I. Introduction

Compounds with one carbon atom have found extensive applications in modern industrial chemistry. The catalytic conversion of methane by water vapour is the principal method for the manufacture of hydrogen and the synthesis gas. Hydrocyanic acid and chloromethanes are obtained from methane. Acetylene is produced by the high-temperature pyrolysis of methane. The synthesis gas obtained by the conversion of methane is the raw material for the manufacture of methanol, which can in its turn be converted into olefins, liquid hydrocarbons, formaldehyde, and other products.

Procedures for the utilisation of C_1 compounds in the preparation of certain petrochemical products (monomers, intermediates, and motor fuels) have been developed vigorously in recent years.

Studies in this field are prosecuted on a broad front: new types of reactions of C_1 compounds are being investigated, new catalysts for processes already known are being developed, and new technological processes are being devised.

The present review deals with a series of new aspects of the chemistry of C_1 compounds of current interest (reactions in the presence of metal complex catalysts, including carbon dioxide fixation processes under mild conditions, direct catalytic synthesis of ethylene from methane, and the conversion of methane into liquid hydrocarbons) and of the technology of certain traditional processes (a new approach to the preparation of catalysts for the conversion of carbon dioxide by water vapour in the synthesis of methanol, the conversion of methane in thermochemical solar energy converters, the use of the principle governing the non-stationary technology in the synthesis of methanol and the oxidation of methanol to formaldehyde under adiabatic conditions). All these aspects are being vigorously developed at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences.

II. Direct catalytic syntheses of hydrocarbons from methane

Reactions involving the direct conversion of methane into valuable chemical products occupy an important place in the problem of catalytic syntheses on the basis of one-carbon compounds. The direct synthesis of ethylene—the key compound in fundamental organic synthesis—from methane is of greatest interest. The development of an effective method of preparation of ethylene from methane would permit a change-over of many petrochemical manufacturing processes to a non-petroleum raw material without altering the structure of these processes.

The conversion of methane into liquid hydrocarbons is also an important and currently interesting problem whose solution will make it possible, apart from all its other aspects, to facilitate the transport of hydrocarbon raw materials from gas deposits to sites where it is utilised.

1. Oxidative dehydrodimerisation of methane

The possibility of converting methane into ethylene even at very high temperatures is limited by the thermodynamic equilibrium.[1] High conversions can be attained only when the reaction is carried out with the participation of oxidants.

The necessity for the use of oxidants greatly hinders the selection of catalysts for this reaction, because, while effectively activating methane, they should at the same time activate oxygen only slightly in order to prevent the extensive oxidation of methane and its conversion products. This factor precludes the use in the given reaction of effective catalysts for the activation of hydrocarbons such as, for example, platinum metals.

The above difficulty can be obviated by carrying out the process in two stages: in the first stage, pure methane is dimerised using the oxygen in the catalyst (oxygen-free dimerisation), while in the second the catalyst is reoxidised by an oxygen-containing gas. In this version, a fairly high selectivity is attained but it is technologically complex and requires the use of catalysts with a high oxygen capacity.

Both a two-stage periodic and a one-stage continuous method for the oxidative dehydrodimerisation of methane are being developed at the present time. The periodic version of the process (with reoxidation of the catalyst) is being developed predominantly by

American investigators, while the continuous method is being studied vigorously in the Federal Republic of Germany, Japan, and the Soviet Union as well as the USA.

Fairly numerous publications devoted to the investigation of the mechanism of the catalytic oxidative dehydrodimerisation have been published during the last two years: the determination of the pathways leading to the formation of the reaction products, the nature of the active centres of the catalyst, and the role of homogeneous stages in the overall process.

(a) Catalysts

The first studies on the dehydrodimerisation of methane to ethylene using solid catalysts were published as late as the 1980's.

The Exxon Company took out a patent for the oxidative condensation of methane with the preferential formation of ethylene.[2] Solid oxides with deposited noble metals were used as the reactant-catalysts. The reaction was carried out with pure methane at 700 °C, the conversion of the methane reaching 44.8% with formation of 8% of ethylene, 3.2% of ethane, and 14.4% of benzene (the residue was coke). The catalyst became rapidly saturated with coke and required prolonged regeneration with oxygen-containing gas.

The interaction of methane with a large number of metal oxides deposited on silica gel has been investigated at 800 °C and a pressure of 15 mmHg.[3,4] At low degrees of conversion, the main reaction products were ethane and ethylene. Thorium dioxide proved to be the most effective catalyst.

Systematic studies on the oxidative dehydrodimerisation of methane via a two-stage mechanism on a large number of metal oxides deposited on Al_2O_3 [5] made it possible to divide these oxides into three groups: inactive, weakly active, and active (Fig.1). The highest yield of the oxidative dehydrodimerisation products (5% for an overall selectivity of 45% with respect to C_2 hydrocarbons) was obtained in the presence of manganese oxide. Here and henceforth the yield of the oxidative dehydrodimerisation products is defined as the fraction of carbon atoms in CH_4 which have been converted into C_2 hydrocarbons (C_2H_4 and C_2H_6) on contact with the catalyst and the selectivity is the fraction of carbon atoms which have been converted into C_2 hydrocarbons relative to the total number of carbon atoms of the methane which has reacted.

A still higher yield is attained in two-stage processes patented by investigators at the Atlantic Richfield Company.[6-22] Deposited oxides of manganese, Group IIIA, IVA, and VA elements, and the lanthanides with added alkali and alkaline earth metals and phosphate ions served as the catalysts in the above studies. The carriers were aluminium, silicon, magnesium, and titanium oxides. Best results were obtained on the $NaMnO_4/MgO-SiO_2$ [18] and Mn_3O_4/SiO_2 [14] systems. The yield of C_2 hydrocarbons at 800 °C was 13.4 and 15.2% respectively in the presence of these systems. The catalysts operate in very short cycles (1–2 min), after which their regeneration is required.

Later analogous catalytic systems were tested under single-stage continuous conditions using a reaction mixture containing oxygen together with methane.[23,24] The maximum yield of hydrocarbons on the Mn_2SiO_4 system at 800 °C was 12.2%.[24]

A higher yield of C_2 hydrocarbons was achieved using nitrous oxide as the oxidant.[25] In the presence of a catalyst containing 12.5% $NaMnO_4$ on MgO at 800 °C and for a reaction mixture containing 50% each of CH_4 and N_2O, yields of 11.7% of ethylene and 5.4% of ethane were attained.

The continuous oxidative conversion of ethane in a mixture with oxygen into C_2 hydrocarbons was first achieved on lead, bismuth, tin, antimony and manganese oxides deposited on alumina and other carriers.[26-28] Best results were obtained on deposited lead oxide catalysts. While the selectivity of the conversion of methane into C_2 hydrocarbons was 50–60%, the yield of the latter was 5%.

Much higher yields were obtained subsequently by the same group of investigators on basic catalysts. In the presence of the 6% NaOH/CaO system at 740 °C and CH_4 and O_2 pressures of 0.35 and 0.14 atm respectively, the yield of C_n ($n \geqslant 2$) hydrocarbons reached 17%.[29,30]

A series of catalysts based on magnesium oxide with added transition metal oxides have also been tested under continuous conditions.[31] The experiments were performed at atmospheric

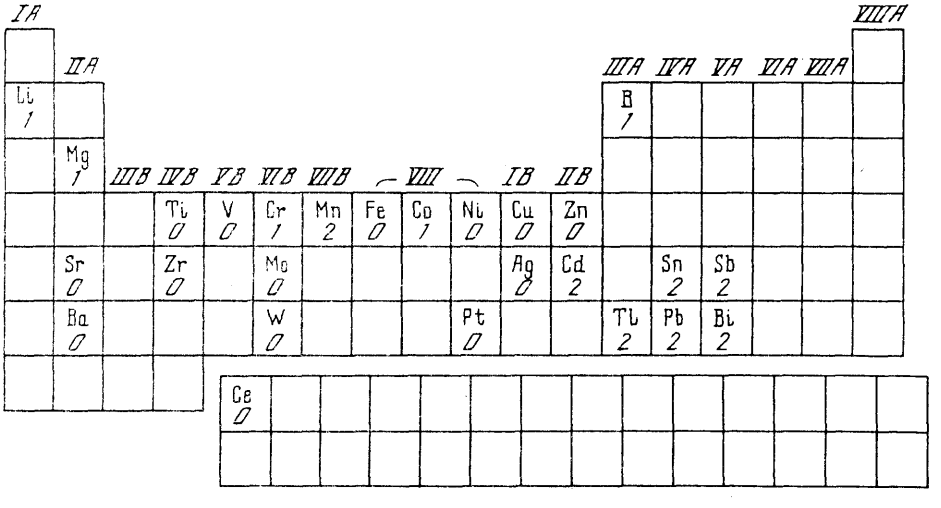

Figure 1. The activity of the oxides of elements in the formation of C_2 hydrocarbons from methane:[5] (*0*) inactive: (*1*) weakly active; (*2*) active.

pressure in a mixture containing 90% CH_4 and 10% O_2. The selectivity of the formation of C_2 hydrocarbons increased with increasing temperature and with decrease in contact time. Best results were obtained on unpromoted magnesium oxide: at 900 °C, the selectivity was 70% for a methane conversion of 9%. Deposited catalysts containing the oxides of Group IIIB elements were also tested under flow conditions.[32] The highest yield of C_2 hydrocarbons (2.3%) was reached in the presence of thallium oxide deposited on an aluminosilicate.

Catalysts not containing variable-valence elements have also been proposed for the oxidative dehydrodimerisation of methane.[33-35] On the 7% Li/MgO catalyst at 720 °C and CH_4 and O_2 pressures of 58 and 26 mmHg respectively, the yield of C_2 hydrocarbons was 19.4% for the ratio $C_2H_4:C_2H_6 = 1:5$. With increase in the pressures of the reactants, the yield falls. An appreciable decrease in the catalyst activity has also been observed during its use for several hours. The low stability of the system has also been noted in another study.[36]

The possibility of the oxidative dimerisation of methane has likewise been demonstrated on lanthanum oxides.[37] Under comparable conditions (725 °C, 40% CH_4, and 1% O_2), approximately the same results were obtained on this catalyst as on the lithium–magnesium system (the yield of C_2 hydrocarbons was approximately 2.5%). The best results were achieved at 725 °C and CH_4 and O_2 pressures in the reaction mixture of 57 and 17 mmHg (the remainder was helium). The yield of C_2 hydrocarbons amounted to 4.7%.

In a study of a series of MgO-based catalysts to which various elements (alkali metals and Group IIIA, IIIB, IVA, and IVB transition elements) had been added,[38] it was established that the yield of C_2-hydrocarbons increases with decrease in the oxidising activity of the catalyst. The latter was estimated from the temperature corresponding to 50% conversion of oxygen. The lowest yield of C_2 hydrocarbons was obtained on catalysts promoted by transition metals and the highest was on the Na/MgO system. At 800 °C and for a methane concentration in the mixture of 2.7%, the yield of C_2 hydrocarbons was 22.4%. An increase in the methane concentration in the mixture produced a sharp fall in the yield of C_2 hydrocarbons.

The influence of the nature of the support on the activity of the lead oxide catalysts in the formation of C_2 products has been investigated.[39] Basic supports proved to be best. The maximum yield of the dimerisation product was reached in the presence of the PbO/MgO system (6.6% of C_2 hydrocarbons at 750 °C and CH_4 and O_2 concentrations of 14 and 1% respectively).

Zeolitic catalysts have also been tested in the reaction involving the oxidative condensation of methane to C_2 hydrocarbons.[40] The Mn/HNa(HSZ)† catalyst, in the presence of which the selectivity in the formation of C_2 reached 50–65% for a methane conversion of 7–19%, was most effective.

Comparative tests under flow conditions on a large number of metal oxides in the oxidative methane dehydrodimerisation reaction have been carried out at 700 °C in the presence of a mixture containing 0.4% O_2 and 18.2% CH_4, the remaining being helium.[41,42] According to the results obtained,[41] which are presented in Fig.2, and in conformity with the results of previous studies, lead and bismuth oxides are some of the most active oxides in the given reaction. Furthermore, a new active catalyst of the oxidative dehydrodimerisation of methane has been discovered, namely samarium oxide. The selectivity of the formation of C_2 hydrocarbons in the presence of this catalyst reached 93%. Unfortunately the authors do not indicate the degree of conversion of methane to which this selectivity corresponds.

Subsequently an attempt was made to improve the catalytic properties of samarium oxide by adding alkali metal compounds.[43] A yield of C_2 hydrocarbons of 21% was attained on samarium oxide modified with lithium at 750 °C and methane and oxygen pressures of 50 and 20 mmHg respectively.

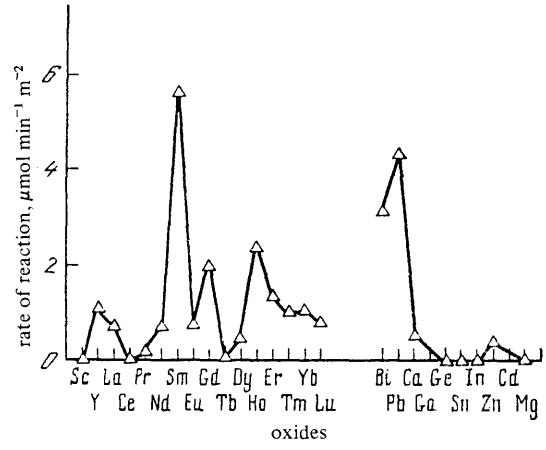

Figure 2. Comparative activities of various metal oxides in the oxidative dimerisation of methane.[42]

On lanthanum aluminate, the yield of C_2 hydrocarbons at 710 °C in a reaction mixture containing 50% of methane and as much air amounted to 12.5%.[44,45] An increase in temperature decreased the yield.

Attempts have been made in a number of studies to improve the properties of the catalysts of the oxidative dehydrodimerisation of methane by promoting them with halides and chalcogenides.[46-51]

Thus it has been suggested that compounds of the chalcogens (S, Se, and Te) be introduced into the catalyst beforehand and that the solid component be periodically made good as the chalcogen is consumed.[46,47] Halogens, especially chlorine, are introduced into the catalyst and a stage involving the treatment of the catalyst with a gaseous promoting agent (methyl chloride) is included in the cycle. Treatment of the catalyst with methyl chloride makes it possible to increase the selectivity with respect to C_n hydrocarbons ($n \geqslant 2$) by 15–20% for the periodic version of the process with reoxidation of the catalyst.

The addition of alkali metal halides to nickel, manganese, samarium, titanium, and zinc oxides[48-51] leads to an overall increase in the yield of C_2 hydrocarbons, mainly as a consequence of the appreciable increase in the yield of ethylene. Thus the yield of C_2 hydrocarbons on nickel(I) oxide promoted with Li_2CO_3 at 750 °C and at methane and oxygen concentrations of 5 and 2.5% respectively reaches 12.7% for a yield of ethylene of 6.9%. When lithium carbonate is replaced by the chloride, the above values are respectively 18.6 and 14.3%.[49] Catalysts promoted with halides are unstable and their activity falls sharply as the halides are decomposed.

†HSZ = high silica zeolite (Translator).

Thus a series of catalytic systems capable of operating under continuous conditions using a reaction mixture incorporating methane and oxygen have now been discovered. The most active catalysts are lead, bismuth, samarium, and manganese oxides. The addition of alkali metals increases the yield of the oxidative dehydrodimerisation products, but diminishes the stability of the catalyst. Promotion with halides also improves the yield of the C_2 hydrocarbons, but these catalysts are rapidly deactivated as a consequence of the loss of the halogen.

The majority of the catalysts ensure a high yield of oxidative dehydrodimerisation products only at a low methane concentration in the reaction mixture and the concentration of ethylene in the converted gas is therefore low even when its yield is high, which hinders its isolation and makes it more expensive.

Table 1 presents the yield of C_2 hydrocarbons in the oxidative methane dimerisation reaction obtained by different workers under continuous conditions.

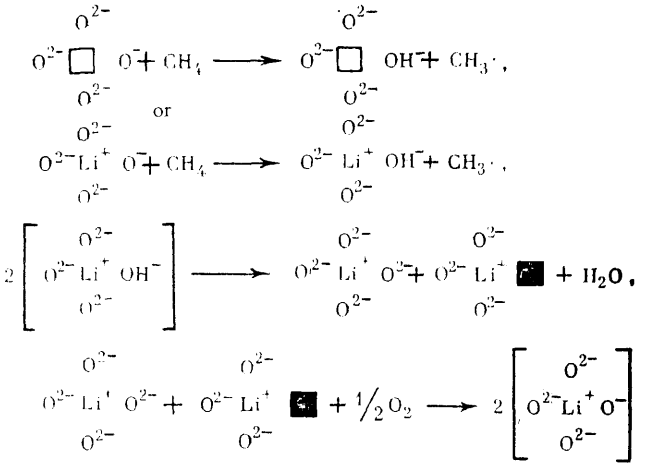
(b) The reaction mechanism

The first mechanism of the formation of ethylene from methane and oxide catalysts when the reaction is carried out in accordance with a two-stage scheme using the oxygen of the catalyst was proposed by Keller and Bhasin.[5] The authors suggest that the reaction proceeds via the formation of adsorbed CH_3 groups, which dimerise in the adsorbed state, and that the ethane obtained under these conditions undergoes subsequent catalytic oxidative dehydrogenation to ethylene:

$$2CH_4 + 2M^{2n+}O_n^{2-} \rightarrow 2OH_{ads} + 2CH_{3\,ads} + 2M^{(2n-2)+}O_{n-1}^{2-}, \quad (1)$$

$$2CH_{3\,ads} \rightarrow CH_3-CH_{3\,ads}, \quad (2)$$

$$2OH_{ads} \rightarrow H_2O + O_{ads}, \quad (3)$$



$$2M^{(2n-2)+}O_{n-1}^{2-} + O_2 \rightarrow 2M^{2n+}O_n^{2-}, \quad (4)$$

$$CH_3-CH_{3\,ads} + M^{2n+}O_n^{2-} \rightarrow CH_2=CH_2 + M^{(2n-2)+}O_{n-1}^{2-} + H_2O. \quad (5)$$

Estimation of the free energy of stage (1) yielded the conclusion that, for the majority of active oxides, this stage is thermodynamically allowed.[5] The involvement of adsorbed methyl groups in the oxidative methane dehydrodimerisation reaction has also been suggested in another study.[52] The source of the extensive oxidation products, which are also formed in this process, may be the methyl groups in the carbonium ion form arising when methane interacts with the acid surface centres.[52]

There exists also another view, according to which methyl radicals pass to the gas phase where the dimerisation products are actually formed.[33-35,53-60] In studies of the interaction of methane with the oxide catalysts of its oxidative dimerisation, methyl radicals were detected in the gas phase.[53] The same result was obtained by the lead mirror method in a study of the interaction of methane with deposited manganese oxide catalysts.[56] In their investigation of the generation of $CH_3^{\cdot}$ radicals on the Li/MgO catalysts, Driscoll et al.[53] concluded that the methyl radicals are formed with participation of the O^- ions on the catalyst surface. Reactions leading to the generation of active centres in the formation of methyl radicals according to these workers[55] are presented in Scheme 1:

Scheme 1

where ■ and □ are the anionic and cationic vacancies respectively.

According to the concept developed by Lunsford and co-workers,[35] the appearance of a radical centre in a binary oxide system is associated with the replacement of the divalent magnesium ion by the univalent lithium ion, which has a suitable radius. The introduction of larger ions (for example, Na^+) should not promote the appearance of such centres, which has in fact been confirmed in experiments where sodium carbonate had been added to MgO.[35] On the other hand, the addition of sodium ions to calcium oxide makes it possible, according to the authors' views, to increase the yield of dehydrodimerisation products.

However, it was shown later that, when magnesium oxide is promoted by sodium ions, it is possible to obtain a more effective catalyst of the dimerisation of methane than the lithium–magnesium system.[38] These results throw doubt on the concept of the methane activation mechanism described above.

It has been suggested[61,62] that the peroxide ions O_2^{2-} can function as the active centres of catalysts based on alkaline earth metal oxides modified by alkali metal ions.

In a study of the mechanism of the dehydrodimerisation of methane on lanthanum oxide,[37] it was not possible to observed O^- ions on the catalyst surface. A methane activation mechanism with participation of O_2^- ions was proposed for this oxide. According to the authors,[37] the extensive oxidation products are formed preferentially via two pathways: with participation of the oxygen of

the catalyst surface:

$$CH_3^{\cdot} + O^{2-} \rightarrow CO,\ CO_2$$

and via methylperoxy-radicals:

$$CH_3^{\cdot} + O_2 \rightarrow CH_3O_2^{\cdot} \rightarrow CO,\ CO_2.$$

Another concept of the activation of methane in its oxidative dimerisation reaction has also been put forward.[63-65] It has been established[63] that the overall rate of conversion of methane and the rate of formation of the dehydrodimerisation products increase with increase in the concentration of the basic centres on the catalyst surface. Furthermore, an increase in the formation of C_2 products is promoted by the presence of electron acceptors in the catalyst.[64] In view of these facts and bearing in mind the overall characteristics of the selective reactions of hydrocarbons involving the C–H bond,[65] by analogy with the scheme proposed previously for the activation of propene with formation of the allyl radical,[66] the following scheme may be proposed for the activation of methane in which the involvement of the basic centres of the catalyst and of electron acceptors is postulated:

$$CH_4 \xrightarrow[-H^+]{Nu^-} CH_3^- \xrightarrow[-e^-]{A} CH_3^{\cdot},$$

where Nu^- is the basic centre of the catalyst and A is an electron acceptor. The methyl radical formed should be relatively weakly bound to the catalyst surface. It may be desorbed to the gas phase and dimerise or it may be converted into the methylperoxy-radical $CH_3O_2^{\cdot}$ after interaction with an oxygen molecule.

The mechanism of the gas-phase reactions in the oxidative dimerisation of methane, which has been analysed in detail,[58-62] includes the following main pathways in the reactions of the methyl radical formed as a result of the heterogeneous activation of methane:

$$CH_3^{\cdot} + CH_3^{\cdot} \rightarrow C_2H_6,$$
$$CH_3^{\cdot} + O_2 \rightleftarrows CH_3O_2^{\cdot},$$
$$CH_3O_2^{\cdot} \rightarrow CO,\ CO_2.$$

Analysis of this scheme taking into account the known rate constants for the individual stages yielded an expression for the limiting selectivity in the formation of C_2 hydrocarbons, which agrees well with experimental data.[66]

Thus fairly selective catalysts of the oxidative dimerisation of methane have now been found and the principal features of the process mechanism have been established. However, a high selectivity is attained as a rule at low reactant concentrations or at low conversions, so that the yield of the target products, in the first place ethylene, is low after a single pass. The stability of the catalyst remains an unsolved problem. The question of the nature of the centres for the activation of methane, without the elucidation of which a purposeful selection and improvement of catalytic systems are impossible, also remains controversial.

Nevertheless, on the basis of the results already obtained, one may hope that an effective industrial process for the synthesis of ethylene from methane will be created in the next few years.

2. Conversion of methane into liquid hydrocarbons on zeolitic catalysts

Zeolitic catalysts are widely used in various hydrocarbon reactions. The appearance of new generation zeolites (pentasils) also made it possible to achieve the syntheses of hydrocarbons from compounds containing one carbon atom in the molecule. In particular, the processes leading to the conversion of methanol into hydrocarbons, the preparation of hydrocarbons from the synthesis gas, and the oxidative synthesis of higher hydrocarbons from methane have been achieved. The first two processes have been studied in detail and the results have been surveyed in a number of reviews.[67-70] The synthesis of higher hydrocarbons from methane on zeolites is a comparatively new and little investigated field.

As a consequence of the chemical inertness and thermodynamic stability of methane, the use of high temperatures is suggested in the known single-stage methods for its conversion into other organic compounds. The reactions of methane at 600 °C in the presence of decationated platinum-containing zeolites of the type of pentasil have been investigated at 600 °C.[71] The only hydrocarbon reaction product was benzene, whose yield reached 6%, while the rest consisted of the products of the extensive oxidation of methane. The absence of higher hydrocarbons is apparently associated with thermodynamic limitations.

The "cracking" of methane on nickel-containing pentasil-type zeolites above 400 °C is of interest.[72] The catalyst specimens subjected to a reducing treatment proved to be inactive. Zeolites of the faujasite type also did not exhibit an appreciable activity in this process. Unfortunately, the authors do not quote the composition of the methane reaction products.

The synthesis of higher hydrocarbons from methane in a single technological stage is thermodynamically possible under milder conditions when oxidants are used. Such a process can be achieved via a stage involving the formation of intermediates of type CH_3X, which are obtained in the oxidation of methane:

$$CH_4 + X{-}R \rightarrow CH_3X + HR$$
$$(X - R = \text{oxidant}),$$

and a stage in which CH_3X is converted into hydrocarbons:

$$nCH_3X \rightarrow nHX + C_nH_m.$$

The catalyst of such a process must be bifunctional, i.e. it must contain a component active in the oxidation stage and a zeolite which propagates the conversion of CH_3X into hydrocarbons.

The reactions of methane on zeolitic catalysts in the presence of oxidants (Cl_2, Br_2, O_2, NO, N_2O, NO_2, and SO_3) have been investigated at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences.[73-75] Catalysts of the chlorination or bromination of methane ($ZnCl_2$ and $CuCl_2$) and catalysts of the oxidation of methane (iron, copper, molybdenum, and cobalt oxides) were added, via impregnation, ion exchange, or mechanical blending to the high-silica zeolite in order to accelerate the oxidation stage. In the presence of molecular oxygen, chlorine, or bromine, the extensive oxidation or halogenation products were formed preferentially. In the presence of nitrous oxide as well as halogens at low concentrations, the formation of higher hydrocarbons was observed. On pentasil-type zeolites without acid transition elements, the selectivity of the formation of aromatic hydrocarbons exceeded 90%

under optimum conditions when N_2O was used as the oxidant and the yield relative to the methane passed through the system reached 40%.

The possibility of carrying out the oxidative synthesis of aromatic hydrocarbons from methane on pentasils using N_2O as the oxidant has also been confirmed in another study.[76]

Thus, in the presence of nitrous oxide, it is possible to attain an appreciable yield of liquid hydrocarbons from methane. Further studies should be directed to the replacement of N_2O by a cheaper and more readily available oxidant.

III. New approaches to the synthesis of catalysts and the carrying out of traditional catalytic processes with participation of C_1 compounds

As already mentioned, large-scale catalytic processes based on C_1 compounds, such as the conversion of methane and carbon monoxide, the conversion of methanol into formaldehyde, etc., have now been achieved in practice in the chemical industry. Despite this, the search for effective catalysts of these processes and of new applications of the reactions underlying them is being vigorously continued together with the development of new technological principles governing their occurrence.

In particular, at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences, methods of synthesis of low-temperature catalysts for these processes via the anionic modification of oxides are being developed, studies are being made of the possibility of using the conversion of methane in the thermochemical solar energy converter, and the technology of the synthesis of methanol under artificially created non-stationary conditions and a new technology of the oxidation of methanol to formaldehyde in reactors with adiabatic beds of an oxide catalyst are being developed.

1. Catalysts of low-temperature processes involving the synthesis of methanol and the conversion of carbon monoxide

The application of refined methods for the purification of the synthesis gas by eliminating sulphur-containing compounds promoted a wide-scale introduction of processes involving the synthesis of methanol and the vapour-phase conversion of CO (the ammonia synthesis stage) at low temperatures. The need to purify the gas is associated with the fact that the low-temperature copper-containing catalysts, which are highly effective in these processes, are deactivated in the presence of even small amounts of sulphur compounds as impurities. Both processes take place mainly on copper–zinc–aluminium, copper–zinc–chromium, or copper–zinc–chromium–aluminium catalysts. The importance of these processes for the chemical industry promoted extensive investigation of the mechanism of the reaction of copper-containing catalysts, their phase composition, and the active state of copper.

(a) The active state of copper

In the very first studies on the catalytic properties of copper-containing catalysts of the synthesis of methanol[77–79] and the conversion of CO,[80,81] it was established that copper oxide is rapidly deactivated at temperatures from 200 °C upwards. The introduction of zinc oxide appreciably improves the properties of the catalyst,[78,79,82] while the addition of a third oxide increases its efficiency still more. Aluminium,[83–85] chromium,[82,86,87] cerium,[88] and manganese[89,90] oxides as well as the oxides of other elements are used as the third component of this kind. Aluminium and chromium oxides are the most effective. Catalysts containing these additives have found industrial applications.

It has been suggested[77–79,82] that the rapid loss of activity by copper oxide is caused by its reduction to the metallic state. The introduction of promoting oxides increases the stability of copper oxide. The above hypothesis lacked experimental confirmation for a long time. On the other hand, the view that the activity of the catalyst in the reactions considered is determined by the metallic copper phase, formed on the surfaces of stable aluminium and chromium oxides or zinc–aluminium and zinc–chromium spinels on activation of the catalyst or under the influence of the reaction medium, gained currency.[91–98] In many cases, the metallic copper phase appears in highly active catalysts after the synthesis of methanol or the conversion of CO. According to numerous data,[92,93,97–100] the activity of the catalysts diminishes with increase in the size of the copper crystals. Catalysts containing 50–70 Å copper crystals are the most active in the conversion of CO.[97] However, numerous attempts[101–104] to find a quantitative relation between the area of the metallic copper, determined by the "chemisorption" method, and the activity of the catalysts in both reactions considered proved unsuccessful. The absence of such a dependence makes the idea that the mechanism of the action of copper-containing catalysts is associated with the formation of the metallic copper phase under the reaction conditions less convincing. In principle, one can postulate that the catalytic reaction between the reactants can occur both on the metallic copper and on surface copper ions in oxide compounds stable under the reaction conditions. The overall activity is in this case determined by the surface area of the active components (phases) and the atomic (ionic) activity of copper in these components. In order to solve the problem of the nature of the active phase, it would be necessary to compare the catalytic properties of metallic copper in a specimen where the possibility of the presence of the ionic form of copper has been ruled out with the catalytic properties of various copper-containing compounds stable under the reaction conditions to such an extent that this completely excludes the formation of metallic copper. However, it proved difficult to characterise the catalytic capacity of purely metallic copper, because the massive specimens have a low surface area and the application of deposited catalysts makes it impossible to guarantee the absence of copper in the ionic form.

Thus it has not yet been possible to characterise quantitatively the catalytic properties of metallic copper in reactions involving the synthesis of methanol in the water vapour conversion of CO. On the other hand, the catalytic properties of compounds in which copper is known to be in the ionic form have been investigated for both reactions.

(b) Catalytic properties of copper-containing oxide compounds

The catalytic properties of copper chromites, ferrites, aluminates, and chromite ferrites, in which part of the copper has been substituted by zinc, magnesium iron(II), and other metal ions, have been investigated in CO conversion reactions.[105–107] Partial substitution

of copper ions ensures the stability of the above compounds in the reaction medium up to high temperatures which prevents the formation of metallic copper under the reaction conditions at 200–270 °C. These compounds have the spinel structure, but contain copper ions in different crystallographic positions, surrounded by oxygen ions in tetrahedral and octahedral configurations. In addition, studies have been made of the properties of solid solutions of copper ions in magnesium oxide which are stable under the reaction conditions.[107] It was found that the specific activities of the spinel are comparable to those of the best industrial catalysts, while the solid solution of copper ions in magnesium oxide is much more active than the latter at 270–300 °C. The activation energy depends on the positions of the copper ions: if they are in tetrahedral positions, the activation energy is 9–10 kcal mol^{-1}, while for the octahedral positions it amounts to 19–20 kcal mol^{-1}. In the presence of the copper–zinc–aluminium–chromium industrial catalyst, the activation energy is 8–13 kcal mol^{-1}.[91]

Depending on the component ratios and the conditions of the synthesis in the copper–zinc–aluminium system, the following copper-containing compounds are formed after heat treatment at 350–400 °C (the temperature at which the industrial catalyst is prepared): copper oxide, solid solutions of zinc and aluminium ions in copper oxide,[108–110] a solid solution of copper ions[109–113] or copper and aluminium[109,110,112,114] in zinc oxide, the copper–zinc–aluminium spinel,[99,109,110,115,116] and a solid solution of copper ions in the spinel.[115] As already mentioned, copper oxide and solid solutions based on it are unstable under the conversion reaction conditions and are rapidly deactivated. The copper–zinc–aluminium spinel and the solid solution of copper and aluminium ions are stable in the reaction medium at least up to 500 °C and their activity is not inferior to that of the most active industrial catalysts.

Among the compounds formed in the copper–zinc–aluminium system, only the solid solution of copper and aluminium ions in zinc oxide is not inferior as regards its activity in the synthesis of methanol and the stability under the conditions of this reaction to the most effective of the known industrial catalysts. The copper–zinc–aluminium spinel is stable under the conditions of the synthesis of methanol, but is much less active than in the conversion reaction.[110,117] These results suggest that the rate of synthesis of methanol depends very greatly on the state of the copper ions and that the state of the copper ions which ensures the necessary activation of the reactants obtains only in the solid solution based on zinc oxide. This explains the marked dependence of the activity of the copper–zinc–aluminium catalyst in the synthesis of methanol on the conditions governing its formation, noted by Bondar' et al.[83] and Shishkov et al.[84] The catalytic properties of the system in the CO conversion reaction also depend on the state of the copper ions, but not so markedly.

The first indication of the high activity of copper ions dissolved in zinc oxide was obtained in a study[112] where it was shown that about 10 at.% of copper is dissolved in zinc oxide in the active copper–zinc catalyst. On the other hand, it is known[118] that the method involving substitution in zinc oxide can lead to the dissolution of not more than 1–2 at.% of copper(II). This is due to the low tendency of copper(II) ions to be involved in tetrahedral coordination with oxygen. It has been suggested that the increased solubility is attained as a result of the dissolution of copper(I) ions. Indeed, an increase in the dissolution of copper in a reducing medium has been observed[112,119] and it has been concluded that the aluminium oxide in the copper–zinc–aluminium catalyst plays the role of a support increasing the surface area of the zinc oxide-based solid solution. However, it has been shown[113,115,117,120] that aluminium fulfils more complex functions in this catalyst.

