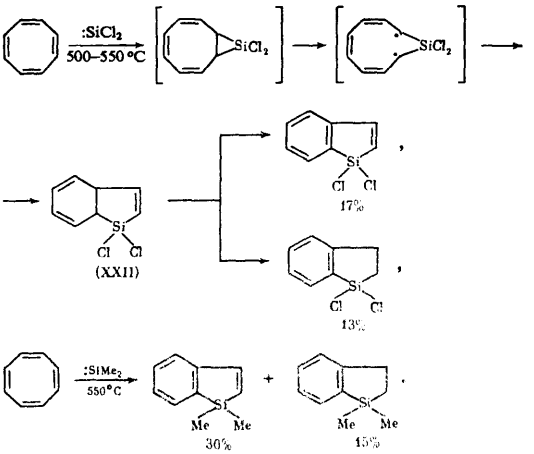
III. Bicyclic compounds

1. Bicyclic compounds with one silicon atom in the ring

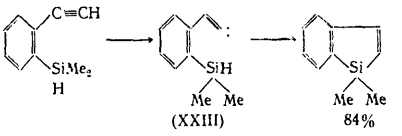


The thermal method proved to be extremely fruitful in the synthesis of bicyclic heterocyclic systems with silicon atoms in the ring. 1,1-Dichloro-1-silaindene was synthesised in a low yield for the first time, simultaneously with 1,1-dichloro-1-silaindan, by the intramolecular thermal cyclisation of dichlorophenylvinylsilane:[8,14,75]

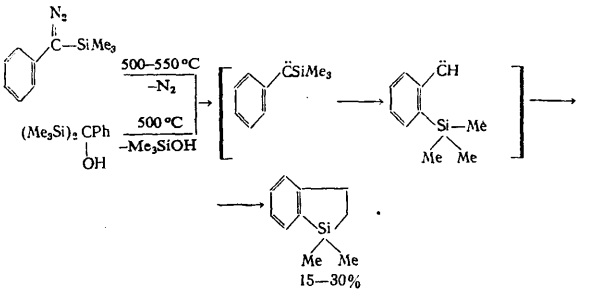
The formation of heterocycles can be explained by the successive occurrence of two stages: the intramolecular thermal alkylation of the initial compound to a saturated heterocycle—1,1-dichloro-1-silaindan—and its subsequent thermal dehydrogenation. The intramolecular dihydrochlorination of dichloro(*o*-chlorophenyl)-vinylsilane also proceeds similarly.[8,75] The pyrolysis of dichlorophenylvinylsilane in the presence of halogenohydrocarbons (chloroform, methylene chloride, chloroethylenes, and hexachloroethane) resulted in an increase in the yield of 1,1-dichloro-1-silaindene to 30% and there was an appreciable rise in the process selectivity—the saturated analogue was not detected and in addition the temperature of the reaction zone was reduced to 520–550 °C.[8,76] The copyrolysis of dichloro(*o*-chlorophenyl)vinylsilane in the presence of another initiator, namely hexachlorodisilane, led to a similar positive result.[8] Using the same principle of pyrolytic synthesis as in the preparation of 1,1-dichloro-1-silaindene, it is possible to cyclise also a series of organosilicon compounds containing the Si–O fragment:



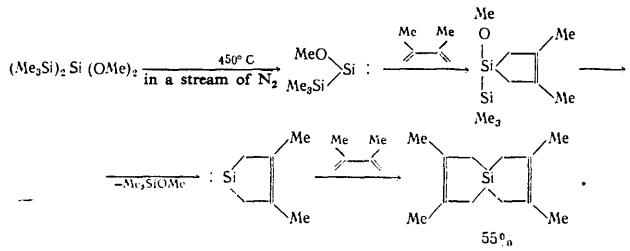
1,1-Dichloro-2-oxa-1-sila-1,2-dihydronaphthalene can be obtained also by the thermal expansion of the benzofuran ring in the presence of trichlorosilane:[8,38–40]



The high yield of the target compound and the ready availability of the starting material make it possible to regard this reaction as a preparative method of synthesis of oxasiladihydronaphthalene.

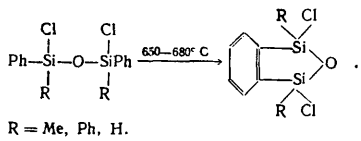


Another method of synthesis of the heterocyclic 1-silaindene and 1-silaindan structures involves the pyrolytic interaction of cyclooctatetraene with hexachlorodisilane[2,8,14,78] and 1,2-dimethoxy-1,1,2,2-tetramethyldisilane,[79] which are sources of dichloro- and dimethyl-silylenes in the gas phase. Tentatively, the 1,2-adduct isomerises to the heterocycle (XXII), which undergoes aromatisation at high temperatures:



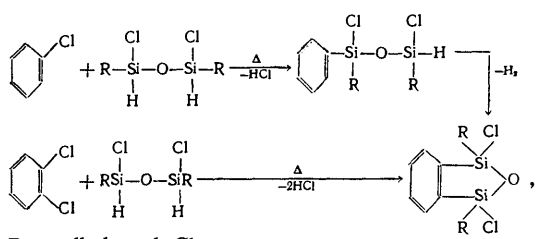
Finally, the specific properties of certain phenylsilylcarbenes, formed in the pyrolytic process from a series of phenyl-substituted organosilicon compounds, have also been used[80–83] for the synthesis of 1,1-dimethyl derivatives of silaindene and silaindan. The recently described study[80] of the vacuum pyrolysis of *o*-dimethylsilylphenylacetylene is novel in this sense. The scheme for the synthesis of 1,1-dimethyl-1-silaindene in this reaction, put forward by the authors, includes the thermally induced acetylene–vinylidene rearrangement of the initial compound to the carbene (XXIII) with the subsequent insertion of the resulting intermediate in a Si–H bond. The high yield of the heterocycle merits special attention:

Well argued evidence for the formation of 1,1-dimethyl-1-silaindan via the intramolecular reactions of phenyltrimethylsilylcarbene has been published in a series of communications.[81–83] The sources from which this α-silylcarbene was generated are phenyltrimethylsilyldiazomethane[81,82] and phenyl-1,1-bis(trimethylsilyl)methanol:[83]



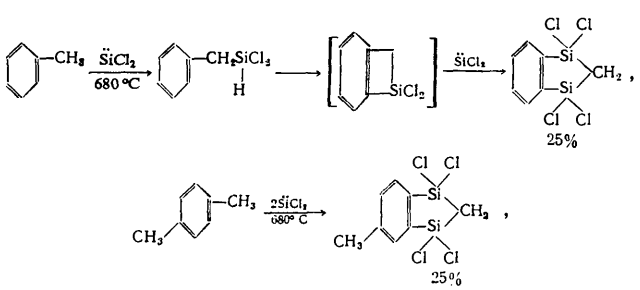
The copyrolysis of 2,2-dimethoxyhexamethyltrisilane in the presence of an excess of dimethylbuta-1,3-diene in accordance with the scheme[84]

may serve as a preparative method of synthesis of 5-silaspiro[4,4]nona-2,7-diene.[84]

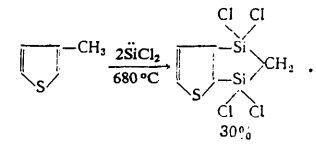


2. Bicyclic compounds with two silicon atoms in the ring

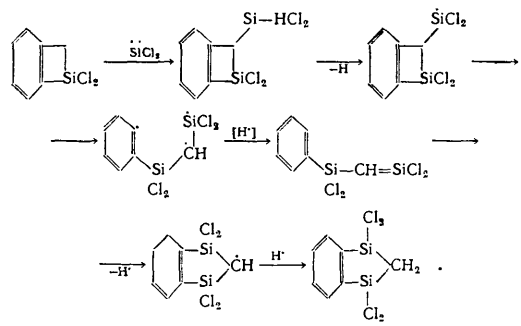
The study of the pyrolytic reactions of various 1,3-diphenyldisiloxanes substituted at a silicon atom has led to the discovery of a new intramolecular cyclisation reaction with elimination of a benzene molecule:[85–87]



R = Me, Ph, H.

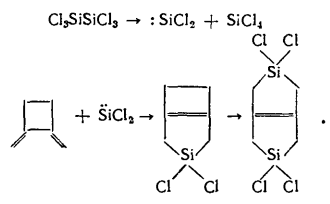


Representatives of a new class of silicon heterocycles—derivatives of 2-oxa-1,3-disilaindan—have been obtained in this reaction in 20% yield. The recovery of the initial disiloxanes amounts to 50%. Heterocycles of a similar kind are also formed via a two-stage scheme—the gas-phase cocondensation of chlorobenzene or *o*-dichlorobenzene with organodihydrodisiloxanes and the subsequent intramolecular cyclisation of the hydrodisiloxane formed:[87,88]



R = alkyl, aryl, Cl.

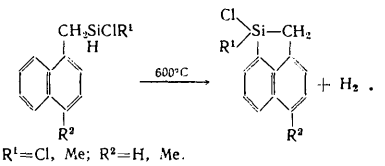
The formation of heterocyclic structures with the disilmethylene group proved possible in the thermal interaction of a series of methyl-substituted aromatic hydrocarbons with a source of dichlorosilylene such as hexachlorodisilane:[2,3,8,14,89–91]



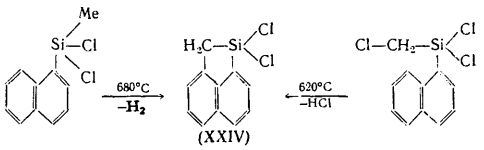
Compounds with a Si—Si bond have not been detected. It may be that conditions for the cyclisation of the primary product of the insertion of $:SiCl_2$ into benzosilacyclobutene are achieved in the first place in this reaction. The next stage represents formally the insertion of $:SiCl_2$ in the $C_{ar}-C_{alk}$ bond of the strained four-membered ring. Bearing in mind the available literature data concerning the insertion of carbenes in the benzyl carbon—hydrogen bond,[92] presumably here too the same type of insertion of the carbene analogue takes place with subsequent elimination of the silyl hydrogen atom. Subsequently, the weakened $C_{ar}-C_{alk}$ bond in the molecule of the strained silacyclobutene is ruptured and the resulting structure undergoes intramolecular addition to the double bond:

The formation of 1,1,3,3-tetrachloro-1,3-disilaindan in the reaction of benzyldichlorosilane with hexachlorodisilane under the conditions investigated has been confirmed experimentally.[91]

Yet another pathway leading to the formation of heterocyclic structures with two silicon atoms has been described.[93,94] The use of 1,2-dimethylenecyclobutane as a dichlorosilylene acceptor has made it possible to synthesise a new unsaturated heterocycle—3,3,7,7-tetrachloro-3,7-disilabicyclo[3.3.0]oct-1(5)-ene:

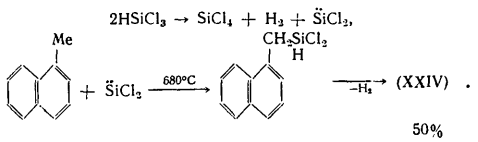


High selectivity of the reaction suggests that yet another carbenoid species is inserted immediately in the $C_{alk}-C_{alk}$ bond of the strained cyclobutene ring of the intermediate heterocycle—the primary product of the addition of $:SiCl_2$ to the conjugated system of double bonds of the initial compound.

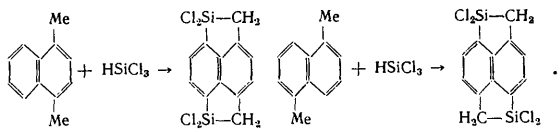


IV. Tricyclic and polycyclic silicon compounds

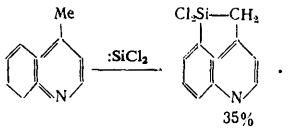
1. Homolytic *peri*-cyclisation reactions of naphthalene derivatives



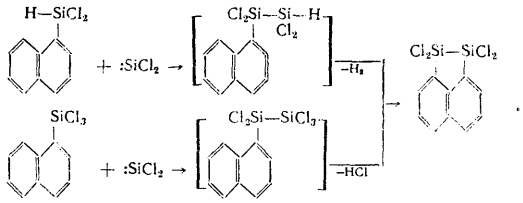
The increased reactivity of the *peri*-hydrogen atom in α-substituted naphthalenes containing the structural fragment necessary for cyclisation, which is induced by its steric interaction with the bulky substituents in the α-position, has made it possible to achieve the specific synthesis of many new classes of tricyclic and polycyclic systems with one or two silicon atoms in the ring, in which there are functional group substituents at the silicon atoms. This principle was first used to obtain a new tricyclic structure—1,1-dichloro-1-silaacenaphthene (XXIV) and its derivatives:[8,14,95-99]



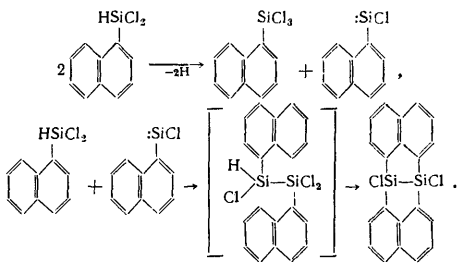
It has been established in a series of studies[8,14,97] that intramolecular cyclisation with formation of 1,1-dichloro-1-silaacenaphthene can take place not only at a Si—H bond but also at C—H and C—Cl bonds but with a lower yield of the heterocyclic compound:



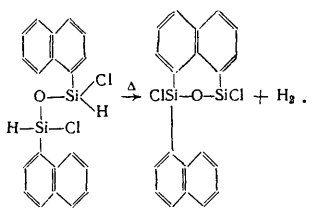
An unusual thermal cyclisation reaction was discovered in 1963 [100] when α-methylnaphthalene was allowed to interact with trichlorosilane, which also led to the synthesis of 1,1-dichloro-1-silaacenaphthene. It was established that this reaction proceeds via the insertion of $:SiCl_2$, formed in the pyrolysis of trichlorosilane,[2,101] in a C—H bond of the methyl substituent with subsequent intramolecular dehydrocyclisation of α-dichlorosilylmethylnaphthalene:[2,8,96,101]



The appreciable selectivity of this interaction, the high yield of compound (XXIV), and the availability of the initial reactants stimulated the development of the method involving the high-temperature *peri*-cyclisation of naphthalene derivatives in the presence of trichlorosilane. The extension of this reaction to 1,4- and 1,5-dimethylnaphthalenes has made it possible to synthesise tetracyclic compounds with two silicon-containing bridges—the corresponding tetrachlorodisilapyracenes:[14,96,98]

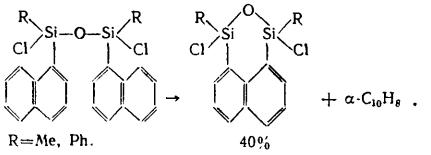


The thermal interaction of 4-methylquinoline with trichlorosilane led to the synthesis of a heterocycle containing silicon and nitrogen atoms in the cyclic system—1,1-dichloro-1-sila-5-azaacenaphthene:[102,103]

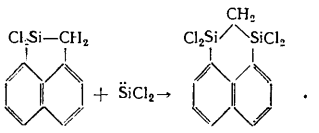


The preparation of the tricyclic 1,1,2,2-tetrachloro-1,2-disila-acenaphthene system, with an extremely stable endocyclic Si—Si bond, is synthetically extremely interesting. This compound was synthesised by the gas-phase copyrolysis of dichloro-α-naphthylsilane or trichloro-α-naphthylsilane in a mixture with trichlorosilane.[9,14,95,101] In this case, the reaction proceeds via the insertion of dichlorosilylene in a Si—H bond and even a Si—Cl bond in the corresponding chloro-α-naphthylsilanes:

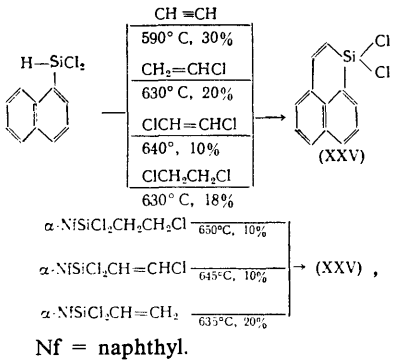
The gas-phase pyrolysis of dichloro-α-naphthylsilane in the absence of trichlorosilane led to the formation of yet another heterocyclic system with an endocyclic Si—Si bond, which has no hydrocarbon analogues, namely dichlorobis(1,8-naphthylene)disilane.[2,14,104,105] The "silylene" mechanism of the formation of this heterocycle, postulating the insertion of the intermediate chloro-α-naphthylsilylene in a Si—H bond of the initial compound, is the most probable:



The possibility of the *peri*-cyclisation of the intermediate insertion product has been confirmed by the synthesis of 1,3-dichlorobis-(1,8-naphthylene)disiloxane by the intramolecular dehydrogenation of the corresponding symmetrical disiloxane:[2,14,87,106]

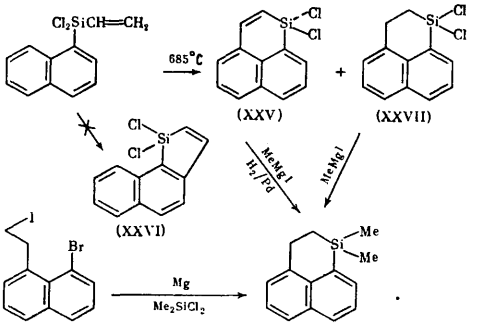


Other thermal reactions of symmetrical disiloxanes with α-naphthyl groups are also of preparative interest. The gas-phase pyrolysis of these compounds eliminates naphthalene and leads to the formation

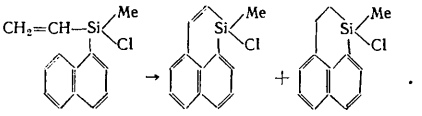


of representatives of a new class of silicon heterocycles—the organochloro-derivatives of 2-oxa-1,3-disilaphenalan:[2,14,87,107]

Similar disilaphenalan structures, where the silicon atoms are linked up to form a six-membered heterocycle via a methylene bridge, have been obtained by the thermal interaction of 1,1-dichloro-1-sila-acenaphthene with trichlorosilane. Formally, the formation of 1,1,3,3-tetrachloro-1,3-disilaphenalan can be represented as the insertion of :$SiCl_2$ in the $C_{ar}-C$ bond:[2,14,101]

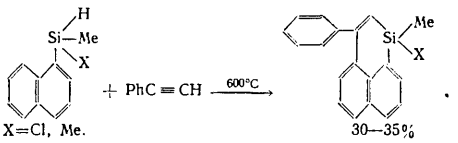


The mobility of the hydrogen atom in the *peri*-position in α-substituted naphthalenes has made it possible to achieve also a series of other thermal reactions designed to obtain a new tricyclic 1,1-dichloro-1-silaphenalene system (XXV), where the silicon atom is incorporated in an unsaturated six-membered ring.[95,108,109] The common features of these reactions are the presence in the initial reactants of, on the one hand, the dichloro-α-naphthylsilyl group and, on the other, of a two carbon atom fragment necessary for the formation of a bridge between the silicon atoms and the C(8) carbon atom of naphthalene:

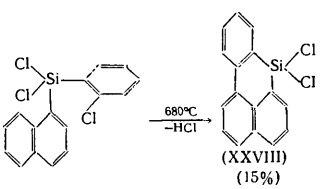


Nf = naphthyl.

A detailed study of the pyrolysis products of dichloro(α-naphthyl)-vinylsilane was undertaken somewhat later.[110] The authors doubted the validity of the postulated structure of compound (XXIV) as a *peri*-cyclisation product. On the basis of literature and their own data indicating the impossibility of obtaining a stable hydrocarbon analogue—the α-halogenophenalene—it was suggested that 1,1-dichloro-1-silaphenalene is thermally unstable and that its structural isomer—the heterocycle (XXVI)—is therefore formed in the pyrolytic reaction investigated. However, two heterocycles, (XXV) and (XXVII), were isolated in the pyrolysis of dichloro-(α-naphthyl)vinylsilane. Their structures were confirmed by the specific synthesis of 1,1-dimethylsilaphenalan:

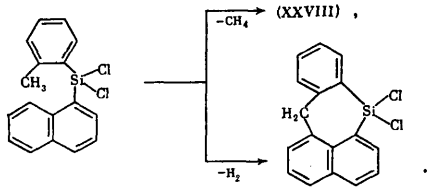


Having thus recognised that the pyrolysis of dichloro(α-naphthyl)-vinylsilane is the best method of synthesis of the heterocycle (XXV), the authors synthesised by this method also 1-chloro-1-methyl-1-silaphenalene mixed with its saturated analogue:



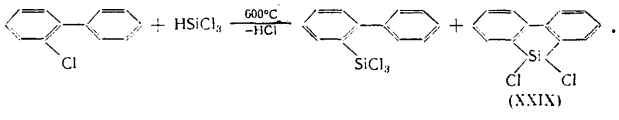
The overall yield of the heterocycles was 25%.

1-Chloro-1-methyl- and 1,1-dimethyl-1-silaphenalenes have been obtained by the thermal interaction of acetylene with chloromethyl-(α-naphthyl)silane and dimethyl(α-naphthyl)silane respectively.[111] Phenylacetylene enters into an analogous *peri*-cyclisation reaction:

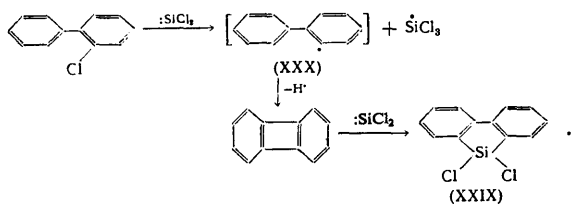


The position of the phenyl substituent in the 1-silaphenalene derivative synthesised has been confirmed by X-ray diffraction data.[111] A more selective method has been proposed[2,14,112] for the synthesis of 1,1-dichloro-1-silaphenalene—by the thermal cyclisation of dichloro(α-naphthyl)vinylsilane in the presence of process initiators (halogenohydrocarbons); the temperature of the reaction zone is then also appreciably reduced (to 520–550 °C). For example, the pyrolysis of dichloro(α-naphthyl)vinylsilane in the presence of hexachloroethane or tichloroethylene leads to the formation of the heterocycle (XXV) in a yield up to 50–60%. The method of the pyrolytic *peri*-cyclisation of naphthalene derivatives has been used successfully also for the synthesis of a new tetracyclic structure—1,1-dichloro-1-sila-2,3-benzophenalene (XXVIII).[2,14,113,114] The latter was synthesised by the intramolecular cyclisation of dichloro(*o*-chlorophenyl)(α-naphthyl)silane:

Compound (XXVIII) is formed also from another *ortho*-derivative—dichloro(α-naphthyl)(*o*-tolyl)silane. However, in this case the



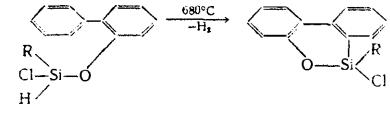
thermal reactions are not so selective and proceed via two mechanisms with ejection of H_2 or CH_4:



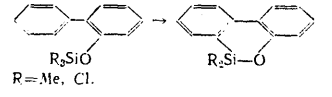
The reaction in which methane is ejected can be accounted for by the tendency to cyclise to a more stable six-membered heterocyclic structure.

2. Thermal cyclisation of *ortho*-substituted biphenyls

The successful use of the mobility of the hydrogen atom in the *peri*-position in α-naphthalene derivatives in order to build up silicon-containing rings aroused interest in the similar cyclisation of *ortho*-substituted biphenyls, which are also a classical example of the manifestation of steric interactions in the aromatic series. The mobility of the *ortho*-hydrogen atoms of *o*-silylbiphenyls has made it possible to devise novel high-temperature methods for the synthesis of new tricyclic silicon-containing structures—the analogues of fluorene and phenanthrene. It was shown[2,115,116] that the interaction of *o*-chlorobiphenyl with trichlorosilane at 600 °C results in the formation of *o*-trichlorosilylbiphenyl, while the subsequent intramolecular cyclisation at higher temperatures (680–700 °C) leads to 9,9-dichloro-9-silafluorene (XXIX) in 45% yield:

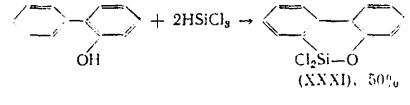


This reaction was the first example of homolytic silylation involving such a high yield with participation of the Si–Cl and C–Ar–H bonds, for which reactions of this type are uncharacteristic. Evidently, the presence of appreciable steric hindrance in the *o*-trichlorosilylbiphenyl molecule and the impossibility of overcoming it without the rupture of the bonds indicated as well as the high temperature of the reaction zone led to the cleavage of the Si–Cl and C_{ar}–H bonds. A new more effective method of synthesis of the heterocycle (XXIX), by the thermal interaction of *o*-chlorobiphenyl with hexachlorodisilane, has been proposed recently;[117] the heterocycle (XXIX) is formed under milder conditions (500–550 °C) and in a higher yield (up to 80%). The principal side product is biphenyl. It is extremely remarkable that *o*-trichlorosilylbiphenyl, which can be regarded in this reaction as the product of the insertion of $:SiCl_2$ and the C_{Ar}–Cl bond of *o*-chlorobiphenyl, is formed in an insignificant yield (up to 5%). The hypothesis of its possible instability under the reaction conditions in the presence of hexachlorodisilane was not confirmed. These factors made it possible to put forward a reaction mechanism via biphenylenes:

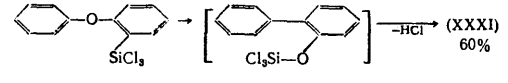


Evidently, the selective abstraction of a chlorine atom from the initial compound by dichlorosilylene leads to the appearance of the radical (XXX), capable of intramolecular cyclisation to biphenylene. On the other hand, the formation of the heterocycle (XXIX) can be regarded as a result of the insertion of $:SiCl_2$ in the strained biphenylene ring. An increase in the $:SiCl_2$ concentration in the reaction mixture increases the yield of the heterocycle, which agrees fully with the proposed reaction mechanism.

The thermal method for the synthesis of silicon-containing heterocycles by the pyrolysis of siloxybiphenyls proved to be extremely fruitful. In contrast to *o*-trichlorosilylbiphenyl, in the latter compounds the relative positions of the atoms seemingly give rise to a much smaller probability of the interaction of the Si–H bonds with the *ortho*-hydrogen atom of the biphenyl group. However, in this case intramolecular cyclisation takes place successfully—the main reaction products are new cyclic compounds with two heteroatoms containing functional group substituents at the silicon atom—derivatives of 9-oxa-10-sila-9,10-dihydrophenanthrene:[2,40,118,119]

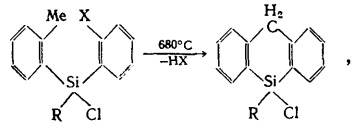


The yield of the heterocycle is ~60% for R = Cl and 30–35% for R = Me or Ph.

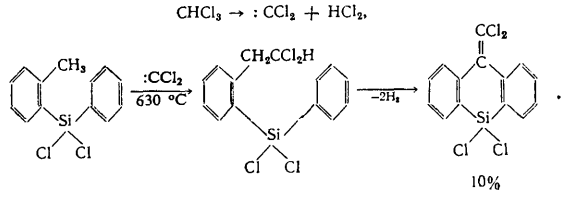


The cyclisation of *o*-siloxybiphenyls can proceed not only at a Si–H bond but also at other bonds involving the silicon atom. However, the yield of the heterocycles is then appreciably lower:[39]

The version of the pyrolytic synthesis of 10,10-dichloro-9-oxa-10-sila-9,10-dihydrophenanthrene (XXXI) from *o*-hydroxybiphenyl, which does not include the stage involving the specific synthesis of *o*-dichlorosiloxybiphenyl, is of great preparative value:[40,120]

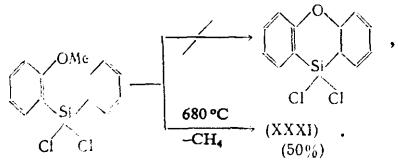


The pyrolysis of phenyl *o*-trichlorosilylbiphenyl ether also leads to the formation of the heterocycle (XXXI). In this case, the cyclisation is accompanied by a rearrangement with formation of the Si–O fragment:[40]

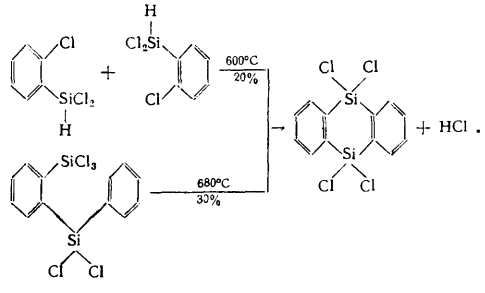


3. Thermal cyclisation of *o*-silylbenzenes

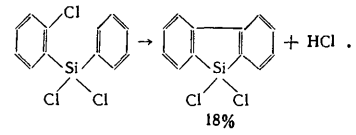
The high-temperature method for the cyclisation of various *o*-substituted benzenes, in which one of the substituents is the silyl group, has opened up extensive possibilities for the synthesis of silicon-containing tricyclic systems. Thus 9-sila-9,10-dihydroanthracenes with the chloro-substituent at the silicon atom have



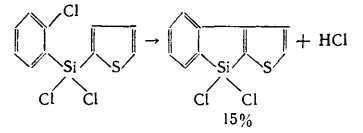
been obtained by the thermal intramolecular cyclisation of dichloro(phenyl)(*o*-tolyl)silane or dichlorobis(*o*-tolyl)silane with ejection of hydrogen or methane:[2,14,95,121,122]



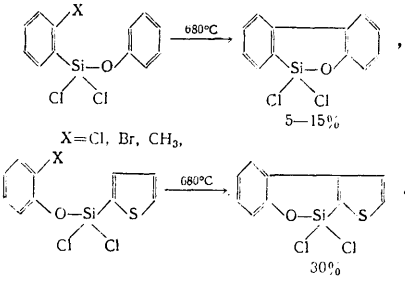
The reactions are distinguished by a high specificity and lead to heterocycles having only the 9-sila-9,10-dihydroanthracene skeleton. 9,9-Dichloro-10-dichloromethylene-9-sila-9,10-dihydroanthracene has been isolated in the cylisation of dichloro(phenyl)(*o*-tolyl)silane in the presence of chloroform or carbon tetrachloride.[2,14,123] Evidently this heterocyclic compound is formed with participation of dichlorocarbene and insertion of the latter in a $C_{alk}-H$ bonds of the initial reactant:



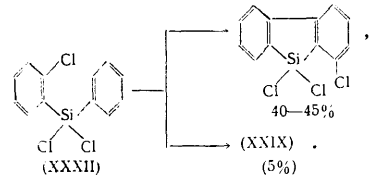
When an attempt was made to synthesise 10,10-dichloro-9-oxa-10-sila-9,10-dihydroanthracene by the pyrolysis of *o*-anisyldichloro(phenyl)silane, 10,10-dichloro-9-oxa-10-siladihydrophenanthrene was isolated instead of the expected heterocycle:[40,124]



It may be that the first stage of this process is also the ejection of methane from the initial compound, but subsequently the silicon atom migrates to the oxygen atom, which is accompanied by cyclisation to the silaphenanthrene structure. The observed rearrangement with formation of the Si–O fragment is undoubtedly of theoretical interest. The heterocyclic system with two silicon atoms in the central ring—9,9,10,10-tetrachloro-9,10-disila-9,10-dihydroanthracene—was obtained by the pyrolysis of dichloro(*o*-chlorophenyl)silane.[95,124,125] The intramolecular cyclisation of dichloro(phenyl)(*o*-trichlorosilylphenyl)silane leads to the same result but with a higher yield:[2,126]

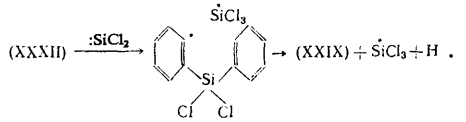


The introduction of a chlorine atom in the *o*-position in dichlorodiphenylsilane promotes the formation of another tricyclic structure—9,9-dichloro-9-silafluorene:[2,85,126]



The cyclisation of another *o*-chloro-substituted derivative—dichloro(*o*-chlorophenyl)thienylsilane—takes place with ejection of hydrogen chloride:[2,85,127]

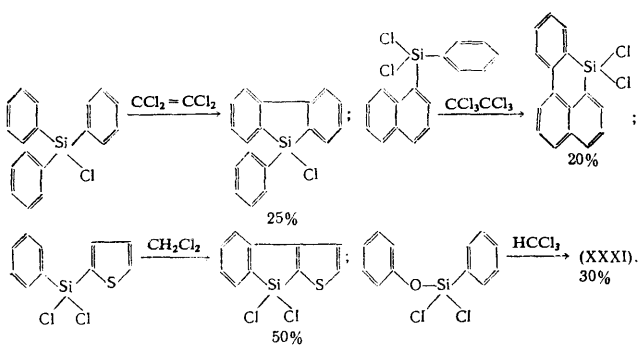
Using the same principle of the pyrolytic synthesis of silicon-containing heterocycles, it is possible to cyclise a series of organosilicon compounds in which two benzene rings are separated by the Si–O fragment instead of the silicon atom alone:[2,40]



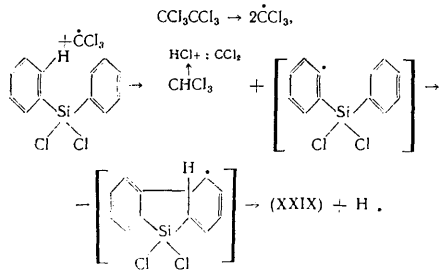
It is extremely remarkable that the copyrolysis of dichloro(*o*-chlorophenyl)phenylsilane (XXXII) with chloroform at 620 °C and with trichloroethylene at 560 °C leads to the virtually selective formation of 1,9,9-trichloro-9-silafluorene; 9,9-dichloro-9-silafluorene (XXIX), unsubstituted in the aromatic ring, was isolated from the reaction mixture in a low yield:[8,14,123]

Thus the cyclisation process takes place in this instance with a high degree of selectivity with respect to the $C_{ar}-H$ bond and not the $C_{ar}-Cl$ bond of the initial compound.

Very interesting results have been achieved in the study of the thermal interaction of a series of organosilicon *o*-chloro-compounds, for example, dichloro(*o*-chlorophenyl)phenylsilane or dichloro(*o*-chlorophenyl)thienylsilane in the presence of sources of dichlorosilylene such as hexachlorodisilane and trichlorosilane. A new gas-phase reaction, involving the formation of silicon-containing heterocycles and having no analogies in the chemistry of carbenes and other intermediates, was discovered in the course of this study. It consists in the selective abstraction of a chlorine atom from the above *o*-chloro-compounds by dichlorosilylene, which promotes the intramolecular cyclisation of these compounds, but the $:SiCl_2$



itself does not enter into the composition of the heterocycle formed.[2,14,128,129] Thus the interaction of compound (XXXII) with hexachlorodisilane at 500 °C affords 9,9-dichloro-9-silafluorene in an almost quantitative yield:



It is extremely instructive that the intermediate formation of a free radical with an unpaired electron at the *o*-carbon atom only, when the radical centre and the aromatic system are close to one another in space, leads to intramolecular cyclisation. The interaction of dichloro(*p*-chlorophenyl)phenylsilane with hexachlorodisilane under the same conditions does not lead to a cyclisation product. Dichloro(phenyl)(*p*-trichlorosilylphenyl)silane—the product of the insertion of $:SiCl_2$ in a $C_{ar}-Cl$ bond of the initial compound—was obtained in this case (yield 30%). The leading role of $:SiCl_2$ in the cyclisation process is also confirmed by the experimental data obtained in the copyrolysis of compound (XXXII) with hexachlorodisilane at the same reaction temperature but at a lower $:SiCl_2$ concentration in the reaction zone. For the reactant ratio (XXXII):HCDS = 1.0–0.5 [HCDS = hexachlorodisilane], the yield of dichlorosilafluorene falls to 40%. This factor may be associated with the fact that the trichlorosilyl radicals formed in the reaction do not participate in the cyclisation process.

4. Cyclisation of unsubstituted chloroarylsilanes

The study of the pyrolysis of unsubstituted aromatic chlorosilanes, for example, such as dichlorodiphenylsilane, dichloro(phenyl)-thienylsilane, chlorotriphenylsilane, and dichloro(α-naphthyl)-phenylsilane, at temperatures up to 700 °C showed that they do not give rise to cyclisation products. The new reaction involving the thermal cyclisation of these compounds in the presence of halogeno-derivatives of methane and ethylene as well as hexachloroethane, which we have proposed, makes it possible to obtain silicon heterocycles with fragments of aromatic systems from more readily available raw material.[8,14,123,130] For example, the pyrolysis of dichlorodiphenylsilane in the presence of $CHCl_3$, CH_2Cl_2, CH_2F_2, and CCl_4 at temperatures in the range 650–680 °C leads to the heterocycle (XXIX) in 30–40% yield. The use of di-, tri-, and tetrachloroethylenes and hexachloroethane in this reaction permits the synthesis of the same heterocycle in a yield up to 60% at a lower temperature of the reaction zone (520–580 °C).[8,14,122,130] Other aromatic organosilicon heterocycles have also been obtained similarly:

The observed thermal interaction, which evidently proceeds via a stage involving the formation of a free radical with the unpaired electron at the *ortho*-carbon atom, is most probably homolytic in character. It may be that unstable species—radicals and carbenes whose formation presupposes the thermal decomposition of the above halogenohydrocarbons—make a significant contribution to this process. The role of these intermediates apparently reduces to creating conditions for intramolecular arylation, for example, in the cyclisation of dichlorodiphenylsilane:

The preparative possibilities of the thermal cyclisation reaction discovered are far from exhausted. It can evidently serve as a basis for the synthesis of various new silicon-containing heterocyclic systems.

Thus inspection of the data presented shows that the thermal gas-phase synthesis is one of the most promising methods of synthesis of organosilicon heterocyclic compounds. The wide-scale employment of this method will undoubtedly lead to the discovery of new highly selective processes for their synthesis.

Isoprenoid petroleum hydrocarbons

Al A Petrov, N N Abryutina
Institute of the Geology and Development of Fossil Fuels of the MNP and the USSR Academy of Sciences

ABSTRACT. The outcome of studies on the chemistry of petroleum carried out during the last 10–15 years is examined. It is shown that petroleum is a very complex mixture of natural products, the most important place among which is occupied by $C_{10}-C_{40}$ isoprenoid hydrocarbons represented by aliphatic, alicyclic, and aromatic compounds.

The relations between the isoprenoid petroleum hydrocarbons and their possible bioorganic precursors are discussed. The possibility of using isoprenoid hydrocarbons (as biomarkers) in discovering the pathways leading to the genesis and chemical evolution of petroleums and also prospecting for petroleum deposits is demonstrated.

The bibliography includes 104 references.

I. Introduction

The identification of a large number of relict hydrocarbons (biomarkers)—compounds retaining the main features of the structure of the initial bioorganic molecules—in petroleums, coals, shales, and other fossil fuels is undoubtedly one of the most important advance in the organic chemistry of the second half of the XXth century. A new independent scientific discipline—organic geochemistry—arose in the middle of the 1960s. Its aim is the study (at the molecular level) of the characteristic features of the composition and structure of the organic molecules in the Earth's core, seas, and oceans. It involves the study of both "modern" compounds as well as compounds formed hundreds of millions of years ago. Much attention has also been devoted to questions concerning the chemical changes in organic molecules under geological conditions. In the course of its development, organic geochemistry has been based on the present scientific level of its precursor—the chemistry of natural products, utilising fully both the methodology and the analytical procedures of the latter. The advances in the study of organic molecules in the Earth's core and, in particular, hydrocarbons, achieved during the last 20–25 years, are very considerable. Thus more than 300 $C_{10}-C_{40}$ hydrocarbons, having a clear biological origin, have been identified in petroleums and other fossil fuels. Not only their structure but also the characteristic features of their stereochemistry, frequently changing during the transformation of bioorganic molecules under geological conditions, have been determined. The practical importance of such studies, especially in the prospecting for petroleum deposits and in problems concerning ecology and the protection of the environment has led to the biannual holding of International Congresses on Organic Geochemistry. The publishing house Pergamon Press has been publishing a special periodic journal. In a number of developed capitalist countries, there are institutes (or large departments) concerned with various problems of organic geochemistry.

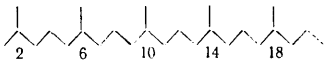
The framework of the present review restricts us to the isoprenoid petroleum hydrocarbons. However, this group of compounds is the most important and the most representative. Advances in this field have been achieved by the efforts of a large group of investigators in England, France, the Federal Republic of Germany, the Soviet Union, the USA, and many other countries.

All the isoprenoid petroleum hydrocarbons can be divided into three large groups: aliphatic isoprenoids, alicyclic isoprenoids, and isoprenoids containing aromatic rings. A common property of the majority of petroleum isoprenoids is their homologous nature. This property is associated with the characteristic features of their genesis. The homologous nature of isoprenoids has one important feature. Since petroleum hydrocarbons are frequently formed via a stage involving the degradation of biopolymers, after three homologues, the next (fourth) homologue is usually (for a regular chain structure) "omitted" as a result of the branched structure of the isoprenoid chain.

The homologous nature of these hydrocarbons makes it necessary to give preference to the term isoprenoid hydrocarbons and to avoid using the term, which is in many cases more usual, terpenoid compounds.

In studies on the most complex mixtures of petroleum hydrocarbons, modern achievements in the analytical chemistry of organic compounds have played a very important role, especially methods such as gas chromatography using high performance capillary columns, combined gas chromatography–mass spectrometry (with computer treatment of data), mass fragmentography and mass chromatography, and also ^1H and ^{13}C nuclear magnetic resonance. Numerous syntheses of model hydrocarbons have undoubtedly played a special role. The majority of compounds examined below were first obtained in laboratories. An extensive scientific literature has been devoted to isoprenoid petroleum hydrocarbons. Here we shall quote references mainly to studies during the last 10–15 years especially since there are already reviews and monographs devoted to

these aspects.[1-3] The data on the mass spectra of certain isoprenoid hydrocarbons examined below may be found in the review of Golovkina et al.[4]



II. Aliphatic isoprenoids

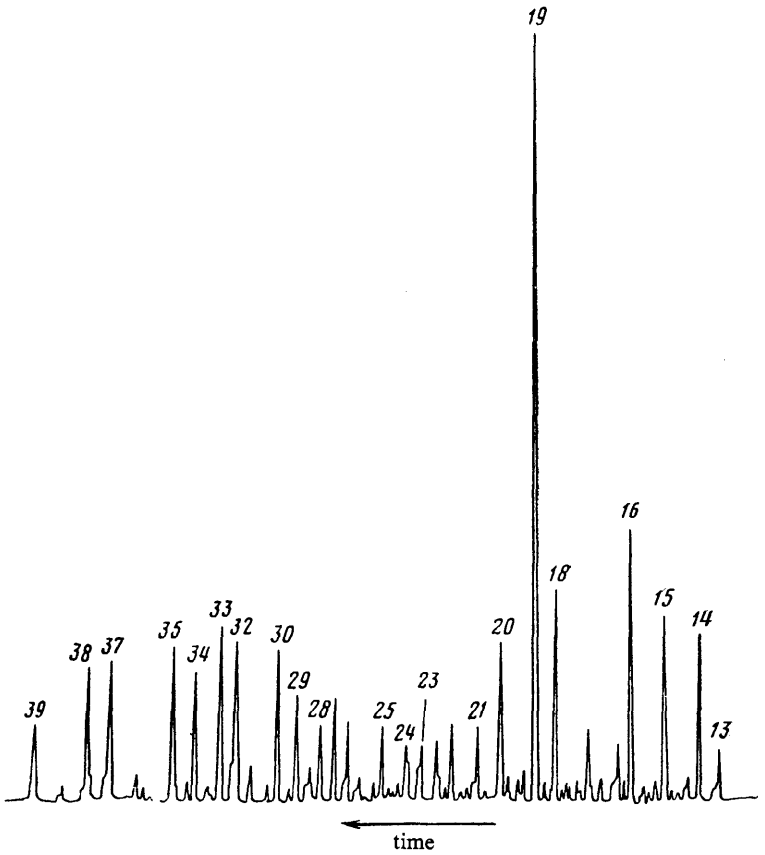
Isoprenoid alkanes (isoprenanes) are compounds whose discovery in natural fossil products has promoted the establishment of modern organic geochemistry. Hydrocarbons important for petroleum such as pristane (2,6,10,14-tetramethylpentadecane) and phytane (2,6,10,14-tetramethylhexadecane) have been described.[5]

Aliphatic petroleum isoprenoids have both regular and irregular carbon chains, the number of their carbon atoms ranging from 9 to 45. There is no doubt that the leading role is assumed by irregular isoprenoids having a structure of the main carbon chain with "head to tail" fragments, which is characteristic of polyisoprene.

1. Regular isoprenoids

It is possible to distinguish the following homologous series of these hydrocarbons: 2,6-dimethylalkanes (C_9-C_{13}); 2,6,10-trimethylalkanes ($C_{14}-C_{18}$); 2,6,10,14-tetramethylalkanes ($C_{19}-C_{23}$); 2,6,10,14,18-pentamethylalkanes ($C_{24}-C_{28}$), etc. For understandable reasons, hydrocarbons having the C_{12}, C_{17}, C_{22}, C_{27}, etc. compositions are absent from the homologous series.

The degradation of any C—C bond in the main chain can result in the formation of only regular isoprenoids. Fig. 1 presents chromatogram of the saturated hydrocarbons of the petroleum from the Severo-Tol'kinskoe deposit (Western Siberia). The predominance of regular $C_{14}-C_{20}$ isoprenoids, which is usual for petroleums, and the much lower concentration of similar structures having the $C_{21}-C_{25}$ composition can be clearly seen. Data on the proportions of regular isoprenoids in other petroleums in the Soviet Union can



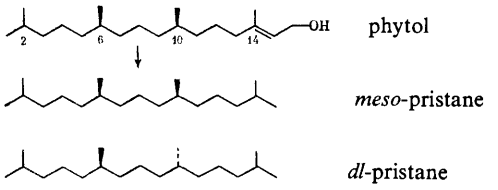


Figure 1. Chromatogram of a mixture of saturated hydrocarbons from petroleum of the Severo-Tol'kinskoe deposits; capillary column (80 m) with Apiezon; linear temperature programming (4 K min^{-1}). Analysis started at 100 °C and ended at 320 °C; the number of carbon atoms in the molecule is indicated; $C_{13}-C_{25}$, isoprenoid alkanes with a regular structure (2,6,10-trimethylalkanes, 2,6,10,14-tetramethylalkanes, etc.); $C_{28}C_{39}$, irregular isoprenoids ("head to head" fragment); 2,6,10,14,17,21,25,29-octamethylhentriacontane (C_{39}); 2,6,10,14,17,21,25,29-octamethyltriacontane (C_{38}); 2,6,10,14,17,21,25-heptamethyltriacontane (C_{37}); nonacosane (C_{35}), etc.[13]

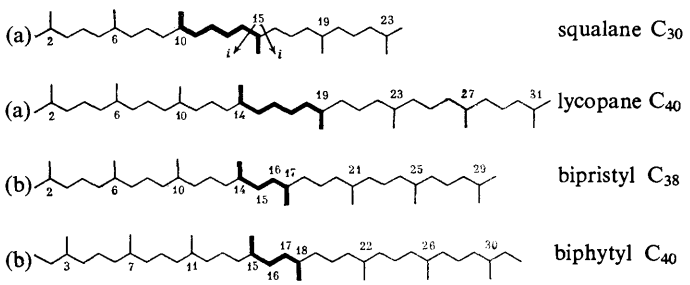
be found in monographs.[1,6] The main source of regular isoprenoids in petroleums is phytol (C_{20}) and solanosol (C_{45}).[7,8] The stereochemistry of isoprenoid alkanes is of interest.[9–11] The relation between the stereochemistry of phytol and the pristane formed from it is considered in Scheme I, whereas *meso*-pristane [having the configuration of the C(6) and C(10) chiral centres characteristic of phytol] clearly predominates in recent fossil deposits (young, "unripe" deposits and also in brown coals), a 1 : 1 mixture of the *meso*- and *dl*-epimers is usually found in petroleums.

Scheme I

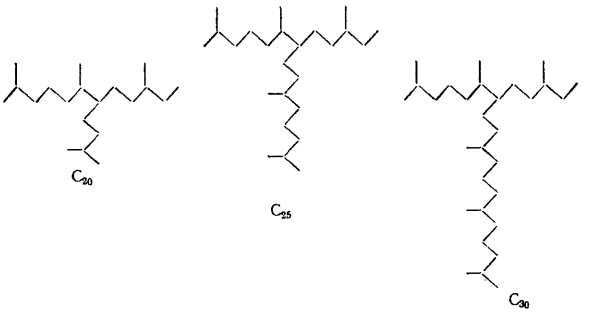


Another (minor) series of regular isoprenoid alkanes belonging to the series of 3,7-dimethyl-, 3,7,11-trimethyl-, and 3,7,11,15-tetramethylalkanes has been described.[1–8] In the original communication,[8] such structures have been called "quasi-regular".

2 Irregular isoprenoids

Two types of isoprenoid alkanes with an irregular structure of the main carbon chain have been found in petroleums: (a) those having an irregular unit of the "tail to tail" type and (b) those having an irregular unit of the "head to head" type (Scheme I).

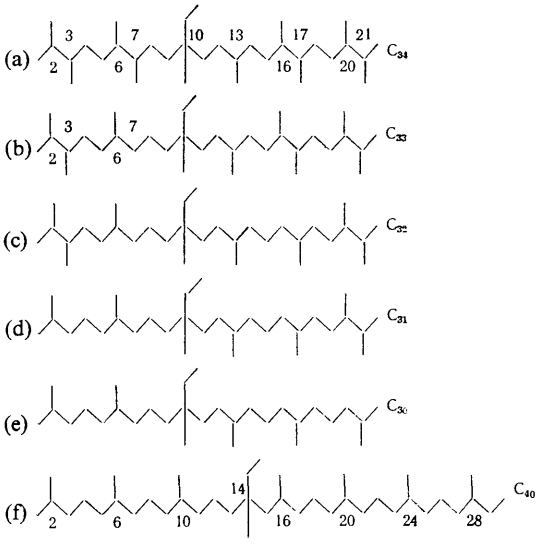
Scheme II



The degradation of the aliphatic chain of irregular isoprenoids can lead to the appearance of two series of homologues: (1) irregular homologues if an irregular unit is retained on degradation, for example, 2,6,10,15-tetramethylalkanes from squalane and 2,6,10,14,17-pentamethylalkanes from bipristyl; (2) the so called pseudoregular homologues[12] in those cases where the rupture of the bond involves an irregular unit. In particular, the degradation of squalane via the pathways (*i*) yields "forbidden" regular 2,6,10-trimethyltetradecane (C_{17}) and 2,6,10-trimethylhexadecane (C_{19}).

The homologous series of irregular isoprenoid $C_{28}-C_{39}$ alkanes (having a "head to head" unit) has been found in the petroleum the Severo-Tol'kinskoe deposit already mentioned[13] (Fig. 1). These hydrocarbons have been identified also in other petroleums.[14,15] The formation of these structures can be accounted for by the microbiological abstraction of hydrogen from the C(1) atom of regular isoprenoids (pristane, phytane, etc.) with subsequent coupling of the radicals (15–16 and 16–17 bonds are formed in bipristyl and biphytyl respectively).

A new series of isoprenoid alkanes, having a T-shaped structure, have been discovered in petroleums in recent years[16,18] (Scheme III).



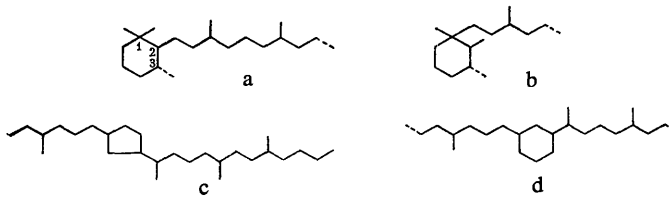
Scheme III

It is of interest that these hydrocarbons are represented only by compounds having the C_{20}, C_{25}, and C_{30} compositions, i.e. they are diterpenoids, sesterterpenoids, and triterpenoids.

There is an unusual group of petroleum isoprenoids containing a geminal methylethyl group.[19–22] Botryococcane (C_{34}) and its lower-molecular-weight homologues ($C_{33}-C_{30}$) and also isolycopane (C_{40}) merit attention here (Scheme IV).

Scheme IV

III. Cyclic isoprenoids



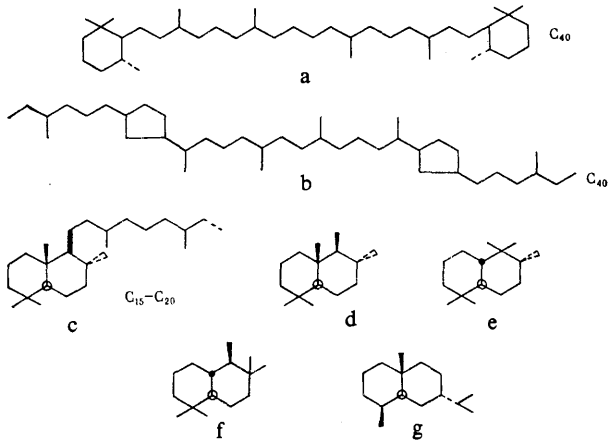
Saturated cyclic petroleum isoprenoids are characterised by different numbers of rings in the molecule (from one to six). These compounds constitute the basis of relict petroleum hydrocarbons (biomarkers).

1. Monocyclic isoprenoids

The simplest monocyclic isoprenoids are 1,2- and 1,4-methylisopropylcyclohexanes.[23] The interesting $C_{10}-C_{30}$ homologous series of isoprenoids, formed by the degradation of the aliphatic chain of β-carotane, has been described.[24,25] The first representative of these hydrocarbons, namely 1,1,3-trimethylcyclohexane, is present in appreciable amounts in almost all petroleums.[1]

Apart from the main homologues (Va), the products of their 1,2-rearrangement (Vb) have also been found.

Scheme V

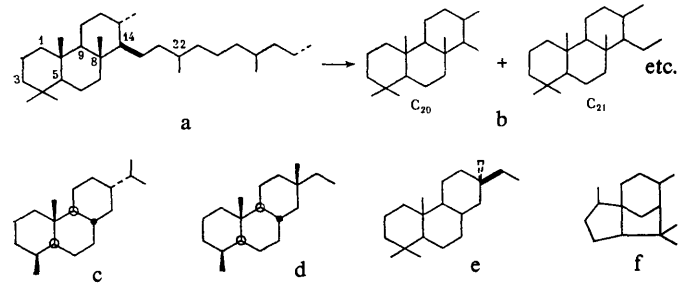


It has been stated that monocyclic isoprenoids with long isoprenoid chains of both irregular (Vc) and regular (Vd) types are present in petroleums.[9] The hydrocarbon (Vd) must be regarded as a saturated compound corresponding to the product of the dimerisation of phytadiene via the Diels–Alder reaction. The presence of lower-molecular-weight homologues of these hydrocarbons in petroleums is also probable.

2. Bicyclic isoprenoids

Among bicyclanes with isolated rings, except perhydro-β-carotane (VIa), bicyclic five-membered cyclanes with isolated rings and isoprenoid chains (VIb) have also been identified in petroleums. There is a larger group of bicyclanes with condensed rings (Scheme VI).

Scheme VI



In this group of compounds, both hydrocarbons with the 8βH-drimane† (VId) skeleton and the products of their 1,2-rearrangement—the structures (VIe) and (VIf)—have been determined in hydrocarbons.[26–28] The parent of this group of compounds is probably the C_{20} hydrocarbon—labdane (VIc); the degradation of its chain results in the formation of the homologous series of tetramethylalkyldecalins. Eudesmane (cadinane) (VIg), present only in the form of the "pure" sesquiterpane, has a different structure.

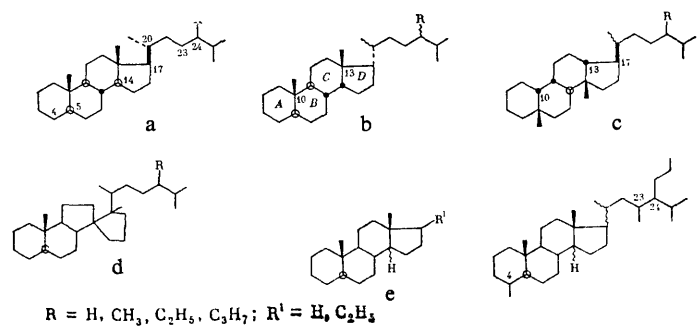
3. Tricyclic isoprenoids

The most interesting representatives of the tricyclic petroleum isoprenoids are undoubtedly hydrocarbons belonging to the homologous series of pentamethylalkylperhydrophenanthrenes, which have been called hydrocarbons of the cheilanthane series. A number of these compounds having the $C_{18}-C_{40}$ composition have been discovered. The compounds have a regular isoprenoid chain which is the reason for the absence of the C_{22}, C_{27}, etc. homologues.[29–32]

The formulae of the hydrocarbons considered are listed in Scheme VII. The C_{25} and higher hydrocarbons are eluted on the chromatograms in the form of two diastereoisomers (22*S* and 22*R*) because the C_{22} atom becomes chiral.

Scheme VII

The hydrocarbons (VIIa, b) can be conveniently identified by mass fragmentography on the basis of the fragment ion with m/z = 191. Apart from cheilanthanes, tricyclic diterpenoids such as fichtelite (VIIc), norpimarane, and pimarane (VIId, e) have also been found in petroleums.[34] Nor can one rule out the possibility of the presence of the sesquiterpane cedrane (VIIf).



4. Tetracyclic isoprenoids

Tetracyclic isoprenoids constitute the largest and most interesting group of isoprenoid petroleum hydrocarbons. Sterane hydrocarbons (Scheme VIII) play an especially major role, because these compounds contain a very large amount of information for the solution of a series of geochemical problems (more will be said about this below).

Furthermore, the steranes, formed from the chemically fairly labile steroids, undergo a series of interesting structural and stereochemical transformations in the Earth's core leading to the formation of a series of hydrocarbons which have no analogues in living nature and which are present only in petroleums. Such are, for example, isosteranes (the 14β,17β-epimers), rearranged steranes, etc.

Thus, as was already mentioned previously, petroleum is a source of completely new types of organic molecules; an example is the discovery of hydrocarbons of the adamantane series in petroleums. Scheme VIII presents the formulae of the principal sterane hydrocarbons discovered in petroleums[1,2,35–41] [a mixture of the (24*S*)- and (24*R*)-epimers for R = C_1-C_3]:

Scheme VIII

R = H, CH_3, C_2H_5, C_3H_7; R¹ = H, C_2H_5

† Here and henceforth the suffixes β and α denote the orientation of the hydrogen atom.

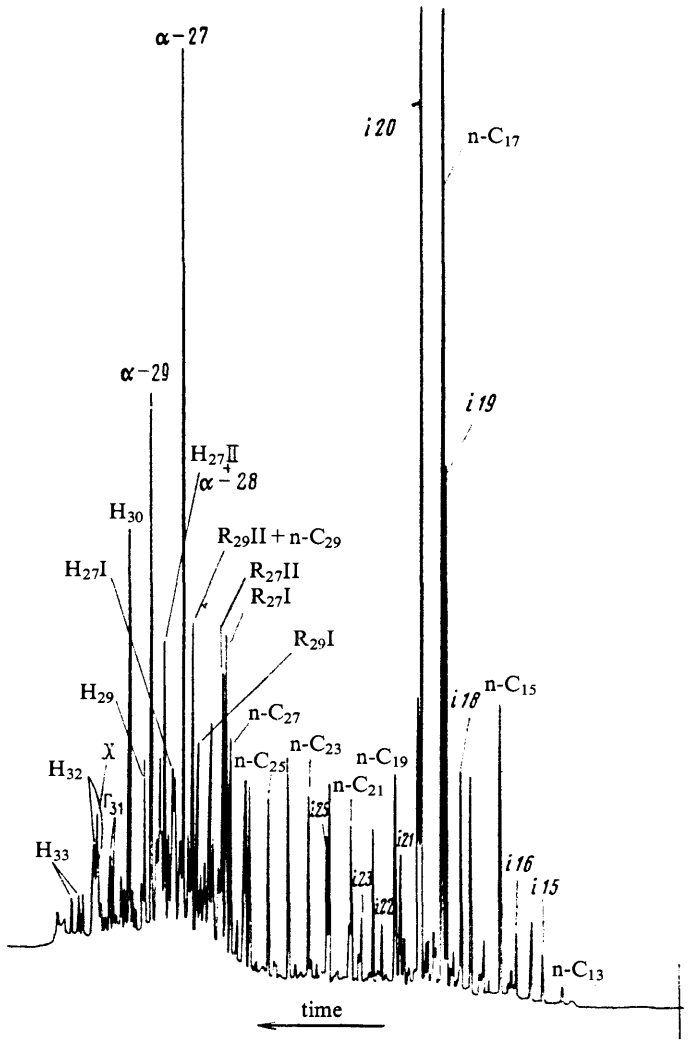


Figure 2. Chromatogram of a mixture of saturated hydrocarbons in the petroleum of the Vostochno-Vystupovichskoe deposit; the analytical conditions were the same as in Fig. 1; n, normal alkanes; *i*, isoprenoid alkanes; α-27, α-28, α-29, regular steranes (5α, 14α, 17α, 20*R*); R_{27}, R_{28}, R_{29}, rearranged steranes (13β, 17α, 20*S* and 20*R*); H, hopanes; in the $C_{31}-C_{35}$ doublet peaks, (22*S*)-epimers are eluted first; X, gammacerane; the numerals indicate throughout the number of carbon atoms in the molecule for R [I (20*S*) and II (20*R*)] and for H_{27} [I (18α-H) and II (17α-H)].

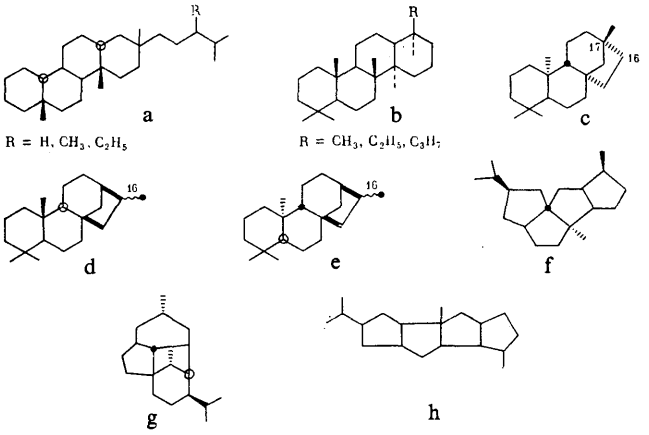
In terms of the steric structure, the hydrocarbons (VIIIa) belong to the series of biological steranes in which the most important chiral centres having the (5α, 14α, 17α, 20*R*)-configuration.[35] Fig. 2 presents a chromatogram of the saturated hydrocarbons of the petroleum from the Vostochno-Vystupovichskoe Deposit (Belorussia).‡ The peaks due to the C_{27}, C_{28}, and C_{29} (5α, 14α, 17α, 20*R*)-steranes (VIIIc) having the same composition are clearly seen.

The concentration of the stereochemically modified (5α, 14β, 17β, 20*S*)- and the corresponding (20*R*)-epimers of compound (VIIIb) in this petroleum is low. The isosteranes/α-steranes ratio is ~0.1. However, in other petroleums this ratio can reach 5 and more up to thermodynamic equilibrium value which is 7 (at 400 K).[1,35] The epimerisation of (5α, 14α, 17α, 20*R*)-steranes with formation of (5α, 14β, 17β, 20*S*)- and the corresponding (20*R*)-epimers is thermodynamically extremely favourable, since the change from the *trans*-junction of the *C/D* rings to the *cis*-junction removes all the strain characteristic of angularly substituted methyl-*trans*-hydrindans. As a result of the simultaneous epimerisation of the C(17) chiral centre, the hydrogen atoms at C(17)–C(20) and the angular methyl group [at C(13)] cease being eclipsed. At the same time, the quaternary C(10) and C(13) carbon atoms remain unaltered, which in fact preserves the high optical activity of the petroleum isosteranes formed. Apart from the epimerisation of the C(14) and C(17) centres, the epimerisation of C(20) also takes place and leads to the appearance on the chromatograms of doublet peaks of the



‡ Al A Petrov, Geologiya Nefti i Gaza, 1988, No. 10, p. 50.

hydrocarbons with the (α, β, β, 20*S*)- and (α, β, β, 20*R*)-configurations formed, whose thermodynamic stabilities are similar. The rearranged steranes (VIIIc) have the characteristic (10α, 13β, 17α)-configuration and also exist in the form of pairs of (20*S*)- and (20*R*)-epimers (these hydrocarbons are sometimes called diasteranes). The proportions of steranes with different molecular weights, the ratio of the α, α, α-steranes and isosteranes, as well as the relative concentrations of the rearranged steranes are some of the most important geochemical characteristics of the petroleums investigated.§ Apart from the steranes already examined, the spirosteranes (VIIId) as well as steranes with shorter substituents at C(17)—androstane and pregnane (VIIIe)—have also been determined in petroleums.[42] In addition, a series of C_{30} steranes (VIIIf), having either a propyl substituent at C(24) or methyl substituents at C(4), C(23), and C(24), have also been found in petroleum.[43] All these steranes can also exist in petroleum in the form of the biological α, α, α-epimers and in the form of their reaction products—(α, β, β, 20*S*)- and the corresponding (20*R*)-steranes with a rearranged skeleton.

Spirosteranes are formed via the acid rearrangement of steranes followed by saturation as a result of a redistribution of hydrogen. Steranes in petroleums are usually determined with the aid of gas chromatography-mass spectrometry on the basis of the principal fragment ions: m/z = 217 for the regular structures and m/z = 259 for the rearranged structures (m/z = 231 and 273 respectively for the 4-methylsteranes).

Hydrocarbons with the perhydrochrysene structure (IXa, b), in particular 17*D*-homosteranes (IXa) and 17, 21, secohopanes (IXb), also belong to tetracyclic isoprenoids.[1,29,44] (The dots designate quaternary and tertiary carbon atoms exhibiting a strong downfield shift in the ^{13}C NMR spectra.)

Scheme IX

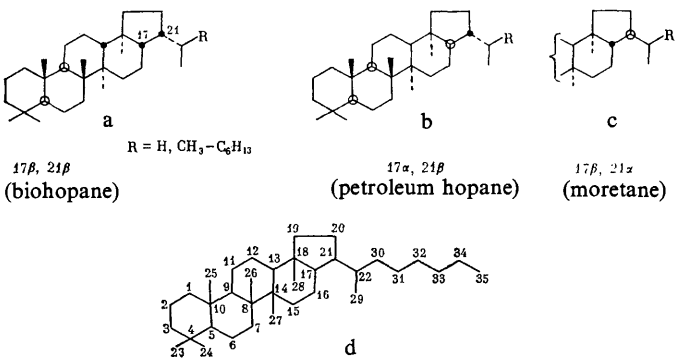
17-*D*-Homosteranes, identified from the fragment ion with m/z = 287, are also products of the skeletal rearrangement of sterenes, proceeding via a carbonium ion mechanism, and can be regarded as compounds formed from diasteranes as a result of the expansion of the *D* ring.

§ Among the regular steranes, the most important hydrocarbons any structure are the (5α, 14α, 17α, 20*R*)-epimers (biosteranes), (5α, 14α, 17α, 20*S*)-epimers, (5α, 14β, 17β, 20*S*)-epimers, and the corresponding (20*R*)-epimers (geosteranes). Among the rearranged steranes, the (10α, 13β, 17α, 20*S*)- and the corresponding (20*R*)-epimers are most important. Data concerning the equilibrium of the epimers considered have been published in a monograph.[35]

The hydrocarbons with the structure (IXb)—the products of the degradation of the *E* ring of hopanes (see below)—are 17, 21-secohopanes having the $C_{24}-C_{27}$ composition.

The group of petroleum diterpanes comprising beyerane (IXc), phyllocladane (IXd), and kaurane (IXe) is very interesting.[45] The hydrocarbons (IXd, e) exist in the form of epimeric pairs (16α- and 15β-).

A remarkable group of tetracyclic C_{19} hydrocarbons (IXf–h), containing mainly five-membered rings, has been examined recently.[46] The compact packing of the carbon atoms make it possible to create a tetracyclic system consisting of only 14 carbon atoms. The key factor in the determination of the structure of the hydrocarbons (IXf–g) is the strong downfield shift in the ^{13}C NMR spectra (65–66 p. p. m. relative to TMS). The hydrocarbons (IXf–h) are most probably formed via the microbiological C_5 cyclisation of the unsaturated monocyclic isoprenoids, such as, for example, cembrene,[47] although, in principle, other pathways and sources are also possible. The relatively very high concentration of the hydrocarbons (IXf–h) in certain petroleums, reaching 1–2%, is noteworthy.



5. Pentacyclic isoprenoids

Together with tetracyclic hydrocarbons, pentacyclic hydrocarbons occupy one of the most important places in the chemistry of petroleum hydrocarbons. Compounds of this type belong to the class of triterpenoid hydrocarbons (triterpanes), although homologous properties are observed here also. It is possible to differentiate two main types of structures:

(a) hydrocarbons with the perhydropicene skeleton (all the rings are six-membered);

(b) hydrocarbons with the cyclopentanoperhydrochrysene skeleton. Hydrocarbons of the second type are much more common in petroleums.

Scheme X

We shall begin the examination of pentacyclic hydrocarbons with the important homologous series of hopane hydrocarbons (Scheme X). Studies by Ourisson's school (France) have played an outstanding role in the determination of the structure and stereochemistry of petroleum hopanes. Ourisson has justly referred to these hydrocarbons as "ubiquitous",[48] because they are present in almost all caustobioliths: in petroleums, coals, shale, peat, etc.[1] The hopane series hydrocarbons are formed in the microbiological processing of natural organic compounds in the early stages of their fossilisation. The pentacyclic tetrahydric alcohol bacteriotetrol (see below), which forms part of the composition of the lipid component of membranes of ancient bacteria, is the source of the hopanes

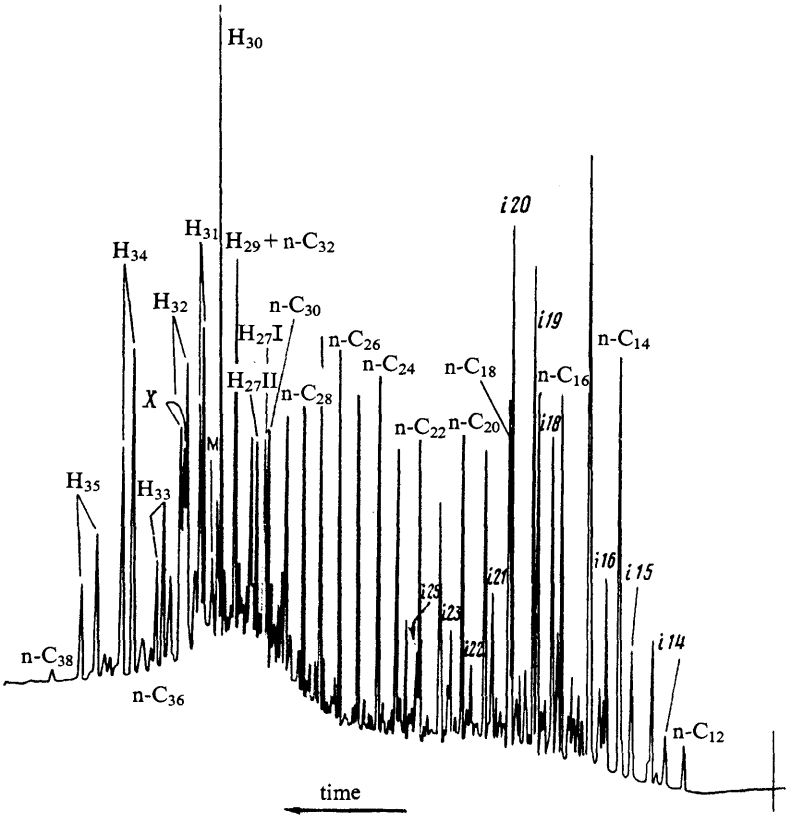


Figure 3. Chromatogram of a mixture of saturated hydrocarbons from the Zapadno-Slavan'skoe deposit; the chromatographic conditions were the same as in Fig. 1; the legend is the same as in Fig. 2. M = moretane.

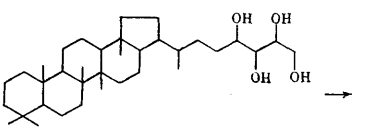
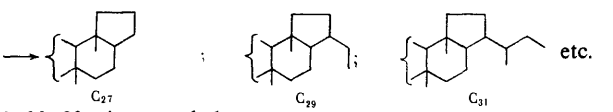
themselves. We may also note that the studies by the school of the famous English organic geochemist Eglinton have played a no less important role in the determination of the structures of other isoprenoid biomarkers (chemofossils) and in establishing organic geochemistry as an independent scientific discipline.[49,50]



A large number of studies have been published on petroleum hopanes.[1,2,51–55]

Scheme X presents the formulae of hopanes having different stereochemistry: (a) biohopane; (b) petroleum hopane; (c) moretane, which is also encountered in petroleums. The numbering of carbon atoms is indicated in the formula (Xd).

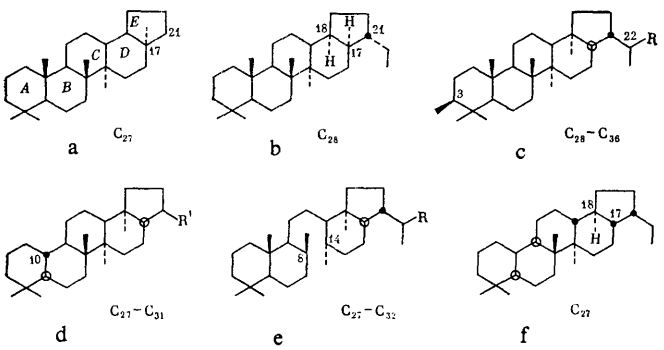


The principal factor determining the energy gain in the isomerisation of the 17β,21β-epimers to the 17α,21β-epimers is again the greater stability of the *cis*-fused angular methylhydrindan. In addition, the change in the configuration of the C(17) chiral centre removes the strain present in biohopane (17β), which arises because the 17–16 and 21–22 bonds (*cis*-orientation) are eclipsed. Calculations have shown that only 3% of biohopane, 12% of moretane, and 85% of petroleum hopane may be present under equilibrium conditions at 400 K.[1] The composition of hopanes in petroleums is very closely represented by the above figures.

As already stated, the tetrahydric C_{35} alcohol bacteriotetrol is believed to be the source of hopanes (Scheme XI).

Scheme XI

C_{35}
bacteriotetral



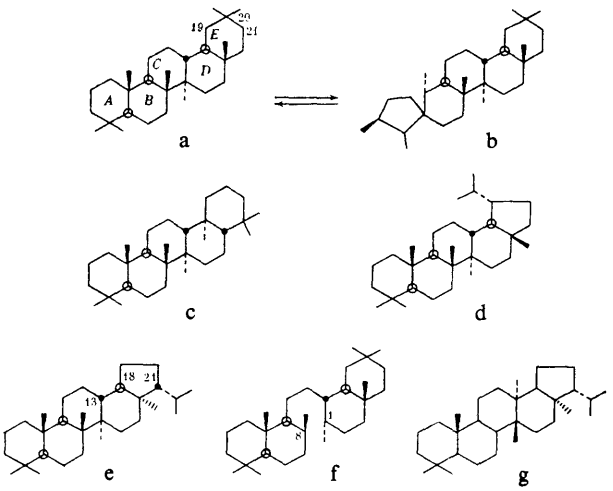
C_{27} 22, 29, 30-trisnormethylhopane; C_{29} adiantane; C_{31} homohopane

The degradation of the main chain of this compound gives rise to the homologous series of $C_{27}-C_{35}$ hopanes (naturally with the exception of the C_{28} hopane).

The minor series of $C_{36}-C_{40}$ hopanes with higher molecular weights has been described.[56] Their aliphatic chains have no additional branches. Dimeric forms of hopanes and saturated

codimers of hopenes and sterenes have also been found.[57,58] The C(22) atom in C_{31} and higher hydrocarbons is chiral and readily undergoes epimerisation. For this reason, the $C_{31}-C_{35}$ petroleum, hopanes emerge on the chromatograms in the form of doublets consisting of the (22*S*)- and (22*R*)-epimers; the (22*R*)-configuration is characteristic of biohopane [the (22*S*)-epimers are naturally absent from biohopanes]. Fig. 3 presents a chromatogram for the petroleum from the Zapadno-Slavan'skoe deposit.¶ This petroleum is exceptionally rich in hopanes. The $C_{27}-C_{35}$ hopane peaks are clearly seen, including the doublet peak due to the $C_{31}-C_{35}$ 17α,21β-hopanes. The hopanes in petroleums are determined usually by mass fragmentography on the basis of the most important fragment ion with $m/z = 191$. Apart from the main ("classical") hopanes examined above, numerous representatives of hopanes with a modified skeleton have been found in petroleums.[1,53,59-63] Some of these compounds are presented in Scheme XII. (We draw attention to the fact that in the names of hydrocarbons the lost methyl group has a number assigned to it as the usual nomenclature for gopanes—see Scheme XI.)

Scheme XII



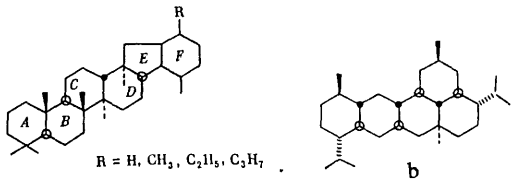
Thus the structure (XIIa), i.e. 17-methyl-22,29,30-trisnormethylhopane, is formed via the rearrangement of the usual C_{27} hopane. The rearrangement proceeds only in the C_{27} hopane, i.e. the hydrocarbon having no substituent at C(21). The structure (XIIb), i.e. 28,30-bisnormethylhopane, was first discovered in Sivinskaya petroleum [Perm Priural'e (Sub-Ural Region)].[1] In constrast to the remaining hopanes, here there is no methyl substituent at C(18). Since the angular methyl group (in the *D*/*E* rings) is absent, the system with a *D*/*E trans*-junction between the rings is more stable. In petroleums, this hydrocarbon is present as two epimers having the following steric structures: 17α,18α,21β and 17β,18α,21α; the structures (XIIc), i.e. 3-methylhopanes, present as a homologous series, have an additional methyl substituent in the *A* ring. The principal fragment ion in this series of hydrocarbons has $m/z = 205$. The chirality of the C(22) atom is manifested in this case starting from C_{32} hydrocarbons. On the other hand, a characteristic feature of the hydrocarbons in the homologous series (XIId) is the loss of the methyl group at C(10). The C(22) atom acquires chiral properties in this case starting with C_{30} hydrocarbons and the principal fragment ion in the mass spectra has $m/z = 177$. These hydrocarbons are mainly present in highly biodegradated petroleums.

The homologous series (XIIe) is represented by the so called 8,14-secohopanes, which are formed via the degradation of the most labile 8—14 bond. Their stereochemistry is the same as that of hopanes. The hydrocarbon (XIIf) is 25,28,30-trisnormethylmoretane.

Whereas the origin of hopanes is attributed mainly to the activity of micro-organisms, petroleums contain also other triterpanes (with the C_{30} composition), whose origin has a direct bearing on the plant materials involved in Continental genesis.[49,64-70]

The structures of some of these compounds are presented in Scheme XIII. All the hydrocarbons illustrated in Scheme (XIII) are triterpanes and contain 30 carbon atoms. Demethylated structures are encountered more rarely.

Scheme XIII

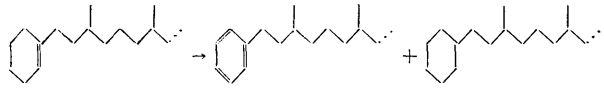


The hydrocarbons (XIIIa) and (XIIIb) (oleanane and spirotriterpane), belonging to the first group, are closely related via the carbonium ion 1,2-rearrangement. Lupane (XIIId), formed as a result of the contraction of the *E* ring with formation of the 19—21 bond and dissociation of the 20—21 bond, is closely related to them. The hydrocarbon (XIIIc) (gammacerane) has been found in large amounts in the petroleum produced by Continential genesis (China, Indonesia, Australia). The hydrocarbon neohopane (isohopane) (XIIIe) is usually present in brown coal, although it is found in small amounts also in petroleums. The hydrocarbon 8,14-secooleanane (XIIIF) is formed as a result of the degradation of the strained 8—14 bond of oleanane similarly to the 8—14-secogopanes examined previously. Fernane (XIIIg) is present in lichens, mosses, and peat.

All the hydrocarbons examined in Scheme (XIII) (including hopane) can be formed as a result of the cyclisation of squalane present in different conformations.[71] Like steranes, all the petroleum triterpanes exhibit a high optical activity, because they each contain four chiral centres formed by non-epimerising quaternary carbon atoms.

In conclusion of this Section, one should consider the homologous series of hexacyclic $C_{32}-C_{35}$ terpenoids discovered recently in petroleums[72] and also dicadinane—a C_{30} pentacyclic triterpenoid[73] (Scheme XIV).

Scheme XIV



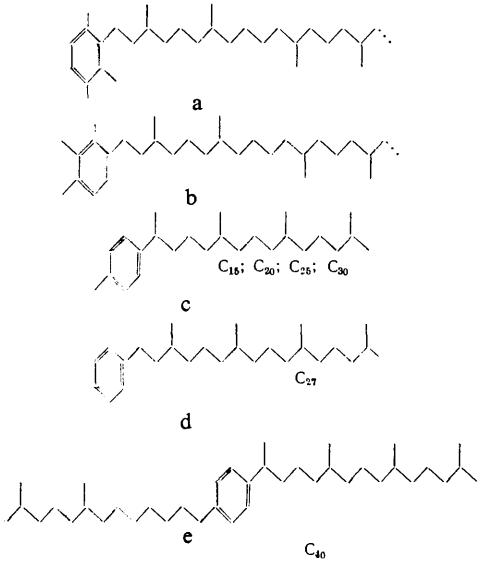
¶ Al A Petrov, *Geologiya Nefti i Gaza*, 1988, No. 10, p. 50.

The hydrocarbons of the first series (XIVa) are formed from bacteriotetrol simultaneously with benzohopanes having a similar structure (with the aromatic *F* ring). This reaction will be examined in greater detail in the next Section.

Bicadinane (XIVb) can be regarded as the product of the dimerisation of cadinene (eudesmane). The presence of two isopropyl groups leaves no doubt about its isoprenoid nature. Bicadinane has certain structural features characteristic of the tetracyclic C_{19} diterpenoids considered above.

IV. Aromatic isoprenoids

Aromatic isoprenoid compounds are usually absent from natural bioorganic objects. Therefore this Section will deal with the secondary products formed as a result of the redistribution of hydrogen (on clays) in hydrocarbons whose six-membered rings contain multiple bonds. Thus the aromaticity of these hydrocarbons is a secondary feature.

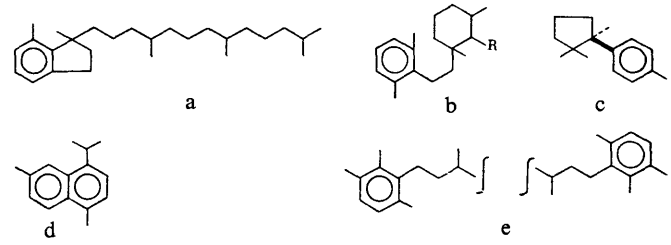


However, the character of the hydrocarbons examined below leaves no doubt about the isoprenoid nature of the compounds from which they have been formed. As will be shown below, overall the aromatic isoprenoid hydrocarbons are very similar in their structure (naturally with certain exceptions) to their alicyclic analogues.

1. Monocyclic hydrocarbons

Scheme (XV) presents the formulae of hydrocarbons [represented mainly by the $C_{10}-C_{30}$ homologous series (XVa, b)] containing a benzene ring and an aliphatic isoprenoid chain.