Copper zinc hydroxoaluminate with a high M(II) : M(III) ratio, having a structure of the hydrotalcite (pyroaurite) type,[115,121,122] and copper-aluminium-zinc hydrocarbonate having a structure of the hydrozincite[84,112,113] or aurichalcite[123] type, are precursors of the active zinc oxide-based solid solution in the preparation of the catalyst by the method involving the precipitation of hydroxo-compounds or the mixing of the components. A study by EPR or electronic spectroscopy of the state of copper in the hydroxo-aluminate with a structure of the hydrotalcite (pyroaurite) type and in the copper-zinc and copper-zinc-aluminium hydroxocarbonates with a structure of the hydrozincite type showed[124] that the copper(II) ions are distributed preferentially at distorted octahedral sites. The concentration of copper(II) ions in the hydroxo-compounds exceeds the maximum possible concentration in zinc oxide.[113] As a result of heating at 350 °C,[125] the above hydroxo-compounds decompose with formation of a solid solution of copper and aluminium ions in zinc oxide and, when the content of copper and aluminium is in excess of a certain level, copper oxide and an aluminium spinel are also formed. The content of copper(II) in zinc oxide is (with retention of the homophase structure) approximately 10 at.% in the copper–zinc system and up to 20 at.% in the copper–zinc–aluminium system. If the copper content in zinc oxide in the copper–zinc–aluminium system reaches 35 at.%, then a certain amount of copper oxide is formed simultaneously.

Heat treatment at higher temperatures is accompanied by the evolution of water vapour and CO_2 and leads to a decrease in the copper content in zinc oxide to 1–2 at.%. According to the data of Hadzhieva et al.,[124] 1–2 at.% of copper(II) substitutes the zinc ions in tetrahedral positions in the zinc oxide, while the remainder is distributed in the form of clusters consisting of several ions. The copper ions in the clusters are apparently in a strongly distorted octahedral environment comprising oxygen ions. In the solid solution of copper and aluminium ions in the low-temperature zinc oxide, virtually all the copper(II) ions exist as associated species. The possibility of such distribution of copper ions is apparently determined by the appearance of defects in the zinc oxide structure as a result of the complete removal of OH^- and CO_3^{2-} groups from the oxide. The impurity anions are removed at a fully defined temperature and the low-temperature zinc oxide is therefore anionically modified.

The formation of anionically modified oxides at low temperatures is characteristic of many metals. For example, anionically modified nickel, magnesium, and copper oxides as well as aluminium and chromium spinels have been obtained.[125]

The degree of oxidation of copper ions on the surfaces of copper-containing compounds, stable under the conditions of the reactions considered, has been investigated by various workers.[111,114,126–132] The results obtained suggest that, under the influence of the reaction medium, the copper ions are reduced to copper(I). According to some data,[133,134] the conversion reaction proceeds via intermediate complexes of the formate type formed from the copper(I) ions. There exist contradictory views concerning the mechanism of the synthesis of methanol. Various mechanisms have been examined in reviews.[135,136]

It follows from the data obtained in the studies examined above that the catalytic activity of the ionic forms of copper is sufficiently high to attribute to these forms the high activity of the industrial copper-containing catalysts of the synthesis of methanol and of the water vapour conversion of CO. Among these forms, a high

activity in both processes is shown by associated copper ions forming part of the composition of the low-temperature anionically modified zinc oxide.

(c) Catalytic properties of the skeletal catalysts

As a result of the leaching of copper-zinc and copper-zinc-aluminium alloys, metal oxide systems are formed[137,138] which can be regarded as metallic copper on the surface of which copper and zinc oxides are present.

According to some data,[139,140] leaching results in the formation of porous copper which is responsible for the activity of the catalyst in the synthesis of methanol. Studies by the XPES and XRES‡ methods[132] have shown that, after leaching, structures resembling those formed on the surface of the copper-zinc–aluminium oxide catalyst predominate on the surface of the skeletal [Raney] copper-zinc-aluminium catalyst, namely associated copper ions incorporating also zinc and oxide ions. Under the reaction conditions, copper ions in the +1 oxidation state catalyse the interaction of the adsorbed CO and H_2O. Consequently the activity of skeletal catalysts in the CO conversion reaction is determined by the copper ions in the oxide compounds.

(d) Resumé

The data examined show that the high activity of all the catalysts investigated, apparently including the skeletal catalyst, can be accounted for by the formation of compounds stable under the reaction conditions and containing copper in the ionic form. In the copper–zinc–aluminium and copper–zinc–chromium catalysts, such compounds in the CO conversion reaction may be the copper-zinc-aluminium and copper-zinc-chromium spinels and a solid solution of copper and aluminium (or chromium) ions in zinc oxide, while in the synthesis of methanol a solid solution of copper and aluminium (or chromium) ions in zinc oxide is a formation of this type. In the case of skeletal catalysts, these compounds are apparently formed as films.

A high concentration of copper in zinc oxide is attained by virtue of the formation at low temperatures (below 500- °C) of zinc oxide with a defective structure—anionically modified by CO_3^{2-} and OH^- groups. This structure ensures the stabilisation of copper ions in the form of associated species in which the copper ions are most probably surrounded by oxygen ions in a square planar configuration. The number of defects (and hence the concentration of copper) and, what is most important, the thermal stability of the anionically modified states in air and under the reaction conditions increase after the incorporation of chromium(III) or aluminium(III) ions in the structure.

One should note that the change in the miscibility of copper and zinc oxides as a result of the anionic modification of the oxide matrix, observed in two investigations,[120,125] has been confirmed in a number of other oxides, including oxides with a complex composition. Presumably this phenomenon may be used to regulate the properties of the oxide catalysts not only in the synthesis of methanol and the water vapour conversion of CO but also in other oxidation-reduction reactions.

2. The synthesis of methanol under artificially created non-stationary conditions

A new highly effective method for the synthesis of methanol, based on catalytic processes under artificially created non-stationary conditions, is examined in the present Section.[141–143] The advantages of such processes are manifested when reversible exothermic reactions are carried out. In this case the optimum regime from the standpoint of the yield of the useful product can be obtained under non-stationary conditions in only one catalyst bed and not in several beds as happens in current large-scale industrial plant. This significantly simplifies the apparatus and makes the process less expensive.

(a) The principle of the method

Suppose that the stationary bed of a copper-containing catalyst was heated beforehand to approximately 260 °C, whereupon synthesis occurs at an appreciable rate. The introduction into the catalyst bed of the reaction mixture with an overall concentration of carbon oxides $c_{CO} + c_{CO_2} \simeq 6$–8 vol. % and a hydrogen concentration $c_{H_2} \simeq 80$ vol. % begins at time $t = 0$. The mixture is at a low temperature (~50 °C), at which the rate of synthesis of methanol is negligible. Under these conditions, the sections of the catalyst bed adjoining the point of entry of the reaction mixture begins to cool down and the reaction mixture is gradually heated to the temperature corresponding to the onset of reaction. The central part of the bed then retains a high temperature for a long time for two reasons: owing to the high ratio C_c/C_r of the heat capacities of the catalyst (C_c) and the reaction mixture (C_r) as a consequence of the evolution of the heat of reaction. According to Kiselev and Matros,[144] the thermal front of the exothermic chemical reaction is formed under these conditions and migrates along the bed at a rate which is lower by a factor approximately equal to C_c/C_r than the rate of penetration of the reaction mixture. At a time approximately equal to $(C_c/2C_r)t_c$, where t_c is the time of contact between the reaction mixture and the catalyst bed, the direction of the supply of the reaction mixture is reversed and the thermal front also begins to migrate in the opposite direction. After several such switch-overs, a cyclic reaction regime is established in the catalyst bed.

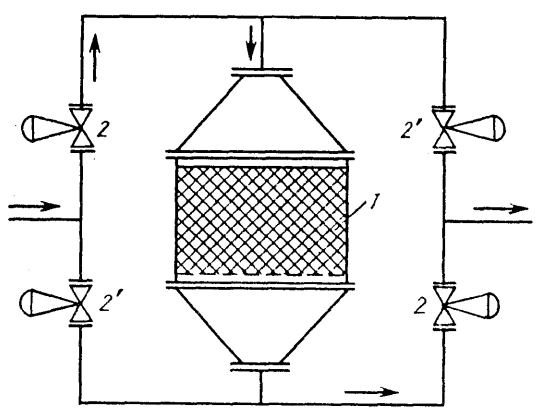


Figure 3. Schematic technological diagram of a reactor with a stationary catalyst bed working in the regime involving the periodic alteration of the direction of supply of the reaction mixture: (*1*) catalyst bed; (*2*) and (*2'*) valves.

The technological scheme for the non-stationary synthesis of methanol described above is fairly simple (it is illustrated in Fig.3). The valves *2* and *2'* shown in the figure open (*2*) and close (*2'*) periodically and simultaneously during the first half-period and

‡X-Ray photoelectron spectroscopy and possibly X-ray fluorescence spectroscopy (Ed. of Translation).

conversely close (*2*) and open (*2'*) during the second half-period, which ensures the establishment of a non-stationary technological regime.

We shall consider briefly the principal disadvantages of the method proposed[145] for the synthesis of methanol under the conditions of the periodic alteration of the direction of supply of the reaction mixture into the stationary catalyst bed.

1. Apart from its principal function of accelerating the chemical reaction, the catalyst plays the role of a regenerative heat exchanger. This makes it possible to make do almost completely without heat exchange equipment, which greatly reduces the requirement for metal in the catalytic unit. For example, the apparatus comprising an expensive and cumbersome external heat exchanger is eliminated in the proposed procedure.

2. Without the introduction of additional energy in the corresponding heat exchange equipment, it is possible to process industrial gases with a low content of carbon oxides, down to $c_{CO} + c_{CO_2} \simeq 0.4$ vol. %. This is of fundamental importance, for example, in the processing of straight-run gases.

3. Conditions which are theoretically nearly optimal from the standpoint of the yield of the useful product are created in the catalyst bed. This makes it possible to employ simple and cheap catalytic apparatus, which is not inferior as regards its characteristics to more expensive and cumbersome industrial apparatus working under traditional stationary conditions. The reason for this is as follows. The synthesis of methanol is a reversible exothermic process and, in the ranges of the temperatures and pressures indicated above, it proceeds close to equilibrium conditions. In the theoretically optimum regime, a decrease in the reaction temperature with increase in the degree of conversion of carbon oxides into methanol is required. When the process takes place in adiabatic catalyst beds under stationary conditions, the opposite picture naturally obtains. Therefore in practice part of the cold gas is conducted through a bypass between the catalyst beds or intermediate heat exchangers are set up in which the reaction mixture is cooled. In the non-stationary regime, there is a section at the exit of the reaction mixture from the catalyst bed where the temperature is reduced and the amount of methanol formed increases. Thus, in a single catalyst bed it is possible to achieve yields of methanol which in the stationary regime are attained when several adiabatic beds are used. Consequently, as a result of a closer approach to the theoretically optimum conditions than in the stationary regime, the design of the reactor and the entire process are greatly simplified.

4. In a catalyst bed working in a non-stationary regime, it is possible to reduce the average temperature by approximately 100 °C. Other conditions being equal (identical initial composition and linear flow rate of the reaction mixture, grain size, and amount of the catalyst), this lowers the hydraulic resistance of the bed by approximately 30%. Furthermore, the overall hydraulic resistance of the system is reduced as a result of the significant simplification of the design of the catalytic apparatus and decrease in the overall length of the tubing.

5. As a result of the simplification of the design of the catalytic unit, which incorporates one catalyst bed, the heat losses to the surrounding medium are reduced severalfold, which is particularly important for the utilisation of straight-run gases for the processing of which it is difficult to create an autothermal regime under traditional stationary conditions.

6. In the existing stationary methods of synthesis, it is necessary to achieve the stabilisation of the initial composition, temperature, and charge of the initial reaction mixture. This requires the creation of a cumbersome and complex automatic control system, especially if account is taken of the time variation of the activity of the catalyst. The non-stationary method permits the processing of the reaction gases with both constant and variable parameters and does not require the development of a special automatic control system.

(b) Mathematical modelling

As already mentioned above, there is no unanimous view concerning the mechanism of the synthesis of methanol on copper-containing catalysts. Thus Pomerantsev et al.[146] and Rozenfel'd and Rusov[147] believe that the process proceeds in accordance with the scheme $CO_2 \rightleftarrows CO \rightleftarrows CH_3OH$. However, in other studies[148,149] it has been suggested that the scheme $CO \rightleftarrows CO_2 \rightleftarrows CH_3OH$ is more probable. The following expressions have been obtained[150] for the rates of synthesis of methanol from CO_2 (w_1) and of conversion of CO (w_2):

$$w_1 = \frac{k_1 c_{H_2}}{1 + b_{H_2O} c_{H_2O}} \left(1 - \frac{c_{CH_3OH} c_{H_2O}}{K_1 c_{H_2}^3 c_{CO_2}}\right),$$

$$w_2 = \frac{k_2 c_{H_2}}{1 + b_{H_2O} c_{H_2O}} \left(1 - \frac{c_{CO} c_{H_2O}}{K_2 c_{H_2} c_{CO_2}}\right),$$

where k_1 and k_2 are the rate constants for the formation of methanol and the conversion of CO respectively, K_1 and K_2 are the corresponding equilibrium constants for the same reactions, b_{H_2O} is the adsorption coefficient for water, and c_i (i = H_2, H_2O, CH_3OH, CO, and CO_2) are the corresponding concentrations.

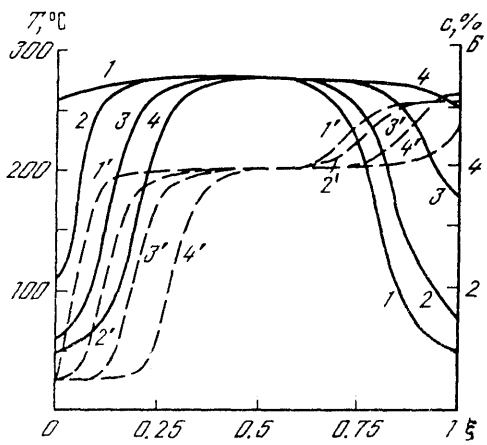

Figure 4. The temperature distribution (continuous lines) and methanol concentration (dashed lines) along the length of the catalyst bed ξ ($0 \leqslant \xi \leqslant 1$) in an established cyclic regime according to mathematical modelling data.[151] The gas moves from left to right. Composition of the initial mixture (vol. %); CO, 3.74; H_2, 81.9; CH_3OH, 0.474; CO_2, 2.033; H_2O, 0.078; N_2, 1.558; CH_4, 10.189. The conventional contact time is 0.5 s, which corresponds to a space velocity of 7200 h^{-1}. Pressure 7.2 MPa; mixture temperature at entry 50 °C; duration of cycle 10 min. The different curves correspond to different times t after the switch-over: (*1*) 0 min (start of half-cycle); (*2*) 1 min; (*3*) 3 min; (*4*) 5 min (end of half-cycle).

Fig. 4 presents examples of the calculation of the temperature and concentration fields in the catalyst bed on the basis of the so called two-phase model taking into account the external heat and mass exchange between the outer surface of the catalyst grain and the stream of the reaction mixture, the longitudinal heat transfer along the catalyst bed, and the internal diffusion inhibition of the reaction within the porous catalyst grain.[151] As can be seen from this figure, a decrease in temperature in the reactor with increase in the degree of conversion of carbon oxide is characteristic of the proposed method. For example, if the initial mixture contains ~5.75 vol. % of carbon oxides and ~0.47 vol. % of methanol, this makes it possible to obtain more than 5 vol. % of methanol at the exit from the bed. We may note that the equilibrium methanol content at 275 °C in the central part of the bed is ~3.9 vol. %, i.e. is appreciably lower.

Calculations have shown that the removal of the heat of the chemical reaction from the central part of the catalyst bed via a heat exchanger permits an increase in the yield of methanol by approximately 15% and an additional gain of heat, which is potentially highly utilisable. In practice both these possibilities are extremely useful. We may note that the yield of methanol in the system considered is much higher than in the traditional four-bed reactor with bypasses for the introduction of the cold gas between the catalyst beds, operating under optimum conditions. An experimental test in the reactor charged with three litres of the catalyst confirmed the possibility of synthesising methanol in a non-stationary cyclic regime and the validity of the principal conclusions reached from the results of mathematical modelling.

3. Oxidation of methanol to formaldehyde in a reactor with adiabatic oxide catalyst beds

The formation of formaldehyde from methanol on oxide catalysts is more economical than on silver-containing catalysts. In connection with the growth of the requirement for formaldehyde, it has become necessary to create plants with a unit capacity in excess of 50 000 to 60 000 tonnes per year. The application of tubular and combined reactors[152] with such capacity is difficult owing to the complexity of their construction and operation. Reactors with adiabatic catalyst beds appear to be most promising.[153]

The principal results of the development of a reactor of this type found by mathematical modelling studies of the kinetics and the temperature and concentration fields in the catalyst bed are briefly summarised in the present Section. The processes within a porous catalyst grain were described in terms of a quasi-homogeneous model. Stationary regimes in the adiabatic bed were determined by analysing the ideal displacement model with respect to matter and heat. The transient regimes in the stationary catalyst bed were calculated with the aid of a model taking into account the mass and heat exchange between the external surface of the grain and the gas stream and also the longitudinal transfer of heat along the skeleton of the catalyst bed.

Since the iron-molybdenum oxide catalyst works at temperatures in the range 220–350 °C[154] and the oxidation of methanol to formaldehyde is accompanied by an appreciable evolution of heat, the process must be carried out in several adiabatic beds arranged in series with removal of heat between them. However, when the process is carried out in this way, the output parameters of the reaction mixture, especially in the first beds, are very sensitive to changes in its input parameters. This hinders the use of catalytic apparatus of this type in carrying out processes involving the partial oxidation of hydrocarbons. Using mathematical modelling methods, it has been possible to put forward a process regime whereby the above difficulties can be overcome.

This required the solution of the following problems: (1) to ensure conditions under which the parametric sensitivity of the output parameters to changes in the input parameters does not exceed that required for technological reasons; (2) to develop an automatic control system which ensures the stabilisation of the technological parameters within specified limits.

The solution of the first problem reduced to the selection of the optimum grain size along the catalyst beds. In the oxidation of methanol to formaldehyde in the presence of the iron–molybdenum catalyst, two consecutive reactions take place: the oxidation of methanol proper and the oxidation of formaldehyde. Kinetic studies have shown[155] that the first reaction is of first order with respect to methanol and is inhibited by water. Formaldehyde hardly influences the rate of oxidation of methanol. The oxidation of formaldehyde is of first order with respect to formaldehyde and is inhibited by methanol and water.

Numerical analysis of the processes occurring on the catalyst grain led to the construction of a model of the observed reaction rates on grains of different size and shape in the temperature range 200 to 350 °C.[154] The characteristics obtained served as the basis for the mathematical modelling of the industrial reactor.

The catalyst grain size was chosen to ensure the permissible parametric sensitivities with retention of a sufficiently high process selectivity. The parametric sensitivity can be reduced by lowering the observed activation energy. When the process passes from the kinetic to the internal diffusion region, the observed activation energy E diminishes by a factor $\exp(\Delta T_{ad}x/RT_0^2)(E/2)$, where ΔT_{ad} is the adiabatic temperature rise in the mixture, x the degree of conversion, and T_0 the input temperature. For the iron-molybdenum catalyst in the specified temperature range, the increase in grain size is virtually the only parameter with the aid of which it is possible to reduce appreciably the activation energy.[156] An increase in grain size improved also the dynamic properties of the adiabatic bed. Furthermore, as a result of the decrease in the observed activation energy with increasing grain size, the possibility of the so called dynamic stoppages is diminished and the transient regimes develop more slowly. Ultimately favourable conditions are created for the automatic control of the process in the bed. However, an increase in grain size, which leads to an increase in the internal diffusion resistance, tends to increase the contribution of the side reaction involving the oxidation of formaldehyde to carbon monoxide and water and requires an increase in the catalyst charge. Thus it is essential to select an optimum catalyst grain size.

For this purpose, calculations have been made of the temperature and concentration fields in the reactor with adiabatic catalyst beds for an initial methanol concentration of 6–6.5 vol. %. The results obtained show that an increase in the grain size R_0 to 3 mm has a significant effect on selectivity in beds III and especially IV but has virtually no influence on the selectivity in beds I and II. The parametric sensitivity greatly diminishes with increase in R_0, reaching the minimum values for $R_0 \geqslant 3$ mm. The analysis led to the selection of the following catalyst grain sizes, R_0 (in mm) in the beds: 3 in beds I and II, 1.5 in bed III, and 1 in bed IV.

It follows from the mathematical modelling data that the adiabatic catalyst beds have the same parametric sensitivity to different input perturbations. Therefore, in order to ensure the stable and reliable operation of the reactor, a special system was developed for the automatic control of the process with removal of

part of the reaction gases via lines bypassing the intermediate heat exchangers.[157]

The results of the mathematical modelling of the reactor with adiabatic catalyst beds were tested and confirmed on the experimental plant of the Novosibirsk Chemical factory with an output of 18–25 kg of 37% formalin per hour. Prolonged use of the experimental plant confirmed that the system for the automatic stabilisation of the temperature regime in the reactor makes it possible to maintain the input parameters to within 1–1.5 °C and the output parameters to within 10–15 °C.

The principal technological and design characteristics of the reactor with adiabatic oxide catalyst beds with an output of 120 000 tonnes of 37% formalin per year are presented below:

Diameter of apparatus, m	4.2
Initial methanol concentration, vol.%	6.5
Blowing rate, $nm^3 h^{-1}$	70000
Linear flow rate, nm s^{-1}	1.4
Overall degree of conversion, %	99.3–99.8
Yield of formaldehyde, %	93.5–94.5
Consumption coefficient with respect to methanol, kg $tonne^{-1}$	423–428
Overall hydraulic resistance, atm	0.4
Conventional contact time	0.38

Thus the possibility, in principle, of oxidising methanol to formaldehyde in a reactor with adiabatic oxide catalyst beds arranged in series has been demonstrated. The application of reactors of this type makes it possible to create plants with a high unit output, such reactors being simple as regards apparatus and easily regulated.

4. The use of the catalytic conversion of methane for the thermochemical transformation of solar energy

The promising nature of yet another somewhat unexpected application of the catalytic reactions of C_1 compounds has been demonstrated most recently. It was established, initially theoretically[158] and then experimentally,[159–161] that the highly endothermic catalytic water vapour or carbonic acid conversion of methane into the synthesis gas can be used for the direct highly effective transformation of solar energy into the energy of chemical fuels. Such transformation is achieved by heating the catalytic reactor with concentrated sunlight up to temperatures of the order of 600–700 °C at which the thermodynamic equilibrium in the mixture of methane with water or CO_2 is displaced towards the high-energy mixture of CO and H_2. The energy stored in the course of the conversion of methane can then be released in another reactor in the form of heat, which is potentially highly utilisable, by carrying out the reverse reaction, also catalytic, involving the conversion of the synthesis gas into methane. With the aid of the above sequence of reactions, it is possible to create fairly effective energy devices with a closed cycle involving the utilisation of C_1 compounds as a chemically active "working heat".

Naturally, in opaque solar catalytic reactors, chemical processes take place in exactly the same way in the presence of the same catalysts as under traditional conditions. However, the efficiency of the solar energy devices definitely depends on the way in which high-density heat fluxes are transferred to the catalyst bed. The design of the catalytic reactors differs greatly in the given case from the usual reactors. A number of such designs with a useful output of several kilowatts have been developed at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences and have been tested under natural conditions.[159–161] In the course of these tests, efficiencies up to 45% in the storage of solar energy and above 20% in the generation of potentially highly utilisable heat (gas temperature up to 700 °C) were recorded during the operation of the closed thermochemical cycle as a whole. Such efficiencies are at present the maximum attained in chemical methods for the transformation of solar energy and the solar catalytic power generating devices developed can be regarded as prototypes of industrial designs.

The prospect for the practical utilisation of chemical methods for the transformation of solar energy depend nowadays on two factors. Firstly, we have the economic factor. All the methods of utilising solar energy known at the present time are more expensive than the traditional methods of generating energy, such as, for example, the combustion of organic fuels, nuclear reactions, etc. In this situation it is to be expected that solar energy will win through gradually as it becomes cheaper, as a result of the scientific and technical progress in this field, while the traditional sources of energy become gradually dearer due to their exhaustion.

The second factor is ecological. Much depends on how dangerous the thermal and chemical pollution of our planet by modern power engineering really is. If it proves intolerable, the development of the ecologically clean solar power engineering may become essential.

IV. Metal complex catalysis in reactions of C_1 compounds

Since its establishment, metal complex catalysis has been and remains a promising field of catalytic chemistry which is associated, firstly, with the possibility, as in this instance, of applying a broad spectrum of highly informative physicochemical research methods and, secondly, with the existence of a solid theoretical basis comprising extensive practical data concerning the reactivity of various coordination and organometallic compounds and the mechanisms of their reactions, which are used in the purposeful search for catalytic systems.[162–169] In order to predict the composition of metal complex catalytic systems, one may use thermodynamic and kinetic analyses of different combinations of stoichiometric reactions of metal complexes, which can be formally incorporated in a closed catalytic cycle.[170] Using this approach, a series of new catalytic systems, suitable for carrying out a wide variety of reactions involving carbon monoxide and formaldehyde, have been discovered at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences.

The problem of the involvement in chemical syntheses of one of the C_1 compounds produced on a large scale, namely carbon dioxide, is of great interest. Here too the application of metal complex catalysts may prove to be extremely promising.

1. Catalytic reactions with participation of carbon monoxide

The liquid-phase conversion of carbon monoxide has been achieved[173] under conditions (temperature, solvent composition, and the nature of the ligands L) such that two stoichiometric reactions with participation of metal complexes can take place simultaneously and at a high rate:

$$L_2MX_2 + CO + H_2O \xrightarrow{2L} L_4M + CO_2 + 2HX, \quad (1)$$

$$L_4M + 2HX \xrightarrow[-2L]{} L_2MX_2 + H_2. \quad (2)$$

The incorporation of these reactions in a closed cycle leads to the

catalytic reaction

$$CO + H_2O \xrightarrow{L_2MX_2} CO_2 + H_2. \quad (3)$$

Special studies led to the discovery of the conditions in the case where M = Pd, L = PPh_3, and X = CF_3COO for reactions (1) [reduction of phosphine complexes of palladium(II)[171]] and (2) [the interaction of $Pd(PPh_3)_4$ with acids[172]] and hence to the determination of the optimal conditions for reaction (3)[173] (Table 3, system *3*).

We may note that the above study[173] was preceded by only two communications[174,175] demonstrating the possibility of achieving the liquid-phase conversion of carbon monoxide (Table 2, systems *1* and *2*).

After the publication of the above investigation,[173] more than twenty metal complex catalytic systems for the liquid-phase conversion of carbon monoxide [the best known of these are presented in Table 2 (systems *4*, *5*, and *6*)], but the catalytic composition proposed by Zudin et al.[173] still remains one of the most active and makes it possible to carry out the reaction under mild conditions (temperature up to 100 °C, atmospheric CO pressure).

Table 2. Catalytic systems for the liquid-phase conversion of carbon monoxide.

No. of system	Composition of complex	Reaction conditions	Activity, mol H_2(mol M)$^{-1}$ h^{-1}	Refs.
1	$Fe(CO)_5$	15% aqueous NH_4OH solution with added $Ba(OH)_2$; 80 °C	0.03	[174]
2	$Rh_6(CO)_6$	aqueous pyridine solution; 450 atm; 210 °C	2.1	[175]
3	$(PPh_3)_2Pd(OAc)_2$	80% aqueous CF_3COOH; 70 °C; CO pressure 0.3 atm	3.0	[173]
4	$K_2PtCl_4 + SnCl_4 \cdot 5H_2O$	20% HCl solution in acetic acid containing 20% of water; 90 °C; CO pressure 0.5 atm	1.0	[176]
5	$Pd(ClO_4)_2 + Ph_2P$– 	aqueous solution; 85–100 °C; CO pressure 0.5 atm	0.25	[177]
6	$HRh(PEt_3)_3$	pyridine; 100 °C; CO pressure 20 atm	10.0	[178]

Catalytic synthesis of hydrogen peroxide via the coupled oxidation of carbon monoxide and water has been achieved under conditions ensuring the incorporation in a closed cycle of three stoichiometric reactions of phosphine complexes of palladium:

$$L_2PdX_2 + CO + H_2O \rightleftarrows L_2Pd + CO_2 + 2HX, \quad (4)$$

$$L_2Pd + O_2 \xrightarrow{-2L} L_2PdO_2, \quad (5)$$

$$L_2PdO_2 + 2HX \xrightarrow{L = PPh_3} L_2PdX_2 + H_2O_2. \quad (6)$$

As can be seen, the combination of reaction (4)–(6) in a catalytic cycle makes it possible to achieve the catalytic synthesis of hydrogen peroxide from oxygen and water in accordance with the equation

$$H_2O + O_2 + CO \xrightarrow{L_2PdX_2} H_2O_2 + CO_2. \quad (7)$$

It is noteworthy that in this process the highly endoergic stage involving the oxidation of H_2O by molecular oxygen to H_2O_2 is coupled energetically with the highly exoergic stage involving the oxidation of CO to CO_2. Previously such coupling of endoergic and exoergic stages was achieved in the catalytic synthesis of acetic anhydride from acetic acid, CO, and O_2.[179]

Reaction (7) was initially predicted on the basis of the considerations formulated above and was then achieved in practice.[180] The catalytic solution consisted of the two-phase water–dichloromethane system. The CH_2Cl_2 phase contained $Pd(OAc)_2$ and PPh_3, while the aqueous phase was a 3% solution of titanium(IV) sulphate, which served as a "trap" for the hydrogen peroxide formed. At 20 °C and atmospheric pressure of the gas phase ($CO:O_2$ = 1:1), the rate of formation of hydrogen peroxide was 0.5 mol (g-atom Pd)$^{-1}$ h^{-1}.

The possibility of the coupled oxidation of alkenes and carbon monoxide by molecular oxygen is determined by the same factor as for systems containing hydrogen peroxide, the oxo-complexes of molybdenum and tungsten being effective epoxidising agents. The idea of combining reaction (7) with the reactions

$$L'_nMO_r + H_2O_2 \xrightarrow{-H_2O} L'_mMO_{r-1}(O_2), \quad (8)$$

$$L'_mMO_{r-1}(O_2) + R{-}CH{=}CH_2 \xrightarrow{H_2O} L'_nMO_r + R{-}\underset{OH}{CH}{-}\underset{OH}{CH_2}, \quad (9)$$

arose. Here M = Ti(IV) or Mo(VI) and L' = Ph_3CO. It would thus be possible to achieve the catalytic process

$$CO + R{-}CH{=}CH_2 + O_2 + H_2O \xrightarrow[L'_nMO_r]{L_2PdX_2} CO_2 + R{-}\underset{OH}{CH}{-}\underset{OH}{CH_2}. \quad (10)$$

Experimental test showed that catalytic solutions containing phosphine complexes of palladium and oxo-complexes of molybdenum or tungsten permit the possibility of the coupled oxidation of carbon monoxide and propene to CO_2 and propylene glycol esters respectively. The most complete utilisation of hydrogen peroxide is attained when a mixture of acetic acid and acetic anhydride is used as the solvent. Thus the rate of formation of propylene glycol diacetate (the product of the interaction of epoxypropane or propylene glycol with acetic acid) was 3.6 mol (g-atom Pd)$^{-1}$ h^{-1} for a selectivity in the conversion of propene into this product of 56% in a system comprising (in mol litre^{-1}) $Pd(OAc)_2$ (5×10^{-3}), Na_3MoO_4 (5×10^{-2}), PPh_3 (5×10^{-2}) and $OPPh_3$ (0.1), using the $HOAc:AC_2O$ = 5:1 (by volume) solvent mixture, at 70 °C and a pressure of the $C_3H_6:CO:O_2$ = 1:1:1 gas phase of 1 atm.

In the absence of carbon monoxide, the rate of oxidation of propene is lower by two orders of magnitude than in its presence and the oxidation products are then exclusively carbonyl compounds. The oxidation of the alkene is in this case caused by the oxidation of PPh_3 by palladium(II) acetate, which leads to the formation of $Pd(PPh_3)_4$ and then $(PPh_3)_2PdO_2$. The latter oxidises the alkene in an acid medium to a carbonyl compound.[181]

Reaction (10) has also been achieved in the absence of a solvent, i.e. under the conditions of heterogeneous catalysis. The catalyst consisted of silica gel grains impregnated with PPh_3, $OPPh_3$, $Pd(OAc)_2$, and Na_2MoO_4, the composition of the gas mixture was $C_3H_6:CO:O_2$ = 1:1:1, the temperature was 90 °C, and the space velocity was 15 000 h^{-1}. Epoxypropane was formed with a

selectivity up to 20%. The increase in space velocity to 100 000 h^{-1} increased the selectivity to 45%. In the absence of carbon monoxide from the gas phase, epoxypropane was not formed.

Both homogeneous and heterogeneous catalysts very rapidly lost their activity as a result of the occurrence of the PPh_3 oxidation processes.

The synthesis of diethyl ketone from ethylene, carbon monoxide, and water. If the stoichiometric reaction (2) proceeds via the intermediate formation of palladium hydride complexes (experimental proof of this when M = Pd, L = PPh_3, and X = CF_3COO has been published[182,183]), then one may expect that, under conditions ensuring the conversion of carbon monoxide, hydrogen and CO will be inserted in the ethylene double bond. Experimental tests showed[184] that the catalytic reaction involving the hydrocarbonylation of olefins to dialkyl ketones does indeed take place in this case:

$$2C_2H_4 + 2CO + H_2 \xrightarrow{Pd^{2+},PPh_3} C_2H_5{-}\underset{\underset{O}{\|}}{C}{-}C_2H_5 + CO_2. \qquad (11)$$

It is known that diethyl ketone is formed together with other oxygen-containing compounds via reaction (11) in the presence of $PdCl_2$ and pyridine dissolved in 12 M HCl at 195–220 °C and 550–650 atm.[185] In the catalytic system,[184] diethyl ketone is formed at an appreciable rate and with a fairly high selectivity (~80%) already at 30–70 °C and atmospheric pressure.

The addition of hydrogen to the CO + C_2H_4 gas mixture in the system[184] increases the selectivity and especially the rate of formation of diethyl ketone (DEK), which reaches 70 moles of DEK per gramme-atom of palladium per hour at the catalytic solution temperature of 70 °C and atmospheric pressure of the $C_2H_4:CO:H_2$ = 2:1:1 gas mixture. This composition is one of the most active among all the known catalytic systems for the synthesis of DEK from C_2H_4, CO, and H_2.

The catalytic synthesis of the DEK from ethylene, carbon monoxide, and hydrogen can be achieved by the gas-phase method using as the catalyst a solution of the phosphine complexes of palladium and an aromatic sulphonic acid injected into the pores of a mineral carrier, the example, silica gel. The highest selectivity in the formation of DEK (96%) and the highest activity (3 moles of DEK per gramme-atom of Pd per hour) at 80 °C and the $C_2H_4:CO:H_2$ = 1:1:2 composition of the gas phase were achieved using sulphosalicylic acid as the "deposited solvent".

Immobilised metal complexes and catalysts of reactions with participation of CO. The search for new catalytic compositions can be greatly extended using the idea of immobilising metal complexes on the surfaces of carriers. In this case, the synthesis of the catalyst reduces to deliberate construction on the carrier surface of a heterogeneous active centre having the composition and structure which we would have required in solution to effect the specified reaction and which cannot be obtained in solution owing to fundamental difficulties (insolubility, mutual deactivation of the components, etc.).[170,187]

When this approach is used, it is possible to synthesise immobilised active centres containing several different transition metal ions selectively activating definite substrates.

Immobilised phosphine palladium-cobalt complexes as catalysts of the hydroformylation of propene. Cobalt carbonyl complexes are known to be catalysts of the hydroformylation of alkenes. This process takes place under fairly severe conditions—at elevated pressure and temperature. The stage involving the decomposition of acylcobalt carbonyl on treatment with hydrogen, leading to the formation of the target product—an aldehyde, is assumed to be the slowest.[188]

Palladium complexes are known to be effective catalysts of the hydrogenation of both different organic and saturated groups and of metal–carbon bonds.[189] In this connection, the idea arose of using a bimetallic palladium-cobalt phosphine complex to facilitate the hydrogenolysis of the Co–C(O)R bond.

The attempts to realise this idea in the "homogeneous version" were not however successful owing to the high lability of the carbonylphosphine-palladium–cobalt complexes, which are rapidly converted into insoluble compounds. A "heterogenised version" of the synthesis of the heterogeneous palladium-cobalt active centre was therefore effected.

Without dwelling on the details of the "assembly" of such a centre on the silica gel surface (they have already been described[190]), we may note that the activity of the immobilised palladium–cobalt complex in the hydroformylation reaction did indeed greatly exceed the activity of the individual palladium and cobalt complexes. The formation of C_4 aldehydes and alcohols on the $\mathbf{P_3}PdCo_2(CO)_6$ catalyst [where $\mathbf{P_3}$ is the $-O-Si(CH_2CH_2CH_2PPh_2)_3$ ligand group immobilised on SiO_2] was observed already at 40 °C ($H_2:C_3H_6:CO$ = 1:1:1 gas mixture, pressure—3 atm), whereas the $\mathbf{P_3}Pd^0$ and $\mathbf{P_3}Co_2(CO)_6$ catalysts were completely inactive under these conditions. The selectivity in the formation of products with a normal structure reached 88% for the heterometallic complex.[190,191]

The following concept concerning the mechanism of the catalytic action of the heterometallic complex was formulated on the basis of the results obtained by kinetic and physicochemical research methods:[192,193]

the active centre incorporates palladium and cobalt atoms separated by a distance permitting their linkage via the CO bridge bond;

the activation of hydrogen and the alkene takes place at the palladium atom, where the alkyl fragment is also stabilised;

CO is activated following its insertion in the Pd–R bond at the cobalt atom, where the acyl fragment is also stabilised;

the hydrogenolysis of the Co–C(O)R bond takes place with participation of hydrogen activated at the palladium atom.

Thus the action of the bimetallic Pd–Co centre resembles that of a conveyor belt at which each participant performs his operation in the most professional manner: palladium hydrogenates and cobalt carbonylates; their closeness ensures the rapid transfer of the "half-finished product" from one to the other.

2. The hydrocondensation of formaldehyde on metal complexes

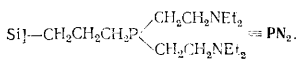
The hydrocondensation of formaldehyde,

$$nCH_2O + H_2 \rightarrow C_nH_{2n+2}O_n \qquad (12)$$

has attracted the attention of investigators as a possible method of synthesis of polyols from an extremely readily available raw material—formaldehyde and hydrogen. Reaction (12) is usually carried out in two stages.

(a) Condensation of formaldehyde to a "formose"—a mixture of carbohydrates in which the number of carbon atoms in the molecule is between 5 and 7:

$$nCH_2O \rightarrow C_nH_{2n}O_n. \qquad (13)$$



(b) Hydrogenation and hydrogenolysis of the "formose" to polyols, mainly to ethylene glycol, propylene glycol, and glycerol:

$$C_nH_{2n}O_n + H_2 \rightarrow C_2H_6O_2;\ C_3H_8O_2;\ C_3H_8O_3 + H_2O. \qquad (14)$$

The first stage—the condensation of formaldehyde to formose, discovered a long time ago by Butlerov, takes place readily in alkaline aqueous solutions and is catalysed by calcium hydroxide. Much more severe conditions are required to achieve the second stage (H_2 pressure 200 atm, temperature 230–280 °C, catalyst—copper-containing spinels).

The mechanism of the catalysis by calcium(II) ions of the condensation of formaldehyde has been fairly thoroughly investigated. It is believed that the growth of the carbon chain of the carbohydrate takes place when a formaldehyde molecule interacts with the enolic form of the carbohydrate molecule coordinated to a calcium(II) ion.[194] In this connection, the idea arose of introducing into the composition of the active centre for the condensation of formaldehyde a palladium ion, which is capable of catalysing the hydrogenation of the C=C bond of the enol and hence of effecting the synthesis of polyols via reaction (12) in a single stage under mild conditions.

The condensation of formaldehyde takes place in media at pH > 8. The application of the above idea in the "homogeneous" version is therefore difficult, since under these conditions the majority of transition metal ions, including palladium(II) ions, tend to form soluble hydroxides. Difficulties arise also when an attempt is made to apply this idea in the "heterogenised" version. Indeed, the heterogenisation of calcium(II) ions as active centres for the condensation of formaldehyde is problematical, since in alkaline media there is no suitable ligand for this ion with which it might be possible to immobilise it on the carrier surface. It therefore becomes necessary to replace the calcium(II) ion by the ion of another element, for example, chromium(III), which is very close to calcium(II) as regards some of its characteristics (octahedral coordination sphere, ionic radius about 1 Å). Taking into account the ability of chromium ions to form very stable complexes with amine ligands, which are stable in alkaline media, it was decided to use immobilised aminepalladiumchromium complexes to effect reaction (12). The phosphinoamine

was used as the ligand for the synthesis of a heteroatomic palladium–chromium complex. Here it was postulated that the phosphorus atom can serve as a site for the coordination of zerovalent palladium ions while, the ethylamine ligands coordinate chromium(III) ions.

An experimental test showed[194] that the immobilised palladium–chromium complex $PN_2PdCr(OH)_3$ does indeed exhibit an appreciable activity [2.1 mol H_2(g-atom Pd)$^{-1}$ h^{-1}] in reaction (12) under mild conditions (temperature 60 °C, H_2 pressure 1 atm, aqueous formaldehyde solution, HCHO concentration 0.1 M) in contrast to the immobilised monometallic palladium complex $P.Pd^0$ ($P = CH_2CH_2PPh_2$ ligand group immobilised on SiO_2) and the chromium complex $N_2Cr(OH)_3$ [$N_2 = CH(CH_2NEt_2)_2$ ligand group immobilised on SiO_2]. The yield of ethylene glycol amounted to 75% relative to the formaldehyde which had reacted.

The results of the study by physico-chemical methods of the state of palladium and chromium ions in the immobilised complexes and also the analysis of the observed kinetics permitted the conclusion that the synergistic effect is caused by the geometrical proximity in the heterometallic active centre of the fragments responsible for the condensation of formaldehyde and the stabilisation of the enolic form [amine complexes of chromium(III)], on the one hand, and for the activation of hydrogen and the hydrogenation of the C=C bond (phosphine complexes of palladium), on the other.

The preferential formation of ethylene glycol can apparently be explained by the higher rate of hydrogenation of the enolic form of glycolaldehyde compared with the rate of the interaction with the next formaldehyde molecule, leading to the synthesis of glyceraldehyde. The absence of catalytic activity for the hydrocondensation of formaldehyde of catalysts consisting of a mixture of immobilised phosphine complexes of zerovalent palladium and diamine complexes of chromium(III) can be explained by the fact that in this case the "palladium" and "chromium" fragments are not close to one another.

3. The reduction of CO_2 under mild conditions

The photosynthetic "fixation" of carbon dioxide by its reduction to carbohydrates, which occurs in all plants and photosynthesising micro-organisms, annually produces up to 10^{11} tonnes of complex organic substances.[196] An important feature of natural photosynthesis, which constitutes its advantage over the majority of industrial catalytic processes, is its occurrence under extremely mild conditions—close to room temperature and at normal pressures in aqueous solutions at a pH close to 7. The high selectivity of photosynthesis is also striking.

The photosynthetic fixation of CO is usually described by the overall reaction

$$CO_2 + 4H^+ + 4A^- \rightarrow {}^1/_6(C_6H_{12}O_6) + 4A, \qquad (15)$$

where A^- are strong one-electron reductants formed under the influence of light in the photocatalytic charge separation and capable of entering into reversible oxidation-reduction reactions.[196,197]

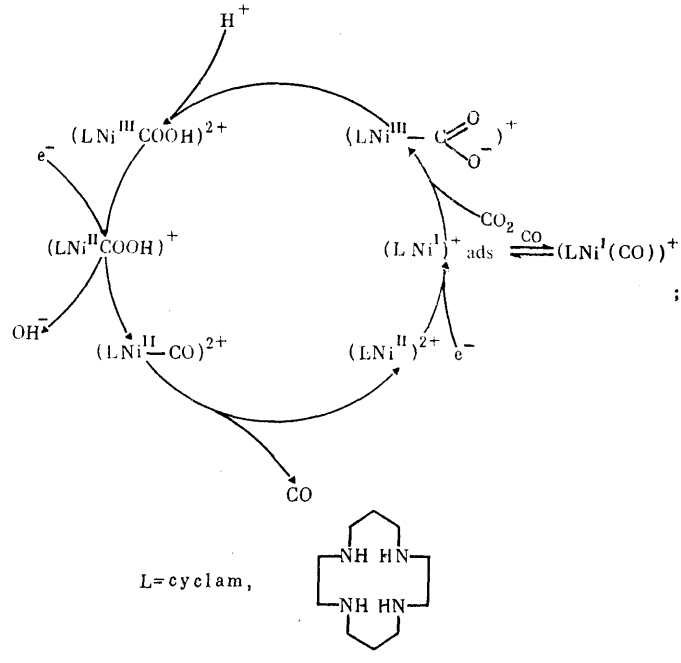
Naturally, at the present time there is as yet no acute need to reproduce reactions of type (15) on an industrial scale. Nevertheless, the interest in artificial systems capable of reducing CO_2 under mild conditions has increased significantly during the last decade. This is due primarily to the intense development of photocatalytic solar energy converters and the consequent natural endeavour to reproduce the principal chemical reactions underlying natural photosynthesis.[158,198] The solution, in principle, of the problem of the modelling of the photosynthesis in plants, where the reduction of CO_2 is coupled with the oxidation of water to O_2, is especially interesting. The reductants A^- in the photocatalytic systems being developed are as a rule photogenerated strong electron donors: either the reduced forms of several organic or metal complex compounds or the conductivity electrons of a series of semiconductors. Even more work has been carried out on systems in which the reductants A^- are generated by cathodes placed in the reaction volume.

It is noteworthy that studies on the reduction of CO_2 under mild conditions are still in the initial stage and are as a rule restricted to the consideration of the possibility of obtaining under such conditions only the simplest compounds—carbon monoxide, the formate ion, methanol, methane, and, rarely, oxalate and glycolate ions, etc.

The principal difficulties in achieving the reduction of CO_2 under mild conditions (in aqueous solutions of carbonate and/or bicarbonate ions or carbon dioxide at a low pressure of the latter)

can be observed even in a cursory analysis of the characteristic features of the process thermodynamics (Table 3). With the exception of the case of the eight-electron reduction of CO_2 to methane, the equilibrium electrochemical potentials of the reduction of CO_2 are significantly more negative than the equilibrium potential of the two-electron reduction of H^+ ions to molecular hydrogen. Thus the reduction of H^+ to H_2 is thermodynamically preferable to any CO_2 reduction process (with the exception of its reduction to methane). In view of the high energy content of the free products of the one-electron reduction of CO_2 as well as other reduced forms of CO_2 with an odd number of electrons,[202,203] the preparation of stable products necessitates the use of special catalysts ensuring the occurrence of multi-electron processes. As a consequence of the specificity of the characteristics of the CO_2 reduction processes mentioned above, these catalysts must be sufficiently selective to prevent the occurrence of the competing process involving the formation of molecular hydrogen.

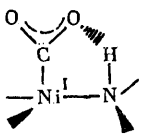
Table 3. Standard electrode potentials $E°$ of certain H^+ and CO_2 reduction reactions in aqueous solutions at pH 0 (according to data in Refs. 199–202).



Electrode reaction	$E°$, V (w.r.t.n.h. e-de)
$2H^+ + 2e \rightarrow H_2$	0.00
$CO_2 + e \rightarrow CO_2^-$	−1.31
$CO_2 + 2H^+ + 2e \rightarrow CO + H_2O$	−0.12
$CO_2 + 2H^+ + 2e \rightarrow HCOOH$	−0.19
$2CO_2 + 2H^+ + 2e \rightarrow H_2C_2O_4$	−0.49
$CO_2 + 4H^+ + 4e \rightarrow HCHO + H_2O$	−0.11
$CO_2 + 6H^+ + 6e \rightarrow CH_3OH + H_2O$	−0.04
$CO_2 + 8H^+ + 8e \rightarrow CH_4 + 2H_2O$	0.17

The insufficient selectivity of metallic electrodes as catalysts has in fact precluded significant advances in the development of methods for the selective electrochemical reduction of CO_2 at these electrodes. As was to be expected, at noble metal and also iron and nickel cathodes, where the evolution of hydrogen takes place with a low overpotential, the current yield in the reduction of CO_2 does not usually exceed 10%. The selectivity in relation to the reduction of CO_2 is significantly higher when one uses electrodes made of non-noble metals such as Cd, Sn, Pb, In, and Zn, at which H_2 is evolved with a high overpotential.[204,205] Apparently molybdenum cathodes exhibit the greatest, almost 100%, selectivity in relation to the reduction of CO_2 (in particular to methanol), but this result is attained only at low current densities (up to 1 mA cm^{-2})[199] or when the process is carried out in aprotic solvents.[204,206]

The failures suffered when metallic cathodes were used necessitated the search for other catalysts of both homogeneous and electrode reduction of CO_2. At the present time definite progress has been achieved in this field, which has developed in the very recent years. A fairly wide range of compounds capable of acting as catalysts in the reduction of CO_2 in both electrochemical and photocatalytic systems have been discovered. As was to be expected, the coordinatively unsaturated complexes of certain variable valence metals, which readily incorporate a CO_2 molecule in their coordination sphere, are especially promising.[207,208] Homogeneous or heterogenised cobalt, nickel, and copper complexes with planar nitrogen-containing ligands such as porphins, phthalocyanines, and tetra-azamacrocycles exhibit the highest catalytic activity. For example, the water-insoluble phthalocyanine complex of cobalt(II) deposited on a graphite cathode, which has been investigated at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences, manifested a significant activity and selectivity in the electrocatalytic reduction of CO_2 to CO.



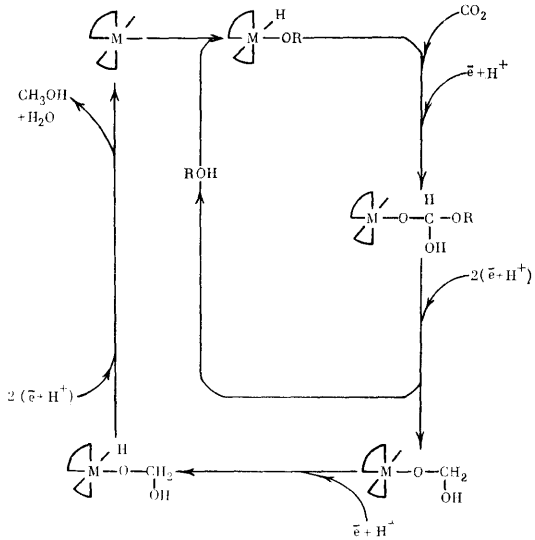
It has been suggested that, in the presence of catalysts of the above type, the reduction of CO_2 takes place in several stages and includes (1) the initial addition of a CO_2 molecule to the central atom of the metal complex subjected to preliminary reduction at the cathode and (2) the reduction of CO_2 and the subsequent release of the reaction products from the coordination sphere of the complex with regeneration of the initial form of the latter. Thus the following schematic catalytic cycle for the electrochemical reduction of CO_2 to CO (Scheme 2) has been proposed[209,210] in the case of a typical catalyst of this kind—the complex $Ni(cyclam)^{2+}$, where cyclam = 1,4,8,11-tetra-azacyclotetradecane.

Scheme 2

It has been established fairly reliably that the substrate for the formation of compounds with reduced forms of carbon does actually consist of CO_2 molecules and not of carbonate or bicarbonate ions from the solution. It has also been suggested that the reduction of CO_2 in the presence of the above catalyst is promoted by the two-centre coordination of the CO_2 molecule via an electrophilic centre (carbon atom) to the nickel(I) ion and via a basic centre (oxygen

atom) to the ligand hydrogen atom bound to nitrogen:

Nevertheless the selectivity in the reduction of CO_2 on the catalyst indicated cannot yet be regarded as entirely satisfactory: a considerable proportion of the reductant is consumed on the evolution of H_2 and not on the reduction of CO_2. Furthermore, CO and the simplest organic C_1 compounds predominate in the products of such reduction, as at metallic electrodes.



The impression has been created that the modest nature of the advances in devising artificial highly selective systems for the extensive reduction of CO_2 is associated with the fact that the direct reduction of the coordinated CO_2 molecule cannot be sufficiently effective by virtue of the specific thermodynamic features of the process noted above. Indeed, nature has followed another pathway, reducing carbon atoms not directly in the CO_2 molecule itself but in the products of the preliminary carboxylation of certain organic compounds, which can be regarded as cocatalysts of the CO_2 reduction process.

Thus in the classical "Calvin cycle"—a cyclic sequence of reactions leading to the fixation of CO_2 in many plants—the reduction of CO_2 is preceded by its binding to the phosphorylated sugar ribulose-1,5-diphosphate, which decomposes in the presence of the enzyme ribulose diphosphate carboxylase into two molecules of 3-phosphoglyceric acid; only this intermediate gives rise, when acted upon by a powerful reductant, to sugars as the final products with a high selectivity and liberates the initial substrate for carboxylation.

Thus one can assume that, in the development of artificial systems for the extensive reduction of CO_2, it is also useful to employ the reaction sequence "carboxylation of the organic substrate-cocatalyst—reduction of the intermediate carboxylic acid". The first experimental data indicating the reality of this approach have also appeared. Thus a study has been made[211-214] of the electrochemical reduction of CO_2 to methanol in the presence of homogeneous catalysts—the iron complexes of Tiron (1,2-dihydrobenzene-3,5-disulphonate) and oxalate and cyanide anions and chromium oxalate and chloride complexes. The electrochemical reduction took place at electrodes passivated with respect to the evolution of hydrogen by an insoluble but electrically conducting layer of Prussian Blue $KFe^{(III)}[Fe^{(II)}(CN)_6]$. It was observed that the process proceeds only in the presence of primary alcohols and under conditions such that the coordination sphere of the metal complex used as the homogeneous catalyst contains at least one labile ligand capable of being substituted by an alcohol molecule. For example, the aquated iron(III) pentacyanide with a labile water molecule in the first coordinated sphere is catalytically active, while iron(III) hexacyanide or nitroprusside does not show any catalytic activity. The primary alcohol molecule plays the role of a cocatalyst and the process itself is believed to proceed in accordance with Scheme 3. In this scheme, as in the photosynthetic fixation of CO_2, a carboxylated organic compound, coordinated to the homogeneous catalyst in the case considered, is reduced.

Presumably further development of this field will make it possible to create in the future fairly selective and therefore practically important systems for the extensive oxidation of CO_2 under mild conditions.

Scheme 3

* * *

Thus considerable progress has been achieved recently both in the search for new ways of converting one-carbon compounds and in the improvement of the traditional catalytic processes based on such compounds. It may be hoped that new processes using compounds with one carbon atom will be developed in the next few years and that those already introduced into industry will be significantly improved.

The mechanism of the partial oxidation of methane

M Yu Sinev, V N Korshak, O V Krylov
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The principal characteristics of the homogeneous and heterogeneous-catalytic conversion of methane into condensation products (C_2 and C_3 hydrocarbons) and partial oxidation products (methanol and formaldehyde) are considered. Data are presented concerning the most effective catalysts and data relating to the mechanism of the activation of methane on oxide and oxide halide catalysts, the nature of the active centres, and the kinetics of the partial oxidation of methane are analysed. It is shown that the oxidative condensation of methane in the presence of the catalysts considered is a heterogeneous-homogeneous process, which imposes special requirements in its practical realisation.

I. Introduction

The limited resources of petroleum and the constant increase in the cost of its extraction have brought to the fore the problem of the search for an alternative raw material for the chemical and petrochemical industry.

In the immediate future natural gas, and primarily its principal component (methane), may become such raw material.[1] Methane is also a side product in a whole series of reactions involved in the processing of organic raw material, including coal, which are likely to become the principal source of organic intermediate products and motor fuels.[2] This gives rise to the problem of devising effective processes for the conversion of methane into valuable products—methanol, formaldehyde, lower alkanes, etc.

Together with its practical importance, the problem of the processing of methane is of considerable theoretical interest, since it is associated with research into the possibility of activating an extremely stable molecule, whose reactivity is significantly lower than that of the target products.

Studies on the heterogeneous catalytic oxidation of methane to useful products can be arbitrarily divided into two parts. One of these is associated with the synthesis of valuable oxygen-containing compounds—methanol and formaldehyde. This aspect has been developing for a very long time and definite results concerning the understanding of the process mechanism and of the influence of the nature of the active centres of the catalysts on their activity and selectivity have been obtained. However, the yields of the useful products on stably operating catalysts do not exceed 3% for methanol and 5–8% for formaldehyde in the oxidation of methane by oxygen or air without the addition of various compounds (nitrogen oxides, halogeno-derivatives) as oxidants and initiators. Thus a significant increase in the yields of valuable oxygen-containing compounds has not so far been achieved in the heterogeneous-catalytic oxidation of methane compared with the homogeneous oxidation.

The second aspect—the catalytic oxidtive condensation of methane to higher hydrocarbons (mainly to ethane, ethylene, propene, and acetylene)—began to develop comparatively recently, about five years ago. Nevertheless, during this extremely brief period a considerable number of effective catalysts have been developed, which makes it possible, for example, to achieve a yield of C_2 hydrocarbons up to 30% relative to the methane passed through the system.

Definite progress has been made also in the understanding of the mechanism of the oxidative condensation of methane; multistage schemes and the simplest kinetic models have been proposed, permitting an explanation of the characteristics of the process including homogeneous stages in which the radicals $CH_3^{\cdot}$ and $CH_3O_2^{\cdot}$ participate.

We must emphasise that the oxidation of methane on the majority of catalysts apparently includes a stage involving the heterogeneous generation of $CH_3^{\cdot}$ radicals and stages in which they undergo further reactions both in the gas phase and on the surface. It therefore appears useful to carry out a brief survey of investigations into the gas-phase oxidation of methane, before proceeding to the consideration of studies on its heterogeneous-catalytic oxidation. Among the latter, most attention will be devoted to studies on oxidative condensation—in our view, the most promising aspect of the selective catalytic oxidation of methane.

II. Reactions of methane in the gas phase

Homogeneous reactions of methane in the gas phase have been studied in greatest detail at the present time; investigations on these lines have been prosecuted for many decades and their results have been surveyed in a number of reviews (see, for example, Refs. 3–5) and new data go on being added.

Owing to the high thermodynamic stability of methane, its conversion into, for example, hydrocarbons at a relatively low temperature is impossible because of the virtually complete shift of

the equilibrium towards methane.[6] With increase in temperature, the equilibrium is displaced and the possibility of the formation of appreciable amounts of hydrocarbons appears. It has been established[3] that the pyrolysis of methane takes place at temperatures above 700 °C in accordance with the scheme

$$CH_4 \xrightarrow{a} C_2H_6 \xrightarrow{b} C_2H_4 \xrightarrow{c} C_2H_2 \xrightarrow{d} \text{aromatic hydrocarbons, coke.} \quad (1)$$

The primary radical formed in the system is $CH_3^{\cdot}$:

$$CH_4 \rightarrow CH_3^{\cdot} + H^{\cdot}. \quad (2)$$

The activation energy for reaction (2) is 90–107 kcal mol^{-1}. Admixtures of other hydrocarbons as well as halogens and oxygen have an initiating effect.

The initiation stage (2) is followed by the chain propagation and termination stages, which can be represented in the following simplified form:

$$H^{\cdot} + CH_4 \rightarrow CH_3^{\cdot} + H_2, \quad (3)$$

$$2CH_3^{\cdot} \rightarrow C_2H_6, \quad (4)$$

$$CH_3^{\cdot} + H^{\cdot} \rightarrow CH_4. \quad (5)$$

The activation energies for the overall stages *b*, *c*, and *d* in Scheme (1) are respectively 64–90, 35–65, and 22–50 kcal mol^{-1}, which indicates a higher reactivity of the condensation products compared with the initial methane.

According to Roscoe and Thompson,[7] the C_2 and C_3 hydrocarbons are formed via a series of radical stages:

$$\begin{gathered} CH_3^{\cdot} + C_2H_6 \rightarrow C_2H_5^{\cdot} + CH_4;\ CH_3^{\cdot} + C_2H_4 \rightleftarrows n\text{-}C_3H_7^{\cdot}; \\ C_2H_5^{\cdot} \rightarrow C_2H_4 + H^{\cdot};\ n\text{-}C_3H_7^{\cdot} \rightarrow C_4H_8 + H^{\cdot}; \\ CH_3^{\cdot} + C_2H_4 \rightarrow C_2H_3^{\cdot} + CH_4;\ CH_3^{\cdot} + C_3H_5^{\cdot} \rightleftarrows C_3H_5^{\cdot} + CH_4; \\ C_2H_3^{\cdot} \rightarrow C_2H_2 + H^{\cdot};\ C_3H_5^{\cdot} \rightarrow CH_2{=}C{=}CH_2 + H^{\cdot}, \text{ etc.} \end{gathered} \quad (6)$$

It was shown in the same study by numerical calculation that the concentration of $CH_3^{\cdot}$ radicals exceeds by more than an order of magnitude the overall concentration of all other radicals. The calculated formation curves for the molecular products at 765 °C describe satisfactorily the experimental data:[8,9] for reaction times up to 500 s, the concentration of ethane is highest among all the hydrocarbon products, while for longer times that of ethylene is highest; if the reaction time exceeds 2290 s, the concentration of propene is higher than that of ethane and, whatever the reaction time, the concentration of propene is 3–4 times higher than that of acetylene. Alkanes heavier than ethane (propane, butane, etc.) are not formed.

The rate of conversion of methane increases significantly in the presence of a large surface area, apparently as a result of the acceleration of the initiation stage. On a carbon surface, and any surface becomes coated with carbon on pyrolysis with deposition of coke,[3] the effective activation energy for the initiation stage may fall to ~50 kcal mol^{-1}.[10] A change in the composition of the surface during the process can influence its rate and direction. Thus, in the presence of MgO [11] at 900 °C, the degree of conversion of methane falls from 22 to 8% during the first 6–7 h, after which it retains a stationary value; however, the yield of hydrocarbons increases from 0.8 to 2.4%. Whereas in an empty quartz reactor the formation of hydrocarbons is not observed for a contact time less than 3 s, with increase in contact time to 10 s the yields of hydrocarbons on the coke-saturated MgO and in the empty quartz reactor are similar.

It must be emphasised yet again that the attainment of high yields of hydrocarbon methane condensation products is limited by the unfavourable equilibrium position even at relatively high temperatures (700–900 °C). Thermodynamic prohibition of the conversion of methane is removed in oxidation processes which take place with a decrease in free energy.

The characteristic features of the homogeneous oxidation of methane have been studied most fully compared with other hydrocarbons.[12] This process is complex, proceeds via a branched chain mechanism, and includes several tens of stages. A whole series of kinetic models have now been proposed for the description of the homogeneous oxidation of methane (see for example, Refs. 13–17). Each of them corresponds to definite homogeneous oxidation reaction conditions (temperature and pressure range, concentration of the components of the reaction mixture, macrokinetic characteristics of the system).

In all the mechanisms proposed, it is assumed that chain initiation takes place in the following stage characterised by an activation energy of ~50 kcal mol^{-1}:[18]

$$CH_4 + O_2 \rightarrow CH_3^{\cdot} + HO_2^{\cdot}. \quad (7)$$

Chain propagation takes place in the following stages:

$$\begin{gathered} CH_3^{\cdot} + O_2 \rightleftarrows CH_3O_2^{\cdot};\qquad CH_3O^{\cdot} \rightarrow CH_2O + H^{\cdot}; \\ CH_3O_2^{\cdot} + CH_4 \rightarrow CH_3OOH + CH_3^{\cdot};\qquad H^{\cdot} + CH_4 \rightarrow H_2 + CH_3^{\cdot}; \\ CH_3O_2^{\cdot} + CH_3^{\cdot} \rightarrow 2CH_3O^{\cdot};\qquad CHO_3^{\cdot} + CH_2O \rightarrow CH_3OH + CHO^{\cdot}; \\ CH_3O_2^{\cdot} + CH_4 \rightarrow CH_3OH + CH_3O^{\cdot};\qquad CH_3O^{\cdot} + O_2 \rightarrow CH_2O + HO_2^{\cdot}; \\ HO_2^{\cdot} + CH_4 \rightarrow H_2O_2 + CH_3^{\cdot};\qquad CHO^{\cdot} + O_2 \rightarrow CO + HO_2^{\cdot}; \\ CH_3O_2^{\cdot} \rightarrow CH_2O + OH^{\cdot};\qquad CO + HO_2^{\cdot} \rightarrow CO_2 + OH^{\cdot}; \\ OH^{\cdot} + CH_4 \rightarrow CH_3^{\cdot} + H_2O;\qquad 2CH_3O_2^{\cdot} \rightarrow CH_3OH + CH_2O + O_2; \\ CH_2O + HO_2^{\cdot} \rightarrow CHO^{\cdot} + H_2O_2;\qquad 2CH_3O_2^{\cdot} \rightarrow 2CH_3O^{\cdot} + O_2, \text{ etc.} \end{gathered} \quad (8)$$

Chain branching occurs in the stages

$$H_2O_2 + M \rightarrow 2OH^{\cdot}, \quad (9)$$

$$CH_2O + O_2 \rightarrow HO_2^{\cdot} + CHO^{\cdot}, \quad (10)$$

$$CH_3OOH \rightarrow CH_3O^{\cdot} + OH^{\cdot}. \quad (11)$$

Chain termination can occur in stages (4) and (5) and also as a result of the destruction of active species ($HO_2^{\cdot}$, $CH_3O_2^{\cdot}$, $CH_3^{\cdot}$, OH, H_2O_2, CH_3OOH) on the reactor walls. The kinetic parameters of the radical destruction processes on the walls are frequently unknown and are estimated from the correspondence of the results of the numerical computation to the experimental data (see, for example, Vardanyan et al.[14]). The rate constants for the majority of the homogeneous stages found by different methods are available in the literature.[19–22]

The data accumulated for the homogeneous gas-phase methane oxidation processes show that the partial oxidation products formed (CH_2O, CH_3OH) exhibit a higher reactivity under the process conditions compared to methane and undergo further successive transformations into extensive oxidation products. As a result, the yield of formaldehyde at 500–600 °C cannot exceed 0.5% relative to the methane passed through the system.[13] The preparation of

methanol requires an increase in pressure to tens of atmospheres;[5,17,23] the yield of CH_3OH can then reach several per cent relative to the methane passed through the system at 400–600 °C.

III. Heterogeneous-catalytic oxidation of methane

The most realistic method of increasing the yield of target products may involve the oxidation of methane in the presence of heterogeneous catalysts. However, for a long time the attempts to create effective catalysts for the conversion of methane into valuable products on the basis of traditional catalytic systems were unsuccessful; in the presence of transition metals and their oxides (see, for example, Refs. 24–26), extensive oxidation of methane mainly takes place; the efficiency of zeolitic catalysts in relation to the partial oxidation in the presence of oxygen is also low.[27]

However, in recent years definite progress has been achieved in the search for catalysts and conditions for the process leading to the partial oxidation of methane.