Scheme XV

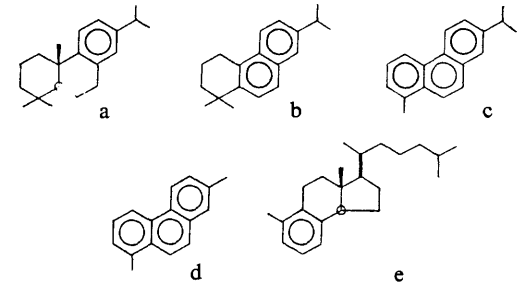


The structure of the hydrocarbons (XVa) and also the absence of the C_{12}, C_{17}, C_{23}, and C_{28} homologues from this series leaves no doubt that we are dealing here with aromatic derivatives of carotane. Hydrocarbons of the series (XVb) having a similar structure are present at lower concentrations. Apart from aromatic derivatives of carotane, $C_{15}-C_{30}$ methylalkylbenzenes (XVc), having a regular isoprenoid chain, have been found in petroleum. In contrast to aromatic carotenoids, C_{15}, C_{20}, C_{25}, and C_{30} hydrocarbons clearly predominate here, i.e. these hydrocarbons are sesquiterpanes, diterpanes, sesterterpanes, and triterpanes. A C_{27} hydrocarbon (XVd), having a regular isoprenoid chain, is present in certain petroleums at very high concentrations. An interesting aromatic phytadiene "dimer" (XVe) has been described.[75]

2. Bicyclic hydrocarbons

The C_{27} indan homologue (XVIa), with a regular isoprenoid chain, has been reliably identified in a number of petroleums[74] (Scheme XVI).

Scheme XVI



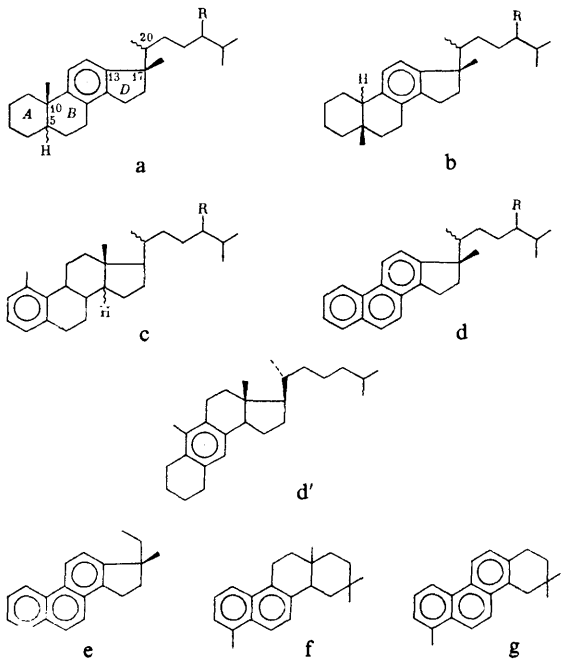
A group of phenylethylcyclohexanes (XVIb), formed via the degradation of the middle ring of the tricyclic isoprenoids (VIIa), has also been described.[57] The interesting hydrocarbon cuparene (XVIc) is a representative of the rarely encountered group of aromatic sesquiterpenoids.[2] Among naphthalene derivatives, cadalane (XVId) is undoubtedly isoprenoid in character.[76] A biaromatic analogue (XVIe) of β-carotane has been described. The hydrocarbon has been called isorenieratene.

3. Tricyclic hydrocarbons

Tricyclic aromatic isoprenoids are relatively less abundant in petroleums. Scheme (XVII) presents the formulae of four hydrocarbons formed on aromatisation of diterpenoids: dehydroabietane (XVIIa), simonellite (XVIIb), retene (XVIIc), and pimanthrene (XVIId).[78] The structure (XVIIe) is formed on degradation on the *A* ring in regular steranes (sterols).[79]

Scheme XVII

4. Tetracyclic hydrocarbons



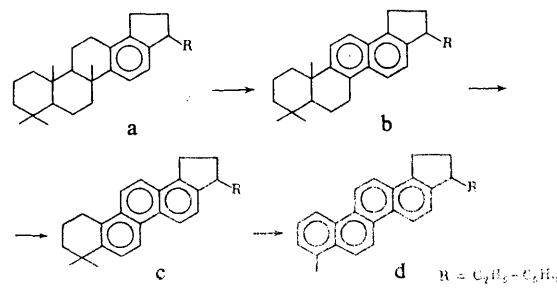
This group of compounds is extremely abundant in petroleums because the interaction of sterols with clays results in the formation, apart from saturated steranes, also of their aromatic analogues having from one to three aromatic rings in the molecule.[80,81]

A fairly large amount of attention has been devoted in the scientific literature to aromatic petroleum steranes.[1,2,82-90]

It has been found that the *C* ring is preferentially aromatised in steranes (steranes with the aromatic *A* ring are less common). Subsequently the *B* and *A* rings are aromatised simultaneously in *C*-aromatic steranes, which leads to triaromatic steranes containing the phenanthrene system. On aromatisation of the *A* ring, the angular methyl group at C(13) migrates to the C(17) atom. On exhaustive aromatisation, the methyl group at C(10) is usually eliminated. Monoaromatic steranes (*C* ring) have been identified in the mass spectra from the fragment with $m/z = 253$ (abstraction of an aliphatic group). In the mass spectra of steranes with an aromatic *A* ring, the principal fragment ion has $m/z = 211$. Triaromatic steranes are characterised by a fragment ion with $m/z = 231$ (also with abstraction of an aliphatic group).

Scheme (XVIII) presents the formulae of the most important aromatic steranes identified in petroleums as well as the formulae of certain other tetracyclic compounds.[91]

Scheme XVIII



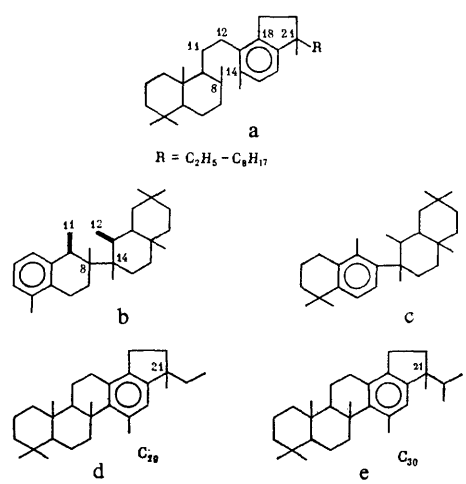
Monoaromatic steranes (XVIIIa) are present in the form of four epimers: 5α,20*R*; 5α,20*S*; 5β,20*R*; 5β,20*S*. In contrast to saturated steranes, in this case the 5β-isomers are more stable (because of the distortion of the *B* ring).[84] The structures (XVIIIa, d) are the most common in petroleums. Their ratio is widely used as an important correlation factor determining the degree of catagenic maturity of the petroleum. Since the exhaustive aromatisation process is accompanied by the degradation of the side chain in steranes, the petroleums contain, apart from the $C_{26}-C_{28}$ steranes [structures of the type (XVIIId)], a series of triaromatic steranes with shorter aliphatic chains, for example, compound (XVIIIe).[89]† Partly aromatised molecules of the pentacyclic triterpanes (XVIIIf, g), which have undergone degradation (*E* rings), have been found in petroleums.[91]

† The sterane (XVIIId′) with an aromatic *B* ring belongs to the class of the rarely encountered anthrasteroids.[89]

5. Pentacyclic hydrocarbons

The formation of pentacyclic aromatic petroleum isoprenoids is wholly associated with the aromatisation of triterpenoids, especially hopane and its homologues. Aromatic derivatives of adiantane, hopane, and homohopanes have been described.[92,93] The aromatisation of the rings takes place gradually in the sequence $D \rightarrow C \rightarrow B \rightarrow A$ with the simultaneous loss of methyl substituents (Scheme XIX).

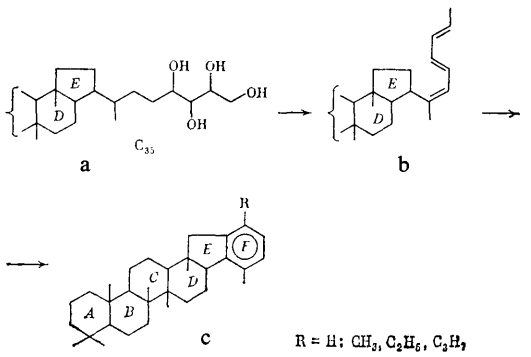
Scheme XIX



Another group of aromatic hydrocarbons formed from hopanes has also been discovered.[94-96] It has been shown that the aromatisation (of the *D* ring) takes place with the simultaneous dissociation of the most labile 8–14 bond. This results in the formation of tetracyclic monoaromatic 8,14-secohopanes of type (XXa) [we may note the interesting 1,3-migration of the methyl group from C(18) to C(21)[96] (Scheme XX)].

An example of other secotriterpanes (XXb, c), formed from oleanane (β-amyrin) with dissociation of the 11–12 bond, has been quoted.[76]

Interesting pentacyclic hopanes (XXd, e) with an aromatic *D* ring have been discovered in Soviet petroleums.[94] As in the case of secohopanes, their formation probable involved the migration of the methyl group from the C(18) atom to the C(21) atom. An intense fragment ion with $m/z = 363$ is characteristic of the mass spectra of these hydrocarbons. It is formed as a consequence of the elimination of the aliphatic substituent at C(21), similar to the elimination of the substituent in monoaromatic steranes ($m/z = 253$) or in secohopanes ($m/z = 365$).



Scheme XX

6. Hexacyclic hydrocarbons

A series of hexacyclic hydrocarbons with one aromatic ring can be obtained from bacteriohopane with the simultaneous formation of hydrocarbons of the hopane series[96–98] (Scheme XXI). These hydrocarbons have been called benzohopanes.

Scheme XXI

The dehydration of the tetrol (XXIa) on clays leads to a series of polyenes (XXIb), capable of intramolecular cyclisation with formation of an aromatic *F* ring. This entails the partial degradation of fragments of the aliphatic chain. In addition to compounds (XXIc), their saturated heterocyclic analogues, described previously, are also formed simultaneously. It is striking that only $C_{32}-C_{35}$ hexacyclic compounds have been found in petroleums in both cases.

V. Conclusion

We shall now describe certain conclusions which arise from the data examined. The large number of studies carried out in recent years on the chemistry and geochemistry of petroleum have demonstrated an appreciable content of aliphatic, alicyclic, and aromatic isoprenoids in the test objects. The structures of all the compounds identified are directly related to those of their biological precursors.

The number of isoprenoid hydrocarbons in petroleums reaches 300 items and their overall concentration is in many instances 20–25% relative to the petroleum hydrocarbons. We may note that the sulphur- and oxygen-containing components of petroleum are also made up mainly of the same structural fragments with a clear predominance of isoprenoid structures.[99,100] All these findings undoubtedly confirm the bioorganic nature of the petroleum, which is a product of the transformation of the lipid component of ancient living matter: algae, bacteria, and higher plants. Petroleum hydrocarbons, which preserve information about the composition and structure of their bioorganic precursors because of their relative chemical stability, have therefore been called biological labels or chemofossils. They are sometimes also referred to as relict compounds.

However, the role of biological labels is not limited to the conclusion that petroleum is bioorganic in origin. They are much more important in modern geochemical methods used in prospecting for petroleum deposits.[1,2,101–104] Thus the characteristics of the qualitative and quantitative distribution of isoprenoid hydrocarbons in petroleums are used to determine the type of organic matter: marine (seaweed, plankton), continental, and highly modified by microbiological action. Typical parameters of the marine matter are, for example, high concentrations of steranes (especially with the C_{27} composition) and phytane. On the other hand, in the petroleums generated from continental (plant) organic matter pristane predominates, there are no steranes, and at the same time triterpanes, such as, for example, oleanane, and diterpanes, such as phyllocladane and kaurane, are present. The intense microbiological processing of organic matter is also indicated by the high concentrations of gopanes and the presence of irregular aliphatic isoprenoids with "head to head" fragments, etc. Isoprenoid petroleum hydrocarbons can be used also to determine the paleo-conditions for the accumulation of deposits and the transformation of organic matter into petroleum. Thus T-shaped isoprenanes and gammacerane arise in highly saline media. Rearranged steranes are usually absent from carbonate deposits (rocks), which are in fact most often formed in terrigenic (argillaceous) deposits. In addition, the proportions of aliphatic isoprenoids, steranes, and hopanes excellent "fingerprints" of particular petroleums,[1,2] which make it possible to determine the source from which they have been formed and the ways in which petroleums have migrated in the Earth's core.

Finally, the change in the stereochemistry of hopanes and especially steranes is widely used to determine the degree of "maturation" (catagenic modification) of organic matter in the regions and deposits up to the petroleum level which have been investigated. This is based on the fact that the initial (immature) organic matter always has the natural (biological) configuration of the labile chiral centres, for example C(17), C(21), and C(22) in hopanes and C(14), C(17), and C(20) in steranes. Petroleums usually consist of a catagenically fairly mature product (corresponding to the E–D stage on the coal metamorphism scale) which has been stereochemically modified. The formation of appreciable petroleum deposits is therefore possible, in principle, only in those places where the organic matter is characterised by the presence of 17α,22β-hopanes and (14β,17β,20*S*)- and the corresponding (20*R*)-steranes.

The distribution of isoprenoid hydrocarbons is also used for the chemical (geochemical) classification of petroleums and also for the estimation of the degree of microbiological transformation of petroleum.[1,2] Thus the practical importance of isoprenoid petroleum hydrocarbons (as well as other biomarkers) is very great. There is no doubt that these compounds have great potential possibilities and that there are good prospects for their wide scale practical use.

Thermostable and fire-resistant polymers based on chloral and its derivatives

V V Korshak (deceased), A L Rusanov
Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The possible ways of using chloral and its derivatives as monomers for the synthesis of fire-resistant and thermostable carbochain and heterochain polymers are examined. Questions concerning the synthesis from chloral of the polyfunctional monomers used to prepare polyheteroarylenes with specific properties are given an especially detailed consideration.

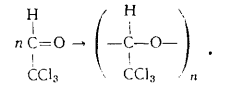
I. Introduction

The development of raw materials for the synthesis of polymers and materials derived from them is a key problem which in many respects determines the successful and intensive development of the chemistry and technology of high-molecular-weight compounds. The problem of ensuring the supply of monomers for the development of polymers with specific properties—fire resistance, thermal stability, etc.—in which considerable progress has been made during the last decade, is especially acute.[1]

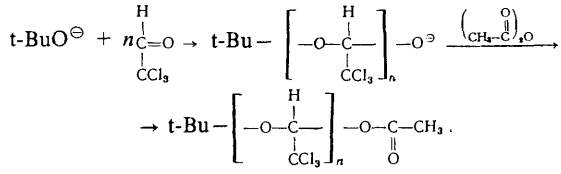
The use of chloral, which is produced on a large scale,[2,3] its output in 1970 in the USA being at the level of 50 000 tonnes annually, as the raw material for the synthesis of monomers of this kind is therefore of considerable interest. Chloral is the starting material for the synthesis of pharmaceuticals, especially pure chloroform, herbicides (sodium trichloroacetate, dichloral-urea) and insecticides of the type of chlorophos.[3] However, the principal application of chloral has always been the manufacture of DDT [4]—a widely used insecticide, whose world production in 1956 was 80 000 tonnes.[5] Between 1942 and 1974, 4.5 million tonnes of DDT were used in the fight against agricultural pests throughout the world[6] and during the antimalarial compaign over a period of many years the application of DDT saved more than 1 billion people from malaria.[7] Furthermore, it helps to eradicate diseases such as the plague, typhoid, sleeping sickness, yellow fever, leishmaniasis, colorado tick fever, etc.[7]



During the last 20–25 years, an acute controversy has developed concerning the toxic effect of DDT on the human organism which it enters as a result of being incorporated in the "food chain", including plants and animals used by man, as a result of which the World Health Organisation forbade the use of this preparation as an insecticide or in any other way leading to the possibility of its being incorporated in the "food chain". Furthermore, many pests (about 200 species) have developed resistance to DDT as a result of its frequent application. Consequently in all the major states a programme for the gradual replacement of DDT has been put in train and in 1963 its manufacture and the associated manufacture of chloral already began to decrease.[3,7] Nevertheless the output of these products has continued to be considerable (mainly for the use of DDT in developing countries[7]) and the manufacturing capacity for chloral and DDT available in the world is capable of meeting the highest requirements for these products.

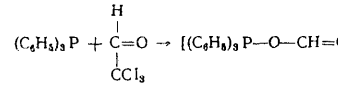
In view of the foregoing, the use of chloral and DDT for the synthesis of polymers with specific properties appeared extremely attractive.

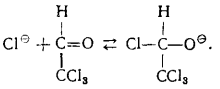
The promising nature of this aspect has been partly demonstrated in a number of studies[8–11] but none of them reflect the set of possibilities inherent in the use of these compounds—direct or indirect—in the chemistry and technology of polymers. Within the framework of this review, we have attempted to consider as widely as possible the ways of utilising chloral and DDT for the preparation of thermostable and fire-resistant polymers.



II. Chloral homopolymers and copolymers

Since the polymerisation of aldehydes, involving the partial dissociation of a carbon–oxygen bond, is a familiar reaction in the synthesis of polymers,[12] it is quite natural that the polymerisation of chloral became the first application of this product in the chemistry of polymers.[12–15] Vogl showed that chloral can polymerise via both anionic and cationic mechanisms:





The tendency of aldehydes to polymerise is correlated with the polarisation of the double bond of the carbonyl group, which is reflected in the position of the C=O band in the IR spectrum. Aldehydes in which the absorption frequency of the carbonyl group is above 1750 cm^{-1} and especially chloral readily polymerise via an anionic mechanism on treatment with nucleophiles.[16] The most widely used initiators are alkali metal alkoxides, tertiary amines, tertiary phosphines, quaternary ammonium and phosphonium salts, as well as organometallic compounds. Even when comparatively weak nucleophiles are employed, the anionic polymerisation takes place at a high rate and leads to the formation of polychloral in a high yield. For example, the block polymerisation of chloral using 0.2 mol% of lithium t-butoxide as the initiator leads to the

formation of polychloral in 85% yield after 3 min.[17] A study of the mechanism of chain propagation by stopping the polymerisation at early stages of the process showed that it proceeds via the mechanism[18,19]

When triphenyl phosphite is used as the initiator,[20] the polymerisation reaction proceeds, according to Hoffmann and Diehr,[21] in conformity with the following scheme:

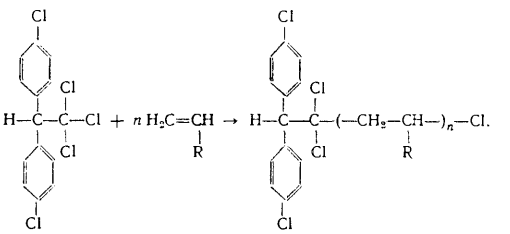
In the presence of anionic initiators, chloral is polymerised by a special method. It consists in carrying out the initiation at a temperature above the limiting value followed by the polymerisation after cooling below the limiting temperature.[14,15,17] This process makes it possible to obtain polychloral in the form of desirable materials.

The cationic polymerisation of chloral can be initiated only by strong Lewis and Brønsted acids (BF_3, CH_3SO_3H, H_2SO_4); the rate of polymerisation is then significantly lower—when 2 mol% CH_3SO_3H is used as the initiator at −5 °C for 300 h, the degree of conversion is only 40%. A noteworthy exception is observed in polymerisation initiated by $AlCl_3$ and $SbCl_2$; in these cases, polychloral was obtained in a high yield, but there are doubts about the purely cationic nature of this process which might have been initiated also by chlorine.[12]

Polychloral is completely insoluble in organic solvents because of its isotactic structure,[12,22] demonstrated by X-ray diffraction, ^{13}C NMR, and ^{35}Cl NQR and caused by the large bulk of the trichloromethyl side groups. The same fragments which are responsible for the high chlorine content in polychloral give rise also to the virtual incombustibility of this polymer.

The mechanical, electrical, and thermal properties of polychloral have been examined.[23] The polymer is characterised by moderate crystallinity; its density is 1.9 g cm^{-3} and its refractive index is $n_D^{25} = 1$. Its thermal expansion coefficient is 4×10^{-5} K^{-1}. Polychloral fibres have a tensile strength of the order of 40 mPa and an elongation on rupture of the order of 25%. The coefficient of friction of polychloral, both static and dynamic, is 0.55.

The dielectric constant of polychloral at room temperature is 2.8, its scattering factor is 0.003, and its electrical resistivity is 4×10 Ω cm.



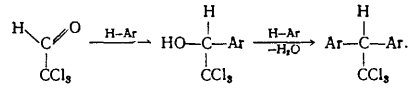
The thermal stability of polychloral obtained as a result of polymerisation is low (220 °C); as for other polyacetals, regardless of the methods of polymerisation subsequent treatment leads to the formation of more stable end groups. Thus the comparatively low thermal stability of the polychloral obtained by the anionic mechanism is due to the presence of alkoxy-end groups with which the depolymerisation process begins. The mechanism of the degradation of the polychloro-compound has been investigated in fair detail.[24] Thermogravimetric analysis of polychloral showed that the unstabilised polychloral is degraded at comparatively low temperatures. The bimodal and even trimodal character of the differential thermogravimetric analysis curves indicate the presence of two or three polychloral fractions with different end groups.[24]

The methods for the introduction of more stable end groups during and after the polymerisation of chloral include the use of the corresponding chain transfer agents, decomposing counterions etc. as well as different versions of the treatment of the polymer already obtained. Thus, when the polymerisation is initiated by triphenylphosphine and the polymer is subsequently treated with PCl_5 in CCl_4, polychloral acquires a greater thermal stability. On heating in an atmosphere of nitrogen at a rate of 20 K min^{-1}, this type of polychloral begins to degrade at 250 °C and the maximum rate of degradation is attained at 340 °C. Thus correctly stabilised polychloral has the same thermal stability as the industrial (i.e. stabilised) polyoxymethylene.

Polychloral does not melt without decomposition. Its hypothetical melting point (~460 °C), which is far removed from its degradation temperature, has been obtained by extrapolating the melting points of chloroal–formaldehyde complexes.[23]

The copolymers of chloral with other monomers have attracted much attention among investigators; copolymers of this product with a wide variety of comonomers have been described in the patent literature. However, one should note that the copolymerisation reactions of chloral with mono- and di-chloroacetaldehydes,[25] aliphatic and aromatic isocyanates,[26–28] ketones, formaldehyde, and trioxane have been studied in greatest detail. The copolymers of chloral with monochloroacetaldehyde are soluble in chloroform, while its copolymers with dichloroacetaldehyde are insoluble. None of the copolymers melt below the thermal degradation temperature and their thermal stabilities are intermediate between those characteristic of the corresponding homopolymers.

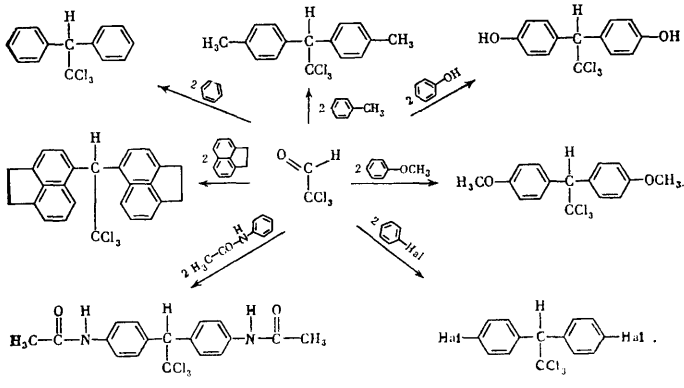
Yet another possible application of chloral in polymerisation processes is associated with the presence in it of the trichloromethyl group, which plays the role, under certain conditions, of an active centre at which radical processes take place. Thus the telomerisation of ethylene, propene, butene, and a number of other polymers using DDT has been examined:[29]



The presence of trichloromethyl substituents in the chloral homopolymers and copolymers leads to the possibility, by analogy with the process examined above,[29] of modifying these polymers by the graft polymerisation reactions. According to a number of investigators,[30–32] such reactions should proceed especially effectively in the presence of metal carbonyls. The radical formation process in the systems considered usually involves electron transfer from the transition metal to the halogeno-derivative; the metal then passes to a higher oxidation state and the halogen-derivative decomposes into ionic and radical fragments.[32]

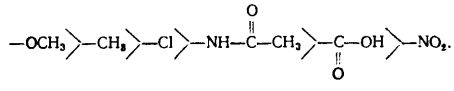
Despite the availability of the starting material, the chloral homopolymers and copolymers as well as their modification products have not found practical applications. The condensation polymers, obtained from chloral derivatives and DDT, are more promising in this respect.

III. Chloral-based condensation monomers



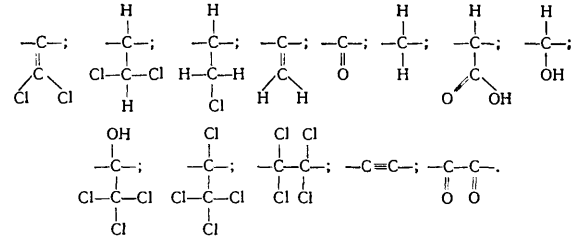
The majority of syntheses of condensation monomers using chloral are based on the well known reactions of this compound with aromatic hydrocarbons, aromatic alkyl-substituted hydrocarbons, and aromatic hydrocarbons containing various functional groups[2] with subsequent reactions of the diaryltrichloroethanes obtained in this way via the central chloroethane fragments and the aromatic rings.

The condensation reactions between chloral and aromatic hydrocarbons and their derivatives, leading to the formation of diaryltrichloroethane derivatives, are carried out in the presence of an acid catalyst and proceed with formation of intermediate carbinols:[33]

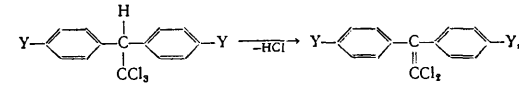


Concentrated H_2SO_4 or its monohydrate, HCl, HF, P_2O_5, H_2PO_4, Lewis acids, and a number of other acid agents are usually employed as catalysts.[2]

In a series of numerous reactions of chloral with aromatic hydrocarbons and their derivatives, the greatest interest attaches, from the standpoint of the synthesis of condensation monomers, to the reactions of chloral with benzene,[34] toluene,[35] acenaphthene,[36] phenol,[37] anisole,[38] acetanilide,[39] and halogenobenzenes—especially chlorobenzene[40] and fluorobenzene.[41] Thes reactions take place in accordance with an idealised scheme and lead to the formation of the target 2,2-diaryl-1,1,1-trichloroethanes in high yields:



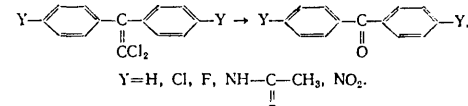
The ease of the reaction of substituted benzenes with chloral varies, in the first place, as a function of the electronic influence of the substituents. According to Yasue and Takai,[42] the reactivity of aromatic rings in reactions with chloral diminishes in the following sequence as a function of the nature of the substituent:



The reactions of 2,2-diaryl-1,1,1-trichloroethanes are carried out in the following ways: (a) the reactions of central 1,1,1-trichloroethane groups; (2) the substitution of the hydrogen atoms in the aromatic rings of diarylchloroethanes and their derivatives with respect to the central group; (3) the reactions of the functional groups, introduced into the aromatic rings of diaryltrichloroethanes and their derivatives with respect to the central group.

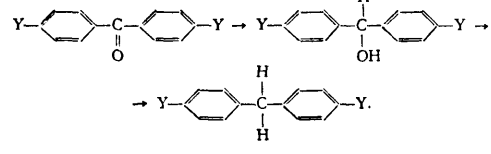
The central trichloroethane groups can undergo various reactions leading to their transformation into groups such as 1,1-dichloroethylene, 1,1-dichloroethane, 1-chloroethane, ethylene, carbonyl, methylene, carboxy-, hydroxy-, trichloroethanol, 1,1,1,2-tetrachloroethane, 1,1,2,2-tetrachloroethane, acetylene, α-dicarbonyl, etc.:

In a series of numerous reactions of the 1,1,1-trichloroethane groups, their dehydrochlorination reactions have been most thoroughly investigated,[43] especially in relation to the following series:



Y=H, Cl, CH_3, OCH_3, OH, NH_2.

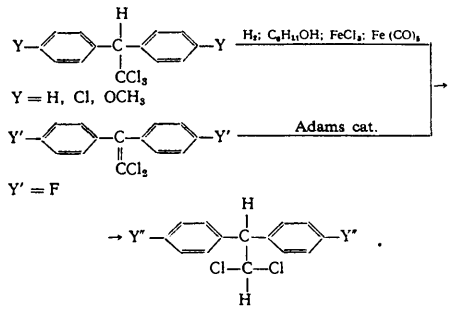
The main dehydrochlorinating agents are alcoholic alkali,[35,40] liquid ammonia,[44] methylamine,[44] LiCl in dimethylformamide (DMF),[45] MOH or M_2CO_3 (M = K or Na) in DMF,[46] and tertiary and heterocyclic amines.[4]



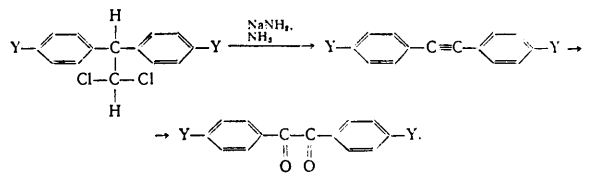
A semiquantitative kinetic study of the dehydrochlorination of various 2,2-diaryltrichloroethanes by KOH in 90% ethanol at the boiling points of the solutions has been carried out[47] and it has been shown that the process proceeds quantitatively and that only one mole of HCl is split off at 80 °C. The kinetics of the dehydrochlorination reaction of diaryltrichloroethanes (which are related to DDT) using NaOH were investigated in a later study.[48] It was found that these processes are second order reactions and proceed via the E_2 mechanism.

In a series of different reactions of the 1,1-dichloroethylene groups, the most thoroughly investigated and most widely used process is their oxidation to keto-groups:[49,50]

Y=H, Cl, F, NH—C(=O)—CH_3, NO_2.



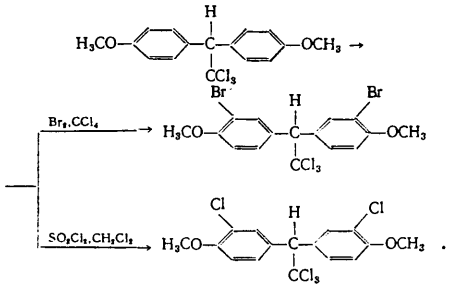
The commonest oxidants of the 1,1-dichloroethylene groups are CrO_3/AcOH, HNO_3/AcOH, and $K_2Cr_2O_7$/AcOH. The diaryl ketones obtained in this way are reduced to the corresponding diphenylmethanols[51,52] and diarylmethanes:[53,54]



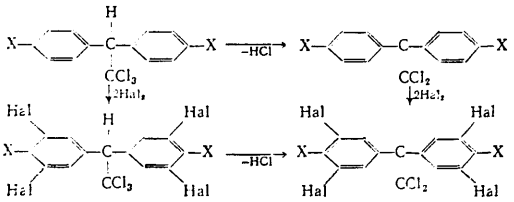
Sodium amalgam[51] and $LiAlH_4$ [52] are used to reduce diaryl ketones to diphenylmethanols; the reduction of diaryl ketones to diarylmethanes is achieved successfully by catalytic hydrogenation using Pd/C [53] or NiRe [54] as catalysts.

Reactions of the 1,1,1-trichloroethane group such as its hydrolysis with formation of 1,1-diarylacetic acids and their subsequent decarboxylation also lead to derivatives of the diphenylmethane series;[55] the same sequence of reactions can be achieved with compounds of the 2,2-diaryl-1,1-dichloroethylene series.[55]

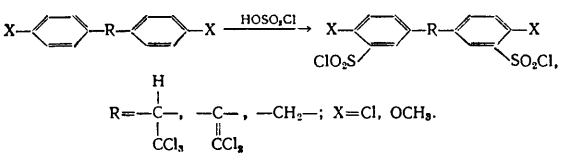
An interesting aspect of the reactions of 1,1,1-trichloroethane groups consists of their reduction processes.[56] In particular, the reduction of 2,2-diaryl-1,1,1-trichloroethanes to 2,2-diaryl-1,1-dichloroethanes has been achieved in cyclohexanol at 110–150 °C using $FeCl_3$ or $Fe(CO)_5$ as catalysts.[55,56] Analogous products have been obtained by reducing 2,2-diaryl-1,1-dichloroethylenes in the presence of the Adams catalyst:[41]



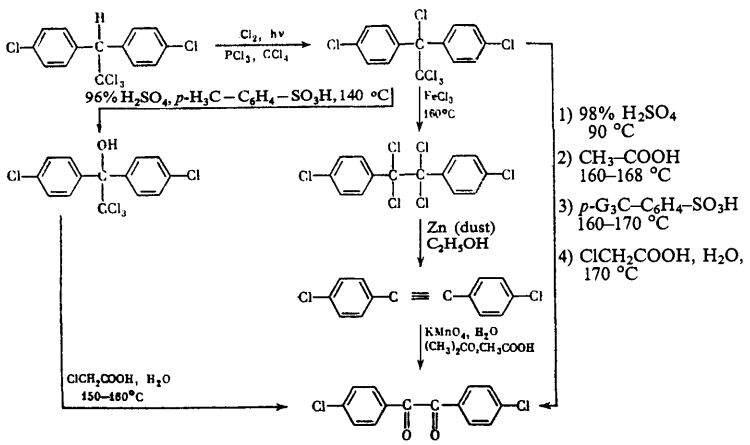
1,2-Diarylacetylenes, subsequently oxidised to benzils,[59] have been obtained by dehydrochlorinating 1,1-dichloroethanes on treatment with $NaNH_2$ in liquid ammonia[57] and also by catalytic dehydrochlorination in the presence of $Mo(CO)_6$:[58]



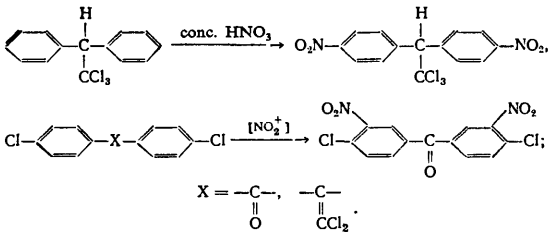
These reactions take place with a change in the carbon skeleton of the molecules, but the isomerisation mechanisms have not been established to this day. A number of reactions of 2,2-diaryl-1,1,1,2-tetrachloroethanes, obtained by chlorinating 2,2-diaryl-1,1,1-trichloroethane derivatives,[50] include a similar isomerisation:[60–65]



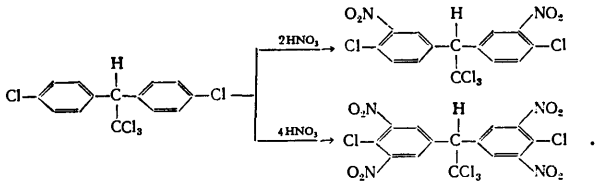
In a series of reactions involving the substitution of hydrogen atoms in the aromatic rings of diaryltrichloroethanes and their derivatives substituted in the central group, the halogenation,[66–69] sulphonylchlorination,[70,71] and nitration[72–75] processes occur most widely. The halogenation of 1,1,1-trichloro-2,2-di(*p*-methoxyphenyl)ethane, namely bromination with bromine in CCl_4 and chlorination with SO_2Cl_2 in methylene chloride, has been described:[66]



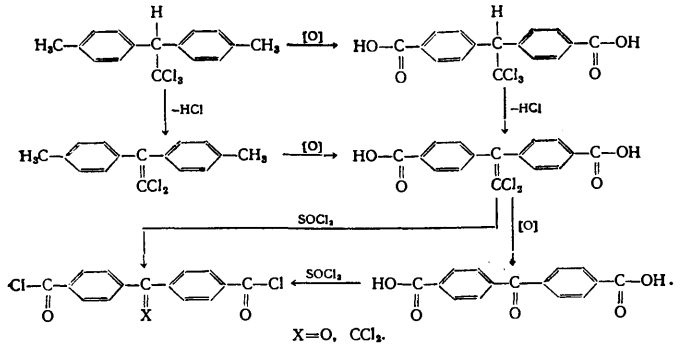
Bisphenols containing an even greater number of chlorine atoms have been obtained by halogenating 1,1,1-trichloro-2,2-di-(4-hydroxyphenyl)ethane with subsequent dehydrochlorination[67–69] or, in the reverse sequence, by dehydrochlorination and then halogenation:



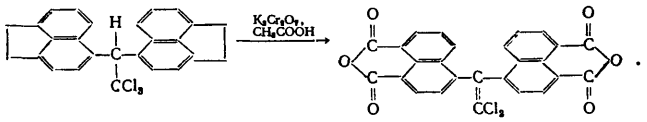
The sulphonylchlorination of the simplest chloral derivatives—DDT, 1,1-dichloro-2,2-di(*p*-chlorophenyl)ethylene, 4,4′-dichlorodiphenylmethane, and 1,1-dichloro-2,2-di(*p*-methoxyphenyl)ethylene [70–71]—led to the corresponding disulphonyl chlorides:



The nitration of diaryltrichloroethanes and their derivatives substituted in the central group has been achieved for a wide range of objects—1,1,1-trichloro-2,2-diphenylethane,[72] 1,1-dichloro-2,2-di(*p*-chlorophenyl)ethylene,[73] 4,4′-dichlorobenzophenone,[73] and DDT:[74,75]

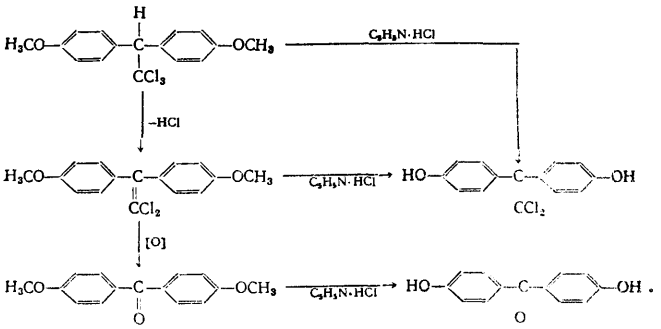


Depending on the conditions under which they are carried out, the latter processes lead to 1,1,1-trichloro-2,2-di(4-chloro-3-nitrophenyl)-ethane or 1,1,1-trichloro-2,2-di(4-chloro-3,5-dinitrophenyl)ethane:



On reaction with caustic alkalis in alcoholic solutions, these compounds are converted into the corresponding dichloroethylene products, which are then oxidised to benzophenone derivatives.[75]

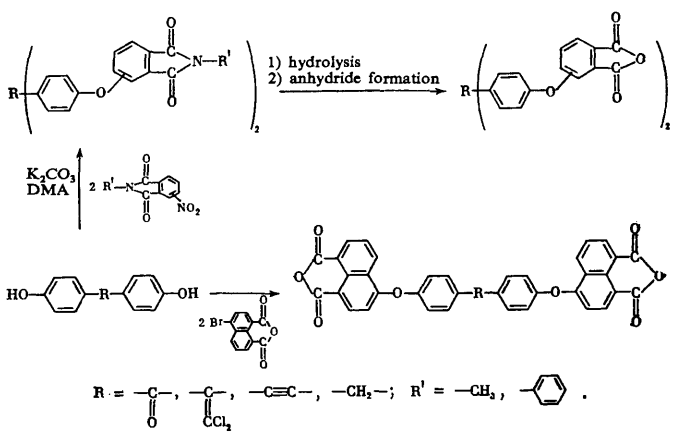
The reactions of the functional groups introduced at various stages of the processes into the aromatic rings of diaryltrichloroethanes and their derivatives substituted in the central group have developed considerably. In particular, diaryltrichloroethanes containing alkyl substituents in the aromatic rings have been oxidised with formation of the corresponding dicarboxylic[76] and tetracarboxylic[36] acids. Thus the oxidation of 1,1,1-trichloro-2,2-di(*p*-tolyl)ethane afforded 2,2-di(*p*-carboxyphenyl)-1,1,1-trichloroethane,[76] which was then made to undergo reactions involving the central group with formation of 2,2-di(*p*-carboxyphenyl)-1,1-dichloroethylene[77] and benzophenone-4,4′-dicarboxylic acid.[78] The same dicarboxylic acids have been obtained by oxidising 1,1-dichloro-2,2-di(*p*-tolyl)ethylene.[77,78]



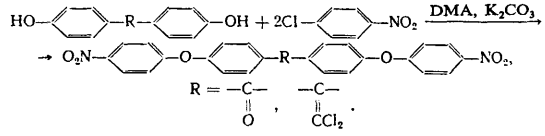
The dicarboxylic acids obtained were converted into the corresponding dichlorides:[77,78]

2,2-Di(4-acenaphthenyl)-1,1,1-trichloroethane was oxidised in a glacial acetic acid using $K_2Cr_2O_7$ or $Na_2Cr_2O_7$ as oxidants.[36] The simultaneous occurrence of the oxidation reactions of the alkylene fragments of the acenaphthenyl units, the conversion of the *peri*-dicarboxy-groups into anhydrides, and the dehydrochlorination of the trichloroethane "bridges" to the 1,1-dichloroethylene bridges were then observed:

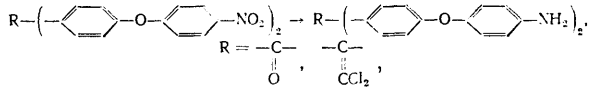
The principal reactions of 1,1,1-trichloro-2,2-di(*p*-methoxyphenyl)ethane and its derivatives substituted in the central group involve the conversion of the methoxy-groups into hydroxy-groups on treatment with pyridine hydrochloride:[68,79]



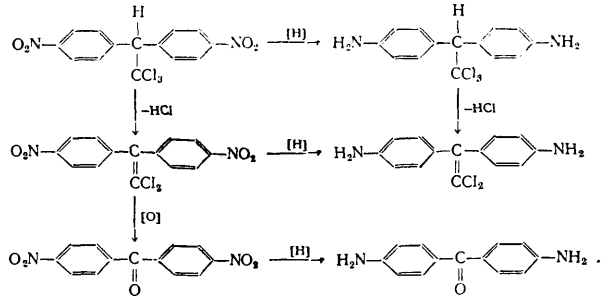
The dehydrochlorination of the 1,1,1-trichloroethane groups to 1,1-dichloroethylene groups takes place simultaneously under the reaction conditions (210 °C).



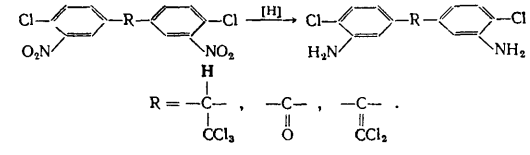
Similar reactions have been used to convert 2,2-di(3-halogeno-4-methoxyphenyl)-1,1,1-trichloroethane into 2,2-di(3-halogeno-4-hydroxyphenyl)-1,1-dichloroethylene:[66]



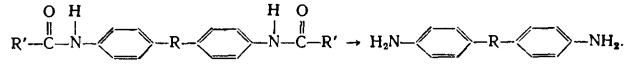
The reactions of the hydroxy-groups of bisphenols involve primarily their conversion into bisphenoxides, which interact vigorously with activated aromatic halogeno- and nitro-compounds. Thus the reaction of bisphenoxides with *N*-substituted 4-nitrophthalimides yielded diimides containing ether linkages; the hydrolysis of these diimides led to the formation of bisphthalic acids, which were then converted into bisphthalic anhydrides.[80–82] Bisnaphthalic anhydrides containing ether linkages were obtained by the reaction of bisphenoxides containing methylene and carbonyl central groups with 4-bromonaphthalic anhydride:[83]



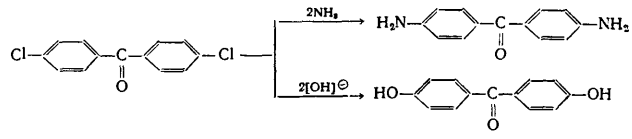
Aromatic dinitro-compounds, each containing two diaryl ether units, have been obtained by the reaction of bisphenoxides with *p*-chloronitrobenzene in dimethylacetamide (DMA) in the presence of K_2CO_3:[84]



The reduction of nitro-groups to amino-groups has been the main pathway in the chemical reactions of nitro-groups present in various derivatives of chloral and DDT. The catalytic reduction of 4,4′-di(*p*-nitrophenoxy)arylenes to the diamines,[84] i.e.

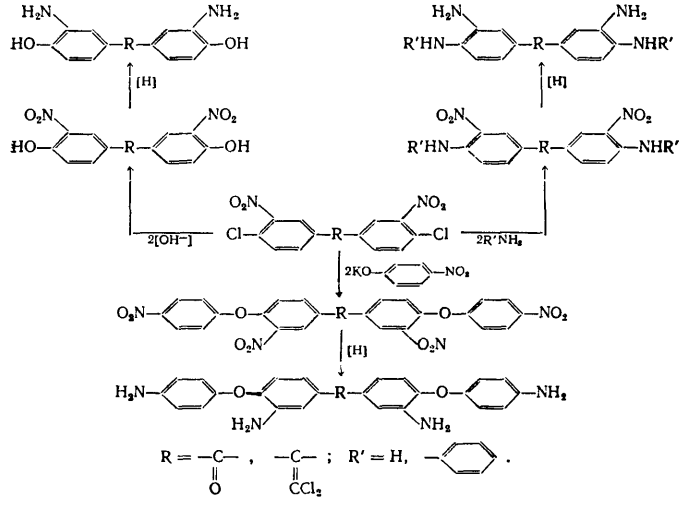


has not been the only reaction of this kind. The simpler dinitro-chloral derivatives 1,1,1-trichloro-2,2-(*p*-nitrophenyl)ethane,[72] 1,1-dichloro-2,2-di(*p*-nitrophenyl)ethylene,[72] and 4,4′-dinitrobenzophenone[74] have also been reduced catalytically:



The same type of reaction has been carried out likewise for di(4-chloro-3-nitrophenyl)arylenes:[75,85,86]

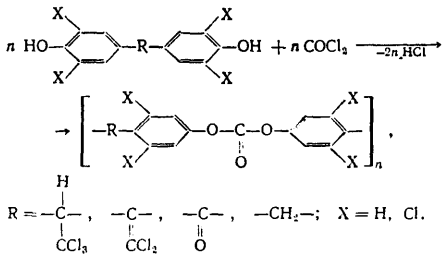
An alternative method of synthesis of aromatic diamines from chloral derivatives is the hydrolysis of the bisamides:[87]



The reactions involving the substitution of halogen atoms in activated aromatic dihalogeno-compounds also constitute an extremely effective approach to the synthesis of diamines. A simple method of synthesis of diamines, for example from 4,4′-dichlorobenzophenone,[73,88] using NH_3 and different catalysts, has thus arisen:

The hydrolysis of the same compound[89,90] with aqueous NaOH using different catalysts, for example CuCl and Cu_2O,[90] led to the formation of 4,4′-dihydroxybenzophenone.

The introduction of nitro-substituents increases sharply the mobility of the chlorine atoms in the aromatic rings of DDT and the products of its reactions via the central group, making them more reactive even compared with the chlorine atoms in di(4-chlorophenyl) sulphone.[91] This fact determines the possibility of the successful use of such products directly in polycondensation processes and also of carrying out various reactions involving the chlorine atoms. In particular, the reactions of such compounds with ammonia and aromatic amines, leading to the corresponding bis(*o*-nitroanilines) and bis(*o*-nitrodiphenylamines), are of considerable interest.[86,92] The chlorine atoms in compounds of this kind are very readily hydrolysed by alkalis;[73] this has been used, in particular, to synthesise 4,4′-dihydroxy-3,3′-dinitrobenzophenone,[73] and they also interact with potassium *p*-nitrophenoxide, forming, for example, 3,3′-dinitro-4,4′-di(*p*-nitrophenoxy)benzophenone.[93]

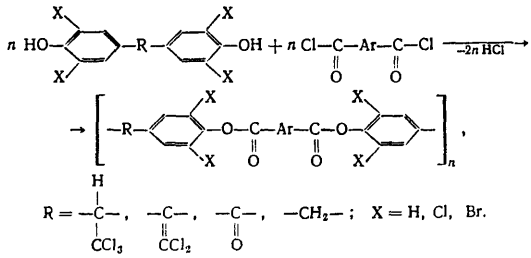


The reduction of the nitro-groups in dinitrodiamines leads to the formation of unsubstituted[86] and *NN*′-diphenyl-substituted[92] bis(*o*-phenylenediamines); the reduction of nitro-groups in bis(*o*-nitrophenols) affords bis(*o*-aminophenols),[73] while the reduction of nitro-groups in 3,3′-dinitro-4,4′-di(*p*-nitrophenoxy)-benzophenone leads to the formation of 3,3′-diamino-4,4′-di(*p*-aminophenoxy)benzophenone:[93]

Analysis of the entire foregoing data enables one to claim that a wide range of varied di- and tetra-functional monomers have been obtained from chloral and DDT. Some of them are of considerable interest from the standpoint of the properties of the polymers based on them and also from the standpoint of their availability and potential cost.

IV. Condensation polymers based on chloral derivatives

In the series of condensation polymers based on chloral and DDT derivatives, polycarbonates obtained in accordance with the scheme



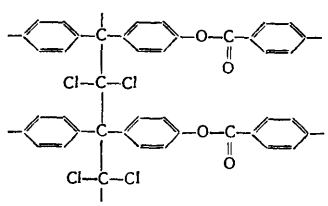
were the first to attract the attention of investigators.[94-98] Since polycarbonates based on 4,4'-dihydroxybenzophenone and di(4-hydroxyphenyl)methane were examined previously,[94-98] in the present review attention is concentrated on polymers derived from bisphenols containing 1,1,1-trichloroethane and 1,1-dichloroethylene central groups.

The first mention of the use of 1,1,1-trichloro-2,2-di(*p*-hydroxyphenyl)ethane and 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene to obtain polycarbonates (as comonomers of bisphenol A) dates back to 1964,[99] when a group of Polish investigators synthesised copolycarbonates by interfacial polycondensation. The subsequent research by the same group of investigators[68,69] led to a series of interesting results, referring, in particular, to the synthesis of homopolycarbonates from 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)-ethylene.[69] Comparison of the properties of homopolycarbonates based on 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene, 1,1,1-trichloro-2,2-di(*p*-hydroxyphenyl)ethane, and bisphenol A[100,101] showed that the homopolymer based on 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene is characterised by a more interesting set of thermal and deformation-strength properties. At approximately 20 °C, the thermal stability of this polymer exceeds that of the industrial polycarbonate obtained from bisphenol A and is superior to it as regards its strength characteristics and, by virtue of the large content (25%) of chlorine, as regards its fire resistance. Further increase in the chlorine content in polycarbonates leads, on the one hand, to a further increase of the thermal stability and fire resistance, but, on the other hand, it entails a sharp diminution of the elasticity of the polymers. Furthermore, systems containing 1,1,1-trichloroethane groups are characterised by a reduced thermal stability—after prolonged exposure to temperatures in the range 100–300 °C they evolve HCl, which is probably associated with the dehydrochlorination of the trichloroethane groups.

The valuable set of properties of the polycarbonates based on 1,1-dichloro-2,2-di(*p*-hydroxyphenol)ethylene combined with the high hydrolytic stability of chlorine-containing polycarbonates[102] have been responsible for the further development of studies in this field,[44,103-108] which were completed by the development of a high-quality thermoplastic.

The thermal stability of the unstabilised and stabilised homopolycarbonates and copolycarbonates as well as their fire resistance have attracted special attention.[109] The study of the chemical composition of the gases evolved on combustion of this polycarbonate[110] and tests on mice using the technique involving the pyrolysis of the polymers in air[111,112] showed that they are characterised by the smallest combustibility, smoke evolution, and toxicity among all the known thermoplastics.

Together with the polycarbonates considered above, polyarylates obtained from the same bisphenols and aromatic dicarboxylic acid dichlorides have aroused considerable interest:[113]

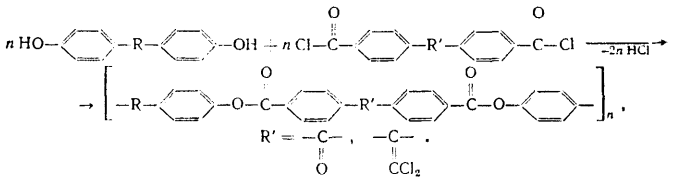


By virtue of the considerations described above in relation to polycarbonates, in the present review attention is concentrated on polyarylates derived from bisphenols containing 1,1,1-trichloroethane and 1,1,1-dichloroethylene central groups, in particular from 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene.[108,114-118] The synthesis of these polymers using the dichlorides of the commonest aromatic dicarboxylic acids—isophthalic and terephthalic—as acid components was achieved by interfacial polycondensation[108,114-16] and also by the acceptor-catalytic polyesterification in solution.[108,118] Polyarylates have been obtained as homopolymers as well as copolymers using bisphenol A as the comonomer.[119,120] The polyarylates obtained are satisfactorily soluble in chlorinated hydrocarbons; they form films and coatings with effective mechanical, dielectric, and optical properties.[116,121] Homopolyarylates based on 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene are characterised by significantly better thermal and electrophysical characteristics than polymers based on other bisphenols.

In terms of their thermal stability and fire resistance, polyarylates based on 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene are superior to industrial polyesters and polycarbonates. The maximum temperature of the long-range use of polyarylate is 180 °C, whilst that of the short-term use is 260 °C. The onset of thermal degradation in air is observed at 360 °C according to the results of dynamic thermogravimetric analysis (DTGA), the weight loss after 150 h at 200 °C amounting to 1%. Their dielectric and mechanical properties do not change after heating at 180 °C for 1000 h.

The properties of polyarylate films can be significantly improved by heat treatment for 2–5 h at 180–250 °C. Thus the heat-treated films become much more chemically stable and lose their solubility in chlorinated hydrocarbons.

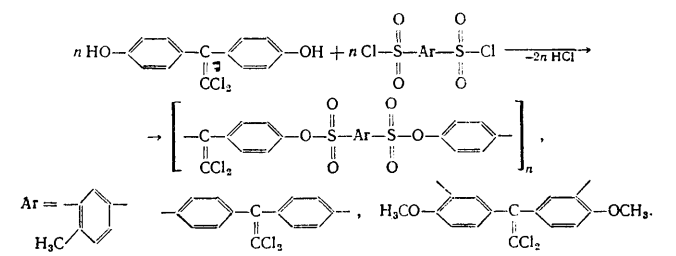
These changes in properties are probably associated with the partial "cross-linking" via the dichloroethylene groups:[108,118]



which has also been noted for polycarbonates.[104]

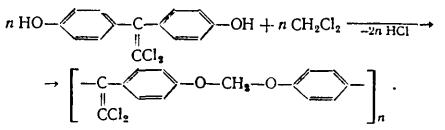
Polyarylates sensitive to UV radiation[122,123] as well as electret[124] and coloured[125] polyarylates have been obtained from 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene.

The attempts to use the polyarylates synthesised as pigmented and non-pigmented coatings[126] to protect pipes transporting hot liquids at 150–200 °C showed that, after use for 2 years, these coatings retain excellent thermal and chemical characteristics as well as good adhesion to metallic surfaces.



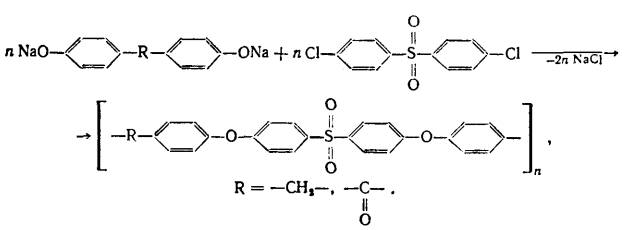
The polyarylates can also be used as constructional materials in the production of components for electrotechnical and radiotechnical purposes.

Together with the bisphenol derivatives of chloral and DDT, the dichlorides of aromatic dicarboxylic acids—benzophenone-4,4'-dicarboxylic acid and 2,2-di(*p*-carboxyphenyl)-1,1-dichloroethylene, which are also chloral derivatives, have been used to synthesise polyarylates:



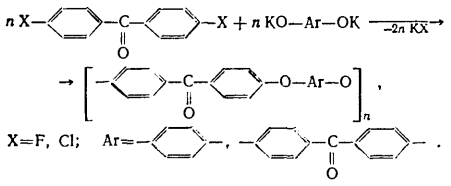
Since polyarylates based on the dichloride of benzophenone-4,4'-dicarboxylic acid were examined in detail previously,[113] in the present review attention is concentrated on polymers based on the dichloride of 2,2-di(*p*-carboxyphenyl)-1,1-dichloroethylene.[118,127–133] These polymers were obtained by interfacial polycondensation[127,128] and acceptor-catalytic polycondensation[118,128–131] methods. According to a number of workers,[118,127–133] the polyarylates synthesised dissolve readily in methylene chloride, chloroform, tetrachloroethane, tetrahydrofuran (THF), and other solvents. Films characterised by a higher fibre resistance and capacity for long term use at 200 °C have been obtained by casting from solutions of these polymers in chloroform. According to Taova et al.,[133] the 1,1-dichloroethylene group has a positive influence on the thermal characteristics of polyarylates.

Together with polyarylates, polysulphonates obtained by the reaction of bisphenols with disulphonyl chlorides have also attracted much attention of investigators; here at least one of the comonomers was a chloral or DDT derivative. In particular, the interaction of 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene with various disulphonyl chlorides, carried out under the conditions of interfacial polycondensation using phase transfer catalysts afforded polysulphates with comparatively high molecular weight characteristics:[108,117,134,135]



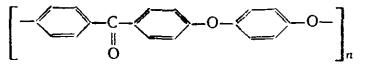
Polysulphonates are superior to the corresponding polyarylates in the first place as regards solubility; in the series of polymers represented by the scheme above,[37] the highest solubility is that of the polysulphonate based on the 1,1-dichloro-2,2-di(3-chlorosulphonyl-4-methoxy)ethylene; this polymer is readily soluble in acetone, cyclohexanone, and xylene,[134] which is due to the presence in it of *ortho*-methoxy-substituents and *meta*-phenylene rings in the main chains of the macromolecules. Polysulphonates with the highest molecular weights are obtained using triethylbenzylammonium chloride or bromide as the phase transfer catalyst. The polysulphonates then form films characteristic by a high fibre resistance as a consequence of the presence in the polymer of a large amount of chlorine and sulphur. The film forming properties of polysulphonates improve significantly when part of the disulphonyl chloride is replaced by isophthaloyl chloride (20 mol%) or terephthaloyl chloride (30 mol%).[136] The thermal decomposition of polysulphonates modified in this way begins at 330 °C; the modification improves the adhesion properties of the polysulphonates, their solubility in the available organic solvents, their resistance to the action of acids and alkalis, and their elastic properties. The mechanical properties of the modified polysulphonates do not change at a temperature of approximately 180 °C.

Together with the synthesis of various types of polyesters, chloral and DDT derivatives have been used successfully to synthesise polyethers. Thus 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene has been used to synthesise polyformals—the products of the condensation of bisphenols with methylene chloride:[137]



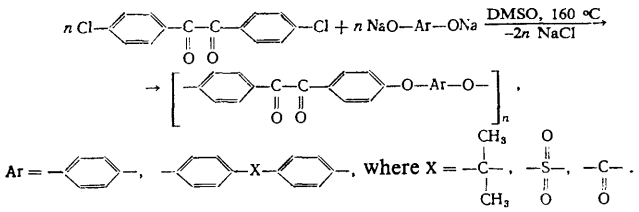
A polyformal was synthesised by the reaction of 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene with methylene chloride in *N*-methyl-2-pyrridinone (MP) in the presence of NaOH.[137] The polyformal thus obtained contained 10–15% of cyclic oligomers. Comparison of the characteristics of the polyformal with those of the analogous polymer obtained from bisphenol A showed that their mechanical properties are comparable but the system containing the 1,1-dichloroethylene group is more heat resistant (by approximately 25 °C) and more fire resistant. The glass point of the polyformal synthesised from 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene is 120 °C and its oxygen index is 43.

The first attempts to synthesis fully aromatic polyethers using chloral and DDT derivatives as the monomers were associated with the development of processes for the interaction of di(4-chlorophenyl) sulphone with different bisphenols,[138,139] especially with di(4-hydroxphenyl)methane and 4,4'-dihydroxybenzophenone:

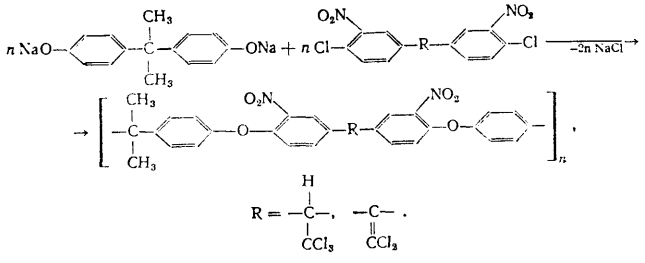


Later studies in this field were associated with the use of 1,1-dichloro-2,2-di(*p*-hydroxyphenyl)ethylene as the bisphenol.[140,141] In the series of these polymers, systems based on 4,4'-dihydroxybenzophenone, characterised by the glass point T_g = 205 °C, attracted most attention by investigators. The possibility of using chloral and DDT derivatives as dihalogeno-components of the reaction attracted even more interest. In particular, polyethers based on 4,4'-dichloro- and 4,4,'-difluorobenzophenone are of considerable

interest.[142,143] These polymers are obtained in accordance with the scheme[144–146]

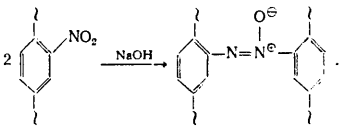


The crystallinity of the polymers formed, referred to as polyetherketones, makes it necessary to synthesise them at high temperatures (up to 335 °C) in solvents such as sulpholan[144] and diphenyl sulphone.[145] One of the representatives of polymers of this class, corresponding to the formula

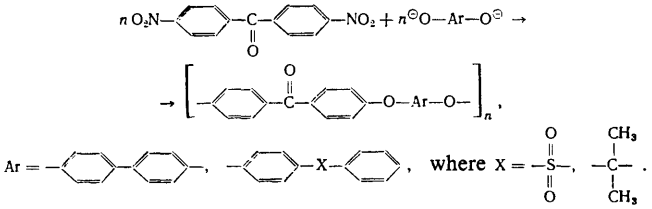


and characterised by T_g = 145 °C and the melting point T_m = 334 °C, was first introduced by the ICI Company in 1982.[143]

Using 4-hydroxythiophenol as the diol component, polythioetherketones were obtained.[147] These are crystalline polymers with $[\eta] \geqslant 0.4$ dl g^{-1} and having a high thermal and chemical stability and effective mechanical properties. The use of *p*-dimercaptobenzene led to polysulphideketones[148] with good thermal characteristics.

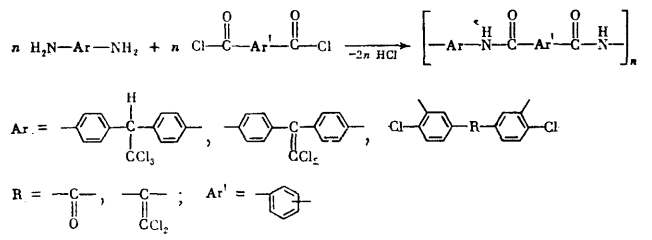


The attempt to use a DDT derivative such as 4,4′-dichlorobenzil as the dihalogeno-reactant[149] led to the formation of oligomeric polyethers, which has the consequence, according to Lesiak and Nowakowski,[149] of the reduced reactivity of 4,4′-dichlorobenzil due to the non-coplanarity of its molecules:



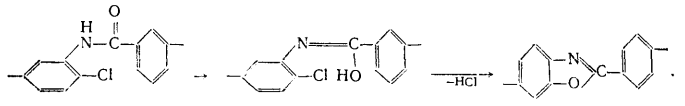
Polymers with extremely low molecular weights have been obtained by the reaction of bisphenol A with 1,1-dichloro-2,2-di(*p*-chlorophenyl)ethylene and 1,1,1-trichloro-2,2-di(*p*-chlorophenyl)ethane;[91,150] high-molecular-weight polyethers have been synthesised only as a result of the activation of the chlorine atoms by introducing nitro-substituents into the monomers:[91,150]

However, it is noteworthy that, when the polycondensation is carried out at high temperatures (more than 80 °C), insoluble products are formed. According to Adam and Husein,[91] this is a consequence of side reactions involving nitro-groups—for example, their coupling in an alkaline medium with formation of intermolecular azoxy-"cross-links":



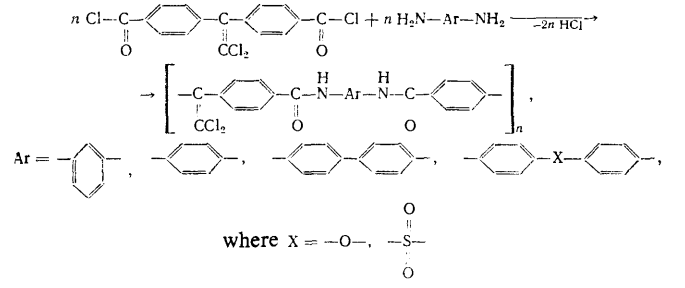
An alternative nucleophilic aromatic nitro-substitution process[151] led to the formation of high-molecular-weight unsubstituted aromatic polyethers based on chloral derivatives: the interaction of 4,4′-dinitrobenzophenone with alkali metal bisphenoxides under the conditions of nucleophilic aromatic nitro-substitution, i.e.

afforded polyetherketones with [η] for solutions in *N*-MP in the range 1.07–1.32 dl g^{-1}.[152] The polyetherketones synthesised are readily soluble in DMF, DMA, and MP. They have melting points in the range 195–255 °C, appreciably below their decomposition temperatures. These are the reasons why materials with a high thermal stability can be obtained from polyetherketones.



Aromatic polyamides have been obtained both from diamino-derivatives of chloral and DDT,[153–156] i.e.

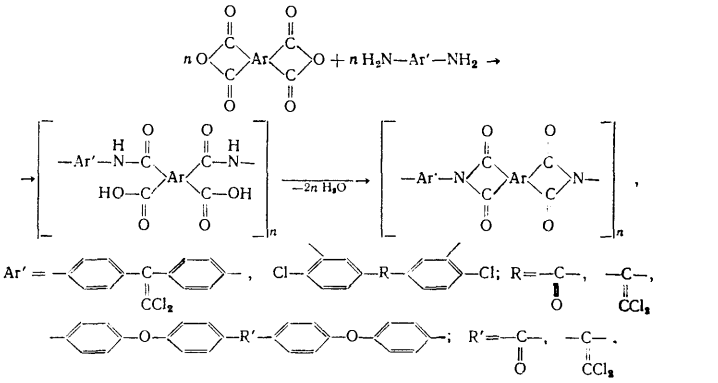
and from the acid dichloride of 2,2-di(*p*-carboxyphenyl)-1,1-dichloroethylene.[157–159]



The initial studies on the synthesis of polyamides from the diamino-derivatives of chloral and DDT were performed using 2,2-di(*p*-aminophenyl)-1,1,1-trichloroethane and 2,2-di(*p*-aminophenyl)-1,1-dichloroethylene[153,154] under the conditions of polycondensation in solution[153] and interfacial polycondensation.[154] This yielded comparatively high-molecular-weight and fire-resistant but sparingly soluble polymers. The change to diamines with less symmetrical structures—3,3′-diamino-4,4′-dichlorobenzophenone and 2,2-di(3-amino-4-chlorophenyl)-1,1-dichloroethylene[155,156]—led to the possibility of obtaining polyamides with improved solubility in organic solvents. A detailed study of the dependence of the principal characteristics of polyamides on their structure[155,156] showed that polymers with 1,1-dichloroethylene groups dissolve somewhat better than systems with carbonyl groups in the main macromolecular chain and that the introduction of chlorine into the aromatic rings imparts a greater fire resistance to the polymers than the introduction of the same amount of chlorine in the form of dichloroethylene groups. Polyamides containing carbonyl groups are less fire

resistant than the analogous systems containing 1,1-dichloroethylene groups but are more heat resistant and more thermostable than the latter. An interesting feature of polyamides containing chlorine atoms as *ortho*-substituents relative to the amide group is their ability to undergo intramolecular dehydrochlorination at elevated temperatures (> 300 °C), which leads to the formation of benzoxazole rings:[160,161]

Overall the polyamides considered are of definite practical interest due to the availability of the initial compounds and to their set of valuable properties of the polymers.

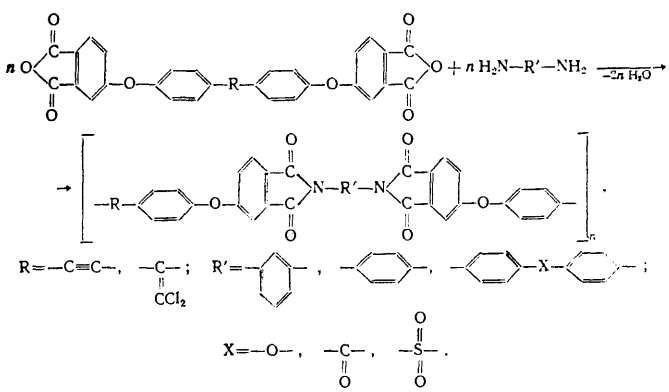


Polyamides based on the acid dichloride of 2,2-di(*p*-carboxyphenyl)-1,1-dichloroethylene,[157–159] obtained in accordance with the scheme

using low-temperature polycondensation in solution[157] and emulsion polycondensation[159] methods, are also extremely interesting from the practical point of view.

The polyamides obtained are high-molecular-weight polymers readily soluble in DMA and MP and with limited solubility in DMF, hexamethylphosphoramide (HMP), and pyridine. They all have a relatively high heat resistance and thermal stability—their softening temperatures reach 310 °C and the temperatures corresponding to a 10% weight loss are in the range 360–405 °C. The high chlorine content in the polyamides (~ 13–18%) is responsible for the self-quenching capacity of these systems. Films obtained from them are not inferior as regards strength to films based on the polyamide of the "phenylon" type. The polyamide obtained using *meta*-phenylenediamine and known under the name "Dneprolon-M" is especially promising.[158]

The use of chloral and DDT derivatives for the synthesis of linear heterocyclic polymers has attracted much attention of investigators in recent years. Among them, the commonest are aromatic polyimides,[1] many of which have been obtained from compounds such as 4,4'-diaminobenzophenone, di(4-aminophenol)methane, etc. i.e. monomers which, as has been shown above, can be obtained from chloral and DDT. Since the methods of synthesis and properties of such polymers have already been examined in detail,[1] in the present review attention is concentrated on polymers which had not been described hitherto. Polyimides based on aromatic diamino-derivatives of chloral and DDT have been obtained by their interaction under mild conditions with the dianhydrides of tetracarboxylic acids in dipolar aprotic solvents with subsequent catalytic conversion of poly(*o*-carboxy)amides into imides in accordance with the scheme

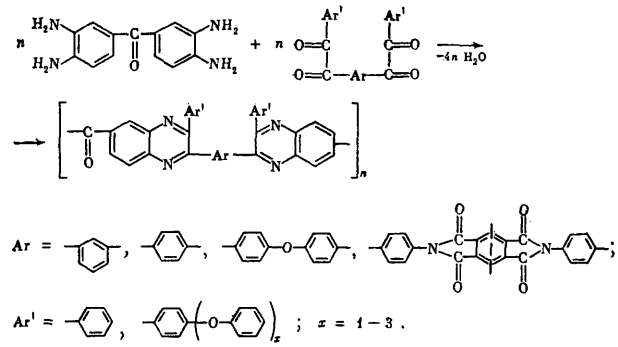


Chloral and DDT derivatives such as 2,2-di(4-aminophenyl)-1,1-dichloroethylene,[162] 3,3'-diamino-4,4'-dichlorobenzophenone, and 2,2-di(3-amino-4-chlorophenyl)-1,1-dichloroethylene[155] have been used in a number of studies[155,156] as the diamines. The commonest bisphthalic anhydrides—the anhydrides of pyromellitic and benzophenone-3,3'-4,4'-tetracarboxylic acids and the 3,3',4,4'-tetracarboxy-derivative of diphenyl sulphone—served as the comonomers of these diamines. The polymers based on 2,2-di(4-aminophenyl)-1,1-dichloroethylene were obtained in the form of comparatively high-molecular-weight {[η] = 1.0–1.4 dl g^{-1}}, heat-resistant (T_{soft} > 280 °C), and fire-resistant [oxygen index (OI) = 36–40] systems which are, however, soluble only in H_2SO_4 and a 3 : 1 tetrachloroethane (TCE)–phenol mixture. The transition from these polymers to polyimides based on 3,3'-diamino-4,4'-dichloroarylenes[155] led, by analogy with a similar structural change in polyamides (see above), to the formation of systems with a significantly greater solubility in organic solvents. Analysis of the dependence of the properties of these polymers on their structure showed that polyimides based on 2,2-di(3-amino-4-chlorophenyl)-1,1-dichloroethylene exhibit the highest solubility and fire resistance, while the best thermal characteristics are those of polyimides based on 3,3'-diamino-4,4-dichlorobenzophenone. The improved capacity of such polymers for being worked into articles is determined not only by their solubility in organic solvents but also by the comparatively mild pressing conditions. Polyimides of this type with the most rigid chains, namely polypyromellitimides, which can be worked by pressing at a temperature exceeding 350 °C, behave under these conditions as thermoreactive systems; intermolecular HCl elimination processes take place during pressing, which results in the formation of "cross-linked" structures characterised by an increased heat resistance.

Diamines containing ether linkages and other groups, for example 4,4-di(*p*-aminophenoxy)benzophenone, have been used to synthesise polyimides.[84] The polyimides obtained from this monomer are high-molecular-weight crystalline systems, whose structure is similar to that of polymers regarded as promising film and constructional materials.[163,164]

Aromatic tetraamino-derivatives of DDT, especially 3,3',4,4'-tetraaminobenzophenone, have been used to obtain polyimides containing *N*-phthalimide *ortho*-substituents.[165] The synthesis of such polyimides reduces to treating the tetraamines with twice the molar amounts of cyclic dicarboxylic acid anhydrides and equimolar

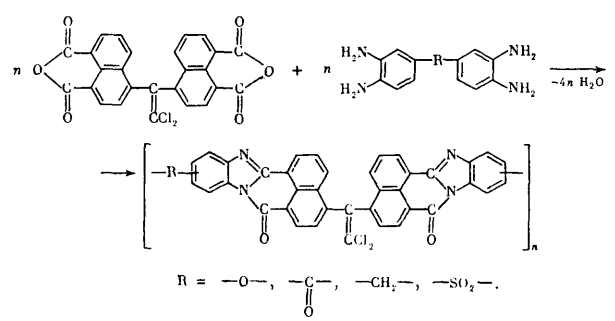
amounts of the dianhydrides of tetracarboxylic acids with subsequent catalytic conversion of the prepolymers thus obtained into imides. The difference between the nucleophilicities of the reaction centres of the aromatic tetramines makes it possible to vary the isomeric composition of the polyimides by altering the sequence in which the mono- and di-anhydrides are introduced into the reaction.[165] When 3,3',4,4'-tetraaminobenzophenone, phthalic anhydride, and various bisphthalic anhydrides were used as the initial compounds, polyimides containing *N*-phthalimide *ortho*-substituents were obtained; these polymers are readily soluble in amide and phenolic solvents and this is combined with high thermal stabilities and heat resistances, differing little in this respect from polyamides based on other di(*o*-phenylenediamines).[165] Fundamentally different results were obtained when 3,3'-diamino-4,4'-di(*p*-aminophenoxy)benzophenone was used as the initial tetramine.[93] The synthesis of polyimide with the initial introduction of phthalic anhydride yields polymers containing predominantly the *N*-(*p*-phenoxy)phthalimide *ortho*-substituents. These polymers exhibit a solubility, unique for polymers of this class, in DMF, DMA, MP, HMP, dimethyl sulphoxide (DMSO), phenolic solvents, tetrachloroethane, chloroform, and cyclohexanone. Their softening temperatures are in the range 245–290 °C and the temperatures corresponding to a 10% weight loss, determined by the DTGA method, are 440–490 °C.



A series of polyimides have also been obtained from non-traditional tetracarboxylic acid dianhydrides derived from chloral and DDT. Thus the synthesis of polyimides from the dianhydrides of di(*o*-dicarboxyphenoxyphenyl)acetylene and 1,1-di(*o*-dicarboxyphenoxyphenyl)-2,2-dichloroethylene has been described. The dianhydrides were made to react with aromatic and aliphatic diamines in organic solvents or in the melt in accordance with the scheme

Polymers based on *m*-phenylenediamine, having T_g = 219–247 °C, temperatures of the onset of thermal degradation in the range 470–500 °C (in air) and 470–545 °C (in N_2), and OI = 45–56 and giving rise to coke residues in the range 64–73%, have been studied in greatest detail.

Polyquinoxalines based on DDT derivatives, in the first place on 3,3',4,4'-tetraaminobenzophenone,[166–170] whose interaction with various bis(α-diketones) has been achieved in accordance with the scheme below, have attracted much attention of investigators.



Scheme

High-molecular-weight polymers have been obtained under the usual conditions[167] of the synthesis of polyquinoxalines—low-temperature polycondensation in protic solvents or in the presence of protic additives. Their heat resistance exceeds by 10–25 °C the analogous systems based on di(3,4-diaminophenyl) ether and they have a high thermal stability under the conditions of dynamic and isothermal thermogravimetric analysis being at the same time readily soluble in phenolic and chlorinated solvents, which makes it easy to work them and convert them into articles. In particular, strong films have been obtained from them. They lose between 5.8 and 32.1% of the initial weight depending on their structure and the duration of thermal ageing at 316 °C.

Carboplastics and adhesives capable of being used for a long time at 316 °C and superior, as regards the retention of their strength characteristics during thermal ageing, to the analogous systems based on 3,3'-diaminobenzidine have been obtained from polyphenylquinoxalines synthesised from 3,3',4,4'-tetraaminobenzophenone.[168,169]

Finally, chloral and DDT derivatives have been used by a number of investigators also for the synthesis of ladder polyheteroarylenes, among which polynaphthoylenebenzimidazoles have been studied in greatest detail. In particular, polymers of this type have been obtained by the reaction of the dianhydride of 2,2-di(4,5-dicarboxynaphthyl)-1,1-dichloroethylene with bis(*o*-phenylenediamines) in phenolic solvents (phenol, *m*-cresol), preferably using benzoic acid as the catalyst:

A characteristic feature of the polynaphthoylenebenzimidazoles thus obtained is ready solubility not only in acid but also in phenolic solvents, which makes it easier to work them and convert them into articles.

The list of uses, presented in this review, of chloral and DDT derivatives in the synthesis of new polymers and materials based on them indicates exceptionally interesting possibilities in the development of this field. The ease of reaction of chloral and DDT

derivatives via the central group, via the functional groups in the aromatic rings, etc. makes it possible to obtain a large number of a wide variety of monomers which are in their turn responsible for a valuable set of properties of the polymers based on them. The possibility of synthesising from available starting materials of high-molecular-weight compounds with improved thermal stability and fire resistance and combined with an improved solubility and capacity for being worked may provide an important stimulus for the intensification of studies in the field under consideration.

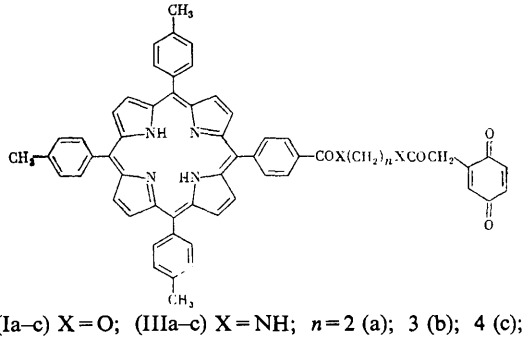
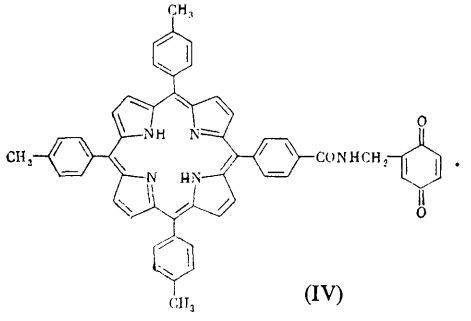
I. Introduction

The electron transfer from the electronically excited chlorophyll molecule or its dimer via intermediate acceptors to the primary quinone-type acceptor is a key step in photosynthesis.[1–4] The efficiency of charge separation in photosynthesis is close to unity. One of the factors ensuring such efficiency is the high degree of the structural organisation of the photosynthetic apparatus. However, the complex structure of the reaction centres of photosynthesising organisms makes it difficult to understand the mechanisms of charge separation in photosynthesis. This and also the attempts to create, by analogy with photosynthesis, artificial systems for the utilisation of solar energy have stimulated the synthesis and study of various compounds which are models of the reaction centres in photosynthesis, such as covalently bound porphyrins with different structures: porphyrin–polymer complexes,[5–7] porphyrin dimers,[8,9] porphyrin–quinone compounds,[10,11] etc.



The electron transfer from the porphyrin, whose molecular structure is similar to that of chlorophyll, to a covalently bound quinone models the primary charge separation stage in photosynthesis. The high electron-accepting capacity of quinones has been demonstrated in a number of studies on the flash photolysis of solutions containing electron-donating additives and quinones.[12–22] However, attempts to model charge separation processes in photosynthesis with the aid of homogeneous solutions have encountered considerable problems. The most important of these is the extremely low, compared with photosynthesis, efficiency of the separation of the oxidised and reduced forms of the reactants in solutions. Despite the fact that effective quenching of the fluorescence of chlorophyll and its analogues by quinones has been observed in solutions, the attempts to detect radical-ions have been unsuccessful.[12,13] This is apparently due to the rapid recombination of the radical-ions as a result of the collisions between the radical-cation of the porphyrin (P^+) and the radical-anion of the quinone (Q^-) in solutions.

The attempts to use micelles,[23,24] liposomes,[25,26] and cyclodextran compounds[27] to stabilise the radical-ions and to elucidate the detailed mechanism of the photoseparation of charges have also failed to yield the desired result. This has in fact stimulated the synthesis and study of porphyrin–quinone compounds (P–Q), in which the porphyrin and the quinone are separated by a system of covalent bonds.

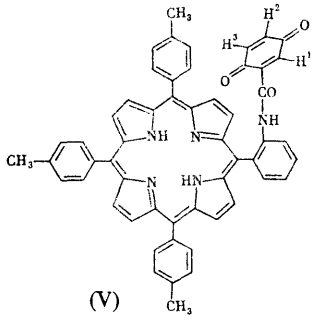


In terms of the character of the bond between the porphyrin and the quinone, all the P–Q compounds synthesised hitherto since 1978 can be divided into two main groups: (1) P–Q compounds with a flexible covalent bond and (2) P–Q compounds with a rigid bond between the porphyrin and the quinone. In addition, covalently bound triads, containing an electron-donating fragment together with P and Q, can be differentiated as an independent group.

II. Porphyrin–quinone compounds with a flexible covalent bond between the porphyrin and the quinone

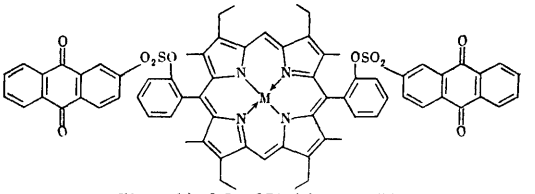
P–Q derivatives with a flexible bond are the simplest and most readily available. There exist different ways of linking P and Q:

(Ia–c) X = O; (IIIa–c) X = NH; n = 2 (a); 3 (b); 4 (c);



(IV)

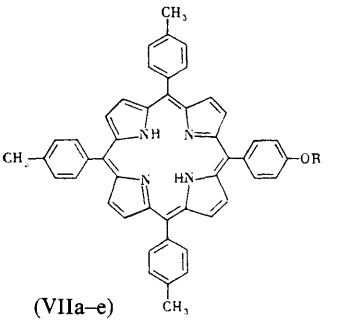
Compounds (I) in which the porphyrin and quinone components are linked by a diol chain of different lengths were some of the first to be synthesised.[28,29] 5-(4-Chlorocarboxyphenyl)-10,15-20-tri(4-tolyl)porphyrin (II), obtained by the Rothemund reaction from pyrrole and a mixture of 4-toluic aldehyde and 4-carboxybenzaldehyde[30] and subsequent treatment with thionyl chloride, was condensed in the presence of pyridine with an excess of the alcoholic component obtained by esterifying 2,5-dimethoxyphenylacetic acid with ethane-1,2-diol (derivative a), propane-1,3-diol (derivative b), and butane-1,4-diol (derivative c) with formation of a porphyrin-dimethoxybenzene derivative. The yield of the product was ~60%. After removing the methyl protecting group with BBr_3 and oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), compound (I) was purified chromatographically on silica gel.



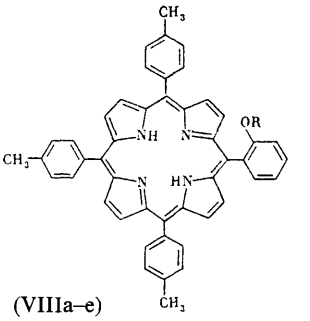
The replacement of the ester linkage by the hydrolytically more stable amide linkage leads to compound (III). It has been suggested[31] that the amide linkage makes the structure more rigid because of its greater similarity to the double bond. The conditions in the synthesis and purification of the derivative (III) are almost identical to those for compound (I), but the hydroquinone adduct was oxidised with PbO_2, which greatly simplified the isolation of the product (III). The yields in the stage involving the condensation of the porphyrin (II) with the amino-component were 40–50%.

In order to obtain the porphyrin-quinone (IV) with a shortened chain, the acid chloride (II) was treated with 2,5-dimethoxybenzylamine.[32] After removing the protecting group and oxidising the hydroquinone component, the product (IV) was obtained similarly to compound (III).

On formation of the amide bond between the two chromophores in the *ortho*-position in the benzene ring of the porphyrin, compound (V) is obtained with a still more rigid structure than compound (IV):[33]

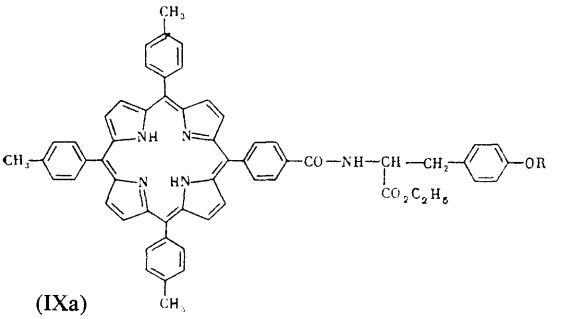


(V)



(VI a, b), M = 2H (a); Zn (b).

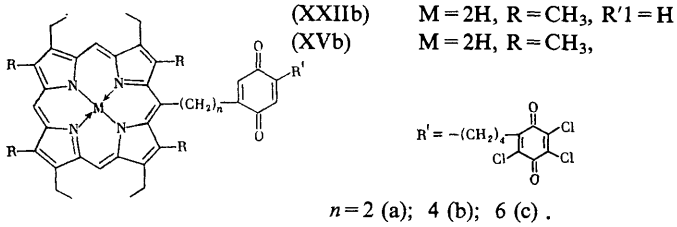
One equivalent of 5-(2-aminophenyl)-10,15,20-triphenylporphyrin, obtained by the Rothemund reaction from pyrrole and a mixture of benzaldehyde and 2-nitrobenzaldehyde and subsequent reduction with $SnCl_4$ in concentrated hydrochloric acid,[34] was treated with 10 equivalents of 1,4-diacetoxy-2-chlorocarbonylbenzene. The yield of the protected hydroquinone derivative was 76%. Selective hydrolysis with HCl in methanol (pH ~1) followed by oxidation with PbO_2 led to the product (V) in 75% yield.



The fact that the sulphonyloxy-derivative involving the *ortho*-position of the phenyl residue in porphyrins has a rigorously defined "folded" conformation[35] led to the idea of synthesising the diquinone compound (VIa).[36] The structure (VIa) was synthesised by condensing 3,3′-diethyl-4,4′-dimethyl-2,2′-dipyrrolylmethane with the corresponding aldehyde in the presence of toluene-*p*-sulphonic acid and subsequent oxidation with DDQ and isolation of the product by column chromatography on silica. The zinc complex (VIb) was obtained by treating the free base (VIa) with zinc acetate:

(VIIa–e)

(VIIIa–e)

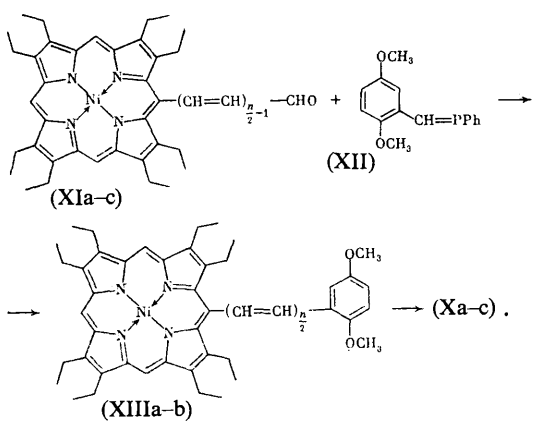


(IXa)

R =  (a),  (b),  (c),  (d),  (e).

A convenient method of synthesis of a large number of derivatives (VII)–(IX) has been developed on the basis of the photoinduced cross-condensation reaction between a phenol-containing porphyrin and a quinone.[37,38] 5-(4-Hydroxyphenyl)-10,15,20-tri(4-tolyl)-porphyrin was irradiated at a wavelength > 590 nm in the presence of a tenfold excess of 1,4-benzoquinone with formation of the condensation product (VIIa). No side products were then detected

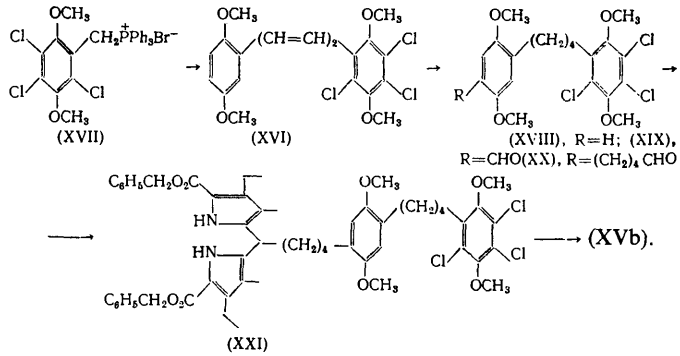
by thin-layer chromatography (TLC) and ^{1}H NMR spectroscopy. Other P–Q derivatives (VIIb–e), (VIIIa–e), and (IXa) were obtained similarly. The yields were 90–94% for a relatively low degree of conversion (6–41%). The condensation took place via a stage involving the formation of the hydroquinone adduct and the subsequent oxidation to the P–Q compound by the excess of the initial quinone:



(D)(Xa–c) M = 2H, R = C_2H_5, R′ = H
(XIVa–c) M = Zn, R = C_2H_5, R′ = H
(XXIIb) M = 2H, R = CH_3, R′1 = H
(XVb) M = 2H, R = CH_3,

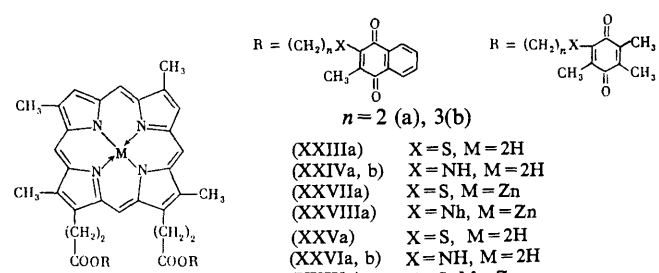
R′ = $-(CH_2)_4-$

n = 2 (a); 4 (b); 6 (c).



In order to avoid the possible influence of the heteroatom in the chain between the donor and the acceptor on the interaction between the chromophores and on the photoinduced intramolecular charge transfer and also the influence of the phenyl residues on the porphyrin ring, compounds (Xa–c) were synthesised. The chromophores were linked by polymethylene chains of different lengths (n = 2–6).[39] The synthesis was carried out as follows. The nickel complexes of octaethylporphyrins (XIa–c),[40,41] containing the formyl group in the *meso*-position, were condensed by the Wittig reaction with the triphenylphosphorane (XII), producing the dimethoxyphenyl complexes (XIIIa–c) in 82–95% yield (the Scheme 1). After removing the protecting group BBr_3, hydrogenation over Pd/C, and oxidation with DDQ, the yields of compounds (Xa–c) were 20–36%. The zinc complexes (XIVa–c) were obtained by treating the porphyrins (Xa–c) with zinc acetate.

Scheme 1

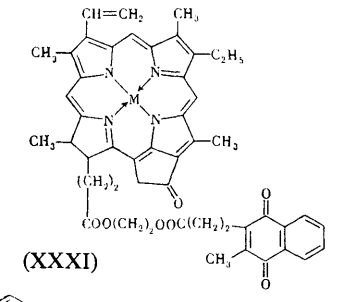


In natural photosynthesis, electron transfer takes place via many stages, which apparently promotes the stabilisation of the state with separated charges. The porphyrin (XVb), containing two series-connected acceptors with a corresponding oxidation-reduction potential (ORP) models such transfer.[42] The presence of two different quinones in this compound ensures a potential gradient in the molecule. The diquinone precursor (XVI) was obtained by the Wittig reaction from 2,5-dimethoxycinnamaldehyde and phosphonium bromide (XVII) (Scheme 2):

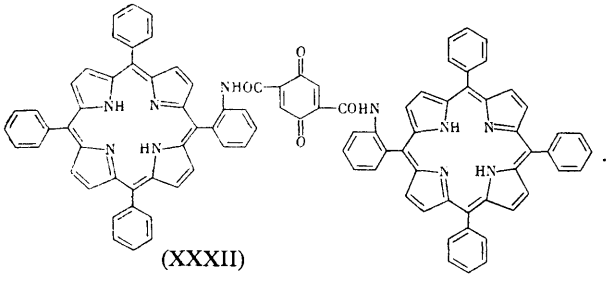
Scheme 2

After hydrogenation to compound (XVIII) over Pd/C, formylation by dichloromethyl methyl ether with formation of compound (XIX), and the lengthening of the chain by means of the Wittig reaction with the corresponding phosphonium salt, the aldehyde (XX) was condensed with 2-benzyloxycarbonyl-3-ethyl-4-methylpyrrole. The yield of the bipyrrole (XXI) was 85%. After removal of the benzyl protecting group from compound (XXI), the condensation of the product with 4,4′-diethyl-5,5′-diformyl-3,3′-dimethyl-2,2′-methylenebis(pyrrole) led to the corresponding aetioporphyrin derivative in 24% yield. Demethylation of the latter with BBr_3 and oxidation with DDQ afforded the diquinone derivative (XVb) (yield 24%).

In order to elucidate more accurately the influence of the second acceptor on the charge separation process, the aetioporphyrin (XXIIb), containing only one quinone residue, was synthesised[43] by a procedure similar to that used for compound (XVb):



n = 2 (a), 3(b)



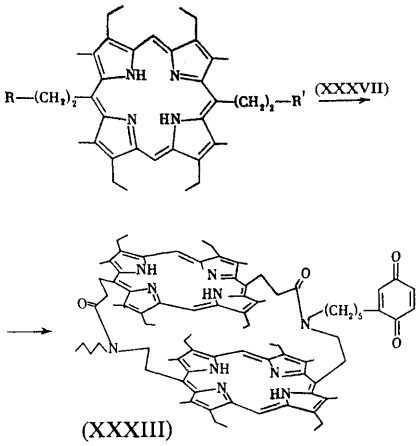
(XXIIIa) X = S, M = 2H
(XXIVa, b) X = NH, M = 2H
(XXVIIa) X = S, M = Zn
(XXVIIIa) X = Nh, M = Zn
(XXVa) X = S, M = 2H
(XXVIa, b) X = NH, M = 2H
(XXIXa) X = S, M = Zn
(XXXa) X = NH, M = Zn.

The present authors[44,45] synthesised P–Q compounds using for the first time deuterioporphyrin IX—a natural porphyrin. The hydroxyquinone derivatives were obtained by adding 2-mercaptoethanol, 2-aminoethanol, and 3-aminopropanol to 2-methylnaphthoquinone and 2,3,5-trimethylbenzoquinone. After purification, the yields were 55–91% for the sulphur containing quinones and 8–25% for the nitrogen-containing quinones. Compounds (XXIII)–(XXX) made it possible to investigate the influence of the nature of the heteroatom linked directly to the quinone fragment on the charge separation process. The condensation of hydroxyquinones with deuterioporphyrin IX using di-t-butyl pyrocarbonate and 4-dimethylaminopyridine led to the diquinone derivatives (XXIII)–(XXVI) in 76–89% yields. After compounds (XXIII)–(XXVI) had been treated

with zinc acetate, the corresponding zinc complexes (XXVII)–(XXX) were obtained:

(XXXI)

(XXXII)



Compound (XXXI) has been synthesised[46] by a method in which carboxy-derivatives of pyrochlorophyll *a* and 2-methylnaphthoquinone were condensed via an ethylene glycol bridge.

It is known that one of the primary donors in bacterial photosynthesis is a chlorophyll "special pair".[47] The model compound (XXXII), in which two 5-(2-aminophenyl)-10,15,20-triphenylporphyrin derivatives are joined together by a bridge containing the benzoquinone structure, was therefore synthesised.[48] However, steric factors hinder the formation of the steric structure of the diporphyrin (XXXII) analogous to the structure of the natural chlorophyll dimer.

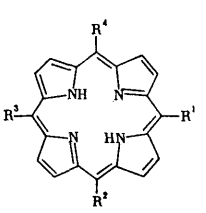
A more adequate model of the "special pair" is a rigid dimeric structure of the "surface to surface" type containing two porphyrin macrocycles connected by two covalent bonds.[49–52]

Compound (XXXIII),[53] in which two aetioporphyrin derivatives are linked covalently in the *meso*-position in the "surface to surface" orientation and benzoquinone is joined to the side chain, may make it possible to elucidate the role of the dimeric porphyrins in the stabilisation of the photoinduced state with separated charges. The synthesis was carried out in accordance with Scheme 3: Successive treatment of the di(methanesulphonate) (XXXIV), obtained by the method of Collman et al.,[54] with butylamine [involving the formation of compound (XXXV)] and with 1-(5-aminopentyl)-2,5-dimethoxybenzene led to the diamine (XXXVI) [the yields in the stages involving the formation of compounds (XXXV) and (XXXVI) were 38 and 67% respectively after chromatographic purification]. After the condensation of the amino-derivative (XXXVI) with the acid chloride (XXXVII) by the method of Collman et al.[54] (the yield in the condensation stage was 42%) and the removal of the methyl protecting group with BBr_3 followed by oxidation with DDQ (yield 28%), the P–Q dimer (XXXIII) was obtained. Compound (XXXIII) was purified by preparative TLC.

Scheme 3

(XXXIII)

(XXXIV), R = R' = OSO_2CH_3, (XXXV), R = OSO_2CH_3, R' = NHC_4H_9



(XXXVI), R = NHC_4H_9, R' = $NH(CH_2)_5$–  , (XXXVII), R = R' = COCl.

III. Porphyrin–quinone compounds with a rigid bond between the porphyrin and the quinone

1. Polymer-based models

In P–Q compounds with a flexible linkage, there is an appreciable conformational mobility determined by external factors such as solvent polarity, the presence of external ligands, etc. This hinders the interpretation of the experimental results for the electron phototransfer in such systems. It therefore became necessary to create model structures in which the orientations of the donor and acceptor are known beforehand. One of the aspects of studies in this field involved the construction of a model of the photoreaction centre on a polymer base.[55] In this model, the porphyrin and quinone groups are distributed along a polymer chain and are separated by a known distance. The average distance between the chromophores can be regulated by altering the pH and the ionic strength of the solution. The copolymerisation of acrylic acid with 5-(10,15,20-tritolylporphyrinyl)phenyl methacrylate and 2-isopropenylanthraquinone led to the corresponding porphyrin-quinone polymer containing on average one porphyrin and three anthraquinone groups in the polymer chain.

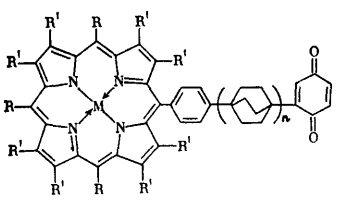
2. Models with a rigid covalent bridge

(XXXVIII) $R^1 = R^2 = R^3 = R^4 = C_6H_3O_2$;

(XXXIX) $R^1 = C_6H_5$; $R^2 = R^3 = R^4 = C_6H_3O_2$;

(XL) $R^1 = R^2 = C_6H_5$; $R^3 = R^4 = C_6H_3O_2$;

(XLI) $R^1 = R^3 = C_6H_5$; $R^2 = R^4 = C_6H_3O_2$;



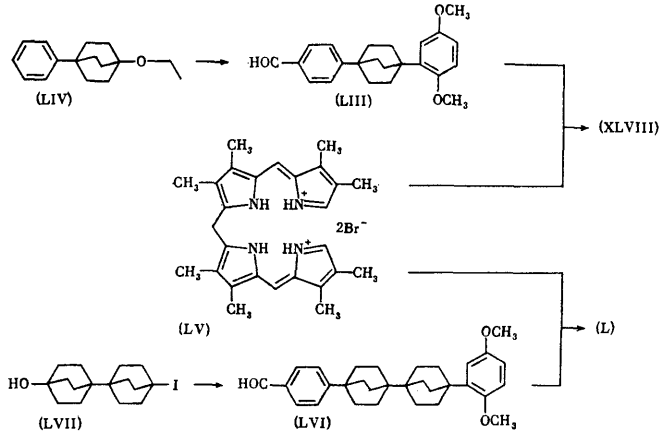
(XLII) $R^1 = R^2 = R^3 = C_6H_5$; $R^4 = C_6H_3O_2$;

(XLIII) $R^1 = R^2 = R^3 = C_6H_5$; $R^4 = C_6H_3O_2$;

(XLIV) $R^1 = R^2 = C_6H_5$; $R^3 = R^4 = C_6H_3O_2$;

(XLV) $R^1 = R^3 = C_{15}H_{21}$; $R^2 = R^4 = C_6H_3O_2$.

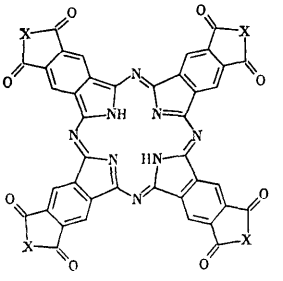
Another way of ensuring the rigidity of the structure is the formation of a C–C bond directly between the porphyrin and quinone components. The first models of this type (XXXIII)–(XLV) were obtained by the Rothemund condensation of pyrrole with an equimolecular amount of either 2,5-dimethyoxybenzaldehyde [in the case of compound (XXXVIII)] or with a mixture of the corresponding aldehydes [in the case of compounds (XXXIX)–(XLV)][56–58] and subsequent treatment with BBr_3 and DDQ. However, in contrast to natural systems, the distance between P and Q in compounds (XXXVIII)–(XLV) is small.



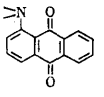
(XLVI) M = 2H, R = H, R' = CH_3, n = 0;
(XLVII) M = Zn, R = H, R' = CH_3, n = 0;
(XLVIII) M = 2H, R = H, R' = CH_3, n = 1;
(XLIX) M = Zn, R = H, R' = CH_3, n = 1;
(L) M = 2H, R = H, R' = CH_3, n = 2;
(LI) M = Zn, R = H, R' = CH_3, n = 2;
(LII) M = 2H, R = n-$CH_3C_6H_4$, R' = H, n = 1.

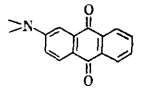
The structures (XLVI)–(LII), in which the P and Q fragments are linked by a rigid covalent bridge of variable length, are more suitable models of the reaction centres in photosynthesis.[59,60] In such compounds, there is a possibility of rotation only relative to the C–C bond. The models (XLVI)–(LII) are suitable for the investigation of the dependence of the efficiency of the charge separation on the distance between the donor and the acceptor.

The synthesis of these compounds is based on the method involving the condensation of linear tetrapyrroles and the corresponding aldehydes with formation of *meso*-substituted porphyrins (Scheme 4).[59]

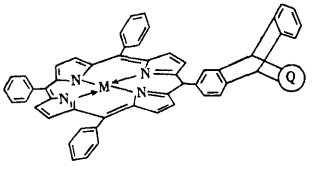


Scheme 4



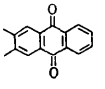


Arylbicyclo[2.2.2]octylbenzaldehyde (LIII), obtained from the ethyl ether of 4-phenylbicyclo[2.2.2]octanol (LIV), was condensed with *ac*-biladiene (LV) in 40% yield. Arylbibicyclo[2.2.2]octylbenzaldehyde (LVI), obtained from 4'-iodo-1,1'-bibicyclo[2.2.2]octan-4-ol (LVII), reacted similarly with *ac*-biladiene (LV) affording a yield of 30%. After the removal of the protecting group with BBr_3, oxidation with PbO_2, and chromatographic purification, the derivatives (XLVIII) and (L) respectively were obtained. Compound (XLVI) was synthesised similarly. Zinc was introduced by treating compounds (XLVI), (XLVIII), and (L) with zinc acetate to form the complexes (XLVII), (XLIX), and (LI) respectively.



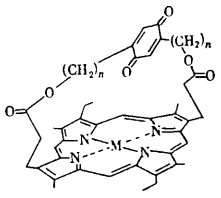
Compound (LII)[60] with the same type of bond but based on a tetraarylporphyrin was obtained by the Rothemund condensation of pyrrole with the appropriate amount of a mixture of 4-methylbenzaldehyde and 1-(4-formylphenyl)-4-(1,4-benzoquinonyl)-bicyclo[2.2.0]octane synthesised from 1-hydroxy-4-iodobicyclo-[2.2.2]octane in three stages.

Phthalocyanines, which are structural analogues of porphyrins, can also behave as electron donors in photochemical processes. The phthalocyanine-quinone compounds (LVIII) and (LIX), which possess only a rotational degree of freedom relative to the C–N bond, were obtained for the first time[61] by condensing the tetraanhydride (LX) with 1- or 2-aminoanthraquinone and subsequent purification by three reprecipitations from dimethylformamide with benzene. The yields of compounds (LVIII) and (LIX) were 38 and 77% respectively:



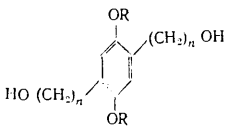
(LVII) X = 
(LIX) X = 
(LX) X = —O— .

In order to increase the rigidity of the linkage and to prevent the rotation of the chromophores relative to one another, the model compounds (LXI)–(LXIII), in which the porphyrin and quinone components are separated by a triptycene bridge, were synthesised:[62]



M = 2H (a); Zn (b)

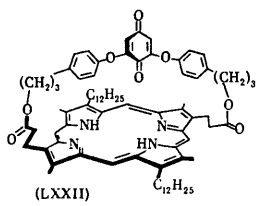
(LXIa, b) Q = 
(LXIIa, b) Q = 
(LXIIIa, b) Q =  .



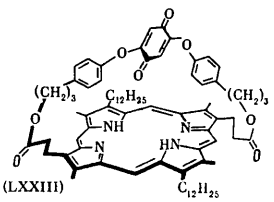
5-(2-Anthryl)-10,15,20-triphenylporphyrin, obtained in 25% yield by condensing a mixture of 2-anthraldehyde, benzaldehyde, and pyrrole, was refluxed in xylene with a fivefold excess of benzoquinone, which led to compound (LXIa) in 40% yield. For the synthesis of compound (LXIIa), the corresponding bicyclic naphthoquinone was obtained by the Diels–Alder addition of naphthoquinone to anthracene with subsequent oxidation *in situ*. After alkylation with dichloromethyl methyl ether and hydrolysis to the aldehyde (yield 30%), the product was condensed with benzaldehyde and pyrrole to form compound (LXIIa) in 15% yield. The derivative (LXIIIa) was obtained similarly by the Rothemund method in 18% yield. The bicyclic anthraquinone necessary for the synthesis of compound (LXIIIa) was obtained from triptycene acylated by phthalic anhydride and treated with polyphosphoric acid.

3. "Capped" porphyrin-quinones

P–Q derivatives, in which the quinone is rigorously oriented over the centre of the porphyrin ring, the so called "capped" porphyrin-quinones, are of considerable interest for the modelling of the charge separation process in photosynthesis. The linkage between the fragments is achieved by means of two or four covalent bridges located opposite one another. The advantages of such model systems consist in the possibility of controlling during synthesis the relative oxidation-reduction potentials of the fragments, the distances between them, and their mutual orientation:

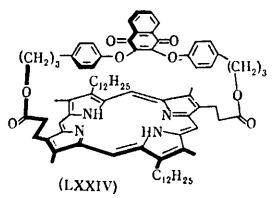


(LXVI) M=2H, n=2;
(LXVII) M=2H, n=3;
(LXX) M=Mg, n=2;
(LXXI) M=Mg, n=3.



(LXVIII) R=CH_3, n = 2;
(LXIV) R=CH_2OCH_3, n = 2;
(LXIX) R=CH_3, n=3;
(LXV) R=CH_2OCH_3, n = 3.

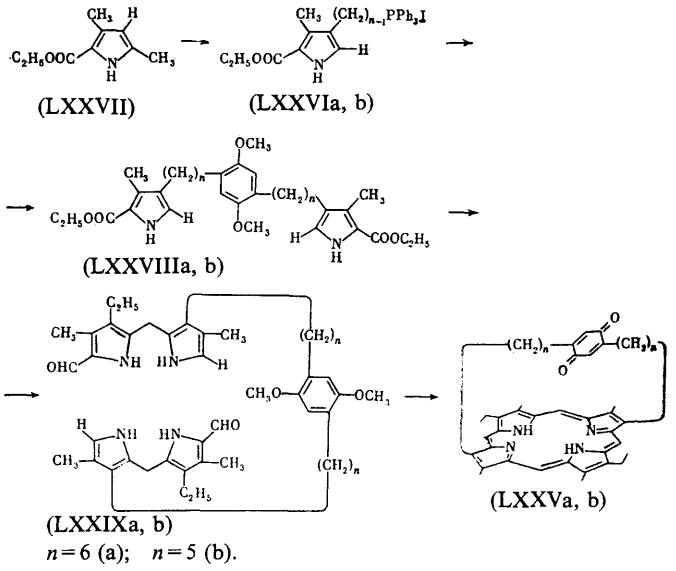
The synthesis of such P–Q compounds is based on porphyrins with a symmetrical structure. The condensation of the acid chloride of mesoporphyrin II with the corresponding hydroquinone derivatives (LXIV) and (LXV) at high dilution in CH_2Cl_2 in the presence of Et_3N afforded "capped" porphyrins in 7 and 15% yields respectively. The subsequent removal of the protecting groups with BCl_3 and oxidation by PbO_2 led to compounds (LXVI) and (LXVII).[63,64] The quinone component was modified as follows: after the Friedel–Crafts chloromethylation in the 2- and 5-positions, 1,4-dimethoxybenzene was converted into the nitrile and the subsequent hydrolysis and esterification with ethanol gave rise to the diester which was reduced to the alcohol (LXVIII). In order to increase the chain length (to n = 3), 2,5-bis(dichloromethyl)-1,4-dimethoxybenzene was treated with diethyl malonate to form the tetraester, from which the ethoxycarbonyl groups were then removed under mild conditions by refluxing in dimethyl sulphoxide and the product was reduced to the diol derivative (LXIX). However, the methyl protecting group cannot be removed by known methods, without decomposing the structure, from the "capped" porphyrins obtained by condensing the acid chloride of mesoporphyrin II with the alcohols (LXVIII) and (LXIX). This problem was solved by replacing the methyl protecting group by the more labile methoxymethyl protecting group. After acylation and demethylation of the alcohol (LXVIII), the resulting hydroquinone was protected by methoxymethyl ether which was followed by deacylation to give the diol derivative (LXIV). The alcohol (LXIX) was modified analogously to give compound (LXV). Magnesium was introduced into the "capped" porphyrins (LXVI) and (LXVII) by Eschenmoser's method[65] with formation of the magnesium complexes (LXX) and (LXXI).



As for the linear P–Q compounds (VII) and (IX),[37,38] the method of photoinduced cross-condensation has been used to synthesise the "capped" porphyrins (LXXII)–(LXXIV) from the modified mesoporphyrin II.[66] The porphyrin component was obtained by condensing 1,5-di(2-chlorocarbonylethyl)-3,7-didodecyl-2,4,6,8-tetramethylporphyrin with 3-(4-hydroxyphenyl)-1-propanol, which led to the formation of the "capped" porphyrins (LXXII)–(LXXIV) on irradiation in the presence of the corresponding quinone derivatives:

(LXXII)

(LXXIII)



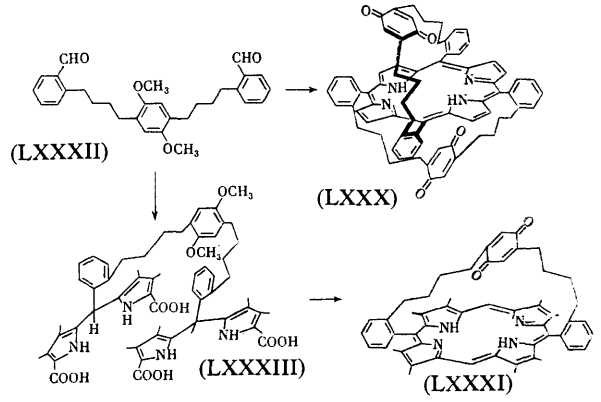
(LXXIV)

In order to achieve different spatial orientations of the donor and acceptor in the molecule relative to one another with the aim of elucidating the dependence of the rate of electron transfer on the relative disposition of the chromophores, the following quinones were selected: 2,6-dichloro-1,4-benzoquinone, 2,5-dichloro-1,4-benzoquinone, and 2,3-dichloro-1,4-naphthoquinone. The yields obtained in the photoreaction were 34, 42, and 8% of compounds (LXXII), (LXXIII), and (LXXIV) respectively. The low degree of conversion in these reactions was due to the formation of intermediate linear monoquinone derivatives, which cyclise after additional irradiation into the "capped" porphyrins (LXXII) and (LXXIII). In the synthesis of compound (LXXIV), the diquinone derivative was obtained as a side product in 10% yield.

The replacement of the ester linkage by an oligomethylene chain made it possible to create a more stable "capped" P–Q system (LXXVa,b).[67] The key stage of the synthesis (Scheme 5) is the double Wittig reaction of the pyrrole-substituted phosphonium salt (LXXVI), obtained from the pyrrole (LXXII) with a free β-position and 1,4-diformyl-2,5-dimethoxybenzene. The subsequent reduction of the corresponding alkenes leads to the oligomethylene-bridged bis(pyrroles) (LXXVIIIa,b) in 83% (for compound a) and 42% (for compound b) yields (after two stages). The condensation of the bis(pyrroles) (LXXVIIIa,b) having free α-positions with two equivalents of 5-chloromethyl-2-(2,2-dicyanoethylene)-4-ethyl-3-methylpyrrole afforded, after hydrolysis and decarboxylation, the substituted bis(dipyrrolylmethane) (LXXIX). The yield obtained in catalysed cyclisation at high dilution, which promotes the intramolecular reaction, was 20–60% after chromatographic purification, depending on the length of the oligomethylene chain. The demethylation BBr_3, which is allowed by the more stable C–C bond than the ester linkage in compounds (LXXVI) and (LXX), and

oxidation by PbO_2 lead to the porphyrins (LXXXa,b) (in 60 and 70% yields respectively):

Scheme 5



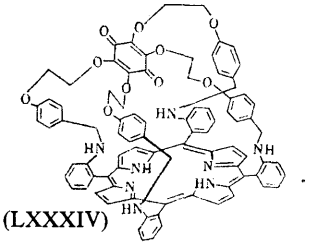
(LXXVII) (LXXVIa, b) (LXXVIIIa, b) (LXXIXa, b) (LXXVa, b)

$n=6$ (a); $n=5$ (b).

According to the strategy of the synthesis, the porphyrin cyclisation is carried out in the last stages, which ensures appreciable yields of the products even for a relatively short chain (n = 5). We may note that Scheme 5 permits the synthesis of "capped" model systems with different chain lengths ($n \geqslant 4$).

The wide variety of ways in which the porphyrin and quinone structures are linked together makes it possible to select the most suitable mutual orientation of the chromophores in the model system. Thus, apart from the compounds described above, the synthesis of the "capped" P–Q derivatives (LXXX) and (LXXXI), containing an oligomethylene chain in the *meso*-position in the porphyrin ring, has been achieved.[68,69] The starting material in the synthesis of compounds (LXXX) and (LXXXI) was the dialdehyde (LXXXII), obtained by the successive modification of 3,3′-(2,5-dimethoxybenzyl-1,4-phenylenedi)-1-propanol (Scheme 6):

Scheme 6



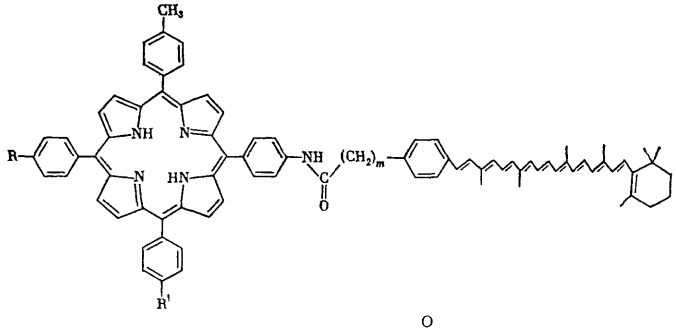
(LXXXII) (LXXX) (LXXXIII) (LXXXI)

The Rothemund condensation of the dialdehyde (LXXXII) with a twofold excess of pyrrole afforded the corresponding porphyrin derivative in 0.1% yield. Its subsequent demethylation with BBr_3 and oxidation with DDQ lead to the diquinone derivative (LXXX) in 41% yield.[68] The extremely low yield of the condensation reaction is due to the lack of specificity in its occurrence, which leads to a large number of cyclisation side products: oligomers and polymers.

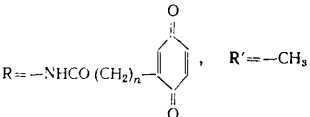
Apart from the procedure described above, the dialdehyde (LXXXII) has been condensed with 2-ethoxycarbonyl-3,4-dimethylpyrrole (yield 78%). After subsequent transesterification with benzyl alcohol and catalytic hydrogenation, the corresponding bis(dipyrrolylmethane) (LXXIII) was obtained. The decarboxylation and subsequent condensation were carried out in dichloromethane in the presence of trichloroacetic acid and triethoxymethane (yield 11%). Demethylation with BBr_3 and oxidation with DDQ of the porphyrin fraction, freed chromatographically from oligomers and decomposition products, led to the "capped" P–Q compound (LXXXI) in 54% yield.

In order to synthesise a rigid structure in which the porphyrin and quinone planes are rigorously parallel, compound (LXXXIV) with four covalent bonds between the P and Q fragments has been synthesised:[70]

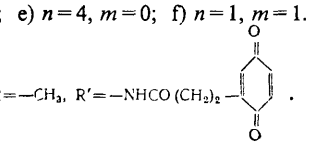
(LXXXIV)



The introduction of an alkoxy-group into fluoranil by treatment with five equivalents of 4-(2-hydroxyethoxy)benzaldehyde in the presence of an excess of CsF led to 2,3,5,6-tetra[2-(4-formylphenoxy)ethoxy]benzoquinone (LXXXV) in 47% yield. The entropically favourable macrocyclisation of the tetraaldehyde (LXXXV) with the αααα-atropisomer of 5,10,15,20-tetra(2-aminophenyl)porphyrin, obtained by the isomerisation of the corresponding atropisomer in the presence of silica gel,[71] occurred with a yield of 85% and the reaction was catalysed by trifluoroacetic acid. The formation of the Schiff base was followed spectroscopically at 330 nm and the kinetic analysis of the reaction mixture was carried out with the aid of high performance liquid chromatography (HPLC). After chromatographic purification and reduction with $NaBH_4$, the "capped" P–Q compound (LXXXIV) was obtained.



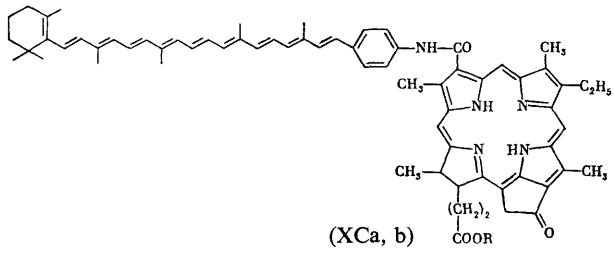
IV. Models with an additional donor (triads)



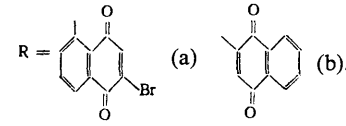
A new stage in the construction of model systems for the investigation of photosynthesis has been the synthesis of compounds containing a donor fragment together with the porphyrin and the quinone. During photosynthesis, the primary charge separation is accompanied by electron transfer from the primary donor to the oxidised chlorophyll-type photosensitiser.[1–4] The introduction of a donor into the P–Q compound made it possible to slow down the recombination of the light-separated charges by means of the dark reduction of the porphyrin radical-cation. Thus the triads make it possible to model more adequately the charge separation processes in photosynthesis.

The carotenoid structure with a system of conjugated double bonds, which participate directly in photosynthesis,[3,4] may serve as a suitable donor. The synthesis of the triads (LXXXVIa–f) and (LXXXVIIc), consisting of a tetraarylporphyrin linked covalently to

the carotenoid and quinone structures by a chain of atoms of different length (n = 0–4, m = 0, 1), has been described:[72,73]



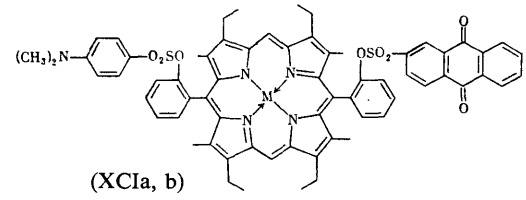
(LXXXVIa–e)  a) $n=0$, $m=0$; b) $n=1$, $m=0$; c) $n=2$, $m=0$; d) $n=3$, $m=0$; e) $n=4$, $m=0$; f) $n=1$, $m=1$.



(LXXXVIIc) 

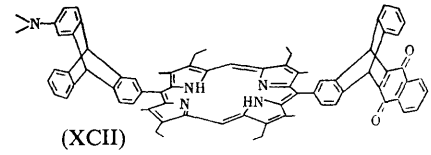
4-(β-apo-7′-carotenyl)benzoic acid (LXXXVIII), obtained by the Wittig reaction from β-apo-8′-carotenal and the corresponding phosphonium salt, was condensed with 5,15-di(4-aminophenyl)-10,20-di(4-methylphenyl)porphyrin (LXXXIX) (obtained by the Rothemund reaction) using dicyclohexylcarbodiimide and 4-dimethylaminopyridine. The same reagents were used in the condensation of carotenoporphyrin with 2,5-diacetoxyphenylacetic acid, while subsequent deacylation with KBH_4 and oxidation with PbO_2 led to the final structure (LXXXVIb). The triads (LXXXVIa,f) were obtained similarly from the corresponding modified hydroquinone derivatives.

However this synthetic scheme was unsuitable for the preparation of compounds (LXXXVIc–e) and (LXXXVIIc), because the corresponding hydroquinone derivatives readily formed lactones with the carboxy-group of the chain in the stage involving the synthesis of the quinone component. Another method of synthesis of the triads was as follows: 2,5-dibenzyloxybenzoic acid was methylated with CH_2N_2, reduced with $LiAlH_4$, and brominated with PBr_3. After malonate synthesis and the removal of the ethoxycarbonyl group, the acid chloride was obtained by treatment with $SOCl_2$ and condensed with the porphyrin (LXXXIX). After the removal of the benzyl protecting group by $(CH_3)_3SiI$ and oxidation by PbO_2, the P–Q obtained was condensed with the acid chloride (LXXXVIII) to form the triad (LXXXVIc). The derivatives (LXXXVId,e) and (LXXXVIIc) were synthesised similarly. By altering the length of the connecting unit between the porphyrin and quinone structures, it is possible to select a distance ensuring effective charge separation:



(XCa, b)

Similar triads (XCa,b), based on chlorophyll and naphthoquinone structures, were synthesised by the stepwise condensation of fragments of the system by a procedure similar to that used for compounds (LXXXVI a,b,f). The carboxy-derivative of methyl-pyrophaeophorbide *a* was condensed with aminocarotenoid by the acid chloride method. After the hydrolysis of the methyl ester by K_2CO_3 and esterification with 2-bromojuglone or lawsone, the corresponding products (XCa, b) were obtained.[74]



We may note that the (LXXXVI), (LXXXVII), and (XC) systems suffer from the same disadvantages as the models with a flexible covalent linkage between the donor and the acceptor.

The triad (XCIa), in which the secondary donor is a dimethylaniline derivative, was obtained by a procedure similar to that for the diquinone structure (VIa).[36] The zinc complex (XCIb) was obtained by treating the free base (XCIa) with zinc acetate.

(XCIa, b)
M = 2H (a); M = Zn (b).

In order to generate the three-component systems (XCII)[75] with a rigorously specified spatial orientation, a rigid triptycene bridge was used, as in compounds (LXI)–(LXIII). *NN*-Dimethylaniline was also chosen as the secondary donor in the triad (XCII). The condensation (catalysed by toluene-*p*-sulphonic acid) of a 1 : 1 mixture of the aldehyde of triptycenonaphthoquinone, obtained by the method of Wasielewski and Niemczyk,[62] and 2-formyl-6-nitrotriptycene, obtained in 95% yield by the Friedel–Crafts formulation of 2-nitrotriptycene with dichloromethyl methyl ether in the presence of $AlCl_3$, with two equivalents of di(3-ethyl-4-methylpyrrolyl)ethane led to a mixture of tetrahydroporphyrins, from which the final product (XCII) was obtained after oxidation with DDQ (overall yield of porphyrin 80%), reduction of the nitro-group with $SnCl_2$/HCl, chromatographic separation (yield 63%), and methylation of the amino-group with $CH_2O/NaBH_3CN$:

(XCII)

The methods of synthesis of all the model compounds examined are extremely varied. However, among them it is possible to distinguish two principal schemes for the construction of the covalent bond between the molecular fragments. The first involves the condensation of the system components with the simultaneous formation of the porphyrin ring.[36,42,56–60,62,67–69,75] The second involves the synthesis of porphyrin-quinones from synthetic[28,29,31–33,37–39,48,53,61,63,64,70,72,73] or natural[44–46,74] porphyrins and chlorins. An extremely large set of different porphyrin and

quinone structures of the model systems is necessary for the optimum selection of the corresponding donors and acceptors in photoinduced electron transfer reactions. The wide variety of the different forms of linkage between the chromophores has arisen because of the search for the most suitable conformations of the model systems and the optimum spatial orientation of their components for a high efficiency of the charge separation process.

V. Spatial disposition and mutual orientation of the fragments in model systems

The efficiency of electron transfer is known to depend significantly on the mutual orientation of the donor and acceptor. A study of the spatial organisation of P–Q compounds is therefore of considerable interest for the elucidation of the mechanism of electron transfer in such molecules.

The following methods are used to investigate the steric structure of P–Q derivatives: NMR spectroscopy, three-dimensional modelling, and X-ray diffraction analysis. The use of three-dimensional modelling is limited because of the presence of a large number of conformations for compounds with a flexible linkage. This method is used most effectively to determine the intramolecular distances between the fragments in structures with a rigid bond where the displacement of the chromophores relative to one another is difficult or almost impossible. Such data make it possible to calculate the probability and degree of overlap of the π-electron systems of the components, which determines the efficiency of the intramolecular electron transfer. Thus the distances between the donor and acceptor fragments have been determined with the aid of three-dimensional models in the porphyrin-quinones (XLVI)–(LII), (LXI)–(LXIII), and (XCII) with a rigid bond. For the three rigidly linked P–Q compounds (XLVI), (XLVIII), and (L), the distances between the chromophores are 6, 10, and 14 Å,[59] while the centres in the similar structure (LII) are at a distance of 16 Å.[60] The donor and acceptor in compounds (LXI), (LXII), and (LXIII) with a triptycene bridge are separated by 10, 10.5, and 11 Å, while the distance between the boundaries of the π-electron systems of the porphyrin and the quinone is >6–7 Å, which weakens significantly the direct overlap of the electron wave functions.[62] For the triad (XCII), the distance between the centres of the porphyrin and the quinone is 10.5 Å, that between dimethylaniline and the porphyrin is 10 Å, and that between dimethylaniline and the quinone is 25 Å.[75] For the "capped" porphyrin (LXXXIV), the distance between the parallel planes of the chromophores has been found to be ~10 Å.[70]

However, for the "capped" structures, this method is rarely used, because it does not permit an accurate determination of the distance between the chromophores. The reason for this is that the possibility of the vibration of the molecular fragments along the bonding axis and the presence of different conformational forms are not ruled out in systems of this kind. In order to investigate the intramolecular orientation of the chromophores and the spatial organisation of such model systems, ^{1}H NMR spectroscopy is employed. Appreciable upfield shifts of the signals due to the protons of the quinone ring [up to 4 p.p.m. for compounds (LXVI)–(LXXI) and (LXXV), up to 2.8 p.p.m. for compound (LXXII), and up to 2 p.p.m. for compounds (LXXX) and (LXXXI) in the ^{1}H NMR spectra relative to the unbound quinones are characteristic of the "capped" P–Q compounds (LXVI)–(LXXI), (LXXII), (LXXV), (LXXX), and (LXXXI)]. This is due to the influence of the ring current of the porphyrin.[63,66–69,76,77] The shifts of the signals for the P–Q compounds with a longer chain [compounds (LXVII) and (LXXVa)] compared with their analogues with a shortened bond [compounds (LXVI) and (LXXVb)] are greater by 0.2–0.65 p.p.m. This effect can be accounted for by the fact that the longer and flexible chain enables the quinone structure to approach the porphyrin more closely and to experience a greater influence of its π-electron system.[67,76,77] This hypothesis is confirmed by three-dimensional modelling[67] and the results obtained for other "capped" porphyrins.[76,78] Similar changes in the ^{1}H NMR spectrum are also characteristic of the proton signals of the methylene chain located above the plane of the porphyrin ring. The influence of the ring current on the chemical shift of these protons diminishes as the porphyrin is approached.[67,76] Thus the signals of the corresponding protons of the propionic residues in compounds (LXVI) and (LXVII) are located in the usual region, but, as a consequence of the rigidity of the structure, all four protons of the propionyl chain are non-equivalent and their signals are distributed in the form of four complex multiplets, each due to 2H, and not a simple AA'BB' system.[63,76]

Further studies on the conformational flexibility of the linkage in compounds (LXVI) and (LXVII) led to the observation of a linear temperature variation of the chemical shifts of the protons of the quinones and the nearest methylene groups. When the temperature is raised, the signals of the protons of the quinone and of its environment undergo a downfield shift [the shift constant is 4.5×10^{-3} p.p.m. K^{-1} for the quione proton and 5.1×10^{-3} p.p.m. K^{-1} for the nearest methylene group in compound (LXVII)]. Thus the distance between the fragments of the molecule increases with increase in temperature and diminishes on cooling.[76]

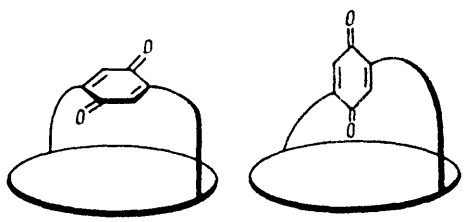


Figure 1. Schematic illustration of two extreme conformations of P and Q in "capped" porphyrin-quinones.[76]

The planes of the porphyrin and the quinone in the "capped" P–Q compounds (LXVI)–(LXXI), (LXXV), (LXXX), and (LXXXI) can be parallel or perpendicular to one another or they can occupy intermediate positions (Fig. 1). The necessary conformation of the fragments can be established in the course of specific synthesis.[66] Thus, when different substituted quinones were employed, "capped" P–Q structures with perpendicular (LXXII), parallel (LXXIII), and orthogonal (LXXIV) spatial orientations of the donor and acceptor were obtained. The molecular structure of the "sandwich" porphyrin (LXXX) has been determined by X-ray diffraction.[79] In compound (LXXX), having the S_4 symmetry, the two quinone rings are rigorously parallel to one another and to the plane of the porphyrin, while the centres of all three fragments coincide. The distance between the planes of the porphyrin and the quinones is

3.42 Å. It has been shown for compounds (LXVI) and (LXVII) that the real conformation constitutes a superposition of both limiting steric structures.[76] From this, it follows that there is virtually no coordination between the donor and acceptor parts in the free bases (LXVI) and (LXVII).[77] In the absence of external ligands, the magnesium complexes (LXX) and (LXXI) have structures in which the carbonyl group of the quinone is coordinated to the central metal ion resulting in the formation of a pentacoordinate intramolecular complex.[76,77] When an external ligand (pyridine[63,76] or 3,5-lutidine[77]) is added, a hexacoordinate complex is formed. This has been confirmed by the bonding constants found. The coordination of the ligand from the sterically unhindered side of the porphyrin plane entails appreciable upfield shifts of the quinone ring proton signals [by 0.6 p.p.m. for compound (LXX) and by 0.3 p.p.m. for compound (LXXI)] and the signals of the protons of the ligand itself. In contrast to magnesium complexes, in the presence of a ligand the zinc complexes have a geometry very similar to that of the free bases (LXVI) and (LXVII), which is due to the pentacoordination limit for zinc itself and the probability of the intramolecular bonding diminishes appreciably.[77]

The determination of the mutual orientation of the fragments for linear P–Q compounds with a flexible bond involves considerable difficulties because of their conformational lability. The time-average conformations of the triads (LXXXVIa–f) and (LXXXVIIc) in solution have been determined[73] from ^{1}H NMR data by conformational analysis on a computer. It was established that in all cases the triads have a linear structure and the quinone rings are arranged at an angle of 90° relative to the covalent bond. The spatial organisations of each of these molecules differ from one another by the orientations of the quinone and carotenoid components relative to the porphyrin plane, which depends on the length of the polymethylene chain (n = 0–4, m = 0–1). For a series of other linear P–Q compounds, only tentative conclusions concerning the mutual disposition of the quinone and porphyrin fragments have been reached with the aid of ^{1}H NMR spectroscopy. Depending on the length of the linkage and its location in the porphyrin ring, there are two possible versions of the steric structure: (1) the molecule has a linear form in which the chromophores are remote from one another and (2) the molecule is characterised by a folded configuration in which the quinone component is located above the plane of the porphyrin ring. However, in the second case it is also impossible to determine the exact position of the acceptor above the plane of the donor. Thus, in the structures (Ia–c),[29] (IIa–c),[31], (XXXIII),[53] and (XCa,b),[74] the porphyrin ring current does not exert an appreciable influence on the chemical shifts of the protons in the quinone component. This finding suggests a linear conformation of the molecule. Upfield shifts of the signals due to the protons of the quinone ring and its closest substituents have been observed for compounds (V),[33] (VIa,b), (XCIa,b),[36] (VIIIa–e),[38] (X)–(XVb),[39,42] and (XXXIIIa)–(XXXa,b).[44,45] This indicates a folded structure of the P–Q molecule. For the more rigid structure (V), the shifts are 0.1 p.p.m. for H(1), 2.0 p.p.m. for H(2), and 3.0 p.p.m. for H(3). This suggests that the H(3) hydrogen is closest to the porphyrin and the H(1) hydrogen is most remote. In the models (VIIIa–e), the maximum shifts are shown by compound (VIIIb), in which there is no substituent in the 3-position in the naphthoquinone component. It has been demonstrated by three-dimensional modelling that the quinone in the structure (VIIIb) can readily rotate about the C–O bond and can assume a position in which the porphyrin and quinone planes are parallel. The π–π interaction between the molecular fragments is then a maximum. For the derivatives (VIIIc–d), the rotation is hindered and the orthogonal conformation, in which the influence of the porphyrin ring current on the quinone is weakened, is optimal.

In the zinc complexes (XIVa–c), the signals of the quinone protons are displaced more ($\Delta\delta$ = 0.42–0.89 p.p.m. depending on the bond length) than in the free bases (Xa–c) ($\Delta\delta$ = 0.24 to 0.34 p.p.m.). This may be associated with the additional coordination of the quinone to the metal ion. For the diquinone derivative (XVb), these values are smaller ($\Delta\delta$ = 0.17 p.p.m.) because of the influence of the second quinone, which apparently prevents the localisation of benzoquinone above the porphyrin ring. Several changes have been observed also for the zinc complexes (VIb) and (XCIb). The addition of pyridine to a solution of the triad (XCIb) induced the formation of a pentacoordinate complex with the external ligand and the simultaneous breakdown of the interaction between the zinc atom and the carbonyl group of the quinone. The signals of the protons of the quinone component then shifted to the level of the free base (XCIa). In the natural P–Q compounds (XXIIIa)–(XXVIa,b), $\Delta\delta$ = 0.23–0.47 p.p.m. for the naphthoquinone-containing compounds (XXIIIa) and (XXIVa,b). The shift of the singlet signals of the methyl protons of the quinone residues in compounds (XXIIIa)–(XXVIa,b) is 0.27–1.43 p.p.m. Thus the molecular conformation in the P–Q compounds with a flexible linkage can be estimated from the shift of the protons of the quinone residues and the nearest substituents.

As stated above, information about the mutual disposition of the fragments of the P–Q molecule is of great interest for the understanding of the mechanisms of charge separation in these systems.

The photochemical properties of the model systems can be considered also on the basis of the available data for their structural features.

VI. Photochemistry of porphyrin–quinone compounds

Among the questions arising in the study of the photochemistry of porphyrin–quinone compounds, the most important are the following: (1) what structural features of the bridging chain determine the efficiency of the electron transport; (2) how should the bridge be constructed so that the direct electron transfer from *P to Q is rapid and the reverse transfer is slow; (3) in what way does the efficiency of the charge separation depend on the oxidation-reduction properties of P and Q. The solution of these problems in the photochemistry of P–Q compounds is of interest as regards the answer to the main question—what features of the organisation of the photosynthetic apparatus in photosynthesising organisms ensure a high efficiency of charge separation.

Considerable advances have now been achieved in the elucidation of the photochemical properties of P–Q compounds. It is possible to distinguish three main aspects of the study of the photochemistry of structures differing in the characteristics of the intramolecular electron transport processes: (1) the photochemistry of P–Q compounds with a flexible linkage; (2) the photochemistry of P–Q molecules with a rigid bridge; (3) the photochemistry of triad systems containing a porphyrin bound covalently to a quinone and an electron donor. The photochemical studies on P–Q compounds have developed in this sequence from the moment of their initiation. The transition from systems with a flexible linkage to P–Q compounds with a rigid bridge made it possible to investigate in greater detail the dynamics of charge separation between the porphyrin and the quinone without the complicating influence of conformational

movements manifested in the study of systems with a flexible linkage. The covalently bound triads constituted the next step towards more adequate modelling of the reaction centres of photosynthesing organisms. In these systems, it is possible to achieve fairly long lifetimes of the light-separated charges. Following the logic of the development of the research into P–Q compounds, we shall consider initially photochemical processes in systems with a flexible linkage.

1. Porphyrin–quinone compounds with a flexible linkage

In the first studies on the synthesis of P–Q compounds, attempts were already made to investigate their photochemical properties. Thus an appreciable quenching of the fluorescence of the porphyrin fragment by the quinone in dioxan and petroleum ether was noted[28,29] for compounds (Ia–c). In petroleum ether, the quenching efficiency proved to be higher than in dioxan. No data concerning the mechanism of the quenching of the fluorescence were obtained in the above studies.

The hypothesis that the quenching of the fluorescence of the porphyrin by the quinone in the P–Q compounds is caused by intramolecular electron transfer was first put forward by Tabushi et al.[33] and Dalton and Milgrom.[56] Since low concentrations of P–Q compounds were used in these studies, it was concluded that an intramolecular mechanism of the quenching of the fluorescence of the porphyrin fragment operates. However, data permitting the exclusion of an alternative explanation of the quenching of the fluorescence, involving intramolecular energy transfer, were not obtained either.[33,56]

It has been observed[56] that the Soret band in the spectrum of compound (XXXVIII) is much broader than in that of the free porphyrin. According to the authors, this indicates the formation of an intramolecular charge-transfer state in the P–Q compound. The complete quenching of the fluorescence of the porphyrin fragment of the P–Q compound was noted (the fluorescence quantum yield was $\Phi < 10^{-3}$). The experimental results were explained by the high efficiency of the electron transfer from the singlet-excited prophyrin fragment to the quinone.

Subsequently the hypothesis that the quenching of the fluorescence of P–Q compounds is caused by electron transfer was used frequently to account for the non-exponential character of the decay of the fluorescence and the dependence of the fluorescence quenching efficiency on the length of the bridge connecting P and Q, the presence of the metal in the P–Q compound, and the nature of the solvent.[39,80,81]

In principle, four mechanisms of the quenching of the fluorescence of the donor D by the acceptor A are possible: (1) energy transfer from *D to A; (2) the mixing of the electronic states of D and A leading to an increase in the non-radiative transition of *D to the ground state; (3) the spin–orbital coupling of the $^1(\pi,\pi^*)$,$^3(\pi,\pi^*)$, and S_0 states of the donor by virtue of the addition of the acceptor; (4) electron transfer from *D to A.

We shall consider each of these quenching mechanisms for a covalently bound P–Q compound. The energy transfer from porphyrin in the S_1 state ($E_{S_1} \simeq 1.8$ eV) to the quinone is unlikely because the lowest excited state of the quinone is fairly high (2.6 eV for benzoquinone in solution[82]). This energy difference is also sufficient to rule out the hypothesis of the mixing of the electronic states of P and Q. The spin–orbital coupling of states also appears unlikely because the efficiency of the quenching of the fluorescence of porphyrins by quinones is determined mainly by their oxidation-reduction properties[83,84] and not by the capacity for spin–orbital coupling.[85] The hypothesis that the electron transfer from *P to Q responsible for the appreciable decrease in the efficiency of the luminescence of the porphyrin in P–Q compounds therefore appears reasonable. Measurements of the redox potentials of the P–Q compounds have shown that the singlet excitation energy of the porphyrin is indeed sufficient in many cases for the formation of the P^+–Q^- pair.[86]

The first study in which the formation of a radical-ion pair on irradiation of P–Q compound was demonstrated was that of Ho et al.[87] By a procedure similar to that used by Kong and Loach,[28,29] it was found that a much lower fluorescence intensity (~10%) is observed for compound (Ib) in methanol at room temperature than for a porphyrin without a quinone residue. At low temperatures, it is possible to detect the EPR signal of the photolysis products in vitreous methanol. Comparison of the EPR spectrum obtained with the individual EPR spectra of P^+ and Q^- enabled the authors[87] to interpret the light-induced EPR signal as a superposition of the EPR spectra of P^+ and Q^-. The efficiency of the formation of radical-ions for a P–Q compound was many times greater than the efficiency of the generation of P^+ and Q^- in a homogeneous solution of the porphyrin and the quinone at the same concentrations of the reactants, not bound to one another, as in the P–Q compound. The subsequent generation of the EPR signals on irradiation of compounds (Ia–c) and their zinc analogues has also been demonstrated in another study.[80]

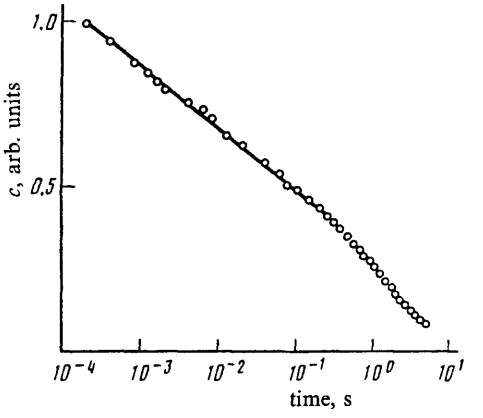

Figure 2. Kinetics of the destruction of the radical-ion pairs P^+–Q^- at T = 160 K in a 98 : 2 vitreous methanol–chloroform structure; c = concentration.[87]

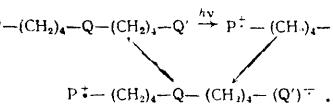
At T = 160 K, the formation of the P^+–Q^- radical-ion pair is followed by the intramolecular recombination of charges, whose kinetics at low temperatures are described by a linear dependence of the number of P^+–Q^- pairs on the logarithm of the observation time (Fig. 2).[87] A similar relation had been observed earlier for the low-temperature recombination of charges in the reaction centres of the photosystems (I) of subchloroplasts.[88] On the grounds that the efficiency of the P^+–Q^- recombination depends strongly on temperature, the logarithmic character of the recombination of charges in compound (I) was explained[87] by the difference between

the activation energies for the recombination of different P^{+}–Q^{-} pairs. The difference may be caused by the presence of several conformations of the carbon chain linking the porphyrin and the quinone. However, it has been noted[88] that other causes of the logarithmic character of the kinetics of the recombination of charges in structures analogous to P–Q are also possible. These may be a difference between the distances over which an electron is transferred from Q^{-} to P^{+} (if the electron transfer does not proceed via the bridge but directly from Q^{-} to P^{+}), a difference between the mutual orientations of P^{+} and Q^{-}, or a difference between the values of some other parameter on which the efficiency of charge recombination depends exponentially.

At room temperature, the quantum yield in the separation of charges in compound (Ib) reaches 0.5%. The addition of tetrabutylammonium perchlorate lowers the rate of charge recombination in P^{+}–Q^{-}.[80] The observed[80] dependence of the fluorescence quenching efficiency on the solvent polarity (the increase in efficiency with increase in polarity) can be explained naturally within the framework of modern models of electron transfer in the condensed phase by the dependence of the charge separation energetics on the parameters of the medium.

Subsequently the light-induced charge separation in the model systems (IIIa–c) was observed by the EPR method. The high resistance of the diamide bridge to hydrolysis enabled the authors[89] to carry out optical, EPR, and luminescence studies on the separation of charges in P–Q compounds. It was observed that spin–exchange and dipole–dipole intramolecular interactions of the P^{+} and Q^{-} radical-ions are manifested in the EPR spectra of vitreous P–Q solutions irradiated with light. The degree of the dipole–dipole interaction ($D \simeq 2.0\ mT$) made it possible to estimate the average distance between the unpaired electrons of P^{+} and Q^{-}, amounting to 10–12 Å for compound (IIIa). Molecular models have shown that this distance corresponds to the conformation of the P–Q compound in which the quinone interacts with the nearest phenyl residue.



The quantum yield in the formation of the $P^{+}Q^{-}$ radical-ion pair, measured by EPR, depends on temperature and increases markedly, to $\Phi \simeq 0.02$, when the temperature is reduced by $\sim$20 K below the melting point of the solvent. On further reduction of temperature, Φ also falls. It has been suggested that charge separation quantum yield in P–Q compounds is determined by the microviscosity of the solvent. The increase in the temperature of the frozen matrix then increases the mobility of the P–Q fragments relative to one another promoting thereby the attainment of conformations favourable for electron transfer. In the temperature range near the melting point of the solvent, the recombination of charges becomes effective and, having reached a maximum, the charge separation quantum yield again diminishes.

The existence of different conformations of compounds (IIIa–c) has been established.[90] The most effective quenching of the fluorescence has been observed for the derivative (IIIb). These data agree with the results of EPR studies.[89]

The charge separation on pulsed irradiation of the derivative (IV) with light has been described.[32] The dependence of the efficiency of electron transfer from the porphyrin to the quinone on the refractive index n of the solvent was found: with increase in n, k_e increased from $1.4 \times 10^{7}\ s^{-1}$ for $n = 1.352$ (diethyl ether) to $7.7 \times 10^{8}\ s^{-1}$ for $n = 1.633$ (1-chloronaphthalene). The results of the above study show that for P–Q compounds the solvent can exert an appreciable influence on the process energetics even when the length of the bridge connecting P and Q is small.

The dependence of the rate of electron transfer from the electronically excited porphyrin fragment to Q and of the rate of the reverse process on the length of the bridge for the derivatives (Xa–c) has been described.[39,42,43] It was established that the reciprocal of the P–Q fluorescence decay time is $10^{9}\ s^{-1}$, $10^{10}\ s^{-1}$, and $10^{11}\ s^{-1}$ for $n = 6$, 4, and 2 respectively. A similar dependence has been observed also for the efficiency of the reverse electron transfer from Q^{-} to P^{+}. The pronounced dependence of the rates of the forward and reverse electron transfers on the length of the bridge connecting P and Q shows that the electron transfer takes place via the tunnel mechanism.[43]

The two-step electron transfer from the porphyrin to trichlorobenzoquinone in the molecule of compound (XV) [P–$(CH_2)_4$–Q–$(CH_2)_4$–Q′] has been investigated.[42,43] The charge separation takes place with participation of the intermediate state P^{+}–$(CH_2)_4$–Q^{-}–$(CH_2)_4$–Q′:

The two-step electron transfer mechanism ensures rapid ($\tau < 10^{-11}$ s) charge separation. This time is much shorter than the time of the single-step charge separation in the molecule of compound (Xc) with a shorter bridge ($\tau > 5 \times 10^{-10}$ s). The greater length of the bridge in the molecule of compound (XV) ensures a comparatively long charge recombination lifetime $\tau = (3\text{–}4) \times 10^{-10}$ s. The present authors' data[42,43] confirm the results[91,107] showing that the multistep electron transfer along the redox potential gradient of the acceptor groups ensures a higher efficiency of charge separation than the single-step process.

2. Porphyrin–quinone compounds with a rigid bridge

The appreciable conformational mobility of the P–Q compounds with a flexible chain precludes the elucidation of the detailed mechanism of the intramolecular electron transfer. One of the ways of solving this problem has been the synthesis of "capped" P–Q structures.

Thus the parallel disposition of the fragments in compound (LXXXIV) ensured an appreciable (greater than 30%) P^{+}–Q^{-} quantum yield for its zinc complex.[92] For the metal-free derivative (LXXXIV), the intramolecular electron transfer was not observed. The appearance of additional luminescence quenching channel reduced the quantum yield and resulted in a two-component character of the P–Q fluorescence decay curve. The electron transfer rate constants, estimated from the biexponential curve, are $k_1 = 3 \times 10^{8}\ s^{-1}$ and $k_2 = 1.5 \times 10^{3}\ s^{-1}$. The electron transfer to the quinone is observed also with participation of the excited triplet state of the porphyrin fragment.

The diquinone compound (LXXX) has been investigated.[79] The small distance between the planes of the porphyrin and the quinone is apparently the cause of the almost complete absence of the luminescence of this derivative compared with its non-quinonoid analogue. A similar effect has been observed also for the monoquinone analogue of compound (LXXX).[69] The quenching of the fluorescence of compounds (LXXX) and (LXXXI) can be explained by electron transfer from the singlet-excited porphyrin fragment to the quinone.

Compounds with a linear structure and a rigid bridge [compounds (XLVI)–(LII) and (LXI)–(LXIII)] provide considerable possibilities for the elucidation of the factors determining the efficiency of the electron phototransfer in P–Q systems.[59,60,62,93] The absence from

the absorption spectra of any manifestations of the interaction of the porphyrin and quinone fragments, typical for systems with a flexible bridge, is characteristic of these compounds. A rigid structure prevents the interactions of the fragments in the ground state. Another characteristic feature of systems with a rigid bridge is the monoexponential character of the fluorescence decay curve, indicating the existence of only one P–Q conformation, in which an effective electron transfer takes place.

It has been observed for compounds (LXI)–(LXIII) that the fluoresence quantum yield of the porphyrin fragment of the P–Q compound is lower than for the individual porphyrin.[62] A correlation was then observed between the free energy of the electron transfer from the donor to the acceptor ($-\Delta G^0$) and the quenching efficiency (see Table 1). The free energy $-\Delta G^0$ was calculated from the formula

$$-\Delta G^0 = E(S_1) - E(P/P^+) + E(Q/Q^-),$$

where $E(S_1)$ is the excitation energy of the singlet state S_1 of the porphyrin fragment, $E(P/P^+)$ the oxidation potential of the porphyrin, and $E(Q/Q^-)$ the reduction potential of the quinone.

Table 1. The free energies $-\Delta G^0$ of the electron transfer from P to Q and the fluorescence quantum yields (Φ) for the P–Q compounds in CH_2Cl_2.[62]

Compound	Φ	$-\Delta G^0$, eV
Tetraphenylporphyrin (TPP)	0.14	—
(LXIIIa)	0.119	0.02
(LXIIa)	0.001	0.29
(LXIa)	<0.001	0.47
Zn complex of TPP	0.023	—
(LXIIIb)	0.002	0.43
(LXIIb)	<0.001	0.70
(LXIb)	<0.001	0.88

A similar correlation has been found for two other solvents: toluene and butyronitrile. The increase in $-\Delta G^0$ with decrease in the dielectric constant of the solvent led to an increase in the luminescence quenching efficiency. This character of the dependence of the luminescence quantum yield on the free energy change shows that the quenching of the luminescence is due to electron transfer from $^*P$ to Q.[91,94–97] This hypothesis is supported also by picosecond absorption spectroscopic data. Wasielewski and Niemczyk[62] were able to record the characteristic absorption bands of P^+ and Q^- in the absorption spectrum of a solution of the zinc complex (LXIIb) in toluene irradiated by a light pulse. The time of the intramolecular charge recombination $P^+-Q^- \rightarrow P-Q$ in this compound is 3.7×10^{-10} s.

The electron transfer rate constant for this process decreases with increase in $-\Delta G^0$.[93] This fact can also be explained within the framework of the modern theories of electron transfer. Indeed, the quantities $-\Delta G^0$ for charge recombination in compounds (LXI)–(LXIII) investigated by Wasielewski and Niemczyk[93] exceed 1 eV. The decrease in k_e with the increase in $-\Delta G^0$ is apparently caused by the fact that the quantity $-\Delta G^0$ exceeds the reorganisation energy (λ is a parameter determining, together with $-\Delta G^0$, the nuclear multiplier k_{nu} in the expression for the electron transfer rate constant):

$$k_{nu} = \exp\left(-\frac{(\lambda + \Delta G^0)^2}{4\lambda RT}\right). \quad (1)$$

Eqn. (1) shows that the increase in $-\Delta G^0$ leads under these conditions to a decrease in the nuclear multiplier and hence in the electron transfer rate constant.

We may note that, in contrast to the "capped" P–Q compounds considered above, the effective electron transfer between the P and Q fragments observed by Wasielewski and Niemczyk[62] takes place over a considerable distance in the conformation hindering the overlap of the π orbitals of the reactants.

A dependence of the efficiency of the transfer from $^*P$ to Q on the dielectric constant and the refractive index of the solvent employed has been observed for the model systems (XLVI)–(LII).[59,60] The electron transfer rate constants reaches its maximum value for an intermediate and (and not the maximum) polarity of the solvent and varies from $k_e = 3.3 \times 10^7$ s^{-1} in propionitrile ($\varepsilon = 27.2$, $n = 1.3659$) to $k_e = 1.6 \times 10^6$ s^{-1} in 2-methyltetrahydrofuran (MTHF) ($\varepsilon = 7.6$, $n = 1.4060$) and falls almost to zero in dibutyl ether ($\varepsilon = 3.04$, $n = 1.3992$) and acetonitrile ($\varepsilon = 37.5$, $n = 1.3441$). Such variation is associated with the fact that the solvation energy of the P^+-Q^- state, which determines the energetics of the charge separation process, depends both on dielectric constants of the solvent and (to a greater extent) on its refractive index.[98] For solvents having similar structures, it is possible to obtain a quantitative correspondence between the quantities k_e, ε, and n.[60]

For the quantitative determination of the tunnelling parameters, the P–Q compounds (XLVIII) and (L) have been investigated.[99] The rate constant for electron transfer from $^*P$ to Q was estimated from the decrease in the luminescence decay time. Typical P–Q fluorescence decay curves are illustrated in Fig. 3. It is seen that the transition from the structure (LI) to compound (XLIX) results in a sharp decrease of the fluorescence decay time. The quantity k_e then increased from $k_e^2 \lesssim 10^7$ s^{-1} to $k_e^1 = 10^{10}$ s^{-1}. Using the maximum value of k_e for the derivative (LI), it is easy to obtain $a_e \leqslant 1.4$ Å and $\nu_e \geqslant 10^{19}$ s^{-1} from the exponential dependence of k_e on the distance R between the donor and acceptor: $k_e = \nu_e \exp(-2R/a_e)$.[97] If the minimum distance between P and Q is used instead of the intercentre distance, then ν_e may be estimated as $\nu_e \geqslant 10^{16}$ s^{-1}.

At $T = 77$ K, the kinetics of the quenching of the fluorescence of compound (XLIX) in vitreous MTHF are non-exponential. This effect is due to the existence in the frozen solution of several rotational conformations of the molecule. The monoexponential character of the decay curve at 298 K shows that at this temperature the rate of rotation exceeds k_e. The decay time of the principal component of the kinetic curve $\tau = 1.1 \times 10^{-10}$ s is almost identical with the value of τ at 298 K. Thus the rate of electron transfer from $^*P$ to Q in the structure (XLIX) is almost independent of temperature.

3. Model systems having a rigorous spatial orientation without a covalent bond between the porphyrin and the quinone

Together with the covalent bonding between the porphyrin and the quinone, a fixed distance between P and Q can be ensured, in principle, also in a number of other ways. Thus the synthesis of a porphyrin bound covalently to β-cyclodextrin (PC) has been described.[100] In a solution containing electron-accepting additives, cyclodextrin coordinates the acceptor molecules in its interior. On

irradiation with light at $\lambda > 550$ nm of a vitreous solution of PC containing added benzoquinone at 77 K, paramagnetic charge separation products are detected, their amount exceeding by a factor of 3–4 that in the control (P + Q solution). The efficiency of the charge separation depends on the oxidation-reduction potential of the electron acceptor. For an oxidation-reduction potential below –0.3 eV relative to the normal hydrogen electrode, a sharp decrease, greater than by an order of magnitude, in the intensity of the EPR signal of the charge separation products was observed when the oxidation-reduction potential changed from –0.3 to –0.6 eV. Such a decrease in the charge separation efficiency is caused, according to Gonzalez et al.,[100] by the rapid reverse charge recombination.

Yet another interesting example of a structure permitting the study of electron transfer between the porphyrin and the quinone, separated by a fixed distance, is provided by planar molecular assemblies obtained by the Langmuir–Blodget method. [101–103] The planar molecular assemblies constitute multilayer structures in which the acceptor layer is separated from the donor layer as a rule by a monolayer made up of saturated aliphatic acid molecules. The thickness of the monolayer and hence the distance between the donor and acceptor can be varied by increasing the number of CH_2 fragments in the acid molecule.

The electron phototransfer from chlorophyll to a quinone in a multilayer structure, where a layer of chloranil, bromanil, or *NN*-distearoyl-1,4-diaminoanthraquinone was deposited on a layer of chlorophyll *a* molecules, has been investigated.[104,105] The structural organisation was such that the phytol fragments of the chlorophyll molecules were turned towards the layer of quinone molecules. Thus the insulating layer consisted of the phytol fragments of the chlorophyll molecules. It was observed that irradiation of such a structure with light leads to electron transfer from chlorophyll to the quinone and the formation of the corresponding radical-ions. The charge separation took place via a two-quantum mechanism. The reason for the inefficiency of the one-quantum reaction channel is apparently the short lifetime of the excited state of chlorophyll *a* and the appreciable distance between the donor fragment of the chlorophyll molecule and the quinone. After the light had been switched off, charge recombination was observed. Its duration ($\tau_{1/2}$) amounted to 6×10^{-4} s and was almost independent of temperature in the range 100–300 K.

The introduction of ubiquinone, plastoquinone, or squalene (whose molecules have an unsaturated chain) into the system led to a tenfold increase in the charge separation efficiency for the given light intensity. The electron transfer became a one-quantum process and occurred with participation of the first excited triplet state of chlorophyll *a*. The observed effect was explained by a change in the form of the barrier to the tunnelling of the electron caused by the insertion of molecules or molecular fragments with a polyisoprene chain in the insulating layer. The use of molecules with a saturated chain in control experiments did not accelerate the electron phototransfer process. The results of the above studies[104,105] demonstrate the fruitfulness of the use of planar molecular assemblies for the investigation of the electron tunnelling mechanisms in porphyrin–quinone systems. However, the uncertainty in the interpretation of the results of experiments with molecular layers due to the non-rigid character of the linkage between the reacting species makes covalently bound P–Q compounds a preferable object for the modelling of photosynthesis and for the study of the mechanisms of electron phototransfer from the porphyrin to the quinone.

4. Covalently bound triads

As already mentioned above, the next step in the modelling of the charge separation process in photosynthesis involved the study of trifunctional molecules (D–P–Q) containing a porphyrin, a quinone, and a donor fragment.[72,73,75,106]

By analogy with photosynthesis, one might have expected that a fairly considerable increase in the lifetime of the separated charges compared with the bifunctional P–Q molecules would be achieved in the trifunctional compounds as a result of the two-step charge separation mechanism. Thus the excitation of the triads (LXXXVI)

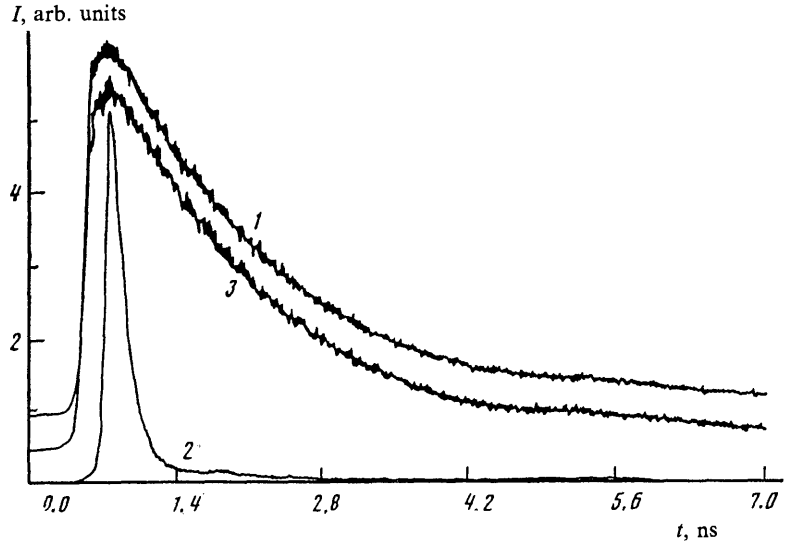


Figure 3. Kinetics of the decay of the fluorescence of compound (XLIX) (curve *1*), compound (LI) (curve *2*), and zinc 2,3,7,8,12,13,17,18-octamethyl-5-phenylporphyrinate (curve *3*); T = 298 K; I = intensity.[99]

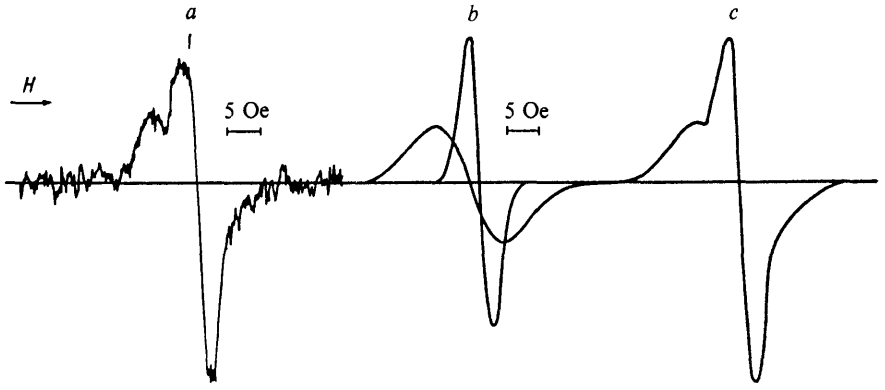

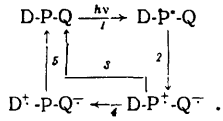

Figure 4. *a*, the EPR spectrum of a vitreous solution of compound (XXIIIa) (10^{-3} M) in triethylamine irradiated with the light from a DKSSh 1000 lamp (KS 10 filter); irradiation time 600 s; power of the light flux 2×10^{-3} W cm^{-2}; T = 77 K; the vertical line indicates the position of the EPR line of polycrystalline αα′-diphenyl-β-picrylhydrazyl;[108,109] *b*, EPR spectra of the radical-anion $P^{\cdot-}$ obtained by photoreduction in triethylamine and the radical-anion $Q^{\cdot-}$ obtained by reduction on a Na mirror; *c*, the calculated EPR spectrum representing a superposition of the EPR spectra of the radical-anions $P^{\cdot-}$–Q and $P–Q^{\cdot-}$; $P^{\cdot-}–Q : P–Q^{\cdot-} = 3:1$.

by a light pulse leads to the rapid (over a period less than 10^{-10} s) formation of $D^{+}–P–Q^{\cdot-}$:[72,73,106]

Charge separation is achieved via electron transfer from the excited singlet porphyrin to the quinone with formation of $D^{+}–P–Q^{\cdot-}$ [reaction (2)]. The formation of $D^{+}–P–Q^{\cdot-}$ [reaction (4)] competes with the charge recombination process [reaction (3)]. The quantum yield in the generation of $D^{+}–P–Q^{\cdot-}$ reaches 0.25. An amount of energy equal to 1 eV is then stored. The charge recombination time in $D^{+}–P–Q^{\cdot-}$ [reaction (5)] is several microseconds. This exceeds by a factor of 10^{6} the charge recombination time for the analogue without a donor fragment.

As in the covalently bound triad considered above, the formation of $D^{+}–P–Q^{\cdot-}$ in compound (XCII) is achieved over a period $< 10^{-10}$ s.[75] However, the charge separation quantum yield and the energy stored were greater than $\Phi = 0.7$ and $\Delta G = 1.4$ eV. The charge recombination time [reaction (5)] was 2.45×10^{-6} s.

Thus the two-step mechanism of electron transfer from the donor to the acceptor ensures a rapid charge separation and makes it possible to attain high quantum yields and lifetimes of the separated charges. The results of studies described in the literature[72,73,75,106] constitute evidence in support of theoretical models of electron transport in photosynthesis,[91,107] according to which the stepwise character of the process actually ensures a high efficiency of the charge separation at the photosynthetic reaction centres.

VII. Modelling of the intermediate stage of the primary charge separation in photosynthesis with the aid of porphyrin–quinone compounds

A simple system for the modelling of the concluding stage of the primary charge separation has been proposed and investigated.[108,109] Electron phototransfer and dark transfer reactions in frozen vitreous matrices comprising solutions of covalently bound P–Q compounds (XXIII)–(XXVI) in an electron-donating solvent were investigated in the above studies. The solvent was triethylamine. The presence of the bridging heteroatom served as an additional lever for controlling the efficiency of the intramolecular electron transfer processes. It was observed that irradiation with light at 77 K of P–Q solutions in the region of the long-wavelength absorption bands of P leads to the formation of the radical-ions $P^{\cdot-}$ and $Q^{\cdot-}$, detected from their characteristic EPR spectra. Fig. 4 presents as an example the experimental EPR spectra of the light-irradiated solutions of compound (XXIIIa) (Fig. 4*a*), the EPR spectra of the individual radical-anions $P^{\cdot-}$ and $Q^{\cdot-}$ (Fig. 4*b*), and the EPR spectrum representing the superposition of the $P^{\cdot-}$ and $Q^{\cdot-}$ signals (Fig. 4*c*). The radical-anions $P^{\cdot-}$ and $Q^{\cdot-}$ were generated by irradiating the pigment in triethylamine with light at 77 K ($P^{\cdot-}$) or by reduction on a sodium mirror ($Q^{\cdot-}$). Fig. 4 shows that the calculated EPR spectrum describes satisfactorily the experimentally observed signal of the light-irradiated solution.

The analysis in the above studies of the possible mechanisms of the formation of the radical-anions $P^{\cdot-}$ and $Q^{\cdot-}$ showed that these species are formed in accordance with the following scheme:

$$P\text{-}Q \xrightleftharpoons[\leftarrow]{h\nu^{1},\,(C_2H_5)_3N} (C_2H_5)_3N^{+} + P^{\cdot-}\text{-}Q \xrightarrow{h\nu^{2},\,(P\text{-}Q)_y}$$
$$\rightarrow (C_2H_5)_3N^{+} + P\text{-}Q + (P^{\cdot-}\text{-}Q)_y \rightarrow (P\text{-}Q^{\cdot-})_y \ .$$

After the absorption of the first light quantum, the P–Q compound is reduced by the nearest solvent molecule $[(C_2H_5)_3N]$. The radical-anions $P^{\cdot-}$–Q formed are unstable and, together with charge recombination, there is a possibility of electron transfer from $P^{\cdot-}$ to Q. After the absorption of the second light quantum by the radical-anion $P^{\cdot-}$–Q, an electron is transferred to remote $(P–Q)_r$ species. The electron is then localised initially at the porphyrin fragment of the P–Q molecule. This is followed by the dark intramolecular electron transfer from the porphyrin fragment of the molecule to the quinone fragment. The kinetics of this process for compound (XXIIIa) are illustrated in Fig. 5. Evidently the intramolecular electron transfer $P^{\cdot-}–Q \rightarrow P–Q^{\cdot-}$ is described by a nearly linear relation between the concentration of the $P^{\cdot-}$–Q species and the logarithm of the observation time. This indicates a difference between the probabilities of the electron transfer from $P^{\cdot-}$ to Q for different P–Q molecules. The causes of this difference are so far obscure. They may involve, for example, different P–Q conformations in the frozen solution, which leads to a difference in the electron transfer distances and (or) different mutual orientations of the molecular fragments relative to one another.