1. Partial oxidation of methane to oxygen-containing compounds

It was noted above that at elevated pressures it is possible to drive the gas-phase methane oxidation process towards CH_3OH. The application of catalysts based on zinc, cadmium, and nickel oxides, which are solid solutions,[28] and the use of a high pressure (up to 100 atm)[29] make it possible to achieve a yield of CH_3OH up to 2% relative to the methane passed through the system for a selectivity of about 80%. Like other heterogeneous catalysts,[5] this system does not give rise to a significant increase in the yield of methanol compared with homogeneous oxidation.

A wide range of oxide and phosphate catalytic systems have been investigated in the reaction involving the oxidation of methane to formaldehyde.[30,31] Catalysts which are weakly reduced by hydrogen (SiO_2, BPO_4, $AlPO_4$) exhibit a high selectivity with respect to CH_2O. Highly passive catalysts are most active as regards CH_2O, which is attributed to the easier desorption of the products from their surfaces. In the series investigated, tin phosphate is the optimum catalyst[32] on which the yield of CH_2O can reach 16% under conditions with circulation of the reaction mixture and the freezing out of the product during the cycle. In the flow regime, the yield of CH_2O during one pass does not exceed 2%.[33]

When aluminosilicates (with an Al_2O_3 content of 10–11%), modified by the addition of metal (Fe, Zr, V, Ni, Mo, Cu, Cd, Bi, Cr) oxides,[34] are used as catalysts, it is also possible to increase the yield of CH_2O (1.9% relative to the methane passed through the system on aluminosilicate containing 1.5% of Fe_2O_3). The maximum yield of CH_2O (2.6%) was obtained on aluminosilicate with added 2% of cerium phosphate and 0.05–0.06% of P_2O_5 at 750 °C. In the presence of this catalyst, it is possible to reduce the reaction temperature approximately by 100 °C with simultaneous increase in the CH_2O yield to 5–5.5% as the result of the introduction of 0.2–0.5% of $(CH_3)_2O$ into the contact zone.[35]

The addition of halogen-containing compounds into the reactant stream also entails an increase in the yield of CH_2O. Catalysts containing deposited transition metal (Ce, Mo, V, Fe, Co) oxides have been described.[36] At 450–600 °C and after the addition of up to 1 mole of HCl per mole of CH_4 to the initial mixture, they make it possible to obtain a yield of CH_2O up to 15% relative to the methane passed through the system.

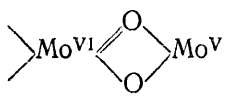
When a deposited palladium catalyst (0.5% of the oxide on Al_2O_3) is used,[37] the introduction of 5 mole % (relative to methane) of CH_2Cl_2 into the stream of the 5 : 1 mixture of air and methane lowers the degree of conversion of methane at 475 °C from 20 to 13% with a simultaneous increase in the CH_2O yield from 0 to 6%. Experiments involving the introduction of CH_2Cl_2 into the mixture of CH_2O with air showed that this entails the suppression of the subsequent oxidation of formaldehyde.

Detailed investigation of the partial oxidation of methane to CH_2O [38] by methods involving separate calorimetric measurements and EPR with the freezing out of radicals showed that, in the presence of KSK silica gel and γ-Al_2O_3, the process takes place partly in the bulk of the gas phase. Evidence was obtained for a heterogeneous-homogeneous mechanism of the oxidation of methane, according to which the gas-phase processes lower the selectivity with respect to CH_2O. The low process selectivity on Al_2O_3 can be explained by the high rate of successive conversion of formaldehyde into carbon oxides as a result of the additional oxidation and decomposition into CO and H_2. The influence of the modification of silica gel by the addition of ZnO, SrO, CdO, B_2O_3, Al_2O_3, CeO_2, Bi_2O_3, V_2O_5, MoO_3, and WO_3 on the yield of methane oxidation products has been investigated. The maximum yield of CH_2O (up to 3.6%) has been obtained on a specimen modified with ZnO.

A communication[39] describing the formation of a complex catalyst containing Fe, Mo, Ni, Mg, and Bi oxides on SiO_2, which makes it possible to obtain CH_2O at 650 °C by oxidising methane with a selectivity of 86.5% for a conversion of 8.9%, has been published recently.

A significant increase in the yield of oxygen-containing products of the partial oxidation of methane can be achieved using N_2O as the oxidising agent. The replacement of O_2 by N_2O leads to an increase in the degree of conversion of methane on the 2% MoO_3/SiO_2 catalyst[40,41] at 550 °C from 0.5 to 6%; the selectivities with respect to CH_3OH and CH_2O are then 38 and 55% respectively. The maximum yield of the partial methane oxidation products is observed when water is added to the initial mixture: at p_{H_2O} = 0.18 to 0.20 atm, the degree of conversion of methane is 26% for selectivities with respect to CH_3OH and CH_2O of 80 and 19% respectively, in the absence of water, the degree of conversion is approximately 4% for an overall selectivity of about 60%. Under the conditions of thermoprogrammed desorption, C_2H_6 and C_2H_4 are evolved at relatively low temperatures (100–200 °C) after the successive admission at 25 °C of N_2O and CH_4 to a specimen, containing molybdenum (V) ions,[41] which had been reduced beforehand; the maximum evolution of CH_3OH occurs at a temperature above 450 °C. Traces of C_2 hydrocarbons are present in the reaction mixture also under the conditions of the continuous supply of a mixture of CH_4 and N_2O.[40,41]

The proposed process mechanism includes the following stages leading to the formation of CH_3OH and CH_2O:[43]



$$
\begin{aligned}
&Mo^{V} + N_2O \rightarrow Mo^{VI}O^{-} + N_2,\\
&Mo^{VI}O^{-} + CH_4 \rightarrow Mo^{VI}OH^{-} + CH_3^{\cdot},\\
&Mo^{VI}O^{2-} + CH_3^{\cdot} \rightarrow Mo^{V}OCH_3,\\
&Mo^{V}OCH_3^{-} + H_2O \rightarrow Mo^{V}OH^{-} + CH_3OH,\\
&Mo^{V}OH^{-} + Mo^{VI}OH \rightarrow Mo^{V} + Mo^{VI}O^{2-} + H_2O,\\
&Mo^{V}OCH_3^{-} + Mo^{VI}O^{2-} \rightarrow Mo^{VI} + Mo^{V}OH + CH_2O.
\end{aligned}
\qquad (12)
$$

The processes

$$8Mo^{VI} + 4O^{2-} + CH_4 \rightarrow 8Mo^{V} + 2H_2O + CO_2, \quad (13)$$

$$2Mo^{V} + N_2O \rightarrow 2Mo^{VI} + N_2 + O^{2-}, \quad (14)$$

can lead to non-selective oxidation. It has been suggested that the active centre has the structure

A difference in the behaviour of the surface CH_3O^- groups on deposited MoO_3, where they react in accordance with Scheme (12) as presented above, and on MgO where their only reaction pathway is decomposition into CO and H_2 [44] has been noted.[42] Nor can one exclude also the possibility of the formation of CH_3OH via the interaction of the $CH_3^{\cdot}$ radicals with water or Si—OH groups.[43]

It has been shown[45] that the mechanisms of the formation of CH_2O at temperatures below and above 540 °C on the 2% MoO_3/SiO_2 catalyst are different. There is a possibility of both the direct formation of CH_2O from the CH_3O^- groups and of the successive conversion of methanol into formaldehyde; the effective activation energies E_a for these two processes are respectively 82 ± 4 and 41 ± 4 kcal mol^{-1} (the latter value virtually agrees with E_a for the formation of CH_3OH, which is 40 ± 2 kcal mol^{-1}).

The 2% V_2O_5/SiO_2 catalyst, in which the deposited component is present as a submonolayer of isolated vanadium ions,[46] also exhibits activity in the formation of partial oxidation products of methane in the presence of N_2O.[47] This system operates at a lower temperture compared with MoO_3/SiO_2; the activation energies E_a for the formation of CH_3OH and CH_2O are respectively 40 ± 4 and 22 ± 2 kcal mol^{-1}. A difference between the mechanisms of the formation of CH_2O on the above systems has been noted: in the case of V_2O_5/SiO_2 there is no successive conversion of CH_3OH into CH_2O and formaldehyde is formed only in the course of the dehydrogenation of the surface CH_3O^- group occurring simultaneously.

The possibility of the conversion of the CH_3O^- group on $Bi_2O_3-SnO_2$ catalysts into both CH_2O (in the absence of water) and CH_3OH (in the presence of water), on the one hand, and into C_2H_6, on the other, has been postulated.[48] In the presence of N_2O at 550 °C, the selectivity with respect to CH_2O on these catalysts can reach 92.2% for a degree of conversion of methane of 2.6%. In the absence of N_2O, methane can be oxidised by the oxygen of the catalyst to CH_2O with a selectivity of about 80%, the activity falling gradually.

The increase in the yield of the methane partial oxidation products in the presence of N_2O as the oxidant has been attributed to the oxidation on the catalyst surfaces of the radical-ions $O^{\cdot-}$, which are capable of abstracting a hydrogen atom from the methane molecules.[49]

It is notable that the mode of the methane oxidation process can change when O_2 is replaced by N_2O. Thus mainly carbon oxides are formed on zeolitic catalysts when O_2 is used;[27] the replacement of O_2 by N_2O leads to the formation of aromatic hydrocarbons, the overall yield at 400 °C on a decationated zeolite with the ratio $Al_2O_3:SiO_2 = 1:68$ can reach 10% for a conversion of methane of 25%.[50] With decrease in the degree of cationation, the yield of hydrocarbons falls.[51]

As already mentioned, when O_2 is used as the oxidant, it is not possible to achieve an appreciable yield of the products of the partial oxidation of methane on oxide and zeolitic catalysts. However, recently major progress has been achieved in effecting another process—the oxidative condensation of methane with formation of C_2 and higher hydrocarbons.

2. Oxidative condensation of methane

(a) Alternate oxidation–reduction of oxide systems

The possibility of obtaining an appreciable yield of the products of the oxidative condensation of methane was apparently first demonstrated in a patent.[52] The process is carried out with methane supplied to solid catalysts containing 0.01–0.2% of a Group VIII or IB metal, chromium and molybdenum oxides, or tungsten, barium, lanthanum, and other oxides on the MgO, TiO_2, ZrO_2, and Al_2O_3 carriers. In particular, when methane is supplied at a temperature of about 700 °C to a specimen obtained by the successive treatment of γ-Al_2O_3 with solutions of magnesium, barium, and chromium nitrates, with an intermediate heat treatment, and then with a solution of H_2PtCl_6, it is possible to obtain 8% of C_2H_4, 3.2% of C_2H_6, 0.056% of C_4H_8, and 14.4% of benzene. Furthermore, 19.3% of methane is converted into condensation products, from which C_2H_4 and C_6H_6 are formed on treatment with water vapour or O_2. The proposed process mechanism involves the formation of dehydrogenated forms on the surface as far as coke and their subsequent interaction with CH_4 to form higher hydrocarbons.

Keller and Bhasin[53] investigated the formation of ethane and ethylene on alternate exposure of metal oxides deposited on α-Al_2O_3 to methane and air. The Mn, Cd, Sb, Tl, Pb, and Mg oxides proved to be the most active and selective at 800 °C. The overall yield of C_2 hydrocarbons on the best specimen, containing manganese, was 5% relative to the methane passed through the system for an 11% conversion. A mechanism was proposed for the formation of the oxidative condensation products:

$$\begin{gathered} CH_4 + M^{(2n)+}O_n^{2-} \rightarrow M^{(2n-2)+}O_{n-1}^{2-} + OH_{ads} + CH_{3,ads}, \\ 2CH_{3,ads} \rightarrow CH_3CH_{3,ads}, \\ 2OH_{ads} \rightarrow H_2O + O_{ads}, \\ 2M^{(2n-2)+}O_{n-1}^{2-} + O_2 \rightarrow 2M^{(2n)+}O_n^{2-}. \end{gathered} \quad (15)$$

Analogous processes leading to the formation of the products of the oxidative condensation of methane with separate supply of methane and oxygen to a solid catalyst have been described in the patent literature.[54–61] The active phase of the catalyst employed contains Mn, Sb, In, Ge, Pb, Sn, and Bi oxides with added alkali or alkaline earth metal cations and phosphate ions on carriers. The selectivity with respect to the sum of hydrocarbons in the first oxidation-reduction cycles can exceed 80% for a methane conversion of about 15%.[55] The Mn/γ-Al_2O_3 catalyst is characterised by a much lower selectivity than Mn/SiO_2.[62] In the latter case, 0.4 ± 0.05 of a gram-atom of oxygen per gram-atom of Mn can be removed reversibly from the catalyst. The increase in the selectivity and stability of the 15% Mn/SiO_2 catalyst when it is modified by the addition of 5% of $Na_4P_2O_7$ [63] has been explained by the decrease in acidity and a change in the phase composition. The introduction of halogen-containing compounds (for example, CH_3Cl) into the stream of methane makes it possible to increase the selectivity to 85–93% for conversions up to 29%.[60]

Although an appreciable yield of the products of the oxidative condensation of methane can be achieved in the processes described, they suffer from two significant disadvantages: the difficulty of achieving in practice an alternating supply of the reactants and a gradual (in many cases extremely rapid) loss of activity by the solid catalyst.

(b) The performance of the process in the continuous regime

After the communications in which the oxidative condensation of methane involving the use of the lattice oxygen of oxide systems was described, data were published on catalysts which made it possible to carry out the process in the continuous regime. For this purpose, use is made of systems which had been employed earlier as sources of lattice oxygen (Mn, Sn, In, Ge, Pb, Sb, Bi, Pr, Tl, Cd oxides on carriers promoted by alkali or alkaline earth metals and stabilised by phosphate ions).[64-67] For example, when a CH_4:air = 1:1 mixture is supplied to a catalyst containing 10% each of Mn (in the form of oxides) and $Na_4P_2O_7$ on SiO_2, the degree of conversion of methane can reach 24.1% for an overall selectivity with respect to C_2 hydrocarbons of 57%.[64]

If N_2O is used as the oxidant, then, for a methane conversion of 28.4%, the selectivity with respect to the sum of C_2 and higher hydrocarbons can reach 68% (800 °C, catalyst—12.5% $NaMnO_4$ on MgO).[65]

In the case of deposited catalysts containing PbO, the highest yield of hydrocarbons is obtained when Al_2O_3 is used as the carrier.[68] At 740 °C, CH_4 and O_2 pressures in the initial mixture of 0.7 and 0.07 atm respectively, and the virtually complete conversion of O_2, the selectivity of the PbO/Al_2O_3 catalysts increases with increase in the PbO content, reaching a maximum value of 57.7% (with respect to the sum of C_2 and C_3 hydrocarbons) for a PbO concentration of 36%. The introduction of 2% of Na_2O into the 6.5% PbO/Al_2O_3 catalyst increases the selectivity with respect to hydrocarbons from 12.9 to 35.4%. The selectivity of catalysts on different carriers decreases in the sequence SiO_2 > Al_2O_3 > aluminosilicates, but the activity of the systems based on SiO_2 is extremely low.

Catalysts obtained by depositing PbO on carriers with a high alkalinity (MgO, CaO, β-Al_2O_3) are even more effective.[69] The conversion of methane and the selectivity with respect to C_2 hydrocarbons on the 5% PbO/MgO catalyst at 750 °C are respectively 13 and 72%.[70] The influence of the basicity of the carrier on the efficiency of the oxidative condensation has been emphasised.[69,70]

After prolonged use of the PbO/Al_2O_3 catalysts at 800 °C (30 h), the selectivity falls from 40 to 7%,[71] which has been attributed to the possible entrainment of lead by the gas stream.

In the series of catalysts containing Ga, In, and Tl oxides on an aluminosilicate carrier (19 mole % SiO_2), the highest yield of C_2 hydrocarbon (2.3%) was observed for the thallium catalysts.[72] Catalysts on aluminomagnesium carriers (20-50 mole % MgO) have a higher activity.

Oxidation catalysts of a new type, not containing metal ions in a variable oxidation state, based on alkaline earth metal oxides modified by alkali metal cations with similar (or smaller) ionic radii were first described and investigated in detail by Lunsford and co-workers.[73-78] These catalysts possess a high activity and selectivity in the oxidative condensation of methane, which has been attributed to the possibility of the formation of substitutional defects in the cationic sublattice and to the appearance of centres of the type Li^+O^-, which can participate in the activation of methane molecules. Thus, on the 7% Li/MgO catalysts, obtained by impregnating MgO with a solution of Li_2O_3 and subsequent heat treatment at 720 °C, the yield of C_2 hydrocarbons, from an initial mixture in which the CH_4 and O_2 pressures were 58 and 36 mm Hg, reached 19.4% (the yield relative to MgO was 1%) and diminished with increase in the reactant concentrations in the initial mixture while their ratio remained constant.[73] With increase in the relative amount of CH_4, the selectivity increases and the degree of conversion falls. CH_3OH and CH_2O are formed in trace amounts. The 15% Na/CaO catalyst also exhibits a high efficiency (the selectivity with respect to hydrocarbons is 52% for a methane conversion of 22%). On the other hand, if the ionic radius of the alkali metal cation is greater than that of the alkaline earth metal cation, the catalytic properties of the system are much worse: on the 20% Na/MgO catalyst, the degree of conversion of methane is 12% and the selectivity with respect to hydrocarbons is 18%.[77]

However, it has been shown, that in the series of catalysts obtained by impregnating MgO with metal (alkali, alkaline earth, transition, etc.) nitrate solutions, specimens containing more than 10% of Na_2O are the most effective: the yield of C_2 hydrocarbons reaches 19.5-22.4% relative to the methane passed through the system at 750-800 °C for a methane concentration in the initial mixture of about 3% (CH_4:O_2 = 2:1).[79] When this method is used to introduce the additive, the lithium-containing catalysts are less effective (the yield of C_2 hydrocarbons at 750 °C is about 9%). The high efficiency of the sodium-containing catalysts has been explained by the influence of Na^+ on the MgO structure.

The study of a large number of metal oxides[80] has led to the conclusion that the highest selectivity is manifested by lanthanide metal oxides (with the exception of Ce, Pr, and Tb). Among them, the most effective is Sm_2O_3, in the presence of which the selectivity with respect to C_2H_6 at low O_2 concentrations (1.6%) can reach 100% at 700 °C.[81]

The modification of Sm_2O_3 by alkali metal ions, carried out by impregnating the catalyst with solutions of their carbonates and subsequent heat treatment, increases the yield of C_2 hydrocarbons.[82] The specimen containing 10 mole % of Li_2O, on which the yield of C_2 hydrocarbons reaches 21% compared with 12% for the unmodified Sm_2O_3 is optimal (750 °C, CH_4 and O_2 pressures in the initial mixture 50 and 20 mmHg respectively).

The modification of Sm_2O_3 with 20 mole % of LiCl instead of Li_2CO_3 [82] increases the yield of C_2H_4 by a factor of 1.5 (to 16.8%) with a slight decrease of the overall yield of the C_2 hydrocarbons. However, such a catalyst, as well as other Sm_2O_3-based systems, works most effectively at low CH_4 and O_2 concentrations: at 750 °C at an overall pressure of 1 atm, and with the ratio CH_4:O_2 = 5:2, the increase in the CH_4 concentration in the initial mixture from 5 to 40% lowers the yield of C_2 hydrocarbons from 15.6 to 7.2% as a result of the decrease in selectivity from 63.4 to 26.9%.

The oxides of other lanthanides also exhibit a higher efficiency at low reactant concentrations: in the presence of La_2O_3, a decrease in the methane pressure in the initial mixture from 313 to 132 mmHg (p_{O_2} = 8.4 and 15 mmHg respectively) increased the yield of C_2 hydrocarbons from 2.53 to 4.4%.[83]

In this respect, lanthanum aluminate, which works effectively in concentrated mixtures, is preferable:[84] at 710 °C in a 1:1 methane–air mixture, the yield of C_2 hydrocarbons was 12.5% for a methane conversion of 25.3%. A disadvantage of this catalyst is its low stability as regards temperature: it loses activity and selectivity even at 800 °C, which has been attributed to the loss of its amorphous structure.[85]

Interesting data have been obtained in studies on transition metal (Ti, Cr, Mn, Fe, Co, Ni, Cu, Zn) oxides modified by alkali metal compounds.[86–88] Systems containing LiCl have the best catalytic properties: whereas the unmodified nickel oxide propagates only extensive oxidation, after the addition of LiCl the overall yield of C_2 hydrocarbons at 750 °C and initial CH_4 and O_2 concentrations of 5 and 2% respectively reaches 28.9% for a C_2H_4 yield of 26.2%. Under the same conditions, the yields of C_2H_4 and C_2H_6 on the 20% $LiCl/MnO_2$ catalyst are respectively 28.1 and 25%. With increase in the reactant concentrations in the initial mixture by a factor of 10, the yield of C_2 hydrocarbons falls approximately by a factor of 1.5.[85]

A serious disadvantage of the catalysts containing alkali metal halides is their rapid deactivation: LiCl containing specimens based on Sm, Ni, and Mn oxides are deactivated in several hours. There is a simultaneous decrease in the ratio C_2H_4/C_2H_6. The deactivation is attributed to the abstraction of chlorine from the catalysts, since CH_3Cl has been detected in the reaction mixture, its amount decreasing in parallel with the loss of activity.[87]

As already mentioned, in the presence of N_2O, the oxidative condensation of methane in the presence of zeolitic catalysts leads to the formation of aromatic hydrocarbons,[50,51] whereas oxidation with oxygen leads to the formation of carbon oxides.[27] Modification of zeolites with manganese promotes the manifestation by the latter of catalytic activity in the oxidative condensation of methane to C_2 hydrocarbons in the presence of O_2.[89,90] The best parameters are attained when manganese-containing catalysts based on the NaH-HSZ † ($SiO_2:Al_2O_3$ = 71) zeolite are used: at 750 °C and with the CH_4:air = 0.83 : 1 ratio, the yield of C_2 hydrocarbons is 9.5%.

Thus a whole series of catalytic systems active in the oxidative condensation of methane are now known. However, the known catalysts suffer from a number of disadvantages, which precludes their practical use:

(1) They all exhibit the optimum efficiency at high temperatures (> 700 °C), which complicates the apparatus needed for the process.

(2) The most effective catalysts work well in mixtures with low CH_4 and O_2 concentrations; as a result, even when the yields of the target products relative to the methane passed through the system are high, their concentration in the reaction mixture is low, which prevents their isolation by the known methods.[91]

(3) The activity and selectivity of many catalysts fall rapidly during their operation because of the entrainment of active components; other catalysts are unstable when overheated, which happens inevitably when the higher exothermic process considered (with a relatively low selectivity) is carried out in a large reactor.

The elucidation of the causes of the above disadvantages and the search for possible ways of eliminating them require the study of the process mechanism.

3. Hypotheses concerning the mechanism of the oxidative condensation of methane

The available literature data on the mechanism of the oxidative condensation of methane relate to the following questions: (1) the nature of the stages involving the activation of CH_4 molecules; (2) the mechanism of the formation of oxidative condensation products; (3) the nature of the active centres of the catalysts.

There exists apparently a unanimous view at the present time concerning the nature of the stage leading to the activation of the methane molecule: it involves the dissociation of a C–H bond with the simultaneous formation of a surface OH group and a methyl fragment. However, the ideas concerning the state of this fragment are different among different workers.

It has been suggested[53,67,92,93] that the CH_3 group bound to the surface is formed in the first stage. On the other hand, in a study of the interaction of CH_4-O_2 and CH_4-N_2O mixtures with catalysts of the oxidative condensation of methane at pressures less than 1 mmHg and temperatures below 450 °C, the liberation of $CH_3^{\cdot}$ radicals into the gas phase was detected by the freezing out method, which indicates the possibility of the formation of radicals not bound to the surface in this stage.[74–76,83]

The possibility of the oxidative condensation of methane via a heterogeneous-homogeneous mechanism was postulated already in one of the first studies on this process.[94] The formation of radicals under the conditions of the catalytic oxidation of methane over a wide temperature range (400–800 °C) at atmospheric pressure has been observed[95] and it has been shown that, in the presence of a more effective catalyst (10 mole % K_2O/Al_2O_3), the rate of formation of radicals is much higher than on a less effective catalyst (θ-Al_2O_3). The formation of radicals has been detected[63] by the lead mirror method in the reduction of the 15% Pb + 5% $Na_4P_2O_7/SiO_2$ system. The volume propagation of the methane oxidation process in the presence of Al_2O_3 and SiO_2 was observed even earlier by methods involving separate calorimetric measurements and the freezing out of radicals,[93] although the products in this study were oxygen-containing compounds.

If the question of pathways leading to the formation of the products of the oxidative condensation of methane in the presence of oxide systems with deposited platinum group metals is ignored,[52] then one must conclude that, according to the majority of investigators, the primary product is ethane. This is indicated by the dependence of the yield of hydrocarbons on temperature and contact time in the presence of MgO-based catalysts[77,96] and catalysts containing Bi_2O_3,[67] PbO,[68] and lanthanide oxides[81,83,84] and also by analogous data obtained in the reduction of Mn/SiO_2 systems with methane.[62,63] It has been noted[97] that the sequence in the formation of C_2 and C_3 hydrocarbons in accordance with the scheme $CH_4 \rightarrow C_2H_6 \rightarrow C_2H_4 \rightarrow C_2H_2$, C_3H_6 ($\rightarrow C_3H_4$) is a general feature of the oxidative condensation of methane on oxide catalysts of different chemical nature. Similar effective activation energies for the formation of ethane—the primary condensation product—have been observed for many catalysts. It amounts to 46.5 ± 1.5 kcal mol^{-1},[98] which is extremely close to the activation energy for the formation of methyl radicals in the presence of the MgO-based catalyst (42 ± 6 kcal mol^{-1} [74]).

The approximate identity of the proportions of the hydrocarbon products in the reduction of various oxide catalysts with methane[62,63] cannot apparently serve as evidence for a heterogeneous-homogeneous process mechanism. A more convincing argument is the closeness of the rates of formation of radicals and oxidative condensation products.[74,95] The homogeneous formation of C_3 and C_4 olefins as a result of the interaction of $CH_3^{\cdot}$ radicals with ethylene and propene respectively is indicated by the sharp increase in their yield when lower olefins are added to methane used to reduce the catalysts.[62,63]

On the other hand, data have been obtained by IR spectroscopy[71] showing the formation on the surfaces of the PbO/Al_2O_3 and Li/MgO catalysts of unidentified surface compounds which can serve, according to the authors, as sources or precursors of ethylene.

† HSZ = high-silica zeolite (Ed. of Translation).

This means that there can exist a parallel pathway leading to the formation of C_2H_4. There are also data according to which methane is converted into ethylene on certain catalysts (for example, $LiCl/Al_2O_3$ [88]) without the formation of appreciable amounts of ethane. The formation of adsorbed CH_3 and CH_2 fragments as well as ethane-like structures has also been observed by Raman spectroscopy in the adsorption of methane on oxidised metallic films at low temperatures.[99]

Thus there exist two views concerning the mechanism of the formation of the products of the oxidative condensation of methane.

(1) The heterogeneous mechanism. The activation of methane is accompanied by the formation of surface CH_3 groups bound to oxygen or metal ions, for example, in the form CH_3O^- [48] or $CH_3^{\delta-}M^{\delta+}$;[67] the interaction of these groups on the surface leads to the formation of ethane, which is successively converted into ethylene. There is a possibility of the parallel formation of ethylene from the surface compounds.[71]

(2) The heterogeneous-homogeneous mechanism. The activation of methane leads to the formation of the $CH_3^{\cdot}$ free radicals (either directly or via the intermediate formation of a CH_3 group bound to the surface[70]); the recombination of the $CH_3^{\cdot}$ radicals in the gas phase results in the formation of ethane, which is successively converted into ethylene as a result of oxidative dehydrogenation on the catalyst.

The choice between these two alternative schemes is of fundamental importance both from the standpoint of the determination of the true process mechanism and from the standpoint of the creation of effective catalysts. If the heterogeneous mechanism is valid, then the catalyst should have the optimum adsorption properties, ensuring the binding of the CH_3 fragments in the necessary form and the possibility of their interaction with formation of ethane (or of its adsorbed precursor). Furthermore, the oxygen present on the catalyst surface must not be too active, so that the bound hydrocarbon fragments are not oxidised to CO and CO_2. In this case, it appears important to examine the nature of the catalyst from the standpoint of its ability to convert the CH_3 groups into electron-deficient or neutral states or states with an electron excess.[70,100] Hence follows the concept of the selection of catalysts on the basis of their acid-base properties.[101] As already mentioned, in a whole series of cases a direct correlation has been observed between the efficiency of the catalysts and their basicity.

On the other hand, according to the heterogeneous-homogeneous mechanism, the efficiency of the catalyst is determined by its ability to generate $CH_3^{\cdot}$ radicals in the gas phase. The possible homogeneous reactions leading to the formation of both the target products (the combination of $CH_3^{\cdot}$ radicals) and of oxygen-containing compounds (the interaction of methyl radicals with O_2 to form the $CH_3O_2^{\cdot}$ radicals) then becomes important for the further course of the process.[77,83,95]

The heterogeneous-homogeneous process mechanism appears more probable at the present time. It is supported by the experimental detection of radicals, formed in the oxidation of methane in the presence of various oxide catalysts, with a direct correlation of the yield of radicals and the efficiency of the catalysts, and by the similarity of the rates of formation of radicals and hydrocarbon products.

The compounds and fragments on the surfaces of catalysts, whose presence has been demonstrated by spectroscopic methods, may not in fact be precursors of the oxidative condensation products but can lead to extensive oxidation. Nor is there reliable evidence of the occurrence of the parallel process involving the formation of ethylene, because in those cases where large amounts of C_2H_4 were formed on the catalysts for a low yield of C_2H_6 the dependence of the yield of products on temperature and contact time was not stated. For low conversions, the primary hydrocarbon product on all the specimens investigated is ethane,[97] as should in fact be the case according to the heterogeneous-homogeneous scheme.

This model can explain also another general feature—the increase in selectivity with increasing temperature for low conversions. In the initial stage of the process, where the only hydrocarbon product is ethane and its successive transformations can be neglected, the set of reactions occurring in the gas phase can be reduced to the following stages:[95]

$$[O] + CH_4 \xrightarrow{k_1} [OH] + CH_3^{\cdot}, \quad (16)$$

$$2CH_3^{\cdot} \xrightarrow{k_2} C_2H_6, \quad (17)$$

$$CH_3^{\cdot} + O_2 \xrightarrow{K_3} CH_3O_2^{\cdot}, \quad (18)$$

$$2CH_3O_2^{\cdot} \xrightarrow{k_4} \text{extensive oxidation products;} \quad (19)$$

$$CH_3^{\cdot} + CH_3O_2^{\cdot} \xrightarrow{k_5} \text{extensive oxidation products.} \quad (20)$$

Analysis of this scheme on the hypothesis that equilibrium has been attained in stage (18) and that the system is quasi-stationary with respect to the sum of the radicals $CH_3^{\cdot}$ and $CH_3O_2^{\cdot}$ makes it possible to obtain an expression for the limiting selectivity S_{lim} determined solely by the processes occurring in the gas phase, provided that the catalyst surface participates only in the radical generation stage (16) and that the parallel extensive oxidation process does not take place on it:

$$S_{lim} = \left[1 + K_3 p_{O_2}\left(\frac{k_4}{k_2} K_3 p_{O_2} + \frac{k_5}{k_2}\right)\right]^{-1},$$

where p_{O_2} is the partial pressure of oxygen, K_3 is the equilibrium constant of stage (18), and k_2, k_4, and k_5 are the rate constants for stages (17), (19), and (20) respectively.

The above expression describes also the temperature dependence of S_{lim}. Since the equilibrium stage (18) shifts to the left with increase in temperature, S_{lim} increases. Experimental data have shown[95] that, on all the catalysts investigated, the observed selectivity for low conversions is below S_{lim}. This indicates the existence of a parallel channel leading to heterogeneous extensive oxidation. Analysis demonstrates that the effective activation energy for the heterogeneous extensive oxidation is as a rule lower than the activation energy for the formation of ethane, which is an additional factor promoting an increase in selectivity with increasing temperature.

There is no unanimous view in the literature concerning the nature of the active centres of the catalysts, which reflects the absence of unanimity as regards the mechanism of the methane activation stage. If it is assumed that bound CH_3 groups, forming ultimately the target products, are present on the surface, then the catalysts should exhibit bifunctionality,[67,70] namely an oxidising capacity (for the dissociation of the C—H bond) and basicity (for the prevention of an electron density deficiency at the CH_3 group). The view has also been expressed[101] that the presence of nucleophilic

(basic) centres is essential for the stabilisation of the proton and the compensation for the energy expended on the heterolytic dissociation of the C–H bond in the stage involving the activation of a CH_4 molecule; in this case the oxidation surface centres should ensure the abstraction of an electron from the CH_3^- group and its transition to an electrically neutral state.

The investigators who adhere to the heterogeneous-homogeneous mechanism[73-77,81,102-104] consider only the nature of the oxidation centres promoting the homolytic dissociation of the C–H bond. Since the oxidation centres occur in both mechanisms, we shall indicate the types of such centres discussed in the literature:

Oxygen bound to readily reducible cations;[53] the participation of oxygen of this type in the process is indicated by the possibility of obtaining oxidative condensation products both under the conditions of alternate oxidation-reduction and under the conditions of continuous catalysis on the same systems.

Oxygen ions O^- existing in the form of the ion pairs M^+O^- (M^+ is an alkali metal ion) in catalysts based on alkaline earth metal oxides modified by alkali metal cations;[73-78] the formation of centres of this type becomes possible in alkaline earth metal oxides as a result of the thermally activated electron transfer from the oxygen anion to the metal cation or due to the presence of a vacancy at a neighbouring cationic site;[74,76] the presence of O^- centres has been postulated also in Sm_2O_3.[81]

O^{2-} ions with reduced coordination in lead, bismuth and magnesium oxide:[76] it may be that centres of this type are identical with the first two types both in PbO and Bi_2O_3,[53] on the one hand, and in the case of alkaline earth metal oxides,[105] on the other.