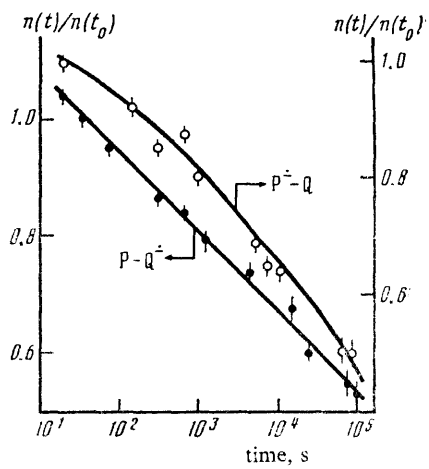

Figure 5. Kinetics of the dark destruction of $P^{\cdot-}$–Q and P–$Q^{\cdot-}$ in an irradiated vitreous solution of compound (XXIIIa) in triethylamine; the time is reckoned from the instant when irradiation ceases; T = 77 K;[108,109] $n(t)$ and $n(t_0)$ are the radical concentrations at times t and t_0.

The use of the quinone fragments of the P–Q molecules, differing in the electron-donating properties, and variation of the heteroatom in the bridge connecting P and Q make it possible to regulate the efficiency of the intramolecular electron transfer from $P^{\cdot-}$ to Q. It has been found that an increase in the oxidation-reduction potential of the quinone fragment of the P–Q molecule lowers the efficiency of the reduction of Q. This result can be explained if it is assumed that in the systems investigated the reorganisation energy is lower than the quantity $-\Delta G^0$ for the process[97] [see also Eqn. (1)].

The results of studies by Strekova and co-workers[108,109] demonstrate the possibility, in principle, of using solutions of P–Q compounds in electron-donating solvents for the modelling of one of the "elementary" stages of the charge separation process in photosynthesis—the stage involving electron transfer from phaeophytin to the primary acceptor. It is known that the electron transfer in photosynthesis from the electronically excited photosensitiser to the primary acceptor does not take place directly and occurs with participation of intermediate acceptors, one of which is phaeophytin.[110]

- - - o0o- - -

We shall now formulate briefly the principal results of experimental studies on the intramolecular electron phototransfer in P–Q compounds, which are convenient models of the reaction centres in photosynthesis.

The possibility of the synthesis of such compounds with a fixed distance between the donor and acceptor and a definite mutual orientation makes it possible, as shown above, to investigate the influence of various factors on the efficiency of electron transport. As in photosynthesis, the transfer of an electron in the P–Q compounds takes place mainly with participation of excited singlet states of the pigments over distances reaching 15–20 Å. The electron transfer is manifested by the efficient quenching of the fluorescence of the porphyrin fragment and is recorded from the appearance of the characteristic EPR signals of the corresponding radical-ions and the appearance of new absorption bands in the optical spectra of the light-irradiated solutions. In conformity with the existing models of electron tunnelling, the probability of the process decreases exponentially with increase in chain length, depends on the mutual orientation of the porphyrin and the quinone, and is determined by the free energy of the reaction. The variation of the length and nature of the bridge and of the mutual orientation of the porphyrin and the quinone by specific synthesis makes it possible to control the electron transport process in the P–Q compounds. The ineffectiveness of the charge separation via the reaction channel involving the participation of the excited triplet state of the porphyrin is apparently caused by the lower energy of the triplet states compared with the singlet states. For $-\Delta G^0 < 1$–2 eV, this should entail, according to theoretical ideas about the mechanisms of electron transfer reactions, smaller rate constants for processes with participation of excited triplet states of the porphyrin. We may note in this connection studies[110–112] in which intramolecular electron transfer and the charge separation processes were investigated in covalently bound porphyrin–viologen and porphyrin–trinitroaryl compounds. According to preliminary data, the charge separation in these compounds takes place mainly with participation of the triplet states of porphyrins. Further investigation of the dependence of the electron transfer efficiency on the spin state of the pigment is of considerable interest for the theory of oxidation-reduction electron transfer reactions.

The solvent apparently plays an important role in the charge transfer in the P–Q compounds. The data obtained hitherto suggest that the medium influences only the process energetics. However, one must expect the involvement of the medium also in the dissipation of the energy of the resonance defect. This hypothesis is supported by the results of a study[113] of the influence of the isotope composition of the medium on the efficiency of the charge separation process in photosynthesis. The covalently bound P–Q compounds are convenient objects for the study of this interesting phenomenon, which is important for the theory of electron transfer and for the understanding of the mechanisms of charge separation in photosynthesis.

An appreciable increase in the lifetime of the separated charges is attained on passing from P–Q compounds to covalently bound triads. The stepwise character of the charge separation in these molecules ensures a high rate of charge separation and a low rate of their dark recombination.

Appreciable progress has now been achieved in the study of charge transfer processes in P–Q compounds. The results of these investigations promote a correct interpretation of data on the kinetics of electron transfer in photosynthesis. The synthesis and investigation of covalently bound triads with different donor fragments and bridging chains and other model structures containing P–Q fragments permit a deeper understanding of the mechanisms of electron transport in biological structures and will assist in progress towards the development of artificial molecular photocatalytic systems for the utilisation of solar energy.

Quantum-chemical studies of the structure and reactivity of carbenes

V I Minkin, B Ya Simkin, M N Glukhovtsev
Institute of Physical and Organic Chemistry at the Rostov State University

ABSTRACT. The results of quantum-chemical studies on the electronic and geometrical structures and of the singlet–triplet splitting of carbenes (methylene and its derivatives, including unsaturated and cyclic carbenes) are examined and surveyed. The factors regulating the geometrical characteristics and the multiplicity of the electronic ground state of carbenes are discussed. The features of the reaction pathways leading to the addition of electrophilic and nucleophilic carbenes to single and double bonds and the structures of the transition states are analysed.

I. Introduction

The improvement of the methods of modern quantum chemistry and especially the colossal progress in the development of high speed computers have created during the last decade a new situation in chemical science. In many fields, theory has become an equal partner of experiment not only in the formulation of general rules and the development of a conceptual language but also in direct quantitative estimation of particular physical and structural characteristics as well as reactivity. The important role of quantum-chemical analysis, which has assumed a parallel or even a leading position, is manifested particularly strikingly in the study of kinetically unstable intermediate compounds whose experimental detection frequently requires the overcoming of considerable difficulties. Carbenes and their analogues are precisely compounds of this kind. An enormous number of original and review communications have been devoted to the theoretical study of carbenes. The fact that carbenes are non-classical organic structures—derivatives of divalent carbon (more precisely dicoordinate carbon), characterised by a very narrow energy gap between the lowest electronic states with different multiplicities—is of special interest for theory. This leads to unique features in the structure and reactions of carbenes which do not fit within the framework of standard classical ideas.

The main task of this review is to demonstrate the role and possibilities of quantum-chemical research in individual principal aspects of the chemistry of carbenes. We shall consider initially a key carbene–methylene. This is a polyatomic molecule which has been subjected to what has probably been the most detailed theoretical study. The structural and energetic parameters of methylene have been calculated in recent years with unprecedented accuracy. The data obtained constitute the basis of the analysis of the geometrical and electronic structures of substituted carbenes and their analogues. Equal attention will be devoted to both quantitative calculations and to qualitative theories which make it possible to treat in general terms the available results and to predict new ones. The description of reactivity will be limited to the consideration of two most representative types of carbene reactions—addition (insertion) to σ and π-bonds.

Although the review deals almost exclusively with studies of the last decade only, it by no means represents an exhaustive treatment even of this period. Nevertheless we hope that the data presented will make it possible to deduce the leading trends in theoretical research into carbenes—the field of chemical knowledge in which the interaction of theory and experiment is especially effective.

II. Methylene

Although the rigorous spectroscopic identification of methylene, obtained in the flash photolysis of gaseous diazomethane, was not achieved until the beginning of the 1960's,[1,2] this simplest divalent carbon compound has been at the centre of attention of chemists—both experimenters and theoreticians—for almost a century since Nef's first "general theory of methylene" (see the relevant reviews[3–5]). The explanation is, firstly, that methylene is the prototype of all carbenes and without due understanding of the nature of its electronic states, structural features, and reactivity, it is impossible to proceed to the formulation of general ideas about the corresponding characteristics of more complex carbenes and their analogues. Secondly, the study of methylene has created a situation, rare as regards its fruitfulness, of a true partnership and mutual enrichment between theory and experiment in chemical science.

In view of the small size of the methylene molecule, in the 1970's it already became possible to calculate all its characteristics using the most powerful arsenal of non-empirical (*ab initio*) quantum-chemical methods, which are comparable to or even superior to modern experimental methods as regards accuracy. Even in the qualitative aspect, the rigorous theoretical conclusions proved to be more accurate than the conclusions drawn from earlier or current experiments. Thus theoretical predictions have stimulated the formulation of more refined experiments and promoted their more accurate interpretation. The need to test and improve quantum-chemical methods, induced by the observed incomplete agreement between the theoretical predictions and experimental data, stimulated in its turn the development of a methodology for the selection of computational models adequate for the problem formulated. The triumphal history, as regards quantum chemistry, of the establishment of the existing views of the electronic and steric structures and

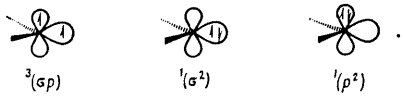
*1According to the σ,p designations, introduced by Hoffmann et al.,[24] the $2a_1$ MO belong to the σ type and the $1b_1$ MO belong to the p type; only the principal components of the two-determinant function are indicated for the 1^1A_1 and 2^1A_1 electronic states.[25] *2The basis set $(5s3p1d/3s1p)$ was used by McLaughlin et al.[16] and 617 configurations were examined taking into account the configuration interaction (CI); the DZP basis set was used by Bauschlicher and Shavitt[18] and in the calculation for the $^1A_1$ state, account was taken of all the singly and doubly excited configurations constructed both relative to the $(2a_1)^2$ configuration and relative to the $(1b_1)^2$ configuration (2R-CI, see Table 2); Meadows and Schaefer[21] used the $(9s6p3d/4s2p)$ basis set; Bauschlicher and Yarkony[23] used the Dunning–Husinaga basis set, supplemented by d and p functions, and the MC SCF method; in the calculation for the 2^1A_1 state, they took into account all the singly and doubly excited configurations (SD-CI, see Table 2). *3A detailed compilation of the singlet-triplet ($^3B_1$–$^1A_1$) CH_2 splittings is given in Table 2. *4The estimate is based on the calculated ($^1B_1$–$^3B_1$) energy difference[22] and the experimental ($^1B_1$–$^1A_1$) difference equal to 98.74 kJ mol^{-1}.[26]
Note. Here and henceforth the numerals in square brackets denote references (Editor of Translation).

energetics of the electronic state of methylene has been described in detail in numerous reviews[5–10] and here we shall trace only concisely the principal stages in the solution of the problems involved, emphasising the final results.

1. Electronic configuration



Methylene belongs to the class of molecules with a triplet electronic ground state, which has been unambiguously demonstrated by the observation of the EPR spectrum of CH_2 in a xenon matrix at 4.2 K.[11,12] The results of almost all sufficiently rigorous computations, both semiempirical (INDO,[13] MINDO,[3,14] MNDO[15]) and non-empirical, agree with the idea that the triplet electronic state of CH_2 is energetically preferred, and this conclusion remains valid for all the geometrical forms of methylene possible in principle: linear ($D_{\infty h}$) and angular (C_{2v}) (Table 1). Fig. 1 presents Walsh's diagram illustrating the dependence of the positions of the energy levels of the valence MO of methylene on the HCH valence angle.

For the electronic valence shell $(1\sigma_g)^2(1\sigma_u)^2(1\pi_u)^2$, the electronic states of the linear molecule are arranged in the following energy sequence:

$$^3\Sigma_g^- < {}^1\Delta_g < {}^1\Sigma_g^+.$$

The angular deformation of the linear structure of methylene induces the splitting of the $^1\Delta_g$ state into the $^1A_1$ and $^1B_1$ states.

The structure of the electronic shells of different electronic states of the angular (C_{2v}) form of methylene is characteristic of biradical systems having virtually degenerate highest partly occupied MO.[7] Table 1 illustrates the types of occupation of the MO of methylene and the corresponding electronic states and also presents data obtained by the most rigorous non-empirical calculations in which account has been taken of the electronic correlation and the experimental data for the geometrical characteristics of these states. On the other hand, the $^3(\sigma p)$ and $^1(\sigma p)$ states are described satisfactorily by the usual one-determinant functions:

The states $^1(\sigma^2)$ and $^1(p^2)$, having the same symmetry, require the application of two-determinant functions taking into account the contributions of doubly excited configurations.

2. The geometry of the electronic ground state

The first non-empirical calculation, carried out in 1960[27] using a minimal basis set of Slater type orbitals with allowance for the introduction of a fairly large number (at that time) of electronic configurations (128), already led to the conclusion that the angular structure of the triplet state $^3B_1$ with a HCH angle of 129° is preferred. However, this conclusion was regarded as one not meriting particular confidence, because the interpretation of the electronic spectrum of methylene, current at the time, although not excluding its assignment to a bent structure,[2,19,28] nevertheless favoured the alternative linear $D_{\infty h}$ form.

The conclusion drawn from subsequent quantum-chemical calculations for the methylene molecule (see Schaefer's detailed review[29]) that the triplet state has a linear structure was regarded as "being in excellent agreement with the observed electronic states of CH_2",[28] whereas predictions of the angular structure were regarded

as a consequence of an unsuccessful selection of the computational method.

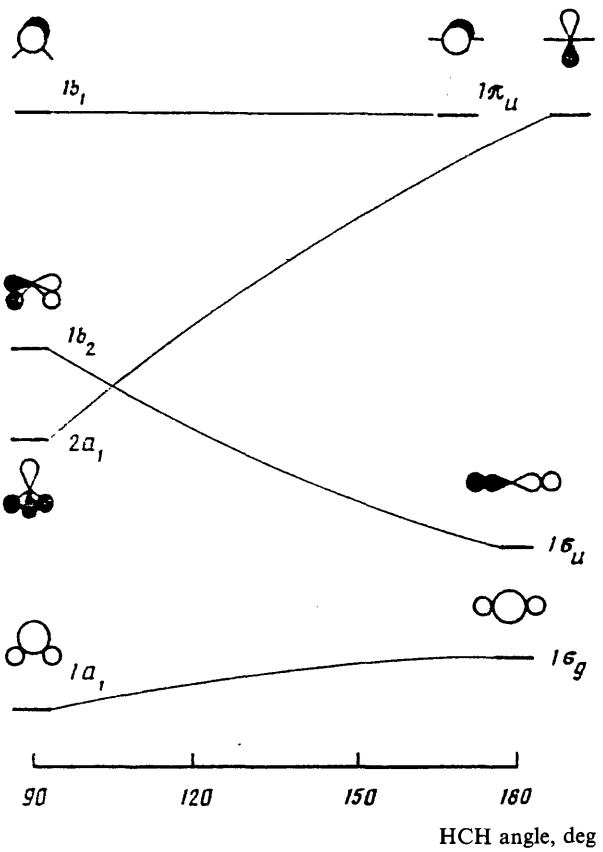


Figure 1. The correlation diagram for the lowest valence MO of the linear and angular structures of methylene illustrating the dependence of the energy levels of the orbitals on the HCH angle.

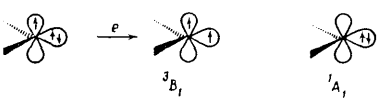
The situation changed radically after non-empirical calculations,[30] performed with an extremely high degree of accuracy (basis set of Gaussian orbitals of the *DZ* type, allowance for 408 configurations including all single and double excitations) and predicting a HCH angle of 135.1° for the angular C_{2v} form of the ground state of methylene. This value proved to be in good agreement with the value 135 ± 8° obtained soon afterwards from the analysis of the EPR spectrum of triplet methylene,[11] which induced a return to the interpretation of the spectroscopic parameters of CH_2 on the basis of the bent structure.[31] According to the best experimental estimate, it is currently believed that the HCH angle for methylene in the $^3B_1$ state is 133.84 ± 0.05° [17] (Table 1). The energy barrier to the planar inversion of the triplet ($^3B_1$) methylene, i.e.



is only 22.32 ± 0.96 kJ mol^{-1} [17] and only two vibrational levels lie below the barrier. This means that the methylene molecule in the ground state should be regarded as essentially quasi-linear, like BaX_2 (X = Cl, Br).[32]

3. Singlet–triplet splitting

The most exact energy difference (ΔE_{S-T}) between the ground triplet ($^3B_1$) and first excited singlet ($^1A_1$) states is 37–38 kJ mol^{-1}. Before proceeding to the discussion of the experimental and calculated data, we may note the difference between the values of ΔE_{S-T} determined experimentally and obtained as a result of the primary quantum-chemical calculation. In the former case, ΔE_{S-T} corresponds to the energy difference between the ground vibrational states (which were designated by T_0) and in the second to the difference (T_e) between the energies of the minima on the potential energy surfaces for the electronic states $^3B_1$ and $^1A_1$. Since in the ground electronic state $^3B_1$ the C–H bonds are shorter and stronger than in the state $^1A_1$ (see Table 1; the experimental energies of the C–H bonds and the theoretical values close to them are 441 kJ mol^{-1} for $^3B_1$ and 410 kJ mol^{-1} for $^1A_1$ [33]), the extension of these bonds in the state $^3B_1$ requires more energy. As a result, the energy of the zero-point vibrations is greater for the triplet state than for the excited singlet state. According to Petek et al.[34] and Bunker and Jensen,[35] $T_e - T_0$ = 0.12 ± 0.71 kJ mol^{-1}. Although allowance for the relativistic correction (about 0.17 kJ mol^{-1} [5,36]) increases this difference to 0.3 kJ mol^{-1}, it is clear that the effects considered are comparatively small.

Up to the middle of the 1970's, ΔE_{S-T} = 33 ± 4 kJ mol^{-1} was adopted as an experimental estimate based on different indirect determinations,[29,37,38] which was in acceptable agreement with the results of most accurate non-empirical quantum-chemical calculations.[6,29,39] However, a direct determination of ΔE_{S-T} in the laser photoionisation of the CH_2^- anion was reported in 1976. This yielded 81.6 ± 2.9 kJ mol^{-1}.[40]

The subsequent series of calculations, in which an increasingly higher accuracy was employed (see the relevant reviews[9,10]) did not bring the theoretical value ΔE_{S-T} and that found by Zittel et al.[40] closer together. This induced theoreticians to reinterpret the experimental data.[41] According to Zittel et al.[40] and Engelking et al.,[41] the beam of CH_2^- anions contains no vibrationally excited ions which could lead to the appearance of additional "hot bands" in the photoelectron spectrum. However, calculation of the energy of the vibrational levels using wave functions obtained with the aid of the generalised valence bond method showed that the fourth vibrational level of CH_2^- lies above the ground vibrational level of the triplet $^3B_1$ state of CH_2,[42] which means that three "hot" bands might have been observed in the photoelectron spectrum of CH_2^- and this band assignment would in fact lead to T_0 = 37.6 kJ mol^{-1} [43,44] in agreement with previous theoretical and experimental data. Modification of the photoionisation experimental method in order to exclude the appearance of "hot bands" made it possible to obtain experimentally T_0 = 37.6 kJ mol^{-1}.[45] Very similar values of T_0 (35.6 ± 2.9 kJ mol^{-1} [46] and 37.86 ± 0.025 kJ mol^{-1} [47]) were found almost simultaneously in other studies whose aim was a direct experimental determination of the energy of the singlet–triplet

splitting in methylene (see also a detailed compilation in other reviews[5,8,9]). At the present time the most accurate experimental estimate of ΔE_{S-T} is believed to be $T_0 = 37.75 \pm 0.058$ kJ mol^{-1}.[20] When account is taken of the corrections for the relativistic effects and the zero-point vibration energy, $T_e = 38.03 \pm 0.84$ kJ mol^{-1} (the diagonal correction to the Born–Oppenheimer approximation is 0.46 kJ mol^{-1} [48]).

4. Methylene as a test structure in quantum chemistry

The theoretical results examined above have generally been achieved with methods giving the highest degrees of accuracy whose employment in the study of more complex carbenes involves considerable computational difficulties. The questions to what extent particular properties of methylene are described by simpler methods, including semiempirical ones and also whether qualitative theoretical ideas adopted in chemistry are applicable to the description of the properties of methylene have therefore acquired extremely great importance. Although the answers to these questions do not guarantee an unambiguous selection of an adequate method for the calculation of the characteristics of more complex carbenes, nevertheless they could be regarded as a very important basis for such a selection and for the estimation of the reliability of a particular calculation.

We shall deal initially with non-empirical calculations (Table 2). The refinement of the results is achieved here both by expanding the set of basis functions and by improving the allowance for electron correlation. In order to obtain geometrical characteristics of methylene in the $^3B_1$ and $^1A_1$ states close to experimental values, it is sufficient to use even the minimal basis set (STO-3G) or the simplest split basis set (3-21G) of the orbitals and the transition from the approximation of the restricted Hartree–Fock method to the unrestricted method and allowance for the energy of electron correlation do not exert a significant influence on the results of the calculation of the CH bond length and the HCH angle.[58,59] On the other hand, Table 2 shows that the selection of the basis set and allowance for the correlation corrections are very important for the estimation of ΔE_{S-T}. When polarisation functions are included in the basis set, the state $^1A_1$ is stabilised to a greater extent because the description of the polarisation orbital of the unshared electron pair $2a_1$ is then improved more than that of the non-polar p orbital $^1b_1$ (Fig. 1). An especially significant improvement is attained when the two-determinant function (TCSCF) is resorted to for the state $^1A_1$. If account is taken of all the single and double excitations relative to both configurations used for the description of this state (2R-CI), it is possible to obtain $\Delta E_{S-T} = 41.0$ kJ mol^{-1}. According to the best estimate of ΔE_{S-T} obtained at the present time by the non-empirical calculation, this quantity is 37.78 kJ mol^{-1},[52] which virtually agrees with the experimental value.

In contrast to the non-empirical computational methods, for which there exists a definite hierarchy ensuring a gradual improvement of the results on going over to higher degrees of accuracy, the semiempirical methods have been parametrised in order to reproduce specific properties (see, for example, Minkin et al.[60]). As a result of this, not only individual properties of a compound but also the properties of all classes of compounds are described better by one of the methods than by others. Comparison of the results of calculations for methylene and its derivatives by the most widely used semiempirical CNDO, INDO,[61] MINDO/2,[62] MINDO/3,[63] and MNDO[15] methods shows quite definitely that preference should be given to the MINDO/3 method. The calculation by this method for the $^3B_1$ state yields the following values: HCH angle 134.1°, $R_{CH} = 0.1078$ nm, and $\Delta E_{S-T} = 36.4$ kJ mol^{-1},[14]† which agrees well with the most accurate experimental data (Table 1).

Table 2. The results of non-empirical calculations of the energy of the singlet–triplet splitting ΔE_{S-T} for methylene (in kJ mol^{-1}).

Basis set	Computational scheme*1					
	SCF	TCSCF	SD-CI	SD(Q)-CI	2R-CI	GVB-RCI
Minimal (2*s*1*p*) for C, (1*s*) for H	167.7 [49]	133.9 [50]				
DZ (4*s*2*p*/2*s*)	135.5 [18, 51]	95.4 [18, 51]	99.2 [18]	92.0 [18]	92.8 [18]	
DZP (4*s*2*p*1*d*/2*s*1*p*)	109.6 [18]	53.5 [18]	61.1 [18]	51.9 [18]	51.0*2 [18]	48.1 [52]
Extended basis set with polarisation functions (6*s*4*p*2*d*/3*s*2*p*)	104.6 [18]	46.4 [18]	55.2 [18]	45.6*3 [18]	44.3*4 [18]	
Very large basis sets [from (8*s*5*p*3*d*/4*s*1*p*) to (9*s*7*p*2*d*1*f*/5*s*2*p*)]	103.7 [18]	44.8 [53]	54.8 [54]	45.2 [54]	41.0 [53]	37.8 [52]

Note. Data presented in two reviews,[5,8] supplemented by the results of subsequent studies, were adopted as a basis; the experimental energy difference is $\Delta E_{S-T} = 37.75 \pm 0.058$ kJ mol^{-1}.[20]

*1For the readers convenience, the notation adopted in the original English language publications has been retained: TCSCF—two-configuration wave function for the state $^1A_1$ (see Table 1); SD-CI—configuration interactions (CI) with allowance for all the singly and doubly excited configurations; SD(Q)-CI—as for SD-CI but account is taken of the correction for fourfold excitations;[55] 2R-CI—allowance for single and double excitations both in the configuration $(2a_1)^2$ and in the configuration $(1b_1)^2$ for the state $^1A_1$; GVB-RCI—calculation by the generalised valence bond method taking into account the restricted CI.

*2With more complete allowance for the CI, $\Delta E_{S-T} = 50.1$ kJ mol^{-1} was obtained.[56]

*3Calculation in terms of the 6-31G basis set.

**Allowance for the electronic configuration in terms of the Meller–Plesset theory (MP4SDTQ) yields $\Delta E_{S-T} = 54.8$ kJ mol^{-1}; expansion of the basis set and extrapolation make it possible to obtain $\Delta E_{S-T} = 34.3$ kJ mol^{-1}.[33]

*4Calculation in terms of the (6*s* 4*p*2*d*; 4*s* 2*p*) basis set yields $\Delta E_{S-T} = 45.6$ kJ mol^{-1}.[57]

The question arises to what extent qualitative theories make it possible to account for the electronic and geometrical structure of methylene. The conclusion that the lowest singlet state of methylene $^1A_1$ or $^1(\sigma)^2$ has a bent structure follows quite definitely from simple orbital ideas and Walsh diagrams. This structure is preferred because of the significant decrease in the energy of the doubly

† However, one should note that the solution obtained by the MINDO/3 method for the state $^1A_1$ is triplet-unstable.[66] This means that the unrestricted Hartree–Fock (UHF) approximation must be resorted to, which makes it possible to obtain for the given state a solution with a lower energy (see, for example, Refs. 67–69). As a consequence of this, ΔE_{S-T} is reduced.

occupied $2a_1$ MO as the valence angle is reduced[64] (Fig. 1). When hybrid orbital ideas are used, i.e. on going over from canonical to localised orbitals, the valence state of the carbon atom of the angular form $^1(\sigma)^2$ of methylene can be described as $(sp^3)^2(sp)^2$, i.e. $s^{3/2}p^{5/2}$,[65] or as $(sp^2)^4$, i.e. $s^{4/3}p^{8/3}$,[8] whereas the valence state of carbon in the linear form is $(sp)^2(p)(p)$, i.e. sp^3. If the valence state of the carbon atom in methylene remained the same as in the ground state of the carbon atom $(1s)^2(2s)^2(2p)^2$, i.e. s^2p^2, singlet methylene would have an angular structure with a valence angle of 90°. In this structure, there is no need for energy expenditure on the $s \rightarrow p$ promotion of a whole electron, as in the transition to the linear form ($s^2p^2 \rightarrow sp^3$) or of "part" of an electron, as in the transition to forms with C–H sp^3-bonds (109.5°) or C–H sp^2-bonds (120°). However, with increase in the valence angle, the repulsion between the electron pairs of these bonds diminishes. The balance between the expenditure on the promotion of an electron from the s to the p orbital, which increases with increase in the valence angle, and the gain attained under these conditions in the repulsion energy of the electrons of the C–H bonds with a simultaneous increase in the strength of the latter as a result of the hybridisation of their constituent carbon orbitals determines the geometry of the singlet methylene.[6,65]

On the other hand, analysis of the Walsh diagram (Fig. 1) for the triplet state $^3B_1$ or $^3(\sigma p)$ does not make it possible to settle reliably on the angular structure. Indeed, the stabilisation attained with decrease in the valence angle of the singly occupied $2a_1$ MO is accompanied by an increase in the energy of the doubly occupied $1b_2$ MO and also by a slight destabilisation of the singly occupied $1b_1$ MO. In particular, Walsh himself was inclined towards the conclusion that the triplet state of methylene has a linear geometrical structure.[64] According to Dewar,[65] the angular structure of the triplet state of methylene can be accounted for within the framework of the idea of σ-conjugation if allowance is made for the fact that the transition, not requiring an energy expenditure on the promotion of s electrons, from the valence state $(sp)^2(p)(p)$, corresponding to the linear structure, to the state $(sp^2)^3(p)$ ensures additional stabilisation of the angular structure as a consequence of the σ-conjugation between the three-hybrid sp^2 orbitals.

III. Derivatives and isoelectronic analogues of methylene

When the hydrogen atoms in the methylene molecule are replaced by the usual substituents (X, Y), the frontier character of the $^3(\sigma p)$ and $^1(\sigma^2)$ states is retained on passing to silylene and other isoelectronic analogues. However, the replacement of the hydrogen atom in CH_2 can induce changes in the XCY valence angle and in the singlet–triplet splitting extending to the stabilisation of the linear form and the reversal of the multiplicity of the ground electronic state. The latter effect is well known. For example, halogenomethylenes as well as silylene SiH_2 and germylene GeH_2 have singlet $^1(\sigma^2)$ ground electronic states.[5,25,70]

The question which substituents promote the stabilisation of the singlet or triplet electronic states is especially interesting, since the reactivity of the carbene depends significantly on the character of the electronic state. The triplet state is preferred if the energy difference between the frontier orbitals is less than the Coulombic repulsion integral J_{12} between the electrons in these orbitals, i.e. $\Delta\varepsilon_{12}-J_{12} < 0$. As a rule, this condition is fulfilled when the splitting of the level of the frontier orbitals $\Delta\varepsilon_{12} \leqslant 1.5$ eV (145 kJ mol^{-1}). With increase in the above energy gap, the ground state of the carbene corresponds to the singlet electronic configuration.[24] Thus the energy gap between the frontier orbitals a_1 and b_1 of methylene is 113 kJ mol^{-1} according to the extremely accurate MP4SDTQ/6-31G** calculations,[71] while for silylene the corresponding value is as much as 217 kJ mol^{-1}.

Hoffmann and co-workers[24,72] formulated qualitatively the general principles of the selection of substituents at the carbene centres which ensures an increase in the energy gap $\Delta\varepsilon_{12}$ and an increased stabilisation of the singlet (compared with the triplet) electronic state of the carbene.[24,72] The substituents must meet the following requirements: (1) they must tend to decrease the XCY valence angle, which leads, as can be seen from Fig. 1, to an appreciable increase in the distance between the σ and p levels; (2) it must have low-lying unoccupied π^* orbitals in one or both substituents; (3) it must have high-lying occupied π or n orbitals in these substituents. The orbital interaction diagrams illustrated in Fig. 2 explain the nature of the stabilisation of the states with closed electron shells.

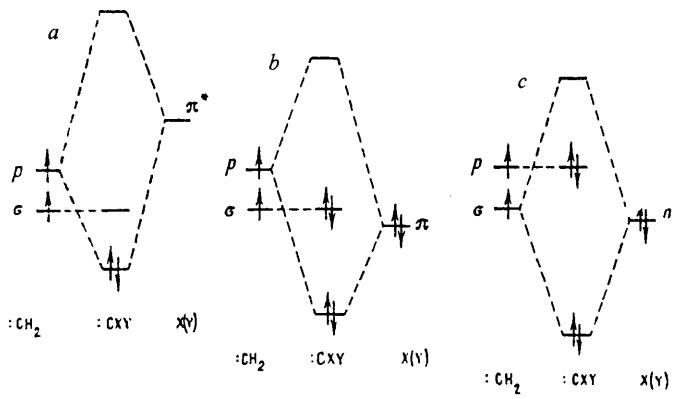


Figure 2. The interactions between the frontier orbitals of methylene (see Fig. 1) and the orbitals of the substituents X and Y in the carbene: CXY; *a*, acceptor substituents with a low-lying unoccupied π^* orbital; *b*, and *c*, donor substituents with high-lying occupied π and n (orbital of the unshared electron pair) orbitals.

Table 3. The singlet–triplet splitting energies ΔE_{S-T} for certain carbenes and their analogues obtained with the aid of non-empirical calculations taking into account the electronic correlation.

*1The experimental values are given in round brackets and the thermochemical estimates are given in square brackets.[74]

*2Here and below the designations indicated in Table 2 are used.

A) TCSCF, allowance for Davidson's correction;[55] basis set: (5*s*4*p*2*d*) for C, (5*s*4*p*2*d*) for F, (3*s*2*p*) for H, (7*s*6*p*2*d*) for Cl, and (10*s*8*p*4*d*) for Br.[74]

B) Generalised valence bond method (GVB); allowance for CI.

C) MP4SDTQ/6-31G*—calculation in terms of the 6-31G* basis set taking into account the electronic correlation on the basis of the Meller–Plesset perturbation theory (see the footnotes to Table 2).

D) (9*s*5*p*/8*s*) basis set for CLi_2 and the (9*s*5*p*/4*s*/8*s*), 2R-CI basis set for CHLi.

E) STO-3G basis set for the triplet states; caculations in terms of the UHF approximation.

F) Basis set of the STO-3G type; CI 2 × 2 for the singlet state.

G) DZ basis set; SD-CI.

H) STO-3G basis set.

I) 6-31G** basis set; MCSCF.

K) (9*s*6*p*3*d*) basis set for silicon and (4*s*2*p*) basis set for hydrogen.

L) 6-31G* basis set; SD-CI.

M) DZ + P basis set; CI with allowance for not only single and double excitations but also triple excitations.

N) (9*s*6*p*3*d*) basis set for nitrogen and (4*s*2*p*) basis set for hydrogen; TCSCF.

*3When account is taken of the full CI, the quantity ΔE_{S-T} varies from −77 to −73 kJ mol^{-1} depending on the basis set.[88]

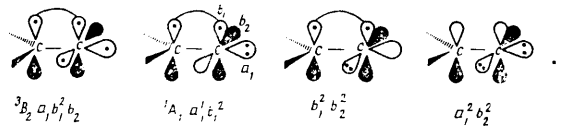
*4In calculations in terms of the DZ + P basis set, allowance for the CI (SD-CI) made it possible to observe two minima on the PES for HSiLi corresponding to different structures of the triplet state $^3A''$; ΔE_{S-T} = 29.3 kJ mol^{-1}.[89]

Table 3 presents a compilation of calculated data, which are currently most accurate, for the singlet–triplet splittings in certain simple derivatives and analogues of methylene (in conformity with the requirements imposed on the computational scheme which were discussed in the previous Section).

The results presented agree well with the predictions of the orbital model. In the presence of *n*,π-donor substituents (halogens, amino- and hydroxy-groups) as well as π-acceptor substituents with low-lying unoccupied π^* orbitals (BH_2, O=), the singlet electronic state of the carbene is highly stabilised. The decrease in the electronegativity of the central atom leads to the same result in the series of isoelectronic analogues of methylene: NH_2^+, CH_2, PH_2^+, SiH_2, GeH_2.

A convenient heuristic model, permitting an extremely reliable prediction of the trend towards the stabilisation or destabilisation of the singlet (triplet) state in carbenes and their analogues $AX_2(AXY)$ from the relation between the electronegativity of the central atom A and the substituents X, has been proposed.[78,90]

The increase in the electronegativity of the substituents X(Y) and in the electropositive character of the central atom A led ultimately to the ionic structure $X^-A^{2+}X^-$, in which A^{2+} has a valence electron shell similar to the shell of the beryllium atom with its singlet electronic state ^1S. Consequently, the above factors tend to stabilise the singlet forms of the carbenes and their analogues, as has been observed, for example, for dihalogenocarbenes, silylene, etc. On the other hand, a decrease in the electronegativity of the substituents X and an increase in the electronegativity of the central atom create conditions for the appearance of the limiting ionic structure $X^+A^{2-}X^+$, in which A^{2-} has the electron shell of the oxygen atom. It has a triplet (^3P) ground electronic term. Hence it follows that such substitutions should stabilise the triplet form of carbene and its analogues. This is confirmed by the preference for the triplet states of the cation $^+NH_2$ and the carbenes CHLi and CHBeH (Table 3).



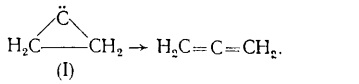
When substituents with a low electronegativity of the central atom, such as those of the Group I–III elements, are introduced at the carbon atom, an interesting stereoelectronic effect appears—the stabilisation of the linear $D_{\infty h}$ structure of the singlet state of the carbene CX_2. The linear form of these carbenes has been predicted qualitatively both within the framework of the delocalised three-centre two-electron bond model[91] and within the framework of the ideas of Pauling's resonance theory.[92] The Li, Be, and B atoms contain unoccupied *p* MO capable of forming common MO with the σ orbital of the singlet carbene, the best overlap conditions and hence the highest stabilisation being attained for the linear and not the angular configuration. The results of non-empirical calculations[59,71,77,78,93] (see also Table 3) agree with this model.

IV. Unsaturated and cyclic carbenes

The multiplicity and electronic structure of unsaturated and cyclic carbenes in their ground states and the reactivity associated with these features are determined by the following three factors: (1) the character of the hybridisation of the σ orbital of the carbene centre, which depends on its valence angle, (2) the aromaticity or anti-aromaticity of the π system which includes the π orbital of the carbene centre, and (3) the effects induced by the involvement of the σ orbital of the carbene centre in the formation of the cyclic σ-conjugation system. The importance of the first two factors was already noted in early theoretical investigations of the electronic structure of carbenes,[24,72,79] while the role of the σ-conjugation began to become clear comparatively recently.[65,94,95] We shall

examine the manifestation of the above effects in relation to the most representative carbenes.

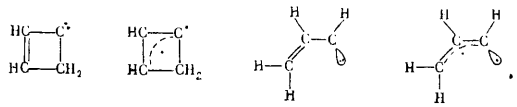
Vinylidene. Vinylidene is the prototype of unsaturated alkylidenecarbenes $R^1R^2C=(C)_n=C$: detected as intermediates in many reactions.[96] It can be regarded formally also as a cyclic carbene whose ring has contracted to the maximum extent, i.e. with the minimum (0°) valence angle at the carbene centre. As a result of this, the non-bonding σ orbital a_1 of the vinylidene has the greatest amount of *s* character[97] and therefore has a lower energy level than the σ orbital in methylene. As a result, the presence of the electron pair in the σ orbital (with the configurations $a_1^2b_1^2$ and $a_1^2b_2^2$) proves to be energetically more favourable than the occupation of the $a_1b_1^2b_2$ orbital corresponding to the triplet state. The largest additional contribution to the wave function of the ground singlet state $^1A_1$ of vinylidene also comes from the $b_1^2b_2^2$ valence configuration:[97]



The results of numerous semiempirical[62,72,98] and non-empirical[97,99–101] calculations agree with experimental data[102] showing that the singlet electronic state of vinylidene is preferable. The calculated values of ΔE_{S-T} are as follows (in kJ mol^{-1}): –85.8 (MINDO/2 [62]), –192.0 [*ab initio*, generalised valence bond method, (4*s*2*p*1*d*, 4*s*2*p*1*d*/2*s*) basis set[99]], and –213.8 (*ab initio*, the same basis set, allowance for electron correlation on the basis of the many-particle perturbation theory[97]).

Structurally vinylidene is the prototropic tautomer of the thermodynamically more stable acetylene and the possibility of the experimental detection of vinylidene therefore depends on the energy barrier to the 1,2-shift of hydrogen:

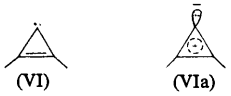
According to the results of non-empirical calculations, the height of this barrier is (taking into account the zero-point vibration energies) 19.2 kJ mol^{-1} [103] or even 3.8 kJ mol^{-1} [104] and it has therefore been suggested that the structure of vinylidene corresponds to a very shallow minimum on the potential energy surface of C_2H_2 or in fact represents the transition state in a degenerate rearrangement of acetylene.[104] Calculations[105] have shown that the energy barrier to the 1,2-shift of hydrogen persists even when a very expanded basis set is used. The barrier has been estimated as 8–17 kJ mol^{-1} (the corresponding lifetimes range from 0.24×10^{-12} to 4.6×10^{-12} s). Experimental studies on the photoionisation of $H_2C=C^-$ have led to the conclusion that the vinylidene does indeed exist and has a lifetime of at least 10^{-14} s.[102] There exist fairly detailed reviews of the theoretical calculations of the 1,2-shift of hydrogen and other migrants in vinylidene and its derivatives.[104,106,107]



Cyclopropylidene (I). There are no experimental data for the multiplicity of the ground electronic state of cyclopropylidene, but, in view of the smallness of the valence angle at the carbene centre, one may expect in this instance the stability of the singlet electronic configuration $^1(\sigma^2)$. The σ-conjugation effect stabilising this configuration should also be manifested. Indeed, although the results of early non-empirical calculations using the orbital basis sets STO-3G [108] and 4-31G [109] indicated a triplet ground state, allowance for electron correlation and the inclusion in the basis set of polarisation functions led to a revision of this conclusion.[79,110,111] The calculated values of ΔE_{S-T} proved to be –52 kJ mol^{-1} [DZP basis set, SD(Q)-CI allowance for configuration interactions[110]] and –39 kJ mol^{-1} (MP3/6-31G** [111]). It is striking that the CH_2CCH_2 valence angle for the singlet state $^1A_1$ is smaller by 6–7° than for the triplet state. This creates an additional strain in the structure of the ground state of cyclopropylidene, which leads to a low-barrier valence isomerisation (of the "bond extension" type) to the more stable allene:

(I)

According to MP3/6-31G** calculations,[111] the barrier to this reaction is 48 kJ mol^{-1} (see also Klett and Johnson[112]).

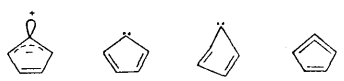


Cyclobutenylidene (II). The role of the effect due to the fusion of the *p* orbital of the carbene centre with the π system of the remaining fragment of the molecule is clearly manifested in the case of cyclobutenylidene, although the CH_2CCH angle in this species is much smaller than the HCH angle in methylene. However, both semiempirical (MINDO/3 [113]) and non-empirical (STO-3G, 2 × 2 CI [79]) calculations make it necessary to give preference to the triplet ground state. The quantity ΔE_{S-T} has been estimated as 25 ± 8 kJ mol^{-1}.[79] The evident explanation is that the triplet cyclobutenylidene is in essence a stabilised σ,π-biradical of the allyl type (III):

(II) (III) (IV) (V)

The structure of the species (III) represents the cyclic analogue of the vinylmethylene (IV), which has been studied both experimentally[114] and theoretically[110,115] and for which a planar structure with a triplet ground electronic state of type (V) has been shown to be preferable.

Cyclopropenylidene (VI). When the *p* orbital of the carbene centre is included in the overall π system of the three-membered ring, the latter contains two π electrons, which means that the singlet $^1(\sigma^2)$ configuration is more favourable than the $^3(p\sigma)$ configuration. An important factor promoting the appearance of the $^1(\sigma^2)$ configuration is also the decrease in the energy of the σ orbital of the carbene atom as a consequence of the increased amount of *s* character as a result of the smaller bond angle as compared with methylene.[116,117] Thus the singlet state 1^1A_1 of the zwitter-ionic[25] π-aromatic type (VIa) is stabilised:

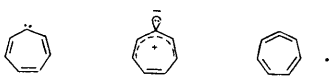


(VI) (VIa)

The stability of the singlet state of cyclopropenylidene has been predicted by both semiempirical[72,118–120] and non-empirical[79,93,121–124] calculations. According to the most accurate estimates, ΔE_{S-T} is –217 kJ mol^{-1} [MK SSP (MCSCF), (4*s*2*p*-C/2*s*-H) basis set[123]] and –294 kJ mol^{-1} (TCSCF, DZ + P basis set[124]). The calculated dipole moment (3.4 D)[124] is extremely high for a hydrocarbon, which agrees well with the prediction that cyclopropenylidene has the structure of the onium anion (VIa).

Cyclopropenylidene has been identified in the matrix isolation of the products of the flash pyrolysis of a quadricyclane derivative[125] and the absence of the EPR signal confirmed the singlet character of its electronic state. Probably by virtue of its π-aromatic character, the species (VI) is distinguished by a fairly high stability towards isomerisation reactions. It is not fortuitous that cyclopropenylidene is one of the components of the molecular clouds in interstellar space.[126]

Cyclopentadienylidene (VII). The singlet π-aromatic six-electron configuration of cyclopentadienylidene arises under the conditions of the double occupation of the $^1(p^2)$ *p*-orbital of the carbene centre, so that the σ orbital remains unoccupied.[25] However, the 6π-electron structure (VIIa) with a carbanion–cation electron distribution (see, for example, the results of calculations by the MINDO/3 and MNDO methods[119,120]) is less stable according to non-empirical MCSCF calculations[127] than the π-antiaromatic 4π-electron structure of the type $^1(\sigma^2)$ (VIIb):



(VIIa) (VIIb) (VIII) (IX)

This unexpected result can be simply explained qualitatively within the framework of the idea of σ-aromaticity and σ-antiaromaticity.[94] In contrast to cyclopropenylidene, whose molecule is both π-aromatic and σ-aromatic, the simultaneous attainment of both π- and σ-aromaticity is impossible for cyclopentadienylidene. The structure (VIIa) is σ-antiaromatic, while the structure (VIIb) is π-antiaromatic. As a result, their energies may prove to be higher than the energy of the triplet state $^3B_1$. Accordingly the zwitterionic singlet state 2^1A_1 ($p^2\sigma^2$) and the singlet state $^1B_1$ of the biradical type ($p^1\sigma^1$) have similar energies for (VIIa), whereas the states 1^1A_1 ($p^0\sigma^2$) and $^1B_1(p^1\sigma^1)$ have similar energies for (VIIb). Consequently the "lumomeric"[128] forms (VIIa) and (VIIb) should be subject to a second-order Jahn–Teller effect and are unstable relative to the b_1-distortion ($a_1 \times b_1 = b_1$) with formation of the structure (VIII) having the C_s symmetry. As a result, the multiplicity of the ground electronic state is determined by the extent to which this distortion stabilises the singlet electronic configuration relative to the structure of the triplet state.

Indeed, according to semiempirical[94,120,129] and non-empirical[130] calculations, the planar structures (VIIa) and (VIIb) do not correspond to minima on the potential energy surface (PES) of the singlet state‡ in contrast to the C_s structure, which has a lower energy. According to the experimental data (see, for example, Wasserman et al.[132] and Baird et al.[133]), calculations by the MINDO/3,[94,120,129] MNDO,[120] and *ab initio*[94,130] methods indicate that cyclopentadienylidene has the $^3B_1$ triplet ground state.

Cycloheptadienylidene (X). With increase in ring size, the effects of σ-aromaticity and σ-antiaromaticity rapidly decay[65] and their role becomes insignificant. The degree of π-aromaticity [the tendency to form the 6π-electron onium anion (Xa)] proved insufficient for the stabilisation of the singlet $^1(\sigma^2)$ state as happens in the case of cyclopropenylidene:

(X) (Xa) (XI)

Indeed the EPR spectrum indicates the triplet character of cycloheptatrienylidene (X),[134,135] which agrees with the results of semiempirical calculations by the MINDO/3[120] and MNDO[120,136] methods. However, the results of non-empirical calculations[137,138] conflict with this conclusion. According to recent calculations (TCSCF, DZ + P basis set[138]), cycloheptatrienylidene nevertheless has a singlet ground state [the planar structure (X) with C_{2v} symmetry, ΔE_{S-T} = –18.8 kJ mol^{-1}]. At the same time, for the equilibrium geometry of the triplet state, the structure of the singlet state has an energy higher by 28.0 kJ mol^{-1}. This can be used to explain the experimental data[134,135] if it is assumed that the rate of the triplet–singlet transition is low and that the carbene (X), generated in the triplet form on photolysis of diazocycloheptatriene, does not have time to relax to the more stable singlet form during the measurement of the spectrum.

It has been shown by semiempirical[120,136,139] and non-empirical[139] calculations that the most stable valence-isomeric form of the carbene (X) is the less symmetrical chiral C_s structure of the singlet cycloheptatetraene (XI), whose energy is lower by 61–96 kJ mol^{-1} than that of the singlet cycloheptatrienylidene. The reactions and rearrangements of cycloheptatetraene (XI) then differ from the reactions of the carbene (X) and different pathways lead to their formation.[140,141]

The energy balance between the carbene and allene forms of cyclic carbenes is determined by the relative contributions of two opposed tendencies: the endeavour to retain the aromaticity in the carbene form and to undergo a transition to a structure with a tetravalent carbon atom. This balance depends primarily on the ring size. Thus, whereas the allene isomer of cyclopentadienylidene (VII) is too strained and does not correspond to a minimum on the PES for C_5H_4,[120] for both cyclononatetraenylidene C_9H_8 and the species (X), the stable cyclic isomer is cyclononapentaene.[120]

V. Reactions of carbenes

The experimental data concerning the influence of the multiplicity of the carbene on its reactivity enabled Skell and co-workers[4,142,143] to formulate definite rules. Firstly, carbenes react at much higher rates in the singlet electronic state than in the triplet state and the absolute rates of typical reactions involving addition to multiple bonds and insertion in C–H bonds normally exceed the rate of intersystem crossing. Secondly, single-stage stereospecific addition to double bonds is characteristic of singlet carbenes, while triplet carbenes react non-stereospecifically, forming initially an intermediate biradical on addition to one of the atoms of the double

‡ *Ab initio* calculations (3-21G basis set) have shown that the planar 6π-electron structures of aza-substituted (2,3-diaza- and 2,3,4- and 2,3,5-triaza) cyclopentadienylidenes also do not correspond to minima on the corresponding potential energy surfaces.[131]

bond. The formation of the trimethylene radical on addition of triplet methylene ($^3B_1$) to ethylene has been confirmed by semi-empirical[62,144] and non-empirical[145,146] quantum-chemical calculations.

Such specificity of the reactivity of carbenes as well as the fact that the majority of the experimentally investigated carbenes have a singlet state have been responsible for the special interest in the reactions of singlet carbenes. The vast majority of theoretical studies have been devoted to their analysis. We shall consider only the reactions involving addition to a carbon–carbon double bond and to single bonds in the study of which the conceptual basis of the theoretical chemistry of carbenes and their analogues has been created.

1. Addition to a C = C bond

From the electronic configuration $^1(\sigma^2)$ of singlet carbenes, one would expect that they should manifest both electrophilic (unoccupied p orbitals) and nucleophilic (the electron pair of the σ orbital) properties. In reactions involving addition to alkenes and other compounds with multiple bonds, the "philicity" of the carbene is determined by the energy gap (ε_{LUMO}–ε_{HOMO}) between the frontier orbitals of the reacting molecules. The stabilising two-electron interaction between these orbitals is greater the smaller the gap and the greater the overlap integral between the frontier orbitals in the region of the transition state of the reaction. The relative disposition of the frontier orbitals of the reactants most typical for carbenes is illustrated in Fig. 3*a*. It corresponds to the predominance of the electrophilic properties of the carbene. Fig. 3*b* illustrates the destabilisation of the p orbital of the carbene after the introduction of strong π-donor substituents X and Y, which has been predicted by non-empirical calculations[147] and which leads to the manifestation of nucleophilic properties ($\sigma \rightarrow \pi^*$ interaction). Finally there is a possibility of the approximate equality of the $\sigma \rightarrow \pi^*$ and $\pi \rightarrow p$ interactions (Fig. 3*c*), which makes it possible to introduce the concept of ambiphilic carbenes.

The "philicity" of the carbene is directly related to the structure of the transition state of the addition reaction. It is well known that the orbital symmetry conservation rules forbid the symmetrical minimum movement pathway (C_{2v}).[144] For electrophilic carbenes with the predominant $\pi \rightarrow p$ interaction, the so called π-approach is preferable (Fig. 3). In the case of nucleophilic carbenes, the best conditions for the overlap of the σ_{CXY} and π^* orbitals are created by the asymmetric σ-approach (Fig. 3*b*). Using certain assumptions, the overlap integrals S between the corresponding frontier orbitals of the carbene and the alkene have been calculated[147,148] in terms of the versions based on the π- and σ-approaches and the energies of the above orbitals have been evaluated, which made it possible to find the stabilisation energies for the two types of interaction of the frontier orbitals:

$$\Delta E \simeq S^2_{HOMO\text{-}LUMO}/(\varepsilon_{LUMO} - \varepsilon_{HOMO} - Q),$$

where $Q \simeq 5$ eV is the correction for the change in the values of ε for the reactants when they approach one another.

The ratio of the stabilisation energies in the nucleophilic (σ) and the electrophilic (π) approaches the theoretical value of the "philicity" $PI_{CXY} = \Delta E_n/\Delta E_e$, which is less than unity for electrophilic carbenes, more than unity for nucleophilic carbenes, and approximately unity for ambiphilic carbenes.

The values obtained are well correlated with the experimental quantities. The following experimentally known carbenes have been assigned to the electrophilic class: BrCCOOEt, MeCCl, CBr_2, PhCBr, PhCCl, PhCF, CCl_2, CFCl, and CF_2 (the electrophilicity diminishes from left to right); MeOCCl and MeOCF are ambiphilic and $(MeO)_2C$ and $MeOCNMe_2$ are nucleophilic. The "philicity" of the carbene can depend even on its conformation. Thus, according to a theoretical estimate,[149] the *cis*-conformer of methoxyphenylcarbene has nucleophilic properties, while its *trans*-conformer is ambiphilic. A review[148] presents calculated data also for the

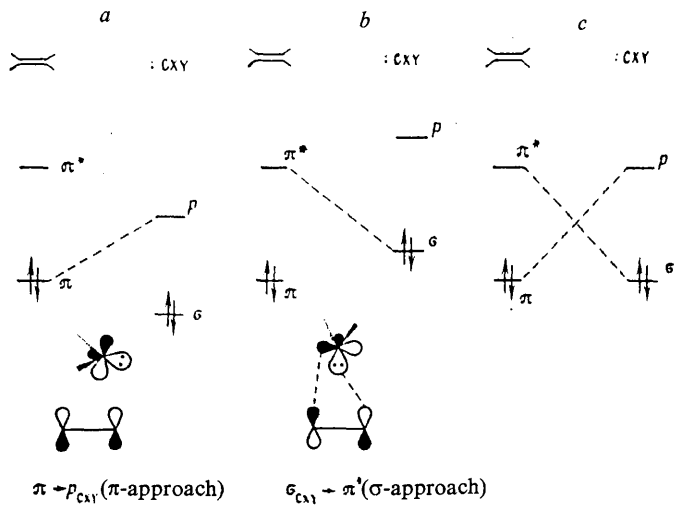


Figure 3. The principal versions of the relative positions of the energy levels of substituted carbenes: CXY and ethylene as a function of the substituents X and Y: *a*, electrophilic carbenes; *b*, nucleophilic carbenes; *c*, ambiphilic carbenes. The order of the energy levels for $:CCl_2$ (*a*) and $:C(NH_2)_2$ (*b*) is maintained.

differences between the orbital energies as a function of the nature of the substituents in the alkene (with the carbene unchanged). Electrophilic carbenes add more readily to alkenes with an electron excess, i.e. after the introduction of π-donors, while nucleophilic carbenes exhibit an increased reactivity following the weakening of the π-bond of the alkene, i.e. after the introduction of acceptor substituents.

Naturally, the "philicity" determined by the method indicated is associated with a specific alkene and on passing from one alkene to another the "philicity" series can be inverted.[148] The causes of this can be understood from Fig. 3: the stabilisation or destabilisation of the π,π^* levels of the alkene induced by the substituents can alter the relative contributions of the π–p and σ–π^* interactions. In practical correlations, the estimates of their extents are frequently restricted to the differences between the energies of the frontier orbitals and the calculation of the quantities ΔE is not resorted to. Thus the relative rate constants for the addition of dichlorocarbene to substituted styrenes are well correlated with the energy difference between the HOMO of styrene and the LUMO of the carbene.[150]

Direct calculations of the reaction pathway leading to the addition of carbenes to alkenes make it possible to discover important details of the internal reaction mechanism. At the level of non-empirical calculations, the reaction of singlet methylene with ethylene has been studied in greatest detail.[151] Like the addition of silylene,[152] this reaction proceeds without a barrier as the attacking species approaches under the plane of the alkene ("internal" approach). The "external" approach of methylene and other carbenes is energetically less favourable[153] and leads to their insertion in a C–H bond.[154] Calculations of reaction pathways of substituted carbenes with the location and identification of the structures of transition states are of greater theoretical interest. The "internal" pathway in the mutual approach of the reactants is a hybrid of the π- and σ-approaches and the transition states of all the reactions investigated have a common structure. In these states $r_1 \neq r_2$. The results of some of the calculations are presented in Table 4.

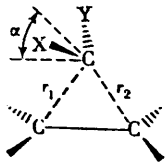

Table 4. Principal geometrical parameters of the structures of the transition states of the reactions involving the addition of carbenes to ethylene according to the results of non-empirical calculations.

Carbene CXY	r_1, nm	r_2, nm	α	Orbital basis set	Refs.
CCl_2	0.195	0.228	19.0	3-21G	[155]
CF_2	0.174	0.216	30.0	3-21G	[155]
FCOH	0.178	0.235	27.6	STO-3G	[147]
$C(OH)_2$	0.178	0.224	49.2	STO-3G	[156]
$C(NH_2)_2$	0.180	0.231	61.2	STO-3G	[156]

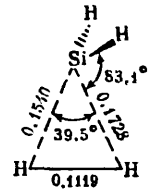
A characteristic of the transition states of the reaction involving addition to an alkene, which is especially sensitive to the "philicity" of the carbene, is the angle of inclination of the carbene plane relative to the plane of the double bond. According to Moss and co-workers,[147,148] one can assume that carbenes for which the angle α is less than 45° in the transition states of the reaction involving addition to alkenes are electrophilic. The angles $\alpha > 50°$ correspond to nucleophilic carbenes. The range $45° < \alpha < 50°$ corresponds to ambiphilic carbenes. Non-empirical[147,155,156] and semiempirical (MNDO)[157] calculations of the reaction pathways leading to the addition of various carbenes to ethylene confirmed this rule.

Calculations of the energy barriers and heats of the addition reaction showed that the selectivity of carbenes (at normal temperatures) is linearly related to their stability.[147] This conclusion, reached in the spirit of the usual activity–selectivity relation, does not, however, explain the experimental data about the entropic control of the addition of dichlorocarbene to alkenes,[158] the temperature dependence of the selectivity of dihalogenocarbenes,[159,160] and the zero and even negative activation energies for many cycloaddition reactions of carbenes.[161,162]

The last effect has come to be usually attributed to the presence on the reaction coordinate of an intermediate complex stable relative to the reactants. Such complexes, corresponding to the very early stages of the π-approach, do indeed appear in non-empirical calculations (basis sets up to the 6-21G level), but, when account is taken of the effects of electron correlation (MP 2/3-21G), they no longer correspond to minima on the PES and cannot therefore exist as kinetically isolatable species.[155,163] The vibration frequencies and entropies of the carbene–alkene reaction system have been calculated[155] at all its stages and the following hypothesis has been put forward. Since the entropy decreases monotonically as the reaction proceeds along the reaction coordinate and these changes are almost independent of the nature of the alkene and the carbene, when the enthalpy is rapidly reduced for reactive carbenes the quantity ΔG is controlled by the entropy term ($-T\Delta S$). Since ΔG reaches a maximum as a result of the increase in this term (with decrease of ΔH along the reaction coordinate), negative activation energies, characteristic of the reactions of the most electrophilic carbenes with electron-enriched alkenes, can also appear. Model potentials have been proposed[155] for the description of ΔH and $-T\Delta S$, which ensure a satisfactory reproduction of the experimental data for the reaction energetics without the inclusion of a stage involving the formation of intermediate complexes.

2. Insertion in single bonds

The reactions involving the addition of carbenes to single bonds, accompanied by the dissociation of the latter, have come to be designated as insertion in the bond. These reactions are extremely characteristic of carbenes and numerous theoretical studies have been devoted to them.[164–170] The calculations have established that the insertion in the H–H, C–H, halogen–halogen, and C–C bonds does not require the overcoming of an energy barrier and proceeds as a concerted reaction which does not follow the path of minimum motion. Two phases can be distinguished in the process involving insertion in a σ-bond: (1) electrophilic attack in which the unoccupied p orbital of the carbene interacts with the bonding orbital of the σ-bond attacked to form a three-centre bond; (2) the subsequent nucleophilic phase determined by the two-electron interaction of the σ orbital of the carbene with the antibonding σ^* orbital. In the second stage, the σ-bond is stretched and dissociates.



Insertion in the H–H bond. It followed from the early semiempirical (EHM) calculations[164] that the linear configuration >C...H–H, characteristic of a mechanism of the abstraction-recombination type, should occur in the reaction involving the insertion of methylene in the H_2 molecule up to the formation of the transition state. However, more rigorous non-empirical calculations[166,167] led to the observation of the extremely rapid formation of three-centre bonds in the initial stage of the reaction. In contrast to the singlet state, methylene in the ground triplet ($^3B_1$) state is inserted in the H–H bond, overcoming the activation barrier predicted by non-empirical calculations[171] (Table 5). The transition state has a linear configuration and the H–H...CH_2 distance is 0.140 nm. Triplet carbenes also tend to undergo hydrogen abstraction reactions ($^3CH_2 + H_2 \rightarrow CH_3 + H$) and the energy barriers in this and similar reactions are about 100 kJ mol^{-1}.[172]

Table 5. Results of non-empirical calculations of the activation barriers in reactions involving the insertion of carbenes and silylenes in σ-bonds.

*The stabilisation energy (E_{st}) of the intermolecular complex relative to the separated reactants is indicated in brackets. The activation barrier differs in such cases from the energy of the complex. For $E_{st} > E_a$, the reaction proceeds without a barrier.

Experimental data for the insertion of silylene in the H_2 molecule are still not available, but according to estimates[178] the lower limit of the activation barrier is 23 kJ mol^{-1}. Theoretical estimates[173,179] (Table 5) agree with this value. Analysis of the structural changes during the reaction $^1SiH_2 + H_2 \rightarrow SiH_4$ led to the conclusion that they are almost identical with those found for the reaction of methylene with hydrogen. The main cause of the appearance of the activation barrier is the different order of the singlet and triplet states of silylene and the appreciable S–T splitting.[180,181] The structure of the transition state in the reaction involving the insertion of silylene in the H_2 molecule is shown below [the distances are expressed in nanometers and the calculation was carried out by the MCSCF (4,4)/6-31G* method]:[178]

The influence of the substitution of the hydrogen atoms in silylene on the exothermicity and activation barrier of the reaction involving insertion in H–H bonds has been investigated in relation to its fluoro- and difluoro-derivatives.[174] The activation barrier increases by ~80 kJ mol^{-1} when one fluorine atom is introduced and by 130 kJ mol^{-1} when two fluorine atoms are introduced. This result is almost independent of the size of the basis set and the allowance for the correlation energy. Analysis of the structures of the transition states made it possible to conclude that they become of a "later" type and that there is a simultaneous decrease in the exothermicity of the insertion reaction, in agreement with Hammond's postulates.

A very high activation barier (171 kJ mol^{-1}) has been predicted in non-empirical calculations[168] for the insertion of the cyclic carbene cyclopropenylidene in the H–H bond. This is apparently caused by the marked destabilisation of the "electrophilic" π^* orbital of the carbene and the associated difficulties in the initial stage of the reaction.

Insertion in C–H and Si–H bonds. The insertion of singlet methylene in a C–H bond proceeds without a barrier or with very low activation barriers (0.9 kJ mol^{-1} for ethane) according to experimental[182] and theoretical[169,175,183] data, while an appreciable barrier (115 kJ mol^{-1}) has been predicted for silylene, which agrees with the experimental observations (70–80 kJ mol^{-1} [184,185]). The transition states of the reactions have angular structures with three-centre bonds.

The insertion of methylene and silylene in a Si–H bond does not require the overcoming of an activation barrier. This experimental conclusion has been reproduced theoretically only after careful allowance for correlation corrections.[175]

Insertion in a C–C bond. According to non-empirical calculations taking into account the correlation energy and using an extended basis set of the type 6-31G,[169] the energy profile of the reaction involving the insertion of methylene in a C–C single bond is mainly determined by steric factors. Thus the activation barrier to the insertion in a C–C bond is very high (192.5 kJ mol^{-1}). On the other hand, the similar reaction with cyclopropane should proceed without activation (the barrier is only 9.2 kJ mol^{-1}). After insertion in a C–C bond of a strained ring, whose electron density has a maximum outside the bond axis, strong electronic interactions become possible over longer internuclear distances and the insertion in strained C–C bonds should therefore proceed without an activation barrier according to Gordon et al.[169] Table 5 presents calculated data also for reactions involving the insertion of carbenes in other bonds of the type X–H.

Naturally, the carbene cycloaddition and insertion reactions examined by no means exhaust the entire wide variety of their reactivity. On the other hand, it is these reactions that determine the fundamental stages in the main types of intramolecular rearrangements of carbenes, including the 1,2-shift, ring expansion, and other reactions.[186–188]

- - - o0o - - -

During the preparation of the review for the press, a number of studies on the electronic structure and reactivity of carbenes were published. In particular, semiempirical (MNDO) and non-empirical (3-21G basis set, TCSCF, SD-CI) calculations for low-energy electronic states of cyclopropenylidene (VI) and cyclopentadienylidene (VII) were carried out.[189,190] The lowest biradical type singlet state $^1A_2$ (structure with the C_{2v} symmetry) of cyclopentadienylidene has a lower energy than the singlet states $1^1A_1(p^0\sigma^2)$ (VIIb) and $^1B_1$. The structure (VIIa) of the state $2^1A_1(p^2\sigma^0)$ does not correspond to a minimum on the PES. Non-empirical calculations[190] did not confirm the existence of the allene-type structure (IX), detected in calculations by the MNDO method.[120]

In order to explain the experimentally observed findings concerning the influence of electron-donating solvents on the reactivity of carbenes, non-empirical calculations (3-21G basis set) were carried out[191] for the addition of methylene to ethylene in the presence of a single water molecule. A complex between water and methylene molecules, whose formation makes it possible to account for the decrease in the electrophilicity of methylene, has been found on the PES.

Spectroscopic study of carbenes in low-temperature matrices

P S Zuev, O M Nefedov
Zelinskii Institute of Organic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The review surveys and gives a systematic account of the literature data on the IR and UV spectroscopic studies on carbenes in low-temperature matrices. The methods of generation and isolation of carbenes in inert matrices at temperatures around 10 K are examined. The possibility of applying the data obtained to the study of the structure of carbenes and to the determination of the mechanisms of reactions involving them is demonstrated.

The bibliography includes 67 references.

I. Introduction

In connection with the wide-scale application of reactions involving carbenes in synthetic organic chemistry, there has been a sharp growth of interest during the last 15–20 years in the detailed investigation of these species by various physicochemical methods. Such studies not only make it possible to detect and identify carbenes but also provide information about their structure, which is important for the interpretation of the reaction mechanisms.

The principal difficulties in the direct spectroscopic detection of carbenes (as well as other unstable molecules) are associated with the high reactivity and the short lifetime of these species under normal conditions. There are two ways of overcoming these difficulties. The first is based on the use of pulse methods in order to create a high concentration of the unstable compounds during a short time interval (10^{-3} s and less). In this case the spectroscopic characteristics of the test species can be obtained with the aid of special high-speed devices. Another, more widely used method consists in the isolation of the unstable intermediates in low-temperature matrices, primarily in inert gas matrices at temperatures below 20 K (the matrix isolation method), which makes it possible to prevent secondary reactions and to increase almost indefinitely the lifetime of these species. The methods for the generation of carbenes in low-temperature matrices will be examined in greater detail below. The application of the matrix isolation method in combination with analytical procedures such as EPR, UV, and IR spectroscopy has proved extremely fruitful.

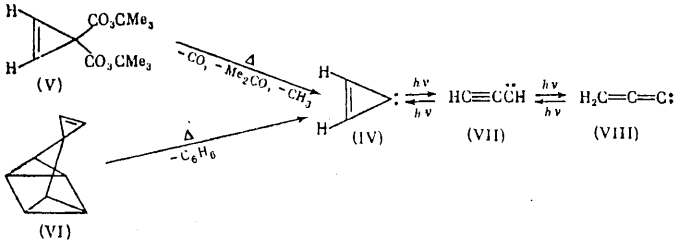
This review discusses the results of IR and UV spectroscopic studies on carbenes in low-temperature matrices obtained during the last 10 years. Earlier investigations have been surveyed in other publications.[1,2] Nor do we examine matrix studies using EPR, since they have been surveyed fairly completely in other reviews.[3–5]

II. Methods for the generation of carbenes in low-temperature matrices

Various methods are used to generate carbene in matrix studies. They can be obtained in the gas phase under the influence of a high temperature or a discharge (electrical, microwave, or radio-frequency) with subsequent freezing of the species formed in a low-temperature matrix. These methods have been examined in another review[6] and here we shall not deal with them in detail. We shall only note that the simplest triatomic carbenes can be isolated from the gas phase. More complex carbenes have sufficient time to undergo secondary reactions during their time of flight from the reactor to the cooled zone.

The most widely used method of synthesis of complex carbenes (i.e. carbenes consisting of more than three atoms) involves their generation by the UV photolysis of precursor molecules, mainly diazo-compounds and diazirines, isolated in inert matrices. The advantage of this method consists in the simplicity of the preparation of the matrix containing the stable initial compound, which is subsequently decomposed directly in the isolated state. The photodissociation of diazo-compounds and diazirines, yields, apart from the corresponding carbenes, also nitrogen molecules which are fairly inert and do not normally enter into recombination reactions with carbene molecules within the matrix cage. The majority of carbenes dealt with in the present review have been obtained by this method. Among other methods for the generation of carbenes in a low-temperature matrix, mention should be made of the reactions of stable molecules with free atoms, in particular with alkali metal atoms. The results of these investigations have been discussed in other reviews.[2,6]

III. IR and UV spectroscopic study of carbenes and their reactions



The comparatively small size of the simplest carbene (methylene) ensures that it has a definite mobility even in frozen inert matrices, which leads to the formation of dimerisation products under these conditions. It was not until 1981 that it became possible to detect[7] in the spectra of the diazomethane photolysis products bands at 1015 cm^{-1} (Ar matrix) and 1109 cm^{-1} (Xe matrix), which were attributed to the deformation vibration of methylene in its ground triplet state.

Dichlorocarbene (III) was formed on UV photolysis of dichloroketen (I), obtained by the thermal reaction of trichloroacetic acid chloride (II) with zinc and frozen in an Ar matrix at 12 K.[8]

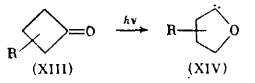
The recombination of the carbene (III) with a CO molecule in the matrix cage was not observed:

$$\underset{\text{(II)}}{CCl_3\overset{O}{\overset{\|}{C}}Cl} \xrightarrow[-ZnCl_2]{\Delta,\,Zn} \underset{\text{(I)}}{Cl_2C{=}C{=}O} \xrightarrow[-CO]{h\nu(\lambda>200\text{ nm})} \underset{\text{(III)}}{Cl_2C:}\,.$$

Cyclopropenylidene (IV) has been obtained from two different sources — compounds (V) and (VI) — by their thermal decomposition in the gas phase.[9,10] The subsequent UV photolysis (λ = 313 and 254 nm) of this carbene in an Ar matrix led to its isomerisation to propargylene (VII) and further to vinylidenecarbene (VIII). The vibration frequencies of the carbene (VIII) were calculated from its matrix IR spectrum and it was shown that it has a singlet ground state. The results agree well with data obtained by the EPR method.[10]

Cyclopropenylidene (IV) has been obtained from two different sources—compounds (V) and (VI)—by their thermal decomposition in the gas phase.[9,10] The subsequent UV photolysis (λ = 313 and 254 nm) of this carbene in an Ar matrix led to its isomerisation to propargylene (VII) and further to vinylidenecarbene (VIII). The vibration frequencies of the carbene (VIII) were calculated from its matrix IR spectrum and it was shown that it has a singlet ground state. The results agree well with data obtained by the EPR method.[10]

$$\underset{\text{(X)}}{N{\equiv}C\overset{N_2}{\overset{\|}{C}}H} \xrightarrow[-N_2]{h\nu} \underset{\text{(IX)}}{N{\equiv}C\ddot{C}H}.$$



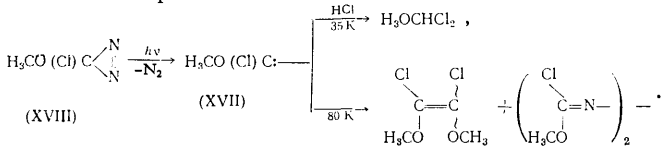
Taking into account the linear structure of the carbene (IX),[11] Dendramis and co-workers[12,13] carried out a full vibrational analysis of the spectra obtained and determined the force field of this species. Analysis of the numerical values of the valence force constants of the CC and CN bonds showed that their multiplicity in both cases is close to two. This as well as the high constant for the interaction of the CC and CN bonds indicate a high degree of delocalisation of electrons in the carbene (IX) and the similarity of its structure to the allene structure $\dot{N}{=}C{=}\dot{C}H$). The UV absorption spectrum of the cyanocarbene (IX) consists of a progression of bands in the range 240–340 nm. Estimation of the energy differences between the members of this progression makes it possible to assign it to the symmetrical stretching vibrations of the N=C=C group of the carbene in the electronically excited state.

The IR spectrum of dicyanocarbene has been obtained and its vibrational spectrum has been calculated.[13]

The IR spectrum of bis(trifluoromethyl)carbene (XI), generated by the UV photolysis (λ > 200 nm) of bis(trifluoromethyl)diazirine (XII), isolated in an Ar matrix at 12 K, has been published.[14,15] In contrast to the photodecomposition of the diazirine (XII), in the low-temperature matrix its gas-phase pyrolysis (300–500 °C) in the absence of the molecular collisions in the thermal reaction zone did not lead to the appearance of the carbene (XI) band in the matrix IR spectrum of the product. The only product of the thermal reaction was perfluoropropene—an isomer of the carbene (XI). The time taken for the rearrangement of the carbene (XI) in the excited singlet state to perfluoropropene has been estaimted[14,15] to be approximately 10^{-5} s:

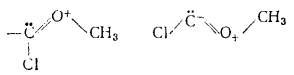
$$\underset{\text{(XII)}}{(CF_3)_2C\overset{N}{\overset{\|}{\underset{N}{}}}} \xrightarrow[-N_2]{\Delta} \underset{\text{(XI)}}{[(CF_3)_2C:]^S} \rightarrow CF_3CF{=}CF_2.$$

Quantum-chemical calculations have shown that oxycarbenes have a singlet ground state,[16,17] which is stabilised by the interaction of the unshared electron pair of the oxygen atom with the unoccupied *p* orbital of the carbene centre. As a result of this, it is impossible to detect such species by EPR, which makes spectroscopic data obtained by other methods especially valuable. However, until recently the only successful example of this kind was a study[18] in which thermally unstable species with an absorption maximum in the electronic spectrum near 360 nm were detected on UV photolysis (λ > 300 nm) of a series of cyclobutanones (XIII) in organic glasses at 77 K. This absorption was attributed to tetrahydrofurylidene (XIV)—an oxycarbene formed from cyclobutanone as a result of photolytic rearrangement with ring expansion:



According to Quinkert et al.,[18] the carbenes (XIV) can be "captured" by alcohols, alkenes, or oxygen with formation of secondary products of the kind usual in such cases.

The attempt to measure the IR spectrum of the hydroxycarbene (XV) on UV photolysis (λ > 220 nm) of the formaldehyde (XVI) in an Ar matrix[19,20] was unsuccessful despite the fact that the structure of the final products of the reactions occurring suggest the intermediate participation of the carbene (XV) in the process. The carbene (XV) is probably sufficiently mobile even in a rigid matrix to be able to diffuse from the matrix cage and enter into the reaction:

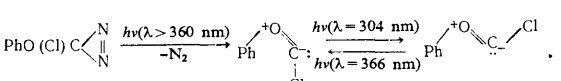


$$\underset{\text{(XVI)}}{H_2CO} \xrightarrow{h\nu} [H_2CO]^* \rightarrow \underset{\text{(XV)}}{[HO\ddot{C}H]} \xrightarrow{H_2CO} H_2C(OH)CHO.$$

Quite recently it has been possible[21,22] to record the IR and UV spectra of chloromethoxycarbene $H_3CO\ddot{C}Cl$ (XVII) and its isotope-substituted analogues $D_3CO\ddot{C}Cl$ and $H_3C^{18}O\ddot{C}Cl$, which were obtained by the UV photolysis (λ > 340 nm) of the corresponding diazirines (XVIII) isolated in matrices (Ar and N_2 12 K, 3-methylpentane, 45 K). At the same time the structure was confirmed by carrying out reactions with HCl and the initial diazirine as well as the dimerisation reaction, which occurs when the matrix is heated to the diffusion temperature:

According to Kasselmayer and Sheridan,[22] the unusually high stretching vibration frequency of the CO bond in the IR spectrum of chloromethoxycarbene (1300 cm^{-1}) is a consequence of an appreciable increase in the multiplicity of the carbon–oxygen bond as a result of the interaction of the unshared electron pairs of the oxygen atom with the unoccupied *p* orbital of the carbene centre.

The increased multiplicity of this bond suggests the possible existence of two isomeric forms of the carbene (XVII):



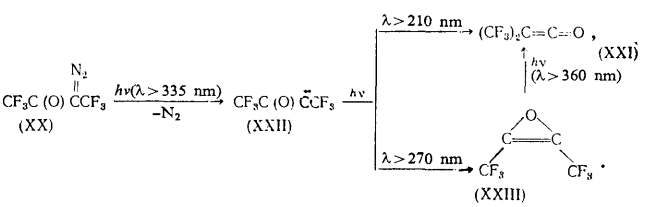
cis-(XVII) *trans*-(XVII).

Analysis of the IR spectra of the carbene (XVII) in different matrices as well as the results of experiments involving its prolonged irradiation with UV light at different wavelengths made it possible to discover the frequencies characteristic of each isomer. For example, the bands at 1310 and 1300 cm^{-1} were assigned to the antisymmetric stretching vibration of the CO bond in the *trans*- and *cis*-isomers respectively (the small frequency difference agrees with calculations of the vibrational spectra of hydroxycarbene[23]). The somewhat greater difference between the vibrational frequencies of the C–Cl bond in the *trans*- and *cis*-isomers of the carbene (XVII) (780 and 755 cm^{-1} respectively) is probably induced by the delocalisation of the unshared electron pair of the oxygen atom over the non-bonding σ orbital of the C–Cl bond.[24] The UV spectrum of the carbene (XVII) isolated in a N_2 matrix contains an absorption band in the region of 360 nm (the authors[22] were unable to differentiate the absorption bands due to different isomers). The extinction coefficient of the carbene was estimated approximately as 65 mol $litre^{-1}$ cm^{-1}.

Prolonged irradiation of the carbene (XVII) in a Ar matrix with UV light (λ > 270 nm) leads to its rearrangement to acetyl chloride, which partly decomposes with formation of keten and hydrogen chloride. The irradiation of compound (XVII) in a N_2 matrix induces the formation, apart from the products indicated, also of small amounts of methyl chloride and CO. The mechanisms of the reactions occurring have not been fully elucidated.

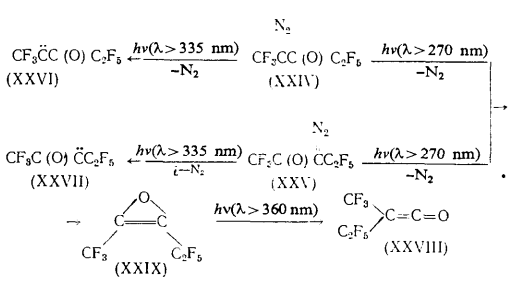
In the course of continuing studies on substituted oxycarbenes, the matrix IR and UV spectra of another representative of unstable species of this class—chloro(phenoxy)carbene (XIX)—were recorded.[25] Groups of bands due to the *cis*- and *trans*-isomers, which can be interconverted on irradiation with UV light at definite wavelengths, were differentiated in the IR spectra of both compound (XIX) and (XVII):

cis-(XIX) *trans*-(XIX)



The higher frequency of the antisymmetric stretching vibrations of the CO bond in both isomers confirms, as in the previous case, its increased multiplicity. The bands at 850 cm^{-1} [*trans*-(XIX)] and 800 cm^{-1} [*cis*-(XIX)] have been assigned to the C–Cl bond stretching vibrations. The authors do not comment on the similar somewhat high C–Cl vibration frequency,[25] although by analogy with the carbene (XVII) one would be justified in expecting frequencies in the range 750–780 cm^{-1}. The UV spectrum of the carbene (XIX) has a broad absorption band with λ = 320 nm whose extinction coefficient has been estimated as 100 cm^{-1} mol^{-1}. Compound (XIX) behaves photochemically similarly to the carbene (XVII): the prolonged photolysis of the carbene (XIX) isolated in a N_2 matrix leads to the formation of benzoyl chloride, chlorobenzene, and CO.

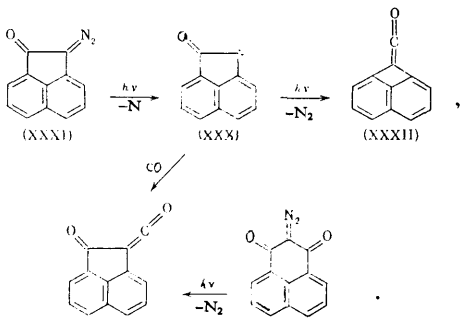
For a long time, the spectroscopic data for carbonylcarbenes of the type R–C(O)–C̈–R′ were restricted to EPR spectra.[26–29] The attainment of higher concentrations of these carbenes, sufficient for their detection in matrices by IR and UV spectroscopy, is prevented by the ease with which they rearrange to the isomeric ketens[30,31] (the Wolff rearrangement):



The rearrangement can be slowed down by stabilising the carbenes by introducing an electron-accepting substituent at the carbene centre and also by increasing the size of the migrating group. The first procedure is more effective, because an increase in the size of the substituent can lead to intramolecular secondary reactions in the carbene (for example, intramolecular insertion in the CH bond[32]).

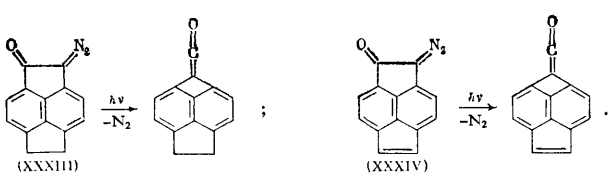
Torres et al.[33] investigated the UV photolysis (λ > 335 nm) of hexafluoro-3-diazo-2-butanone (XX) in an Ar matrix. Together with bis(trifluoromethyl)keten (XXI), the carbene (XXII), which on subsequent irradiation (λ > 210 nm) was converted into the keten (XXI), was detected in the photolysis products by IR spectroscopy:

On the other hand, the irradiation of the carbene (XXII) by light at a longer wavelength (λ > 270 nm) leads to the appearance in the IR spectrum of bands due to a new unstable species, which is also converted into ketens on prolonged irradiation. The appearance of these new bands was explained by the formation of bis(trifluoromethyl)oxirene (XXIII) in the matrix. The intermediate formation of oxirenes has been postulated in a number of reactions,[34–36] but previously they could not be detected spectroscopically. Theoretical calculations have shown that oxirenes are thermodynamically less stable than the isomeric carbonylcarbenes.[37]



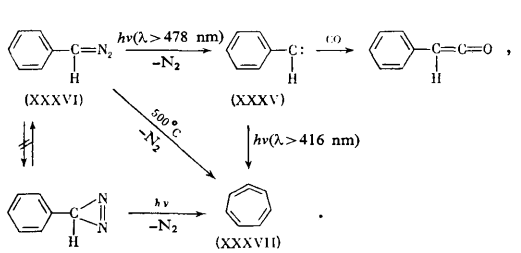
In order to confirm the conclusion that the oxirene (XXIII) is formed, a study was made[33] of the UV photolysis of two other perfluorodiazoketones—2-diazo-octafluoro-3-pentanone (XXIV) and 3-diazo-octafluoro-2-pentanone (XXV)—in an Ar matrix at 12 K:

Apart from the bands of the corresponding carbenes (XXVI) and (XXVII), the bands of only one unstable species were detected in the IR spectra of the products of the photolysis of compounds (XXIV) and (XXV) by UV light at λ > 270 nm. The conversion of this species into the keten (XXVIII) on further irradiation confirms its oxirene structure (XXIX).