The peroxide ions O_2^{2-},[98,103,104] which may be stabilised in systems containing alkali and alkaline earth metal cations with large ionic radii.[106]

By analogy with the gas-phase process

$$O^- + CH_4 \rightarrow OH^- + CH_3^{\cdot}, \qquad (21)$$

which occurs at a high rate even at room temperature, it has been suggested that the activation energy for a reaction of this type with participation of the O^- ions of the Li/MgO catalyst surface is also low.[77] The high observed activation energy for the formation of ethane (55 ± 1.6 kcal mol^{-1}) and the increase in selectivity with increase in temperature associated with it have been explained by the difficulty of reactivating the surface centre via the scheme:

$$\begin{aligned} &2Li^+{-}OH^- \rightarrow Li^+{-}O^{2-} + Li^+{-}[*] + H_2O, \\ &Li^+{-}O^{2-} + Li^+{-}[*] + \tfrac{1}{2}O_2 \rightarrow 2Li^+{-}O^- \end{aligned} \qquad (22)$$

or

$$\begin{aligned} &2Li^+{-}OH^- \rightarrow Li^+{-}O^- + Li^+{-}[*]^- + H_2O, \\ &Li^+{-}[*]^- + \tfrac{1}{2}O_2 \rightarrow Li^+{-}O^-, \end{aligned} \qquad (23)$$

where [*] is an oxygen vacancy and $[*]^-$ an oxygen vacancy with a captured electron.

However, this scheme does not agree with the phenomenon, observed by the same workers,[74,75] of the decay of the radical formation process via reactions of types (16) when N_2O is used as the oxidant (in the presence of O_2, there is no decay), because the filling of the oxygen vacancies, formed as a result of the dehydroxylation via schemes (22) and (23), should occur in the presence of N_2O at least no less effectively than in the presence of O_2.

The difficulty of the reoxidation of N_2O is also indicated by the data of Otsuka and Hatano:[107] when O_2 as the oxidant is replaced by N_2O, the conversion of CH_4 in the presence of the Sm_2O_3 catalyst decreases significantly. At the same time, the selectivity at relatively low temperatures (below 680 °C) increases in the presence of N_2O, which is fully explicable within the framework of the heterogeneous-homogeneous mechanism, since the extensive oxidation processes in the gas phase proceed via the $CH_3O_2^{\cdot}$ radicals whose formation is impossible in the absence of molecular oxygen.

As regards the basicity of the catalyst, an alternative explanation of its influence on their efficiency in the oxidative condensation of methane is apparently possible. It has been shown[108] that one of the pathways leading to the formation of the extensive oxidation products may be the decomposition of formaldehyde via the reaction

$$CH_2O \rightarrow CO + H_2. \qquad (24)$$

As already mentioned, the formation of CH_2O in the oxidation of methane takes place most effectively on catalysts with a high acidity.[30-33] The increase in selectivity with respect to hydrocarbons after the introduction of alkaline additives can then be attributed to the decreased contribution of this extensive oxidation channel as a result of the suppression of the acid centres.[68]

Together with the increase in selectivity, after the introduction of alkali and alkaline earth metal cations, an increase in the rate of formation of the products of the oxidative condensation of methane is also observed.[72,98,102] This is associated with the increase in the amount of the active forms of oxygen, for example O^- (in alkaline earth metal oxides with alkali metal additives[73-78]) or O_2^{2-} (in the M_2O/Al_2O_3 [97] and BaO [103,104] systems). Whereas the efficiency of the M_2O/Al_2O_3 catalysts increases under these conditions with increase in the ionic radius of the alkali metal cation,[97,102] the opposite variation is observed for the M_2O/MgO and M_2O/CaO systems,[77,102] which can be readily explained by the influence of the alkali metal cation on the properties of the oxygen of the catalysts. Thus the observed relation between basicity and catalyst efficiency can be purely superficial and may not be determined by the involvement of the basic centres directly in the stage involving the activation of CH_4 molecules. The final elucidation of this question requires additional research.

4. Kinetics of the oxidative condensation of methane

Some light may be thrown on the mechanism of the process by studying its kinetics. Unfortunately, one should note that, on the majority of the catalysts described in the literature, the kinetics of the oxidative condensation of methane have not been studied. The 7% Bi_2O_3–9% K_2CO_3/Al_2O_3 [67] and 34% PbO/Al_2O_3 [68] systems are an exception. Formal power equations of the following type were used for the kinetic description in both cases:

$$r_i = k_i p_{hc}^m p_{O_2}^n, \qquad (25)$$

where r_i is the rate of the ith process, k_i the observed rate constant, p_{hc} and p_{O_2} are the hydrocarbon and oxygen pressures respectively, and m and n are the effective reaction orders with respect to carbon and oxygen respectively.

The kinetic parameters obtained in the above studies[67,68] are listed in Table 1.

The kinetic parameters quoted in these studies[67,68] have been scarcely discussed apparently because of their formal character and low information content. The activation energies for the formation of CO, determined by Hinsen et al.,[68] illustrate qualitatively the observed increase in selectivity in the temperature range up to 700–750 °C without, however, any explanation of this finding.

Table 1. Kinetic parameters of the overall stages of the oxidative condensation of methane on the 7% $Bi_2O_3-K_2CO_3/Al_2O_3$ (I) [67] and 20% PbO/Al_2O_3 (II) [68] catalysts.

Stage	Catalyst					
	I				II	
	m	n	m	n	E, kcal mol^{-1}	k_i
$CH_4 \rightarrow C_2H_6$	2	1	1.1±0.3	0.8±0.2	24	$6.0\cdot10^4$
$CH_4 \rightarrow CO_2$	0.3	1	1.5±0.3	0.4±0.1	12	$1.5\cdot10^6$
$C_2H_6 \rightarrow C_2H_4$	1	2.5	1±0.2	0.8±0.1	1.5	$1\cdot10^2$
$C_2H_6 \rightarrow CO_2$	0	1.4	—	—	—	—
$C_2H_4 \rightarrow CO_2$	0	0.6	1.6±0.3	0.8±0.3	−52	$1\cdot10^{-10}$

The kinetics of the oxidation of methane on the 20% PbO/Al_2O_3 catalyst have been studied in detail.[95,104] For low conversions, taking into account the contribution of the homogeneous stages, the rate of the process in the ethane formation pathway is described by the kinetic equation characteristic of processes occurring via an oxidation-reduction mechanism:

$$r_1 = \frac{k_r p_{CH_4} k_{ox} p_{O_2}}{k_r p_{CH_4} + k_{ox} p_{O_2}}, \quad (26)$$

where k_r and k_{ox} are the rate constants for the reduction of the active centres by methane and for their reoxidation by oxygen respectively and p_{CH_4} and p_{O_2} are the methane and oxygen pressures respectively.

The kinetics of the conversion of ethane into ethylene on this catalyst are described by an analogous equation, which can be obtained on the assumption that two oxidised centres participate in the process:

$$r_2 = \frac{4k'_r p_{C_2H_6} k_{ox}^2 p_{O_2}^2}{(k_{ox} p_{O_2} + (k_{ox}^2 p_{O_2}^2 + 8k'_r p_{C_2H_6} k_{ox} p_{O_2})^{-1/2})^2}, \quad (27)$$

while k'_r is the rate constant for the reduction of the active centres by ethane and $p_{C_2H_6}$ is the ethane pressure.

The reoxidation rate constants, found in experiments with methane and ethane, proved to be extremely close, from which it was concluded that the same active centres are involved in both processes. The rate constants for the interaction of ethane with oxidised active centres were 10–20 times higher at identical temperatures than the corresponding constants for methane. From the pre-exponential factor for the constant k_r (assuming the impact character of the reduction stage), it was found that the surface concentration of the active centres is 0.3% of a monolayer on the catalyst surface.

Analysis of Eqn. (26) made it possible to explain the similarity of the effective activation energies E_{eff} for the formation of ethane on different catalysts.[95] It was shown that the following expression is valid for E_{eff}:

$$E_{eff} = \frac{\kappa E_r + E_{ox}}{1 + \kappa} \quad (28)$$

where E_r and E_{ox} are the activation energies for reduction and reoxidation respectively and $\kappa = k_{ox} p_{O_2} / k_r p_{CH_4}$.

For κ not differing greatly from unity, E_{eff} is close to half the sum of E_r and E_{ox}. On the other hand, if E_{ox} increases linearly with decrease in E_r, then E_{eff} is approximately constant in the series of catalysts. When one of the processes—reduction or reoxidation—takes place at a significantly lower rate than the other, the rate of the overall process is naturally determined by the kinetic parameters of the slower stage. Thus it has been shown[104] that in the case of BaO the reoxidation stage is slow which induces an increase in E_{eff} to a value in excess of 60 kcal mol^{-1}.

According to Sinev et al.,[98] the rates of the extensive oxidation of methane and ethane on the 20% PbO/Al_2O_3 catalyst are described by kinetic equations of the Langmuir type, which indicates the involvement of adsorbed forms in the reaction. This means that the mechanisms of the oxidative condensation and extensive oxidation differs significantly.

5. Reactions of methane on photoactivated and mechanically activated oxides

Additional information about the mechanism of the process considered has been obtained in studies on oxide systems subjected to photochemical[109–114] and mechanochemical[115–118] activation.

The action of radiation (in the visible, UV, X-ray, and γ-ray ranges) on TiO_2 [109–111] and other simple oxides[112,114] and also on SiO_2 and Al_2O_3 modified by vanadium and molybdenum ions[109,113] leads to the photosorption of methane. When the system is heated, C_2 and C_3 hydrocarbons as well as CH_3OH and C_2H_5OH appear in considerable amounts in the thermal desorption spectrum in addition to methane and carbon oxides. A certain amount of other hydrocarbons can be collected in a cooled trap even when methane is passed over photoactivated specimens at room temperature,[110] which indicates an extremely low activation energy for their formation. The principal characteristics of the photostimulated condensation of methane have been formulated by Kotova.[114]

(1) In the photoreactions of methane on oxides, two competing processes occur simultaneously: the formation of hydrocarbons and the formation of oxygen-containing compounds. On irradiation in the region of the intrinsic absorption by the oxide, the second process predominates, while outside this region (in the region where the defects absorb) the first process is dominant.

(2) The first stage of the process is homolytic dissociation of the C–H bond; the dissociative adsorption of hydrocarbons is accompanied by the formation of excited surface OH groups.

(3) After a time, the surface is poisoned by the reaction products and the efficiency of the photoconversion of methane decreases; the surface can be regenerated by a high-temperature treatment in oxygen.

(4) The presence of H_2 and O_2 in the system decreases the yield of hydrocarbons.

(5) There exist analogous dark reactions of methane, which may indicate the similarity of the mechanisms of the dark conversion and photoconversion of methane. It has been suggested that weakly coordinated oxygen ions in a charged state close to −1, whose properties are analogous to those of photoinduced hole O^- centres, participate in the dark process.

Thus data on the photoreactions of methane also indicate the involvement of weakly coordinated oxygen of the oxides and centres of type O^- in its activation. The direct use of these data for the description of the mechanism of the catalytic oxidative condensation of methane is precluded by the fact that, among the systems investigated in photostimulated processes, only La_2O_3 is effective in the usual catalytic reaction.[83] The dark reactions of methane leading to its conversion into other hydrocarbons have been observed on Ga_2O_3, SnO_2, and α- and η-Al_2O_3,[114] which are poor catalysts of oxidative condensation. Furthermore, the postulated intermediate carbon-containing compounds have not been detected experimentally and the mechanisms discussed are hypothetical.

The study of the centres formed on oxides surfaces disordered by mechanical activation (in the first place on SiO_2 and GeO_2 [115–118]) has shown that some of them are very highly reactive in relation to molecule such as those of H_2 and lower paraffins and are capable of inducing the dissociation of H−H and C−H bonds. Such centres include strained Si−O−Si bridges, the radical centres $-\overset{\diagdown}{\underset{\diagup}{\dot{S}i}}$, $-\overset{\diagdown}{\underset{\diagup}{Si}}\dot{O}$, and $-\overset{\diagdown}{\underset{\diagup}{Si}}O\dot{O}$,[117] as well as groups of the peroxide type $-\overset{\diagdown}{\underset{\diagup}{Si}}-O-O-\overset{\diagup}{\underset{\diagdown}{Si}}-$.[118] The interaction of methane with these centres proceeds via reactions of type (16), the oxy-radicals $SiO^\cdot$ and $-\overset{\diagdown}{\underset{\diagup}{Ge}}O^\cdot$ (in the case of GeO_2) being most active. The $CH_3^\cdot$ radicals are formed on them with an exothermic effect of 14–17 kcal mol^{-1} and an activation energy close to.[117] The methyl fragments formed are bound to centres of different types, present in a large amount on the mechanically activated surface (=Si:, $-\overset{\diagdown}{\underset{\diagup}{Si}}O\dot{O}$, $-\overset{\diagdown}{\underset{\diagup}{Si}}-O-\overset{\diagup}{\underset{\diagdown}{Si}}-$, $-\overset{\diagdown}{\underset{\diagup}{Si}}-O-O-\overset{\diagup}{\underset{\diagdown}{Si}}-$) and undergo further reactions (more far reaching dehydrogenation and decomposition accompanied by isomerisation[117]). It is notable that methyl radicals have also not been detected in these investigations, although the authors identified by EPR a series of paramagnetic products of their interaction with various surface centres (=$SiCH^\cdot$, $-\overset{\diagdown}{\underset{\diagup}{Si}}CH_2^\cdot$, $-\overset{\diagdown}{\underset{\diagup}{Si}}OCH_2^\cdot$).

Unfortunately the centres formed on mechanically disordered surfaces are thermally unstable (because of their non-equilibrium nature) and are annealed at lower temperatures than those at which oxidative condensation of methane takes place. This factor as well as the absence of information in the relevant communications[115–118] about the hydrocarbon methane conversion products necessitates some caution in using the above data for the description of the mechanism of the oxidative condensation.

The mechanism of the formation of C_2 hydrocarbons in the presence of oxides modified by alkali metal halides apparently appears to be somewhat different.[82,86–88] However, in this case too a heterogeneous-homogeneous process is most likely with the participation of an atomic halogen, for example chlorine, in the initiation stages:

$$Cl + CH_4 \rightarrow HCl + CH_3^\cdot, \quad (29)$$

$$Cl + C_2H_6 \rightarrow HCl + C_2H_5^\cdot. \quad (30)$$

Chlorine atoms can be formed both in the decomposition of Cl_2 molecules formed via the Deacon reaction

$$2HCl + O_2 \rightarrow H_2O + Cl_2, \quad (31)$$

and in the direct oxidation of the alkali metal chloride melt on the oxide surface. The possibility of the oxidative condensation of methane via the oxidation of halides analogously to the hydroxychlorination of hydrocarbons is indicated by the high efficiency of the same transition metal oxides with added alkali metal halid salts in both reactions.

At high temperatures and appreciable concentrations of water in the reaction mixture, the reversible hydrolysis of the halides (for example, LiCl), i.e.

$$2LiCl + H_2O \rightleftharpoons Li_2O + 2HCl \quad (32)$$

can maintain the optimum concentration of HCl in the system, ensuring both its supply to the gas phase in order to effect reaction (31) and its binding, which precludes its being carried away from the reaction zone. However, at high concentrations of the $CH_3^\cdot$ radicals and $Cl^\cdot$ atoms, there is a high probability of the reaction

$$CH_3^\cdot + Cl^\cdot \rightarrow CH_3Cl, \quad (33)$$

which leads to the active component being carried away and to the loss of catalytic activity.[88]

- - - o 0 o - - -

The available literature data on the reactions leading to the conversion of methane into methanol, formaldehyde, and hydrocarbons, including unsaturated and aromatic hydrocarbons, show that heterogeneous-catalytic processes constitute the most promising method for the conversion of methane into intermediate products of organic and petrochemical synthesis.

Many oxide systems exhibit catalytic activity in the oxidative condensation of methane to other hydrocarbons. However, virtually all the known catalysts suffer from the same disadvantages, which preclude the practical realisation of the process. The most effective catalysts afford the maximum yield of the target products at 700–750 °C, i.e. at an extremely high temperature.

According to its nature, the process is heterogeneous-homogeneous, which may lead to an appreciable influence of the reactor material and its parameters, especially at high temperatures. The highest yields of C_2 hydrocarbons have been observed, as a rule, in quartz reactors. The practical realisation of the process necessitates the use of metallic reactors and it is to be expected that at temperatures of 600 °C and above the rate of the extensive oxidation of methane will increase under the influence of the reactor material and hence selectivity will fall appreciably.[53]

This difficulty can be overcome, on the one hand, by creating highly efficient catalysts capable of propagating the process at lower temperatures and, on the other hand, by suppressing the activity of the reactor walls with respect to the extensive oxidation of methane.

The problem of the increase in the volume concentration of the products of the oxidative condensation of methane, which would greatly facilitate the task of their isolation and would increase the economic effectiveness of the process, is no less important. It is therefore necessary to achieve the stable operation of the catalyst at a high concentration of the reactant in the initial mixture.

The use of oxide systems, in which lattice oxygen exhibits a high mobility and activity, may prove promising. The oxidative condensation of methane on such catalysts under the conditions of alternate reduction-oxidation would permit the attainment of the maximum possible volume concentrations of useful products.

Despite the complexity of the catalytic activation of methane, the advances achieved in this field, especially as regards the oxidative condensation of methane, permit one to hope that practical solution to the problem will be found in the near future. This will be assisted by broadening the research into the mechanism and kinetics of the catalytic oxidation of methane.

The role of the adsorbed forms of hydrogen and oxygen in the reaction of oxygen-containing one-carbon molecules on membrane catalysts

V M Gryaznov, S G Gul'yanova, Yu M Serov
Patrice Lumumba University of Friendship Among Nations, Moscow

ABSTRACT. The role of various adsorbed forms of hydrogen and oxygen in hydrogenation and oxidation reactions respectively on palladium alloy and silver membrane catalysts is examined. The possibility of altering the ratio of the concentrations of hydrogen and oxygen on the working surface and in the layer near the surface of the catalyst after the introduction of these substances into the reaction zone, either by means of diffusion through the bulk of the metal or as part of a mixture with oxygen-containing one-carbon molecules, is demonstrated. When the above ratio is altered, there is a change in the selectivity and activity of the corresponding catalysts.

I. Introduction

The interaction of diatomic gases with the surface of a metal can be accompanied by their molecular adsorption, subsequent dissociation of the adsorbed molecules, and also surface diffusion of the adsorbed atoms and in certain cases their dissolution in the bulk of the metal. The last phenomenon is manifested most strikingly in the hydrogen–palladium and oxygen–silver systems. The high solubility and mobility of the hydrogen and oxygen atoms in palladium and silver respectively, combined with the catalytic activity of palladium in hydrogenation and dehydrogenation reactions and of silver in oxidation reactions, made it possible to create on the basis of these metals membrane catalysts which permit the introduction of one of the reactants into the reaction zone by diffusion through the metal.[1,2] Depending on the thickness of the membrane, the state of its entry and exit surfaces as regards the permeating gas, and the nature of the gases in contact with these surfaces, the rate of transfer of the gas through the metal may be limited[3] both by one of the stages indicated above and by the release of the diffuse species from the bulk of the metal onto the surface, surface diffusion, the recombination of atoms to molecules, and the desorption of the latter to the gas phase.

Thus, when a diatomic gas is introduced, it is possible to generate on the catalyst surface concentrations of adsorbed species which differ from the concentrations of the same species when hydrogen or oxygen are introduced in a mixture with substances to be hydrogenated or oxidised respectively.

The catalytic hydrogenation of carbon oxides is of interest in connection with the search for the possible replacement of the petroleum raw material, while the oxidation of methanol is an important industrial process requiring detailed investigation. When these reactions are carried out, the different ways of supplying hydrogen or oxygen to the catalyst surface can provide new information about the influence of the type of adsorbed forms on the catalytic reactions.

II. Diffusion of hydrogen through palladium membranes

For thick membranes at fairly high temperatures and hydrogen pressures, the rate-limiting stage is the diffusion of hydrogen through the bulk of the metal.[4] In the case of thin membranes at lower temperatures and low hydrogen pressures, the processes occurring at the gas–metal interface are rate-limiting.

The study of the interaction of hydrogen with the (110) and (111) faces of a palladium single crystal by the slow electron diffraction method[5] showed that the dissociative adsorption of hydrogen does not require an activation energy, while the presence of the hydrogen dissolved in palladium does not influence the structure of its adsorption layer. Moreover, it has been shown that the removal of the adsorbed hydrogen promotes its inflow to the surface from the bulk of the metal. On the other hand, the desorption of hydrogen at 368–413 K requires an activation energy of about 80 kJ mol^{-1} and takes place via the recombination of two adsorbed atoms, the adsorption centres being located in hollows between the surface palladium atoms.[6]

Data concerning the influence of the adsorbed hydrogen on the electronic work function[7–9] show that the sign of the charge on the adsorbed structures depends on the degree of surface coverage of palladium. At low coverages (up to 0.05), predominantly the negatively charged form $H^{\delta-}$ is formed, while with increasing coverage a layer of the positively charged form $H^{\delta+}$ is produced. The same result has been observed also on the exit surface of a palladium membrane in the diffusion of hydrogen. According to Cattania et al.,[10] the study of thermal desorption from the surface of palladium makes it possible to observe four different states of

hydrogen: two of these are the states of the surface chemisorbed forms and two others refer to hydrogen under the external layer of metal and are associated with the dissolution of hydrogen. According to Dus,[7] one of the surface forms of hydrogen, namely the positively charged form, can dissolve in palladium.

Thus one can postulate that the positively charged atomic form of hydrogen, which exists in the layer at the surface in a state subsequently designated by $H_b^{\delta+}$, participates in its transport through the palladium membrane. When thin palladium membranes are used, the transport process in the bulk of the metal can be fairly rapid, while the release from the surface layer onto the surface encounters certain difficulties. The concentration of the $H_b^{\delta+}$ species in the surface layer is then greater than under conditions where the exit surface of the membrane comes into contact with hydrogen at the same partial pressure in the absence of the diffusion flux. Probably, when the hydrogen pressure at the exit surface of the membrane is high and the degree of coverage of this surface by hydrogen is therefore considerable, the hydrogen is adsorbed mainly in the positively charged form which can be designated by $H_a^{\delta+}$.

III. The influence of the method of introduction of hydrogen into the reaction zone on the hydrogenation of carbon monoxide in the presence of palladium alloys

Since the permeation of hydrogen through thin membranes is limited by stages recurring at the gas–metal interface, the ratio of the concentrations of the hydrogen forms $H_a^{\delta+}$ and $H_b^{\delta+}$ depends on the composition of the membrane catalyst, the state of its surface, temperature, the partial pressures of the reactants, their adsorption capacities, and also on the method of introduction of the initial substances into the reaction zone. If hydrogen enters the reaction zone as a result of diffusion through the membrane catalyst, then the ratio $H_a^{\delta+}/H_b^{\delta+}$ is smaller than in the case where hydrogen is supplied to the working surface of the membrane catalyst in a mixture with the substance to be hydrogenated. This has been confirmed by data[11,12] obtained in a study of the hydrogenation of carbon oxides on a palladium alloy in membrane catalysts, where the method of supplying hydrogen to the working surface was varied.

The catalysts were foils and thin-walled tubes made of binary palladium alloys. In experiments with tubes when hydrogen was supplied to the reaction zone via diffusion, the inner surface of the tubes served as the entry side, while the substance to be hydrogenated was supplied to the outer side of the tube. In experiments on the hydrogenation of a mixture of the given substance with hydrogen, the gas having a specified composition passed to the outer surface of the tube while an inert gas was present inside the tube in a closed volume. The catalysts in the form of foil were placed in a stainless steel reactor and were fixed so that two identical chambers were formed. In order to carry out experiments under diffusion conditions, hydrogen was supplied to one of the chambers, while the substance to be hydrogenated was introduced into the other. The mixture was made to react in one of the chambers, while the other contained helium.

In the hydrogenation of carbon monoxide on binary palladium alloy membrane catalysts with 10 wt.% of ruthenium or with 6 wt.% of nickel[11] in the temperature range 523–683 K, methane, ethane, ethylene, water, and carbon dioxide were detected among the reaction products. The method of introduction of hydrogen into the reaction zone and the catalyst composition did not alter the nature of the products, but they did influence the rate of their formation (Tables 1 and 2).

The rate of formation of ethane and methane in the reaction of carbon monoxide with hydrogen diffusing through a palladium–ruthenium membrane catalyst was appreciably lower than in the hydrogenation of CO in a mixture with hydrogen (Table 1). Conversely, the rate of formation of ethylene when the reaction was carried out under diffusion conditions was much higher than in the hydrogenation of the mixture. It is quite likely that the $H_b^{\delta+}$ form present under the layer of surface atoms participates in the formation of the olefin, the amount of this form being greater when hydrogen is introduced into the reaction zone via diffusion through the membrane catalyst, while in the formation of alkanes the main role is assumed by hydrogen in the $H_a^{\delta+}$ form, the amount of which on the surface is greater in the hydrogenation of CO in a mixture with hydrogen. The fact that, regardless of the method of introduction of hydrogen into the reaction zone, the rate of formation of ethane is always lower than the rate of formation of methane evidently demonstrates that the addition of atomic hydrogen to the CH_3

radicals is faster than the dimerisation of the latter if it is assumed that CH_x radicals are formed via the hydrogenation of the surface carbon.

The differences between the hydrogen permeabilities of the palladium–ruthenium and palladium–nickel alloys[13] affect the concentrations of the adsorbed forms of hydrogen and their ratios. The activation energy for the permeation of hydrogen through a palladium–nickel alloy is greater than through a palladium–ruthenium alloy. This is apparently one of the main reasons why the rate of formation of methane when hydrogen is supplied via diffusion through a palladium–nickel alloy increases with increase in temperature to a greater extent than under analogous conditions on a palladium–ruthenium alloy (Table 1) and at 683 K exceeds the rate of formation of methane under the same conditions in the reaction of a mixture of CO and H_2.

The rates of formation of ethylene in the hydrogenation of carbon monoxide by diffusing hydrogen are higher on both catalysts over the entire experimental temperature range than in the case where a mixture of CO and H_2 is supplied. An analogous dependence of the rate of formation of ethane on the way in which the reaction is carried out on the palladium–nickel catalyst is probably due to the fact that the ethane is formed from ethylene via the hydrogenation of the latter.

Table 2 shows that the highest rates of formation of carbon dioxide were observed when carbon monoxide came into contact with palladium alloys in the absence of hydrogen. The latter suppressed the disproportionation of CO most effectively when it was introduced into the reaction zone via diffusion. The decrease in the rate of formation of carbon dioxide in the presence of hydrogen is apparently associated with the occurrence of a process in which the adsorbed oxygen species, formed on dissociation of CO, react with the hydrogen atoms to form water. The dependence of the rate of disproportionation of the way in which hydrogen is introduced into the contact zone also indicates a change in the ratio of the different adsorbed forms of hydrogen on the working surface. In all probability, adsorbed hydrogen atoms, localised in the surface layer of the alloy ($H_b^{\delta+}$), interact preferentially with the adsorbed atomic forms of oxygen.

The formation of carbon dioxide in the interaction of CO with palladium alloys in the absence of hydrogen indicates the dissociation of carbon monoxide. One can therefore postulate that hydrocarbons are formed from CO and H_2 on palladium alloys via the hydrogenation of the surface carbon formed on dissociation of carbon monoxide, which agrees with literature data.[14]. As shown above, the rate of formation of a particular hydrocarbon depends on the relative amounts of the different forms of hydrogen adsorbed on the working surface of the catalyst, which interact with the carbon monoxide dissociation products.

A study has been made to elucidate the role of the hydrogen entering the surface of the catalyst from its bulk phase.[15] A palladium–nickel foil was treated with hydrogen, after which its supply was stopped and CO was brought up to the working surface. Methane, ethane, ethylene, carbon dioxide, and water were found among the reaction products. As can be seen from Figure 1, a decrease in the rate of formation of methane and ethane begins immediately after the supply of carbon monoxide is begun, while the rate of formation of ethylene remains constant for almost 1.5 h and only then diminishes. This confirms the hypothesis that the $H_b^{\delta+}$ form of hydrogen participates in the formation of ethylene from carbon monoxide on the palladium–nickel catalyst. The decrease in the rate of formation of methane from the very beginning of the reaction indicates its involvement in the synthesis of the $H_a^{\delta+}$ form of hydrogen. The content of the latter on the surface diminishes rapidly after a time, since the $H_a^{\delta+}$ form is produced as a result of the transfer of the hydrogen dissolved in the metal onto the surface, which is in all probability the rate-limiting stage of the hydrogen transfer through a thin palladium–nickel membrane under the given conditions. The analogy in the character of the variation of the rates of formation of ethane and methane may be attributed to the fact that hydrogen adsorbed in the $H_a^{\delta+}$ form also participates in the formation of ethane from ethylene under the conditions investigated.

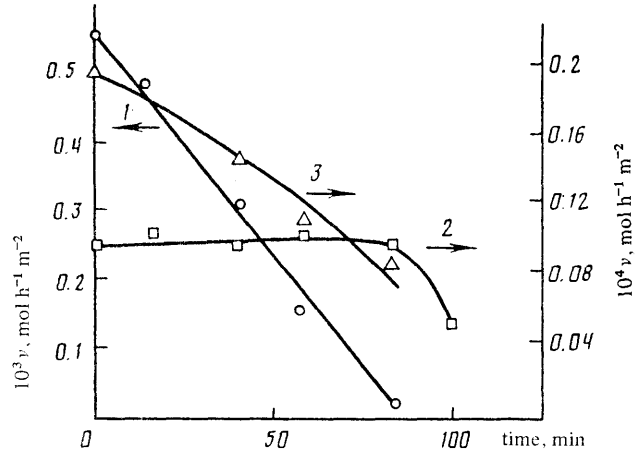

Figure 1. Time variation of the rates v of formation of methane (curve *1*), ethane (curve *2*), and ethylene (curve *3*) in the hydrogenation of carbon monoxide with hydrogen, dissolved beforehand in a palladium–nickel alloy, at 593 K.[15]

	683	288.7	238.7

*The activity was calculated from the sum of the rates of formation of the carbon-containing reaction products.

The overall catalytic activities of the binary palladium–ruthenium and palladium–nickel alloys (Table 3) can be calculated from the data presented in Tables 1 and 2. The overall activity of the palladium–nickel alloys depends only slightly on the way in which

hydrogen is introduced into the reaction zone, while the palladium–ruthenium catalyst is much more active in the hydrogenation of CO in a mixture with hydrogen than in its hydrogenation by the diffusing hydrogen, mainly as a result of the higher rate of formation of CO_2 and methane. In the reaction of a mixture of carbon monoxide and hydrogen, the activity of the palladium–nickel catalyst is much lower than that of the palladium–ruthenium alloy because of the lower rates of formation of carbon dioxide and methane in the presence of the former catalyst. When hydrogen is supplied into the reaction zone via diffusion, the activities of the palladium–nickel and palladium–ruthenium catalysts differ only slightly at 583–683 K.

The influence of the second component of the palladium alloy on its catalytic activity can be attributed both to a change in the concentrations of the different forms of adsorbed hydrogen and to the character of the adsorption of CO, which is indicated by data on the disproportionation of carbon monoxide in the absence of hydrogen (Table 2).

IV. Hydrogenation of carbon dioxide on membrane catalysts

The change in the ratio of the atomic forms of hydrogen on the working surface of the catalyst also affects the yield of the carbon dioxide hydrogenation products. It has been shown[16] that the maximum yield of methane when hydrogen is supplied via a palladium–ruthenium alloy membrane coated electrochemically by ruthenium is twice as high as in the hydrogenation of carbon dioxide in a mixture with hydrogen under the same conditions.

The state of the working surface of the catalyst and its chemical composition also influence the activity of the membrane catalyst. The study of the interaction of carbon dioxide with hydrogen which has diffused through a palladium–ruthenium alloy membrane catalyst showed that the activity of the latter is low in the hydrogenation of carbon dioxide to methane. The electrochemical deposition of a ruthenium layer[16] on the hydrogen exit surface of the palladium–ruthenium membrane catalyst increased sharply (by three orders of magnitude) the yield of the carbon dioxide hydrogenation products, among which ethane, carbon monoxide, and water were detected. Over the entire temperature range from 523 to 773 K, the rate of formation of methane increases with increase in the amount of hydrogen supplied through the membrane, which is consistent with literature data,[17] according to which the conversion of carbon dioxide into methane proceeds more vigorously on a ruthenium surface saturated beforehand with atomic hydrogen than on a clean ruthenium surface.

Thus the deposition of a layer of substance catalytically active in a specific reaction on a hydrogen-permeable membrane extends the possibilities of membrane catalysts. Nickel as well as ruthenium belongs to the group of the most active methane formation catalysts. The electrochemical deposition of a nickel layer 5×10^{-7} m thick on the exit surface of a palladium–ruthenium membrane catalyst[18] did not alter its permeability to hydrogen or the activation energy for the diffusion of hydrogen, which indicates a porous structure of the nickel layer and an insignificant influence of the latter on the transfer of hydrogen through the palladium–ruthenium alloy. During the hydrogenation of carbon dioxide with hydrogen, diffusing through such a catalyst, at 553 K and above, methane is formed, while an increase of temperature by a further 100 K leads to the appearance of carbon monoxide and small amounts of C_2–C_4 hydrocarbons. The rate of formation of methane in the hydrogenation of a mixture of carbon dioxide and hydrogen is always lower than the values obtained under the same conditions when hydrogen is supplied by diffusion.