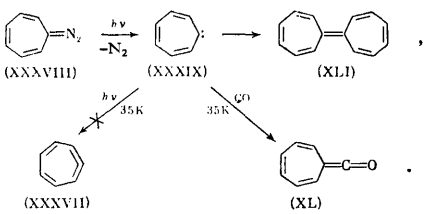
The IR and UV spectra of α-ketocarbene (XXX) were obtained on UV photolysis by light at λ = 365 ± 8 nm of the diazo-compound (XXXI) isolated in an Ar matrix at 10 K. The

formation of the carbene (XXX) was confirmed by the reactions with O_2 and CO:

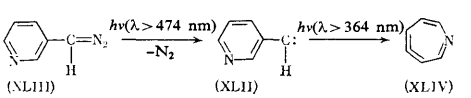


Further irradiation of the carbene (XXX) (λ = 625 ± 8 nm) leads to the Wolff rearrangement and the formation of the keten (XXXII).

In contrast to the example examined above, the attempts to generate ketocarbenes with similar structures by the matrix photolysis of the diazo-compounds (XXXIII) and (XXXIV) were unsuccessful: in both cases, the only detectable products of the photolytic reaction were the corresponding ketens obtained as a result of the Wolff rearrangement (XXXVIII).



The IR and UV spectra of phenylcarbene (XXXV), formed on UV photolysis (λ > 478 nm) of phenyldiazomethane (XXXVI) in an Ar matrix, have been recorded.[39] Prolonged irradiation of the matrix-isolated carbene (XXXV) by UV light at a shorter wavelength (λ > 416 nm) leads to the disappearance from the IR spectrum of the absorption band characteristic of the aromatic ring and the methylidyne group and to the appearance of IR bands of an unknown compound. The same compound was detected among the products of the gas-phase pyrolysis of phenyldiazomethane (XXXVI) (500 °C), frozen in the matrix, and also on matrix photolysis of phenyldiazirine. The presence in its spectrum of bands at 1824 and 1816 cm^{-1}, close to the 1810 cm^{-1} band characteristic of the allene linkage of 1-azocyclohepta-1,3,4,6-tetraene,[40] indicates the formation of the cycloheptatetraene (XXXVII)—the product of the intramolecular reaction of the carbene (XXXV) with ring expansion. Analysis of the products of the matrix UV photolysis of various deuteriated phenylcarbenes has confirmed the proposed mechanism:



Systematic matrix studies of this rearrangement have shown that isomerisation with ring expansion and the formation of cycloheptatetraenes is a widely occurring reaction of many arylcarbenes.[41,42] The dimerisation reaction of the cycloheptatetraene (XXXVII) has also been investigated by matrix IR spectroscopy and it has been possible to discover alternative sources of this interesting cyclic compound.[42]

The IR and UV spectra of the triplet cycloheptatrienylidene (XXXIX) have been recorded quite recently[43] after the UV photolysis (λ > 574 nm) of diazocycloheptatriene (XXXVIII) in an Ar matrix. This carbene interacts with the CO added to the matrix, forming the keten (XL), and also dimerised with formation of heptafulvalene (XLI):

Experiments have shown that this cannot be converted into the cycloheptatriene (XXXVII) either thermally or photolytically. The presence in the electronic spectrum of compound (XXXIX) of an absorption maximum in the long-wavelength region at 530 nm suggests a planar structure of this carbene, which agrees well with EPR data.[43]

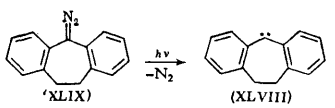
According to the results of Chapman and Sheridan,[44] pyridylcarbene (XLII), whose IR spectrum has been recorded on UV irradiation (λ > 474 nm) of 3-diazomethylpyridine (XLIII) in an Ar matrix, undergoes a photolytic rearrangement similar to that of phenylcarbene (XXXV). Thus its photolysis by UV light at λ > 364 nm leads to the formation of 1-azacyclohepta-1,3,4,6-tetraene (XLIV):

The IR and UV spectra of halogeno(phenyl)carbenes PhĊCl (XLVa), PhĊBr (XLVb), and PhĊF (XLVc), generated by the UV photolysis (λ > 300 nm) of the corresponding diazirenes (XLVI) in inert gas matrices at 10 K[42,45–47] or in a 3-methylpentane matrix at 77 K,[48] have been described in the literature. A correspondence was observed between the electronic spectra of the carbenes (XLVa)–(XLVc), formed in a 3-methylpentane matrix, and the spectra obtained on flash photolysis of the diazirines (XLVIa)–(XLVIc) in gaseous benzene or isooctane at 23 °C:[48]

(XLVI) (XLV)

R = Cl (a), Br (b), F (c), CF_3 (d).

Phenyltrifluoromethylcarbene (XLVd), whose IR spectrum has also been recorded, has been obtained similarly by the UV photolysis of phenyltrifluoromethyldiazirine (XLVId) and phenyltrifluoromethyldiazomethane, both frozen in an Ar matrix.[47]

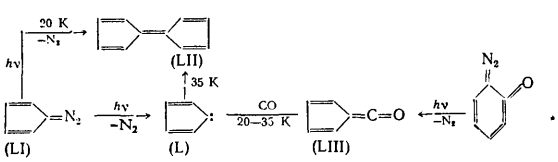


The electronic absorption and emission spectra of diphenylcarbenes (XLVII) have been obtained in the photolysis of diphenyldiazomethane isolated at 20–77 K in various crystals and vitreous organic matrices.[49–54] The spectrum of this carbene is characterised by the presence of two structureless broad bands with maxima at 301 nm (ε = 25000) and 465 nm (ε = 300) and possibly a third band at 240 nm.[51] The assignment of the observed bands to compound (XLVII) was based on their disappearance when the

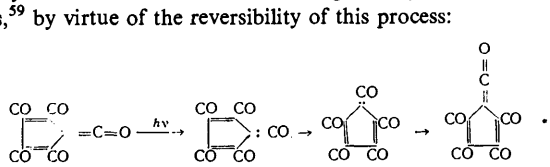
matrix was heated and on the appearance of the absorption of benzophenone (in the presence of oxygen), on the parallel decrease in the intensities of the UV bands and the EPR signal due to the given carbene, and on the quantitative analogy with the electronic spectrum of the diphenylmethyl radical (absorption maxima at 336 and 515 nm). The absorption spectra of different 4-substituted diphenylcarbenes have a similar form with two main bands in the UV and visible regions. The electronic spectra of these carbenes have already been surveyed.[28]

Polarisation studies on the carbenes (XLVII), (XLVII)-d_{10}, and 4,4′-dichloro- and 4,4′-dibromo-diphenylcarbenes have made it possible to characterise the electronic configurations of the ground and first excited triplet states of these carbenes as $(p\pi)^1(p\sigma)^1$ and $(p\sigma)^1(\pi^*)^1$. Further investigations demonstrated the $(p\pi)^1(\pi^*)^1$ configuration of the second excited triplet state with an energy higher by 1000 cm^{-1} than that of the first excited triplet state.[52]

The IR spectrum of diphenylcarbene has been published.[55]



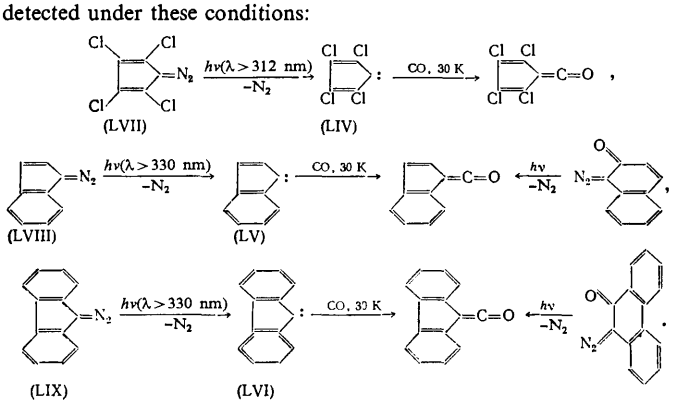
The electronic spectrum of 10,11-dihydrodibenzo[*a*,*d*]cycloheptenylidene (XLVIII) (λ_{max} = 510 nm) has been obtained in the photolysis of the corresponding diazo-compound (XLIX) frozen in various organic matrices at 77 K:[51]



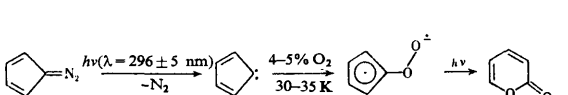
(XLIX) (XLVIII)

Later[56] the UV spectrum of this species was recorded in the flash photolysis of the diazo-compound (XLIX) in solutions in hydrocarbons at 20 °C.

After the first, partly unsuccessful (owing to the unsuccessful selection of experimental conditions) attempts to stabilise cyclopentadienylidene (L) in an inert matrix,[57,58] its IR and UV spectra were recorded.[59] The carbene (L) was obtained by the UV photolysis (λ > 300 nm) of diazocyclopentadiene (LI) isolated in low-temperature inert matrices. The reliability of the frequency assignments to compound (L) in the IR and UV spectra obtained was confirmed by the occurrence in the matrix at 20–35 K of the dimerisation of compound (L) to fulvalene (LII) and the formation of the keten (LIII) on interaction of compound (L) with the CO added to the N_2 matrix:

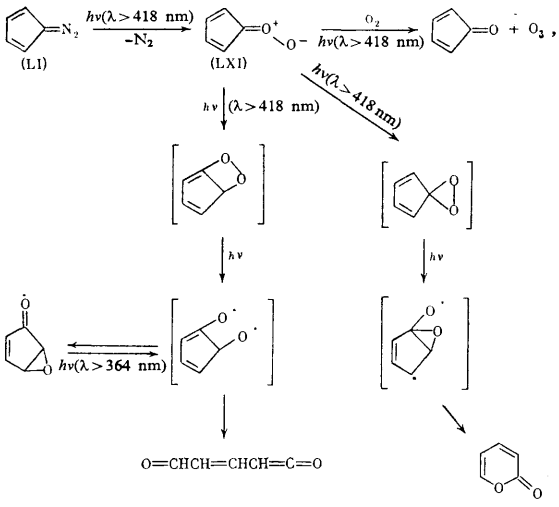


The carbene (L) is extremely reactive even at liquid helium temperature and, under the conditions of insufficient matrix dilution (less than 1000 : 1), it readily dimerises to compound (LII). Furthermore, even when the matrix dilution is raised to 100000 : 1, a certain amount of the dimer (LII) is formed. Such high reactivity in compound (L) may be associated with its ability to rotate within the matrix cage. Photolysis by polarised light of the keten (LIII), obtained by the interaction of compound (L) with a CO molecule in a CO matrix, leads to an appreciable reorientation of the initially randomly oriented keten molecules, most probably, according to the authors,[59] by virtue of the reversibility of this process:

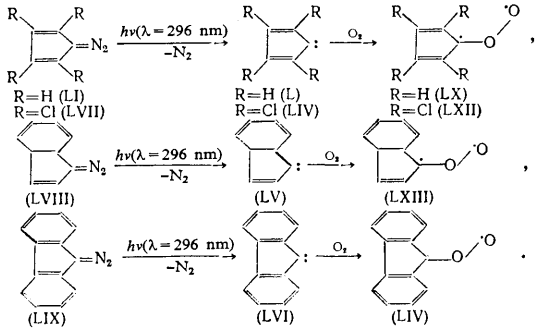


It has been possible to record[60] the IR and UV spectra of several derivatives of the carbene (L)—tetrachlorocyclopentadienylidene (LIV), indenylidene (LV), and fluorenylidene (LVI). They were all formed on UV photolysis of the corresponding diazo-precursors (LVII)–(LIX) in inert matrices and had a triplet ground state. The UV spectrum of compound (LVI), stabilised in a matrix, is close to the UV spectrum of the triplet (LVI) obtained by flash photolysis.[61] In contrast to compound (L), the dimerisation of the carbenes (LIV)–(LVI) was observed neither during their generation nor in the course of subsequent heating until the complete evaporation of the material of the matrix. According to Bell and Dunkin,[60] the possible causes of this are, firstly, the appreciably greater bulk of the carbenes considered compared with compound (L), which hinders their diffusion in the matrix and, secondly, the pronounced shielding of the carbene centres by the bulky substituents, which creates steric hindrance to dimerisation. For comparison, one should note that the formation of the dimer of the carbene (LVI) was observed only in the photolysis of diazofluorene (LVII) in solution.[62]

At 30 K in inert matrices with added CO, the carbenes (LIV)–(LVI) give rise to the corresponding ketens, although they exhibit under these conditions a lower reactivity than compound (L). Furthermore, the carbenes (LIV)–(LVI) were stabilised in a pure CO matrix at 12 K, whereas the free carbene (L) could not be detected under these conditions:



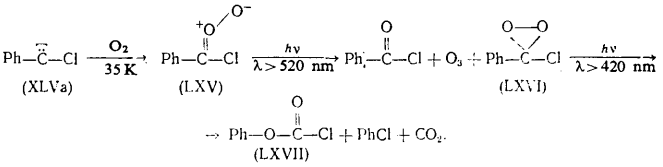
The different reactivities in relation to CO exhibited by compound (L) and its derivatives (LIV)–(LVI) may be associated, on the one hand, with the different degrees of shielding of the carbene centres and, on the other, with the different rates and hence different energies of the triplet–singlet transition of these carbenes, which necessarily precedes their reactions with singlet CO molecules.[60] The reactions of the carbenes (L) and (LIV)–(LVI) with oxygen have been investigated in a number of studies. Thus the carbene (L), generated on UV photolysis of diazocyclopentadiene (LI) in a N_2 matrix to which 4–5% of O_2 had been added, reacted with O_2 at 30–35 K, affording a new photolabile substance, which was converted on subsequent photolysis into α-pyrone:[63]



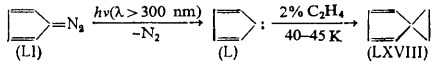
Careful analysis of the IR spectra of the compound obtained as well as examination of the isotope composition of the products formed in the presence of oxygen having the composition $^{18}O_2$ and $^{16}O^{18}O$ made it possible to attribute to this compound the structure of the oxide (LX).

Chapman and Hess,[64] who carried out the UV photolysis of compound (LI) under conditions close to those employed by Bell and Dunkin[63] (Ar matrix with addition of 25% of O_2, 10 K), also observed the formation of a photolabile product. However, the latter differed markedly from compound (LX) in terms of its set of frequencies in the IR, although the results of experiments involving the further irradiation of this compound do not conflict with the idea that it has an *O*-oxide structure [Chapman and Hess[64] postulated a zwitter-ionic structure of the carbonyl oxide (LXI) and not the radical form put forward by Bell and Dunkin[63]].

Later,[65] these discrepancies were accounted for by the fact that compound (LXI) could be formed as a result of the direct reaction of compound (LI) with O_2 without the participation of the carbene (L), especially since the usual photolytic decomposition of compound (LI) is observed on irradiation with light at a much shorter wavelength ($\lambda > 300$ nm). Furthermore, different isomers of the same carbonyl oxide may have been detected in the above studies:[63,64]



The reactions of O_2 with the carbenes (L) and (LIV)–(LVI), isolated in N_2 matrices at 10 K, were investigated by UV spectroscopy:[65]



The carbonyl oxides (LX) and (LXII)–(LXIV) obtained were characterised by the presence in their electronic spectra of absorption maxima in the range 395–460 nm.

The reaction of chloro(phenyl)carbene (XLVa) with O_2 has been investigated.[45] When the Ar matrix containing 4% O_2 was heated together with the carbene (XLVa) stabilised in it from 10 to 35 K, the IR absorption of the carbene slowly weakened and new bands appeared in the spectrum, which the authors[45] assigned to the carbonyl oxide (LXV). Compound (LXV) proved to be so photolabile that it disappeared even on exposure to the IR emission from the spectrometer. The spectrum of this compound was recorded only by employing a silicon filter ($\lambda > 1100$ nm). Photolysis of compound (LXV) by light at $\lambda > 520$ nm led to its partial decomposition to benzoyl chloride and also to its rearrangement to the dioxiran (LXVI), which was converted into phenyl chloroformate (LXVII) on further irradiation. The UV spectra of compounds (LXV) and (LXVI) obtained agree well with the known spectra of the corresponding compounds of these classes:[63–65]

Finally matrix IR spectroscopy was used recently[66,67] for the direct observation and investigation of the principal reaction of carbenes—their [1 + 2]cycloaddition to alkenes—in the specific instance of the interaction of cyclopentadienylidene (L) with ethylene. UV photolysis ($\lambda > 300$ nm) of diazocyclopentadiene (LI) in an Ar matrix with added 2% C_2H_4 at 12 K resulted in the appearance in the IR spectrum of intense bands due to compound (L) together with weak bands due to its dimer (fulvalene) as well as spiro[2,4]hepta-4,6-diene (LXVIII) (734 and 560 cm^{-1}). The photolysis was continued until the complete disappearance of the bands of the initial compound (LI):

Subsequent heating of the matrix from 12 to 40–45 K resulted in a synchronous decrease in the intensity of the bands of the carbene (L) and the simultaneous intensification of the bands of the spiro-compound (LXVIII), which indicates the occurrence of the direct reaction of the carbene (L) with ethylene (Fig. 1). It must be emphasised that this is absolutely the first successful example of the direct spectroscopic investigation of the reactions of a carbene with organic acceptors.

— o0o—

In conclusion we may note that the appearance in recent years of a large number of publications devoted to the direct spectroscopic study of carbenes and the examination of their reactions with trapping reagents and secondary reactions in low-temperature matrices indicates the growing importance of the matrix isolation method not only as a way of stabilising the carbenes and of

determining their analytical characteristics but also as an important instrument for the study of the mechanisms of processes in which they participate.

Electrochemical methods for the generation of carbenes and their analogues

V E Petrosyan, M E Niyazymbetov
Zelinskii Institute of Organic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The present review surveys and analyses the results of studies devoted to the use of electrochemical methods for the generation of carbenes, nitrenes, and also dichlorogermylene. The cathodic and anodic processes leading to the formation of these species are considered separately. Attention is concentrated on questions concerning the generation of dihalogenocarbenes in the cathodic reduction of polyhalogenomethanes and of dinitrocarbene in the anodic oxidation of dinitromethylides. In addition, data are presented concerning the possibility of the cathodic generation of carbene and nitrene radical-anions and the study of their properties. The examples of reactions involving electrochemically generated carbenes and their analogues examined in the review indicate that there are realistic prospects for the creation of highly selective processes leading to the electrochemical carbene synthesis.

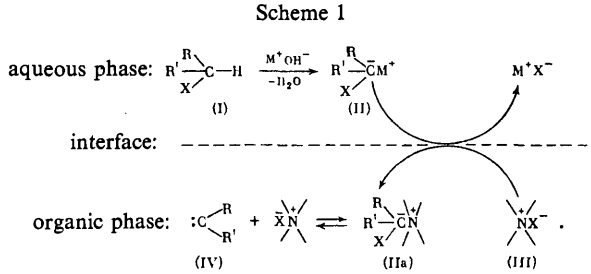
I. Introduction

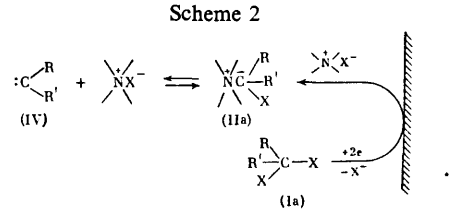


The various methods for the generation of carbenes are based on a fragmentation process initiated as a rule by the application of some kind of method involving a physical influence on a suitable organic substrate. Fragmentation results in the synchronous or successive dissociation of all the chemical bonds belonging to one reaction centre of the substrate molecule.

The aim of the present review is to show that, together with common methods for exerting a chemical influence such as, for example, thermolysis or photolysis, the electrochemical method can be used successfully for the generation of carbenes. In the last case, the fragmentation of the organic substrate leading to the formation of a carbene becomes possible because of the electrochemical activation of the substrate as a result of the transfer of one or several electrons. Such activation can be achieved as a result of the occurrence of both cathodic and anodic processes depending on the nature and structure of the substrate. Generally speaking, the method for the electrochemical generation of carbenes and their analogues has not yet come to be widely used and this review is perhaps the first attempt at a survey of the available experimental data. Nevertheless the many advantages of this method give rise to confidence that it has good prospects.

II. Reduction processes

One of the commonest methods of generating carbenes is the α-elimination of a substituent (usually a halide ion) from the carbanionic centre of a thermodynamically unstable anion. The conditions for the formation of such an anion exert a decisive influence on the efficiency of the generation of the carbene as a whole. Nowadays the greatest popularity has been gained by Makosha's method,[1] which is based on the following processes presented in Scheme 1:



Scheme 1

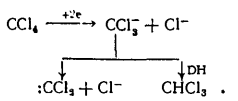
The thermodynamically unstable carbanion (II) [zwitter-ion?] generated in the aqueous phase exchanges at the interface the metal cation for the tetraalkylammonium cation of the corresponding salt (III), catalytic amounts of which are added to the organic phase. The ion pair (IIa) formed migrates into the bulk of the organic phase where it dissociates with formation of the carbene (IV).

An alternative electrochemical method of generating the ion pair (IIa) does not require the presence of a base in the system and involves the reduction at the cathode of the C–X (X = halogen) bond of the precursor: †

Scheme 2

† In the light of the results of recent studies,[2] the following process occurs under certain conditions:

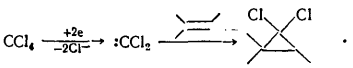
$$\rangle C{-}H + e \rightarrow \rangle C^{-} + {}^{1}/_{2}H_{2}.$$



This is yet another possibility, in principle, of an effective electrochemical generation of a thermodynamically unstable carbanion and later a carbene. This possibility is being investigated at the present time.

Despite the fact that the process illustrated in Scheme 2 is evidently attractive, it would be premature to speak of its advantages over the thoroughly investigated process shown in Scheme 1. There is no doubt that the development of research into the electrochemical generation of carbenes (Scheme 2) has aroused interest both as regards the solution of specific synthetic problems and as a source of additional information about the mechanism of the process illustrated in Scheme 1.

1. Generation of carbenes



The possibility, in principle, of carrying out Scheme 2 was demonstrated as early as the beginning of the 1960's by Wawsonek and Duty,[3] who used the method of classical polarography to investigate the electrochemical reduction of various halogenomethanes in acetonitrile (AN) and dimethylformamide (DMF) and established that two electrons are transferred in the first stage [$E_{1/2}$ = –0.25 V (saturated calomel electrode)] of the reduction of CCl_4 at a Hg cathode in AN in the presence of Bu_4NBr as the supporting electrolyte. It is accompanied by the dissociation of the C–Cl bond and the formation of the carbanion CCl_3^-, which is partly protonated under the experimental conditions, affording $CHCl_3$, and undergoes partial fragmentation, which leads to the dichlorocarbene and Cl^-:

Scheme 3

The relative contributions of the above reactions depend on the proton-donating capacity of the medium. In the presence of proton donors (for example, H_2O), $CHCl_3$ is formed preferentially. The dichlorocarbene generated via Scheme 3 has been detected chemically by trapping it with an alkene (the yield of the adduct has not been indicated):[3]

Scheme 4

This process has been achieved at a Hg cathode in AN in the presence of Bu_4NBr as a supporting electrolyte at 20 °C and a current density of $(4-7) \times 10^{-3}$ A cm^{-2}. In view of the identity of the polarographic behaviour of CBr_4 and CCl_4, the same workers[3] concluded that dibromocarbene is probably formed on reduction of CBr_4. In addition, it has been suggested[3] that the reduction of CF_2Cl_2 and $PhCCl_3$ leads to difluoro- and phenylchloro-carbenes respectively. However, the formation of these carbenes has not been confirmed chemically.

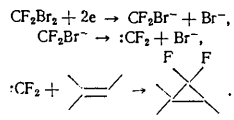
Almost 20 years were needed before the conversion of alkenes into cyclopropanes in the electrochemical reduction of halogenomethanes was brought to the preparative level.[4–6] The successful solution of this problem was promoted by the rational selection of the electrode material and the solvent. Thus the current yield of cyclopropanes reaches 80% in the reduction of CCl_4 at a lead electrode in $CHCl_3$ in the presence of alkenes (Table 1, experiments 1–4).[4]

According to the authors,[4] the following processes can also lead to the formation of dichlorocarbene in the electrolysis of CCl_4 in $CHCl_3$ under these conditions:

Scheme 5

$$CHCl_3 + 2e \rightarrow CHCl_2^- + Cl^-,$$
$$CHCl_3 + CHCl_2^- \rightarrow CCl_3^- + CH_2Cl_2,$$
$$CCl_3^- \rightarrow :CCl_2 + Cl^-.$$

Table 1. The electrolysis conditions and the yields of the products of the conversion of alkenes into cyclopropanes by electrochemically generated dihalogenocarbenes.



No. of expt.	Initial halogeno-methane	Carbene formed	T, °C	Solvent	Bu_4NBr concentration, M	Electrode	j, mA cm^{-2}	Alkene employed	Yield* of cyclopro-pane	Refs.

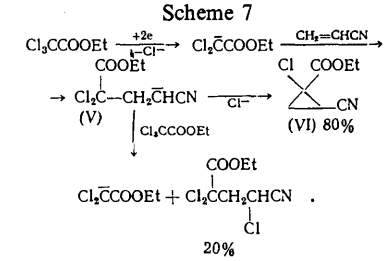
* Calculated relative to the product isolated.

Indeed the electrolysis of $CHCl_3$ itself in the presence of 2-methylbut-2-ene afforded *gem*-dichlorocyclopropane in 22–25% yield.[4] Dichlorocarbene can be generated from CCl_4 also in CH_2Cl_2 whose acidity is insufficient for the protonation of CCl_3^-. The yield of cyclopropanes from alkenes proved to be fairly high also under these conditions (Table 1, experiment 5).

The reduction of CF_2Br_2 at a platinum cathode in CH_2Cl_2 leads to $:CF_2$, which interacts with 2-phenylpropene or 2-methylbut-2-ene to form difluorocyclopropane derivatives in good yields (Table 1, experiments 6 and 7):[5]

Scheme 6

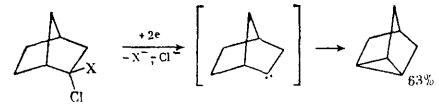


The reduction of $CFBr_3$ takes place similarly at a lead cathode. It leads to :CFBr, which forms bromofluorocyclopropane derivatives in the presence of alkenes (Table 1, experiments 8–10).[6]

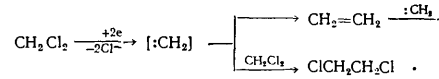
We may note that the (IIa) → (IV) reaction stage presented in Schemes 1 and 2 provides an incomplete idea about the reactivity of the intermediate anion (IIa). In reality, this anion is capable of being partly protonated even in aprotic media of the type of AN, DMF, and propylene carbonate[5] (see Scheme 3). The polarisation curves for the reduction of CCl_4 then show a wave (the second wave) corresponding to the reduction of $CHCl_3$. It is of interest that the height of the second wave depends on the presence in the solution of an alkene, which functions as an acceptor of carbenes.[7] In certain cases, such data can serve as indirect confirmation of the formation of the carbene intermediate.[7]

The protonation of the anion (IIa) can influence greatly the efficiency of the generation of the carbene. For example, whereas the rapid proton exchange reactions between $CHCl_3$ and the electrochemically generated anion CCl_3^- do not lower the yield of dichlorocarbene on reduction of CCl_4 in chloroform because they lead to the same readily fragmented anion CCl_3^-,[4] the reduction of CF_2Br_2 in chloroform affords F_2CH_2. Owing to the high basicity of the intermediate anion CF_2Br^-, it is better to generate $:CF_2$ in the latter case in the less acid CH_2Cl_2.[5] In the generation of the highly basic anions (IIa) (see Scheme 2) in a medium containing the cations NR_4^+ (R = alkyl), account must be taken of the possibility of the Hofmann cleavage of the cations (for R ≠ Me) with formation of alkenes under the influence of compound (IIa) as a base.

In media with weak proton-donating properties, the carbene formed on fragmentation of the intermediate anion (IIa) interacts with alkenes, as shown in Schemes 4 and 6. However, when the double bond has been activated in relation to nucleophilic attack, the anion (IIa) can react rapidly with the alkene and the stage (IIa) → (IV) (see Scheme 2) is then excluded. This possibility has in fact been examined in detail by Baizer and Chruma[8] [including the process involving the anion CCl_3^- generated by the electrochemical reduction of CCl_4 at a mercury cathode in DMF in the presence of NEt_4Cl as the supporting electrolyte at an electrolysis potential of –0.85 V (w.r.t. sat. calomel electrode) and at a temperature of 25–45 °C]. It must be emphasised that, together with the products of the addition of the carbanion to the double bond, cyclopropane derivatives can also be formed in this case, as happens, for example, in the reduction of trichloroethyl acetate in the presence of acrylonitrile[8] (Scheme 7):



Scheme 7

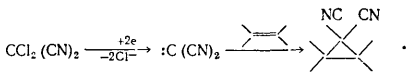


It is significant that cyclopropane (VI) is formed exclusively as a result of the intramolecular cyclisation of the adduct of the carbanion with the alkene (V).[8]

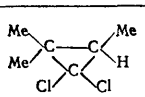
The data examined above are extremely important for the selection of optimal conditions for the synthesis of cyclopropanes with participation of electrochemically generated carbenes.

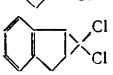
The electrochemical reduction of organohalogen compounds in accordance with Scheme 2 can be used to generate not only halogenocarbenes but also carbenes with a different structure. Thus, in the reduction of 2,2-dichloronorbornane [$E_{1/2}$ = –1.54 V (sat. c. e.)] or 2-bromo-2-chloronorbornane [$E_{1/2}$ = –0.83 V (sat. c. e.)] at a mercury cathode in DMF in the presence of NEt_4Br as the supporting electrolyte, the intermediate carbene is inserted in a C–H bond, which leads to a high yield of an intramolecular cyclisation product:[9]

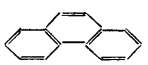
According to Mottus and Ort,[10] the electrolysis of a CH_2Cl_2 solution containing $AlCl_3$ at an aluminium cathode leads to dichloroethane, ethylene, and cyclopropane (the yields have not been indicated), which are regarded as the methylene conversion products:

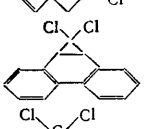


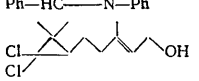
The reduction of different halogenomethanes by the electrochemically generated solvated electrons [aluminium cathode coated with lithium and magnesium in solution in hexamethylphosphoramide (HMP) containing LiCl and $MgCl_2$] leads to a mixture of gases (ethane, ethylene, cyclopropane, etc.), whose formation is explained by the participation of methylene.[11] In the presence of an alkene, the corresponding cyclopropanes were obtained:

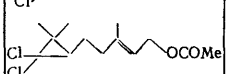










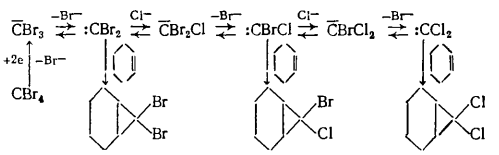


It has been shown by the polarographic method[12] that the carbene intermediate is formed also in the electrochemical reduction of 9,9-dichlorofluorene. Similarly, dicyanocarbene is formed as an intermediate in the reduction of dichloromalononitrile.[13] The results of polarographic studies and of electrolysis at a controlled potential [E = –0.47 V (rel. Ag/Ag^+), Hg cathode, AN, NBu_4Br,

0–5 °C] in the presence of tetramethylethylene made it possible to describe this process by the following scheme:

However, the yield of the cyclopropane proved to be less than 1%.

Table 2. The material and current yields of the products of the electrolysis of CCl_4 (c = 0.5 M) in $CHCl_3$ in the presence of various organic substrates.



No. of expt.	Substrate	T, °C	Product	Yield, % w.r.t. material	Yield, % w.r.t. current	Refs.
1	$Me_2C{=}CHMe$	—5		—	66*	[14]
2		—5		90	45	[14]
3		0—5		75	32	[14]
4		25		90	12.5	[14]
5	Ph—HC=N—Ph	15—20	Ph—HC—N—Ph	80	19	[14]
6		—5		26	13	[15]
7		20		61	32	[15]
8	$PhCH_2OH$	27—28	$PhCH_2Cl$	83	36	[14]
9	Ph_2NH	20	Ph_2NCHO	95	58	[14]

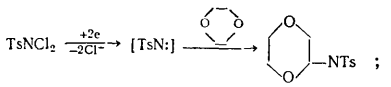
Note. The electrochemical reduction was carried out at a lead cathode at j = 2–4 mA cm^{-2} in the presence of 0.35 M NR_4Br (R = alkyl) as the supporting electrolyte.
* According to Fritz and Kornrumpf,[4] the yield is 80%.

After the studies which confirmed the carbene mechanism of the processes considered above, it was important to assess the possibility of the synthetic application of the electrochemically generated carbenes. In particular, studies[14,15] on the electrolysis of CCl_4 at a lead cathode in $CHCl_3$ in the presence of organic substrates of different nature have shown that the dichlorocarbene generated in this way is capable of interacting under mild conditions with the C=C and C=N double bonds, forming cyclopropane and aziridine adducts (Table 2). According to the mechanism adopted,[16,19] the interactions with an alcohol and an amine (Table 2, experiments 8 and 9) proceed via the intermediate formation of ylide structures and lead to benzyl chloride and diphenylformamide respectively.

Dichlorocarbene reacts selectively with geraniol and geranyl acetate (Table 2, experiments 6 and 7) at the terminal double bond. The above reactions are highly selective. Cathodic electrolysis (lead cathode, j = 1–3 mA cm^{-2}) of CBr_4 in the presence of NBu_4BF_4 as the supporting electrolyte in cyclohexene-containing AN leads to the exclusive formation of 7,7-dibromonorcarane,[20] while the electrolysis of CBr_4 in CH_2Cl_2 in the presence of benzyltriethylammonium chloride as the supporting electrolyte results in a mixture of 7,7-dibromo, 7-bromo-7-chloro-, and 7,7-dichloro-norcaranes in an overall yield up to 85%. A number of reactions, inititated by the interaction of the electrochemically generated dibromocarbene with a chloride ion, take place during the electrolysis:[20]

Scheme 8

By varying the nature of the supporting electrolyte, it is possible to obtain predominantly (up to 65%) a particular dihalogeno-derivative (Scheme 8) as a mixture with other dihalogeno-derivatives obtained in an overall yield of ~80%.

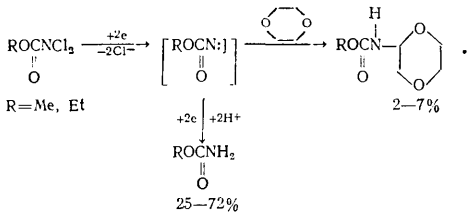


The examples considered above reveal good prospects for the creation of electrochemical processes for carbene synthesis, which may compete with traditional methods. It follows from the analysis of literature data that the formation of cyclopropane derivatives in high yields is promoted by carrying out the process at a relatively low current density (j = 1–5 mA cm^{-2}), a high alkene concentration relative to the source of the carbene, the use of halogenomethanes as solvents, and the use of tetraalkylammonium halides as supporting electrolyte salts, the readily soluble tetrabutylammonium salts being preferable. Furthermore, the replacement of NBu_4Br in the electrochemical synthesis of difluorocarbene from CF_2Br_2, for example, by NEt_4Br, promotes faster formation of a passivating layer of polytetrafluoroethylene on the electrode.[5] (We may note, however, that the question of the passivation of the electrode as well as the main causes of the low degree of conversion of the organic substrate has still been little investigated.)

2. Generation of carbene analogues

Nitrenes. The electrochemical reduction of organohalogen compounds makes it possible to generate also a nitrene, which is an important reaction intermediate.

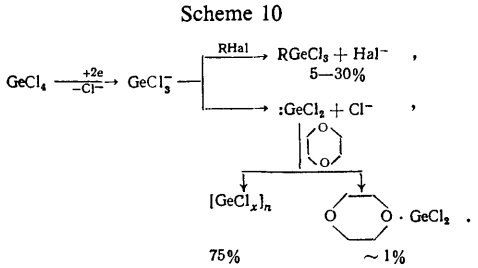
On the basis of the results of preparative electrolysis in galvanostatic and potentiostatic regimes, the possibility of generating nitrenes from the corresponding *NN*-dichloro-derivatives at different electrodes (Pt, Zn, Cu, Hg, and C) has been demonstrated.[21–23] The electrochemical reduction of *NN*-dichloro-derivatives of toluene-*o*- and toluene-*p*-sulphonamides in the range of potentials 0.30–0.35 V takes place with transfer of two electrons.[21–23] As a result, the N–X (X = halogen) bond is ruptured in the first stage, as in the reduction of polyhalogenoalkanes. The fragmentation of the N-anion formed under these conditions (cf. Scheme 2) leads to a nitrene. Indeed, the electrochemical reduction of *NN*-dichlorosulphonamides at a platinum cathode in AN in the presence of $LiClO_4$ as the supporting electrolyte and 1,4-dioxane, with which nitrenes react,[24]



affording the products of insertion in a C–H bond, led to the formation of the corresponding adduct:

Ts = *p*-$MeC_6H_4SO_2$. 32%

Nitrenes can be generated similarly also in the cathodic reduction of *NN*-dichlorocarbamates under the same conditions,[22,23] but in this case the yield of the product of the insertion of the nitrene in a C–H bond of dioxane proved to be fairly low and the main reaction product was the corresponding carbamate:

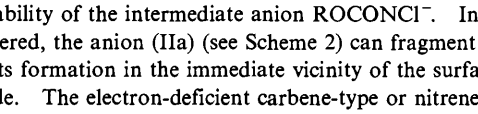


Scheme 9

Such a ratio of the electrolysis products is most probably due to the increased lability of the intermediate anion $ROCONCl^-$. In the case considered, the anion (IIa) (see Scheme 2) can fragment at the instant of its formation in the immediate vicinity of the surface of the electrode. The electron-deficient carbene-type or nitrene-type intermediate formed under these conditions is rapidly reduced at the electrode without having sufficient time to enter into the chemical reaction with the added substrate. The latter process can, in principle, partly compete with the reduction process. This (or a similar) situation evidently actually occurs in the electrolysis of *NN*-dichlorocarbamates (Scheme 9).

Germylenes. The electrochemical approach proved to be promising also for the generation of carbene analogues such as germylenes. This approach is based[25] on the electrochemical reduction of the readily available tetrachlorogermane, which had not been investigated previously. It has been established by methods involving the rotating disc electrode with a ring and electrolysis at a controlled potential [Pt cathode, AN with NEt_4ClO_4 as the supporting electrolyte, $E = -0.5$ V (rel. Ag/Ag^+)] that two electrons are transferred in the first stage of the electrochemical reduction of $GeCl_4$ with formation of the thermodynamically unstable anion $GeCl_3^-$:

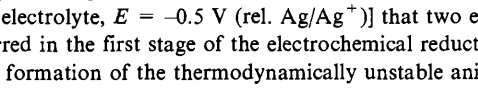
Scheme 10



The formation of $GeCl_3^-$ has been confirmed,[26] in particular, by its interaction with organic halogeno-compounds added to the electrolysed solution. In the absence of RX (X = halogen), the $GeCl_3^-$ anion fragments with formation of a labile dichlorogermylene and then germanium subchlorides in 75% yield.[21] The intermediate formation of dichlorogermylene is demonstrated by its familiar[27] reaction with dioxane (Scheme 10), which leads to the formation of a stable complex.

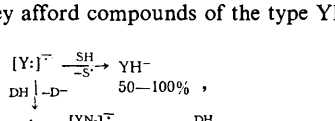
3. The reduction of carbenes and nitrenes

It is quite evident that, since carbenes are electron-deficient species, they should be readily reduced. Therefore the very possibility of the cathodic generation of carbenes, which is at first sight surprising, depends on the lifetime of the intermediate carbanion (IIa) (see Scheme 2). In the case of extremely unstable anions, the carbene (or nitrene—see Section 2) formed on their fragmentation disappears rapidly via a cathodic reaction without having sufficient time to interact with a suitable substrate.



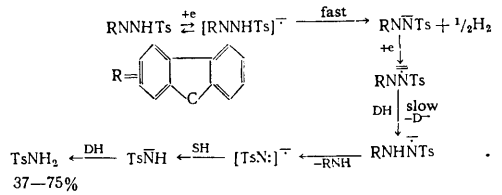
The mechanism of the cathodic reduction of carbenes was first discussed by McDonald and co-workers.[28,29] The authors chose as objects of their investigation diazo-compounds and no longer polyhalogeno-derivatives. It was postulated that the addition of an electron [$E_{p/2} = -1.68$ V (sat. c. e.), Pt cathode, DMF, NEt_4Br] initiates the fragmentation of these substances with evolution of a N_2 molecule, as happens, for example, during thermolysis. Their investigations made it possible to put forward the following mechanism of the reduction of diphenyldiazomethane:[28]

Scheme 11



A similar mechanism has been proposed for the formation and subsequent reactions of the fluorenylidene radical-anion.[29] However, a more careful investigation of this process by high-temperature cyclic voltammetry showed that diazofluorene is reduced via a stage involving the dimerisation of the radical-anion of the diazo-compound.[30]

In subsequent studies,[31,32] it was shown by chronoammetry and low-temperature controlled potential electrolysis that the reduction of $(EtO_2C)_2CN_2$ and 2-diazo-5,5-dimethylcyclohexa-1,3-diene (diazodimedone) does indeed proceed with formation of the radical-anions of diazo-compounds. These radical-anions subsequently eliminate a N_2 molecule via a first-order reaction ($k = 8 \pm 2$ s^{-1} and 1.0 ± 0.1 s^{-1} at –38° and –84 °C respectively), forming carbene radical-anions:

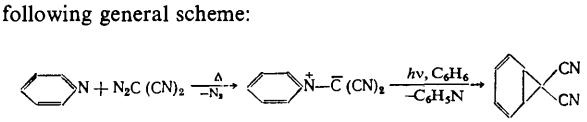


(*a*) $E_{p/2} = -1.0$ V [rel. Cd(Hg)/$CdCl_2$), cathode—vitreous carbon, DMF, NBu_4ClO_4; (*b*) $R_{p/2} = -1.82$ V (rel. Pt), Pt cathode, PrCN, NBu_4ClO_4.

In the absence of a proton donor, the above carbene radical-anions $[Y:]^-$ abstract preferentially a hydrogen atom, which leads to YH^-, while in the presence of benzoic acid, guanidinium perchlorate, or $(CF_3)_2CHOH$ they afford compounds of the type YH_2:

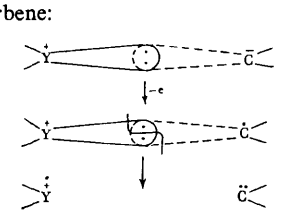
The carbene radical-anion $[PhC(O)\ddot{C}Ph]^-$, whose most characteristic reaction is the abstraction of a hydrogen atom from the solvent, is formed via a similar mechanism.[31] The formation

of the tosylnitrene radical-anion in the electrochemical reduction of fluorenone tosylhydrazone [$E_{p/2}$ = –0.28 V (sat. c. e.), Pt cathode, DMF, NBu_4ClO_4] was demonstrated recently with the aid of cyclic voltammetry, chronoammetry, and electrolysis at a controlled potential:[32]



Thus the data presented above indicate the possibility of the generation and investigation of the properties of carbene and nitrene radical-anions. It may be expected that studies in this field will continue, especially to determine the oxidation-reduction as well as the electrophilic properties of carbenes and nitrenes.

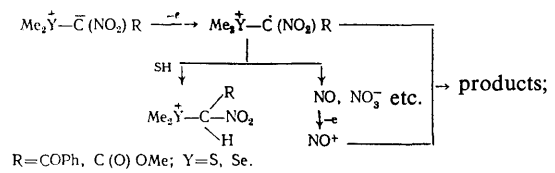
III. Oxidation processes



In the examples quoted above (see Section II), the electrochemical approach to the investigation of carbenes and their analogues was achieved in almost all cases via the generation of the corresponding thermodynamically unstable anions. However, from the methodological standpoint, one may be concerned with the electrochemical generation of not only anionic intermediates but also any other intermediates, whose fragmentation would be accompanied by the formation of carbenes. Data for the formation of such intermediates in the electrochemical oxidation of organic substances available at present are examined below.

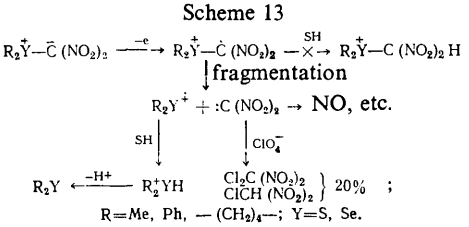
1. Generation of carbenes

Ylides are known[1] to be formed or to behave as intermediates in many reactions of carbenes, carbenes with electron-accepting substituents leading to stable ylides. At the same time, even stable ylides can again become sources of carbenes on irradiation or under the influence of heat. For example, the processes described by Rieser and Friedrich[35] and by Streith et al.[36] can be represented by the following general scheme:



Thus the problem of generating carbenes from stable ylide structures reduces to breaking the ylide linkage in the required way by employing some kind of method involving a physical influence. One of such possibilities consists in the electrochemical oxidation of the ylide to the corresponding radical-cation, whose fragmentation would lead to a carbene:

Nitromethylides were selected as the objects of study.[37–39] The interest in these compounds was due to the possibility of generating a nitrocarbene in this way. The attempts to obtain nitrocarbenes from the corresponding α-nitrodiazo-compounds[40,41] or the alkali metal salts of polynitro- and halogenopolynitro-alkanes[42,43] proved unsuccessful.‡ Perhaps only the report[44] of the probable generation of arylnitrocarbenes from the silver salts of aryldinitromethanes is well founded: the thermolysis (at 100 °C) of these salts in the presence of alkenes leads mainly to isoxazoline *N*-oxide—the product of the 1,3-dipolar addition of an arylnitrocarbene.

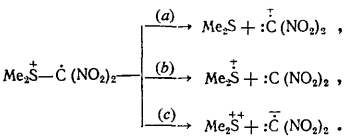


It has been shown[45] that on the polarisation curves for sulphonium§ and selenonium mononitromethylides, recorded at a platinum anode in AN in the presence of $LiClO_4$ as the supporting electrolyte, there is a single oxidation wave with $E_{1/2}$ = 1.4–1.5 V (rel. Ag/0.1 N Ag^+), its position depending on the structure of the ylide. However, the interaction of the radical-cations produced by the one-electron oxidation of the above ylides at E = 1.6 V (rel. Ag/0.1 N Ag^+) with the solvent, in which a hydrogen atom is abstracted and onium structures are formed, is faster than their fragmentation:[45]

Scheme 12

A number of indirect data[45] have indicated the possibility of the partial fragmentation of the mononitromethylide radical-cations during prolonged electrolysis, but the Y–C bond (Scheme 12) is not then involved. Thus the attempts to obtain nitrocarbenes by the anodic oxidation of nitromethylides were unsuccessful. The electrochemical oxidation of dinitromethylides (Scheme 13) yielded different results:

Scheme 13

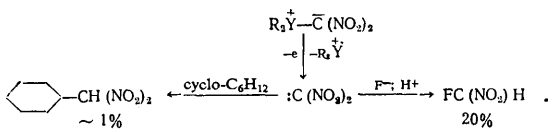


In the course of a study by the disc electrode method with a ring at an annular electrode, the formation of Me_2S was detected at the instant when dimethylsulphonium dinitromethylide was oxidised at the disc electrode; furthermore chloro-derivatives of dinitromethane were isolated from the products of the electrolysis [E = 1.9 V (rel. Ag/0.1 N Hg^+)] of the above dinitromethylide.[37] These data permit the conclusion that the intermediate radical-cation (see

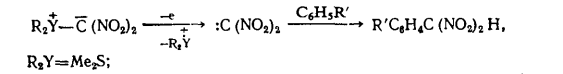
‡ After the present review had been written, the formation of a nitrocarbene intermediate in the interaction of nitrodiazomethane with electron-enriched alkenes in the presence of rhodium acetate became known (P E O'Bannon, W P Dailey, *Tetrahedron Lett.*, 1988, **29** 987).

§ These conditions were standard for all the experiments described in this Section.

Scheme 13) fragments with retention of the sulphide and dinitromethyl fragments, i.e. at the Y—C bond.



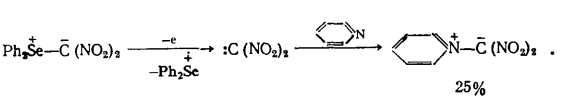
Scheme 14



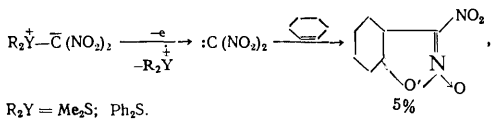
The enthalpies of the possible fragmentation pathways have been calculated in relation to the dimethylsulphonium dinitromethylide radical-cation by the MINDO/3 method.[37] The calculation showed that pathways (*a*) and (*c*) are more endothermic by 268 ± 63 and 1239 ± 63 kJ mol^{-1} than pathway (*b*) leading to the formation of a dinitrocarbene (Scheme 14). According to the calculated data, the dinitrocarbene has a singlet ground state, which is more favourable than the triplet state (the difference is 26 kJ mol^{-1} [37]).

A convenient criterion for the quantitative description of the electrophilicity of carbenes is known[46,47] to be the energy of the LUMO. This permits the calculation, within the framework of the MINDO/3 method, of the electronic structures of a series of singlet carbenes of the type :CR_2 [R = OH, F, Cl, CN, C(O)H, or NO_2] and makes it possible to demonstrate[37] that dinitrocarbene is the most electrophilic carbene in the series considered, because it has the lowest energy of the LUMO. This conclusion was then justified experimentally by introducing the electrochemically generated dinitrocarbene into reactions characteristic of electrophilic carbenes.[38,39]

The carbene mechanism explains satisfactorily the nature of the products formed in the electrochemical oxidation of dinitromethylides in the presence of cyclohexane and the fluoride ion:[38]



Like other electrophilic carbenes, dinitrocarbene interacts with the aromatic ring. The formation of the corresponding aryldinitromethanes can be explained by the insertion of dinitrocarbene in a C—H bond of the aromatic ring:[38]



$R_2Y = Me_2S$;
R′ = H (yield 50%), Cl (40%), CN (15%), NO_2 (10%).

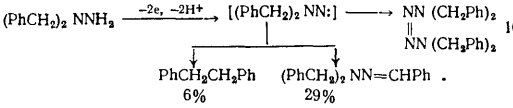
This process occurs even in the presence of substrates deactivated with respect to electrophilic attack. The electrolysis of dinitromethylides in the presence of pyridine entails the transylidation process:[39]

Another process characteristic of carbenes is their addition to a C=C bond. Calculation by the MINDO/3 method[38] for the interaction of dinitrocarbene with ethylene showed that the 1,3-addition of dinitrocarbene is preferable to the cyclopropane formation reaction. This conclusion agrees with data for the anodic electrolysis of dinitromethylides in the presence of cyclohexene:[38]

$R_2Y = Me_2S$; Ph_2S.

For comparison we may note that the dinitromethyl radical, which is also a highly electrophilic species,[48] generated by the electrochemical oxidation of the dinitromethane anion, either does not enter at all into reactions similar to those discussed above or it forms products in much lower yields.

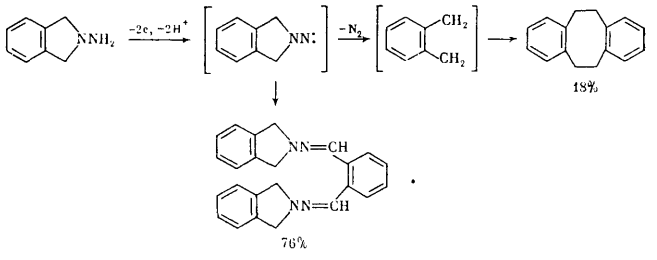
2. Generation of carbene analogues



Nitrenes. Under anodic oxidation conditions, it is possible to generate also species such as nitrenes. As early as the beginning of the 1970's, investigators[49,50] studying the electrochemical oxidation of 1,1-disubstituted hydrazines concluded that this process includes a stage involving the intermediate formation of nitrenes. In this case, the anodic activation of the substrate is accompanied by fragmentation of a different type from that described in subsection 1, namely the elimination of protons. This conclusion is confirmed by data for the oxidation of 1,1-diphenylhydrazine at a platinum anode. In acidified (by the addition of $HClO_4$) AN, this process leads to the quantitative formation of the diphenyldiazenium cation (a protonated nitrene), which can be fully reconverted into the initial hydrazine by electrochemical reduction:[49]

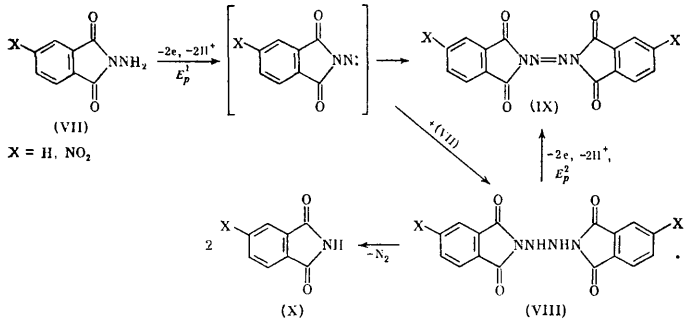
On the other hand, in the presence of pyridine (Py), which facilitates the deprotonation of the intermediate radical-cations, the oxidation of 1,1-diphenylhydrazine proceeds via the formation of a nitrene, which rapidly dimerises to afford a quantitative yield of tetraphenyltetrazene:

Subsequently it was shown[51–53] that the electrochemical oxidation of *NN*-dibenzylhydrazine at E = 0.16 V (rel. Ag/Ag^+) at a platinum anode in AN in the presence of NBu_4BF_4 as the supporting electrolyte leads to bibenzyl, 1,1,4,4-tetrabenzyl-2-tetrazene, and benzaldehyde dibenzylhydrazone in material yields of 6, 10, and 29% respectively.[51] The mechanism of the formation of these substances includes stages with participation of a nitrene as a reactive intermediate:



When the process is carried out on graphite (E = 0.37 V), tetrazene and the hydrazone are formed in 11 and 49% yields respectively, while bibenzyl is formed only in trace amounts.[51].

The electrochemical oxidation of *N*-aminodihydroisoindole at a platinum anode in the aprotic medium (AN) in the presence of the NBu_4BF_4 supporting electrolyte leads to 1,2,5,6-dibenzo-1,5-cyclooctadiene and a substituted *o*-xylylene[51,52] in current yields of 18 and 76% respectively. It is suggested that the two-electron oxidation of *N*-aminodihydroisoindole proceeds via the formation of a metastable



nitrene-type intermediate. The latter either splits off a N_2 molecule, forming a biradical whose dimerisation leads to a cyclooctadiene derivative, or gives rise to an *o*-xylene derivative via a complex mechanism:

Scheme 15

The electrochemical oxidation of *N*-aminophthalimide and of its tetrachloro- and 3-nitro-derivatives has been investigated[53] by cyclic voltammetry and electrolysis at a controlled potential (Pt anode, 0.1 N NBu_4BF_4 or 0.4 N $LiClO_4$ supporting electrolyte in AN). It was established that these compounds are oxidised in the first stage [E_p^1 = 0.99, 1.31, and 1.20 V (rel. Ag/Ag^+) respectively] with transfer of two electrons and two protons to the corresponding nitrenes, whose subsequent reactions lead to 1,4-diphthalotetrazans and 1,4-diphthalotetrazenes. In the second stage ($E_p^2 \geqslant 1.68$ V), the tetrazan is oxidised to the tetrazene. The overall process is described by Scheme 16:

Scheme 16

The yields and ratios of the products depend on the electrolysis conditions (Table 3). The tetrazene (IX) can be obtained also under conditions excluding the possibility of the electrochemical oxidation of the tetrazan (VIII) to the tetrazene (IX) (the controlled electrolysis potential is in the range of the E_p^1 potentials), which confirms the intermediate formation of a nitrene. During electrolysis, the tetrazan (VIII) decomposes partly with elimination of N_2, affording the product (X).

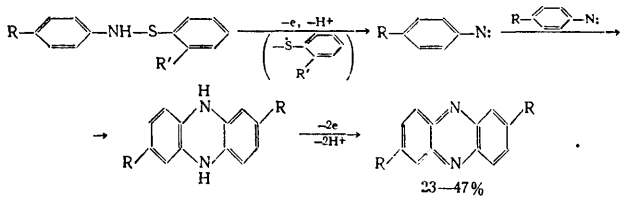


Table 3 shows that electrolysis at higher anodic potentials leads mainly to the formation of the tetrazene (IX), because the tetrazan (VIII), formed as a result of the insertion of the nitrene in a N—H bond of the initial aminophthalimide, is oxidised at the electrode to the tetrazene (IX). It is of interest to note that electrolysis at the potentials of the first wave in the presence of the NBu_4BF_4 supporting electrolyte leads preferentially to the formation of the tetrazan (VIII), while in the presence of the $LiClO_4$ supporting electrolyte the tetrazene (IX) is formed preferentially. Evidently ionic association effects influence significantly the mode of the reactions with participation of the intermediate nitrene. This question merits special consideration. At any rate, the examples presented demonstrate clearly the possibility of controlling the oxidation process (Scheme 16) depending on the electrolysis conditions.

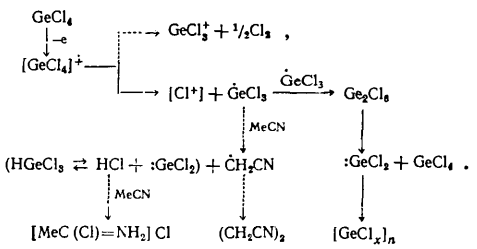
Table 3. Yields of the products of the anodic oxidation of *N*-aminophthalimide (RH) and its nitro-derivative (RNO_2).[53]

Starting material	Supporting electrolyte	*E* in electrolysis, V(rel. Ag/Ag^+)	*Q*, F mol^{-1}	Current (material) yield		
				(VIII)	(IX)	(X)
RH	0.1 *N* NBu_4BF_4	1.3	0.5	80 (40)	—	—
RH	0.1 *N* NBu_4BF_4	1.9	0.5	0	64 (16)	—
RH	0.4 *N* $LiClO_4$	1.3	0.8	9 (6)	66 (27)	15 (12)
RH	0.4 *N* $LiClO_4$	2.0	1.0	0	86 (43)	10 (10)
RNO_2	0.4 *N* $LiClO_4$	1.3	0.8	0	51 (21)	29 (24)
RNO_2	0.4 *N* $LiClO_4$	2.0	1.0	0	64 (32)	21 (21)

Note. The oxidation was carried out at a platinum anode in AN.



The nitrene can be generated under the conditions of anodic electrolysis also by the electrochemical oxidation of 2,4′-substituted benzenesulphenanilides.[52] On a graphite cathode in AN in the presence of the $NaClO_4$ supporting electrolyte, this process takes place with abstraction of one electron and leads to the cleavage of the S—N bond in the intermediate radical-cation (see Section II. 1). The nitrene formed enters into a intermolecular reaction involving insertion in a C—H bond, producing an adduct, which is subsequently oxidised at the electrode with transfer of two electrons and two protons, affording a phenazine:[52]

It is noteworthy that the electrochemical oxidation of *N*-aminophthalimides (see above) can compete successfully with the chemical methods for the synthesis of relatively unstable 2,3-unsubstituted tetrazans and tetrazenes, while the electrochemical oxidation of 4-substituted benzenesulphenanilides constitutes in essence a new method of synthesis of 2,7-disubstituted phenazines, which are otherwise difficult to obtain.[54–59]

Germylenes. According to Petrosyan et al,[26] dichlorogermylene is formed not only in the cathodic reduction of $GeCl_4$, as a result of the fragmentation of the intermediate anion $GeCl_4^-$ (see Section II, subsection 2), but also in the anodic oxidation of $GeCl_4$. The mechanism of the electrochemical oxidation of $GeCl_4$ (Pt anode, AN, $LiClO_4$) can be described[26] by the following scheme (the dashed

lines indicate minor processes) on the basis of data obtained by methods involving a rotating disc electrode with a ring and electrolysis at a controlled potential:

The intermediate radicals $\dot{G}eCl_3$ dimerise rapidly, affording Ge_2Cl_6, which readily disproportionates with formation of dichlorogermylene. The latter has been detected as a stable complex with dioxane (see Section II, subsection 2). The preparative electrolysis is accompanied by the formation of germanium subchlorides from dichlorogermylene in 60% yield. The intermediate radicals $\dot{G}eCl_3$ are capable of abstracting a hydrogen atom from AN, giving rise to $\dot{C}H_2CN$ and $HGeCl_3$, which indicates the presence in the reaction mixture of trace amounts of $(CH_2CN)_2$ and $[CH_3C(Cl)=NH_2]Cl$.

In conclusion, we may note that the observed ability of $GeCl_4$ to function as a source of dichlorogermylene under the conditions of both cathodic and anodic processes merits special attention and the development of electrochemical studies on these lines should lead to new interesting findings. The latter may prove valid also for the tetrachlorides of other Group IV elements, which have been hardly studied hitherto.

Halogen-containing carbenes

R R Kostikov, A P Molchanov, A F Khlebnikov
Leningrad State University

ABSTRACT. The electronic and steric influence of the substituents at a multiple bond and of the presence of a heteroatom in the molecule on the reactivity of compounds in relation to halogenocarbenes is examined. The mechanisms of the interaction of carbenes with single bonds are discussed and data on new methods for the generation of halogenocarbenes are reported.

The bibliography includes 140 references.

I. Introduction

Halogenocarbenes are used more often than other carbenes because of both their relatively ready availability and the synthetic importance of halogenocyclopropanes and other compounds obtained with the aid of halogenocarbenes. In terms of the extent to which these carbenes have been investigated as regards their thermodynamic properties, their structure (by quantum-chemical methods), and their simplest gas-phase reactions, this group of carbenes is inferior only to methylene and, partly, phenylcarbenes.

It has been shown in recent years that all mono- and di-halogenocarbenes have a singlet ground state. According to non-empirical calculations, the energy differences between the singlet and triplet states of carbenes are as follows (kJ mol^{-1}; the experimental values are given in brackets): CH_2 −46(−38);[1] CHF 55 ± 8 (< 63); CHCl 23 ± 8; CHBr 17 ± 8;[2] CF_2 205; CCl_2 71; CBr_2 46.[3] The enthalpies of formation ΔH_f^0 (singlet) of a number of carbenes have been determined experimentally (kJ mol^{-1}): CH_2 425 ± 2; CF_2 −180 ± 8; CClF 46 ± 4; CCl_2 238. We may also indicate the ionisation potentials of the same carbenes (eV): CH_2 (triplet) 10.396; CF_2 12.24 ± 0.01; CFCl 10.9 ± 0.3; CCl_2 9.76.[4] There have been numerous studies in which the geometrical structures of halogenocarbenes have been determined experimentally or calculated.[1–4]

This review deals with questions of the reactivity of halogenocarbenes generated in the liquid phase, namely the influence of electronic and steric factors and also the influence of the heteroatom in the substrate on the rate of reaction. Data are presented on new methods for the generation of halogenocarbenes.

II. Reactions with unsaturated compounds

This process has been investigated in greatest detail. The interaction of halogenocarbenes with unsaturated compounds leads to halogen-containing strained cyclic systems, which can be used as synthons in organic synthesis. On the other hand, this reaction is the simplest cheletropic process and has therefore attracted the attention of theoretical chemists.

1. The influence of the electronic effects

In order to determine the reactivity of double bonds in relation to halogenocarbenes, the method of competing reactions was already used in the first investigations. It was established that the relative rate constants are correlated with the σ^+ constants of the substituents in the aromatic ring for the reactions of dichlorocarbene with ring-substituted styrenes (−0.42),[5] 1-arylbuta-1,3-dienes (−0.42),[6] 2-arylbuta-1,3-dienes (−0.36),[7] 2-arylpropenes (−0.38),[8] 2-arylbut-1-enes (−0.37),[7] methyl esters of substituted cinnamic acids (−0.33), and arylideneanilines (−0.36).[9] The type of the correlation equation and the negative sign of the ρ constant (given above in brackets) indicate a transition state in which the reaction centre is positively charged and is involved in a direct polar conjugation with the substituent.

In the interaction with diene, triene, and tetraene hydrocarbons, dichlorocarbene adds to the terminal double bond. Its reactivity in the series buta-1,3-diene (0.48), *trans*-hexa-1,3,5-triene (1.27), styrene (1.0), 1-phenylbuta-1,3-diene (1.87), 1-phenylhexa-1,3,5-triene (2.02), 1-phenylocta-1,3,5,7-tetraene (2.02), and 2-phenylbuta-1,3-diene (4,38) is satisfactorily correlated with the localisation energies of the methylene carbon atom (L_r^+) calculated by the SCF PPP method as the difference between the energies of the π electrons of the hydrocarbon and the carbonium formed from it after the removal of the CH_2 fragment:[10,11]

$$\lg k_{\text{rel}}^{CCl_2} = -(0.57 \pm 0.05)L_r + 11.7; \quad r = 0.978; \quad s = 0.07, \; n = 7.$$

Similar correlations with the ionisation potentials (IP) have been observed for conjugated hydrocarbons ($\lg k = 4.53 - 0.53\text{IP}$; $r = 0.99$) and for non-conjugated hydrocarbons ($\lg k = 10.17 - 1.05\text{IP}$; $r = 0.99$).

For the estimation of the selectivity of the carbene, Moss proposed the carbene selectivity index m_{CXY} (relative to dichlorocarbene) calculated from the equation[12]

$$m_{CCl_2}^{CXY} = \lg (k_i/k_0)^{CXY} / \lg (k_i/k_0)^{CCl_2}. \quad (1)$$

The values of m_{CXY} can be calculated from the constants σ_R^* and σ_I of the substituents at the carbene centre by the equation[13,14]

$$m_{CXY} = -1.10 \sum_{XY} \sigma_R^+ + 0.53 \sum_{XY} \sigma_I - 0.31. \quad (2)$$

The selectivity of the carbene increases with increasing π-donor and σ-acceptor effects of the substituents at the carbene centre (Table 1). For $m_{CXY} \leqslant 1.5$, the carbene exhibits electrophilic properties (dihalogenocarbenes). Carbenes with nucleophilic properties [dimethoxycarbene, dimethylamino(methoxy)carbene] have a selectivity index $\geqslant 2.2$. Carbenes having a selectivity index in the range $1.5 < m_{CXY} < 2.2$ are ambiphilic: they react as electrophilic species with nucleophilic alkenes and they react as nucleophiles with an electrophilic double bond. Such carbenes include chloro(methoxy)carbene,[15,16] chloro(phenoxy)carbene,[17,18] fluoro(phenoxy)carbene,[19] and fluoro(methoxy)carbene.[13,14]

Note. The indices m_{CXY} have been calculated from Eqns. (1)–(4); the ratios k_i/k_0 in Eqn. (1) were taken from the literature.[13,14,22,23]

* According to the data of Kostikov and de Miegere.[20]

** According to Moss et al.,[21] the difference from the value obtained by Eqn. (1) is due to the different conformation of the carbene as a result of steric interactions.

*** Calculated for the conformation with the benzene ring rotated by 90°.

**** The ambiphilicity of carbenes was demonstrated.[15,19]

The dependence of the selectivity of the carbene on the series of alkenes selected for its determination has been demonstrated for the reactions of dihalogenocarbenes with alkylethylenes and styrenes.[5] Difluoro- and chlorofluoro-carbenes exhibit a greater selectivity in reactions with alkylethylenes than dichlorocarbene, while in reactions with ring-substituted styrenes they actually show a lower selectivity (Table 1).

Schoeller and co-workers[24–26] demonstrated within the framework of the one-electron perturbation theory that the selectivity index S can be defined by the following equation

$$S \equiv \partial(\Delta E)/\partial\Delta = \partial(\delta E_I + \delta E_{II})/\partial\Delta \,, \qquad (3)$$

where

$$\delta E_I = \langle\pi|H|p\rangle^2 \cdot (E_p - E_\pi)^{-1};\ \delta E_{II} = \langle\sigma|H|\pi^*\rangle^2 \cdot (E_\sigma - E_{\pi^*})^{-1};\ E_\sigma,\ E_p,\ E_\pi,$$

and E_σ, E_p, E_π, and E_{π^*} are the energies corresponding to the HOMO and LUMO of the carbene and the alkene. The selectivity indices calculated by Eqn. (3) are listed in Table 1. The values obtained agree well with the experimental data and data calculated by Eqn. (2). In the case of halogeno(phenyl)carbenes, a good agreement has been obtained for the conformation in which the benzene ring has been rotated by 90° (the values are given in brackets). The application of the molecular orbital perturbation method permits the calculation of the selectivity index of the carbene by means of the equation

$$m_{CXY} = d^X d^Y \Delta_{i0}^{CXY}/\Delta_{i0}^{CCl_2}, \qquad (4)$$

where d^X and d^Y are empirical constants of the substituents at the carbene centre, $\Delta_{i0}^{CXY} = (\varepsilon_{HOMO}^{i} - \varepsilon_{LUMO}^{CXY})^{-1} - (\varepsilon_{HOMO}^{0} - \varepsilon_{LUMO}^{CXY})^{-1}$ and ε_{HOMO}^{i}, ε_{HOMO}^{0}, and ε_{LUMO}^{CXY} are respectively the orbital energies of the HOMO of the ith and standard alkenes and of the LUMO of the carbene (Table 1).

Calculations by non-empirical methods have confirmed the dependence of the selectivity of the carbene on the relative positions of the frontier orbitals of the carbene and the alkene.[13] For electrophilic carbenes, the main contribution comes from the interaction of the unoccupied p orbital of the carbene with the HOMO (π) of the alkene, while for nucleophilic carbenes the main contribution is that of the interaction of the HOMO (σ) of the carbene with the LUMO (π*) of the alkene. For ambiphilic carbenes, the selectivity is appreciably influenced by the substituents at the double bond of the alkene: electron-donating substituents promote the manifestation of the electrophilic properties by the carbene, while electron-accepting substituents promote the manifestation of nucleophilic properties.

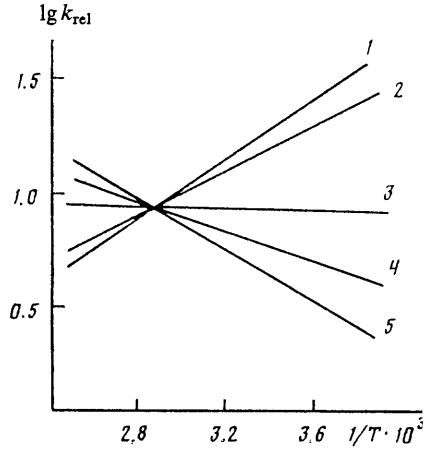

Figure 1. Temperature dependence of the relative reactivities of dihalogenocarbenes ($\lg k_{rel}$) for the 2,3-dimethylbut-2-ene/2-methylpropene pair[27]: *1*, :CF_2; *2*, :CFCl; *3*, :CCl_2; *4*, :CBrCl; *5*, :CBr_2.

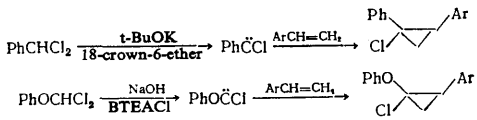
The systematic study of the selectivity of dihalogenocarbenes at different temperatures undertaken by Giese and co-workers[27–29] demonstrated that the selectivity of dichlorocarbene in relation to the 2,3-dimethylbut-2-ene/2-methylpropene pair does not vary, while for



other carbenes it depends on temperature (Fig. 1). At 90° + 10 °C, the selectivity of all the dihalogenocarbenes is the same, while at higher temperatures fluorine-containing carbenes proved to be less selective than other carbenes but dibromocarbene is more selective. Thus, for the chosen pair of alkenes the reaction with dichlorocarbene can be assigned to the isoenthalpic series. This has to be set against the finding that the enthalpy of activation for the reaction of dibromocarbene with isobutene is higher than for the reaction with tetramethylethylene ($\Delta\Delta H^{*}$ = 6 kJ mol^{-1}). On the other hand, the enthalpy of activation for the reaction of difluorocarbene with isobutene is smaller than for the reaction with tetramethylethylene ($\Delta\Delta H^{\#}$ = −11 kJ mol^{-1}), which suggests that the entropy of activation plays the main role. The selectivity of dichlorocarbene in relation to the series of 2-arylpropenes is also independent of temperature ($\Delta\Delta H^{\#}$ = 0). On the other hand, the enthalpies of activation for the reactions of alkylpropenes increase with increase in the degree of branching of the alkyl group.[30] The selectivity index of dibromocarbene (m_{CBr_2}) depends on the degree of substitution at the double bond and assumes the following values: 1.1 for monosubstituted alkenes, 0.86 for disubstituted alkenes, and 0.73 for trisubstituted alkenes, which corresponds to the usual relation between activity and selectivity: a less reactive alkene exhibits a greater selectivity.[31]

Table 2. The relative rate constants for the reactions of chloro(phenyl)- and chloro(phenoxy)-carbenes with ring-substituted styrenes ($RC_6H_4CH=CH_2$) at different temperatures.[17,18]

*Photolysis of chloro(phenoxy)diazirine.[17,18]

The selectivity of chloro(phenyl)carbene in reactions with styrene increases with increasing temperature,[32] while the selectivity of chloro(phenoxy)carbene, generated from dichloro(phenoxy)methane and NaOH, diminishes (Table 2):[33]

where BTEACl = benzyltriethylammonium chloride.

It may be that the different temperature dependences of the selectivities of these carbenes are because chloro(phenyl)carbene is electrophilic while chloro(phenoxy)carbene is nucleophilic. It has been shown[17,18] that chloro(phenoxy)carbene, generated by the photolysis of chloro(phenoxy)diazirine, is ambiphilic in the reactions with both styrenes (see Table 2; k_{rel} = 1.42 and 1.33 for *p*-trifluoromethylstyrene and *p*-nitrostyrene) and with other alkenes (for example, k_{rel} is 0.36 for hex-1-ene, 1.00 for pent-2-ene, 7.3 for isobutene, 3.0 for tetramethylethylene, 3.7 for methyl acrylate, and 7.3 for acrylonitrile).

The absolute rate constants for the interaction of arylhalogenocarbenes, generated by the flash photolysis of the corresponding arylhalogenodiazirines, with unsaturated compounds have been measured.[34] It follows from the temperature dependence of the absolute rate constants for the reactions of chlorophenylcarbene with a series of alkenes that the reactions have a negative ethalpy and entropy of activation and that the changes in the enthalpy of activation are responsible for the observed series of reaction rate constants (Table 3).[35]

Table 3. Thermodynamic parameters of the reactions of chloro(phenyl)carbene with alkylethylenes.[35]

Alkene	$\Delta\Delta H^{\neq}$, kJ mol^{-1}	$\Delta\Delta S^{\neq}$, J mol^{-1} K^{-1}	$\Delta\Delta G^{**}$, kJ mol^{-1}	k_{abs}^{*}, litre mol^{-1} s^{-1}	k_{rel}^{*}

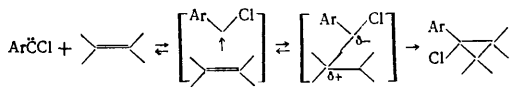
Hex-1-ene	−6.3	−88	18.8	$3.8\cdot10^{6}$	0.012

*At 25 °C.
**From k_{abs}.



In order to account for the negative activation energy, the hypothesis was put forward that an intermediate complex between the carbene and the alkene is formed and that it can subsequently either decompose into the initial reactants or can give rise to cyclopropane. In all probability, this is either a π-complex of the carbene with the alkene or a "close pair" of the reactants in the solvent cage:

$$\ddot{\text{C}}\text{Cl}_2 + \text{alkene} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \ddot{\text{C}}\text{Cl}_2/\text{alkene},$$

$$\ddot{\text{C}}\text{Cl}_2/\text{alkene} \xrightarrow{k_2} \text{cyclopropane},$$

$$k_{obs} = k_1k_2/(k_{-1}+k_2).$$

The rate constants for the reactions of halogenophenylcarbenes with alkenes increase with increasing pressure in the reaction system and are independent of the solvent employed, which is consistent with the reversible formation of a carbene–alkene complex or an early transition state:

The introduction of electron-donating substituents into the aromatic ring stabilises the carbene and lowers its reactivity, while the introduction of electron-accepting substituents increases the reactivity (Table 4). Electron-accepting substituents favour the

conversion of the transition state into the final cyclopropane, stabilising the negative charge on the carbene atom, while the dissociation of the complex into the initial carbene and alkene is hindered. On the other hand, if the substituent is electron-donating, the degree of dissociation of the complex into the initial reactants increases. However, the data in Table 4 show that the selectivity of the carbene hardly changes when the substituent in the aromatic ring is altered. On the other hand, it does depend significantly on the character of the halogen atom at the carbene centre.[38] It is seen from Table 4 that the rate of addition to the double bond increases with decrease in the selectivity of the carbene in the sequence $F\ddot{C}Ph > Cl\ddot{C}Ph > Br\ddot{C}Ph$.

Table 4. The absolute rate constants for the addition of 4-$RC_6H_4\ddot{C}X$ to alkenes (k_{abs}, litre mol^{-1} s^{-1}) at 25 °C.[37,38]

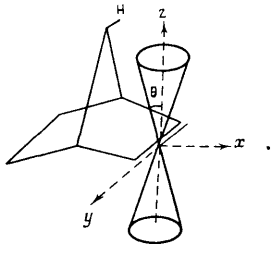
* Values for *trans*-pent-2-ene.

According to non-empirical calculations, complexes are not formed in the reactions of halogenocarbenes with alkenes (only complexes in a solvent cage are possible) and there is no activation barrier to cycloaddition.[39] The observed negative activation energies are probably a common feature of the reactions of all species with a high energy. In such cases the enthalpic activation barrier is absent and there is an entropic barrier. At low temperature, dichloro-, bromochloro- and dibromo-carbenes should then be non-selective and their reactions with alkenes should be diffusion-controlled.

The determination of the relative reactivities of deuterio-substituted 1-monosubstituted and 1,1-disubstituted ethylenes in relation to dichlorocarbenes showed that the "reverse" secondary isotope effect is observed for the CH_2 group in the given reaction ($k_H/k_D \simeq 0.73-0.80$), whereas for the CH group it is close to unity (0.90–0.94).[40] This result indicates a mechanism of the addition of the carbene to the C=C bond in which the carbene locks onto the methylene carbon atom of the double bond to a greater extent than onto the neighbouring atom.

2. The influence of steric effects

The study of reactions of dichloro- and dibromo-carbenes with α- and β-substituted styrenes showed that the reactivity of the double bond depends both on the type of its substitution and on the steric effects of alkyl groups:[41]



$$\lg k^{\beta}_{CCl_2} = -0.46 + 0.76 \lg k^{\alpha}_{CCl_2},$$
$$\lg k^{\alpha}_{CBr_2} = -0.20 + 0.84 \lg k^{\alpha}_{CCl_2},$$
$$\lg k^{\beta}_{CBr_2} = 0.94 \lg k^{\beta}_{CCl_2}.$$

The correlations obtained from the data in Table 5 between the reactivities of dichloro- and dibromo-carbenes show that α-alkylstyrenes are more sensitive than β-alkylstyrenes to changes in the substituent both at the double bond and at the carbene atom. This can be explained by the fact that in the transition state the carbene and the methylene group attacked by it are apparently in the *anti*-planar conformation.

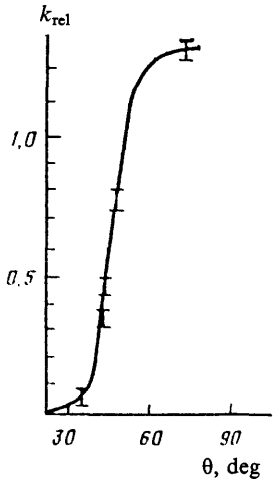
The determination of the reactivities of the double bonds in bicyclic alkenes containing a *cis*-1,2-disubstituted C=C bond led to the conclusion that the approach of the carbene to the bond can be achieved only in a specific region of space, which can be represented by a cone whose axis (0*z*) passes through the centre of the double bond and is at right angles to it:[42]

The minimum angle of the cone (2θ) is about 60°. If any group (H atom) enters the cone located above the double bond, then the approach of the carbene is hindered. Fig. 2 presents the dependence of the reactivity of the double bond in relation to dichlorocarbene on the angle θ calculated for hydrogen atoms closest to the 0*z* axis for different molecules. With increase in the angle θ, the reactivity of the double bond rises, in agreement with the increase in the accessibility of the bond to the approach of the carbene. It is seen from the values of k_{rel} that the rate of addition of the carbene is a maximum for $\theta > 60°$ and that the reaction does not occur if $\theta < 30°$.

The additivity of the influence of the steric effects of the substituents at the double bond on the reactivity of the latter in the reaction of dichlorocarbene with adamantylidene-substituted 1,3-dienes and allenes has been established.[43] The reactivity of the double bond adjoining the adamantane ring is then low and mainly adducts involving the double bond remote from it are formed:

≡ Ad >.



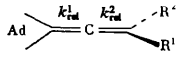


Figure 2. Dependence of the reactivity of the 1,2-disubstituted C=C bond on the angle θ.[40]

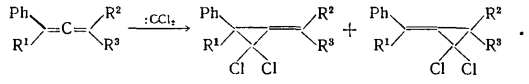
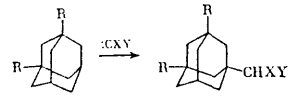


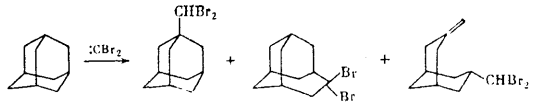
Comparison of the values of k_{rel} for allenes of the adamantane series shows that the reactivity of the double bond closest to the ring diminishes in proportion to the increase in the number of methyl groups at the C(3) atom, while the reactivity of the remote bond then increases.

R^1	R^2	k^1_{rel}	k^2_{rel}
H	H	0.47	0
H	Me	0.28	0.32
Me	Me	0	3.2

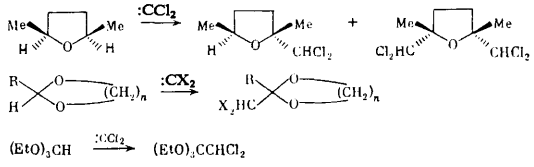


Comparison of the values of k_{rel} for the above allenes with model methylallenes has shown that the influence of the substituents at the C(3) atom of the allene system on the reactivity of the C(1)=C(2) bond can be represented by the equation $k_{rel} = (s'/s'')k_i$, where k_i is the relative rate constant for the reaction of the carbene with the C(1)=C(2) bond of the allene without a substituent at the C(3) atom and s' and s'' are coefficients taking into account the steric shielding of the double bond of the allene by the substituents at the C(3) atom from different sides of the plane of the C(1)=C(2) bond (s_H = 1, s_{Ad} = 0.36, s_{Me} = 0.16).

Adducts involving the most substituted double bond are formed exclusively in the interaction of dihalogenocarbenes with allene hydrocarbons containing aromatic substituents.[44] The reactivity of the bond adjoining the phenyl group can be estimated from the above equation in which the coefficient s for the substituents at the C(3) atom are 1.00 (H), 0.16 (Me), and 0.0 (Ph):



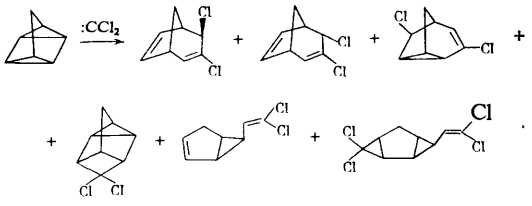
III. Reactions with saturated compounds



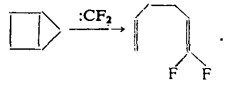
The interaction of halogenocarbenes with single bonds has been investigated much less than the interaction with a double bond. Halogenocarbenes are inserted fairly readily only in a tertiary C–H bond. Thus the reaction of dichlorocarbene, generated under phase-transfer conditions, with adamantane and 1-methyl- and 1,3-dimethyladamantanes leads to the formation of insertion products in high yields.[45] The reaction of dibromocarbene with adamantane results in the formation, apart from the product of insertion in a tertiary C–H bond, also of products involving the expansion and cleavage of the ring:[47]

R=H, Me, X=Y=Cl (Ref.45);
R=H, X=Y=Br (Ref.45);
R=H, X=Cl, Y=CCl=CCl$_2$ (Ref.46).