The study of the temperature variation of the rate of formation of methane has shown[18] that the experimental activation energy for the reaction changes at 578 K, which may be due to a transition from the ferromagnetic to the paramagnetic state of the Ni–Pd–Ru layers formed near the nickel grains on the palladium–ruthenium foil as a consequence of the diffusion of the metal atoms. The change in activation energy may be associated with a magnetic transformation in pure nickel. Thus the presence of a thin layer of disperse nickel leads to magnetocatalytic effects without affecting the permeability of the palladium–ruthenium alloy to hydrogen.

The deposition of a lanthanum-containing nickel coating on the hydrogen exit surface of a palladium–ruthenium membrane catalyst[19] increased the rate of hydrogenation of carbon dioxide to methane compared with the rate of formation of methane on the same catalyst without the modifying element. However, the rate of reaction in the presence of lanthanum increased only in the temperature range from 573 to 663 K. Further increase of temperature resulted in a sharp fall of the rate of formation of methane, probably as a consequence of the formation of the catalytically inert lanthanum carbonate. The high stability of the latter precludes the regeneration of the catalyst.

As a result of the electrochemical deposition of a rhodium coating on a palladium–ruthenium membrane catalyst,[20] methane did not begin to form until 688 K, and although its content in the reaction products did increase with increase in temperature, it was appreciably (almost by a factor of four) smaller than the amount of carbon monoxide formed, traces of which were observed already at 473 K. An increase in the partial pressure of hydrogen at the hydrogen exit surface of the membrane catalyst from 200 to 725 mmHg increased somewhat the yield of methane and did not affect the yield of carbon monoxide. The formation of hydrocarbons with higher molecular weights was not observed.

Thus the method of introduction of hydrogen into the reaction zone as well as the deposition of dispersed layers of active metals on the hydrogen exit surface of the membrane catalyst influence the ratio of the concentrations of different forms of adsorbed hydrogen, which alters the selectivity and activity in the carbon dioxide hydrogenation process.

V. The role of adsorbed oxygen in the oxidation of methanol

Silver foil, which makes it possible to introduce oxygen into the reaction zone via diffusion through the metal, may be used as a membrane oxidation catalyst. The process involving oxygen transfer through silver membranes may include the same series of stages as the adsorption of oxygen on silver, in the forward and reverse sequences.[21] The adsorption of oxygen on silver in the temperature range from 453 to 623 K is known[22] to proceed in accordance with the scheme

$$O_{2\,gas} \rightarrow O_{2\,ads}^{-} \rightarrow 2O_{ads}^{-} \rightarrow 2O_{lat}^{2-}.$$

However, the rate-limiting stage in the transfer of oxygen through silver may not be the same as in the adsorption of oxygen from the gas phase.

The study of the permeability of silver tubes with walls 10^{-4} m thick to oxygen showed[23] that it is proportional to the square root of the oxygen pressure at the oxygen entry surface of the tube. This indicates the involvement of oxygen atoms in the rate-limiting stage of the transfer of oxygen through silver. The electrochemical deposition of a layer of silver on the oxygen exit surface of a silver membrane increases its permeability to oxygen by more than an order of magnitude,[24] but the linear dependence of this parameter on the square root of the oxygen pressure at the entry surface of the membrane is retained. All these factors show that the rate-limiting stage in the transfer of oxygen through thin silver membranes is the process occurring on the oxygen exit surface in which oxygen atoms participate.

The states of the oxygen, arriving via diffusion through membranes or as a result of adsorption from the gas phase, on the exit surface of the membrane have been investigated mass-spectrometrically[25] using a modernised ion source. In the immediate vicinity of the mass spectrometer ion source, a silver tube with walls 10^{-4} m thick was placed and the composition of the gas phase in contact with its outer surface was investigated. Furthermore, an additional cathode and potential-carrying grids were introduced into the ion source, which made it possible to investigate the species adsorbed on the outer surface of the silver tube by the method of the electron-stimulated desorption of ions (ESDI). Two peaks can be observed in the mass spectrum of gaseous oxygen: the molecular (O_2^+) peak with a mass number of 32 and a fragment (O^+) peak with a mass number of 16. The ratio of the intensities of these two peaks (I_{32}/I_{16}) was found to be close to 20 by the usual gas analysis. As can be seen from Table 4, approximately this value has been recorded when oxygen was admitted directly onto the outer surface of the silver membrane in the ionisation chamber. A similar value was also obtained when oxygen was supplied by diffusion through a silver tube at 665 K. However, in this case the decrease in the temperature of the membrane was accompanied by a decrease in the I_{32}/I_{16} ratio, which indicates the appearance in the gas phase of an additional source of oxygen atoms. These may be the atoms desorbed from the surface. The proximity of the membrane to the ionisation region makes it possible to record them. An analogous effect has been observed in a study by the ESDI method, which is probably associated with the enrichment of the exit surface of the silver membrane during the diffusion of oxygen through it in adsorbed forms, which on electron bombardment of the surface are capable of being desorbed to the gas phase in the form of the positively charged O^+ ions.

Since the entire oxygen which has diffused through the silver membrane passes to the ionisation chamber, the intensities of the molecular (O_2^+) and fragment (O^+) oxygen peaks are proportional to the permeability of the given silver membrane to oxygen under stationary conditions.

The activation energy calculated from the temperature variation of the intensity of the peak with a mass number of 32 exceeds the corresponding value found by measuring the height of the peak, with a mass number of 16, the same effect being observed for both methods of analysis. Presumably, in the diffusion of oxygen into a vacuum through a thin silver membrane, its exit surface is enriched in atoms capable of being desorbed into the gas phase on electron impact, the number of such species increasing with decrease in temperature. Furthermore, at low temperatures the surface diffusion process as a result of which the lattice oxygen passes to the adsorbed state, preceding the recombination stage, is hindered and the release of atoms into the gas phase becomes possible which, as already stated above, is the cause of the decrease in the ratio I_{32}/I_{16} (Table 4) and also of the lower activation energy calculated from the variation of the intensity of the peak with a mass number of 16.

Table 4. The ratios of the intensities of the mass spectrometric peaks with mass numbers 32 and 16 (I_{32}/I_{16}) for different methods of supplying oxygen to the exit surface of a silver membrane and at different temperatures.[25]

Method of introduction of oxygen	Analytical method	T, K						
		525	548	570	591	613	634	665

Methanol was oxidised[21] on the outer surface of a silver tube with walls 1×10^{-4} m thick. When a mixture of methanol and oxygen was supplied to the outer surface, the inner part of the tube was evacuated.

The permeability of silver to oxygen under the conditions of the oxidation of methanol by diffusing oxygen exceeded its permeability to oxygen in the diffusion of the latter into a vacuum under the same conditions to a greater extent the lower was the experimental temperature. In the interaction of methanol vapour with diffusing oxygen on the exit surface of the silver membrane catalyst, oxygen did not appear in the gas phase until 619 K. On further increase in temperature, its amount also rose and the permeability of the silver membrane catalyst to oxygen diminished, approaching the value obtained for the diffusion of oxygen into a vacuum. The activation energy for the transfer of oxygen through a silver membrane catalyst during the oxidation of methanol is smaller by 25 kJ g-atom^{-1} than in the diffusion of oxygen into a vaccum. This is in fact the difference between the activation energies calculated from the intensities of the O_2^+ and O^+ peaks in the analysis of the gas phase near the exit surface of the silver membrane.[25] The decrease in the activation energy for the transfer of oxygen through silver under methanol oxidation conditions can be due to the interaction of the substances being oxidised on the exit surface of the silver with oxygen species which participate in the stage preceding the rate-limiting stage of the transfer of oxygen to a vacuum. According to the scheme presented above, this form may be the lattice oxygen O_{lat}^{2-}.

The supply of oxygen by diffusion through a silver membrane catalyst evidently creates on the working surface, at temperatures below 619 K, a higher concentration of this form than in the adsorption of oxygen from the gas phase. Thus, in the oxidation of methanol by diffusing oxygen, the yield of formaldehyde at 619 K reached 85%, while in the case where a mixture of methanol with oxygen was used under the same conditions, the maximum yield of formaldehyde was 23 %. Apart from formaldehyde, carbon monoxide and dioxide as well as water were formed in the reaction.

The amount of carbon monoxide formed per unit time was independent of temperature, while the rate of formation of carbon dioxide increased on heating. However, the yield of carbon dioxide did not exceed 22% even at the highest experimental temperature (673 K).

Thus the ratio of different forms of oxygen on the silver surface depends on the method of supplying oxygen through the surface of the membrane catalyst and this affects the process selectivity, since oxygen species dissolved in the surface layer of the metal participate in all probability in the formation of formaldehyde from methanol on silver.

The role of the adsorbed forms of hydrogen and oxygen in the reaction of oxygen-containing one-carbon molecules on membrane catalysts

V M Gryaznov, S G Gul'yanova, Yu M Serov
Patrice Lumumba University of Friendship Among Nations, Moscow

ABSTRACT. The role of various adsorbed forms of hydrogen and oxygen in hydrogenation and oxidation reactions respectively on palladium alloy and silver membrane catalysts is examined. The possibility of altering the ratio of the concentrations of hydrogen and oxygen on the working surface and in the layer near the surface of the catalyst after the introduction of these substances into the reaction zone, either by means of diffusion through the bulk of the metal or as part of a mixture with oxygen-containing one-carbon molecules, is demonstrated. When the above ratio is altered, there is a change in the selectivity and activity of the corresponding catalysts.

I. Introduction

The interaction of diatomic gases with the surface of a metal can be accompanied by their molecular adsorption, subsequent dissociation of the adsorbed molecules, and also surface diffusion of the adsorbed atoms and in certain cases their dissolution in the bulk of the metal. The last phenomenon is manifested most strikingly in the hydrogen–palladium and oxygen–silver systems. The high solubility and mobility of the hydrogen and oxygen atoms in palladium and silver respectively, combined with the catalytic activity of palladium in hydrogenation and dehydrogenation reactions and of silver in oxidation reactions, made it possible to create on the basis of these metals membrane catalysts which permit the introduction of one of the reactants into the reaction zone by diffusion through the metal.[1,2] Depending on the thickness of the membrane, the state of its entry and exit surfaces as regards the permeating gas, and the nature of the gases in contact with these surfaces, the rate of transfer of the gas through the metal may be limited[3] both by one of the stages indicated above and by the release of the diffuse species from the bulk of the metal onto the surface, surface diffusion, the recombination of atoms to molecules, and the desorption of the latter to the gas phase.

Thus, when a diatomic gas is introduced, it is possible to generate on the catalyst surface concentrations of adsorbed species which differ from the concentrations of the same species when hydrogen or oxygen are introduced in a mixture with substances to be hydrogenated or oxidised respectively.

The catalytic hydrogenation of carbon oxides is of interest in connection with the search for the possible replacement of the petroleum raw material, while the oxidation of methanol is an important industrial process requiring detailed investigation. When these reactions are carried out, the different ways of supplying hydrogen or oxygen to the catalyst surface can provide new information about the influence of the type of adsorbed forms on the catalytic reactions.

II. Diffusion of hydrogen through palladium membranes

For thick membranes at fairly high temperatures and hydrogen pressures, the rate-limiting stage is the diffusion of hydrogen through the bulk of the metal.[4] In the case of thin membranes at lower temperatures and low hydrogen pressures, the processes occurring at the gas–metal interface are rate-limiting.

The study of the interaction of hydrogen with the (110) and (111) faces of a palladium single crystal by the slow electron diffraction method[5] showed that the dissociative adsorption of hydrogen does not require an activation energy, while the presence of the hydrogen dissolved in palladium does not influence the structure of its adsorption layer. Moreover, it has been shown that the removal of the adsorbed hydrogen promotes its inflow to the surface from the bulk of the metal. On the other hand, the desorption of hydrogen at 368–413 K requires an activation energy of about 80 kJ mol^{-1} and takes place via the recombination of two adsorbed atoms, the adsorption centres being located in hollows between the surface palladium atoms.[6]

Data concerning the influence of the adsorbed hydrogen on the electronic work function[7–9] show that the sign of the charge on the adsorbed structures depends on the degree of surface coverage of palladium. At low coverages (up to 0.05), predominantly the negatively charged form $H^{\delta-}$ is formed, while with increasing coverage a layer of the positively charged form $H^{\delta+}$ is produced. The same result has been observed also on the exit surface of a palladium membrane in the diffusion of hydrogen. According to Cattania et al.,[10] the study of thermal desorption from the surface of palladium makes it possible to observe four different states of

hydrogen: two of these are the states of the surface chemisorbed forms and two others refer to hydrogen under the external layer of metal and are associated with the dissolution of hydrogen. According to Dus,[7] one of the surface forms of hydrogen, namely the positively charged form, can dissolve in palladium.

Thus one can postulate that the positively charged atomic form of hydrogen, which exists in the layer at the surface in a state subsequently designated by $H_b^{\delta+}$, participates in its transport through the palladium membrane. When thin palladium membranes are used, the transport process in the bulk of the metal can be fairly rapid, while the release from the surface layer onto the surface encounters certain difficulties. The concentration of the $H_b^{\delta+}$ species in the surface layer is then greater than under conditions where the exit surface of the membrane comes into contact with hydrogen at the same partial pressure in the absence of the diffusion flux. Probably, when the hydrogen pressure at the exit surface of the membrane is high and the degree of coverage of this surface by hydrogen is therefore considerable, the hydrogen is adsorbed mainly in the positively charged form which can be designated by $H_a^{\delta+}$.

III. The influence of the method of introduction of hydrogen into the reaction zone on the hydrogenation of carbon monoxide in the presence of palladium alloys

Since the permeation of hydrogen through thin membranes is limited by stages recurring at the gas–metal interface, the ratio of the concentrations of the hydrogen forms $H_a^{\delta+}$ and $H_b^{\delta+}$ depends on the composition of the membrane catalyst, the state of its surface, temperature, the partial pressures of the reactants, their adsorption capacities, and also on the method of introduction of the initial substances into the reaction zone. If hydrogen enters the reaction zone as a result of diffusion through the membrane catalyst, then the ratio $H_a^{\delta+}/H_b^{\delta+}$ is smaller than in the case where hydrogen is supplied to the working surface of the membrane catalyst in a mixture with the substance to be hydrogenated. This has been confirmed by data[11,12] obtained in a study of the hydrogenation of carbon oxides on a palladium alloy in membrane catalysts, where the method of supplying hydrogen to the working surface was varied.

The catalysts were foils and thin-walled tubes made of binary palladium alloys. In experiments with tubes when hydrogen was supplied to the reaction zone via diffusion, the inner surface of the tubes served as the entry side, while the substance to be hydrogenated was supplied to the outer side of the tube. In experiments on the hydrogenation of a mixture of the given substance with hydrogen, the gas having a specified composition passed to the outer surface of the tube while an inert gas was present inside the tube in a closed volume. The catalysts in the form of foil were placed in a stainless steel reactor and were fixed so that two identical chambers were formed. In order to carry out experiments under diffusion conditions, hydrogen was supplied to one of the chambers, while the substance to be hydrogenated was introduced into the other. The mixture was made to react in one of the chambers, while the other contained helium.

In the hydrogenation of carbon monoxide on binary palladium alloy membrane catalysts with 10 wt.% of ruthenium or with 6 wt.% of nickel[11] in the temperature range 523–683 K, methane, ethane, ethylene, water, and carbon dioxide were detected among the reaction products. The method of introduction of hydrogen into the reaction zone and the catalyst composition did not alter the nature of the products, but they did influence the rate of their formation (Tables 1 and 2).

Table 1. The rates of formation of hydrocarbons (10^3 mol h^{-1} m^{-2}) in the hydrogenation of CO on palladium–ruthenium and palladium–nickel alloys at different temperatures with hydrogen supplied to the reaction zone via diffusion through the catalyst (1) or in a mixture with CO (2).[11]

The rate of formation of ethane and methane in the reaction of carbon monoxide with hydrogen diffusing through a palladium–ruthenium membrane catalyst was appreciably lower than in the hydrogenation of CO in a mixture with hydrogen (Table 1). Conversely, the rate of formation of ethylene when the reaction was carried out under diffusion conditions was much higher than in the hydrogenation of the mixture. It is quite likely that the $H_b^{\delta+}$ form present under the layer of surface atoms participates in the formation of the olefin, the amount of this form being greater when hydrogen is introduced into the reaction zone via diffusion through the membrane catalyst, while in the formation of alkanes the main role is assumed by hydrogen in the $H_a^{\delta+}$ form, the amount of which on the surface is greater in the hydrogenation of CO in a mixture with hydrogen. The fact that, regardless of the method of introduction of hydrogen into the reaction zone, the rate of formation of ethane is always lower than the rate of formation of methane evidently demonstrates that the addition of atomic hydrogen to the CH_3

radicals is faster than the dimerisation of the latter if it is assumed that CH_x radicals are formed via the hydrogenation of the surface carbon.

The differences between the hydrogen permeabilities of the palladium–ruthenium and palladium–nickel alloys[13] affect the concentrations of the adsorbed forms of hydrogen and their ratios. The activation energy for the permeation of hydrogen through a palladium–nickel alloy is greater than through a palladium–ruthenium alloy. This is apparently one of the main reasons why the rate of formation of methane when hydrogen is supplied via diffusion through a palladium–nickel alloy increases with increase in temperature to a greater extent than under analogous conditions on a palladium–ruthenium alloy (Table 1) and at 683 K exceeds the rate of formation of methane under the same conditions in the reaction of a mixture of CO and H_2.

The rates of formation of ethylene in the hydrogenation of carbon monoxide by diffusing hydrogen are higher on both catalysts over the entire experimental temperature range than in the case where a mixture of CO and H_2 is supplied. An analogous dependence of the rate of formation of ethane on the way in which the reaction is carried out on the palladium–nickel catalyst is probably due to the fact that the ethane is formed from ethylene via the hydrogenation of the latter.

Table 2 shows that the highest rates of formation of carbon dioxide were observed when carbon monoxide came into contact with palladium alloys in the absence of hydrogen. The latter suppressed the disproportionation of CO most effectively when it was introduced into the reaction zone via diffusion. The decrease in the rate of formation of carbon dioxide in the presence of hydrogen is apparently associated with the occurrence of a process in which the adsorbed oxygen species, formed on dissociation of CO, react with the hydrogen atoms to form water. The dependence of the rate of disproportionation of the way in which hydrogen is introduced into the contact zone also indicates a change in the ratio of the different adsorbed forms of hydrogen on the working surface. In all probability, adsorbed hydrogen atoms, localised in the surface layer of the alloy ($H_b^{\delta+}$), interact preferentially with the adsorbed atomic forms of oxygen.

The formation of carbon dioxide in the interaction of CO with palladium alloys in the absence of hydrogen indicates the dissociation of carbon monoxide. One can therefore postulate that hydrocarbons are formed from CO and H_2 on palladium alloys via the hydrogenation of the surface carbon formed on dissociation of carbon monoxide, which agrees with literature data.[14]. As shown above, the rate of formation of a particular hydrocarbon depends on the relative amounts of the different forms of hydrogen adsorbed on the working surface of the catalyst, which interact with the carbon monoxide dissociation products.

A study has been made to elucidate the role of the hydrogen entering the surface of the catalyst from its bulk phase.[15] A palladium–nickel foil was treated with hydrogen, after which its supply was stopped and CO was brought up to the working surface. Methane, ethane, ethylene, carbon dioxide, and water were found among the reaction products. As can be seen from Figure 1, a decrease in the rate of formation of methane and ethane begins immediately after the supply of carbon monoxide is begun, while the rate of formation of ethylene remains constant for almost 1.5 h and only then diminishes. This confirms the hypothesis that the $H_b^{\delta+}$ form of hydrogen participates in the formation of ethylene from carbon monoxide on the palladium–nickel catalyst. The decrease in the rate of formation of methane from the very beginning of the reaction indicates its involvement in the synthesis of the $H_a^{\delta+}$ form of hydrogen. The content of the latter on the surface diminishes rapidly after a time, since the $H_a^{\delta+}$ form is produced as a result of the transfer of the hydrogen dissolved in the metal onto the surface, which is in all probability the rate-limiting stage of the hydrogen transfer through a thin palladium–nickel membrane under the given conditions. The analogy in the character of the variation of the rates of formation of ethane and methane may be attributed to the fact that hydrogen adsorbed in the $H_a^{\delta+}$ form also participates in the formation of ethane from ethylene under the conditions investigated.

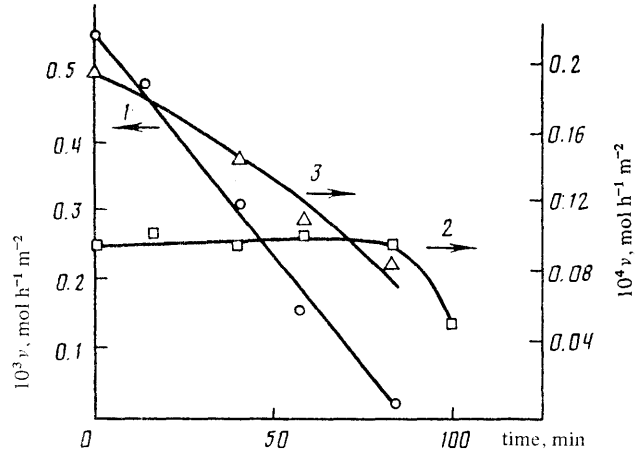

Figure 1. Time variation of the rates v of formation of methane (curve *1*), ethane (curve *2*), and ethylene (curve *3*) in the hydrogenation of carbon monoxide with hydrogen, dissolved beforehand in a palladium–nickel alloy, at 593 K.[15]

*The activity was calculated from the sum of the rates of formation of the carbon-containing reaction products.

The overall catalytic activities of the binary palladium–ruthenium and palladium–nickel alloys (Table 3) can be calculated from the data presented in Tables 1 and 2. The overall activity of the palladium–nickel alloys depends only slightly on the way in which

hydrogen is introduced into the reaction zone, while the palladium–ruthenium catalyst is much more active in the hydrogenation of CO in a mixture with hydrogen than in its hydrogenation by the diffusing hydrogen, mainly as a result of the higher rate of formation of CO_2 and methane. In the reaction of a mixture of carbon monoxide and hydrogen, the activity of the palladium–nickel catalyst is much lower than that of the palladium–ruthenium alloy because of the lower rates of formation of carbon dioxide and methane in the presence of the former catalyst. When hydrogen is supplied into the reaction zone via diffusion, the activities of the palladium–nickel and palladium–ruthenium catalysts differ only slightly at 583–683 K.

The influence of the second component of the palladium alloy on its catalytic activity can be attributed both to a change in the concentrations of the different forms of adsorbed hydrogen and to the character of the adsorption of CO, which is indicated by data on the disproportionation of carbon monoxide in the absence of hydrogen (Table 2).

IV. Hydrogenation of carbon dioxide on membrane catalysts

The change in the ratio of the atomic forms of hydrogen on the working surface of the catalyst also affects the yield of the carbon dioxide hydrogenation products. It has been shown[16] that the maximum yield of methane when hydrogen is supplied via a palladium–ruthenium alloy membrane coated electrochemically by ruthenium is twice as high as in the hydrogenation of carbon dioxide in a mixture with hydrogen under the same conditions.

The state of the working surface of the catalyst and its chemical composition also influence the activity of the membrane catalyst. The study of the interaction of carbon dioxide with hydrogen which has diffused through a palladium–ruthenium alloy membrane catalyst showed that the activity of the latter is low in the hydrogenation of carbon dioxide to methane. The electrochemical deposition of a ruthenium layer[16] on the hydrogen exit surface of the palladium–ruthenium membrane catalyst increased sharply (by three orders of magnitude) the yield of the carbon dioxide hydrogenation products, among which ethane, carbon monoxide, and water were detected. Over the entire temperature range from 523 to 773 K, the rate of formation of methane increases with increase in the amount of hydrogen supplied through the membrane, which is consistent with literature data,[17] according to which the conversion of carbon dioxide into methane proceeds more vigorously on a ruthenium surface saturated beforehand with atomic hydrogen than on a clean ruthenium surface.

Thus the deposition of a layer of substance catalytically active in a specific reaction on a hydrogen-permeable membrane extends the possibilities of membrane catalysts. Nickel as well as ruthenium belongs to the group of the most active methane formation catalysts. The electrochemical deposition of a nickel layer 5×10^{-7} m thick on the exit surface of a palladium–ruthenium membrane catalyst[18] did not alter its permeability to hydrogen or the activation energy for the diffusion of hydrogen, which indicates a porous structure of the nickel layer and an insignificant influence of the latter on the transfer of hydrogen through the palladium–ruthenium alloy. During the hydrogenation of carbon dioxide with hydrogen, diffusing through such a catalyst, at 553 K and above, methane is formed, while an increase of temperature by a further 100 K leads to the appearance of carbon monoxide and small amounts of C_2–C_4 hydrocarbons. The rate of formation of methane in the hydrogenation of a mixture of carbon dioxide and hydrogen is always lower than the values obtained under the same conditions when hydrogen is supplied by diffusion.

The study of the temperature variation of the rate of formation of methane has shown[18] that the experimental activation energy for the reaction changes at 578 K, which may be due to a transition from the ferromagnetic to the paramagnetic state of the Ni–Pd–Ru layers formed near the nickel grains on the palladium–ruthenium foil as a consequence of the diffusion of the metal atoms. The change in activation energy may be associated with a magnetic transformation in pure nickel. Thus the presence of a thin layer of disperse nickel leads to magnetocatalytic effects without affecting the permeability of the palladium–ruthenium alloy to hydrogen.

The deposition of a lanthanum-containing nickel coating on the hydrogen exit surface of a palladium–ruthenium membrane catalyst[19] increased the rate of hydrogenation of carbon dioxide to methane compared with the rate of formation of methane on the same catalyst without the modifying element. However, the rate of reaction in the presence of lanthanum increased only in the temperature range from 573 to 663 K. Further increase of temperature resulted in a sharp fall of the rate of formation of methane, probably as a consequence of the formation of the catalytically inert lanthanum carbonate. The high stability of the latter precludes the regeneration of the catalyst.

As a result of the electrochemical deposition of a rhodium coating on a palladium–ruthenium membrane catalyst,[20] methane did not begin to form until 688 K, and although its content in the reaction products did increase with increase in temperature, it was appreciably (almost by a factor of four) smaller than the amount of carbon monoxide formed, traces of which were observed already at 473 K. An increase in the partial pressure of hydrogen at the hydrogen exit surface of the membrane catalyst from 200 to 725 mmHg increased somewhat the yield of methane and did not affect the yield of carbon monoxide. The formation of hydrocarbons with higher molecular weights was not observed.

Thus the method of introduction of hydrogen into the reaction zone as well as the deposition of dispersed layers of active metals on the hydrogen exit surface of the membrane catalyst influence the ratio of the concentrations of different forms of adsorbed hydrogen, which alters the selectivity and activity in the carbon dioxide hydrogenation process.

V. The role of adsorbed oxygen in the oxidation of methanol

Silver foil, which makes it possible to introduce oxygen into the reaction zone via diffusion through the metal, may be used as a membrane oxidation catalyst. The process involving oxygen transfer through silver membranes may include the same series of stages as the adsorption of oxygen on silver, in the forward and reverse sequences.[21] The adsorption of oxygen on silver in the temperature range from 453 to 623 K is known[22] to proceed in accordance with the scheme

$$O_{2\,gas} \rightarrow O_{2\,ads}^{-} \rightarrow 2O_{ads}^{-} \rightarrow 2O_{lat}^{2-}.$$

However, the rate-limiting stage in the transfer of oxygen through silver may not be the same as in the adsorption of oxygen from the gas phase.

The study of the permeability of silver tubes with walls 10^{-4} m thick to oxygen showed[23] that it is proportional to the square root of the oxygen pressure at the oxygen entry surface of the tube. This indicates the involvement of oxygen atoms in the rate-limiting stage of the transfer of oxygen through silver. The electrochemical deposition of a layer of silver on the oxygen exit surface of a silver membrane increases its permeability to oxygen by more than an order of magnitude,[24] but the linear dependence of this parameter on the square root of the oxygen pressure at the entry surface of the membrane is retained. All these factors show that the rate-limiting stage in the transfer of oxygen through thin silver membranes is the process occurring on the oxygen exit surface in which oxygen atoms participate.

The states of the oxygen, arriving via diffusion through membranes or as a result of adsorption from the gas phase, on the exit surface of the membrane have been investigated mass-spectrometrically[25] using a modernised ion source. In the immediate vicinity of the mass spectrometer ion source, a silver tube with walls 10^{-4} m thick was placed and the composition of the gas phase in contact with its outer surface was investigated. Furthermore, an additional cathode and potential-carrying grids were introduced into the ion source, which made it possible to investigate the species adsorbed on the outer surface of the silver tube by the method of the electron-stimulated desorption of ions (ESDI). Two peaks can be observed in the mass spectrum of gaseous oxygen: the molecular (O_2^+) peak with a mass number of 32 and a fragment (O^+) peak with a mass number of 16. The ratio of the intensities of these two peaks (I_{32}/I_{16}) was found to be close to 20 by the usual gas analysis. As can be seen from Table 4, approximately this value has been recorded when oxygen was admitted directly onto the outer surface of the silver membrane in the ionisation chamber. A similar value was also obtained when oxygen was supplied by diffusion through a silver tube at 665 K. However, in this case the decrease in the temperature of the membrane was accompanied by a decrease in the I_{32}/I_{16} ratio, which indicates the appearance in the gas phase of an additional source of oxygen atoms. These may be the atoms desorbed from the surface. The proximity of the membrane to the ionisation region makes it possible to record them. An analogous effect has been observed in a study by the ESDI method, which is probably associated with the enrichment of the exit surface of the silver membrane during the diffusion of oxygen through it in adsorbed forms, which on electron bombardment of the surface are capable of being desorbed to the gas phase in the form of the positively charged O^+ ions.

Since the entire oxygen which has diffused through the silver membrane passes to the ionisation chamber, the intensities of the molecular (O_2^+) and fragment (O^+) oxygen peaks are proportional to the permeability of the given silver membrane to oxygen under stationary conditions.

The activation energy calculated from the temperature variation of the intensity of the peak with a mass number of 32 exceeds the corresponding value found by measuring the height of the peak, with a mass number of 16, the same effect being observed for both methods of analysis. Presumably, in the diffusion of oxygen into a vacuum through a thin silver membrane, its exit surface is enriched in atoms capable of being desorbed into the gas phase on electron impact, the number of such species increasing with decrease in temperature. Furthermore, at low temperatures the surface diffusion process as a result of which the lattice oxygen passes to the adsorbed state, preceding the recombination stage, is hindered and the release of atoms into the gas phase becomes possible which, as already stated above, is the cause of the decrease in the ratio I_{32}/I_{16} (Table 4) and also of the lower activation energy calculated from the variation of the intensity of the peak with a mass number of 16.

Table 4. The ratios of the intensities of the mass spectrometric peaks with mass numbers 32 and 16 (I_{32}/I_{16}) for different methods of supplying oxygen to the exit surface of a silver membrane and at different temperatures.[25]

Method of introduction of oxygen	Analytical method	T, K						
		525	548	570	591	613	634	665

Methanol was oxidised[21] on the outer surface of a silver tube with walls 1×10^{-4} m thick. When a mixture of methanol and oxygen was supplied to the outer surface, the inner part of the tube was evacuated.

The permeability of silver to oxygen under the conditions of the oxidation of methanol by diffusing oxygen exceeded its permeability to oxygen in the diffusion of the latter into a vacuum under the same conditions to a greater extent the lower was the experimental temperature. In the interaction of methanol vapour with diffusing oxygen on the exit surface of the silver membrane catalyst, oxygen did not appear in the gas phase until 619 K. On further increase in temperature, its amount also rose and the permeability of the silver membrane catalyst to oxygen diminished, approaching the value obtained for the diffusion of oxygen into a vacuum. The activation energy for the transfer of oxygen through a silver membrane catalyst during the oxidation of methanol is smaller by 25 kJ g-atom^{-1} than in the diffusion of oxygen into a vaccum. This is in fact the difference between the activation energies calculated from the intensities of the O_2^+ and O^+ peaks in the analysis of the gas phase near the exit surface of the silver membrane.[25] The decrease in the activation energy for the transfer of oxygen through silver under methanol oxidation conditions can be due to the interaction of the substances being oxidised on the exit surface of the silver with oxygen species which participate in the stage preceding the rate-limiting stage of the transfer of oxygen to a vacuum. According to the scheme presented above, this form may be the lattice oxygen O_{lat}^{2-}.

The supply of oxygen by diffusion through a silver membrane catalyst evidently creates on the working surface, at temperatures below 619 K, a higher concentration of this form than in the adsorption of oxygen from the gas phase. Thus, in the oxidation of methanol by diffusing oxygen, the yield of formaldehyde at 619 K reached 85%, while in the case where a mixture of methanol with oxygen was used under the same conditions, the maximum yield of formaldehyde was 23 %. Apart from formaldehyde, carbon monoxide and dioxide as well as water were formed in the reaction.

The amount of carbon monoxide formed per unit time was independent of temperature, while the rate of formation of carbon dioxide increased on heating. However, the yield of carbon dioxide did not exceed 22% even at the highest experimental temperature (673 K).

Thus the ratio of different forms of oxygen on the silver surface depends on the method of supplying oxygen through the surface of the membrane catalyst and this affects the process selectivity, since oxygen species dissolved in the surface layer of the metal participate in all probability in the formation of formaldehyde from methanol on silver.

Development of ideas concerning the mechanism of the Fischer–Tropsch synthesis

E V Slivinskii, Yu P Voitsekhovskii
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

ABSTRACT. The principal stages in the development of ideas concerning the mechanism of the Fischer–Tropsch synthesis and its modifications are examined and the available literature data about the synthesis are surveyed. Attention has been concentrated on the analysis of modern ideas concerning the mechanism of the interaction of CO and H_2 on the basis of the latest advances in metal complex catalysis. The possibility of the existence of the postulated intermediates and of the occurrence of suggested elementary steps has been demonstrated in relation to model organometallic systems.