Dihalogenocarbenes are inserted, with moderate yields, in the C–H bonds of alkyl-substituted aromatic hydrocarbons: ethylbenzene, cumene, and diphenylmethane.[48,49] The carbene is easily inserted in a C–H bond in the α-position with respect to a C–O bond, for example in tetrahydrofuran,[50] dioxolan,[51,52] dioxane,[52] and ethers:[51]

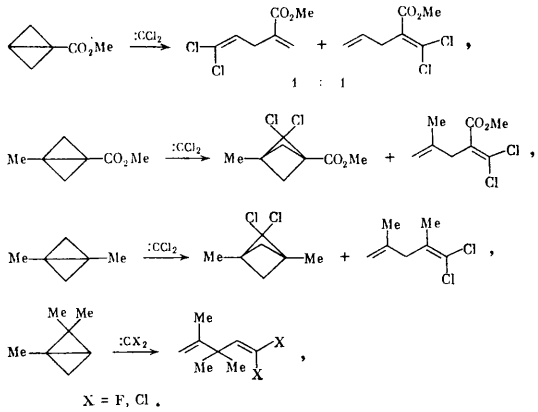


The interaction of dichlorocarbene with alkoxides leads to products of the insertion of the carbene in the α-CH bond in satisfactory yields:[53]

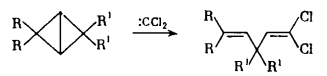


$$RCH_2OLi \xrightarrow[THF]{CHCl_3,\ t\text{-}BuOLi} RCH(OH)CHCl_2,$$

R=Ph, CH=CH$_2$, CH=CHPh.

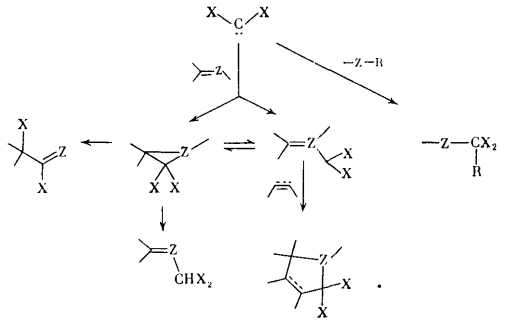


The interaction of dihalogenocarbenes with quadricyclane affords a low yield of a mixture of the same adducts as with norbornadiene but in other proportions:[54,55]



Difluorocarbene, generated from bromodifluoromethyltriphenylphosphonium bromide in the presence of KF, reacts with bicyclo[2.1.0]pentane, producing a very low yield (0.5%) of 1,1-difluorohexa-1,5-diene.[56] An adduct is not formed with bicyclo[3.1.0]hexane:

The interaction of 1,3-disubstituted bicyclobutane derivatives with dichlorocarbene leads to bicyclo[1.1.1]pentane or penta-1,4-diene derivatives depending on the nature of the substituents. The methyl ester of bicyclobutane-1-carboxylic acid reacts with dichlorocarbenes, forming only 1,1-dichloro-2-methoxycarbonylpenta-1,4-diene and the corresponding 4-methoxycarbonyl derivatives,[57] the reaction of the methyl ester of 3-phenylbicyclobutane-1-carboxylic acid gives rise to bicyclopentane derivatives, while the methyl ester of 3-methylbicyclobutane-1-carboxylic acid affords a mixture of substituted bicyclopentane and penta-1,4-diene.[58,59] The reaction of 1,3-dimethylbicyclobutane with dichlorocarbene produces a mixture of 2,2-dichloro-1,3-dimethylbicyclo[1.1.1]pentane and 1,1-dichloro-2,4-dimethylpenta-1,4-diene, whose ratio depends on the method of generation of the carbene.[60] The reaction of 1,2,2-trimethylbicyclobutane with both dichlorocarbene[61] and difluorocarbene[56] produces only a 1,1-dihalogeno-3,3,4-trimethylpenta-1,4-diene:

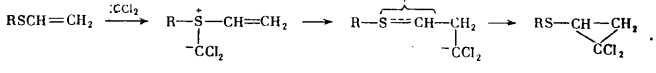


The reaction of 2,2,4,4-tetraalkylbicyclobutanes with dichlorocarbene afford only substituted penta-1,4-dienes:[62]

According to quantum-chemical calculations, the interaction of singlet carbene with bicyclobutane can proceed as a result of the attack by the free 2*p* orbital of the carbene on the HOMO of the bicyclobutane, which is located mainly on the C(1)–C(3) bond. The approach of the carbene "from the side", leading to the formation of penta-1,4-diene, is then more favourable than attack "from above", which leads to bicyclopentane.[56]

IV. Reactions with compounds containing heteroatoms

When the molecule contains a heteroatom having an unshared electron pair, the carbene can interact with the latter, forming an ylide. The possible pathways in the reactions of a carbene with compounds containing a heteroatom are indicated schematically below:



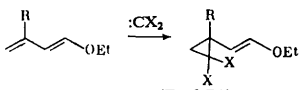
1. Oxygen- and sulphur-containing compounds

The ethers of 2,2-dihalogenocyclopropanols are formed in the reactions of dihalogenocarbenes with vinyl ethers.[63,64] In their reactions with dichlorocarbene, vinyl ethers are 10–20 times more reactive than the corresponding carbon analogues (alk-1-enes), which indicates an appreciable mesomeric involvement of the oxygen atom in the stabilisation of the transition state. It has been shown for a series of α-heterosubstituted styrenes $PhCX=CR^1R^2$, where X = OAlk, Cl, or Br, that the following relation holds:[65]

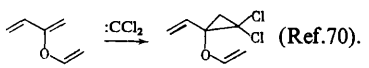
$$\lg k_{rel} = 10.41 - 18.2\ 2\Delta\varepsilon_j - 2.16m,$$

where $\Delta\varepsilon_f = \varepsilon_{\text{styrene HOMO}} - \varepsilon_{\text{carbene LUMO}}$ and m is the number of substituents at the β-carbon atom of the double bond.

The interaction of dichlorocarbene with unsaturated sulphides affords both cyclopropane derivatives[66,67] and the products of the dehydrochlorination of the latter.[67,68] Table 6 lists the relative rate constants for the addition of dichlorocarbene to vinyl ethers and vinyl sulphides. It is seen from these data that vinyl sulphides are 5–6 times more reactive than the corresponding vinyl ethers. This result cannot be explained solely by the different electronic influences of the group RX on the double bond. In its reactions with the sulphides, dichlorocarbene probably interacts not with the double bond but with the sulphur atom, forming an ylide, which then undergoes a 1,3-sigmatropic shift, affording a dipolar ion, which cyclises to cyclopropane:[69]



This hypothesis agrees with the correlation between the constants k_{rel} for the reactions of dichlorocarbene with vinyl sulphides, on the one hand, and the ionisation potentials of the unshared electron pair (IP) and the coefficient c_S of the sulphur atom involved in the



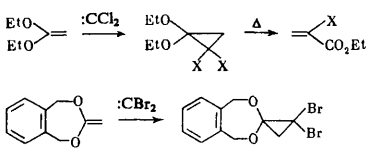
HOMO of the sulphides, on the other, in accordance with the equation

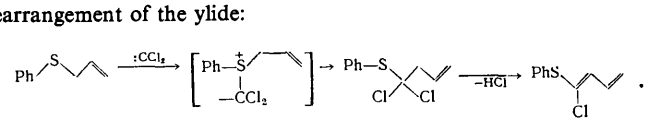
$$\lg k_{rel} = -(4.79 \pm 0.5) + (17.8 \pm 1.7) c_S^2/(IP - 6.8).$$

In reactions of dihalogenocarbenes with dienes containing an alkoxy-group, the carbene adds to the double bond at the end of the conjugation system or to a "cross-conjugated" bond:

R = H, Me; X = Cl (Ref.71)
R = H, X = Br (Ref.72)

In the reactions with dichloro- and dibromo-carbenes, 1,1-diethoxy-ethylene produces cyclopropanone ketals, which are converted into halogenoacrylic acid esters on heating. On the other hand, the spirocyclic dibromoketal is stable and can be used in syntheses:[73]





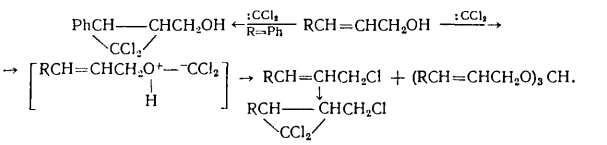


Table 6. The relative rate constants for the addition of dichlorocarbene to sulphides and ethers of the type $RXCH=CH_2$ relative to cyclohexene.

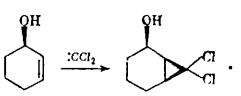
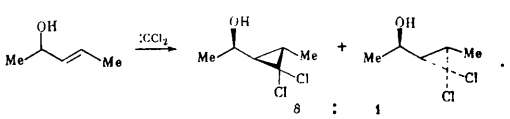
R	k_{rel}	
	X=S (Ref.69)	X=O (Ref.70)
Me	7.1	1.5
Et	—	1.7
n-Bu	10.1	1.7
iso-Bu	8.2	1.4
t-Bu	5.5	6.2
Ph	3.3	0.69
$CH_2=CH$	2.9	0.6

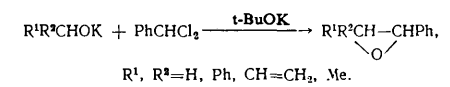
The interaction of dichlorocarbene, generated by the phase-transfer method, with allyl phenyl sulphide led to the isolation of 1-chloro-1-phenylthiobuta-1,3-diene,[74] obtained as a result of the dehydrochlorination of the product of the [2,3]sigmatropic rearrangement of the ylide:



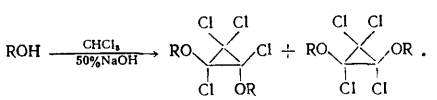
Dichlorocarbene, generated by the phase-transfer method, reacts with substituted allyl alcohols to form substituted (2,2-dihalogeno-cyclopropyl)carbinols in high yields.[75] The thermolysis of (bromodichloromethyl)phenylmercury in allyl alcohol yields allyl chloride, allyl formate, and chloroform.[76] The interaction of dichlorocarbene, generated under the conditions of phase-transfer catalysis, with allyl and cinnamyl alcohols proceeds via two pathways, involving the double bond and the hydroxy-group; in the case of allyl alcohol, 2,2-dichloro-1-chloromethylcyclopropane, triallyloxymethane, and allyl chloride are formed. The main product of the reaction with cinnamyl alcohol is 3,3-dichloro-1-hydroxy-methyl-2-phenylcyclopropane; in addition, 3-chloro-1-phenylprop-1-ene and 3,3-dichloro-1-chloromethyl-2-phenylcyclopropane are formed:[77]



It has been shown by the methods of competing reactions that the ratios of the activities of the hydroxy-group (in both alcohols) and double bonds in cinnamyl alcohol, allyl alcohol, cinnamyl chloride, and allyl chloride are approximately 1 : 1.2 : 0.04 : 0.3 : 0.01 in reactions with dichlorocarbenes.

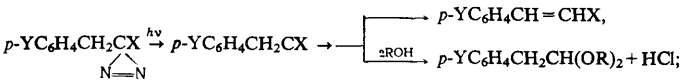


The reactions of cyclic allyl alcohols with dichlorocarbene readily give rise to dichlorocyclopropane derivatives. In conformity with the directing effect of the hydroxy-group, the reaction of 2-cyclohexenol gives rise to a mixture of the *syn*- and *anti*-products in proportions of 13 : 1, whereas 2-cycloheptanol and 2-cyclooctenol afford only the *anti*-adducts:

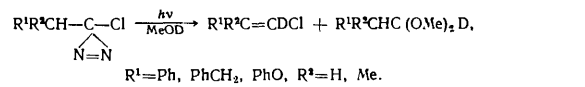


In the case of acyclic allyl alcohols, the most stable rotational isomer is converted into a dichlorocyclopropane and the reaction takes place predominantly from the side of the hydroxy-group:[78]

Chloro(phenyl)carbene, generated from benzylidene dichloride on treatment with potassium t-butoxide, reacts with alkoxides to form oxirans:[79]

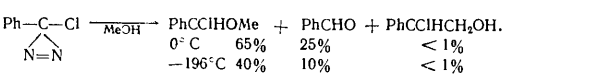


When dichlorocarbene was generated by the phase transfer method using ethanol-containing chloroform, 1,1,2,3-tetrachloro-2,3-diethoxycyclopropane was obtained.[80] A mixture of stereoisomeric 2,3-dialkoxy-1,1,2,3-tetrachlorocyclopropanes is also formed in the reactions with isobutyl and neopentyl alcohols,[81] while benzyl and phenylethyl alcohols afford the corresponding ortho-esters:



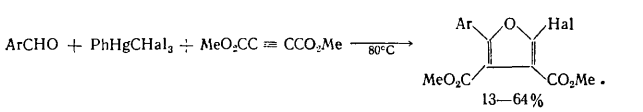
It follows from kinetic experiments that the reaction of benzylchlorocarbenes, obtained from the corresponding diazirines, with alcohols involves the insertion of the carbene in the O—H bond

of the alcohol dimer or oligomer via the electrophilic attack of the carbene on the unshared electron pair of the oxygen atom with the reversible formation of an ylide intermediate:[82,83]

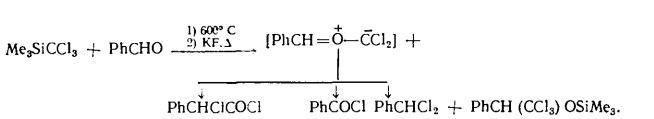


X=Cl, Br; Y=H, Me, Cl;
R=Me, Et, CH_2.

The study of the reactions of substituted benzylchlorocarbenes with MeOD showed that the carbene is partly protonated by the alcohol and that the subsequent elimination of the proton leads to an alkene or an ether:[84]

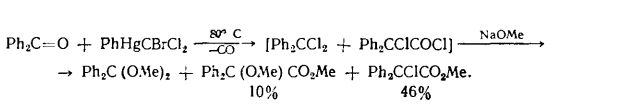


R^1=Ph, $PhCH_2$, PhO, R^2=H, Me.

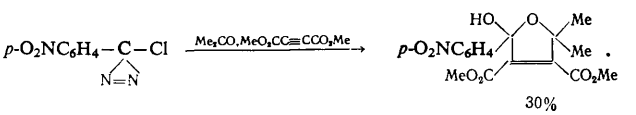


The photolysis of chloro(phenyl)diazirine in methanol at 0 °C and in a matrix at –196 °C showed that an increase in the yield of the products of the insertion of singlet chloro(phenyl)carbene in a C–H bond is not observed when the temperature is reduced and the principal reaction pathway remains the insertion in the O–H bond:[85]

In the reactions of dichloro- and dibromo-carbenes, generated from phenyltrihalogenomethylmercury derivatives, with benzaldehydes, dihalogenocarbonyl ylides are formed. These have been detected in reactions with dipolarophiles:[86,87]

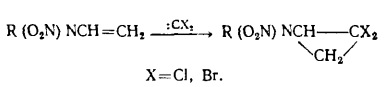


Vacuum flash pyrolysis of Me_3SiCCl_3 involves the formation, together with benzaldehyde, of dichlorocarbonyl ylide,[88] which then reacts according to the following mechanism:

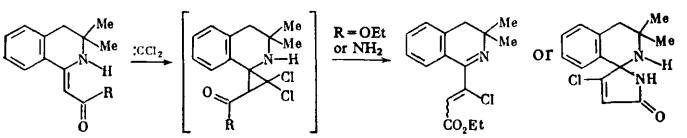


When $PhHgCBr_3$ is heated in the presence of aldehydes and ketones, a deoxygenation reaction is observed:[89]

In contrast to the reactions of dichlorocarbene derived from $PhHgCBrCl_2$ with aromatic aldehydes, it was not possible to detect carbonyl ylides in the reactions with aromatic ketones.[90] It has been suggested that for steric reasons the latter are readily converted in this instance into oxirans, whose reactions lead to the final products:[90]

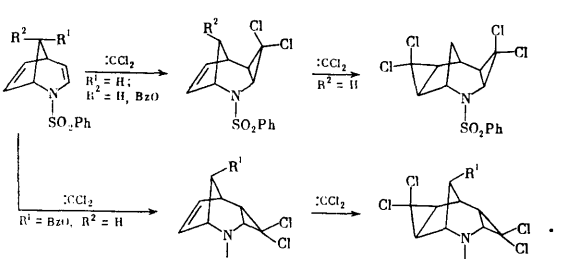


The reaction of chloro(*p*-nitrophenyl)carbene with acetone produces an ylide, whose formation has been detected by means of the reactions with dipolarophiles:[91]

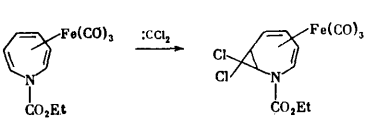


2. Nitrogen-containing compounds

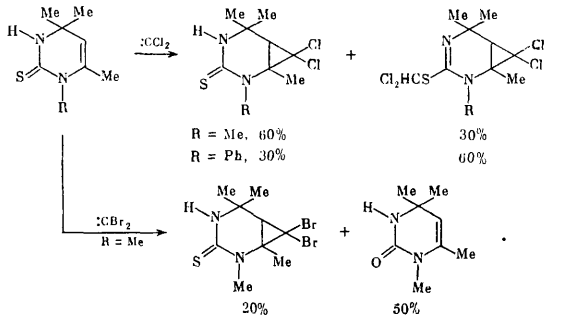
Substituted aminocyclopropanes have been obtained in the reactions of halogenocarbenes with enamines. The reactions of *N*-nitroenamines with dichlorocarbenes[92] and dibromocarbenes[92,93] lead to the formation of the corresponding dihalogenocyclopropanes in yields ranging from 20 to 60%:



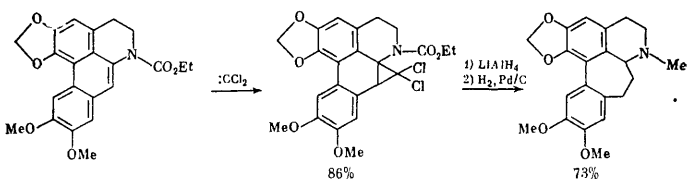
X=Cl, Br.



The dichloropropanes formed in the interaction of dichlorocarbene with 1-(R-carbonylmethylene)-3,3-dimethyl-1,2,3,4-tetrahydroisoquinolines are converted into a 1-azadiene or a spirolactam under the reaction conditions:[94]



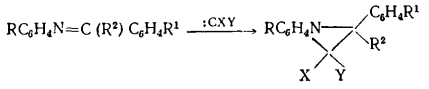
The influence of the stereochemistry of the enamine on the stereoselectivity of the cycloaddition of dihalogenocarbenes has been investigated. *N*-(Benzenesulphonyl)-2-azabicyclo[3.2.1]octa-3,6-dienes react with dichlorocarbene predominantly via the C(3)=C(4) bond, whereupon the stereochemistry of the cycloaddition is determined by the substituent at the C(8) atom:[95]



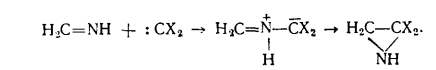
The addition of dichlorocarbene to tricarbonyl[*N*-(ethoxycarbonyl)-azepine]iron takes place selectively:[96]

The reactions of 1-substituted 4,4,6-trimethyl-1,4-dihydropyrimidine-2(3*H*)-thiones with dihalogenocarbenes lead to the corresponding cyclopropane derivatives:[97]

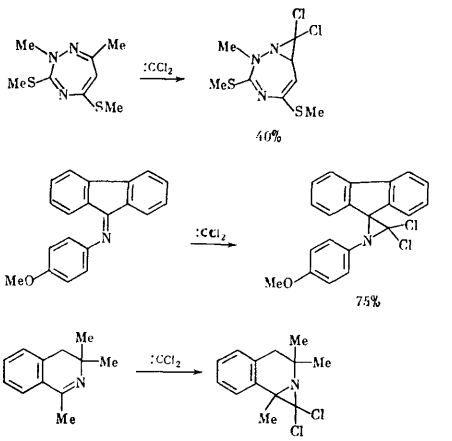
The addition of dichlorocarbene to the enamine double bond with subsequent ring expansion has been used to synthesise homoaporphines:[98]



A similar strategy, involving the addition of a dihalogenocarbene to the double bond in 1,2-dihydroisoquinolines and subsequent cleavage of the three-membered ring at the bond opposite to the CX_2 group, has been used in the synthesis of benzazepines.[99–101] In these cases, the dihalogenocarbene added to the enamide group:

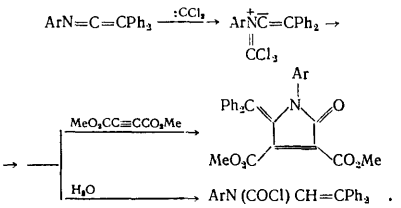


$R^1, R^2 = O$, $R^3 = Me$; $R^1 = H$, $R^2 = Ph$, $R^3 = Ac$; X = Cl, Br.



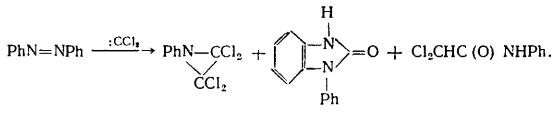
The reactions of bromine-, fluorine-, and chlorine-containing dihalogenocarbenes with aromatic azomethines, leading to the formation of *gem*-dihalogenoaziridines, have been studied in detail.[9] The relative reactivities of the azomethines in the reactions with dibromo- and dichloro-carbenes are then correlated with the basicities of the azomethines. Asymmetric carbenes react stereoselectively:[9]

Quantum-chemical calculations for the interaction of methylene and dichlorocarbene with formaldimine have shown that in all cases the reaction begins with the formation of an ylide (without an activation barrier), which then cyclises to aziridine with a small activation barrier:[102]

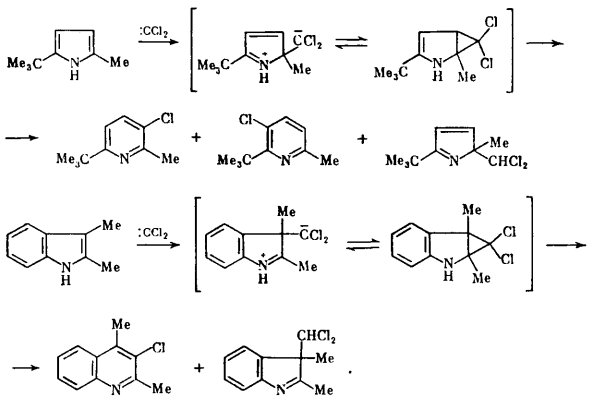


Dichlorocarbene reacts with *trans*-cinnamylideneaniline only at the C=N bond with formation of 3,3-dichloro-1-phenyl-2-(*trans*-2-phenylvinyl)aziridine.[9] 2,2-Dibromo-3-(4-nitrophenyl)-1-phenylaziridine[103] as well as a substituted triazepine[104] and spirocyclic aziridines[94,105] have been synthesised by the reactions of azomethines with dihalogenocarbenes generated under the conditions of phase-transfer catalysis:

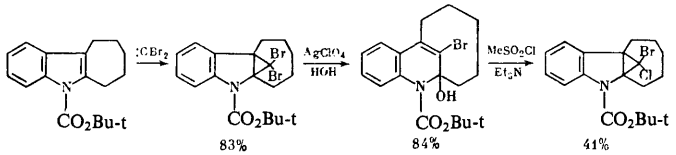
The reactions of acetophenone anils with dichlorocarbene, generated by treating $CHCl_3$ with potassium t-butoxide, afforded the corresponding *gem*-dichloroaziridines in 40–80% yields.[106] Perfluorinated carbenes do not form aziridines on reaction with fluorinated azomethines, while $(CF_3)_2C=NH$ reacts with bis(trifluoromethyl)carbene to give the product of insertion in a H–N bond.[107] On the other hand, the reaction of difluorocarbene with the imine derivative of glycine leads to an aziridine, which is formed as a result of the rearrangement of the primary difluoroazomethine-ylide:[108]



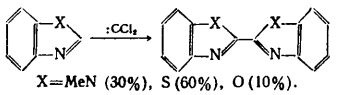
The reactions of keten imines with dichlorocarbene, generated by the thermal catalytic decomposition of sodium trichloroacetate, involve only the C–N bond and lead to the formation of the corresponding carbamoyl chlorides as a result of the hydrolysis of the intermediate keten imine-ylides.[109,110] The relative reactivities of compounds containing cumulated C=C and C=N bonds in the reactions with dichlorocarbene, obtained from chloroform and potassium t-butoxide at 0 °C (k_{rel} is 1.0 for $PhN=C=CPh_2$, 0.7 for p-$ClC_6H_4N=C=CPh_2$, 1.1 for p-$MeOC_6H_4N=C=CPh_2$, and 0.44 for PhN=CHPh), have been measured for the first time.[110] The formation of keten imine-ylides has been confirmed by their reactions with olefinic and acetylenic dipolarophiles:[111]



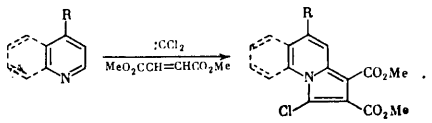
1-Phenylbenzimidazol-2-one has been isolated in the reaction of azobenzene with dichlorocarbene, generated under the conditions of phase-transfer catalysis together with tetrachloroaziridine, which is also formed in the reactions of azobenzene with phenyltrihalogenomethylmercury reagents.[112,113] 1-Phenylbenzimidazol-2-one is



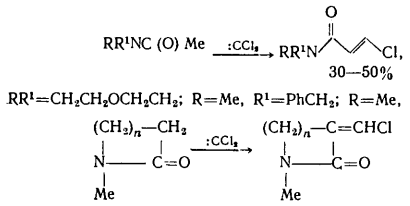
formed via the intermediate *gem*-dichlorodiaziridine:



The study of the mechanism of the interaction of dichlorocarbene, generated from $PhHgCCl_3$ and NaI, with 2,5-dialkylpyrroles and 2,3-dialkylindoles[114,115] showed that, in a neutral (aprotic) or weakly alkaline (protic) medium, the reaction proceeds via the same intermediate:

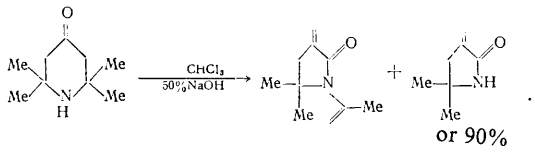


In the reaction of dibromocarbene with cycloheptenoindole, a tetracyclic adduct was obtained and was converted by a ring opening process into the corresponding dihydroquinoline, undergoing an unusual retrocyclisation:[116]



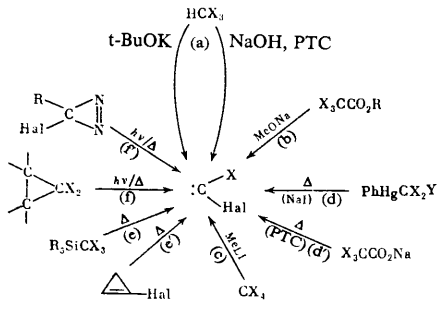
In dichlorocarbene generating systems, benzazoles afford bibenzazoles:[117]

It has been established recently that six-membered azaheterocycles react with dichlorocarbene to form unstable cyclic immonium ylides, whose cycloaddition leads to 3-chloroindolizines which are otherwise difficult to obtain:[118]



The corresponding (*E*)-3-chloroacetamides and α-chloromethylenelactams have been obtained from tertiary acetamides and lactams:[119]

Under the conditions of the thermal catalytic decomposition of sodium trichloroacetate in chloroform, trichloroacetamides are reduced to dichloroacetamides as a result of the chlorophilic CCl_3 elimination reaction:[120]



The interaction of dichlorocarbene with 2,2,6,6-tetramethylpiperidin-4-one results in ring contraction:[121,122]

V. Methods for the generation of halogenocarbenes

Numerous methods for the preparation of halogenocarbenes are now known. A general scheme illustrating the methods of generation is presented below and includes the following: (a) classical methods for the formation of dihalogenocarbenes from haloforms with the aid of potassium t-butoxide or 50% sodium hydroxide solution in the presence of a phase-transfer catalyst (PTC): (b) treatment of trihalogenoacetic acid esters with sodium methoxide: (c) the interaction of organolithium compounds with tetrahalogenomethanes: (d) thermal decomposition of phenyltrihalogenomethylmercury derivatives or sodium trihalogenoacetates (a catalyst may be used to reduce the temperature at which the decomposition takes place): (e) thermal decomposition of trihalogenomethylsilyl derivatives or 1-halogenocyclopropenes: (f) the photolysis or thermolysis of halogenocyclopropanes or halogenodiazirines.

Halogenocarbenes can be generated in this way in both neutral and alkaline media and thermolysis or photolysis can be used for this purpose.

New ways of generating halogenocarbenes appeared recently and these will be examined below.

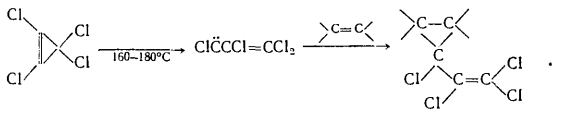
Dichlorocarbene has been obtained by treating CCl_4 with KOH in t-butyl alcohol and dimethyl sulphoxide.[123] The addition of carbene to alkenes takes place stereospecifically and the yields of cyclopropanes are 48–93%.

Dichlorocarbene is formed under the conditions of phase-transfer catalysis from trimethylsilyl trichloroacetate in the presence of KF.[124] The yields of cyclopropanes reach 70% when CH_2Cl_2 is used as the solvent and $NBu_4^+I^-$ or 18-crown-6-ether are used as catalysts. Dichlorocarbene is also formed in the vacuum flash thermolysis of trimethyl(trichloromethyl)silane at 600 °C.[88] Dichloro- and dibromo-carbenes have been generated by the photolysis of 11,11-dichloro- or 11,11-dibromo-tricyclo[4.4.1.0^{1,6}]-undeca-2,4,8-triene at 25 °C; the yield of the corresponding cyclopropanes in the reaction with cyclooctene reaches 80%.[125]

New methods have been proposed recently for the generation of difluorocarbenes—for example, by the reaction of phosphines and phosphites with bromodifluoromethyl(triphenyl)phosphonium salts:[126]

$$Ph_3P^+CF_2BrBr^- + Ph_3P + Me_2C{=}CMe_2 \rightarrow \underset{\underset{CF_2}{\diagup\diagdown}}{Me_2C{-}CMe_2}\ .$$
35%

Difluorocarbene, obtained from the complex $(CF_3)_2Cd.glyme$, reacts stereospecifically with alkenes:[127]



$$(CF_3)_2Cd.glyme + AcBr + Me_2C{=}CMe_2 \xrightarrow{-30°C} \underset{\underset{CF_2}{\diagup\diagdown}}{Me_2C{-}CMe_2} + AcF$$
70% 96%.

The mechanism of the generation of $:CF_2$ from $PhHgCF_3$ on treatment with the iodide anion has been investigated.[128] The formation of difluorocarbene has been postulated in the reaction of HCF_2SO_2F with nucleophiles.[129] The interaction of HCF_2SO_3H with P_2O_5 yielded $HCF_2SO_3CHF_3$, which was formed as a result of the insertion of $:CF_2$ in the initial compound.[130] The influence of the conditions in the reaction of HCF_2SO_2R (R = F, OPh, $OCH_2CF_2CHF_2$, C_6F_5, $OCHF_2$, NHPh, or NMePh) with bases and acids on the intermediate formation of difluorocarbene, the latter giving rise to an adduct with 2,3-dimethylbut-2-ene, has been investigated.[131]

Chloro(trifluoromethyl)carbene has been generated by the photolysis of the corresponding diazirine at 25 °C.[132] The addition of $F_3C(Cl)C:$ to *cis*- and *trans*-but-2-enes takes place stereospecifically but the yields of the corresponding cyclopropanes are low. Chloro(phenoxy)carbene has been obtained similarly on photolysis of diazirine.[17] Cyclopropanes have been obtained in the presence of alkenes in 10–30% yield. Fluoro(methoxy)carbenes have been generated by the thermolysis and photolysis of fluoro(methoxy)-diazirine;[133] in the presence of acrylonitrile and methyl acrylate, the corresponding cyclopropanes were obtained in low yields. The intermediate formation of halogenocarbenes has been postulated in the stereoselective synthesis of 1-halogeno-2-siloxyalkenes:[134]

$$X_3CCHR^2OSiMe_2R^1 \xrightarrow{BuLi} X\ddot{C}CHR^2OSiMe_2R^1 \rightarrow \underset{H}{\overset{X}{\diagup}}C{=}C\underset{R^2}{\overset{OSiMe_2R^1}{\diagdown}}$$
68–96%; X=Cl, Br

In recent years, increased attention has been paid to the study of halogeno(vinyl)carbenes, whose synthetic value is associated with the fact that it is possible to construct with their aid one of the main structural elements of pyrethroids—the vinylcyclopropane fragment. The thermolysis of tetrachlorocyclopropene (> 150 °C) results in the formation of perchlorovinylcarbene,[20,47,135,136] which reacts with alkenes to form the corresponding cyclopropanes (in approximately 60° yield) or is inserted in C–H bonds of heptane and adamantane:

Other halogenovinylcarbenes, namely $Cl_2C{=}CCl\ddot{C}F$, $Cl_2C{=}CH\ddot{C}Cl$, and $Cl_2C{=}CCl\ddot{C}Cl$ obtained by treating the corresponding halogenoalkenes with lithium amides, form halogenovinylcyclopropanes in low yields.[137] The formation of $Me_2C{=}CCl\ddot{C}Cl$ has been postulated in the reaction involving the treatment of 2,2,3-trichloro-1,1-dimethylcyclopropane with MeLi.[138] New (2-chlorovinyl)carbenes have also been obtained by the reaction of $MeClC{=}CHCHCl_2$ and 2-chloro-1-(dichloromethyl)cyclopentene with potassium t-butoxide.[139] The addition of these carbenes to *cis*-but-2-ene takes place entirely stereospecifically. Chloro(2-furyl)- and chloro(2-thienyl)-carbenes have been obtained by treating 2-dichloromethyl-substituted furan and thiophen derivatives with potassium t-butoxide and dibenzo-18-crown-6 ether.[140]

Carbene synthesis and chemical reactions of cyclopropene-3-carboxylate esters—promising intermediates for organic synthesis

M N Protopopova, E A Shapiro
Zelinskii Institute of Organic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The data on the methods of synthesis and chemical reactions of cyclopropene-3-carboxylate esters have been correlated and classified. Particular attention has been given to the direct carbene synthesis of cyclopropene esters, which provides an accessible route to compounds of this series. In studying the chemical reactions particular attention has been given to selective reactions that provide the opportunity of using cyclopropene-3-carboxylate esters in organic synthesis to obtain various types of compounds.

The bibliography includes 112 references.

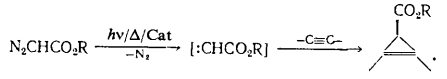
I. Introduction

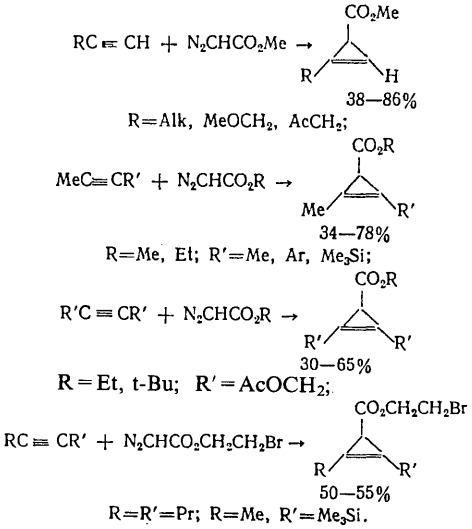
The preparation of cyclic molecules containing three carbon atoms by the reaction of aliphatic diazo compounds with unsaturated acceptors using the diazo method and a study of their chemical reactions constitute one of the most productive trends in the use of carbene reactions in organic synthesis.

In 1956 D'yakonov[1] used the synthesis of ethyl 2-methyl-3-phenylcyclopropene-3-carboxylate to demonstrate the possibility of employing the diazo method to obtain these compounds which were very novel at that time from readily available acetylenes. At the end of the 1950s and the beginning of the 1960s a series of studies was carried out by Breslow[2–4] into the synthesis using the diazo method and an investigation of the simplest chemical properties of cyclopropene esters.



However, a systematic and detailed study of the reactions of cyclopropene-3-carboxylate esters only became feasible during the 1970s when the D'yakonov method was substantially improved by Soviet[5–7] and foreign[8] research workers, which led to cyclopropene-3-carboxylate esters becoming the most readily available class of carbofunctional cyclopropene compounds. During these years the varied reactivity of cyclopropene esters was demonstrated, which was an indication of their future potential in organic synthesis to obtain derivatives of cyclopropane, cyclopropene and cyclobutane, various furans, γ-butyrolactones and α-pyrans, and also many acyclic carbofunctional compounds.

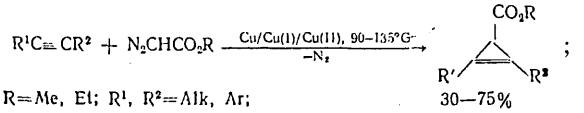
Despite the large number of experimental studies in the literature, there are no review publications on the chemistry of cyclopropene-3-carboxylate esters. The last review on the chemistry of cyclopropene compounds[9] dates back to 1966 and contains very limited information on the properties of cyclopropene-3-carboxylate esters.



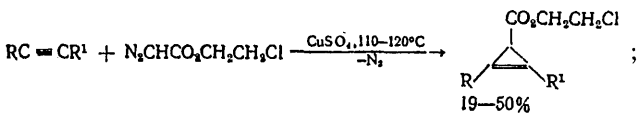
The present work is the first attempt to give a systematic account of the literature material including the studies of the present authors on the synthesis and chemical reactions of cyclopropene-3-carboxylate esters and it reflects the state of this topic at the end of 1987.

II. Synthesis of cyclopropene-3-carboxylate esters by the diazo method

The diazo method is based on the carbene decomposition reaction of alkyl diazoacetates (ADA) that takes place on exposure to radiation, heating, or catalysts (Cat). Addition of the resulting free or complexed carbenes to triple bonds gives cyclopropene-3-carboxylate esters:[10]



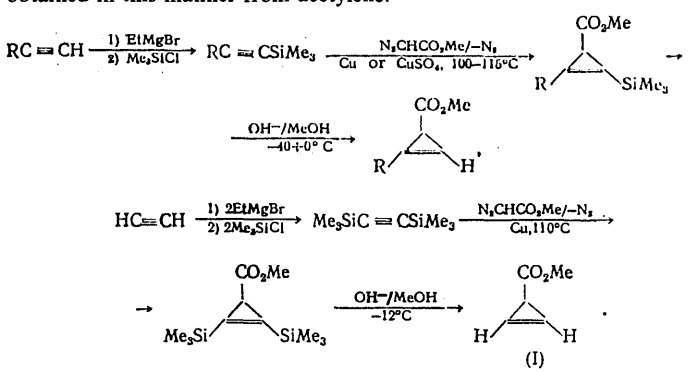
The most important preparative synthesis is the thermocatalytic method for decomposition of alkyl diazoacetates. By using rhodium compounds (for example, rhodium acetate) as catalysts for this process, it is possible to obtain cyclopropene-3-carboxylate esters in high yield even at room temperature from both terminal and internal (including those substituted with functional groups) acetylenes:[8,11–16]



In order to suppress the secondary formation of fumarate and maleate esters—formal dimers of the carbenes—the reaction is carried out with a 2.5–3-fold molar excess of acetylene.

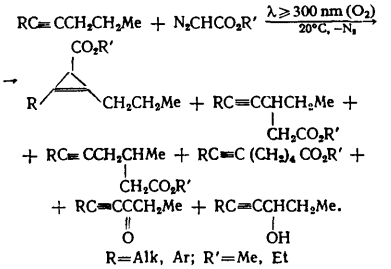
The use of traditional copper catalysts requires a temperature of 90–140 °C for the decomposition of ADA and gives satisfactory yields of cyclopropene esters only in the case of disubstituted acetylenes which are usually employed in 2–10-fold molar excess relative to ADA:[13,17–23]

R=Me, Et; R¹, R²=Alk, Ar; 30—75%



19—50%

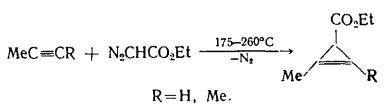
R=Pr, R¹=Pr, Me_3Si; R=cyclo-C_3H_5, R¹=Me_3Si.



The yield of products and the selectivity of the process depend to a significant extent on the concentration of catalyst. For example, in the case of copper bronze a molar ratio of catalyst to acetylene of 0.02 : 1 is the otpimum,[22] while when using copper salts the optimum ratio is 0.001 : 1.[21]

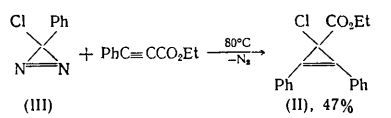
When ADA are reacted with terminal acetylenes in the presence of copper compounds, the corresponding cyclopropene-3-carboxylate esters are formed in yields not greater than 16%.[7,24] The synthesis of such cyclopropenes can be carried out more effectively by using the so-called silyl protection method, which is based on the ready hydrolytic cleavage of the C–Si bond in trimethylsilyl-substituted cyclopropene-3-carboxylate esters.[6,25–29] In particular, the methyl ester (I) of the simplest cyclopropene-3-carboxylic acid † was obtained in this manner from acetylene.[26]

Significant disadvantages of this method are its multistage nature and the insufficiently high overall yields of cyclopropene esters (25–30%).



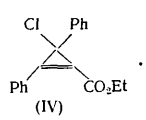
In the photolytic initiation of the reaction between acetylenes and ADA, products derived from the introduction of carbenes into the C–H bond—the corresponding esters of acetylenic acids—are formed together with cyclopropenes, while in the presence of air acetylenic ketones and alcohols are further formed. As a result the yield of cyclopropene esters from internal acetylenes does not usually exceed 40%,[11,12] only in rare cases does it reach 60%,[32] while from terminal acetylenes it is 17–20%.[22]

The preparation of cyclopropene-3-carboxylate esters purely by a thermal reaction between ADA and disubstituted acetylenes requires a temperature of 130 °C or above[24,31] and it is usually accompanied by destruction and oligomerisation of the initial and final products as well as by a number of other side reactions, as a result of which the yields of cyclopropene esters do not exceed 20%.[31,32]



Cyclopropene-3-carboxylate esters that are unsubstituted or monosubstituted at the double bond cannot be obtained at all under normal conditions by thermal reaction of ADA with acetylene or 1-alkynes. Acetylene and its derivatives when heated with ADA to 100 °C form only pyrazoles,[33–36] and at higher temperatures (150–200 °C) the initial and final products are almost completely converted into tar.[24]

However, by carrying out the process in a flow reactor, a short residence time of the products in the hot zone and a large dilution of the reaction mixture with the initial acetylene can be achieved so that cyclopropene esters are obtained in preparative yields (30–35%).[7,24] This method in particular was used to synthesise ethyl 1-methyl- and 1,2-dimethyl-cyclopropene-3-carboxylates (yields 28–30%) from gaseous acetylenes and ethyl diazoacetate:[7,24]



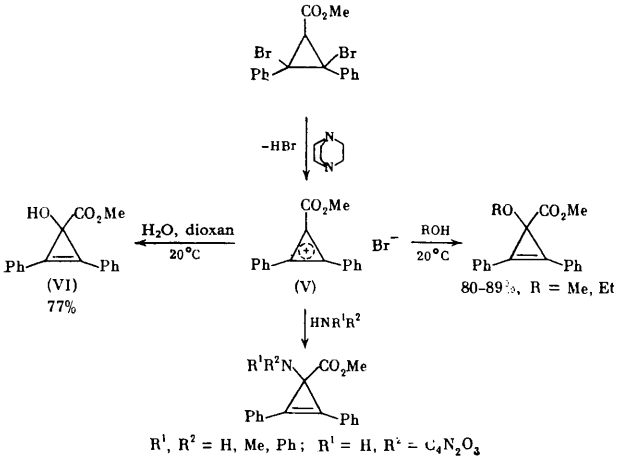
R=H, Me.

In the cyclopropenation of unsaturated compounds, diazirines can be used as diazo components.[37] However, only one example of the use of the latter to obtain cyclopropene esters is known—the synthesis of ethyl 1,2-diphenyl-3-chlorocyclopropene-3-carboxylate (II) from chlorophenyldiazirine (III) and ethyl propiolate:[38]

(III) (II), 47%

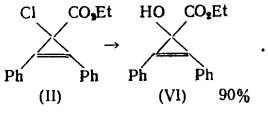
Unfortunately, DeBoer[38] did not discuss the reasons for the formation of ester (II) instead of the expected ester (IV)

(IV)



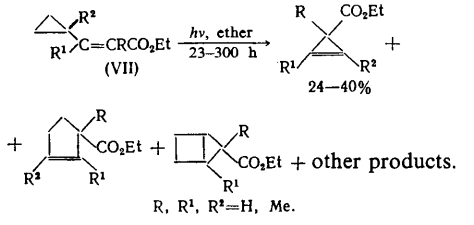
It is possible that the reaction, without involving phenylchlorocarbene, takes place as a [1,3]-dipolar addition of diazobenzyl chloride N_2=C(Cl)Ph, which is an isomer of (III),[37,39] to ethyl propiolate followed by elimination of nitrogen and migration of chlorine.

† Ester (I) was obtained as a solution in CCl_4.[26,27]



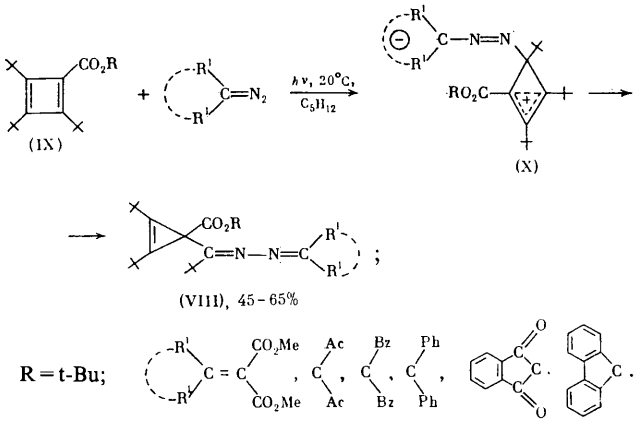
III. Other methods for synthesising cyclopropene-3-carboxylate esters

As well as the development of the diazo method, alternative processes for the synthesis of cyclopropene-3-carboxylate esters have been elaborated. Thus, according to the findings of Komendantov et al.,[40,41] 3-hydroxy-, 3-alkoxy-, and 3-aminocyclopropene-3-carboxylate esters can be obtained from methyl 1,2-dibromo-1,2-diphenylcyclopropane-3-carboxylate by a scheme that involves formation of the cyclopropenyl bromide (V) (Scheme 1).



Scheme 1

In addition to this method, 1,2-diphenyl-3-hydroxycyclopropene-3-carboxylate esters (VI) can be obtained from the corresponding 3-chlorocylopropene-3-carboxylate esters (II) by treatment of a solution of (II) in acetone at 25 °C with sodium bicarbonate:[38]



Cyclopropene esters are also obtained by the photolytic decomposition of cyclopropylvinylcarboxylate esters (VII).[42]

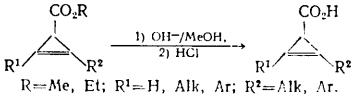
However, the reaction is not selective, and the yields of cyclopropenes do not exceed 40%.

Examples are known of the synthesis of tetrasubstituted cyclopropene-3-carboxylate esters (VIII) by photochemical reaction of a cyclobutadienecarboxylate ester (IX) with diazo compounds.[43]

It has been suggested that the reaction takes place via an intermediate betaine structure (X)

However, these methods are specific in nature and do not have wide importance for preparative synthesis.

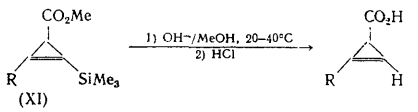
IV. Chemical reactions of cyclopropene-3-carboxylate esters



Cyclopropene-3-carboxylate esters constitute a class of alicyclic compounds with unique properties since they contain several interdependent reaction sites in the molecule—an ester group, a ring double bond and a strained three-carbon ring. In a number of cases by choosing the conditions it is possible to achieve reaction selectivity on one of the reaction sites. This fact is of importance for preparative synthesis since it is possible to obtain synthons with a three-carbon ring or carbofunctional acyclic compounds.

1. Reactions taking place with preservation of the three-carbon ring

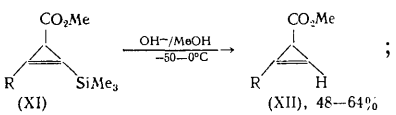
(a) Reactions involving the ester group



Cyclopropene-3-carboxylate esters undergo reactions that are typical for esters—alkaline and acid hydrolysis, reduction, nucleophilic addition of organometallic compounds. In the majority of cases these reactions take place with preservation of the three-carbon ring and can give other cyclopropene derivatives from accessible cyclopropene esters.[11,14,16,32,44-46]

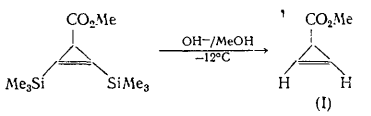
Hydrolysis. Methyl and ethyl cyclopropene-3-carboxylates when treated with alcoholic or aqueous alkaline solutions at 20–40 °C are readily saponified to the corresponding acids (yields of 40% to 92%).[11,13,18,19,21,31,32,47,48]

When the temperature is lowered to 0 °C, the rate of hydrolysis decreases substantially,[26,27] and when it is increased to 90–120 °C, as well as saponification of the ester group exocyclic migration of the cyclopropene double bond occurs (when there is an alkyl substituent on the double bond), giving the corresponding alkylidenecyclopropanecarboxylic acids (see IV, 1b).



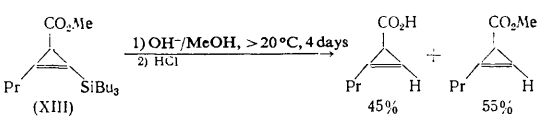
Hydrolysis of 1- or 1,2-silyl-substituted cyclopropene-3-carboxylate esters has several special features as a result of the presence of the labile C–Si bond in the molecule, and depending on the temperature and substituent in the silyl group gives different products.[26,27] Thus, at temperatures above 20 °C hydrolysis of 1-trimethylsilyl-2-alkylcyclopropene-3-carboxylate esters (XI) in methanol gives the corresponding alkylcyclopropene-3-carboxylic acids with yields of up to 95%.[26,27,32]

(XI)



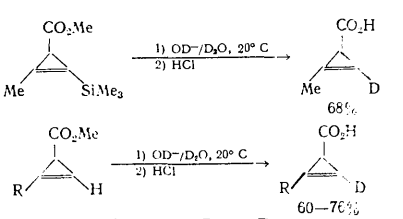
R=Alk.

On the other hand, at temperatures, of 0 °C and below only cleavage of the C–Si bond occurs in esters (XI) without saponification of the ester group. As a result, cyclopropene-3-carboxylate esters (XII) or (I) that are monosubstituted at the double bond are selectively formed:[25–29]



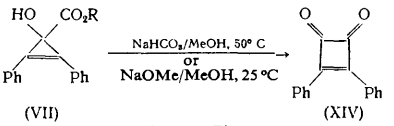
(XI) (XII), 48–64%

R=Alk.



(I)

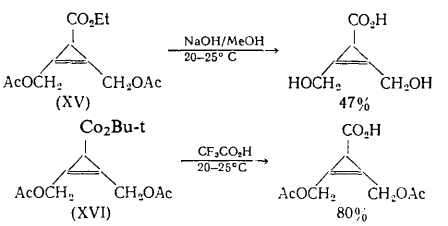
Replacement of the $SiMe_3$ group by $SiBu_3$ inhibits cleavage of the Ci–Si bond in ester (XIII) to such an extent that the reaction only takes place at temperatures above 20 °C, being accompanied by hydrolysis of the ester group and formation of a mixture of 1-propylcyclopropene-3-carboxylic acid and its methyl ester in approximately equal amounts:[26,27]



(XIII) 45% 55%

Removal of the silyl protecting group by hydrolysis in deuterated solvents gives 1-alkyl-1-deutero-substituted cyclopropene-3-carboxylic acids (the latter can also be obtained directly from the corresponding 1-alkylcyclopropene-3-carboxylate esters):[49]

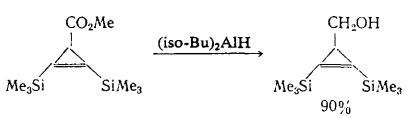
R-iso-Pr, n-Bu, t-Bu.



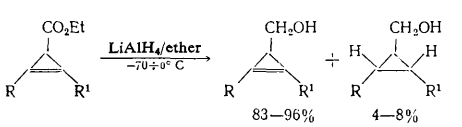
The alkaline hydrolysis of 3-hydroxycyclopropene-3-carboxylate esters (VII) takes place in an unusual manner. When these compounds are treated with bases, they undergo a reverse benzil rearrangement at the same time as hydrolysis of the ester group, as a result of which the cyclobutenedione (XIV) is formed in almost quantitative yield:[38,40]

(VII) (XIV)

R=Me, Et.



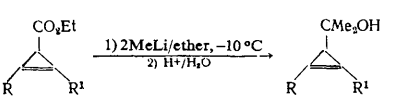
In contrast to methyl and ethyl esters, t-butyl esters are stable to bases and only form the corresponding acids by acidic hydrolysis, which can be of use for synthetic purposes. Thus, while all the ester groups present are saponified even at room temperature when ethyl ester (V) undergoes alkaline hydrolysis, acid hydrolysis of the corresponding t-butyl ester (XVI) under mild conditions can give the corresponding acid in 80% yield.[14]



(XV)

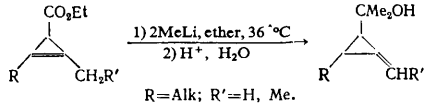
(XVI)

Reduction to alcohols. The ester group of cyclopropene-3-carboxylates can be reduced selectively to an alcohol with diisobutylaluminium hydride.[50]



Reduction of the ester group with $LiAlH_4$ only takes place selectively at temperatures not exceeding 0 °C. In this case the cyclopropene double bond is also partially reduced.[11,51–53]

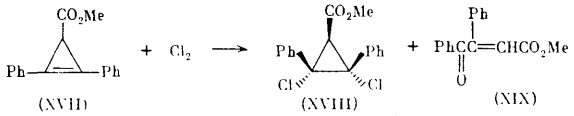
R, R^1=Alk, R=Me; R^1=$SiMe_3$.



Above 0 °C only cyclopropylcarbinols are formed (see IV, 1b).

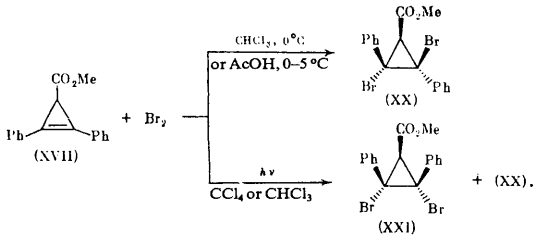
Nucleophilic addition to the alkoxycarbonyl group. The only examples of this type of reaction for cyclopropene-3-carboxylate esters are those that occur with methyllithium and butyllithium. Thus, at –10 °C the reaction of ethyl 1,2-dialkylcyclopropene-3-carboxylates with methyllithium in ether gives the corresponding tertiary alcohols (yields of 60–75%).[47,48]

R, R^1=Alk.



At higher temperatures, exocyclic migration of the cyclopropene double bond occurs together with alkylation, resulting in formation of the corresponding alkylidenecyclopropyldimethylcarbinols in yields of up to 70% (see IV, 1b).[47,48,54]

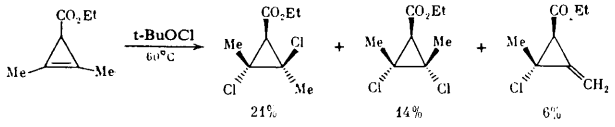
(b) Reactions involving the ring double bond



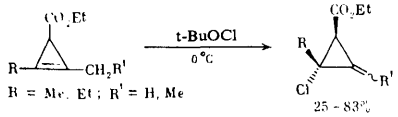
Addition of electrophiles. The presence of the ring double bond is responsible for the ability of cyclopropene-3-carboxylate esters to add on electrophilic reagents. In this case the ester group present has a stabilising effect on the three carbon ring,[55] and it assists in preservation of the ring and formation of the corresponding polyfunctional cyclopropanes.

Chlorination of the double bond of methyl 1,2-diphenylcyclopropene-3-carboxylate (XVII) occurs by a *cis*-addition in a *trans*-orientation relative to the ester group, and the yield of methyl dichlorocyclopropanecarboxylate (XVIII) varies from 35% to 71% depending on the reaction conditions.[56] The process is accompanied to a slight extent by opening of the cyclopropene residue and formation of the butenoate (XIX).

71% (*h*ν, CCl_4)
41% (diffuse light, 0 °C, CCl_4)
35% (AcOH, 15°C)

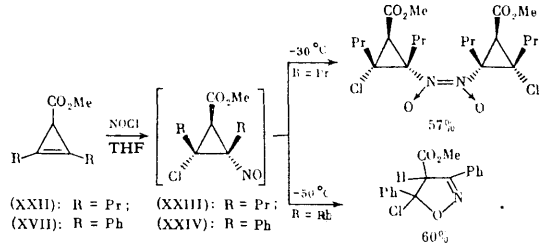


The stereochemistry of the addition of bromine to the ring double bond depends on the experimental conditions, *cis*- or *trans*-addition occurring with a *trans*-orientation relative to the ester group. Thus, bromination of ester (XVII) in chloroform or acetic acid in the dark or diffuse light takes place exclusively by *trans*-addition, giving methyl 1,2-dibromo-*cis*,*trans*-1,2-diphenylcyclopropane-3-carboxylate (XX) in 40% yield.[40]

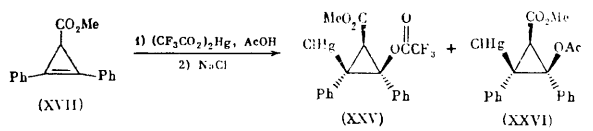


On the other hand, in tetrachloromethane or chloroform on irradiation *cis*-addition of bromine mainly takes place with formation of methyl 1,2-dibromo-*cis*,*cis*-1,2-diphenylcyclopropane-3-carboxylate (XXI) in 80% yield. In this case the isomeric ester (XX) is formed in very small quantities.[40]

It was assumed[40] that the dependence of the yields of halogenation products on the reaction conditions is due to different mechanisms for addition of chlorine or bromine to ester (XVII). An ionic mechanism is assumed in diffuse light and in a polar solvent and a radical mechanism in the presence of radiation. The higher yields of dichloro- and dibromo- cyclopropanes (XVIII) and (XXI) obtained by irradiation may be due to the higher stability of an intermediate cyclopropyl radical compared to the stability of a cyclopropyl cation or the corresponding chloronium or bromonium cations.[40,56]

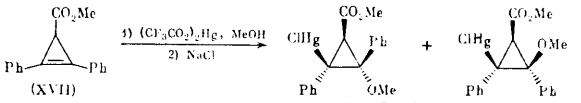


Halogenation of cyclopropene esters may also be carried out using t-butyl hypochlorite. However, in this case at 60 °C addition of chlorine is not selective and gives a mixture of *cis*- and *trans*-isomers of dichlorocyclopropanes together with methylenechlorocyclopropanes—substitution and isomerisation products.[57,58]

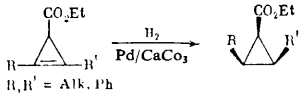


By reducing the temperature to 0 °C the reaction can be mainly directed towards formation of methylenechlorocyclopropanes; in a number of cases this can be important for preparative synthesis.[57,58]

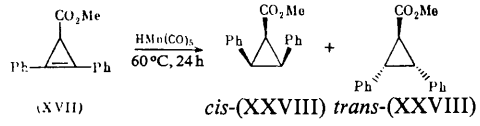
Cyclopropene esters (XXII) and (XVII) can add on nitrosyl chloride. However, the nitrosyl chlorides (XXIII) and (XXIV) formed in this process have low stability and depending on their structure either dimerise or undergo opening of the three-carbon ring:[59]



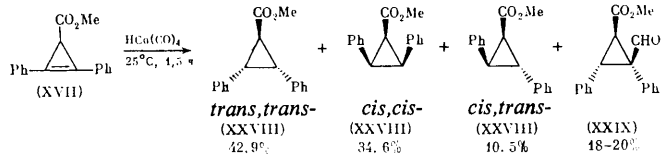
Mercuration of cyclopropene-3-carboxylate esters takes place with preservation of the cyclopropane residue,[60,61] and the reaction conditions have a considerable effect on both the stereochemistry of addition of mercury salts to the ring double bond and the nature of the resulting products formed. Thus, addition of mercuric trifluoroacetate to the diphenylcyclopropene ester (XVII) in acetic acid occurs by a *cis*-mechanism in a *cis*-orientation relative to the ester group and gives (as a result of subsequent treatment with NaCl) the 1-chloromercuro-2-trifluoroacetoxycyclopropanecarboxylate ester (XXV) together with a small quantity of the solvolysis adduct (XXVI); the ratio of (XXV) : (XXVI) = 87 : 13.[61]



Reaction of the same ester (XVII) with mercuric trifluoroacetate in methanol leads exclusively to solvolysis adducts—the corresponding 1-chloromercuro-2-methoxycyclopropanes (XXVII)— with the

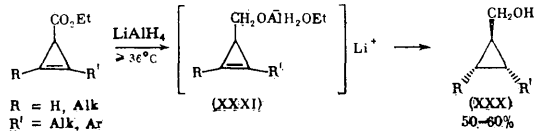


trans,cis-isomer, which is formed by *trans*-addition, predominating [ratio of *trans,cis*-(XXVII) : *cis,cis*-(XXVII) = 85 : 15).[60,61]

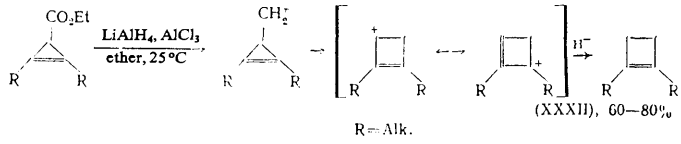


Reduction. The ring double bond of cyclopropenecarboxylate esters is reduced by metal carbonyl hydrides, lithium aluminium hydride, and hydrogen in the presence of catalysts. The most selective and frequently used method is reduction of cyclopropene esters by catalytic hydrogenation using palladium supported on $CaCO_3$ as the catalyst. As a result, only *cis,cis*-1,2-dialkylcyclopropane-3-carboxylate esters are formed in yields up to 98%.[18,19,42,62,63]

Reduction of methyl diphenylcyclopropenecarboxylate (XVII) with manganese pentacarbonyl hydride is not stereospecific and gives a mixture of isomeric cyclopropanecarboxylate esters in quantitative yield, although the *cis*-isomer is mainly formed [ratio of *cis*-(XXVIII) : *trans*-(XXVIII) = 7 : 1]: [64]

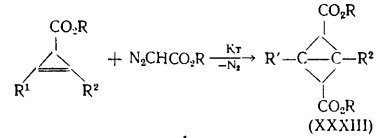


Reduction of the same ester (XVII) with cobalt carbonyl hydride is not selective and all possible isomeric 1,2-diphenylcyclopropane-3-carboxylate esters (XXVIII) are formed with a total yield of 88%.[65]



In this case hydroformylation of ester (XVII) is a competing process, resulting in the formation of ester (XXIX) with a yield of about 22%.

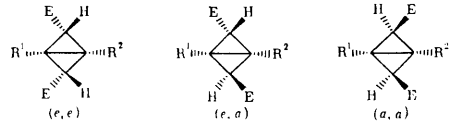
In contrast to the reagents considered above, lithium aluminium hydride mainly reduces the ester group in cyclopropene esters, and depending on the temperature reduction can also be accompanied by hydrogenation of the ring double bond. Thus, at 0 °C only cyclopropene alcohols are formed (see IV, 1a), while at higher temperatures the corresponding cyclopropylcarbinols are formed, only as a single *trans,trans*-isomer (XXX).[51-53]



The stereospecific formation of (XXX) is due, according to Vincens et al.,[51,53] to the intramolecular nature of the reduction of the double bond in the intermediate alkoxyaluminium hydride (XXXI).

In the presence of $AlCl_3$ reduction of cyclopropene esters with $LiAlH_4$, which occurs via intermediate carbocations, is accompanied by expansion of the three-membered ring and formation of cyclobutenes (XXXII).[66]

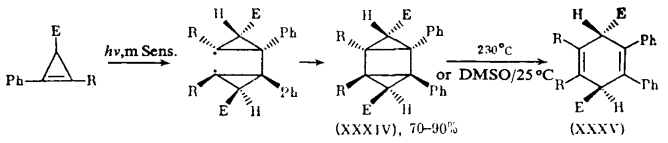
Cycloaddition. Because of the presence of the double bond, cyclopropene-3-carboxylate esters undergo a cycloaddition reaction with various enophiles to give the corresponding bicyclo[*n*.1.0]-carboxylate esters (n = 1–4). In a number of cases these reactions are important for preparative synthesis.



[1 + 2]-Cycloaddition. The only known example of reactions of this type is the addition of alkoxycarbonylcarbenes, which are generated by catalytic decomposition of alkyl diazoacetates, to the double bond of cyclopropene esters. In this process the corresponding bicyclobutane adducts (XXXIII) are formed in 25–42% yield:[67-70]

R = Me, Et, t-Bu; R^1 = H, Pr, Bu, Ph; R^2 = Pr, Bu, Ph, $SiMe_3$; Cat = Cu (110 °C), $Rh(OAc)_2$ (25 °C).

In certain cases diesters (XXXIII) are formed as by-products (2–5%) in the preparation of cyclopropene esters from acetylenes and alkyl diazoacetates.[14,28,71]

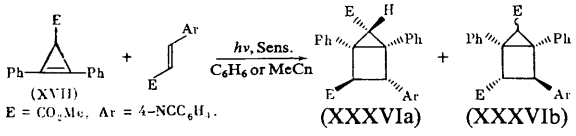


As regards the stereoselectivity of this reaction, it is known that di-t-butyl esters (XXXIII) are only formed as a single (*e,e*)-isomer,[14] while the dimethyl and diethyl esters are formed as two (*e,e*)- and (*e,a*)-isomers, the ratio of which varies from 3 : 1 to 1 : 1 depending on the nature of the substituents R^1 and R^2.[28,67-70,71] The sterically hindered (*a,a*)-isomer is not formed in a single case.

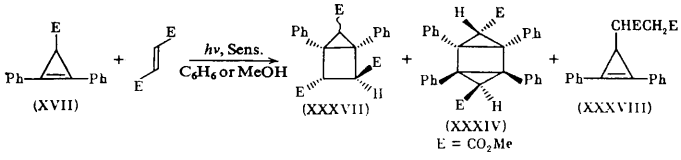
E = CO_2Me, CO_2Et, CO_2Bu-t

[2 + 2]-Cycloaddition. Reactions of this type involving cyclopropene-3-carboxylate esters only occur on photolysis and have limited importance for preparative synthesis. In particular, homodimerisation of cyclopropene esters to the corresponding tricyclohexanedicarboxylate esters (XXXIV) in the presence of a sensitiser (for example, trioxanone) takes place stereospecifically via biradical intermediates which are characterised by the greatest delocalisation of electrons.[72-76] Esters (XXXIV) when heated to

230 °C or when dissolved in dimethyl sulphoxide at 25 °C are quantitatively converted to cyclohexadienedicarboxylate esters (XXXV).[72]

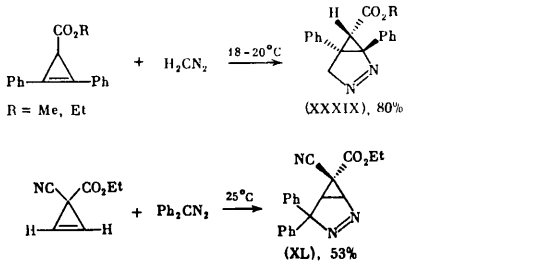


R = Me, Ph; E = CO_2Me.

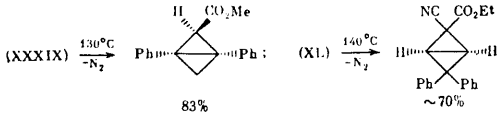


In two studies[77,78] there are reports about the possible formation of tricyclohexanes (XXXIV) together with the isomeric cyclohexadienes (XXV) [77] by carrying out this reaction with direct photolysis. However, attempts to reproduce the reported results[77,78] proved unsuccessful;[72–76] cyclopropene esters underwent opening of the three-carbon ring with formation of alkoxyfurans. This difference in the behaviour of cyclopropene esters under conditions of direct and sensitised photolysis is attributed[72–76] to the different multiplicity of the excited state of cyclopropene.

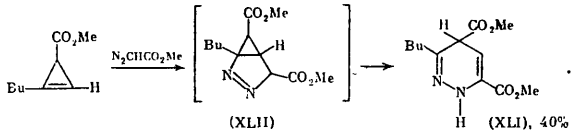
According to the results of two studies[72,79] photochemical cyclodimerisation of 3-substituted cyclopropene-3-carboxylate esters doe not occur because of considerable steric hindrance.



There are known examples of the cross-[2 + 2]-cycloaddition of cyclopropene esters to electron-deficient olefins taking place by sensitised photolysis.[74] Thus, the photochemical reaction of ester (XVII) with methyl *p*-cyanocinnamate gives the corresponding bicyclopentane adducts (XXXVIa, b) with an *exo*-configuration of the alkoxycarbonyl group.

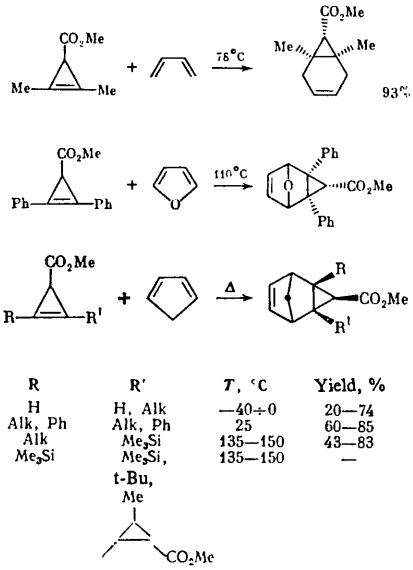


However, the reaction of the same ester (XVII) with dimethyl fumarate is less sensitive, and both the bicyclopentane *exo*- and *endo*-isomers (XXXVII) are formed.



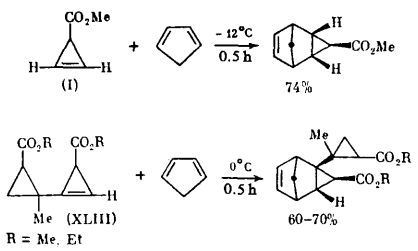
[3 + 2]-Cycloaddition. In the absence of decomposition catalysts diazoalkanes react at room temperature with cyclopropene-3-carboxylate esters by a [3 + 2]-cycloaddition to give the corresponding pyrazolines solely as their *exo*-isomers.[80–82]

The reaction can have preparative value for the synthesis of bicyclo[1.1.0]butanecarboxylate esters, which are formed in high yield by thermolysis of pyrazolines (XXXIX) or (XL).[80,82]



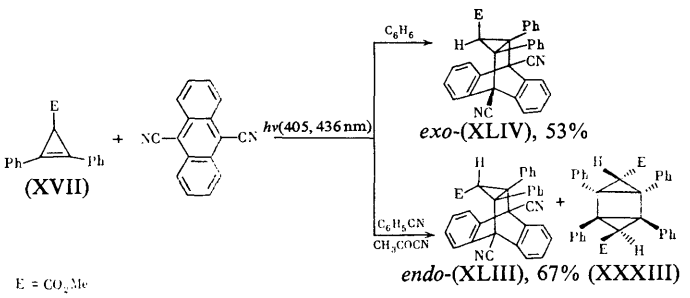
The reaction of methyl 1-butylcyclopropene-3-carboxylate with methyl diazoacetate in the absence of catalysts also apparently takes place by a [3 + 2]-cycloaddition [via the initially formed bicyclic pyrazoline (XLII)] to give the pyridazine (XLI):[70]

[4 + 2]-Cycloaddition. These are the most characteristic of all the cycloaddition reactions of cyclopropene-3-carboxylate esters and are those the most frequently used in synthesis.



Cyclopropene esters react with butadienes,[83,84] cyclopentadiene,[27–29,30,84–87] and furan[85,87] to form the corresponding adducts, the reactions with cyclic dienes taking place with strict selectivity. When cyclopropene esters are reacted with cyclopentadiene, the *endo*-adducts are exclusively formed, and with furan the corresponding *exo*-adducts are formed.

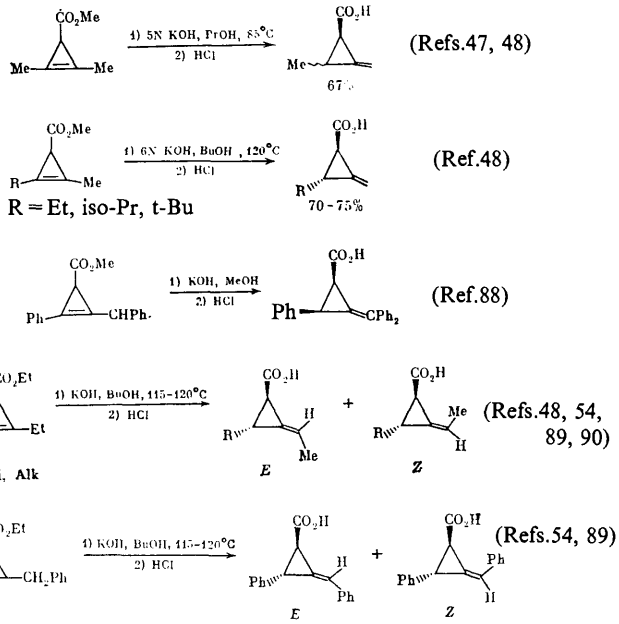
R	R'	*T*, °C	Yield, %
H	H, Alk	—40÷0	20—74
Alk, Ph	Alk, Ph	25	60—85
Alk	Me_3Si	135—150	43—83
Me_3Si	Me_3Si, t-Bu, Me	135—150	—



The activity of cyclopropene esters as dienophiles is determined by the nature of the substituents on the ring double bond and the steric accessibility of this bond. Thus, unsubstituted and monosubstituted cyclopropene-3-carboxylate esters are the most active, reacting with cyclopentadiene even at 0 °C and below.[27,29,86] Because of this it was possible to use cyclopentadiene as a trap for cyclopropene esters that have low stability under normal conditions. It was this method that

was used to "capture" the simplest methyl cyclopropene-3-carboxylate (I) and esters (XLIII), which are unstable in a pure state above 0 °C.[27,29,86]

The least active dienophiles are cyclopropene esters with a trimethylsilyl group on the double bond, which form the corresponding adducts only on boiling in xylene for many hours; and the introduction of a further trimethylsilyl or other bulky substituent on to the ring double bond completely prevents a reactions with cyclopentadiene.[27,28,86]



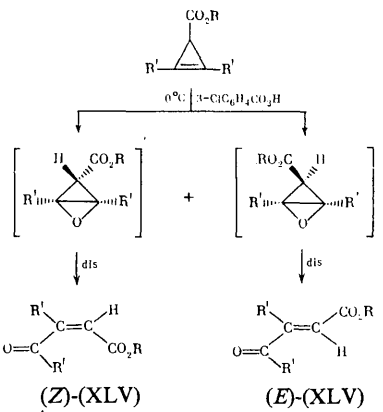
[4 + 2]-Cycloaddition reactions of cyclopropene esters with electron-deficient dienes are also possible by photolysis, with the structure of the adducts formed depending to a considerable degree on the experimental conditions. Photochemical reaction of ester (XVII) with 9,10-dicyanoanthracene in benzene gives the *exo*-adduct (XLIV), while in acetonitrile or benzonitrile the sterically hindered *endo*-adduct (XLIII) is formed. In the latter case the cyclodimer (XXXIII) is also formed together with *endo*-adduct (XLIII).

This difference in the results of the reaction was attributed by Brown-Wensley et al.[74] to differences in the nature of the intermediates in relation to the polarity of the medium.

Exocyclic migration of the double bond. In a number of unsaturated compounds with a three-carbon ring, compounds with an *exo*-configuration of the double bond are thermodynamically more stable than the isomeric alkylcyclopropenes; this causes the latter to be isomerised to the corresponding alkylidenecyclopropanes by the action of bases.[55]

Exocyclic migration of the double bond in alkyl- or benzyl-substituted cyclopropene-3-carboxylate esters occurs, in addition to saponification of the ester group, on treatment with alcoholic alkali solutions at 85–120 °C.[47,48,54,88–90] As a result, 1-methylenecyclopropane-3-carboxylate esters are formed from 1-methylcyclopropene-3-carboxylate esters, while 1-ethyl- or 1-benzyl-substituted cyclopropene-3-carboxylate esters give 1-ethylidene- or 1-benzylidene-cyclopropane-3-carboxylate esters as mixtures of their (*Z*)- and (*E*)-isomers with the latter predominating.

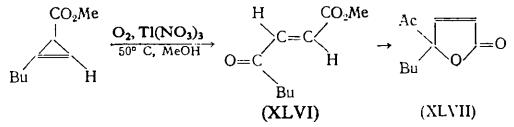
Potassium t-butoxide and sodium methoxide in absolute solvents do not cause cyclopropene esters to react in these ways.[91]



2. Reactions of cyclopropene-3-carboxylate esters with opening of the three-carbon ring

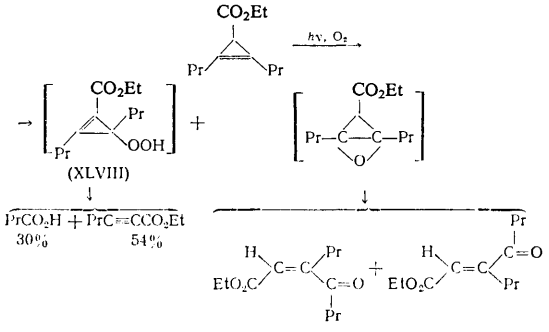
The reactions discussed in the previous section indicate that the three-carbon ring of cyclopropene-3-carboxylate esters, in particular for those disubstituted on the double bond, is quite stable. However, acids, oxidising agents or transition metals can cause the ring to open with formation of acyclic compounds.

(a) Oxidation



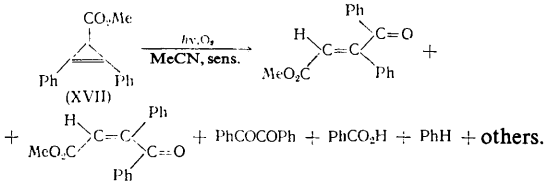
Oxidation of cyclopropene-3-carboxylate esters with chloroperbenzoic acid at 0 °C takes place via an epoxidation stage and gives isomeric unsaturated ketones (XLV) in almost quantitative yields (Scheme 2).[92–95]

Scheme 2



Peracetic and perbenzoic acids do not cause cyclopropene esters to react at all.[94]

The formation of vinylketone (XLVI) occurs in the oxidation of methyl 1-butylcyclopropene-3-carboxylate with oxygen in the presence of thallium nitrate at 50 °C in methanol. However, (XLVI) is gradually converted during the reaction to lactone (XLVII).[70]

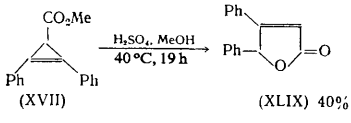


(XLVI) (XLVII)

In the oxidation of cyclopropene esters with oxygen by sensitised photolysis, the yield of vinylketones does not exceed 15%. The main products of the photooxidation of 1,2-dipropylcyclopropene-3-carboxylate esters are butyric acid and ethyl hex-2-ynoate, which are formed as a result of decomposition of the initially generated hydroperoxide (XLVIII).[95]

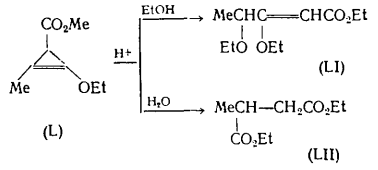
(XLVIII)

The photooxidation of ester (XVII) is not selective and leads to a complex mixture of products.[74]



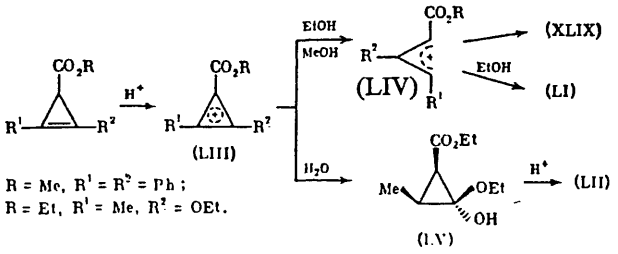
(XVII)

(b) Reactions with acids



Cyclopropene-3-carboxylate esters are fairly stable towards acids. At 20–25 °C they withstand prolonged contact (up to 40 h) with concentrated hydrochloric, hydrobromic, sulphuric, and hydrofluoric acids.[96,97] However, on boiling with alcoholic or aqueous acid solutions cyclopropene esters undergo ring-opening to form various carbofunctional compounds.

Thus, when ester (XVII) is boiled for many hours with a methanol solution of sulphuric acid, lactone (XLIX) is obtained.[96]

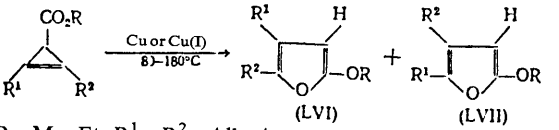


(XVII) (XLIX) 40%

Under similar conditions the ethoxycyclopropene-3-carboxylate ester (L) is converted to ethyl diethoxypentenoate (LI) in 50% yield, while in an aqueous solution of *p*-toluenesulphonic acid the diethyl ester (LII) is obtained in quantitative yield without formation of the corresponding furanone.[98]

(L) (LI) (LII)

It has been proposed[96,98] that the driving force of all these processes is protonation of the ring double bond to form the cyclopropyl cation (LIII), which isomerises in alcohol solution to the allylic cation (LIV), which then cyclises to lactone (XLIX) or reacts with the solvent to form acid (LI). In aqueous solution hydration of cation (LIII) gives ketal (LV), which is isomerised by the action of acid to ester (LII).

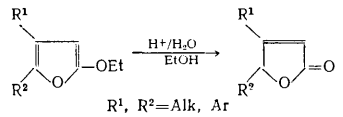


R = Me, R¹ = R² = Ph;
R = Et, R¹ = Me, R² = OEt.

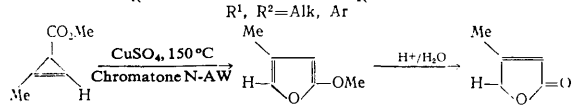
(LIII) (LIV) (LV)

(c) Catalytic reactions of cyclopropene-3-carboxylate esters

Reactions of cyclopropene-3-carboxylate esters on treatment with copper compounds. The most numerous examples of catalytic reactions of cyclopropene esters are those occurring in the presence of copper compounds. Among these the isomerisation of cyclopropene-3-carboxylate esters to alkoxyfurans is the most familiar.[21,55,99,100]

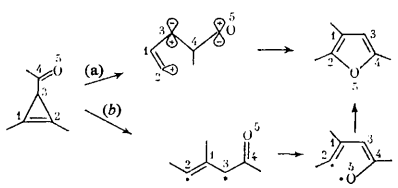


(LVI) (LVII)



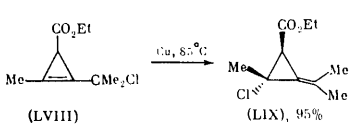
R = Me, Et, $R^1 = R^2$ = Alk, Ar;
R = Et, R^1 = Me, R^2 = Ph (LVI : LVII = 19 : 1), n-Bu (LVI : LVII = 1 : 1) t-Bu (LVI : LVII = 1.2 : 1);
R = Et, R^1 = Et, t-Bu, R^2 = H.

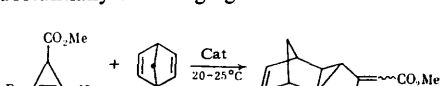
In an inert atmosphere with exclusion of moisture alkoxyfurans are the main reaction products, so this can be regarded as a preparative method.[55,99,100]



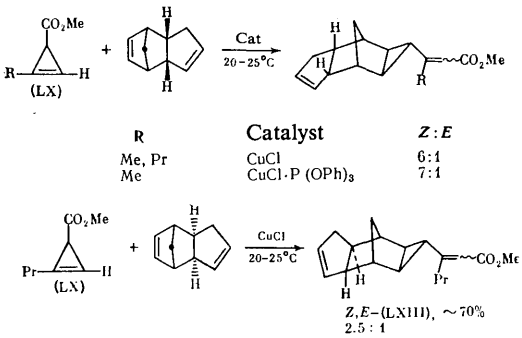
Asymmetrically substituted cyclopropene-3-carboxylate esters are converted to form two isomeric alkoxyfurans (LVI) and (LVII) in total yields of up to 90%, the ratio of which is determined by the substituents on the cyclopropene double bond.[100] Isomerisation of 1-substituted cyclopropene-3-carboxylate esters only gives product (LVI), which corresponds to cleavage of the C(2)–C(3) bond of the cyclopropene ring.[7,22] However, the yield of alkoxyfuran (LVI) does not exceed 20–25%, which is apparently due to oligomerisation of the initial cyclopropene ester and final alkoxyfuran during the reaction.

In the presence of traces of moisture and acids, alkoxyfurans are readily hydrolysed to the corresponding furanones,[19,100] which in specific cases[7] are the only identifiable reaction products.

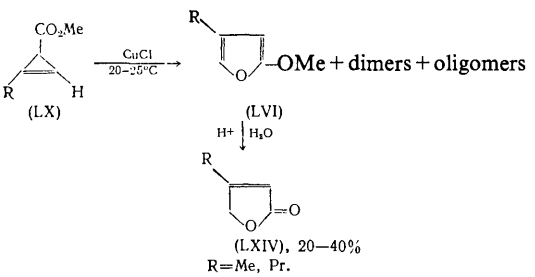




According to Komendantov et al.,[100] the formation of alkoxyfurans can take place either by a concerted [1,3]-sigmatropic rearrangement of cyclopropene esters [route (*a*)], which is no longer forbidden in the presence of a catalyst, or by a non-concerted route (*b*) via a biradical that is formed by opening of the three-membered ring. In this case the role of the catalyst is to reduce the energy of activation for isomerisation through the formation of an organocopper complex and hence weaken the σ-bonds.

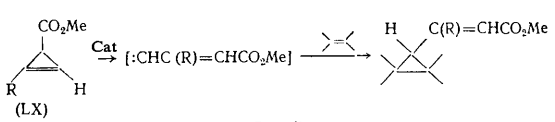


However, for cyclopropene ester (LVIII), which contains a chlorine atom in the α-position of the alkyl substituent on the double bond (in contrast to the esters considered above), in the presence of copper at 85 °C an exocyclic migration of the double bond and chlorine to form the ester (LIX) occurs rather than isomerisation to an alkoxyfuran.[101] The same reaction of ester (LVIII) occurs without copper but at a higher temperature (150 °C).



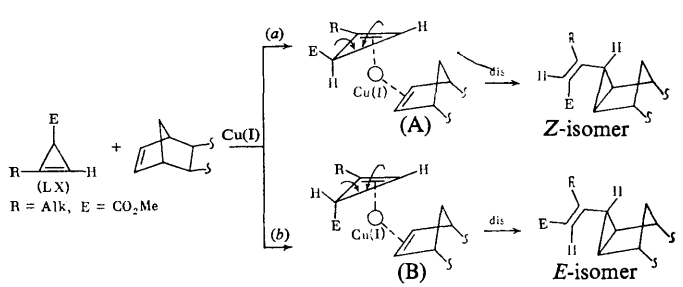
Comparatively recently[102,103] it was found that 1-alkylcyclopropene-3-carboxylate esters (LX) in the presence of Cu(I) compounds can selectively vinylcyclopropanate the strained ring double bond in norbornadiene and dicyclopentadiene to give cycloadducts (LXI)–(LXIII) exclusively as the *exo,anti*-isomers. In this case the ratio of (*Z*)- to (*E*)-isomers varies according to the nature of the substituent R in the cyclopropene ester, the structure of the unsaturated compound and the nature of the catalyst, increasing substantially on changing from CuCl to its complexes.[103]

R	Catalyst (Cat)	*Z*:*E*
Me	CuCl	1.3:1
	CuCl·2Me$_3$SiC≡CMe	2.5:1
	CuCl·P(OPh)$_3$	3:1
Pr	CuCl	1.7:1
	CuCl·2Me$_3$SiC≡CMe	2.5:1
	CuCl·P(OPh)$_3$	4:1
C_5H_{11}	CuCl	1.8:1
	CuCl·P(OPh)$_3$	7:1



With other unsaturated compounds—1,5-cyclooctadiene, cyclohexene, methylenecyclobutane, methyl acrylate—esters (LX) do not give vinylcyclopropane adducts but are converted to lactones (LXIV), as a result of hydrolysis of the initially formed alkoxyfurans (see above), and oligomers.[103]

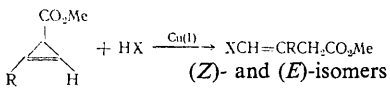
When esters (LX) are reacted with cyclopentadiene, diene adducts are formed in 70% yield.[103]



According to the results of three studies[102,104,105] the formation of cycloadducts (LXI)–(LXIV) may be due to addition to the double bonds of vinylcarbene intermediates which are generated by catalytic isomerisation of cyclopropenes (LX).

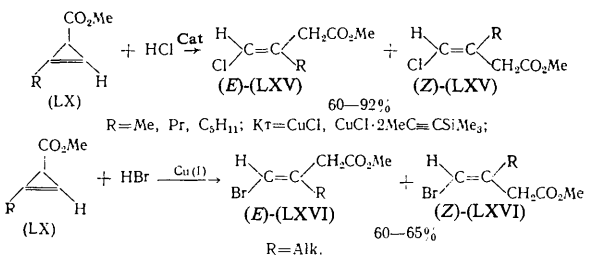
R=Alk.

However, the high regioselectivity and stereoselectivity for formation of the vinylcyclopropane adducts is more consistent with the reaction taking place within the coordination sphere of Cu(I) according to a concerted mechanism (Scheme 3).[103]



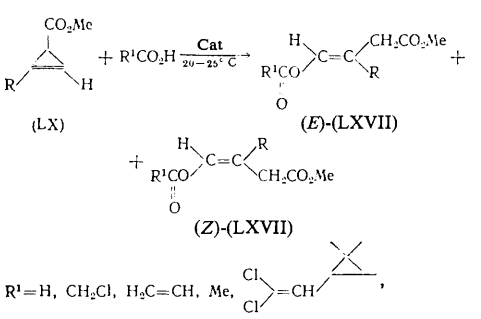
Scheme 3

In this case the exclusive *exo*-addition of the reaction species to the double bond of norbornadiene is due to *exo*-coordination of the copper atom with the initial cyclodiene. The selective formation of



the *anti*-isomer and the ratio of (*Z*)- to (*E*)-isomers are established when cyclopropene (LX) coordinates with the olefin complex of univalent copper and is determined by the stereoselectivity of the subsequent conversions, being governed by the principle of conservation of orbital symmetry. The presence of bulky ligands in the coordination sphere of copper, particularly when changing from CuCl to the complex catalysts $2MeC{\equiv}CSiMe_3.CuCl$ and $(PhO)_3P.CuCl$, must reduce the probability of coordination of the type (B) in favour of (A), in other words, it leads to an increase in the yield of (*Z*)-isomer, which in actual fact occurs.

During the last few years we have discovered a new reaction of methyl 1-alkylcyclopropene-3-carboxylates (LX) with proton-donor reagents of the general type HX, which takes place on treatment with copper(I) chloride at room temperature. This reaction, which is undoubtedly of interest for preparative synthesis, leads to the formation of the corresponding (*Z*)- and (*E*)-isomers of 4-substituted methyl 3-alkylbutenoates.[97,106-108]

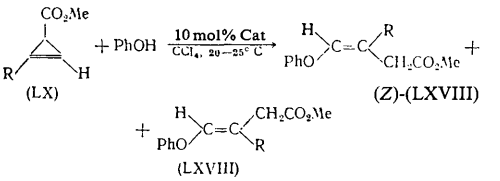


R=Alk, X=Cl, Br, R^1CO_2, ArO, CN, $R^2C{\equiv}C$.

Gaseous HBr, hydrochloric acid, and hydrogen chloride (whatever the method of generation) at 20–25 °C in the presence of copper (I) chloride or its complex readily add on to the C(2)–C(3) bond in (LX) to form methyl 4-bromo- or 4-chloro-butenoates (LXV) and (LXVI), mainly as their (*E*)-isomers.[97,106]

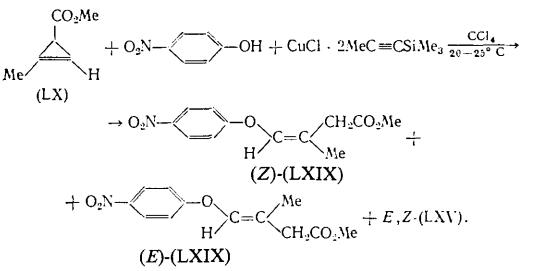
R=Alk.

Carboxylic acids whose pK_a values occur within the region 3 to 7 (monochloroacetic, formic, acrylic, acetic, permethrinic) react in a similar manner with cyclopropene esters (LX). In this case the yields of the resulting (*Z*)- and (*E*)-4-acyloxybutenoate esters (LXVII) amount to 58–95%.[97,106]



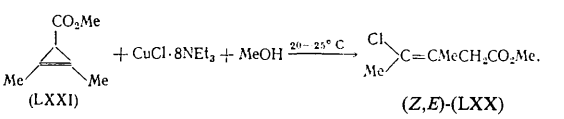
R=Alk, R^1=H, CH_2Cl, $H_2C{=}CH$, Me, ,

Cat = $CuCl.2MeC{\equiv}CSiMe_3$



Stronger carboxylic acids that have pK_a values of 0–2 (trifluoro-, trichloro-, and dichloro-acetic acids as well as hydrofluoric acid) do not add on to cyclopropene esters (LX) in the presence of CuCl but rapidly convert them to 4-alkylfuranones (LXIV).[97]

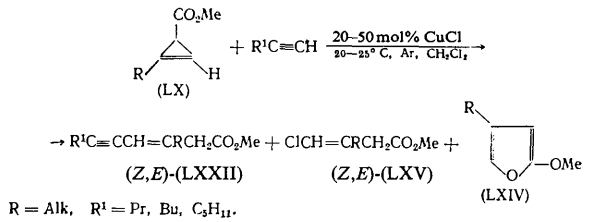
On the other hand the catalytic addition of phenol to esters (LX) proceeds quite smoothly, giving methyl phenoxybutenoates (LXVIII) in 50–80% yield, mainly as the (*Z*)-isomer.[97,106]



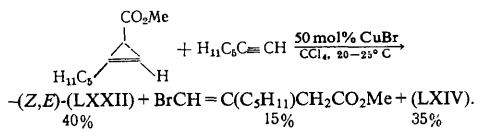
R = Me, C_5H_{11}; Cat = $CuCl.2MeC{\equiv}CSiMe_3$.

Reaction of esters (LX) with 4-nitrophenol under the same conditions gives mainly oligomeric products. However, in the presence of 100 mol% of an acetylene complex of copper(I) chloride, *p*-nitrophenol an add on to a cyclopropene ester (LX, R = Me) in a similar manner to phenol to form (*Z*)- and (*E*)-methyl 4-(*p*-nitrophenoxy)-3-methylbut-3-enoates (LXIX) (5 : 1) with a total yield of 30%. The main reaction products here are isomeric 4-chloro-3-methylbut-3-enoate esters (LXV) (total yield 45%),[97] in the formation of which nitrophenol appears only as a proton donor, while CuCl is a source of Cl, in other words, it acts as a reactant rather than a catalyst:

This trend is shown to an even greater extent for 2,4-dinitrophenol, methanol, butyl mercaptan, and 5-methyl-4-cyclohexene-1,2-dicarboximide. Their reaction with esters (LX) in the presence of the complex $CuCl.2MeC{\equiv}CSiMe_3$ gives only (*Z*)- and (*E*)-4-chlorobutenoate esters (LXV), the quantity of which increases as the amount of added CuCl increases.[97]

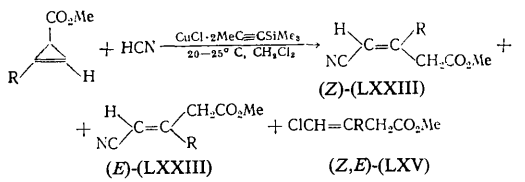


The only example of the catalytic addition of HCl units to 1,2-disubstituted cyclopropene-3-carboxylate esters is formation of the corresponding 4-chloropentenoate esters (LXX) by reaction of the cyclopropenoate ester (LXXI) with an equivalent quantity of the complex $CuCl.8NEt_3$ and methanol.[106]



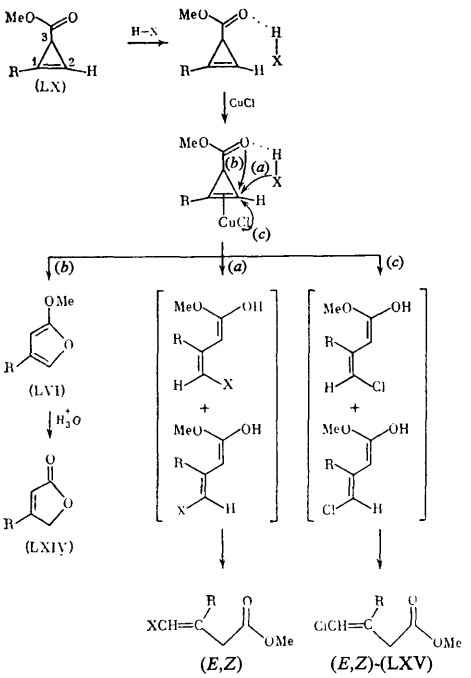
Esters (LXX) are formed in 30% yield mainly as the (*Z*)-isomer [(*Z*) : (*E*) = 5 : 2].

Among compounds that contain a mobile hydrogen atom on a carbon atom (terminal acetylenes, HCN, nitro- and trinitro-methane, ethyl cyanoacetate, bromoform) an [H–X]-addition reaction with 1-alkylcyclopropene-3-carboxylate esters can only be achieved with



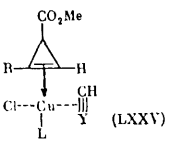
terminal acetylenes and HCN,[97,107] which, in contrast to the other compounds with a mobile hydrogen atom that were studied, are able to form complexes with CuCl. In this case esters (LX) and 1-alkynes in the presence of 20–50 mol% CuCl react to form the corresponding 3-alken-5-ynoate esters (LXXII) (yield ~65%) mainly as their (*Z*)-isomers[105] together with chlorobutenoate esters (LXV) (yields 10–20%) and methoxyfurans (LXIV) (yield 5–10%). The selectivity of the process and the yields of esters (LXXII) depend significantly on the reaction conditions, primarily on the ratio of reactants and the relative quantity of CuCl.[97,107]

The reaction of cyclopropene ester (LX, R = C_5H_{11}) with 1-heptyne in the presence of CuBr occurs in a similar manner:[97]



Addition of gaseous HCN in the presence of CuCl.2MeC≡CSiMe$_3$ to cyclopropenes (LX) also takes place fairly readily, the formation of 4-cyanoalkylbutenoate esters (LXXIII) also being accompanied by partial hydrochlorination of (LX) to chlorobutenoate esters (LXV). The maximum yield of esters (LXXIII) (60–65%) occurs with incomplete conversion of (LX) (66–70%) and a quantity of CuCl.2MeC≡CSiMe$_3$ equal to 20 mol%.[107]

Treatment of esters (LX) with trinitromethane, nitromethane, bromoform, or ethyl acetate at 25 °C in the presence of 10–100 mol% of $CuCl_2$.2MeC≡CSiMe$_3$ complex gives only chlorobutenoate esters (LXV).[97]

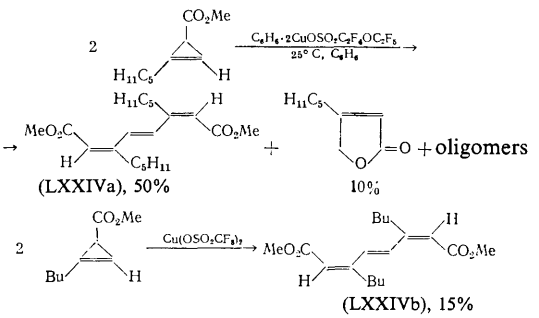


As regards the mechanism of the reaction between cyclopropene esters and proton-donor reagents HX (Scheme 4), it is most likely that the formation of 4-substituted 3-butenoate esters takes place within the coordination sphere of copper.[97] In the presence of the reagents HX (hydrogen halides, carboxylic acids, phenols) that are capable of solvating cyclopropene esters (LX) and thus become part of an organocopper complex, attack by nucleophile X on the C(2) atom of the ring becomes possible and (*Z*)- and (*E*)-methyl 4-X-3-alkyl-3-butenoates are formed [route (*a*)].

Scheme 4

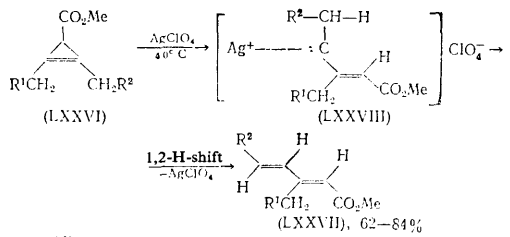
This process is significant or fundamental (yield of products 30–95%) in the case of HCl, HBr, carboxylic acids with pK_a 3–7, phenol, and nitrophenol. In the presence of carboxylic acids with pK_a 0–2, isomerisation to a methoxyfuran is preferred [route (*b*)], apparently because of the low nucleophilicity of residue X.

The formation of addition product by catalytic reaction of cyclopropene esters with terminal acetylenes and HCN takes place according to the same scheme. However, in this case the reagents HX are drawn into the reaction zone by formation of a complex with CuCl:



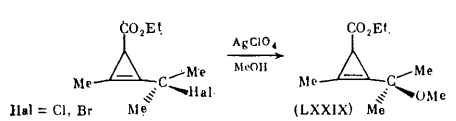
R = Alk,
Y = N or CR^1.

In the resulting organocopper intermediate (LXXV) coordination of the terminal acetylenes or HCN with CuCl leads to weakening of the C–H bond, an increase in the nucleophilicity of the C≡Y residue and convergence of the proton-donor reagent with the cyclopropene molecule, thus creating a favourable opportunity for nucleophilic attack on the C(2) atom to form the corresponding enynoate or cyanobutenoate esters (LXXII) and (LXXIII).[97]



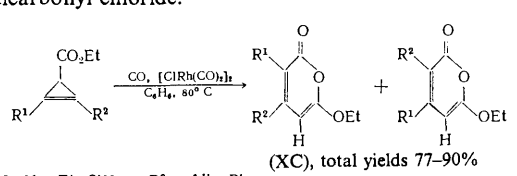
In the reaction of cyclopropene esters with HX reagents in the presence of CuCl, a competing process is also possible—addition of HCl units to the C(2)–C(3) bond to form (*Z*)- and (*E*)-methyl 4-chloro-3-alkyl-3-butenoates (LXV) [route (*c*)]. In this case the HX reagents only act as proton donors, while CuCl acts as the chlorine donor. This route is the main one for reactions of the esters in the presence of 20–100 mol% CuCl with methanol, 2,4-dinitrophenol, butyl mercaptan, cyclohexenedicarboximide, bromoform, trinitromethane, nitromethane, and ethyl cyanoacetate.

When CuCl or its complexes are replaced by $CuOSO_2C_2F_4OC_2F_5$ or copper(II) triflate, the main reaction route of 1-alkylcyclopropene-3-carboxylate esters is their stereoselective dimerisation with ring-opening to give hexatrienecarboxylate esters (LXXIV), which are the formal dimers of vinylcarbenes [:CHC(R)=CHCO$_2$Me] isomer with (LX).[70,109]



The same reaction of (LX) on treatment with $CuOSO_2C_2F_4OC_2F_5$ occurs in the presence of norbornadiene or acetic acid; neither vinylcyclopropene adducts (LXI) nor acyloxybutenoate esters (LXVII) (R^1 = Me) are formed in these cases.[97]

Reactions of cyclopropenecarboxylate esters in the presence of other metals. Apart from copper compounds the action of other metals, in particular, Ag, Pt,[110] Fe,[32] Rh,[16] on cyclopropene-3-carboxylate esters has been studied. Thus, in the presence of $AgClO_4$ (40 °C) or $AgBF_4$ (80 °C) or PtO_2 (220 °C), 1,2-dialkylcyclopropene-3-carboxylate esters (LXXVI) are converted to the dienoate esters (LXXVII).[110] It was proposed[110] that formation of (LXXVII) occurs via a vinylcarbene intermediate (LXXVIII), although the concerted mechanism proposed for copper compounds cannot be ruled out in this case.



R^1, R^2 = H, Alk.

However, when chlorine or bromine at an α-position relative to the double bond is present in the side chain of a cyclopropene esters, ring-opening does not occur on treatment with $AgClO_4$ in MeOH but nucleophilic substitution takes place to give esters (LXXIX).[111,112]

It was recently demonstrated that α-pyrones can be obtained by carbonylation of cyclopropene-3-carboxylate esters in the presence of rhodium dicarbonyl chloride:[16]

R^1 = H, Me, Et, $SiMe_3$; R^2 = Alk, Ph.

In most cases the reaction is stereospecific, only isomer (XC) being formed, which makes this reaction valuable for preparative synthesis.

Other metal compounds—$Ni(COD)_2$, $MoCl_2-AlEt_3$, WCl_5-SnMe_4, a Ziegler–Natta catalyst—only cause cyclopropene esters (LX) to oligomerise.[70]

- - - o 0 o - - -

Thus, the material reviewed here demonstrates the availability of cyclopropene-3-carboxylate esters and their ability to undergo different chemical reactions with high conversion rates and selectivity. This makes it vital to carry out studies on the use of the reactions of cyclopropene-3-carboxylate esters and compounds derived from them in the directed organic synthesis of compounds with various useful properties.

Carbene complexes in catalysis

I I Moiseev
Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

ABSTRACT. The methods for forming carbene complexes in catalysis are analysed in the case of the catalytic conversions of hydrocarbons, acids, carbonyl compounds, carbon monoxide, and methanol.

The bibliography includes 85 references.

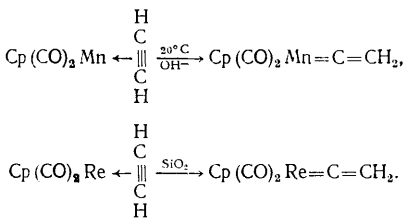
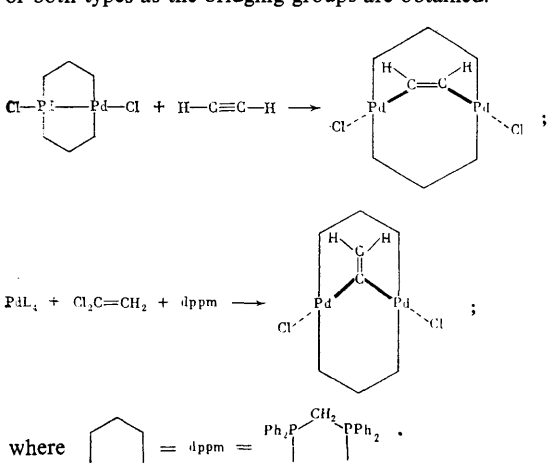
I. Introduction

When the role of coordination compounds that contain carbene ligands is considered, most attention is usually given in catalysis[1–10] to the interaction between the carbene complex and substrate. Questions relating to the formation of such complexes have been examined to a considerably lesser extent. The present review is devoted mainly to examining those reactions, including model reactions, that result in the formation of carbene molecules and their complexes during the catalytic conversions of the main classes of organic compounds that are most frequently used in industrial and laboratory synthesis.



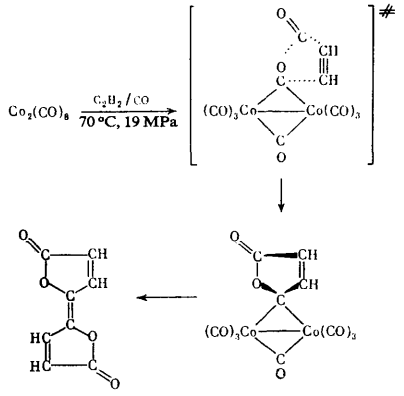
II. Alkynes

The idea that carbene molecules participate in the intermediate stages of catalytic processes was first suggested by Neff.[11] According to this hypothesis, addition reactions to acetylene such as those of hydrogen halides include the isomerisation of acetylene to the so-called "isoacetylene", which is free vinylidene, and reaction of the latter with hydrogen halides:



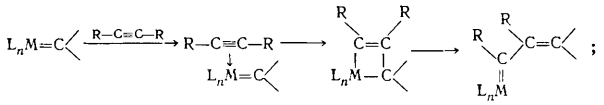
Neff did not elucidate the role of the catalyst, usually Hg^{2+} salts, in these reactions. This hypothesis was later contradicted by other ideas, according to which the reaction of acetylene with hydrogen halides takes place via an intermediate π-complex of Hg^{2+} with an acetylene molecule.[12,13] as well as a complex of a nucleophile with acetylene,[14] the so-called "reverse π-complex", in which bonding between the attacking reagent and the unsaturated ligand only occurs as a result of dative interaction.

However, it should be noted that when the central atom is a good electron donor, acetylene π-complexes and acetylides can be converted to vinylidene derivatives:[15–17]



Thus as a result of the stabilisation of the vinylidene ligand in the internal coordination sphere of the transition metal complex, the reaction, which in the case of free acetylene and vinylidene requires the expenditure of about 167 kJ mol^{-1} of energy,[18] becomes possible. Quantum-chemical analysis of the interaction between the Cu^{1+} ion and acetylene and vinylidene indicates that there is stronger bonding of the latter with the central atom.[19] The relative stability of these types of complexes must depend to a considerable extent on the nature of the central atom. It cannot be ruled out that in time addition reactions to alkynes that take place with the involvement of carbene complexes as key intermediates will be discovered.

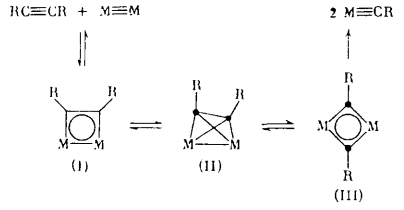
Reactions of alkynes in the presence of polynuclear systems are complicated by the possible formation of complexes with 1,2-vinylidene in addition to a symmetrical π-complex and a complex with a 1,1-vinylidene ligand.[20] Thus, for $Pd_2(\mu\text{-}Q)_2Cl_2$, where Q is bis(diphenylphosphino)methane, derivatives containing vinylidene ligands of both types as the bridging groups are obtained:[21]



A number of cyclisation processes of alkynes which take place via intermediate complexes with bridging carbene ligands are known.[21]

Scheme 1

It is believed that the polymerisation of alkynes by carbene complexes of transition metals takes place via the cycloaddition of the alkyne to a carbene complex to form a metallocyclobutene followed by conversion of the latter to a complex with a new carbene ligand:[22]

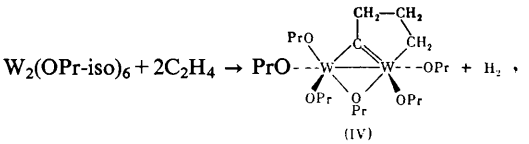


$L_nM = WCl_2[P(CH_3)_3]_2$.

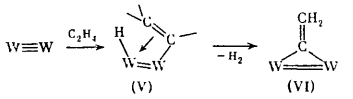
Reaction of alkynes with ditungsten (3+) alkoxides that contain a W≡W bond gives carbyne complexes[23]

$$W_2(OBu\text{-}t)_6 + RC{\equiv}CR \rightarrow 2RC{\equiv}W(OBu\text{-}t)_3.$$

The W≡C bond is apparently so strong that the energy released on forming it compensates that expended on cleavage of the C≡C bond (~830 kJ mol^{-1}) and the reaction takes place in benzene at 25 °C. It is assumed that in this reaction the alkyne first adds on to the W≡W multiple bond to form the dimetallocyclobutadiene (I). The latter isomerises to complex (II), and both the electrons of the π-bonds of the initial ligand and the electrons of the π-bonds of the initial complex take part in formation of bonds between the metal atoms and the organic ligand. Isomerisation of this complex to the symmetrical dimetallocyclobutadiene (III) and dissociation of the latter result in formation of the observed and carbyne complex.

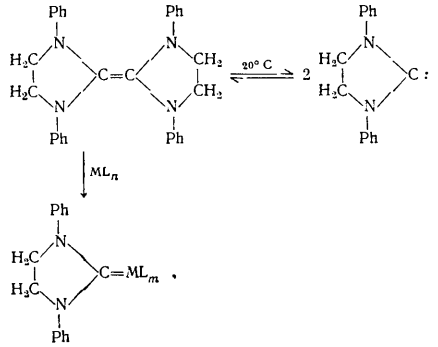


The isolated carbyne complexes catalyse the disproportionation of alkynes.

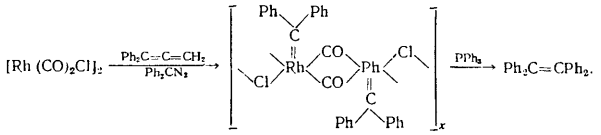


III. Alkenes

In the reaction of ditungsten hexa-alkoxides with alkynes the oxidation state of the metal atom increases as a result of oxidative addition. Oxidation of the metal is probably one of the driving forces for cleavage of the alkyne and formation of a carbyne complex. In the analogous reaction with an alkene the oxidation state of the metal would change to a lesser extent, which is evidently the explanation for the reaction of alkenes with ditungsten hexa-alkoxide not giving carbene analogues of the carbyne complexes.

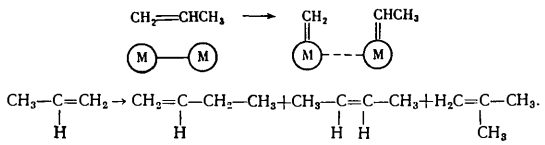


When $W_2(OPr\text{-}iso)_6$ is reacted with ethylene, complex (IV) containing a 5-membered metallocycle is formed:[24]

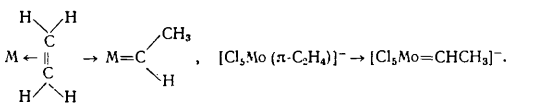


The driving force of this process is also oxidation of the metal atoms of the initial tungsten compound with the alkene. This process is believed to involve the intermediate formation of complexes with vinyl (V) and vinylidene (VI) ligands:

Cleavage of the C=C bond with formation of carbene complexes occurs comparatively rarely under mild conditions. Thus, it was possible to obtain a number of Pd(II), Pt(II), Au(I), Rh(I), Cr(0), and Re(0) complexes from electron-rich unsaturated compounds that can partially decompose to free carbenes even at 20 °C:[25-27]

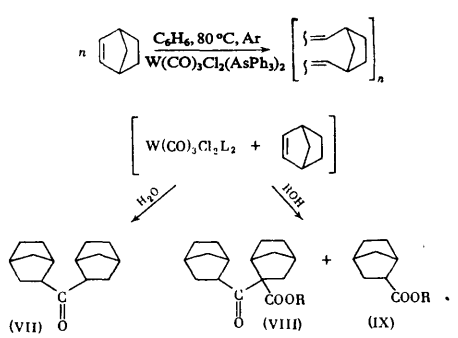


In the reaction of a Rh(I) complex with 1,1-diphenylallene (*o*-xylene, 4 h), which probably undergoes cleavage within the coordination sphere of the central atom to diphenylcarbene and vinylidene ligands, a polymeric complex of rhodium with diphenylcarbene was obtained. The same complex was synthesised by treating the initial rhodium complex with diphenyldiazomethane. Treatment of the carbene complex generated with PPh_3 gave tetraphenylethylene:[28]

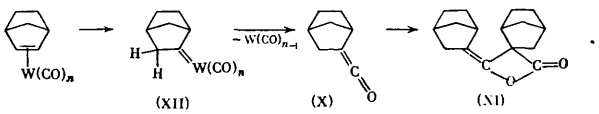


The cleavage of lower alkenes to give carbene complexes of transition metals appears to be a fairly general phenomenon only under relatively severe conditions. Thus, comparison of the

behaviour of CH_2N_2/H_2 and CO/H_2 mixtures, reaction of which with metals very probably leads to the formation of carbene intermediates, with the behaviour of a $CH_2=CHCH_3/H_2$ mixture showed that in all cases the distribution of products conforms to the same rule. This observation led to the conclusion that on Ru, Fe, Rh, and Os deposited on silica gel, alkenes dissociate at 1 atm and 250–300 °C to form carbene ligands, and the resulting complexes catalyse the homologisation of olefins:[29]

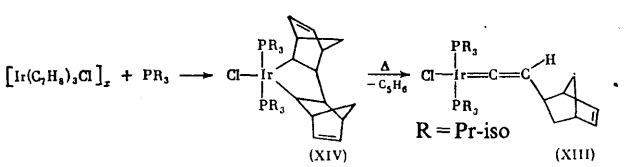


Another possible general method for the formation of carbene complexes from olefins assumes the internal isomerisation of a π-coordinated olefin to a carbene ligand. Quantum-chemical analysis showed that this type of isomerisation was energetically unfavourable for Pd(II) complexes but was practicable for Mo(IV) complexes:[30]

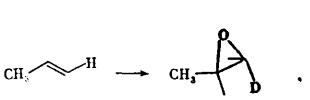


The theory concerning the mutual interconversion of alkyl- or dialkyl-carbene ⇄ alkene has been repeatedly discussed in the literature. Before the publication of the first X-ray diffraction studies devoted to an analysis of Zeise salt,[31] it was proposed[32] that this first known alkene π-complex was in fact a complex with methylcarbene. It transpired subsequently, however, that this view was incorrect and that even the isomerisation of alkenes in solutions of palladium and platinum salts takes place by routes that do not involve intermediate carbene complexes.[33] Nevertheless, it was not ruled out that in Mo(0) and W(0) carbonyl complexes the conversion of an alkene or alkadiene to a carbene ligand is possible. This is suggested by the results obtained from a study of the reaction between diphenylcarbenepentacarbonyltungsten and conjugated dienes.[34] Metathesis of lower olefins by contact with photoreduced molybdenum silicate catalysts that contain Mo(IV) ions is assumed to take place by a chain mechanism involving carbene intermediates that are generated by isomerisation of a π-coordinated alkene by means of an intramolecular 1,2-shift of an H atom.[35]

Chemical confirmation that such mechanisms occur was first obtained during a study of the reaction between norbornene and a tungsten(II) complex[36–38]

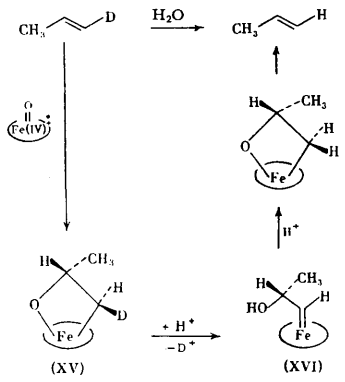


The composition of the observed products derived from alcoholysis and hydrolysis of the reaction mixture [compounds (VII), (VIII), and (IX)] clearly indicates that there is isomerisation of coordinated norbornene to the corresponding carbene ligand, which on reacting with coordinated CO is converted to ketene (X), giving the dimer (XI):[36–38]



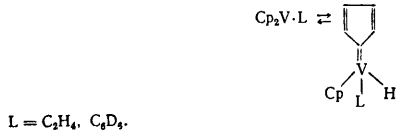
Ketone (VII) and ketocarboxylate ester (VII) are formed by the reaction of (XI) with water or alcohol, while the formation of (IX) results from the addition of alcohol to ketene (X). 2-Norbornylidene-phenylmethane was detected in the products resulting from interaction of the reaction mixture with benzaldehyde, which suggests that carbene complex (XII) is present in the mixture.

It is not ruled out that the 1,2-shift of an H atom, as detected by Bensze and Kraut-Vass,[38] which results in isomerisation of the π-coordinated alkene to the corresponding coordinated carbene is quite a general route for forming carbene intermediates. Another route which is apparently specific to norbornadiene occurred during a study of the behaviour of iridium complexes with this diene.[39] It was found that when polymeric tris(norbornadiene)iridium chloride was reacted with triisopropylphosphine in benzene at 50 °C, the square-planar vinylidene complex (XIII) was readily formed. At lower temperatures there is the formation of the polycyclic product (XIV), which is a precursor of the final vinylidene complex:



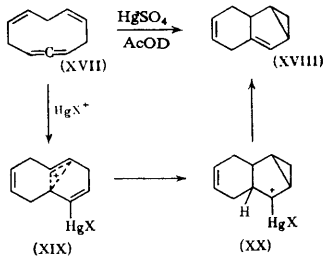
It is likely that in the first stage of this reaction during displacement of norbornadiene ligands by trialkylphosphine, the former undergo oxidative addition to the central atom, culminating in the formation of intermediate complex (XIV), which contains a substituted iridocyclopentane ring. This process is probably assisted by an increase in electron density on the iridium atom as a result of the initial addition of the strong donor ligand—triisopropylphosphine. Thermal elimination of cyclopentadiene from (XIV) should result in the formation of an intermediate with an iridocyclopentene residue. However, this intermediate probably isomerises to the more stable vinylidene complex (XIII) even as it is being formed.

In the epoxidation of propylene in D_2O containing cytochrome R-450, regiospecific and stereospecific substitution of the H atom situated *trans* to the CH_3 group occurs with replacement by a D atom:[40]



Under these conditions H/D exchange takes place between propylene and the solvent. It has been suggested that the reaction of the alkene with the active centre of cytochrome [$Fe^{4+}=O$] takes place

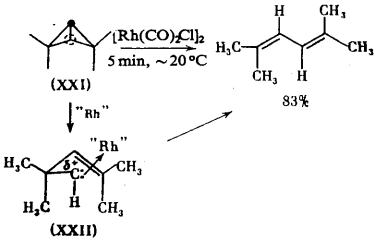
via the intermediate (XV) containing a four-membered metallocycle. Deprotonation of (XV) gives the carbene complex (XVI):



The process of protonation and deprotonation permits isotope exchange. The simultaneous cleavage of the Fe–O and Fe–C bonds in a complex of the type (XV), accompanied by elimination of epoxide, results in the formation of an alkene oxidation product.

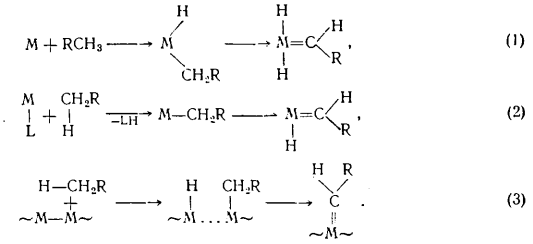
Isotope exchange between ethylene and deuterobenzene in the presence of bis(cyclopentadienyl)vanadium occurs by a mechanism that involves the conversion of a cyclopentadienyl complex to a complex containing a cyclopentadienylidene ligand and hydride:[41]

The reversible insertion and elimination of ligand L on the V–H bond accounts for the observed deuterium exchange.



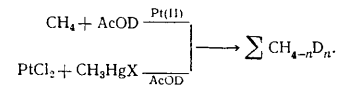
According to Thies et al.[42] cyclisation of the allene derivatives (XVII) to (XVIII) when treated with mercuric sulphate in acetic acid

involves attack by the mercury cation on the allene group. Then, after migration of the double bonds, the organomercury derivative (XIX) with delocalisation of the positive charge is formed. This non-classical cation is stabilised on being converted to carbene complex (XX), in which the C carbene atom has a positive charge. Elimination of the HgX^+ cation accompanied by a 1,2-shift of the H atom lead to the formation of the observed product (XVIII).[42]



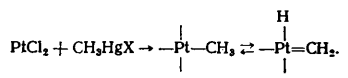
IV. Alkanes and their derivatives. Activation of C–H, C–C, and C–Cl bonds

The cleavage of C–C bonds in reactions of alkanes with metal complexes under mild conditions is a rare phenomenon. However, if the compound contains strained rings, cleavage of these bonds is considerably facilitated. Examples are known of the isomerisation of derivatives of cyclopropane, bicyclobutanes, and related hydrocarbons by treatment with silver, platinum, palladium, rhodium compounds, etc. It is thought that these reactions can take place via carbene intermediates. For example, 2,2,4,4-tetramethylbicyclo[1.1.0]butane (XXI) when treated with dimeric rhodium carbonyl chloride isomerises to 1,1,4,4-tetramethylbutadiene.

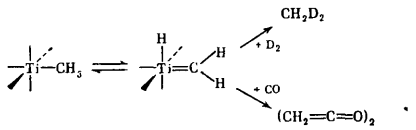


It appears that at the first stage oxidative addition of the initial hydrocarbon (XXI) to the Rh(I) atom takes place with cleavage of the weakest C–C bond (that common to both rings) and a compound containing two Rh–C σ-bonds is formed. As a result of the cleavage of one of the Rh–C bonds and one of the neighbouring C–C bonds, this complex is converted to a carbene–olefin complex (XXII, which isomerises to the final product.[43]

H/D exchange reactions of alkanes that are catalysed by metals or their coordinate compounds[44,45] are often represented by schemes involving oxidative addition of the alkane to a metal atom [reaction (1)] or replacement of ligand L by an alkyl within the coordination sphere of the complex [reaction (2)] followed by elimination of an α-hydrogen atom to form a carbene derivative:

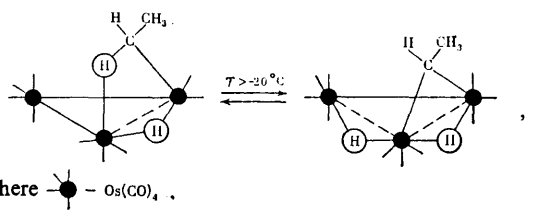


Oxidative addition of the alkane to a metal or polynuclear compound with cleavage of the metal–metal bond is probably much more energetically favourable than reaction (1) [reaction (3)].



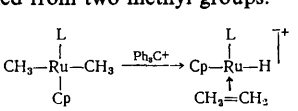
In the alkylation of $PtCl_2$ with methylmercury derivatives in the presence of deuteroacetic acid, the same series of deuteromethanes was detected[46] as in experiments on exchange between CH_4 and CH_3COOD in solutions containing Pt(II) chloride complexes:[46]

This phenomenon can be regarded as confirmation of the intermediate formation of methylplatinum complexes in H/D exchange between CH_4 and CH_3COOD. The simultaneous occurrence of not only monodeuterated products but also multiple exchange products in the reaction mixture indicates that there is an equilibrium between methyl and carbene



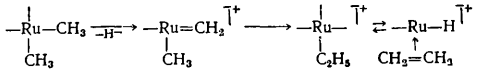
It appears that interconversions of alkyl and carbene hydride complexes occur quite widely in the chemistry of organic derivatives of transition metals. Thus, the simultaneous formation of all the deutero derivatives of methane with di- and tri-deuteromethanes predominating when the system $TiCl_4$ + $AlClMe_2$ is reacted with deuterium suggests[45] the following equilibrium is taking place:

Formaldehyde and ketene dimer were found amongst the products of the reaction between carbon monoxide and the $TiCl_4$ + $AlClMe_2$ mixture. The formation of ketene conforms well with the proposal that titanium carbene complexes are present during the experiments.[47]



Not only methyl but also other alkyl derivatives display a tendency towards α-elimination of an H atom and formation of a complex containing both a carbene group and a coordinated hydride.[1-6,48] Analysis of PMR spectra of solutions of $HOs_3(CO)_{10}C_2H_5$ showed that above –20 °C this complex, which contains an ethyl group, is converted to a methylcarbene complex:[49]

where – Os(CO)$_4$.

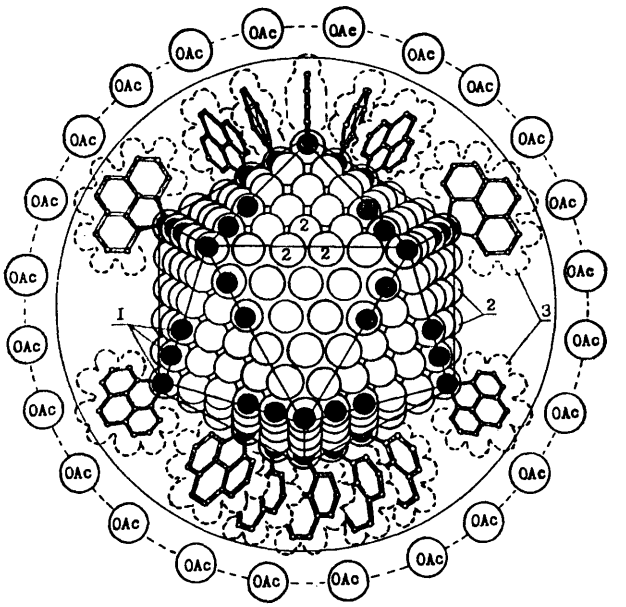


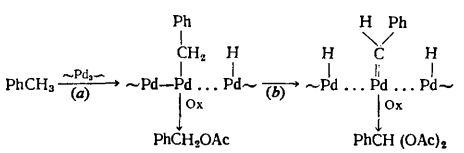
The process of α-elimination is assisted since in the initial complex one of the α-hydrogen atoms of the coordinated ethyl group converges with an Os atom as if ready for transposition to a bridging hydride ion.

The process in which a coordinated alkyl group is converted to a carbene ligand as a result of the elimination of a hydride ion is widely used in preparative work. Carbocations and other electrophiles are used as the H^- acceptor. Similar processes probably occur in catalysis, such as during oxidative dehydrogenation of hydrocarbons where a suitable oxidising agent can accept H^-. These types of processes may be responsible for the formation of new carbon–carbon bonds. A particular indication of this is given by the model reaction of a dimethylruthenium complex with triphenylcarbocation (hydride ion acceptor), as a result of which coordinated ethylene is formed from two methyl groups:[50]

Cp = η^5 cyclopentadienyl.

It appears that the complex formed after elimination of the hydride ion, containing both a coordinated methyl group and a carbene ligand, isomerises to a complex with an ethyl group as a result of insertion of coordinated carbene into the ruthenium–methyl bond. Elimination of a β-hydrogen atom from the ethyl group gives the observed final product:





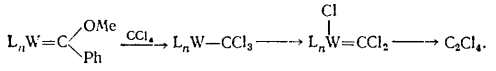


Figure 1. Hypothetical structural scheme of the very large cluster $Pd_{561}Phen_{60}(OAc)_{180}$: *1*, Pd atoms on the edges of the icosahedron that are available for coordination with phenanthroline molecules; *2*, Pd atoms that are available for coordination with substrate; *3*, coordinated phenanthroline molecules.[51,52]

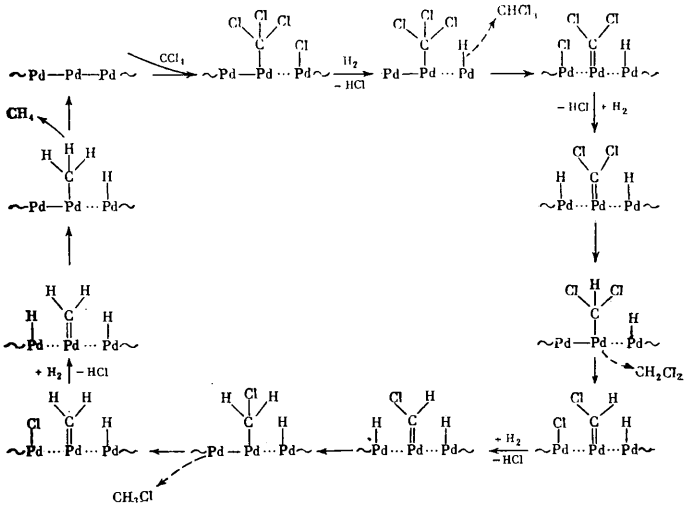
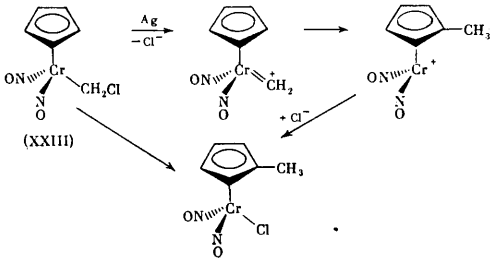
Palladium clusters with the hypothetical formula $Pd_{561}Phen_mO_nX_l$ (m = 60, n = 0, X = OAc, l = 180; m = 80, n = 60, X = PF_6, l = 60) [51,52] catalyse the oxidative acetoxylation of alkenes and arylalkanes. Analysis of molecular models (Fig. 1) shows that out of 252 palladium atoms of the external layer of the compact metal core of these compounds only 30–40 are sterically accessible to substrate molecules. The results of determining the number of active sites in the cluster by an inhibition method [53] are consistent with this conclusion. It follows also from molecular models that the active sites of such clusters contain three palladium atoms. This makes it possible to simplify the discussion of the mechanism of the interaction between substrate and cluster by considering only three out of all the palladium atoms. In the acetoxylation of toluene appreciable quantities of benzylidene diacetate are formed together with benzyl acetate.[54] Since benzyl acetate is not oxidised to benzylidene diacetate under the experimental conditions, this indicates that when the route responsible for the formation of benzylidene diacetate occurs, a toluene molecule does not leave the surface of the cluster until two hydrogen atoms have separated from it. This condition is met by a scheme involving the oxidative addition of toluene to a group of three palladium atoms [stage (*a*)] and also elimination of an H atom from a coordinated phenylmethyl group to give a coordinated phenylcarbene [stage (*b*)].

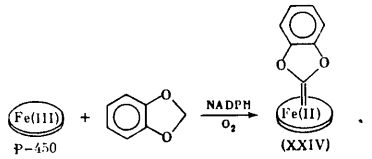


The reaction products, as in the acetoxylation of alkenes, are formed by transfer of electrons from the coordinated organic ligands and H atoms to the oxidising agent (Ox).

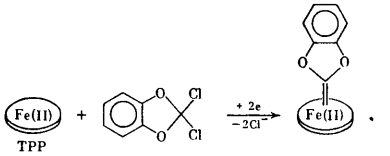
Processes related to α-elimination apparently occur during the conversion of haloalkanes using transition metal compounds. Thus, tetrachloroethylene is amongst the products from the reaction between CCl_4 and pentacarbonylphenylmethoxycarbenotungsten, in addition to CO, HCl, CH_2Cl_2, and $CHCl_3$. The occurrence of tetrachloroethylene may be due to the formation of a trichloromethyltungsten derivative and its conversion by α-elimination of a chlorine atom from the CCl_3 group to a dichlorocarbene complex.[55] The latter is the source of tetrachloroethylene:



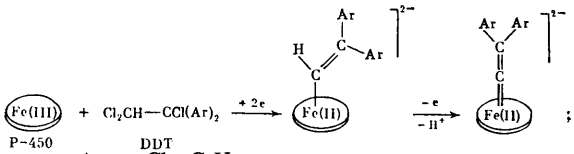
In the reactions of CCl_4 with hydrogen on palladium catalysts obtained by reduction of palladium(II) compounds in the presence of alcohols, $CHCl_3$, CH_3Cl, and CH_4 are all formed at the same time.[56] The simultaneous formation of these products indicates that a substrate molecule can, without leaving the surface of the catalysts, replace more than one Cl atom with H. In the same way as for the oxidative acetoxylation of toluene, these phenomena can be accounted for by a scheme that involves the oxidative addition of CCl_4 to two atoms of the "triplet" of Pd atoms with alternating stages for replacement of Cl atoms on palladium by H atoms and α-elimination of Cl atoms to form a carbene ligand. Addition of H atoms to the latter results in regeneration of a coordinated halomethyl group. According to this scheme, the observed reaction products are formed by reductive elimination of a methyl or halomethyl radical and H or Cl atoms. The yield of reaction products is determined by the ratio of rates for reductive elimination and α-elimination:



Scheme 2



Elimination of the Cl^- ion from the chloromethyl group bonded to the chromium atom and formation of an intermediate chromium carbene complex are responsible for the silver-catalysed migration of the CH_2 group in the chloromethyl residue to the cyclopentadienyl ring of complex (XXIII):[57]

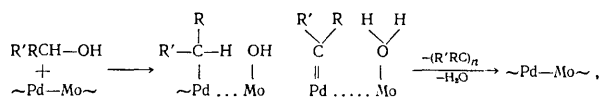


The formation of carbene complexes from compounds containing C–H and C–Hal bonds plays an important part in redox processes which take place in living organisms.[58] Thus, it is thought that during oxidative metabolism of 1,3-benzodioxole, a powerful insecticide synergist, a complex is formed in which the iron atom of cytochrome P-450 is bonded to a carbene ligand that is generated after the removal of two H atoms from the methylene group of 1,3-benzodioxole:[58]

An analogue of complex (XXIV) was obtained from tetraphenylporphyrin (TPP) and 2,2-dichloro-1,3-benzodioxole:

It is thought that carbene complexes also occur during the reductive metabolism of a number of inhalation anaesthetics by cytochrome P-450. When the insecticide 2,2-bis(*p*-chlorophenyl)-1,1,2-trichloroethane (DDT) is reacted with the cytochrome P-450 analogue, iron(II) tetraphenylporphyrinate, a very stable arylvinylidene complex is obtained:[58]

Results which suggest that σ-alkyl and carbene complexes of iron undergo interconversion during the oxidation or reduction of a number of substrates with cytochrome P-450 have been obtained.[59–61]



V. Alcohols

In recent years the reactions of methanol on high-temperature zeolite catalysts of the type ZSM-5 have stimulated considerable interest.[62] At 300–500 °C a mixture of hydrocarbons—alkanes, alkenes, arenes, etc.—is formed from methanol. In practical terms

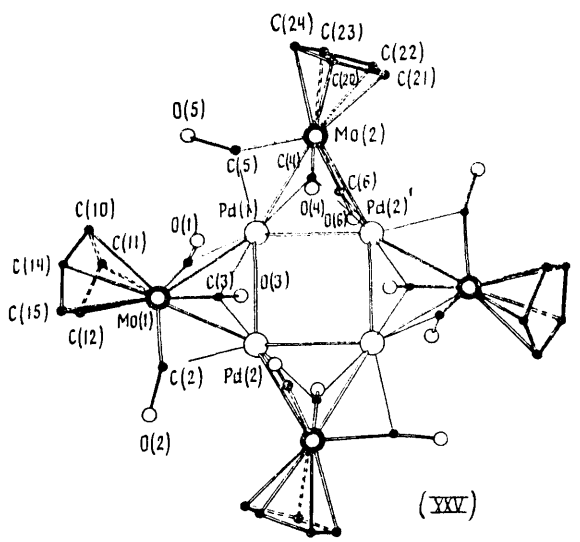
those reactions of the greatest interest are selective conversions of methanol, such as:

$$2CH_3OH \longrightarrow CH_2{=}CH_2 + 2H_2O,$$
$$3CH_3OH \longrightarrow CH_3CH{=}CH_2 + 3H_2O,$$
$$3CH_3OH \longrightarrow CH_2 - CH_2 + 3H_2O,$$
$$\quad\quad\quad

diethyl ether nor ethylene is formed. This suggests that the elimination of water is not catalysed by either protons or Lewis acids. In the dehydration of benzyl alcohol, approximately equal quantities of *trans*-stilbene and water are formed. These findings may be interpreted by assuming that an H atom and hydroxyl radical are eliminated from the same carbon atom of the alcohol molecule to form a carbene ligand that is stabilised through coordination. It should be noted that homonuclear palladium clusters such as $Pd_4(CO)_4(OAc)_4$ and mononuclear molybdenum carbonyl complexes do not catalyse this reaction. It is probable that the Pd–Mo bond which occurs in complex (XXV) is absolutely essential for catalysis. It is possible that the alcohol, when introduced on to this bond in the Pd_4Mo_4 group, alkylates the Pd atom and oxidises the Mo atom, to which a hydroxyl group is added. After transfer of a proton from the coordinated alkyl to the coordinated hydroxyl on the reaction site, an H_2O molecule bonded to the Mo atom and a carbene ligand coordinated with the Pd atom are formed.

$$PhCH_2OH \xrightarrow[80^\circ C]{«Pd_4Mo_4»} PhCH{=}CHPh + 2H_2O.$$

Elimination of these ligands and restoration of the palladium–molybdenum bond complete the catalytic cycle.



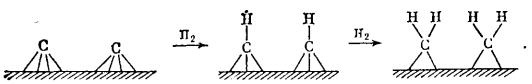


Figure 2. Structure of the anion of the palladium–molybdenum cluster with the composition $Na_2\{Pd_4[CpMo(CO)_3]_4\}.2THF$.[70]

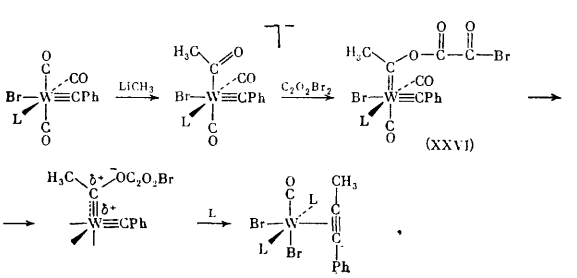
VI. Carbon monoxide

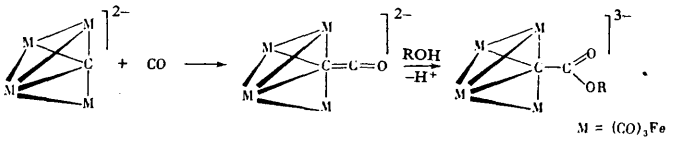
The theory concerning the formation of intermediate carbene complexes has been widely applied in discussions of the mechanism of the hydrogenation of carbon monoxide (Fischer–Tropsch reaction) on both solid catalysts and in solution.[75] It is thought that both coordinated (adsorbed) carbonyl groups and carbide carbon, i.e. C atoms actually coordinated, participate in reduction processes. Thus, for the most general case the reduction of CO is based on the reaction:

$$M(CO)_n + M^1 \xrightarrow[-M^1O]{} (CO)_{n-1}MC.$$



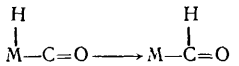
It may be assumed that M^1O subsequently reacts with CO or H_2, resulting in regeneration of the catalyst. Depending on the nature of the catalyst, it appears that routes involving hydrogen and $M(CO)_n$ or $(CO)_{n-1}MC$ or both compounds together take place. It is thought, however, that intermediate carbene species are formed in all these reactions. Thus, carbene complexes play a key role in the initiation of this process, which has the kinetic characteristics of a chain process (primary reactions of coordinated carbonyl, conversions of the carbide atom to carbyne and carbene groups), in chain growth, in reactions of metal acyl derivatives, and others.[73] For example, reduction of carbide complexes by heterogeneous catalysis is depicted by a scheme that involves the formation of intermediate carbyne and carbene compounds (without specifying the nature of the groups bonded to the C atom)

Carbene complexes constitute a source of alkenes and alkanes. It would appear that alkynes could be formed from carbyne complexes, but the synthesis of acetylene in the gas phase according to the reaction



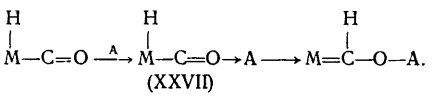
$$2CO + 3H_2 = HC{\equiv}CH + 2H_2O$$

is fairly improbable thermodynamically (ΔG^0_{298} = + 26.5 kJ mol^{-1}) and is not feasible under mild conditions. There has only been one report[76] about the synthesis of acetylene from CO and H_2 at 1 atm and 100 °C in the presence of graphite intercalation compounds with $FeCl_3$ (composition C_9FeCl_3) activated with potassium naphthalide. The nature of the processes taking place in this system is unclear. It should be noted, however, that the synthesis of acetylene from CO to H_2 will probably occur if it is interlinked with any exoergic process. Thus, for example, in the model reaction in which LiMe serves as the reducing agent instead of H_2 while one of the oxygen atoms of a carbonyl group is removed using oxalyl bromide, the carbyne group PhC≡ is included in the composition of the final alkyne PhC≡CMe:[77]



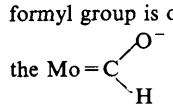
In this case not only is phenylacetylene formed but an exoergic process also takes place—the partial hydrolysis of oxalyl bromide. It is of considerable importance that this synthesis takes place via an intermediate carbene-carbyne complex (XXVI).

Another route for converting carbide complexes assumes the formation of intermediate ketenides—analogues of transition metal vinylidene derivatives—by a scheme[78] such as



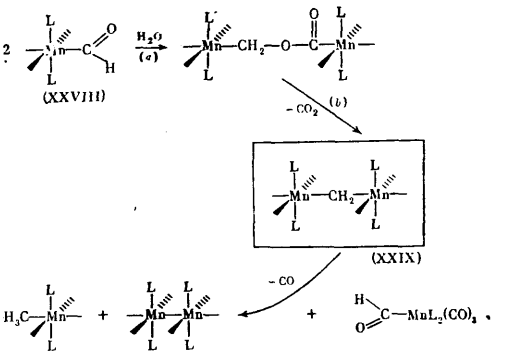
M = $(CO)_3Fe$

Hydroxycarbene groups play a key role during the reduction of coordinated CO groups. Migration of a coordinated H atom to coordinated CO



is somewhat unfavourable thermodynamically and difficult kinetically.[79] For this process $\Delta G^0_{298} > 0$ and $E_\alpha > 167$ kJ mol^{-1}. Analysis[79] of the experimental data indicated that in all cases isomerisation of the carbonyl hydride complex to a formyl derivative only takes place when there is a proton or aprotic acid A in the system which is capable of forming an adduct with the carbonyl hydride complex (XXVII):

(XXVII)

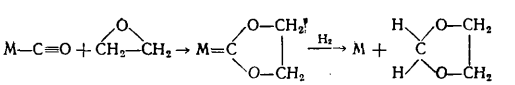


Apart from a proton, cations of alkali and alkaline earth metals as well as complexes of virtually all transition metals can act as electrophile A. It appears that because of the increase in effective positive charge on the carbon atom of the carbonyl group in adduct (XXVII), transfer of the coordinated hydride from the metal to carbon is facilitated. The final product is hydroxycarbene complex in which the H atom has been replaced by electrophile A. It is probable that the higher the stability of such a hydroxycarbene complex, the stronger is the influence of thermodynamic factors that assist this transfer of the H atom. Addition of two hydrogen atoms to this hydroxycarbene complex results in the formation of a complex with a hydroxymethyl ligand MCH_2OH, which on reaction with synthesis gas can give methanol, oxygenated products with a longer chain, and other products.

It should be noted that in the formyl derivative of molybdenum $C_5Me_5(CO)_2(PPh)_3MoCHO$, the vibration frequently ν_{CO} of the formyl group is only 1602 cm^{-1}, which suggests that a structure with the  bond predominates. In fact, this and related complexes are readily protonated or methylated to form cationic hydroxycarbene complexes with the composition

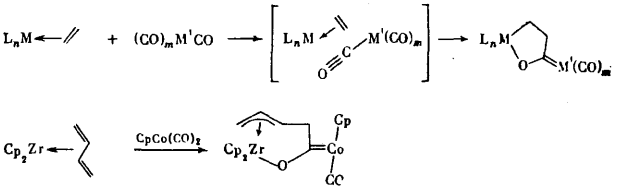
$$[(\eta^5\text{-}C_5Me_5)(CO)_2(PPh_3)Mo{=}C(H)OR^-]^+X^-,$$

R = H or Me, $X^- + CF_3COO^-$ or PF_6^- (Ref.80).



However, there are examples which suggest that conversion of the CHO group to CH_3 can occur by a more complex route[81] than that discussed above:

(XXVIII) (XXIX)



In fact, reduction of the manganese formyl complex (XXVIII) incorporates a redox disproportionation involving a water molecule [stage (*a*)], elimination of CO_2 from the complex with a bridging ester group [stage (*b*)] and finally the formation of a binuclear complex (XXIX) with a bridging carbene. Reduction of this methylene derivative with a third molecule of formyl complex (XXVIII) gives a methyl derivative and a dimeric derivative with a Mn–Mn bond.

In the schemes reviewed in the literature, the reactions of carbonyl complexes with reagents which are present in the system other than H_2 and hydride complexes are not usually taken into account. It is possible that the inclusion of oxygenated compounds as potential reagents would considerably extend our ideas about possible routes for reducing CO. Thus, it was shown[82] that carbonyl complexes of Fe, Ru, Mn, and Re can react with ethylene oxide to form dioxocarbene complexes that are potential sources of cyclic formaldehyde acetal:

M = $CpFe(CO)_2^+$, $CpRu(CO)_2$, $CpMn(CO)(NO)^-$, $Re(CO)_4Cl$, $Ru_3(CO)_{11}$, $Re_2(CO)_9$.

In a similar manner the condensation of a π-coordinated alkene or diene with a coordinated carbonyl leads to carbene complexes[83] which can be hydrogenated to obtain oxygenated compounds in a Fischer–Tropsch synthesis:

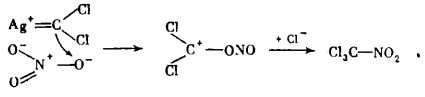
Reactions of this type are to be expected for Group IV elements, which can apparently form fairly strong bonds with the oxygen atom of the coordinated carbonyl group. Probably this "double" coordination of CO assists the cycloaddition of carbon monoxide and the coordinated alkene or alkadiene as depicted in the scheme shown here.

VII. Carbonyl compounds and carboxylic acids

Information about reactions in which a carbonyl compound acts as a donor of a carbene ligand is extremely limited. This is not surprising if we consider the strength of the C=O bond and the need to use a very powerful reducing agent to bond to the O atom being removed from this group. Amongst reactions of this type, in which the formation of intermediate carbene complexes may be presumed, should be included the reduction of benzophenone to tetraphenylethylene:[84]

$$2Ph_2C{=}O \xrightarrow[97\%]{\text{Red, } TiCl_3/THF} Ph_2C{=}CPh_2,$$

Red = Zn, $LiAlH_4$, Li, K.



The titanium complex present in the system evidently has different functions compared to the reducing agents used. It cannot be excluded that the Ti atom first coordinates ketone molecules and then—after the removal of O atoms on treatment with the reducing agent—forms a complex with diphenylcarbene, which undergoes conversions to give tetraphenylethylene:

$$Ph_2C{=}O \xrightarrow{\text{Red, } TiX_n} Ph_2C{=}TiX_n \xrightarrow[-TiX_n]{} Ph_2C{=}CPh_2.$$

The thermolysis of anions of trihalo-substituted carboxylic acids is one of the oldest methods for generating carbenes.[85] However, the effect of transition metals on this process and on the reactions of dihalocarbenes formed in the system has hardly been studied at all. One of the few known reactions is the synthesis of chloropicrin[85] by thermolysis of trichloroacetate in the presence of silver nitrate:

$$Cl_3CC(O^-)=O \xrightarrow{AgNO_2} Cl_3C{-}NO_2.$$

It cannot be excluded that the dichlorocarbene formed in the system is stabilised by coordinating with the silver ion, and then acting as a fairly strong electrophile it attacks the nitrate ion according to the scheme

From the examples given in this review it follows that in principle the generation of carbene complexes is to be expected from elements of virtually all Groups of the Period Table in their reactions with the most important examples of organic substrates. It is probable that structural factors which enhance the strength of the metal–ligand bond must assist the formation of intermediate carbene complexes. Identification of these factors constitutes a problem of theoretical chemistry and undoubtedly plays an important part in determining the mechanism of many catalytic processes and predicting the activity of catalyst complexes. It would not be an exaggeration to say that carbenes and coordinated compounds that contain them as ligands should be regarded as just as important and as widely occurring intermediates as carbocations and *C*-centred free radicals were traditionally considered to be. The genetic bond which exists between these intermediate species and their complexes is responsible for the interconversions of these intermediates.

Transition metal complexes of unsaturated carbenes: synthesis, structure, and reactivity

A B Antonova, A A Ioganson
Institute of Chemistry and Chemical Engineering, Siberian Division of the USSR Academy of Sciences, Krasnoyarsk

ABSTRACT. The methods of synthesis, structure, physicochemical properties, and reactivity of transition metal complexes containing unsaturated carbene ligands (vinylidenes, allenylidenes, and heterocumulenylidenes) are examined. Attention is concentrated on heterometallic compounds. The prospects for the development of the chemistry of unsaturated carbene complexes and their use in organic and organometallic synthesis are discussed.

The bibliography includes 280 references.

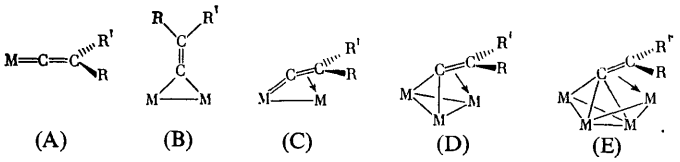
I. Introduction

The chemistry of unsaturated carbene complexes (UCC) is a new field which has arisen at the junction between organometallic, coordination, and organic chemistry and has been developing vigorously during the last decade. Unsaturated carbenes include unsaturated species with an unshared electron pair at an *sp*-hybridised carbon atom C_α and a $C_\alpha=C_\beta$ double bond: vinylidene (ethenylidene) $:C=CH_2$ and its homologues $:C=CHR$ and $:C=CRR'$, allenylidenes (propadienylidenes) $:C=C=CR_2$, ketenylidene $:C=C=O$, and other heterocumulenylidenes $:C=C=S$, $:C=C=C=O$. The involvement of unsaturated carbenes in organic reactions has been described in Stang's reviews.[1–3]

Unsaturated carbenes, which are unstable in a free state, can be stabilised by coordination to Group V–VIII transition metal atoms in low oxidation states. The first structurally characterised complex $(CO)_8Fe_2(\mu\text{-}C=CPh_2)$ was obtained in 1966 by Pauson and Bagga[4] in 3% yield by the interaction of diphenylketen with iron carbonyl. After the discovery in 1974–1978 of the possibility of the formation of UCC from acetylenes and metal carbonyl complexes[5–7] and also from π-acetylenic[8] and σ-alkynyl[9] complexes, simple general methods of synthesis were developed, which made UCC quite readily available. This stimulated a rapid development of their chemistry.

According to the review of Bruce and Swincer,[10] about 150 stable UCC were known in 1983; in their molecules the vinylidene, allenylidene, and heterocumulenylidene ligands were bound to one or several identical or different metal atoms: Cr, Mo, W, Mn, Re, Fe, Ru, Os, Co, Rh, and Ni. During the last 6 years, the number of such complexes has trebled. The first UCC containing Pt,[11–13] Pd,[14] Ir,[15] and Ta[16] have been synthesised. A new type of bonding of unsaturated carbenes in dinuclear complexes—lateral bridge-type η^1, η^2-coordination—has been discovered.[17–19]

The heterometallic UCC, the first representative of which—$Cp_2(CO)_4MnRe(\mu\text{-}C=CHPh)$—was obtained in 1978,[20] are of special interest. Exotic cluster UCC, such as $CpNiRu_3.(\mu_4\text{-}C=CHR)(\mu\text{-}H)(CO)_9$,[21,22] $CpWOs_3(\mu\text{-}C=CHC_6H_4Me)(\mu\text{-}H).(\mu\text{-}O)(CO)_9$,[23] and $(Ph_3P)_2Au_2Ru_3(\mu_3\text{-}C=CHBu^t)(CO)_9$ [24] have been synthesised by various methods. A general approach to the synthesis of dinuclear and polynuclear complexes, in which mononuclear and dinuclear UCC are used as "building blocks", has been recently discovered on the basis of the application of Hoffmann's isolobal principle[25] (see Section IV, subsection 2). This makes it possible to obtain compounds containing the atoms of two and three different transition metals, including platinum metals, in specified combinations and proportions. Heterometallic UCC can be applied in homogeneous and heterogeneous catalysis. Their employment for the creation of new polymetallic materials (powders, coatings, etc.), necessary for different branches of modern engineering, is promising.



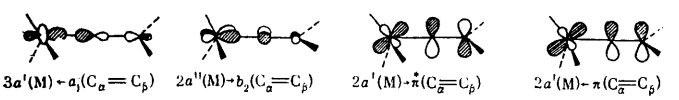
At the present time UCC have been segregated as a special class of organometallic compounds with unusual electronic structures and reactivities. The ease of the formation of UCC from a wide variety of sources and the multiplicity of their reactions suggest that they can be active intermediates in many catalytic reactions involving transition metal atoms. The first examples of the direct use of UCC as catalysts of organic synthetic processes and stoichiometric reactions, leading to valuable organic substances which are difficult to obtain otherwise, have appeared.

In the present review, attention is concentrated on studies performed during the last five years; references to investigations published up to 1982 are given in another exhaustive review.[10]

II. Types of coordination of unsaturated carbenes to metal atoms. The structural and spectroscopic characteristics of the complexes

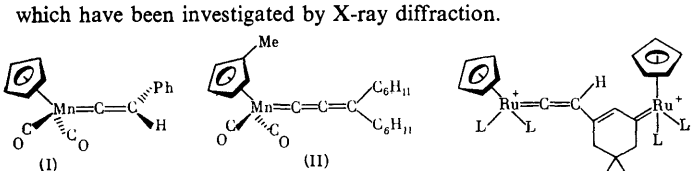
In contrast to the carbenes $:CR_2$ and :CRX (R = H, alkyl, aryl; X = halogen, OR, NR_2, etc.), which form bonds with only one or

two metal atoms,[26–30] five types of coordination are known for vinylidenes:



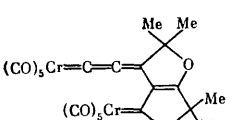
(A) (B) (C) (D) (E)

Coordinations of types (A)–(D) are now known for cumulenylidene complexes.



A detailed analysis of the nature of the bonding of unsaturated carbenes to metal atoms has been carried out only for the simplest of such species—vinylidene :C=CH$_2$. The occupied a_1 and π Mo and the unoccupied b_2 and π^* MO of vinylidene participate in the formation of bonds with the metal.[31–33] The character of the bonding of other unsaturated carbenes, isolobal with vinylidene, to metal atoms is apparently similar.

Vinylidene complexes and allenylidene complexes of type (A) contain a linear metallallene M=C=C or metallacumulene M=C=C=C system. Their M–C$_\alpha$ σ-bond is formed as a result of the overlap of the a_1 HOMO of the ligand with $3a'$ LUMO of the metallic fragment. The π-component of the M–C$_\alpha$ bond is formed as a result of the reverse transfer of electron density from the occupied $2a''$ and $2a'$ orbitals of the metal to the unoccupied b_2 and π^* MO of the ligand. Ultimately, the M–C$_\alpha$ bond should have a character intermediate between that of a double and triple bond.



$3a'(M) \leftarrow a_1(C_\alpha{=}C_\beta)$ $2a''(M) \rightarrow b_2(C_\alpha{=}C_\beta)$ $2a'(M) \rightarrow \pi^*(C_\alpha{=}C_\beta)$ $2a'(M) \leftarrow \pi(C_\alpha{=}C_\beta)$

Indeed, very short M–C$_\alpha$ distances have been found in the molecules of vinylidene complexes[10,15,34–48] and allenylidene complexes,[49–53] which have been investigated by X-ray diffraction.

(I) (II) (III), L = PPh$_3$

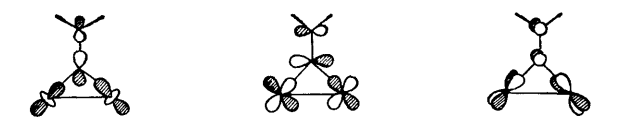
(IV)

The Mn=C$_\alpha$ bond lengths in the vinylidene derivatives of cymantrene [1.68(2) Å in the complex (I),[6,34] 1.79(2) Å in $(C_5H_4Me)(CO)_2Mn{=}C{=}CMe_2$,[54] and 1.75(2) Å in $Cp(CO)_2Mn{=}C{=}CHC_6H_4CBr{=}CH_2$ [45]] and in the allenylidene complex (II) (1.806 Å [51]) are smaller than in the dimethylcarbene compound $Cp(CO)_2Mn{=}CMe_2$ (1.872 Å [55]) and approach the length of the Mn≡C triple bond (1.665 Å) in the carbyne complex $[Cp(CO)_2Mn{\equiv}C{-}CH{=}CPh_2]^+$.[56] The Ru=C distance in $Cp(PMe_3)_2Ru{=}C{=}C{=}CPh_2$ [1.884(5) Å [52]] and the Ru=C (vinylidene) distance (1.83 Å) in the bimetallic complex (III)[48] are shorter than the Ru=C (carbene) distance in compound (III) (1.93 Å). The Cr=C (allenylidene) and Cr=C (carbene) distances in the furofurandiylidene complex (IV) are respectively 1.913(7) and 9.73(6) Å.[50]

According to MO calculations,[31,32] the horizontal conformation of vinylidene and the vertical conformation of allenylidene are more favourable in type (A) complexes. Such conformations have in fact been established by X-ray diffraction for the majority of the complexes, for example, in (I) and (II). However, the barrier to rotation about the M–C$_\alpha$ bond is low (~4 kcal mol^{-1}).[32] In the NMR spectra of type A complexes with a $=CR_2$ (R = H or alkyl) terminal group, magnetic equivalence of the substituents R is therefore frequently observed.[8,57,58] The vertical conformation of phenylvinylidene has been observed in the crystal structure of $Cp[P(OMe)_3](Br)Mo{=}C{=}CHPh$.[36]

Owing to the presence of two unoccupied orbitals available for bonding to the metal, vinylidenes are some of the strongest π acceptors. Analysis of the IR spectra of the complexes $Cp(CO)_2MnL$ established the series based on the diminution of the electron-accepting properties of L:

$$SO_2 > CS > \boxed{C{=}CHPh} > AsF_3 > CO > PF_3 > \eta^3\text{-}PhC{\equiv}CPh > CPh_2 > PPh_3.$$

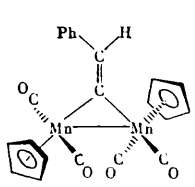


According to this series, the vinylidene ligand C=CHPh is greatly superior to carbenes and π-acetylenes in its electron-accepting capacity.[7]

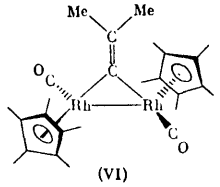
In the vinylidene complexes, the LUMO is mainly concentrated on the C$_\alpha$ atom, while the HOMO is concentrated on the C$_\beta$ atom.[32] Accordingly, in the vinylidene complexes the attack by the nucleophile is directed to the C$_\alpha$ atom and that by electrophiles is directed to the C$_\beta$ atom. In the allenylidene complexes, there are two electrophilic centres (C$_\alpha$ and C$_\gamma$) and one nucleophilic centre (C$_\beta$). By virtue of the presence of the electrophilic centre, the electrochemical reduction of the complex (I) is much easier ($E_{1/2}$ = –1.99 V)[59] than the reduction of the isoelectronic complexes $Cp(CO)_2MnL$ (L = CO: $E_{1/2}$ = –2.70 V; $L = \eta^2$-HC≡CPh: $E_{1/2}$ = –2.38 V).[60]

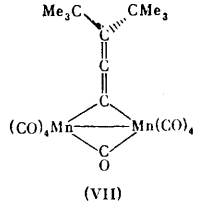
The presence in the ^{13}C NMR spectra of type (A) complexes of a signal at very low field is consistent with reduced electron density at the C$_\alpha$ atom: δ = 320–390 p.p.m. for vinylidene complexes (Fig. 1), δ = 250–380 p.p.m. for allenylidene complexes, and even δ = 440.6 p.p.m. in the spectrum of $(CO)_5Cr{=}C{=}C{=}C{=}O$.[61] The C$_\beta$ chemical shifts are in the range δ = 100–145 p.p.m. for vinylidene complexes and 140–190 p.p.m. for allenylidene complexes.

The C$_\alpha$=C$_\beta$ bond length in type (A) vinylidene complexes (1.30–1.38 Å) differs little from the C=C bond length in alkenes, whereas in allenylidene complexes it is somewhat shorter (~1.25 Å). The ν(C=C) frequencies in the IR spectra of vinylidene ligands are in the range 1590–1690 cm^{-1}, while the ν(C=C=C) frequencies of the allenylidene ligands are in the range 1900–1940 cm^{-1}.[62]



In the type (B) complexes, where the unsaturated carbene bridging ligand is linked symmetrically to two metal atoms, there are two M–C$_\alpha$ σ-bonds, which are formed as a result of the overlap of the a_1 and b_2 MO of the ligand with the MO of the metallic fragments, consisting mainly of the d_{z^2} and d_{xz} AO of the metal atoms.





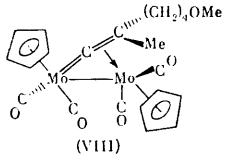
$d_{z^2}(M) \leftarrow a_1(C_\alpha{=}C_\beta)$ $d_{xz}(M) \rightarrow b_2(C_\alpha{=}C_\beta)$ $d_{yz}(M) \leftarrow \pi(C_\alpha{=}C_\beta)$

The optimum overlap is achieved when the b_2 MO of the ligand is arranged parallel to the metal–metal bond axis. This leads to the formation of the planar methylene dimetallacyclopropane system in the μ-vinylidene complexes. The coplanarity of the metallocycle and the =CRR′ fragment has been established in X-ray diffraction studies of a large number of vinylidene complexes of type (B),[10,12,13,23,63–76] for example, in the complexes (V)[6,76] and (VI).[65]

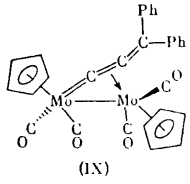
In the μ-allenylidene complexes $[(CO)_5W]_2(\mu\text{-}C=C=CPh_2)$ [77] and (VII),[78] the substituents at the C_γ atom are in a plane perpendicular to that of the metallocycle.

(V)

(VI)

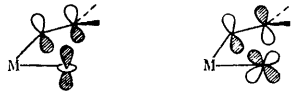


(VII)



In type (B) complexes there is a possibility of the partial conjugation of the M–C_α and $C_\alpha=C_\beta$ bonds as a result of the overlap of the π and π* MO of the ligand with the MO, having a suitable symmetry, of the metal-containing fragments, the degree of which should depend on the donor–acceptor characteristics of the latter. Indeed, the M–C_α bonds in μ-vinylidene complexes are appreciably stronger[79] than in the related compounds with the μ-CR_2 or μ-CRX ligands, for which such conjugation is impossible.[28,80,81]

In type (B) UCC, there is apparently a higher electron density at the C_α atom than at the C_α atom in mononuclear type (A) compounds. This is indicated by the appreciable upfield shift of the C_α signal in the ^{13}C NMR spectra of type (B) complexes (δ = 240–290 p.p.m.) (see Table 1). The results of a polarographic study indicate a decrease in the electrophilicity of the bridging carbon atom in the complex (V) compared with the C_α atom of the terminal vinylidene ligand in the complex (I): the first stage in the reduction of compound (V) (2*e*, $E_{1/2}$ = –1.81 V) corresponds to the homolytic cleavage of the Mn–Mn bond and one of the Mn–C_α bonds is cleaved only in the second stage (1*e*, $E_{1/2}$ = –2.23 V).[59]

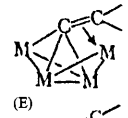


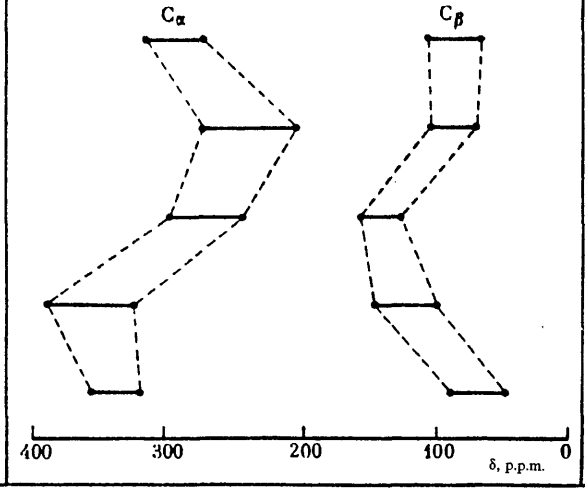
In contrast to the UCC of types (A) and (B), where the ligand supplies two electrons to the metal atoms, in complexes of types (C)–(E), the unshared electron pair of the C_α atom and the π-system of the $C_\alpha=C_\beta$ bond particpate in the bonding to the metal atoms and the unsaturated carbene thus becomes a donor of four electrons.