The bibliography includes 197 references.

I. Introduction

At the beginning of the 20th century Sabatier[1] and then Fischer and Tropsch[2,3] first achieved the catalytic synthesis of organic compounds from CO and H_2. Apart from the synthesis of methane[1] and aliphatic hydrocarbons, mainly having the normal structure,[2,3] from the synthesis gas (a mixture of CO and H_2), during the last decades other organic compounds have been synthesised, including methanol,[4] lower alkanes,[5] polymethylenes,[6] isoalkanes,[7] olefins,[8] high alcohols,[9] acids,[10,11] and polyols.[12] With the exception of certain compounds such as acetylene and formaldehyde, there are no thermodynamic limitations to the preparation of a wide range of organic products by this procedure.[13]

At the present time the term Fischer–Tropsch synthesis is given to the set of reactions involving the direct conversion of CO + H_2 into a mixture of aliphatic hydrocarbons and oxygen-containing compounds in which the number of carbon atoms ranges from two upwards. Typical catalysts of these reactions are Ni, Co, Fe, and Ru.[14,15] Under certain conditions, the predominating products of the conversion of the synthesis gas are oxygen-containing compounds in the presence of iron catalysts and hydrocarbons in the presence of cobalt catalysts. Nickel catalysts are known to effect the selective synthesis of methane,[15] although it has been recently reported[16] that the coprecipitated Ni–Ti–Mg catalysts, promoted with Na and Cu, are effective in the synthesis of higher aliphatic alcohols. A distinctive feature of the ruthenium catalyst is its capacity to effect the formation of high-molecular-weight polymethylenes from CO and H_2. Other Group VIII metals (Ir, Pd, Pt, Os, and Rh) exhibit an insignificant activity in the Fischer–Tropsch (FT) synthesis.

As a consequence of the increased interest in the FT synthesis after the petroleum embargo in 1973, there was a sharp increase in the number of publications on this question. Among them, mention must be made of certain monographs[14,17,18] and reviews.[15,19–31]

However, the latest complete review devoted directly to the mechanism of the FT synthesis in the Soviet periodical literature dates back to 1967,[32] although this topic has been briefly discussed in a number of communications by Soviet authors.[33–37]

II. The carbide mechanism

The first version of the carbide mechanism was proposed by Fischer and Tropsch. They suggested that this mechanism involves the formation of metal carbides and their hydrogenation to oxygen-free intermediates (for example, methylene species), whose polymerisation leads to the formation of the set of products observed.[2,3,88] In the course of the development of these views, a more detailed mechanism, supported by certain kinetic studies, was proposed.[39,40]

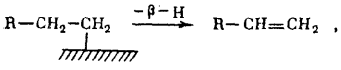
After this hypothesis had been forgotten for many years, there has been an appreciable growth of interest in it during the last 8–10 years. Furthermore, at the present time this is regarded as one of the main hypotheses.

The "neocarbide" theory originated from the studies by Wentercek et al.[41] and Araki and Ponec.[42] The elegant study by Goodman and Yates,[43] using doubly labelled CO, also confirmed the presence of a carbon monoxide dissociation stage in the FT synthesis. The formation of the following intermediate species on the (111) surface of nickel has been established by secondary ion mass spectrometry (SIMS):[44] C^+, CH^+, CH_2^+, CH_3^+, O^+, CD^+, CD_2^+, CD_3^+, $NiCO^+$, $NiOH^+$, $NiCH_2^+$, $NiCH_3^+$, $NiCH^+$, and NiC^+. It has been shown that surface oxygen-free species of the type CH_x (x = 0–3), formed via the CO dissociation stage, are intermediates on the Ni, Co, and Ru catalysts deposited on SiO_2.[45] In the study quoted, the Ni, Co, and Ru catalysts were first converted into the carbide form with the aid of ^{13}CO. The subsequent interaction of ^{13}CO and H_2 on their surface led to the formation of $^{13}CH_4$ methane and a number of normal alkanes containing several ^{13}C atoms in a single molecule, i.e. the carbide carbon participates in the formation of hydrocarbons.

The possibility of the rapid dissociative adsorption of CO on typical metallic catalysts of the FT synthesis and the presence of this stage, as the initial stage, in the mechanism of such synthesis have been confirmed by a series of experimental data and a large group of supporters.[46-53]

A significant confirmation of the carbide hypothesis was obtained in two investigations.[54,55] In the decomposition of diazomethane in the presence of hydrogen over a typical FT synthesis catalyst (Ru, Co, Fe), a mixture of mainly linear alkanes and alkenes was formed. The proportions of the products obeyed the Schulz–Flory equation and was typical for syntheses from CO and H_2. For practical purposes, it is convenient to express this equation in the logarithmic form

$$\lg(m_P/P) = \lg(\ln^2\alpha) + (\lg\alpha)P,$$



where P is the number of carbon atoms in the product molecule, m_p the weight fraction relative to the overall product, of the hydrocarbon (or the oxygen-containing compound) in which the number of carbon atoms is P, α is the probability of chain propagation defined as $\alpha = r_p/(r_p + \Sigma r_{tr})$, where r_p and r_{tr} are the rates of chain propagation and transfer respectively. If the molecular weight distribution obeys this equation, then the plot of $\lg(m_p/P)$ against P should be represented by a straight line. Furthermore, in this equation there is an "internal control", since α is determined both by the slope ($\lg\alpha$) and the intercept on the ordinate axis [$\lg(\ln^2\alpha)$]; the two values obtained should be identical.

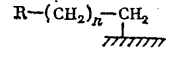
C_1-C_{18} hydrocarbons have been obtained from $CH_2N_2 + H_2$ and $CO + H_2$ mixtures over Co and Fe, the selectivity of their formation depending in both cases to equal extents on the reaction conditions. Thus the increase in the H_2 partial pressure led to an increase in the alkane : alkene ratio and to a decrease of the average molecular weight. High molecular-weight polymethylenes were formed over Ru in both cases, which is typical of catalysts of this kind.[6] On the other hand, the decomposition of diazomethane in the presence of H_2 over Ni and Pd yielded not only methane but also higher hydrocarbons, although nickel is known to be a typical methane formation catalyst. However, at a pressure of 68 atm, the proportions of the products of the synthesis from CO and H_2 in the presence of this catalyst proved to be close to those obtained in experiments involving the treatment of the nickel catalyst with hydrogen for 1 atm after the decomposition of diazomethane over it. In the decomposition of the $CH_2N_2 + H_2$ mixture over Cu, only methane and ethylene were detected in the reaction products.

The gas-phase decomposition of diazomethane itself over metallic catalysts at 200 °C under the conditions used led in all cses to the formation of only one product–ethylene. Hence it follows that, in the absence of H_2, the methylene intermediates formed only dimerise with subsequent desorption of ethylene as the final product; the oligomerisation of the intermediate has not been observed. On the basis of the similarity of the proportions of the products of the conversion of $CO + H_2$ mixtures, on the one hand, and $H_2 + CH_2N_2$ mixtures, on the other, it has been concluded[54,55] that the mechanisms of the two processes are identical and that the methylene intermediates may polymerise, the polymerisation being initiated by the presence of the M–H bond on the catalyst surface. Although the authors[54,55] did not investigate the possible ways of the generation of CH_2 fragments on the catalyst surface, it had been noted earlier that the CH_x fragments on typical catalysts of the FT synthesis can be formed as a result of the hydrogenation of the carbides produced on the surface in the dissociative adsorption of CO. In their view, the data presented confirm the carbide hypothesis[23,38] and make it possible to justify the following mechanism proposed initially by Biloen et al.:[45]

Chain termination takes place either as a result of the elimination of β-hydrogen atoms with formation of α-olefins, i.e.

or as a consequence of the reduction of the M–C bond and the formation of alkanes:

We may note that in the studies quoted[54,55] only one feature of the carbide mechanism was demonstrated—the ability of the methylene intermediates to form hydrocarbons on polymerisation, but the question of the ways in which these intermediates arise under the conditions of the real synthesis from CO and H_2 in the absence of diazomethane remained unresolved.



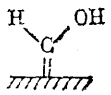
As regards the question of the origin of the CH_2 fragments on the catalyst surface, we may note that they may be formed both on the metal carbide (as a result of the interaction of hydrogen with the M–C intermediate arising in the dissociative adsorption of CO) and via the stepwise hydrogenation of the non-dissociatively chemisorbed CO. The answer to this question actually determines whether the carbide mechanism operates in a particular catalytic system.

Since the involvement of the CH_2 intermediates both in the chain initiation and chain propagation stages is postulated only in the carbide mechanism of the FT synthesis, the experimental data quoted by Brady and Pettit[54] concerning the influence of the additional $^{12}CH_2$ groups obtained by the preliminary decomposition of diazomethane on the proportions of the products in the synthesis from ^{13}CO and H_2 in the presence of a cobalt catalyst are consistent solely with the carbide hypothesis. Furthermore, in the experiment on the Co catalyst using mixtures of ^{13}CO, H_2, and $^{12}CH_2N_2$, the distribution of ^{13}C and ^{12}C in the propane formed also corresponds only to the carbide mechanism.

Analogous conclusions have also been reached in a study[56] where CH_xCl_{4-x} (x = 1–3) was used as the source of the surface CH_x intermediates.

However, the possibility of the formation of different forms of carbon in the dissociative adsorption of CO[57-60] very greatly complicates the question of the mechanism of the formation of methylene intermediates on the catalyst surfaces.

The carbide hypothesis presupposes that different alkyl fragments of the type



are present on the surface as intermediates in the chain propagation stage. Use of the novel method of the so called "chemical trapping agents" (pyridine, cyclohexene)[61-63] made it possible to demonstrate that alkyl intermediates are precursors of the hydrocarbons obtained.

Thus the set of experimental data available at present makes it possible to regard methylidyne, methylene, methyl, and R-alkyl species bound to the surface as possible intermediates in the FT synthesis. The carbide mechanism explains satisfactorily the formation of different hydrocarbons. On the other hand, the appearance of oxygen-containing products, which are known to be capable of predominating in the overall products under certain conditions, is inexplicable in terms of this mechanism. The explanation of the presence of oxygen-containing compounds in the reaction products by postulating a chain termination stage as a result of the insertion of CO in the M–C(Alk) bond in the carbide mechanism[25,64] is rather unconvincing, since this chain termination pathway does not explain the entire wide variety of the oxygen-containing reaction products formed.

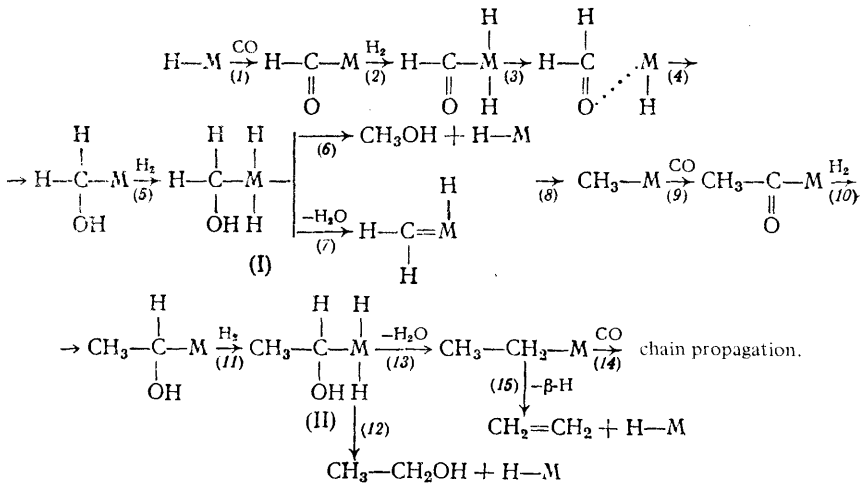
III. The condensation mechanism

In the 1950's Stroch et al.[65] and independently Eidus[32] put forward the hypothesis that hydroxymethylene groups are formed on the surface of the metal from the adsorbed CO and the chemisorbed atomic hydrogen and that C–C bonds arise as a result of condensation with elimination of water. The following arguments have been quoted in support of this hypothesis: (1) the experimentally established fact that an adsorbed complex with the CH_2O stoichiometry is formed;[66–68] (2) the fact that the amount of CO and H_2 adsorbed from the mixture exceeds the overall amount of these substances adsorbed separately; (3) the detection of compounds having the composition CH_2O and other oxygen-containing intermediates[69] by gas-phase mass-spectrometry; (4) identification of oxygen-containing compounds on the surfaces of iron catalysts;[70] (5) evidence for the stability of chemisorbed complexes of the type[71]

based on quantum-chemical calculations.

However, it has been shown convincingly[37,72,73] that the possible contribution by processes involving the condensation of both methylene and hydroxycarbene intermediates is extremely insignificant, at least on iron catalysts. So far the condensation mechanism of chain propagation has not been widely recognised. Despite the major advances in organometallic chemistry, the occurrence of a condensation reaction of the type[22]

$$M{=}CHOH + M{=}CHOH \rightleftarrows M{=}CHCOH{=}M + H_2O$$



has not been established. However, the formation of oxygen-containing intermediates in the FT synthesis, which is at present the subject of vigorous discussion, has served as the basis of mechanisms which constitute an alternative to the condensation mechanism

IV. The mechanism based on the insertion of CO

The mechanisms of the FT synthesis according to which chain propagation is a result of the insertion of activated CO in the M–C bonds have been proposed by Schulz and co-workers[74,75] and later by Henrici-Olive and Olive.[76] Pichler and Schulz[74] postulate the formation of two-centre intermediate compounds, while Henrici-Olive and Olive[76] assume the possibility of a whole cycle of reactions on a mononuclear active centre. The mechanism proposed by Henrici-Olive and Olive (Scheme 1), most frequently discussed recently, is presented below:

In the first stage, CO is inserted into the M–H bond of the surface hydride and a primary formyl complex is formed. This is followed by stages involving the oxidative addition of H_2 [stage (2)] and the reductive elimination of the formyl ligand [stage (3)], leading to the formation of formaldehyde and a metal hydride. However, the formaldehyde does not leave the coordination sphere of the metal and remains bound to the active centre via the CO group. The interaction of the metal hydride with the aldehyde [stage (4)] with subsequent oxidative addition of hydrogen [stage(5)] entails the

Scheme 1

appearance of the intermediate (I). The intermediate can be converted via two pathways: either as a result of reductive elimination [stage (6)], which leads to the formation of methanol and a metal hydride as the kinetic chain transferring agent, or as a result of the elimination of water [stage (7)] with formation of a carbene intermediate, which is converted into a σ-bonded methyl complex after rearrangement [stage (8)]. The next CO molecule is coordinated to the active centre and is inserted in the $M-CH_3$ bond [stage (9)], which leads to an acyl intermediate. Stage (10) corresponds to the sum of stages (2)–(4), but differs by the fact that the hydrocarbon chain becomes longer by one carbon atom. The oxidative addition of hydrogen [stage (11)] results in the formation of the intermediate (II), which is converted via reactions of type (6), (7), and (8) into either ethanol and a metal hydride [stage (12)] or into a metal alkyl [stage (13)]. The metal alkyl is either subjected to the insertion of the next CO molecule [stage (14)] and then propagates the growing chain or affords, after β-elimination of a hydrogen atom [chain termination—stage (15)], the final product—an α-olefin (ethylene in the given stage). According to the authors, the metal hydride is responsible for the occurrence of secondary hydrogenation and isomerisation reactions [reactions (16) and (17)]:

$$R-CH=CH_2 + H-M \begin{cases} \xrightarrow{(16)} R-\underset{\displaystyle M}{\underset{|}{CH}}-CH_3, \\ \xrightarrow{(17)} R-CH_2-CH_2-M. \end{cases}$$

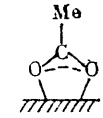
Since α-olefins are the primary products of the synthesis, the predominance of methyl-substituted structures among the isomeric products becomes understandable.

The main evidence in support of this mechanism is its analogy with metal complex catalysis.[77–83] Thus the formation of alkylbenzenes in the presence of the $W(CO)_6.AlCl_3$ catalytic system has been considered as one of the decisive pieces of evidence:[78]

$$C_6H_6 + nCO + H_2 \rightarrow C_6H_5(CH_2)_nH + H_2O,$$
$$n = 1-5,$$

the proportions of the alkylbenzenes obeying the Schulz–Flory relation. However, it has been shown that [84] the side chain in alkylbenzenes is formed with participation of the carbon atoms of the benzene ring: when carbon-labelled benzene was used, alkylbenzenes with the carbon label in the side chain were obtained.

Nevertheless, the migration insertion of CO in the M–C bond is a well known reaction in the chemistry of carbonyl complexes.[85] In fact, this involves the migration of the alkyl group to the carbonyl ligand coordinated to the metal, which has been demonstrated for the reaction[86,87]



$$CH_3Mn(CO)_5 \underset{-CO}{\overset{+CO}{\rightleftarrows}} CH_3COMn(CO)_5.$$

There is also significant evidence that chain propagation in the FT synthesis takes place as a result of the insertion of CO in the M–C bond.[88,89] The interaction of CO, H_2, and $C_6H_5C\equiv CH$ in the presence of a premelted iron catalyst yielded aromatic alcohols with C_3-C_8 side chains whose proportions obey the Schulz–Flory statistics. The introduction of phenylacetylene made it possible to synthesise aromatic alcohols at temperatures in the range 110–130 °C, but the reaction proper between CO and H_2 is not observed and the C–C bonds can therefore be formed only as a result of the incorporation of CO in the chain without its preliminary interaction with H_2 and without dissociation (the mechanisms of the CO + H_2 + alkyne reactions will be considered below).

Attempts have been made[90,91] to detect on the surface of the working catalyst the structures postulated in the mechanism described. Convincing evidence for the existence of the acyl group

and the acetate

as precursors of the oxygen-containing C_2 compounds has been obtained by IR spectroscopy *in situ* on the surfaces of the Rh/SiO_2 and $Rh-Mn/SiO_2$ catalysts.[91] An attempt has also been made to detect structures of the acyl type on the Fe/SiO_2 surface using diethylamine as the chemical trapping agent. The reaction between the acyl carbon of the postulated oxygen-containing intermediate and diethylamine in the presence of hydrogen should have led to the formation of either *NN*-diethylamides or *N*-alkyldiethylamines. Among the reaction products, *NN*-diethylformamide, *NN*-diethylacetamide, and C_1-C_4 *N*-alkyldiethylamines were found in the experiment. However, this is not unambiguous evidence for the presence of oxygen-containing intermediates on the surface of the working catalyst, because the above products might have been formed via other pathways.

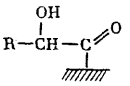
We may also note studies, [80–83] in which the latest experimental data confirming the carbide mechanism have been analysed.[80–83] It was shown that data[45,54,55] interpreted within the framework of the carbid theory do not nevertheless constitute unambiguous proof of the absence of the CO insertion stage as the chain propagation stage and that they are fully consistent with the mechanism proposed by Henrici-Olive and Olive.[76]

Kagan et al.,[37] who regard the synthesis of compounds from CO and H_2 as a heterogeneous-catalytic chain reaction initiated, as a result of the interaction of CO and H_2, by an oxygen-containing intermediate (chain initiation step), hold a similar view on the mechanism of the FT synthesis. Chain propagation takes place as a result of the successive addition of CO and H_2 to a hydroxymethylene complex of this kind or its homologues without a preliminary interaction between them. In the course of chain propagation, the complex undergoes intermediate dehydration and is lengthened by one CH_2 group with migration of the active centre to the end of the growing chain.

Aliphatic[92,93] and aromatic[89,94] alcohols, and α ω-diols or their monoethers[95] have been synthesised using respectively acetylene, phenylacetylene, and propargyl alcohol and its ethers as the third component.

Thus the possibility of a large series of syntheses based on CO and H_2 via the initiated hydrocondensation of CO was established. This method makes it possible to obtain compounds belonging to a wide variety of classes using the corresponding initiator (by varying the group R in the terminal alkyne $R-C\equiv CH$):

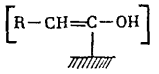
$$R-C\equiv CH + CO + H_2 \rightarrow R(CH_2)_nOH,$$
$$R = H;\ Ph,\ CH_2OH,\ CH_2OMe,\ CH_2OBu\text{-}t;\ n \geqslant 3.$$



The presence of the $(CH_2)_nOH$ fragment is common to all these compounds.

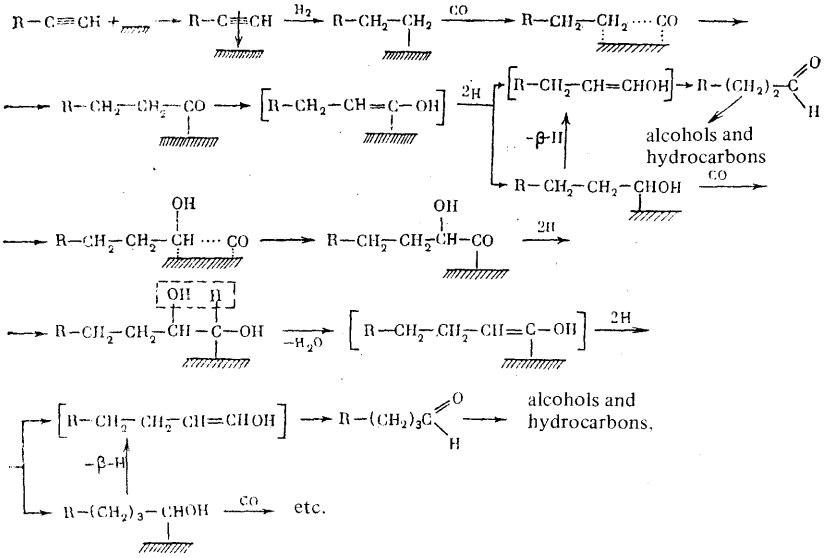
Comparison of the syntheses of higher aliphatic alcohols from CO and H_2 [37] with the initiated syntheses showed that the mechanisms of these reactions are similar and probably differ solely by the chain initiation stage, i.e. by the way in which the primary complex is formed.

Detailed investigation of the mechanism of initiated syntheses by comparison with the available literature data suggested a mechanism of this process which accounts for the origin of the products detected (Scheme 2).†



The studies published by Kline et al.[96] indicate the possibility of the formation of π-bonded acetylene $Fe_2(C_2H_2)$ when it interacts with the active centre of an iron catalyst. The idea that the chain initiation step involves the catalytic interaction of the alkyne with CO and H_2 is confirmed by the fact that the alkyne is in all cases incorporated only once in each molecule of the reaction product; its inclusion in the growing chain has not been observed.[88,97-99] This follows from the constancy of the molar radioactivity of C_3-C_9 alcohols in experiments with mixtures of CO, H_2, and $HC\equiv{}^{14}CH$.[97] Chain initiation takes place much more readily when alkynes are introduced into the mixture of CO and H_2. The syntheses with participation of these complexes can be achieved under conditions which are non-traditionally mild for the FT process: at temperatures in the range 110–130 °C and pressures in the range 25–50 atm. The products of the CO and H_2 interaction proper were not then detected. This agrees with the claim that the insertion of CO in the M–H bond is energetically more favourable than its insertion in the M–C bond.[100] The possibility of achieving initiated syntheses under mild conditions shows that the insertion of CO in the M–C bond is in fact the only possible way in which chain propagation can take place because the formation of intermediates as a result of the interaction of CO with H_2 or of reactions of CO itself would have naturally led to the appearance of the products of the interaction of CO and H_2.

The formation of the primary complex from CO, H_2, and the alkyne in the first stage of initiated hydrocondensation was confirmed by carrying out the homogeneous model synthesis of aromatic alcohols from CO, H_2, and iron carbonyl complexes of phenylacetylene. The set of products formed proved to be analogous to that obtained in the synthesis of aromatic alcohols from CO and H_2 with participation of phenylacetylene in the presence of a premelted iron catalyst.[99] In this case, chain propagation also proceeds via the insertion of CO in the Fe–C bond, as in the mechanisms considered previously in this Section.[74-76] This hypothesis is supported by the results of studies[101,102] in which the formation of hydroxyacyl complexes of the type



was established and the reaction involving the insertion of CO in the M–C bond in the hydroxyalkyl complex was achieved.

Surface enolic intermediates of the type

have been detected in the hydrogenation of ketones on the surface of premelted iron catalysts.[103]

Scheme 2

†See E V Slyvinsky, Yu P Voitsechovsky, and S M Loktev *Proceedings of the 9th International Congress on Catalysis, Calgary, 1988*, Vol. 2, p. 729

The possibility of the dehydration of diol structures with formation of surface enolic intermediates has been confirmed by carrying out the model reaction involving the dehydration of ethylene glycol to the expected acetaldehyde in the presence of the same catalyst.[104]

The detection of the R and CH_2OH groups in the reaction products in the α- and ω-positions respectively supports the hypothesis that, after the chain initiation step, the alkyne incorporated in the hydrocarbon chain moves away from the active centre without participating in the chain propagation stages. Comparison of the relative selectivities[105,106] shows that the primary products of the initiated syntheses are aldehydes, while alcohols and hydrocarbons are formed as a result of secondary hydrogenation reactions (probably via independent pathways).

Chain termination apparently occurs as a result of the β-elimination of hydrogen and its oxidative addition.

Although the majority of the reactions representing the individual stages of the mechanism based on the insertion of CO are known in organometallic chemistry, nevertheless for a long time it was not possible to achieve the homogeneous version of the FT synthesis. The advances in organometallic catalysts in recent years made it possible to obtain numerous pieces of evidence in support of these mechanisms (see Section VI).

V. Other mechanisms

The so called "hybrid mechanisms", in which the individual elements of different mechanisms are combined, have been considered recently in a number of studies. In their investigation of the influence of the Ni–Cu catalysts on the selectivity of the hydrogenation of CO, van Barneveld and Ponec[107] suggested that carbon monoxide is capable of dissociating on the surface, generating carbide carbon atoms, which are hydrogenated to hydrocarbon intermediates (for example, methylene species):

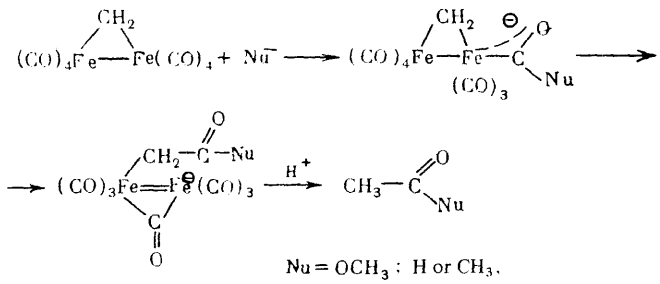
$$\left.\begin{array}{l} CO \rightarrow C + O \quad (a) \\ C + xH \rightarrow CH_x \quad (b) \end{array}\right\} \text{chain initiation.}$$

If a dual character of the adsorption of CO (with and without dissociation) is postulated, then chain propagation can proceed via the insertion of non-dissociatively adsorbed CO in the M–alkyl bond formed in the chain initiation stage with subsequent hydrogenation of the oxygen-containing intermediate:

$$\left.\begin{array}{l} CH_x + CO_{ads} \rightarrow (CH_xCO) \quad (c) \\ CH_xCO + nH \rightarrow H_2O + (CH_xCH_{n-2}) \quad (d) \\ CH_xCH_{n-2} + CO \rightarrow (C_2H_{(x+n-2)}CO) \quad (e) \end{array}\right\} \text{chain propagation.}$$

The oxidative addition of hydrogen to the intermediate surface complex leads to chain termination:

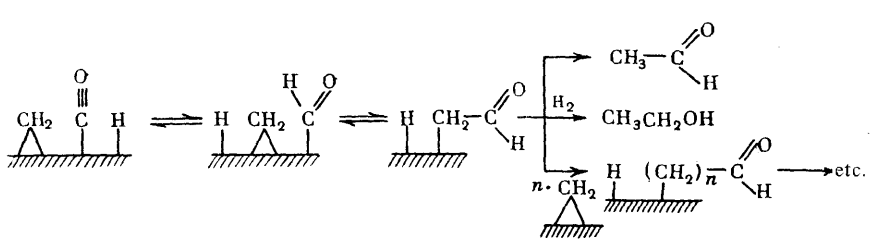
$$CH_xCH_{n-2} + yH \rightarrow \text{hydrocarbons} \} \text{ chain termination.}$$



However, it had been shown earlier[108] that the only product obtained from carbide carbon on a premelted iron catalyst is methane.

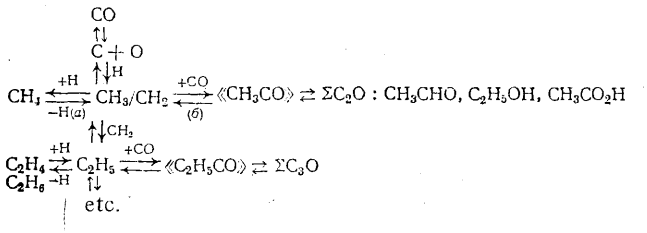
A similar mechanism, combining the features of the carbide mechanism and the mechanism based on the insertion of CO, has also been adopted by Matsumoto and Benett.[109]

In a study of the Ru/SiO_2 and Co/kieselguhr systems, it was shown that only the conversion into methane takes place via the carbide mechanism, while C_n ($n \geqslant 2$) products are formed with participation of non-carbide intermediates.[110] A mechanism has been proposed for chain propagation, on the basis of the experimental data, via the condensation of hydroxylated intermediates:



$$CH_4 \overset{2H_2}{\leftarrow} [C] + H_2O \rightleftarrows [CHOH],$$
$$2[CHOH] + H_2 \rightleftarrows [C_2H_4OH] + H_2O,$$
$$[C_2H_4OH] + [CHOH] + H_2 \rightleftarrows [C_3H_6OH] + H_2O.$$

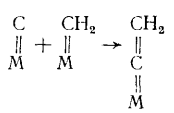
The study of the characteristic features of the model stoichiometric reaction



enabled Hackenbruch et al.[111] to postulate a novel hybrid mechanism, which has received definite confirmation in experiments on the synthesis from CO and H_2 in the presence of the Co/SiO_2 heterogeneous catalysis using methanol as the third component (nucleophile) and also in experiments with labelled reactants. The results agree with the postulated Scheme 3:

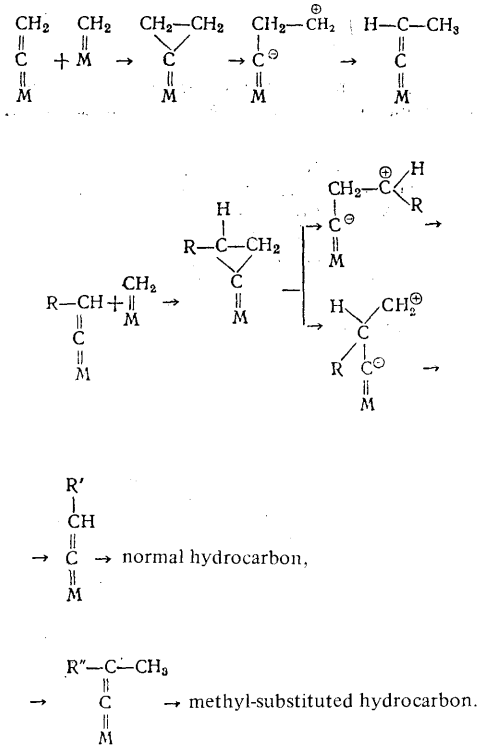
Scheme 3

Chain initiation takes place as a result of nucleophilic attack by the hydride on the CO molecule coordinated to the active centre with formation of a formyl intermediate. The interaction of the formyl group or its homologues (acyl groups) with the surface methylene intermediates leads to chain propagation, while chain termination is a consequence of the oxidative addition of hydrogen to M–C bond or the β-elimination of hydrogen.



A mechanism has been proposed[113,114] for the formation of hydrocarbons and oxygen-containing products in the presence of promoted deposited rhodium catalysts on the basis of data obtained using ^{13}C-labelled reactants[112] and IR spectroscopy *in situ* under high pressure:[91]

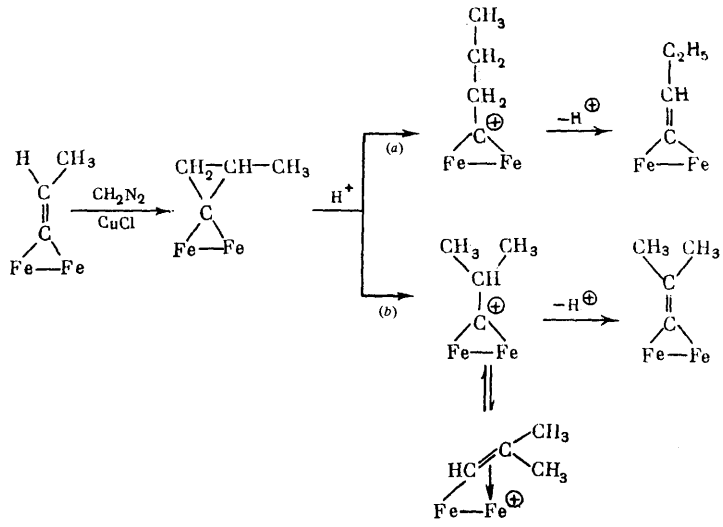
The chain propagation in the formation reactions of hydrocarbons and oxygen-containing compounds includes the same stages and takes place on centres for the dissociative adsorption of CO, while chain termination probably occurs on different centres [stages (*a*) and (*b*)]. The C_n ($n \geqslant 2$) oxygen-containing compounds have a common precursor; for the C_2 compound, this is the "CH_3CO" acyl group formed when CO is inserted in a CH_3 or CH_2 surface hydrocarbon intermediate.