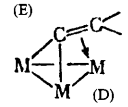
In the recently synthesised type (C) compounds with the lateral η^1, η^2-coordination of the unsaturated carbene,[17–19] for example in the complexes (VIII) and (IX)

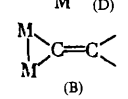
(VIII)

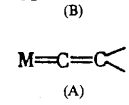
(IX)

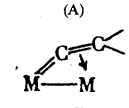






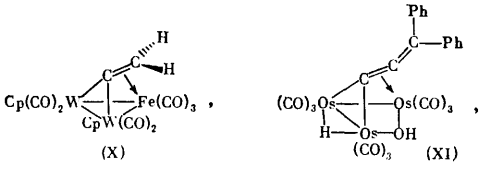






the C_α atom is linked to one of the metal atoms by a double bond similar to the M=C_α bond in mononuclear type (A) UCC. The bond between the unsaturated carbene and the second metal atom is formed as a result of the overlap of the π and π* MO of the $C_\alpha=C_\beta$ bond with the *d* orbitals of the metal.

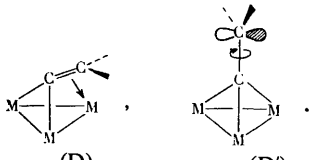
The ^{13}C NMR spectroscopic data for type (C) complexes agree well with this bonding pattern: the C_α chemical shift is at very low field (δ = 320–340 p.p.m.), while the C_β chemical shift has undergone an upfield shift (δ = 45–85 p.p.m.) as a consequence of electron transfer from the second M atom to the π* MO of the $C_\alpha=C_\beta$ bond, compared with compounds of types (A) and (B) (Fig. 1). Thus the difference between the chemical shifts of the C_α and C_β signals in the type (C) complexes reaches ~300 p.p.m.



The η^2-coordination of the $C_\alpha=C_\beta$ bond to the metal lengthens it slightly [to 1.380 Å in the complex (VIII)[18] and to 1.336 Å in the complex (IX) [19]] and bends the metallacumulene chain [the

Table 1. Characteristics of the vinylidene ligands.

Type of complex	^{13}C NMR spectrum	C=C bond length, Å
 (E)		1.41–1.45
 (D)		1.37–1.43
 (B)		1.29–1.38
 (A)		1.29–1.34
 (C)		1.38

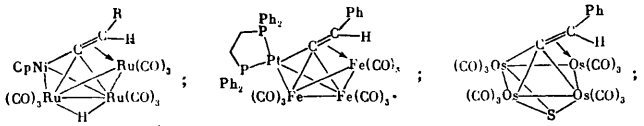


Mo–C_α–C_β valence angle is 168.5° in compound (VIII) and 167.2° in compound (IX), while the C_α–C_β–C_γ angle in compound (IX) is 144.5°].

Type (D) coordination combines elements characteristic of types (B) and (C). In the μ_3-vinylidene and μ_3-allenylidene complexes, examples of which are compounds (X)[82] and (XI),[83] i.e.

(X) (XI)

the unsaturated carbene forms two C_α–M σ-bonds with two metal atoms and a π-bond with the third metal atom:



(D) (D′)

According to X-ray diffraction data,[10,24,82–88] the M–C_β distances in all type (D) compounds are appreciably longer than the M–C_α distances, while the $C_\alpha=C_\beta$ bonds are significantly extended (1.37–1.43 Å). The frequencies ν(C=C) in the IR spectra of complexes of this type are also displaced to the region below 1400 cm^{-1}.[89] According to MO calculations for $[(CO)_9Co_3(\mu_3\text{-}C=CH_2)]^+$,[90,91] the lateral μ_3,η^2-coordination of the vinylidene ligand (D) is more favourable than the centrosymmetrical μ_3-coordination (D′), but the difference between their energies is small. The stereochemical non-rigidity of the μ_3-vinylidene complexes, observed in the NMR spectra, is probably caused by the presence in these compounds of a weak M–C_β bond and the possibility of the transition of the molecules in solutions to the (D′) configuration.

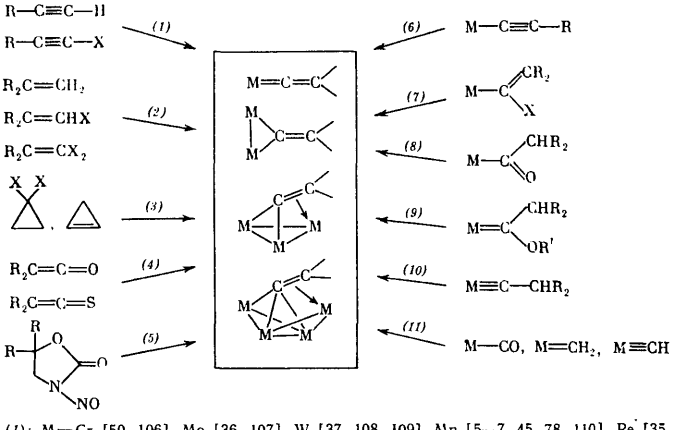
By virtue of the transfer of electron density from the three M atoms to the C_α atom, the latter can apparently acquire nucleophilic properties. This is especially characteristic of μ_3-ketenylidene complexes,[92,96] for example, $[(CO)_9Fe_3(\mu_3\text{-}C=C=O)]^{2-}$.[96] The reduction of the electrophilicity of the C_α atom in type (D) vinylidene complexes is apparently indicated by the appreciable upfield shift of the C_α signal in their ^{13}C NMR spectra (δ = 200–280 p.p.m.) compared with types (A)–(C) (see Table 1).

In the μ_4-vinylidene complexes of type (E),[21,22,97–104] for example, in the complexes (XII),[22] (XIII),[104] and (XIV),[101] the unsaturated carbene is linked by C_α–M σ-bonds to three metal atoms and the $C_\alpha=C_\beta$ fragment is π-coordinated to the fourth metal atom:

(XIIa): R = Bu^t
(XIIb): R = Pr^i (XIII) (XIV)

X-Ray diffraction analysis has shown that the M–C_α bonds in type (E) complexes are stronger than the M–C_β bonds and that the C_α–C_β distance (1.41–1.45 Å) approaches the length of a C_{sp^2}–C_{sp^2} single bond (1.46 Å). The downfield shift of the C_α signal in the ^{13}C NMR spectra (δ = 270–310 p.p.m.) suggests an electrophilic character of this atom in type (E) compounds, whose chemical properties have not yet been investigated.

It is noteworthy that the positions of the C_α and C_β signals in the ^{13}C NMR spectra of the complexes examined are greatly influenced not only by the mode of coordination of the unsaturated carbene[105] but also by the nature of the metal atoms and their surrounding ligands, which is reflected in the wide ranges of the chemical shifts illustrated in Table 1. At the same time, the difference Δδ between the C_α and C_β chemical shifts for the majority of types of UCC is more individual than the positions of the C_α and C_β signals themselves. This makes it possible to establish reliably the type of coordination of the unsaturated carbene ligand on the basis of the ^{13}C NMR spectra for many UCC with a known number of metal atoms.



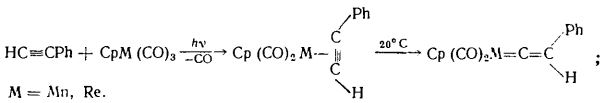
III. The synthesis of unsaturated carbene complexes

The sources and methods of formation of unsaturated carbenes in the coordination spheres of transition metal atoms are much more varied than in organic chemistry.[1] Unsaturated carbene ligands are formed both from organic molecules (alkynes, alkenes, cyclopropanes, cyclopropenes, ketens, *N*-nitrosooxazolidinones) and from the organic ligands forming part of the composition of the complexes (acetylide, vinyl, acyl, carbene, carbyne) (Scheme 1). The formation of vinylidene ligands at metallic centres also from single-carbon fragments (CO, CH_2, CH) is known.

Since it is impossible to give an exhaustive survey of all the methods of synthesis of UCC within the framework of a general publication, in this Section we shall consider only the most general or especially interesting methods of preparation of these compounds.

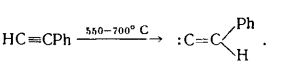
Scheme 1

Sources of unsaturated carbene ligands



(*1*): M=Cr [50, 106], Mo [36, 107], W [37, 108, 109], Mn [5–7, 45, 78, 110], Re [35, 39, 78, 111], Fe [53, 58, 112], Ru [43, 48, 58, 64, 84, 109, 113–116], Os [46, 101–103], Co [84, 109, 113, 117], Rh [15, 38, 118–120], Ir [15], Pt [121].
(*2*): M=Ta [16], Fe [67, 68, 122], Ru [123], Os [123–125], Co [66, 126], Pd [14].
(*3*): M=Mo [87], Fe [127], Os [128].
(*4*): M=Fe [4, 40, 129].
(*5*): M=Co, Rh [65, 69].
(*6*): M=W [130, 131], Fe [58, 132], Ru [9, 21, 22, 24, 41, 42, 44, 47, 83, 100, 116, 133], Os [85, 134–136], Pt [13].
(*7*): M=Mo, W [137], Fe, Co [138], Os [139–142], Rh [142].
(*8*): M=Fe [143].
(*9*): M=Cr, W [49], W, Pt [12].
(*10*): M=Mo [144, 145], W [12, 72, 82], Fe [82, 86, 146–152], Ru [64, 153, 154], Os [72, 155], Ir [156], Pt [12].
(*11*): M=Mn [143], Fe [147–149, 157–164], Ru [153, 164–167], Co [74].

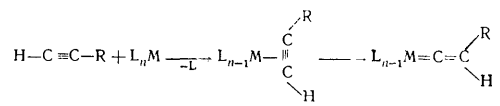
Note. Here the numerals in square brackets denote references (Ed. of Translation).



1. Generation of unsaturated carbene ligands from organic molecules

(a) The acetylene–vinylidene rearrangement

The most general method of synthesis of complexes with monosubstituted vinylidenes involves the acetylene–vinylidene rearrangement (AVR) at metallic centres. AVR was first observed for Mn and Re complexes:[5–7,35]

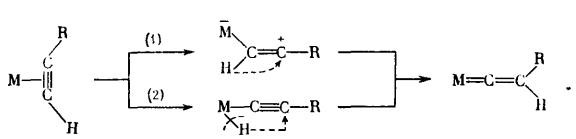


The isomerisation of free acetylenes to vinylidenes is known[1] to occur under severe conditions:

According to calculations,[33] the energy of acetylene is lower by 44 kcal mol^{-1} than that of vinylidene and the activation energy for the AVR is 76 kcal mol^{-1}. On coordination to the metal, the thermodynamic stabilities of acetylene and vinylidene are reversed: $Cp(CO)_2Mn=C=CH_2$ has an energy lower by 32 kcal mol^{-1} than the π-acetylene isomer. This is responsible for the easier occurrence of the AVR at a metallic centre at 5–65 °C.

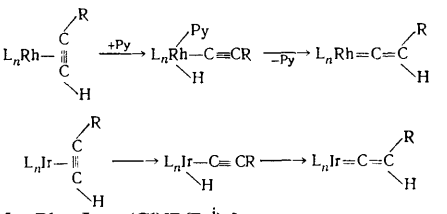
The principle features of the AVR, its mechanism, and its driving force can be elucidated only now as a result of the accumulation of information about the conditions governing the occurrence of the reaction for a large number of metals (see Scheme 1 and the bibliography quoted in it as well as the review of Bruce and Swincer[10]) with different ligand environments.

In all cases, the synthesis of unsaturated carbenes from acetylenes proceeds via the intermediate formation of π-acetylene complexes:



R = H, Alk, Ar, C(OH)R$_2$, COOR etc.

However, they frequently cannot be detected because of the high rate of the AVR, for example, in the formation of $Cl(dppe)_2Re=C=CHPh$ from HC≡CPh and $Cl(dppe)_2Re(N_2)$.[39]



Two alternative mechanisms of the conversion of a π-alkyne complex into a vinylidene complex are most probable:

(1) a two-stage process involving the conversion of the alkyne into a metal-stabilised vinyl cation and the subsequent 1,2-shift of an H atom;[33]

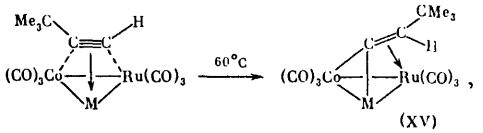
(2) oxidative addition of the alkyne to the metal with formation of a hydride–acetylide intermediate with subsequent dissociation of the M–H bond and protonation (intra- or inter-molecular) of the C_β atom:[7,33]

According to calculations,[33] the mechanism (1) is energetically more favourable but it does not take into account the active role of the metallic centre in the reaction. Although the oxidative addition of alkynes to a metal[168] and the protonation reactions of σ-alkynyl complexes with formation of vinylidene complexes (see below) have been thoroughly investigated, experimental confirmation of the mechanism (2) has been obtained only recently. It has been shown[15] that the reactions involving the conversion of the π-acetylene complexes of rhodium and iridium into the vinylidene complexes proceed via intermediate hydride-acetylide compounds:

R = H, Me, Ph; $L_n = (Cl)[P(Pr^i)_3]_2$.

The ease of the AVR increases with increasing basicity of the metallic centre. The spontaneous isomerisation of π-acetylene complexes to vinylidene is observed more often for sixth-Period transition metals (W, Re, Os, Ir) than for their lighter analogues. The rearrangement is promoted by the presence of donor ligands in the coordination sphere of the metal atom. When the basicity of the metallic centre is insufficient, the presence of bases is required for the occurrence of the AVR.

Thus the isomerisation of the π-complexes of iridium quoted above takes place spontaneously, but the rearrangement of the analogous rhodium complexes requires the presence of pyridine, which participates in the formation of the hydride-acetylide intermediate.[15] The vinylidene complexes $[(C_5Me_5)(PPh_3)(CO)Os=C=CHR]^+$ are obtained in quantitative yields in the reactions of the alkynes HC≡CR (R = Bu^t, Ph) with $(C_5Me_5)(PPh_3)(CO)OsI$ in the presence of $AgBF_4$ (CH_2Cl_2, 22 °C), but a vinylidene complex is not formed under these conditions from $(C_5Me_5)(CO)_2OsI$.[46] The complex $Cp(CO)_2Re(\eta^2\text{-}HC\equiv CPh)$ is converted into $Cp(CO)_2Re=C=CHPh$ in a neutral medium,[35] while the isomerisation of $Cp(CO)_2Mn(\eta^2\text{-}HC\equiv CPh)$ to $Cp(CO)_2Mn=C=CHPh$ takes place either on a column with Al_2O_3 at pH 9–10 [7] or in the presence of catalytic amounts of hexamethylenetetramine.[110] On passing to alkynes HC≡CR with substituents R having more pronounced electron-accepting properties than Ph, the rearrangement of the π-complexes of Mn requires stronger bases: PhLi (for $HC\equiv C\text{–}C_6H_4\text{–}C\equiv CH$-4) and Bu^{t}Li or KOH (for HC≡CCOOMe).[10,45] The role of the bases in these reactions apparently consists in increasing the basicity of the metallic centre, which can be achieved by their interaction either directly with the metal atom or with the CO ligands.



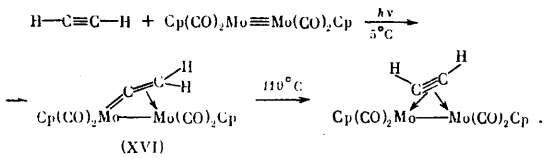
The rearrangement to vinylidene complexes is unknown for π-acetylene complexes of transition metals at the beginning of the Period, in which the metal atom has an unfilled 16-electron shell, for example, $Cp(CO)Nb(\eta^2\text{-}PhC\equiv CEPh_3)_2$ (E = Si, Ge, Sn)[169] or $Br_2(PPh_3)_2M(\eta^2\text{-}HC\equiv CR)$ (M = Mo, W; R = Bu, Ph).[170] On the other hand, the 18-electron complex $(dppe)(CO)_3W(\eta^2\text{-}HC\equiv CPh)$ isomerises spontaneously to the vinylidene complex at 20 °C.[108] The spontaneous conversion of the 18-electron Mn,[7] Re,[111] and Ru[114,115] complexes with the η^2-ligands $PhC\equiv CEPh_3$ (E = Si, Ge, Sn) or $RC\equiv CSiMe_3$ (R = H, Ph) into compounds with the vinylidene groups C=CHR is preceded by the elimination of the EPh_3 or $SiMe_3$ substituents; the solvent serves as the source of the H atom in such cases.

On the basis of the foregoing, one can postulate that the endeavour of the electron-rich metal atom to reduce its electron density is in fact responsible for the rearrangement of the η^2-alkyne to the vinylidene with more marked electron-accepting properties.

Apart from the energy gain, the AVR is also favourable for steric reasons, since the vinylidene incorporated in the metallallene system creates a much smaller steric hindrance in the ligand environment of the metal than the η^2-coordinated alkyne.

The AVR has been less thoroughly investigated for polynuclear systems than for mononuclear systems. The conversion of the halogenoalkynes RC≡CX (R = Bu, Ph, Br, I; X = Cl, Br, I) in reactions with dinuclear cobalt complexes into the vinylidene ligands μ_2-C=CXR as a result of a 1,2-shift of the halogen atom has been reported.[117]

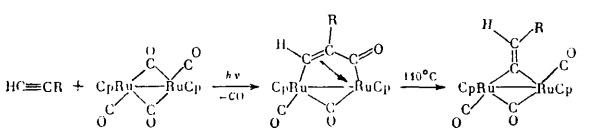
The ready isomerisation of the μ_3-alkyne clusters $RuCO_2$,[84,88,113] MoRuCo,[171] and WRuCo [109] into the μ_3-vinylidene clusters has been observed:



(XV)

where M = $Co(CO)_3$, $Mo(CO)_2Cp$ (XV), or $W(CO)_2Cp$.

The phenylvinylidene clusters (XIV),[101] $Os_6(CO)_{20}(\mu_3$-C=CHPh), and $Os_5(CO)_{15}(\mu_4$-C=CHPh) have been obtained by the interaction of PhC≡CH with $Os_4(CO)_{12}(\mu_3$-S) and $Os_6(CO)_{20}$(MeCN).[102]



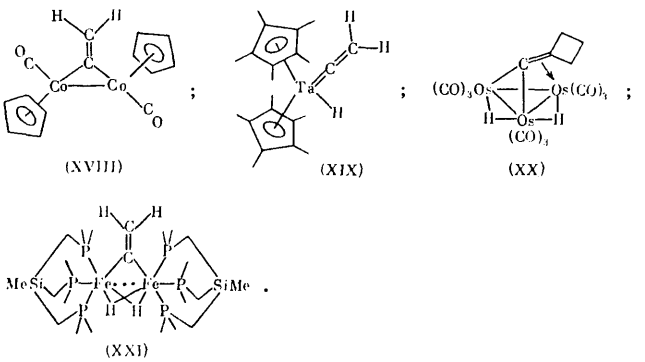
The first type (C) complex with the lateral coordination of vinylidene has been obtained by the photochemical reaction of acetylene with an unsaturated Mo_2 complex:[17]

(XVI)

The reverse isomerisation of the vinylidene to the alkyne is possible for the complexes (XV) and (XVI) with the η^2-coordination of the C=C fragment to the metal: on treatment with the $Cp(CO)_3Mo^-$ anion in boiling tetrahydrofuran (THF)[171] for compound (XV) and on boiling in toluene for compound (XVI).[17]

The reaction

R = H, Ph



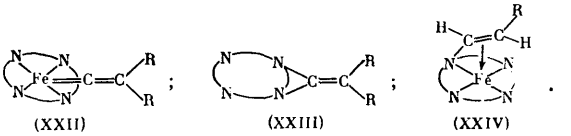
(XVIIa): R=H,
(XVIIb): R=Ph,

as a result of which the alkyne is initially inserted into the Ru–CO bond and the intermediate then isomerises with formation of the complex (XVII),[64,172,173] is a special case of the conversion of an alkyne into a vinylidene.

(b) The synthesis of vinylidene complexes from alkenes

Not only 1,1-dihalogenoalkenes and vinyl halides—the traditional precursors of vinylidene species,[1] but also ethylene and its homologues can serve as sources of the vinylidene ligands.

The complexes $Cp_2(CO)_3Fe_2[\mu$-C=C$(CN)_2]$[10,122] and $Cp_2(CO)_2$.$Co_2[\mu$-C=$CH_2]$ (XVIII),[66,126] have been obtained by the reaction of 1,1-dihalogenoalkenes with carbonylmetallate anions. An example of the dehalogenation of 1,1-dihalogenoalkenes by neutral complexes involving the transfer of Cl atoms to the metal is provided by the formation of $Cl_2(\mu$-dppm$)_2Pd_2(\mu$-C=$CH_2)$ from $H_2C=CCl_2$ and $Pd(PPh_3)_4$ in the presence of dppm:[14]

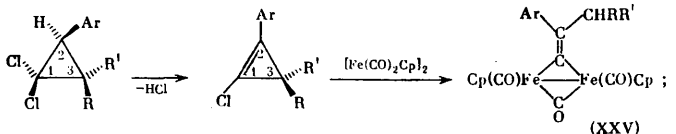


(XVIII) (XIX) (XX) (XXI)

The migration of the vinyl hydrogen atom to the metal during the reaction of $H_2C=CHMgBr$ with $(C_5Me_5)_2TaCl_2$ leads to the complex (XIX).[16]

Processes involving the transfer of two alkene hydrogen atoms to the metallic centre are characteristic of polynuclear systems. A series of complexes $H_2(CO)_9M_3(\mu_3$-C=CRR′) (M = Ru, Os) of type (D) have been obtained by reactions of $H_2C=CRR'$ with $M_3(CO)_{12}$.[10,123] The cluster (XX) has been synthesised recently from methylenecyclobutane and $Os_3(CO)_{12}$ by a similar procedure.[124,125] The unusual complex (XXI) has been obtained by treating (tmps)Fe(μ^4-C_6H_6) [tmps = $MeSi(CH_2PMe_2)_3$; 7 atm, 50 °C] or $[(tmps)_2Fe_2Cl_2]^+$ (1.5 atm, Na/Hg, 20 °C) with $H_2C=CH_2$.[67,68] The formation of the μ-vinylidene and μ-hydride ligands from $H_2C=CH_2$ can be regarded as a model of the first stage in the chemisorption of ethylene on the surfaces of metals.

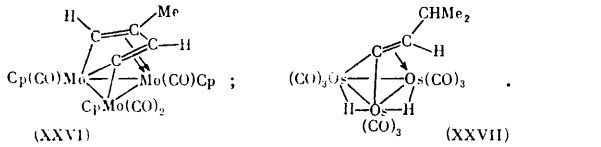
The report by Mansuy[174,175] that the products of the reactions of $Cl_3CCH(C_6H_4Cl$-4$)_2$ (the insecticide DDT) with Fe-porphyrins (*in vitro*) and with cytochrome P-450 (*in vivo*) are vinylidene complexes of the type (TPP)Fe=C=CR_2 (XXII) aroused much interest:[10]



(XXII) (XXIII) (XXIV)

Similar products have been obtained by the reaction of $M_3(CO)_{12}$ (M = Fe, Ru) with *NN′*-vinylideneporphin (XXIII).[176] Later Castro and Wade[177] concluded from the results of an NMR spectroscopic study of the reactions of DDT with Fe-porphyrins that the compounds formed are not the vinylidene complexes (XXII) but the π-alkene complexes (XXIV). However, a recent X-ray diffraction study[178] of the tetraphenylporphyrin derivative of DDT, i.e. the complex (TPP)Fe=C=$C(C_6H_4Cl$-4$)_2$, confirmed that Mansuy's original hypothesis[174,175] was correct.

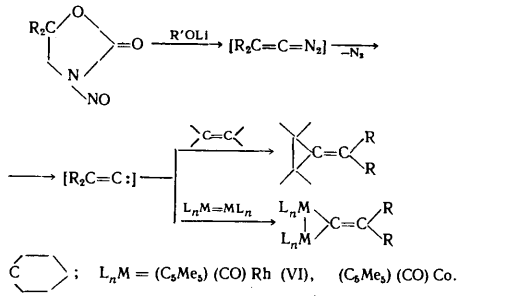
(c) The synthesis of vinylidene complexes from cyclopropanes and cyclopropenes



The vinylidene complexes (XXV) are readily formed in heterophase reactions of 2-aryl-1,1-dichlorocyclopropanes with $[Cp(CO)_2$.$Fe]_2$ (NaOH, $NBu_4^+HSO_4^-$, THF/H_2O, 20 °C).[127] The cycloalkanes are dehydrochlorinated in the first stage in these reactions, with

formation of chlorocyclopropenes, which then react with the bimetallic centre, this being accompanied by the selective cleavage of the C(1)–C(3) bond:

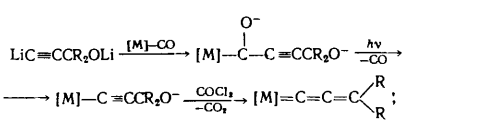
Ar = Ph, C_6H_4Me-4, C_6H_4OMe-4; R = H, Me; R' = H, Me, Ph.



3,3-Dimethylcyclopropene adds at 20 °C with ring opening to the complexes $Cp_2Mo_2(CO)_4$ and $H_2Os_3(CO)_{10}$ containing multiple metal–metal bonds; thermolysis of the adducts leads to the μ_3-vinylidene clusters (XXVI)[87] and (XXVII)[128] respectively:

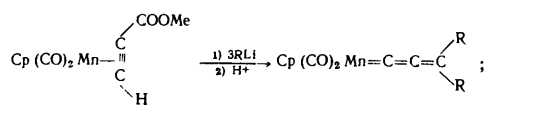
(XXVI) (XXVII)

(d) The synthesis of vinylidene complexes from *NN'*-nitrosooxazolidinones



The successful use of the isolobal analogy between the C=C and M=M double bonds enabled Herrmann et al.[65,69] to develop a novel method of synthesis of vinylidene complexes with the aid of diazo-compounds formed when cyclic *N*-nitrosourethanes are treated with Bu^tOLi:

CR_2 = CMe_2, C; L_nM = $(C_5Me_5)(CO)Rh$ (VI), $(C_5Me_5)(CO)Co$.



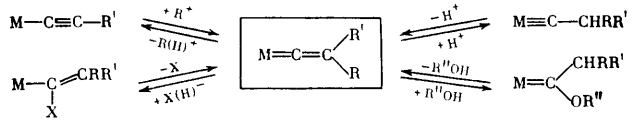
(e) The synthesis of cumulenylidene complexes

t-Propargyl alcohols and their dilithio-derivatives are widely used for the synthesis of the allenylidene complexes of Cr, W, Mn, Re, Fe, and Ru:[10,48,50,53,77,106]

R = Alk, Ar.

The salts and esters of propiolic acid are also used for this purpose:[8,10,57]

R = Bu^t (II), C_6H_{11}, CH_2Ph, Ph.

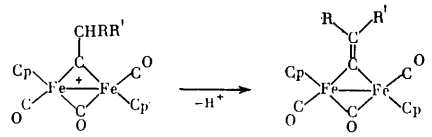


Together with simple dialkyl- or diaryl-allenylidene complexes, more complex products, for example compound (IV), are formed in these reactions.[50]

The oxapropatrienylidene complex $(CO)_5Cr=C=C=C=O$ has been obtained from $[ICr(CO)_5]^-$ and $AgC\equiv CCOONa$ in the presence of $AgBF_4$ and $CSCl_2$.[61]

2. The synthesis of unsaturated carbene complexes from complexes with σ-organic ligands

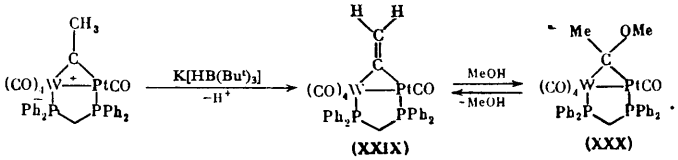
The general approach to the synthesis of vinylidene complexes from complexes with σ-alkynyl, vinyl, carbyne, and carbene ligands (Scheme 2) is based on the conversion of these ligands into vinylidenes on treatment with acid and bases. Scheme 2 also illustrates the possibility of the interconversion of complexes of these types proceeding via vinylidene complexes and determining the chemical behaviour of the latter (see Section IV):



Scheme 2

R = H, Alk; X = H, Hal; R'' = Me, Et.

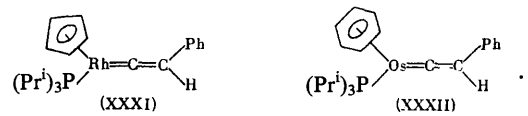
The addition of cations to the nucleophilic C_β atom in complexes with the M–C≡CR group is a general method of synthesis of mononuclear vinylidene complexes of W, Fe, Ru, and Os. The acetylide complexes can be protonated by acids[9,10,116] and alkylated with the aid of R_3O^+ (R = Me, Et),[9,131] $MeSO_3F$,[130,132] or RX (R = Me, Et, Ph, CH_2; X = halogen).[44,58,131] Tropylium[41] and arenediazonium[41,133] cations and halogen atoms[42,47] add to the C_β atom. On treatment of $H(CO)_9Os_3(\mu_3\text{-}C\equiv CCPh_2OH)$ with CF_3COOH, the OH group migrates from the C_γ atom to the Os_3 ring, which results in the formation of the μ_3-allenylidene cluster (XI).[83]



A second general method of synthesis of vinylidene complexes consists in the deprotonation of carbyne complexes, which proceeds under mild conditions on treatment with a wide variety of reagents. A proton is eliminated from $Cp[P(OMe)_3]_2Mo\equiv C\text{–}CH_2Bu^t$ in the reactions with BuLi, CF_3I, and PhN_2^+.[144,145] The methylcarbyne complex $[Cp_2(CO)_2(\mu\text{-}CMe_2)Ru_2(\mu\text{-}CCMe)]^+$ is converted into $Cp_2(CO)_2(\mu\text{-}CMe_2)Ru_2(\mu\text{-}C=CH_2)$ in the presence of water.[153] A series of vinylidene complexes (XXVIII) have been obtained by treating μ-carbyneiron cationic complexes with MeLi, NH_4OH, or $NaHCO_3/H_2O$:[146–149]

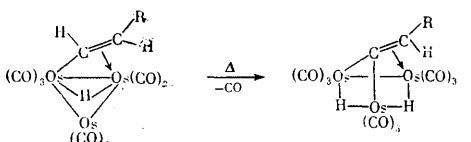
(XXVIII)

R and R' = H, Alk, $-(CH_2)_n-$; n = 4, 5.



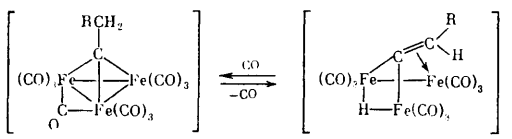
The heterometallic vinylidene complex (XXIX) has been obtained by a similar procedure:[12]

(XXIX) (XXX)



It has also been synthesised from the μ-carbene complex (XXX) as a result of the elimination of MeOH on Al_2O_3 at pH 9–10; the last reaction is reversible.[12]

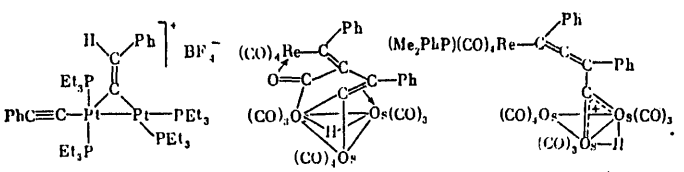
The allenylidene compounds $(CO)_5M=C=C=C(Ph)(NEt_2)$ are formed as a result of the elimination of EtOH on treatment of the carbene complexes $(CO)_5M=C(OEt)CH=C(Ph)(NEt_2)$ (M = Cr, W) with BF_3 or $AlEt_3$.[49] The vinylidenerhodium complex (XXXI) and the vinylideneosmium complex (XXXII) have been obtained by eliminating HCl in reactions of $L_n(Cl)M-CH=CHR$ with NEt_3 and Bu^tLi respectively:[142]



(XXXI) (XXXII)

In the synthesis of type (D) vinylidene complexes from carbonyl clusters with μ-vinyl ligands [compounds (XXXIII)][10,139–141] or μ-carbyne ligands [compounds (XXXV)],[150–152] a hydrogen atom migrates from the ligand to the metallocycle, which precedes the elimination of a CO group from the metal:

(XXXIII) (XXXIV)



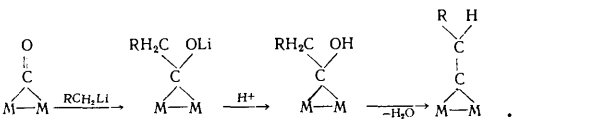
R = H, Alk, Ph, C_5H_4FeCp;

(XXXV) (XXXVI)

R = H, Pr, Ph, C(O)Me, COOMe.

A series of polynuclear vinylidene complexes have been synthesised by adding metal-containing fragments or molecules to σ-alkynyl complexes. Thus the complex (XXXVII) has been synthesised by the interaction of $(PEt_3)_2Pt(C\equiv CPh)_2$ with $[HPt(PEt_3)_2.(Me_2CO)]BF_4$.[13] The combination of alkynyl ligands in $(CO)_5.Re-C\equiv CPh$ and $H(CO)_{10}Os_3(\mu-C\equiv CPh)$ led to the unusual μ_3-vinylidene complex (XXXVIII), which rearranges to the complex (XXXIX) with an allenyl-substituted μ_2-carbyne ligand on treatment with PMe_3Ph:[85,135,136]

(XXXVII) (XXXVIII) (XXXIX)



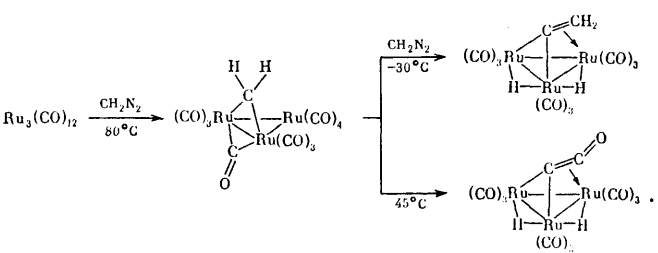
Heating of the complex $H(CO)_9Ru_3(\mu_3-C\equiv CR)$ (R = Pr^i, Bu^t) with $[CpNiCO]_2$ in the presence of H_2 leads to the complexes (XII).[21,22] The pentanuclear vinylidene cluster $(Ph_3P)_2Au_2Ru_3(\mu_3-C=CHBu^t).(CO)_9$ is formed in the reaction of $[(CO)_9Ru_3(\mu_3-C\equiv CBu^t)]^-$ with $[(Ph_3PAu)_3O]BF_4$.[24]

The heteronuclear vinylidene complex (X) has been obtained by the reaction of the two carbyne complexes $Cp(CO)_2W\equiv CMe$ and $CpWFe_2(\mu_3-CC_6H_4Me\text{-}4)(CO)_9$ at 80 °C.[82]

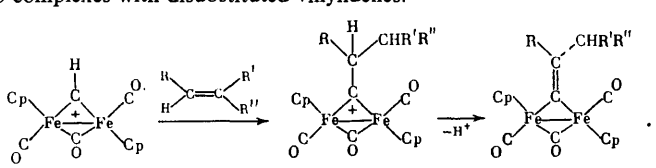
3. The formation of vinylidene ligands from CO, CH_2, and CH

In view of the growing interest in the synthesis of organic products from CO and H_2,[179] the possibility of the formation of unsaturated carbenes as a result of the reduction of CO at metallic centres merits special attention.

The conversion of CO groups into $C=CH_2$ was first noted in the reaction of $Ru_3(CO)_{12}$ with $NaBH_4$.[10,166] Stone and co-workers[157] developed a preparative method of synthesis of $Cp_2(CO)_3Fe_2.(\mu-C=CH_2)$ (XXVIII) (yield 80%) by the successive treatment of $Cp_2(CO)_2Fe_2(\mu-CO)_2$ with MeLi and CF_3COOH at –60–0 °C. The synthesis of compound (XVII) and of its FeRu analogue has been achieved similarly.[153,164,165] It has been shown for $(CO)_8(\mu_4-PPh)_2.Co(\mu-CO)_2$ that complexes with monosubstituted vinylidene can be obtained by this method: using BuLi as the alkylating agent, $(CO)_8(\mu_4-PPh)_2(\mu-CO)Co_4(\mu_2-C=CHPr)$ has been synthesised.[74] It is suggested that the process proceeds via the formation of a μ-methyl-(hydroxy)carbene intermediate, whose dehydration leads to the vinylidene complex:



The conversion of the terminal CO group into $C=CH_2$ takes place in the reaction[143]



$$CpMn(CO)_3 \xrightarrow[2)(CF_3SO_2)_2O]{1)\,MeLi} [Cp(CO)_2Mn{=}C{=}CH_2] \longrightarrow [Cp(CO)_2Mn]_2(\mu\text{-}C{=}CH_2).$$

The formation of the complex $Cp_2(CO)_2Fe_2(\mu-C=CH_2)_2$ on treatment of $Cp_2(CO)_2Fe_2(\mu-CO)_2$ with the Wittig reagent $Ph_3P=CH_2$ has been reported.[158]

Ruthenium and osmium clusters with the μ-methylene ligand, which readily combines with CO or with a second CH_2 fragment with transfer of two H atoms to the metallocycle and the formation of new C–C bonds, may be key compounds in the synthesis of UCC:[167]

The μ-methylidyne complex $[Cp_2(CO)_3Fe_2(\mu-CH)]^+$ readily combines with alkenes, including cycloalkenes, via the C–H bond, being converted into compounds with more complex μ-carbyne ligands, whose deprotonation on treatment with $NaHCO_3/H_2O$ leads to complexes with disubstituted vinylidenes:[147–149,159–163]

Processes involving the growth of the carbon chain with formation of C=C double bonds, similar to the reactions illustrated above, can probably occur in the surface reduction of metal-containing catalysts with CO.

IV. The reactivity of the complexes

The complexes of unsaturated carbenes are usually crystalline brightly coloured substances, many of which are stable in air at 20 °C. Their thermal stability increases with increase in the number of metal atoms in the molecule on passing from type (A) to type (E). Neutral UCC are soluble in aliphatic hydrocarbons, while the ionic complexes are soluble in polar organic solvents. In solutions, the UCC as a rule gradually decompose.

The UCC exhibit a high and varied reactivity due to the presence of several reaction centres in their molecules. Reactions involving the cleavage of the M–C_α, C=C, and C–H bonds are known for the type (A), (B), and (D) complexes. Cyclo-addition reactions via the electron-rich M=C and C=C bonds and reactions involving insertion in a C–H bond are characteristic of the type (A) complexes. By virtue of the clear-cut charge distribution in the metallacumulene chains $M=\overset{+}{C}_\alpha=\overline{C}$ and $M=\overset{+}{C}_\alpha=\overline{C}_\beta=\overset{+}{C}_\gamma$ (see Section II), the reactions of type (A) UCC with electrophiles and nucleophiles are distinguished by a high regioselectivity.

1. The cleavage of the M–C_α and $C_\alpha=C_\beta$ bonds

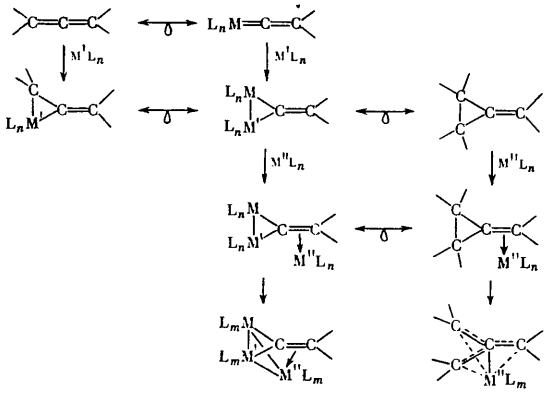
The study of the mass spectra of the carbonyl complexes $[(CO)_4Fe]_2(\mu\text{-}C=CPh_2)$,[4] $[Cp(CO)_2M]_n(C=CHPh)$ (M = Mn, Re; n = 1, 2),[180] and $Cp(CO)_2Mn=C=C=CR_2$ (R = Bu^t, C_6H_{11})[8,57] indicates a greater strength of the M–C_α bonds compared with M=CO. The $[C=CPh_2]^+$ fragments recombine with formation of the butatriene $[C_4Ph_4]^+$ and the radialene $[C_6Ph_6]^+$,[4] while the $[C=C=CR_2]^+$ fragments recombine into the hexapentaene $[C_6R_4]^+$.[8,57]

The high strength of the M–C_α bonds in the UCC prevents the use of the latter as the sources of unsaturated carbenes. The formation of the hexapentaenes $R_2C=C=C=C=C=CR_2$ (R = Bu^t, C_6H_{11}, CH_2Ph) on thermolysis of the complexes $Cp(CO)_2Mn=C=C=CR_2$ is known.[8,57] The complex $(CO)_5Cr=C=C=C=O$ eliminates the C_2 species in hexane at 0 °C and is converted into $Cr(CO)_6$, whose treatment with Me_2SO/MeOH leads to dimethyl malonate.[61]

Ethylene is evolved on hydrolysis and methanolysis of $(C_5Me_5)_2.(H)Ta=C=CH_2$ (XIX).[16] Treatment of $Cp_2(CO)_3Fe_2(\mu\text{-}C=CH_2)$ (XXVIII) with H_2 lead to the evolution of ethane.[146] Cp_2Fe, $Cp_2Fe_2(CO)_4$, and $Cp_3(\mu\text{-}CO)_3Fe_3(\mu_3\text{-}CMe)$ are formed when compound (XXVIII) is refluxed in Bu_2O.[99]

The cleavage of the C=C bond on photolysis of compound (XVII) leads to $Cp_2(CO)_3Ru_2(\mu\text{-}CH_2)$.[165,173] Treatment of $[(\eta^5\text{-}C_9H_7)(PPh_3)_2Ru=C=CHPh]^+$ with O_2 affords $[(\eta^5\text{-}C_9H_7).(PPh_3)_2Ru\text{–}CO]^+$,[43] while after the oxidation of $[Cp(PPh_3)(L)Ru=C=CHPh]^+$ (L = PPh_3, CO) (CH_2Cl_2, 25 °C), PhCHO and PhCOOH were isolated in addition to the carbonyl complexes.[181]

The possibility of the involvement of type (E) vinylidene complexes in metathetical reactions of alkenes has been demonstrated: when the complex (XII) was heated with $D_2C=CD_2$ (toluene, 70 °C), the formation of $D_2C=CHBu^t$ was detected.[182]



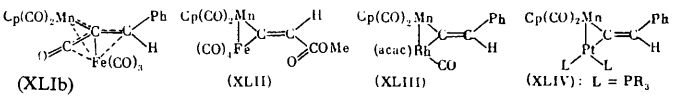
The cleavage of the ketenylidene ligand into C and CO takes place in the reaction of $H_2(CO)_9Os_3(\mu_3\text{-}C=C=O)$ with $(C_2H_4)_2PtL$ [L = $P(C_6H_{11})_3$] in toluene at 20 °C, which leads to the carbonyl-carbide clusters $H_2(CO)_9Os_3Pt(\mu_4\text{-}C)(CO)L$ and $H_2(CO)_9Os_3Pt_2.(\mu_5\text{-}C)(\mu\text{-}CO)L_2$.[183]

2. Addition to the M=C_α, C=C, and C–H bonds

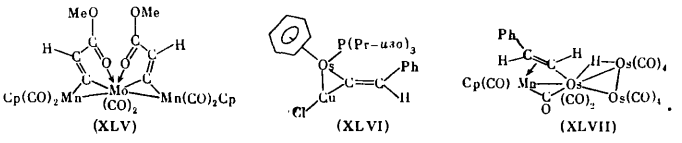
(a) Metallation of the M=C=C system

The metallallene system-containing type (A) complexes $L_nM=C=CR_2$, the character of the bond in which was examined in Section II, are isolobal with the organic allenes $R_2C=C=CR_2$, because the L_nM and R_2C fragments are in isolobal correspondence with one another.[25] The ability of allenes to coordinate transition metal atoms with formation of π-complexes is widely known. The fact that the type (A) complexes are isolobal with allenes is manifested by their ability to combine with coordinatively unsaturated and electron-unsaturated species $[L_nM]$ at the M=C_α bond. The type (A) complexes are then converted into type (B) compounds with bridging unsaturated carbenes (Scheme 3):

Scheme 3



The possibility of the metallation of the M=C=C system was first demonstrated in relation to reactions of a vinylidene derivative of cymantrene (I):[7,20,184]

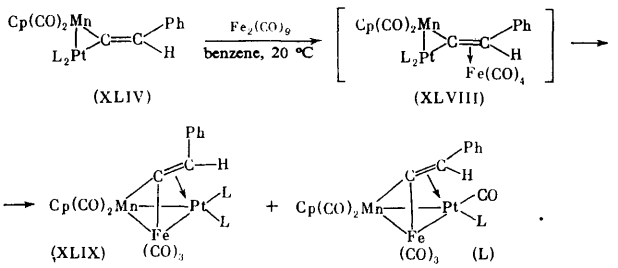


ML_n = Mn $(CO)_2$ Cp (V),
Re $(CO)_2$ Cp (XL),
Fe $(CO)_4$ (XLIa).

By virtue of the tendency of certain neutral type (A) vinylidene and allenylidene complexes to be converted into a more stable type (B) compound, such reactions sometimes proceed spontaneously.[7,53,57,77,118,143]

A series of dinuclear vinylidene complexes with Mn–Mo,[71,185] Mn–W,[71,185] Mn–Mn,[7,186] Mn–Re (XL),[20] Mn–Fe (XLII),[63,187] Mn–Rh (XLIII),[75] and Mn–Pt (XLIV),[11,79,188] bonds as well as the trinuclear bisvinylidene complex (XLV)[71] have been obtained from $Cp(CO)_2Mn=C=CHR$ [R = Ph (I) or COOMe]. The unusual dinuclear complex (XLIb) with an organometallic ligand of the trimethylene-methane type is formed as a result of the isomerisation of compound (XLIa) via the intramolecular carbonylation of the C_α atom:[184]

(XLIb) (XLII) (XLIII) (XLIV): L = PR_3

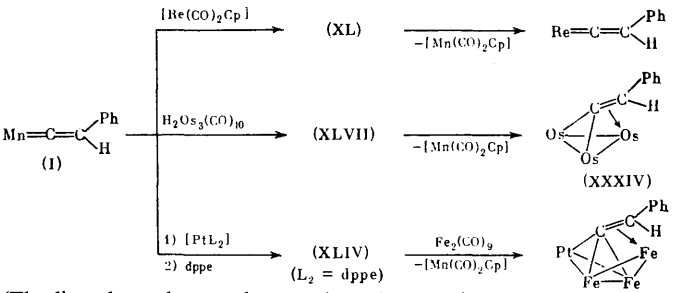


(XLV) (XLVI) (XLVII)

μ-Vinylidene compounds with Rh–Cr, Rh–Mn, Rh–Fe, and Rh–Cu bonds[70,189] have been obtained by the metallation of the Rh=C=C system in compound (XXXI), while the addition of CuCl to compound (XXXII) led to the synthesis of the complex (XLVI) with an Os–Cu bond.[142] The possibility of the addition of unsaturated cluster molecules to type (A) vinylidene complexes has been demonstrated in the formation of compound (XLVII) from the complex (I) and $H_2Os_3(CO)_{10}$.[190,191]

The allenylidene complexes $L_nM=C=C=CR_2$ combine with the $[M'L_n]$ fragment at the $M=C_\alpha$ bond with formation of type (B) μ-allenylidene compounds; compounds with W–W,[77] Mn–Mn,[62,63] Fe–Fe,[53] and Mn–Fe[63] bonds have been obtained in this way.

The type (B) complexes, incorporating the planar $\overline{MM'}(\mu\text{-}C=CR_2)$ system (see Section II), are isolobal with methylenecyclopropanes and, like the latter, can combine with yet another metal-containing fragment (see Section 3). The reaction of compound (XLIV) [L = PPh_3 or $P(OR)_3$] with $Fe_2(CO)_9$ results in the formation of the type (D) complexes (XLIX) and (L), whose molecules contain Mn, Pt, and Fe atoms:[104,192,193]



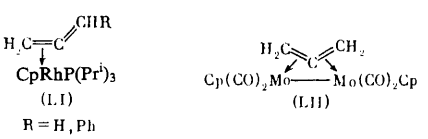
The metallation of type (B) vinylidene complexes with the aid of transition metal carbonyl hydrides involves the hydrogenation of the C_β atom of the vinylidene and the formation of μ_3-carbyne complexes. The cluster $Cp_2(CO)_6MnFe_2(\mu_3\text{-}CMe)$ has been obtained by treating the complex (XXVIII) with $H_2Mn_3(CO)_{12}$.[98,99] The trinuclear clusters $Cp_3(CO)_3MoCo_2(\mu_3\text{-}CMe)$ and $Cp_2(CO)_5MnCo_2(\mu_3\text{-}CMe)$ are formed in the reactions of $HMo(CO)_3Cp$ and $HMn(CO)_5$ respectively with $Cp_2(CO)_2Co_2(\mu\text{-}C=CH_2)$ (XVIII).[66,126]

An example of the metallation of type (D) μ_3-vinylidene clusters is the synthesis of $H(CO)_{11}Fe_3Rh(\mu_4\text{-}C=CHR)$ (R = H, Ph) from $[H(CO)_9Fe_3(\mu_3\text{-}C=CHR)]^-$ and $[ClRhCO]_2$ in the presence of $TlBF_4$.[194]

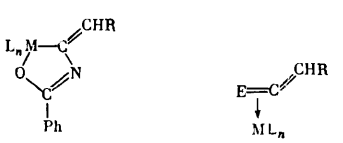
In a number of instances, the stabilisation of heterometallic intermediates similar to compound (XLVIII) is achieved as a result of the elimination of one of the metallic fragments and its substitution by new groups $[M'L_n]$. The reaction of a vinylidene complex of type (XLIV), where L_2 = dppe, with $Fe_2(CO)_9$ results in the formation of $(dppe)PtFe_3(\mu_4\text{-}C=CHPh)(CO)_9$ (XIII).[104] The tetranuclear complex $Cp(CO)_9FeCo_3(\mu_4\text{-}C=CH_2)$ has been obtained by heating compound (XXVIII) with $Co_2(CO)_8$ or $Co_4(CO)_{12}$.[98,99] The interaction of $(CO)_9Co_2Ru(\mu_3\text{-}C=CHBu^t)$ with $NaMo(CO)_3Cp$ leads to the formation of the complex (XV) as a result of the exchange of one of the $Co(CO)_3$ groups for $Mo(CO)_2Cp$.[109,171]

The possibility of the transfer of an unsaturated carbyne from one metal atom to another is of special interest. In the transfer of the C=CHPh ligand from the Mn to the Re atom,[20] to the Os_3 metallocycle,[190,191] and to the "butterfly" type cluster $PtFe_3$ [104] (Scheme 4), the cleavage of the $Mn=C_\alpha$ bond is preceded by the stage involving the formation of new metal–carbon and metal–metal bonds:

Scheme 4



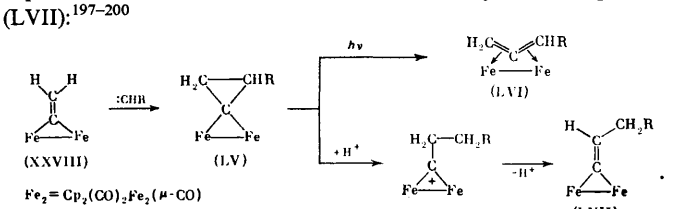
(The ligands at the metal atoms have been omitted.)



The transmetallation reactions can be used to synthesise UCC for which convenient direct methods of synthesis are not available.

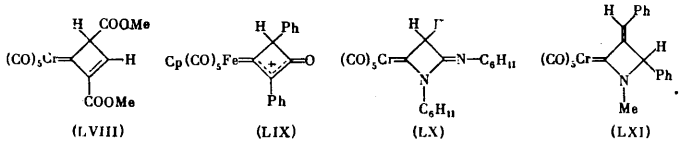
(b) The addition of unsaturated organic compounds

The type (A) compounds (XXXI) and the type (C) compounds (XVI) combine with methylene at the electron-rich $M=C_\alpha$ bond, being converted into the corresponding allene π-complexes (LI) [195] and (LII):[17]



The [2 + 3]cycloaddition of benzoylnitrene to the $M=C_\alpha$ bond, which occurs in the reactions of compounds (XXXI) and (XXXII) with benzoyl azide at –78 °C, affords in 70–80% yield the complexes (LIII) with five-membered heterocycles, whose acidification leads to the corresponding immonium salts.[196] The π-complexes of thio-, seleno-, and telluro-ketens (LIV) have been obtained in the reactions of compound (XXXI) and (XXXII) with chalcogens:[119,120,142]

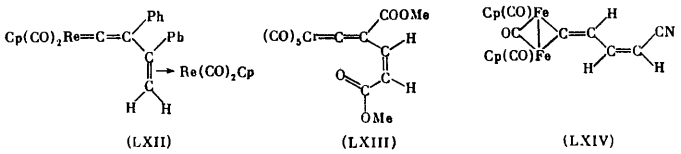
$L_nM = Cp[P(Pr^i)_3]Rh$, $(\eta^6\text{-}C_6H_6)[P(Pr^i)_3]Os$;
R = H, Ph; E = S, Se, Te.



The carbenes :CHR (R = H, COOEt) add to the type (B) complex (XXVIII) at the $C_\alpha=C_\beta$ bond with formation of the cyclopropylidene compounds (LV), which isomerise on UV irradiation to the π-allene complexes (LVI) and the subsequent protonation and deprotonation reactions convert them into the vinylidene complexes (LVII):[197–200]

The structures of compounds (LV) and (LVI) have been confirmed by X-ray diffraction.[197,199]

The photochemical reaction of $Cp_2(CO)_3Ru_2(\mu\text{-}C{=}CH_2)$ (XVIIa) with ethylene leads to the μ-carbene complex $Cp_2(CO)_3Ru_2[\mu\text{-}C(Me).CH{=}CH_2]$.[165,173]

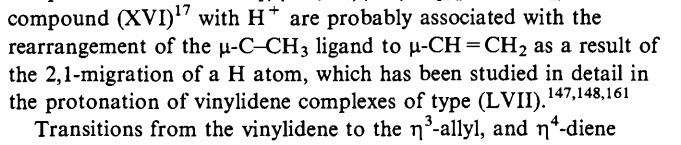


A wide variety of complexes with cyclic carbenes have been obtained by the [2 + 2]cycloaddition to the vinylidene ligand of alkynes, σ-acetylide complexes, carbodiimides, and imines—for example, compounds (LVIII),[106] (LIX),[201] (LX),[202] (LXI),[203] and others:[10]

(LVIII) (LIX) (LX) (LXI)

The complex (III) is formed as a result of the [3 + 3]cycloaddition of $Cp(PPh_3)_2Ru^+{=}C{=}CHC(Me){=}CH_2$ to $Cp(PPh_3)_2.Ru^+{=}C{=}C{=}CMe_2$.[48]

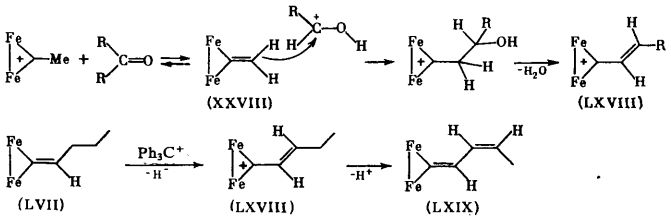
The insertion of alkynes in the C–H bond of the C=CHR ligands led to the butadienylidene complexes (LXII),[35] (LXIII),[106] and (LXIV):[204]



(LXII) (LXIII) (LXIV)

3. The reactions of unsaturated carbene complexes with electrophiles and nucleophiles

(a) The addition of electrophiles to the C_β atom in type (A) and (B) complexes



In conformity with the nucleophilic character of the C_β atom in type (A) and (B) UCC (see Section II), the protonation of these compounds leads to mononuclear[36,37,56,108,130,205] and dinuclear[10,12,56,64,66,126,146,147,149,160–163,204] carbyne complexes respectively (see Scheme 2). The instances of the formation of σ,π-vinyl complexes on treatment of $[(\eta^5\text{-}C_9H_7)(CO)Rh]_2(\mu\text{-}C{=}CH_2)$[118] and compound (XVI)[17] with H^+ are probably associated with the rearrangement of the μ-C–CH_3 ligand to μ-CH=CH_2 as a result of the 2,1-migration of a H atom, which has been studied in detail in the protonation of vinylidene complexes of type (LVII).[147,148,161]

Transitions from the vinylidene to the η^3-allyl, and η^4-diene complexes of molybdenum have been achieved by adding carbonium ions to the C_β atom and by subsequent reactions of the carbyne ligands.[144] The complexes (LXV) (M = Fe, R = H;[206] M = Ru, R = Me[73,207]), (LXVI),[73] and (LXVII)[207] with highly unsaturated bridges have been obtained by the electrophilic addition of $[Cp_2(CO)_3M_2(\mu\text{-}CR)]^+$ (M = Fe, Ru; R = H, Me) to the complexes (XXVIII) with R = R′ = H and (XVIIa) with subsequent shifts of the H atom along the chain or the loss of H_2:

(LXV) (LXVI) (LXVII)

The condensation of the μ-methylcarbyne with the aldehydes RCHO (R = Bu^t, C_6H_4Me-4, CH=CHPh), leading to the vinylcarbynes (LXVIII), proceeds via the intermediate formation of compound (XXVIII) and the electrophilic attack by the protonated aldehydes on its C_β atom:[208]

(XXVIII) (LXVIII)

(LVII) (LXVIII) (LXIX)

On the other hand, treatment of a vinylidene complex of type (LVII) with Ph_3C^+ induces the dehydrogenation of the vinylidene side chain, which makes it possible to achieve a conversion to the vinylvinylidenes (LXIX) via the vinylcarbynes (LXVIII).[15]

(b) Deprotonation of the vinylidene ligand

A general reaction of type (A) complexes with the C=CHR ligands is deprotonation on treatment with various bases, which leads to σ-acetylide compounds[10,43,46,58,107,116,143] (see Scheme 2).

In a number of instances, the deprotonation is accompanied by the simultaneous elimination of a substitutent from the vinylidene side chain, for example:[58]

The dehydration of the γ-vinylidene alcohols $L_nM{=}C{=}CHC.(OH)R_2$ is a general method of synthesis of the allenylidene complexes $L_nM{=}C{=}C{=}CR_2$ (M = Mn,[109,110] Fe, Ru [48,52]).

The formation of the η^2-keten ligand $CH_2{=}C{=}O$ from $\mu\text{-}C{=}CH_2$ at a diruthenium centre, which occurs on hydrolysis of the product of the deprotonation of the vinylidene complex (XVII) on Al_2O_3, is of interest.[209]

(c) The reactions of vinylidene ligands at polynuclear centres

In contrast to the type (A) and (D) UCC, the metallic centre is actively involved in the reactions of type (D) vinylidene complexes and the mode of their reactions with electrophiles and nucleophiles depends on the charge on the cluster.

The neutral complex (XXXIV) (R = H) reacts with CF_2COOD, combining with D^+ at the Os–Os bond and being converted into $[(\mu\text{-}H)_2(\mu\text{-}D)(CO)_9Os_3(\mu_3\text{-}C{=}CH_2)]^+$;[210] the analogous reaction of compound (XXXIV) (R = C_5H_4FeCp) proceeds via the intermediate formation at −30 °C of the unstable σ,π-vinyl complex $(\mu\text{-}H)_2(CO)_8(\mu\text{-}CO)(CF_3COO)Os_3(\mu\text{-}CD{=}CHR)$.[140]

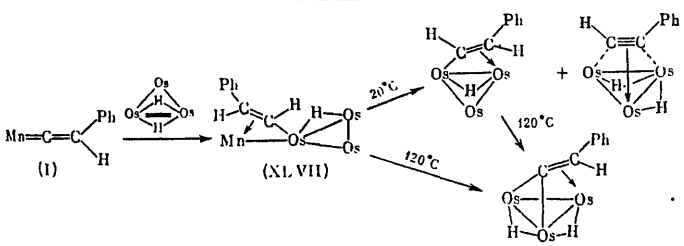
Treatment of the anionic complex (XXXVI) (R = H) with D^+ in the presence of H_2 leads to $(\mu\text{-}H)_3(CO)_9Fe_3(\mu_3\text{-}C\text{–}CH_2D)$, whereupon the H_2 molecule adds to the metallic core with formation of hydride bridges.[211] On the other hand, the cation $[(C_5Me_5)_3(\mu\text{-}CO)_3Ru_3.(\mu_3\text{-}C{=}CH_2)]^+$ is converted into the μ_3-carbyne clusters $(C_5Me_5)_3.(\mu\text{-}CO)_3Ru_3(\mu_3\text{-}C\text{–}CH_2R)$ (R = H, Me) on treatment with $NaBH_4$ or MeLi.[154]

The reactions of the vinylidene complexes (XV) [171] and (XXXIV)[105,212] with H_2 (60–100 °C) entail the selective addition of one H atom to the C_β atom and of the other to the metal–metal bond. It has been shown recently[100] that the hydrogenation of $(CO)_{13}(\mu\text{-}PPh_2)Ru_5(\mu_5\text{-}C{\equiv}CPPh_2)$ (1 atm, 80 °C), leading to the cleavage of the C≡C bond, takes place stepwise with absorption of

three H_2 molecules and the successive formation of clusters with μ_4-vinylidene, μ_4-carbyne, and μ_5-carbide ligands and at each stage of this process one H atom adds to the C_β atom of the ligand, while the other becomes a bridge at the Ru–Ru bond:

$$[M](C{\equiv}CPPh_2) \xrightarrow{H_2} [HM](C{=}CHPPh_2) \xrightarrow{H_2} \longrightarrow [H_2M](C{-}CH_2PPh_2) \xrightarrow[-2CO]{H_2} [H_3M'](\mu_5\text{-}C)(CH_3PPh_2),$$

$[M] = (CO)_{13}(\mu\text{-}PPh_2)Ru_5$, $[M'] = (CO)_{11}(\mu\text{-}PPh_2)Ru_5$.



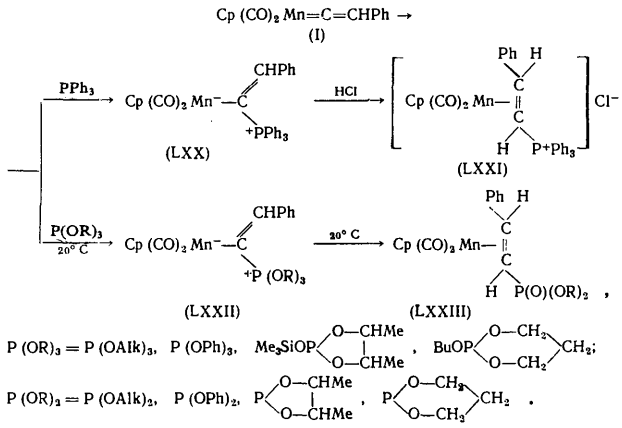
There is no doubt that in the interconversions of the vinylidene, carbyne, and other ligands at polynuclear centres, the metallic core of the cluster functions as a "hydrogen sponge", combining with hydrogen from outside and then transferring it to the ligand and also participating in processes involving H transfer from one part of the molecule to the other.

The migration of an H atom from the metallic core to the C_β atom of vinylidene has been observed in the conversion of the vinylidene complexes (XXXVI) into the carbyne complexes (XXXV) on treatment with CO at 20 °C[150–152] (see above).

The formation of the formylcarbyne cluster $(\mu\text{-}H)_3(CO)_9Os_3.(\mu_3\text{-}C\text{–}CHO)$ in the reaction of $[(\mu\text{-}H)_2(CO)_9Os_3(\mu_3\text{-}C{\equiv}CH)]^+$ with H_2O at 0 °C proceeds via a stage involving the isomerisation of the unstable hydroxyvinylidene complex $(\mu\text{-}H)_2(CO)_9Os_3[\mu_3\text{-}C{=}CH(OH)]$ via the intramolecular transfer of a H atom from the hydroxyl to the Os_3 ring.[134]

An example illustrating the migration of a H atom from the Os_3 ring to the organic ligand and in the reverse direction is provided by the reactions of phenylvinylidene in the presence of the $MnOs_3$ system illustrated in the scheme below:[190,191]

Scheme 5



(I) (XLVII)

(d) The addition of nucleophiles to the C_α atom

Reactions involving the addition of nucleophiles are most characteristic of the type (A) UCC $L_nM{=}C{=}CRR'$, which have a very markedly electrophilic C_α centre (see section II). The hydrogenation of vinylidene complexes leads to σ-vinyl complexes (see Scheme 2).[10] When vinylidene complexes are acted upon by alcohols, thiols, ammonia, and primary and secondary amines, the nucleophilic species (OR^-, SR^-, NH_2^-, NHR^-, NR_2^-) adds selectively to the C_α atom, while a hydrogen atom adds to a C_β atom and Fischer carbene complexes are formed.[10,12,116,143,213] A direct method of synthesis of alkoxycarbene complexes from $W(CO)_6$, alkynes, and alcohols via vinylidene intermediates has been proposed recently:[214]

$$W(CO)_6 \xrightarrow{RC{\equiv}CH} (CO)_5W(HC{\equiv}CR) \longrightarrow \longrightarrow (CO)_5W{=}C{=}CHR \xrightarrow{R'OH} (CO)_5W{=}C\begin{matrix}CH_2R\\OR'\end{matrix}.$$

Pyridine[143] and tertiary phosphines,[10,45,215–217] none of which contain an active H atom, add to the C_α atom of the vinylidene complexes of Mn, Re, and Fe with formation of zwitter-ionic complexes, for example, (LXX):[215]

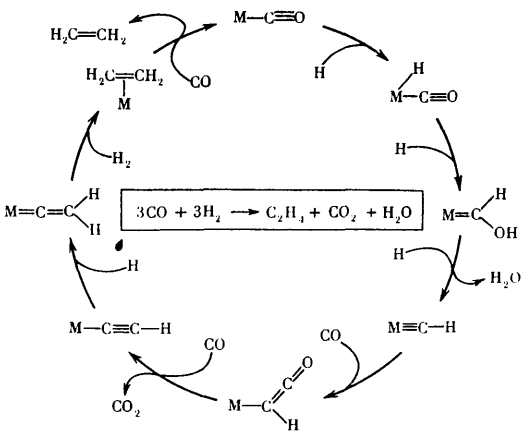
(I) (LXX) (LXXI) (LXXII) (LXXIII)

$P(OR)_3 = P(OAlk)_3$, $P(OPh)_3$, Me_2SiO, BuO; $P(OR)_2 = P(OAlk)_2$, $P(OPh)_2$, P.

The ionic π-alkene complex (LXXI) is formed from compound (LXX) on treatment with HCl.[218] The products of the addition of phosphites to compound (I)—the zwitter-ionic complexes (LXXII)—are spontaneously converted into the neutral vinylphosphonate π-complexes (LXXIII) as a result of the Arbuzov reaction.[219–221]

The allenylidene complexes $L_nM{=}C{=}C{=}CR_2$, having two electrophilic centres, combine with electrophiles (OR^-, SR^-, NR_2^-, PR_3) at either the C_α atom or the Cγ atom depending on their electron-donating capacity.[10,51,106,216]

V. Prospects for the utilisation of unsaturated carbene complexes



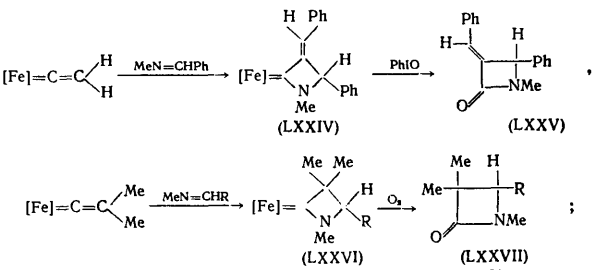
The vigorous development of the chemistry of the UCC during the last decade has led to a better understanding of the rules governing the formation, structure, and chemical behaviour of compounds of this new class. By virtue of the development of convenient preparative methods of synthesis (see Section III), not only individual UCC but also a series of related complexes have become available. Reactions involving the successive metallation of unsaturated carbenes, in which mono-, di-, and tri-nuclear UCC are used as "building blocks" as well as transmetallation reactions have led to the possibility of the specific synthesis of compounds whose molecules incorporate the atoms of several transition metals in definite combinations and proportions, for example, MnFe, MnRh, MnPt, RhCu, OsCu, $MoCo_2$, $MnCo_2$, Co_2Ru, MoCoRu, MnFePt, $MnOs_3$, $FeCo_3$, Fe_3Rh, Fe_3Pt, etc. There is no doubt that such compounds can find applications both directly (in catalysis) and for the preparation on their basis of new polymetallic materials (powders, coatings, films, ceramics, etc.).

The examples of the formation of unsaturated carbene ligands from a wide variety of sources, including single-carbon sources, presented in Section III, permit the conclusion that the UCC or the unsaturated carbene species present on the surface of the catalyst can participate in many catalytic processes. The ketenylidene Fe, Ru, and Os clusters are regarded as model compounds in the study of the reactions of CO on the surfaces of metals. It has been reported[222] that the synthesis of methyl acetate from CO, H_2, and

MeOH in the presence of $[Fe_6(CO)_{16}C]^{2-}$ proceeds via the intermediate $[(CO)_{12}Fe_4(\mu_4\text{-}C{=}C{=}O)]^{2-}$. The observed proportions of linear and branched hydrocarbons in Fischer–Tropsch processes have been explained by the formation of surface vinylidene species and their subsequent reactions.[223]

On the basis of the latest advances in the chemistry of organic compounds of transition metals, a model has been proposed for the mechanism of the catalytic synthesis of alkenes from CO and H_2 at a metallic centre, including vinylidene intermediates (Scheme 6).[224] The known reactions of complexes of Group VI–VIII transition metals, occurring with high degrees of conversion under mild conditions, serve as prototypes of each stage in this cycle.

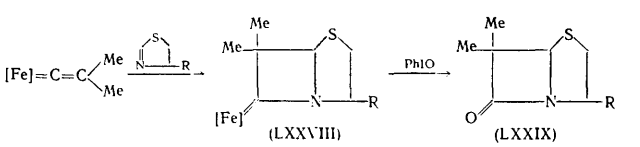
Scheme 6



The selective formation of the butatriene *trans*-$(Bu^t)HC{=}C{=}C{=}CH(Bu^t)$ in the catalytic dimerisation of $HC{\equiv}CBu^t$ in the presence of the complex $H_2Ru(CO)(PPh_3)_3$ (50 cycles per Ru atom) proceeds via the AVR stage and the subsequent combination of two butylvinylidene species in the coordination sphere of Ru.[225]

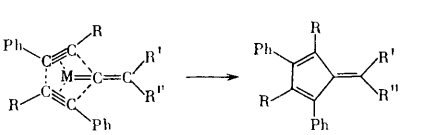
The "small-scale chemistry"—the synthesis of organic substances necessary for modern medicine, agriculture, the special polymer industry, the food and perfume industry, etc.—have nowadays assumed increasing current interest. The new approaches to the synthesis of these substances should satisfy criteria such as high selectivity, productivity, low cost, low energy consumption by the processes, and their ecological safety.[226,227]

The reactions of unsaturated carbenes at metallic centres, examined in Section IV, include processes involving the hydrogenation, dehydrogenation, carbonylation, phosphorylation, and isomerisation of unsaturated organic groups, the growth of the carbon chain, and the formation of C_3–C_6 carbocyclic and heterocyclic compounds. As a rule, these processes proceed at 20–60 °C and atmospheric pressure. The high regioselectivity and stereoselectivity of the majority of the reactions are striking. Many organometallic compounds are formed in nearly quantitative yields. These complexes contain as the ligand an organic molecule capable of existing in a free state (alkene, allene, keten) or an organic group which constitutes a synthon prepared for further processes. The removal of the metal-containing fragment and the isolation of the organic product from these complexes do not usually present special difficulties. All these factors make the synthesis of a wide variety of organic substances with the aid of UCC extremely attractive.



The synthesis of a series of β-lactams (LXXV) and (LXXVII) from imines and the available vinylidene iron complexes via [2 + 2]cycloaddition stages (–78–+25 °C) with formation of the azetidinylidene complexes (LXXIV) and (LXXVI) and their subsequent oxidation can serve as an example:[228]

[Fe] = Cp (CO) (PPh_3) Fe^+; R = Ph, C_6H_4Me-3, C_6H_4Me-4, CH=CHPh.

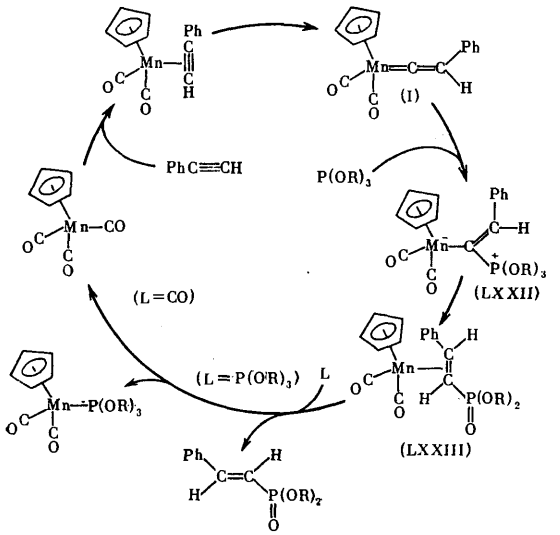


α-Benzylidene-β-lactam (LXXV) has been obtained similarly from the chromium complex (LXI).[203]

The interaction of the complex $\{Cp(CO)[P(OMe)_3].Fe{=}C{=}CMe_2\}^+$ and 2-thiazoline derivatives with subsequent oxidation of the carbene intermediate (LXXVIII) leads to bicyclic β-lactams with the penicillin structure (LXXIX):[229]

[Fe] = Cp (CO) $[P(OMe)_3]$ Fe^+; R = H, COOEt.

The possibility of obtaining unsaturated cyclic compounds involving vinylidene complexes is illustrated by the "assembly" of fulvenes from two alkyne molecules and a vinylidene ligand in the coordination spheres of palladium[230] and molybdenum:[231]



M = Pd, R = R'' = H, R' = Ph; M = Mo, R = Ph, R' = R'' = CN.

A fundamentally new approach to the synthesis of vinylphosphonic acid esters (usually obtained by the esterification of the chlorides of phosphonic acids or by the reactions of alkyl phosphites with alkynes or halogenoalkenes at 150–170 °C) is based on the interaction of phosphites with an unsaturated carbene in the coordination sphere of a transition metal atom.[219–221, 232]

The cyclic Scheme 7 illustrates the successive stoichiometric reactions: the formation of $Cp(CO)_2Mn{=}C{=}CHPh$ (I) from $CpMn(CO)_3$ and $PhC{\equiv}CH$, the conversion of the complex (I) into

the phosphonium complex (LXXII) and the styrylphosphonate complex (LXXIII), and the isolation from the latter of a phosphorus-containing alkene on treatment with $P(OR)_3$ or CO.

Scheme 7

In practice, styrylphosphonates are synthesised in one stage, without the isolation of the intermediate complexes (LXXII) and (LXXIII), in aliphatic or aromatic hydrocarbons:

$$Cp(CO)_2Mn{=}C{=}CHPh + 2P(OR)_3 \xrightarrow[4\text{–}6\ h]{20\text{–}60^\circ C} \longrightarrow \begin{matrix} Ph \\ H \end{matrix}\!\!>\!C{=}C\!<\!\begin{matrix} H \\ P(O)(OR)_2 \end{matrix} + Cp(CO)_2MnP(OR)_3.$$

The reaction is rigorously stereoselective and the styrylphosphonates formed in quantitative yields have exclusively the trans-configuration.[221,232] With the aid of this method, it is possible to obtain not only dialkyl but also the diaryl and cyclic esters of styrylphosphonic acids which are otherwise difficult to obtain.

It is to be expected that the number of examples of the use of UCC in the syntheses of organic compounds will increase. Since many UCC are prochiral or incorporate a chiral metallic centre, they will probably find applications in the asymmetric synthesis of biologically active substances and preparations.

- - - o0o - - -

The enhancement of interest in the chemistry of UCC and the expansion of studies on these lines in many countries have been reflected in a sharp increase in the number of publications during the last 2–3 years†. Information has been published about the improvement of the methods of synthesis and the discovery of new useful properties of these compounds, and new possible applications of such substances are being vigorously sought. All these factors permit an optimistic prediction of the development of the chemistry of UCC and of the realisation of its potential practical possibilities in the immediate future.

†During the preparation of the review for the press, new communications appeared on this topic.[233–280]

Carbene methods for the introduction of acyl and acylmethyl groups into organic molecules

O G Kulinkovich
Belorussian State University, Minsk

ABSTRACT. A systematic account is given of data on the reactions involving the insertion of dihalogeno-, keto-, and alkoxycarbonyl-carbenes in carbon–hydrogen and carbon–heteroatom bonds as well as reactions involving the conversion of alkenes into cyclopropane derivatives followed by ring opening, leading to the introduction of acyl, acylmethyl, and alkoxycarbonylmethyl groups into organic substrates.†

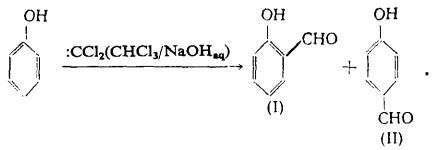
I. Introduction



Many important methods for the synthesis of organic compounds with functional group substituents are based on the creation of a carbon–carbon bond as a result of the introduction of acyl or acylmethyl groups into an organic substrate.[1] Together with the traditional methods for the introduction of these fragments into organic molecules by means of reactions with participation of anions, radicals, and cations, methods based on the use for such purposes of carbene reactions have been acquiring recently increasing synthetic importance. The wide availability of dihalogeno-, keto-, and alkoxycarbonyl-carbenes and their specific reactivity in relation to carbon–hydrogen and carbon–heteroatom bonds as well as carbon–carbon multiple bonds constitute a basis for the effective employment of these highly reactive species as agents transferring acyl and acylmethyl groups. In the present review, an attempt is made to give a systematic account of the literature data on this question, individual aspects of which have also been examined in monographs[2,3] and other reviews.[4–12]

† This article was intended for publication in issue No. 7 (1989) of this journal, which was devoted to the chemistry of carbenes.

II. Insertion in carbon–hydrogen and carbon–heteroatom bonds

1. The Reimer–Tiemann reaction

Despite the potentially great possibilities of the method for the introduction of acyl groups into organic substrates by the insertion of heterosubstituted carbenes in carbon–hydrogen or carbon–heteroatom bonds, they remain little investigated at the present time. However, the Reimer–Tiemann reaction is an exception.[13,14] In its classical version, the yield of salicylaldehyde (I) is 20–25% and that of 4-hydroxybenzaldehyde (II) is 8–10%. Quaternary ammonium salts do not exhibit activity as phase-transfer catalysts in this reaction, whilst in the presence of catalytic amounts of tertiary amines the yield of salicylaldehyde increases to 49–65% while that of compound (II) changes only slightly:[15]

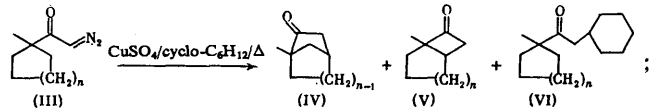
In the presence of β-cyclodextrin, dichlorocarbene attacks exclusively the *para*-position.[16] Then an essential condition for the attainment of high process selectivity is the maintenance of a chloroform : cyclodextrin molar ratio less than unity throughout the reaction. The catalytic action of cyclodextrin can be explained by the formation of its ternary complex with chloroform and phenol in which spatial proximity between the *para*-position of the aromatic ring and dichlorocarbene, formed in a cyclodextrin cage as a result of the reaction of chloroform with the hydroxide ion, is ensured.[17]

The selectivity of the Reimer–Tiemann reaction also increases after the addition of poly(ethylene glycol) to the reaction mixture as a result of the formation, according to Neumann and Sasson,[18] of its complex with the phenoxide anion in which the *ortho*-positions in the benzene ring are sterically blocked.

2. Insertion of keto- and alkoxycarbonyl-carbenes in carbon–hydrogen bonds

The introduction of acylmethyl and alkoxycarbonylmethyl groups into organic substrates via the insertion of keto- and alkoxycarbonyl-carbenes, generated from the corresponding diazocarbonyl compounds, in carbon–hydrogen bonds is an important synthetic method, to the development of which numerous studies have been devoted (see the relevant reviews[7,9,19,20]). The highest yields of the products

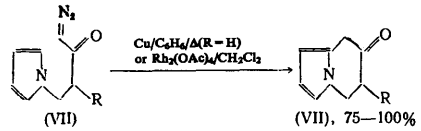
are then produced when rhodium carboxylates are used as catalysts:[21–24]



$$R-H+N_2CHCOOC_2H_5 \xrightarrow{Rh(OCOCF_3)_2/22\,^\circ C} \underset{29-92\%}{R-CH_2COOC_2H_5} + N_2,$$

$R = C_5-C_8$ alkyl, cycloalkyl.

The synthetic value of the method is limited owing to the low regioselectivity of the reaction and also the necessity to use a large excess of the alkane to prevent the oligomerisation of the carbene and the poisoning of the catalyst.[22]



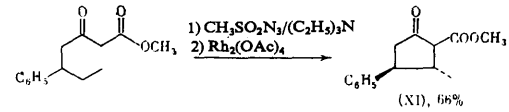
The insertion of keto- and alkoxycarbonyl-carbenes in C–H bonds of alkenes, alkynes, arenes, and heteroarenes usually competes with processes involving cyclo-addition to multiple bonds.[7,9,20,25] Diethyl diazomalonate and α-diazoacetophenone are also capable of affording the products of the insertion of the corresponding carbenes into the allyl C–H bonds of vinyl ethers.[26]

In contrast to intermolecular reactions in which ketocarbenes are inserted in non-activated C–H bonds, intramolecular processes of this kind are frequently characterised by a higher regioselectivity.[25,27–33] Thus the thermal decomposition of diazomethyl ketones (III) in cyclohexane over anhydrous copper sulphate affords mixtures of cyclopentanones (IV), cyclobutanones (V), and the products (VI) of the insertion of the ketocarbene in the solvent:[27]

$n = 3$ (a), 2 (b), 1 (c), 0 (d).

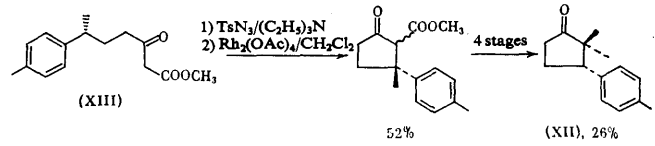
With the exception of the reaction of 1-diazoacetyl-1-methylcyclobutane (IIId), derivatives of cyclopentanone (IV) are the main products [the yields are 50–75% of (IVa), 58% of (IVb), 19% of (IVc), and 1% of (IVd)] for a cyclopentanone : cyclobutaneone = 8–16 : 1 ratio; the products of insertion in the C–H bonds of cyclohexane (VI) are formed in an insignificant amount. The diazoketone (IIId) is converted under these conditions predominantly into compound (VId) (yield 29%). The authors demonstrated the possibility of using this method for the construction of the cyclopentane ring in steroids.[27] On the other hand, the reactions involving the intramolecular insertion of ketocarbenes in non-activated C–H bonds in conformationally less mobile systems proceed with a low regioselectivity and as a rule lead to products in low yields.[27] This method has been used effectively for the synthesis of bicycloanones containing the indole fragment.[34,35,41] Thus the decomposition of 1-diazo-4-(1-pyrrolyl)-2-butanone (VII) in the presence of copper powder leads to a quantitative yield of dihydroindolizinone (VIII):[34]

R = H (a), C_6H_5 (b), 4-$CH_3OC_6H_4$ (c); 4-$NO_2C_6H_4$ (d).



In the case of compounds (VIIb–d), the corresponding indanones are formed in 14–22% yield as a result of the competing insertion of the ketocarbene in the benzene ring.

In view of the important role which β-dicarbonyl compounds play in organic synthesis and the possibility of their ready conversion into α-diazo-derivatives,[35] the results of studies[25,28,30,32,33,36,37] on the intramolecular insertion of α-acetyl-substituted alkoxycarbonylcarbenes in C–H bonds have atttracted attention. In contrast to the corresponding α-diazoketones (see above), in this case the conformationally mobile compounds (IX) exhibit a much more marked tendency towards intramolecular cyclisation with formation of 2-methoxycarbonylcyclopentanones (X):[28]



$R^1 = CH_3$, iso-C_3H_7, C_8H_{17}, $CH=CH_2$, $CH_2CH=C(CH_3)_2$;
R^2, $R^3 = H$, CH_3.