Analogous reaction mechanisms according to which oxygen-containing products and hydrocarbons are formed on different catalytic centres[90,115,116] or via different pathways,[117] had also been proposed previously. This was based on the difference between the coefficient α (the chain propagation parameter) in the Schulz–Flory equation for oxygen-containing products and hydrocarbons. However, according to data[118] for alcohols and hydrocarbons obtained in the presence of iron catalysts, the coefficients α are similar, which enabled Kagan et al.[37] and Berke et al.[119] to put forward the hypothesis that in the presence of iron catalysts, oxygen-containing compounds and hydrocarbons have a common precursor—a surface alkyl intermediate. The formation of methyl-substituted compounds as the principal isomeric products of the FT synthesis and the absence of a quaternary carbon atom in them was the reason why a modified version of the carbide mechanism was put forward.[120]

It is suggested that in this case the chain initiation stage involves the interaction of a surface carbon atom with a methylene intermediate to form the primary vinylidene complex:

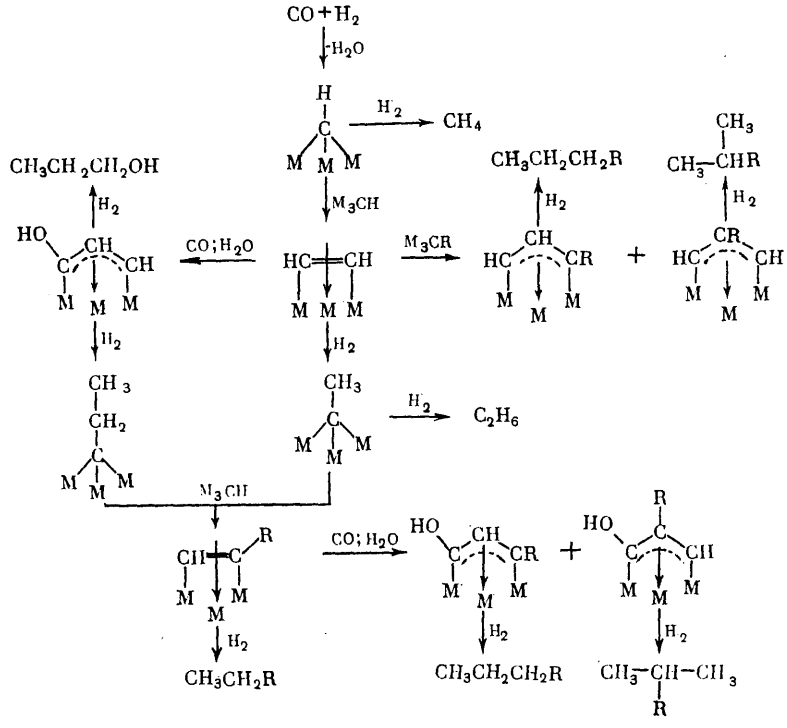
Chain propagation takes place as a result of the interaction of the surface methylene groups with this complex to form a cyclopropylidene intermediate, which then readily rearranges to the normal or methyl-substituted homologues of the initial vinylidene complex:



Scheme 4

Analysis of the stability of the carbonium ions formed made it possible to explain why the methyl-substituted products predominated and to put forward a mechanism for the formation of trace amounts of ethyl-substituted compounds.[120] In contrast to the insertion mechanisms described previously, here it is suggested that, in the growing vinylidene complex, the α-carbon atom in relation to the metal remains constantly bound to the metal and that the methylene intermediate is inserted in the double bond between the α- and β-carbon atoms in the surface compound.

However, the results of a study of the model homogeneous reaction of a cyclopropylidene complex of this kind permit the claim[121] that the methylene-vinylidene mechanism postulated[120] conflicts with experiment, because in the model reaction (Scheme 5) the pathway (*a*) does not occur (if the FT synthesis took place via the methylene-vinylidene mechanism, branched isomers should have predominated among its products, which has not been observed experimentally):



Scheme 5

On the basis of a model reaction carried out on ruthenium clusters, a mechanism has been proposed[122] for chain propagation, whose key stage is the addition of an alkyne to an alkylidyne (CR) with formation of a 1,3-dimetalloallyl, which is then hydrogenated and converted into an alkylidyne (CCH_2R) containing one CH_2 group more than the initial alkylidyne:

In the interaction of CO with H_2 on the surface, water and a surface methylene or methylidyne group are formed. The interaction of two methylidyne groups leads to the formation of an acetylene complex bound to the surface, whose reduction leads to the appearance of ethylidyne. The products of the hydrogenation of any alkylidyne is the corresponding alkane and the β-elimination of

Scheme 6

hydrogen from the intermediate containing more than two carbon atoms can lead to the formation of an α-alkene. The reaction of an alkyne with methylidyne or CO + H_2O leads to intermediates which serve as sources of the formation of branched hydrocarbons and oxygen-containing compounds. Analysis of the products of a model reaction carried out on a ruthenium cluster[122] permits the claim that the main products of the FT synthesis in this case should be unbranched compounds and that 2-methyl derivatives should predominate among the isomeric structures. According to Scheme 6, the principal oxygen-containing compounds are terminal functional compounds.

An interesting pathway leading to the formation of a C–C bond in the catalytic hydrogenation of CO has been proposed.[123] The authors[123] believe that the C–O bond is dissociated as a consequence of the deoxygenation of a formyl surface complex with its subsequent conversion into an alkyl surface compound. The only products of the deoxygenation of formaldehyde in its interaction with a titanium complex (I) were μ-oxotitanium complexes (II) and ethylene:

$$\underset{\text{(I)}}{2[CpTiCl_2(THF)_{1.5}]} + CH_2O \rightarrow \underset{\text{(II)}}{[CpTiCl_2]_2O} + CH_2{=}CH_2.$$

The data obtained suggested two mechanisms of the formation of ethylene (Scheme 7):

Thus one can postulate the possibility of the formation of surface CH_2 groups via the successive reactions

$$CO + H_2 \rightarrow (CH_2O) \xrightarrow{\text{deoxygenation}} (CH_2).$$

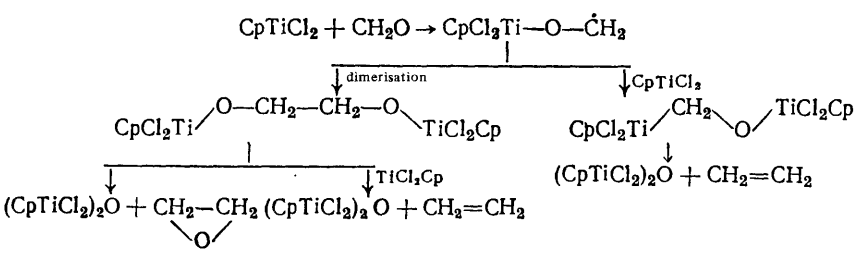
This pathway is an alternative to the mechanisms according to which the reaction of the CH_2O intermediate is accompanied by dehydration.[37,74,76]

An unusual example of the formation of a C–C bond has been described.[124] The carbonyl complex Tâ(CO)$_2$(dmpe)$_2$Cl [dmpe = 1,2-bis(dimethylphosphino)ethane] was reduced to Ta($Me_3SiOC{\equiv}COSiMe_3$)(dmpe)$_2$($SeiMe_3$), which contains an acetylenic diether ligand incorporating the C≡C multiple bond. A similar method of formation of a C–C bond in the reduction of the carbonyl ligand using metallic sodium had been described earlier.[125]

VI. The mechanism of the Fischer–Tropsch synthesis from the standpoint of organometallic synthesis

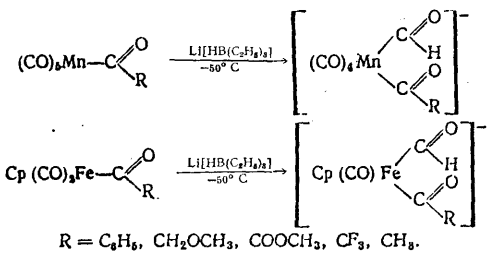
The vigorous investigation of reactions involving the homogeneous hydrogenation of carbon monoxide during the last few years[126] made it possible to obtain interesting information about the mechanisms of the individual stages of this reaction and about the structures and reactivities of the postulated intermediates in the FT synthesis.

In a number of studies,[28,127–135] it has been postulated that CO is hydrogenated via the pathway



$$M{-}CO \rightarrow M{-}CHO \rightarrow M{-}CH_2OH \rightarrow M{-}CH_3,$$

in which the key intermediates are formyl and hydroxymethylene complexes.

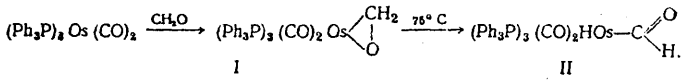


The first formylmetal complex has been obtained in a reaction with participation of the mixed anhydride of formic and acetic acids.[136] Subsequently the possibility of the hydride attack on the carbonyl coordinated in the metal complex was demonstrated convincingly in a series of model systems. Initially a large set of anionic formylmetal complexes was obtained by treating various metal carbonyls with strong hydride donors such as the trialkoxyboron hydrides $Na^+HB(OCH_3)_3^-$ and $K^+HB[C_3H_7\text{-iso}]_3^-$.[137] The structures of the mononuclear formylmetal complex $(C_2H_5)_2\overset{+}{N}$.[3,5-$(CH_3)_2C_6H_3O)_3P$]$(CO)_3FeCHO^-$ and the dinuclear complex $(C_2H_5)_4\overset{+}{N}(CO)_9Re_2CHO^-$ have been most fully characterised.[138,139]

The formation of a series of unstable formylmetal complexes of many metals has been demonstrated with the aid of physicochemical analytical methods (IR spectroscopy, ^{13}C NMR, and especially ^1H NMR, because the proton in the $-C\overset{O}{\diagdown\!\!\diagup H}$ group gives rise to the characteristic chemical shift δ = 14–16 p.p.m.).[140] It is of interest that, on treating the anionic ion complex $(CO)_4FeCHO^-$ with hydrogen chloride, the formation of formaldehyde was observed. Treatment of osmium and iridium carbonyl clusters with hydride donors of the type of $Li[HB(C_2H_5)_3]$ leads to the reduction of one of the carbonyl ligands to the formyl ligand and the formation of the cluster anions $[Os_3(CO)_{11}CHO^-]$ and $[Ir_4(CO)_{11}CHO^-]$.[141,142] Carbonyl complexes containing acyl ligand as well as the formyl

Scheme 7

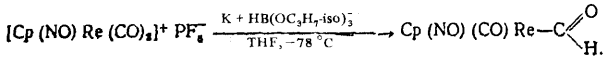
ligand synthesised:[143]



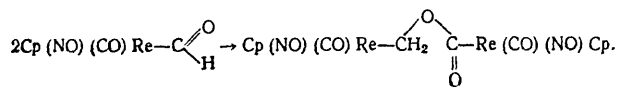
$R = C_6H_5$, CH_2OCH_3, $COOCH_3$, CF_3, CH_3.

The study of the properties of the fairly stable anionic iron carbonyl complex $[(C_6H_5O)_3P](CO)_3Fe-CHO$ showed that the formyl complexes can function also as hydride donors in relation to ketones, alkyl halides, and metal carbonyls (in the last case a new formylmetal complex is formed) and as "the target" of further hydride attack.[137,138]

Quantum-chemical calculations[144] indicate the instability of the formyl complex $[(CO)_4FeCHO]^-$, but analogous calculated data of the same workers[145] show that the alkali metal ion (Li^+), coordinated to the carbonyl ligand of the $[HFe(CO)_4]^-$ anion, promotes the insertion of CO in the Fe–H bond (the migration of the hydride group to the carbonyl ligand), affording a stable formyl complex in which the alkali metal ion is coordinated to the formyl oxygen.



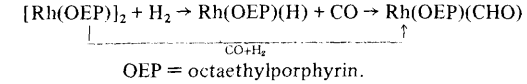
The neutral formylmetal complex (II) and not the anionic complex is probably a closer analogue of the surface intermediates formed in the FT synthesis. It was first detected when formaldehyde was added to an osmium carbonyl complex with subsequent rearrangement:[146]



I II

The complex (I) contains coordinated formaldehyde, which can be regarded as a tautomer of the hydroxymethylene ligand $-C\begin{matrix}H\\OH\end{matrix}$.

The reduction of the carbonyl ligand to the formyl ligand via external transfer of hydride hydrogen was first achieved by means of the reaction [147]

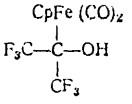


The complex Cp(NO)(CO)ReCHO has also been synthesised, isolated, and identified in other studies.[148,149] It has been shown that the formyl complex can behave as a hydride donor in relation to the formyl group:[150]

According to numerous data obtained in the study of the reactions leading to the formyl complexes of rhenium,[147–149] titanium,[151] and niobium and iron,[152] an obligatory condition for the formation of such compounds is probably only the outer-sphere transfer of hydride hydrogen as a result of the nucleophilic attack by strong hydride on the coordinated carbonyl.

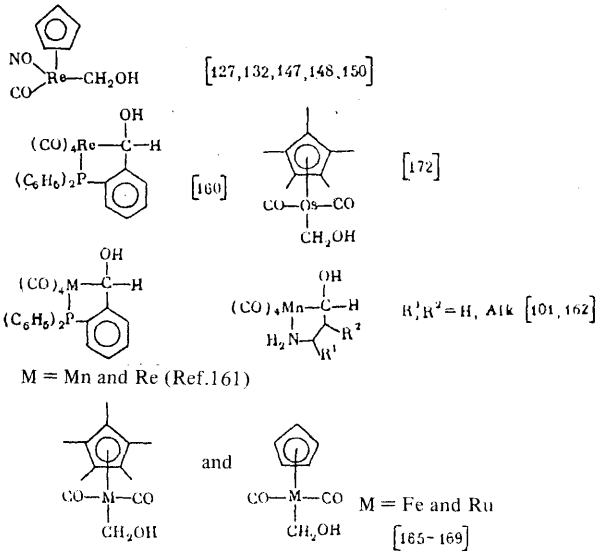
However, there have been a number of reports[153–156] about the inner-sphere hydride transfer in carbonyl hydride complexes. Thus the complex $[CpFe(CO)_2H]$ in solution in an alcohol R–OH forms the intermediate [CpFe(CO)(CHO)(ROH)], in which the formate HCOOR is produced as a result of the interaction between the ligands CHO and R–OH.[153] The synthesis of a formyl complex by the direct insertion of CO in the M–H bond has also been reported:[157–158] the authors of these studies achieved the following reactions:

OEP = octaethylporphyrin.



The formyl complex proved to be stable in the solid state and in solution in benzene.

Thus the possibility of the existence of the structures $M-C\begin{matrix}O\\H\end{matrix}$ as intermediates in the FT synthesis has been established for a large group of metals.

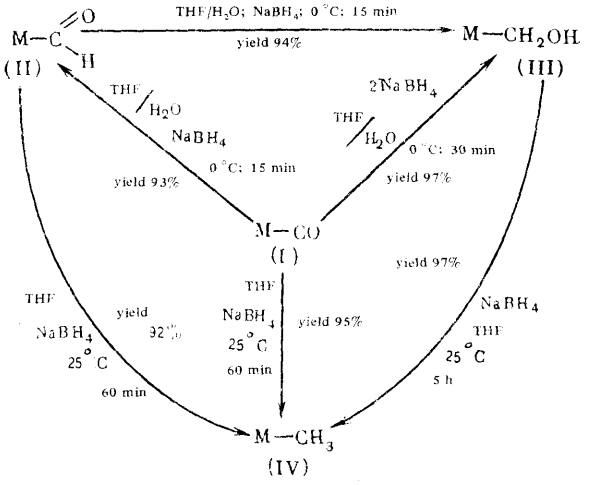


It was noted above that the involvement of the α-hydroxymethylene complex

as the most important intermediate has also been postulated in the mechanisms of the FT synthesis based on the insertion of CO. A structure close to the hydroxymethylene structure was first identified by Blackmore et al.:[159]

Subsequently it was possible to obtain similar complexes for rhenium,[101,127,132,147,148,150,160–162] osmium,[163,164] iron,[119,165–169] ruthenium,[165–169] manganese,[101,161,162] and rhodium.[170,171] Some of them are presented below [the numerals in square brackets denote references (Translator)]:

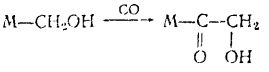
M = Mn and Re (Ref. 161)



and

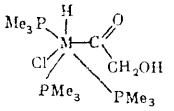
All the intermediate forms in the CO hydrogenation reaction in the presence of model systems have been isolated and identified.[148–150] The reduction of CO in the mononuclear rhenium

carbonyl complex has been achieved using $NaBH_4$ as the reductant.[148] The existence of the postulated stages and intermediates in the FT synthesis, namely M–CO, M–CHO, $M-CH_2OH$, and $M-CH_3$, has been demonstrated.

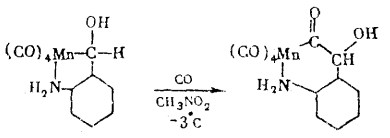


The authors were able to obtain, isolate, and identify the following compounds: $CpRe(CO)(NO)CHO$ (II), $CpRe(CO)(NO)CH_2OH$ (III), and $CpRe(CO)(NO)CH_3$ (IV). It was established that the reduction reaction pathways are in accordance with the parallel-consecutive Scheme 8:

Scheme 8

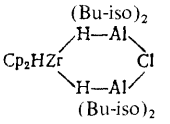


Similar results have been obtained in other studies.[149,150]

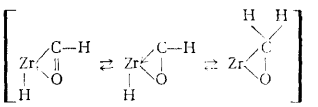


Although the possibility of the migration insertion of CO in the M–C bond has been demonstrated,[85–87] the attempts to achieve the formation of an α-hydroxyacyl complex in the presence of the hydroxylated complexes indicated via the reaction

were unsuccessful.[132] Such a hydroxyacyl complex is assumed to be an intermediate in certain mechanisms of the FT synthesis. A complex of this kind has, however, been obtained recently by the oxidative addition of 2,5-dihydroxy-1,4-dioxan to $(C_8H_{14})M(PMe_3)_3Cl$, where M = Ir or Rh:[102]

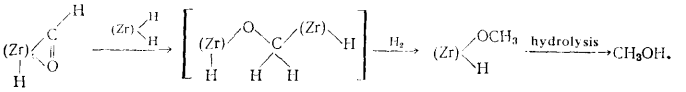


A hydroxyacyl complex is also formed in the carbonylation of an α-hydroxyalkyl complex:[101]



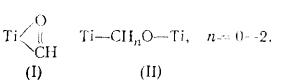
The possibility of the formation of diacyl complexes of the type $PhCH_2-C(=O)-C(=O)-M(CO)_4$ as a result of the double insertion of CO has been demonstrated.[173,174]

Cases are known where the hydrogenation of carbonyl ligands leads to the formation of not only the oxygen-containing products, typical for catalytic reactions based on CO and H_2. Thus it has been shown[175] that the following complex is formed in a solution of diisobutylaluminium hydride (DIBAH) in the presence of Cp_2ZrCl_2:



Its treatment with carbon monoxide at a pressure of 1–4 atm and room temperature leads to the precipitation of $CpZrCl_2$ and the formation of a mixture of aluminium alkyls, the hydrolysis of the latter resulting in the formation of aliphatic C_1-C_5 n-alcohols. The proposed reaction mechanism includes the dissociation of the complex with elimination of DIBAH and the liberation of a coordination site at the Zr atom. Intramolecular migration of the Zr–H hydride or external attack on the Al–H hydride is tentatively the first stage in the reduction of CO. There are data indicating the stoichiometric reduction of CO to methanol using pentadienylzirconium complexes.[127,153] On the basis of a series of indirect data, it has been postulated that a formylzirconium hydride complex is a key intermediate:

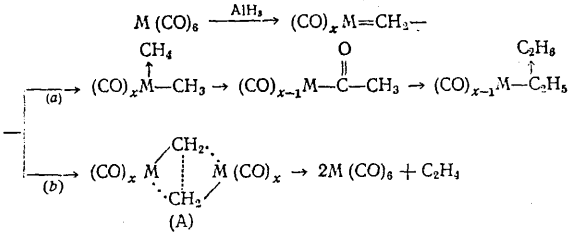
Such binding of the formyl ligand ensures, according to the authors, its stabilisation. The methoxy-ligand is formed in accordance with Scheme 9:



Scheme 9

A similar scheme has been described by Fachinetti et al.[176]

C_1-C_4 hydrocarbons have been obtained by treating $(CO)_5MnCH_3$ or $CpFe(CO)_2CH_3$ with carbon monoxide and B_2H_6.[177]

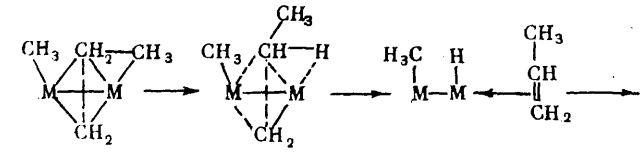


The homogeneous hydrogenation of CO to methane has been achieved[129] using $Cp_2Ti(CO)_2$. After the reaction, the active titanium complex is converted into the inactive octanuclear cluster $Cp_6Ti_8O_8$, whose formation is attributed to the liberation of water in the methane formation process. The π-formyl (or η^2-formyl) complex (I) or the μ_2-complex (II) is an intermediate in this case:

The stoichiometric reduction of CO in the interaction of $CpNbH_3$ with the metal carbonyls $M(CO)_6$, where M = Mo, W, or Cr, at 45 °C and a pressure of 1 atm in the presence of hydrogen leads to the formation of a mixture of C_1-C_3 hydrocarbons (the main product is C_2H_6).[178]

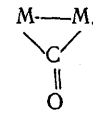
The stoichiometric model reaction involving the multistage reduction of CO to valeric acid has been achieved recently. After treatment with strong hydrogenating agents ($LiAlH_4$ or $NaBH_4$), the complex $[CpFe(CO)_2(PMe_3)]^+PF_6^-$ was converted into $Cp(PMe_3)(CO)FeMe$. Treatment of this complex with carbon monoxide at atmospheric pressure in the presence of $AgBF_4$ in tetrahydrofuran (THF) or CH_2Cl_2 led to the acyl complex $Cp(PMe_3)(CO)FeC(O)Me$, the reduction of which with tetrahydroborates afforded the alkyl complex $Cp(PMe_3)(CO)FeEt$. Numerous repetition of the CO insertion reaction and of the reduction of the resulting acyls made it possible to obtain the compound $Cp(PMe_3)$. .$(CO)FeC(O)Bu$. Finally treatment of this acyl complex with bromine water led to valeric acid $CH_3(CH_2)_3COOH$.[179]

The conversion of CO and H_2 into ethylene with a selectivity of 95% (the remainder being ethane and traces of methane and propane) in the $M(CO)_6$ (M = Cr, Mo, or W) system in the presence of a fourfold excess of AlH_3 in THF at 22 °C has been reported.[180] Experiments with deuterium have shown that AlH_3 is the only source of hydrogen. In order to account for the "anomalous" selectivity with respect to ethylene, the authors suggested the existence of carbene intermediates (A):

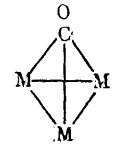


The pathway (*a*) includes the CO insertion stage leading to the formation of C_2 and C_3 hydrocarbons, while the pathway (*b*) leads to the dimerisation of the carbene intermediates, which gives rise to ethylene. The pathway (*b*) is probably preferred. Similar conclusions have been reached in other investigations.[181,182]

An interesting method of reducing CO by protonating polynuclear clusters with strong acids has been applied.[183] Treatment of the anionic cluster $[Fe_4(CO)_{13}]^{2-}$ with the strong protonating agent HSO_3CF_3 at room temperature led to the formation of methane, its yield depending greatly on the acidity of the medium. Isotope data showed that methane is formed from the carbonyl ligand as a result of the direct attack by an acid proton; after the elimination of water, a carbide is formed whose hydrogenation leads to methane:



Interesting data supporting the carbide mechanism of the FT synthesis have been obtained in a study of the interaction of $[(RhC_5Me_5)_2Cl_4]$ with $LiCH_3$, which resulted in the formation of *cis*- and *trans*-$[(RhC_5Me_5)_2(\mu\text{-}CH_2)_2Me_2]$.[184] Propene, methane, and traces of ethylene are formed on pyrolysis of the *trans*-isomer, which confirms the possibility of the polymerisation of methylene species on the metal surface, initiated by a metal hydride, as the key stage in the carbide mechanism:

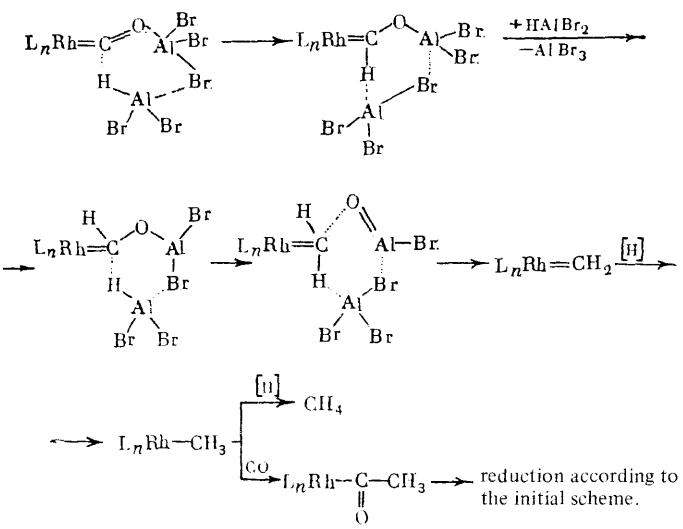


Much work has been devoted in recent years to the creation of homogeneous catalysts of the FT synthesis. It was shown in 1977[185] that the carbonyl clusters $Os_3(CO)_{12}$ and $Ir_4(CO)_{12}$ in toluene at 140 °C, a synthesis mass ratio ($CO:H_2$ = 1:4), and a pressure of 2 atm convert the CO + H_2 mixture into methane at an insignificant rate (the degree of conversion of CO is 1% after 3–5 days). The addition of PPh_3 or PMe_3 increases slightly the activity of the catalysts and leads to the appearance of traces of ethane and propane. The authors note that the reduction of CO requires specifically polynuclear clusters in order to achieve the many-centre CO–metal interaction. Such activation of CO reduces greatly the C–O bond order.[19,186] It has been suggested[19,187] that cluster systems make it possible to model more effectively the characteristics of heterogeneous catalysis than mononuclear homogeneous systems. When CO is coordinated to two or more transition metal atoms, the bond order is greatly reduced. Thus whereas terminal carbonyl ligands are usually characterised by $\nu(CO) = 2000-2100\ cm^{-1}$, for bridged carbonyl complexes $\nu(CO) = 1700-1850\ cm^{-1}$ is characteristic of CO ligands bound to two metal atoms:

The bridged carbonyls linked to three metal atoms,

are characterised by an even greater decrease in the bond order involved in the binding of CO, because $\nu(CO) \simeq 1600\ cm^{-1}$ for μ^3-CO.[21]

The significant role of Lewis acids as effective cocatalysts in the homogeneous CO hydrogenation reaction has been confirmed in a study[188] that was a continuation of investigations initiated by Thomas et al.[185] Thus the clusters $Ir_4(CO)_{12}$, $Rh_6(CO)_{16}$, $Rh_4(CO)_{12}$, and $Ru_3(CO)_{12}$ exhibited a high activity in the homogeneous CO-hydrogenation reaction in $AlCl_3$, $AlBr_3$, or BBr_3 melts at 180 °C and 1 atm, the activity of, for example, $Ir_4(CO)_{12}$, being approximately 100 times greater under these conditions than in the absence of the Lewis acid.[188] The reaction products were C_1-C_4 hydrocarbons and their ratios depended greatly on the reaction conditions—temperature, pressure, and the catalytic system used.



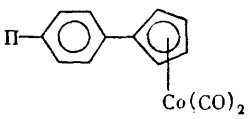
The carbonyl cluster $Os_3(CO)_{12}$ (the precursor of the catalyst) and BBr_3 (solvent and cocatalyst) proved to be active in the hydrogenation of CO to C_1-C_5 hydrocarbons.[189] It was shown that the osmium cluster $Os_2(CO)_6Br_4$, acting as the catalyst, is formed during the reaction.

Comparison of the data of Demitras and Muetterties[188] and Choi and Muetterties[189] with those of Thomas et al.[185] permits the conclusion that the presence of the Lewis acid does indeed stimulate the formation of the C–C bond in the hyrogenation of CO. It has been suggested[189] that BBr_3 facilitates the insertion of CO in the Os–C bond with formation of intermediates of the type $Os-CR-OBBr_3$.

Similar results have been obtained in the presence of the complex $Ir_4(CO)_{12}$ in a flow reactor, where the productivity of 0.2 mol of CO per mole of $Ir_4(CO)_{12}$ per minute was achieved with respect to C_1-C_6 hydrocarbons.[190]

When the $M_n(CO)_m-AlBr_3-Al$ homogeneous catalytic system was used, a mixture of C_1-C_4 hydrocarbons was formed from CO and H_2.[191,192] The metals tested fell within the following series in terms of their activities: Rh > Ir > Ru > Os > Ni. Under the catalytic conditions, an aprotic system possessing strong reducing and acid properties is formed in this case. The binding of the water evolved in the reduction process prevents the decomposition of the catalytic process. Apart from aluminium, magnesium or $LiAlH_4$ may be used as the reductant. The following mechanism has been proposed on the basis of the experimental data:[192]

Scheme 10



A whole series of processes involving the reduction of CO by hydrogen in the presence of soluble Rh clusters at high temperatures and very high pressures have been patented.[193] The reaction products are methanol, ethylene glycol, and propylene glycol. The true catalyst is the polynuclear anionic cluster $[Rh_{12}(CO)_{34}]^{2-}$ formed under the reaction conditions from various precursors.

It has been suggested that the rhodium bis-sulphide cluster $[Rh_{17}(CO)_{32}(S)_2]^{8-}$ be used for the conversion of the CO + H_2 mixture into aliphatic alcohols.[194]

As already mentioned above, it is best to use polynuclear metallic active centres in the hydrogenation of CO. However, some workers believe that the active centre for the hydrogenation of CO has the structure of a mononuclear complex.[133] The homogeneous hydrogenation of CO by hydrogen to ethanol (main product), ethanol, propanol, and the formates of these three alcohols using as the catalyst the mononuclear carbonyl hydride $HCo(CO)_4$, formed under the reaction conditions from the $Co_2(CO)_8$ cluster, has been reported.[195] The conversion of the CO + H_2 mixture into methanol and methyl formate has been observed using the ruthenium clusters, unstable under reaction conditions (225–275 °C, 1300 atm) as the catalyst precursors.[196] It was then established that the true reaction catalyst is mononuclear ruthenium pentacarbonyl $Ru(CO)_5$.

Mention should be made of a study[197] in which the homogeneous hydrogenation of CO to a mixture of C_1-C_{20} normal alkanes (170–200 °C, 30 atm, CO : H_2 = 1 : 3, solvent—n-octane) was achieved in the presence of an immobilised cobalt catalyst:

grafted to a polymer П. Control experiments established that activity in this reaction is shown in fact by the immobilised mononuclear cobalt centre and not by soluble cobalt compounds or metallic cobalt.

—o0o—

In conclusion one should note that the enormous amount of experimental data concerning the mechanism of the FT synthesis accumulated at the present time makes it possible to assume confidently that the reaction proceeds via a multiplicity of pathways. The preference for a particular pathway is determined by the composition of the catalyst, the conditions of the synthesis, and a number of factors, the type of catalyst being decisive.

The synthesis of ethylene glycol from formaldehyde

G A Korneeva, S M Loktev
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

ABSTRACT. The literature and patent data on the hydroformylation of formaldehyde to glycolaldehyde—an intermediate in the synthesis of ethylene glycol—are surveyed. The principal types of catalytic systems based on rhodium and cobalt carbonyl complexes and the characteristic features of the reaction are examined and compared with the hydroformylation of olefins. The reaction mechanism is discussed in the light of the reactions of the formaldehyde complexes of transition metals.
The bibliography includes 116 references.

I. Introduction

The wide-scale employment of ethylene glycol in various fields has led to an increasing requirement for this compound. The world output of ethylene glycol in 1983 was 4.5 million tonnes.[1] It is obtained industrially from ethylene as the raw material, the cost of which has been continuously growing.

The search for new methods of synthesising ethylene glycol, especially without involving ethylene, is of practical interest. Methods based on the use of the synthesis gas (Table 1) are recognised as being the most promising.

According to technical-economic forecasts,[1] processes involving the carbonylation of formaldehyde are especially attractive. Information about them is available in recently published monographs[3–6] and reviews.[2,7–15]

Apart from the procedures listed in Table 1, the following methods of synthesis of ethylene glycol are known.

(1) Condensation of formaldehyde:

$$2\,CH_2O \rightarrow HOCH_2CHO \xrightarrow{H_2} CH_2OH{-}CH_2OH.$$

The process is carried out[16] in the presence of alkaline catalysts, deposited on zeolites, at 90–100 °C using aqueous formaldehyde solutions. The yield of glycolaldehyde is about 12% and the rate of its formation is 2.5–4.5 mol litre^{-1} h^{-1}.

(2) Redox reaction (radical coupling, radical condensation):[8,17–20]

$$CH_3OH + CH_3OH \rightarrow CH_2OH{-}CH_2OH + (H_2),$$
$$CH_3OH + CH_2O \rightarrow CH_2OH{-}CH_2OH.$$

The reaction is carried out either in the liquid phase or in the gas phase at a pressure of 5–14 MPa at 225–350 °C using radical generators. The yield of ethylene glycol is 200 kg m^{-3} h^{-1}.

(3) The coupling of methyl formate with formaldehyde:[5,21]

$$HCOOCH_3 + CH_2O \rightarrow HOCH_2COOCH_3.$$

Table 1. The synthesis of ethylene glycol and its derivatives.[1]

Starting materials	Catalyst	Temperature, °C	Pressure MPa	Products	Selectivity, %	Turnover number, 10^3 s^{-1}
$CO + H_2$	$Cs_3Rh_{17}(CO)S_2$	200	100	ethylene glycol methanol	69 21	18.1
$CH_3OH + CO + O_2$	PdI_2—$CuSO_4$	120	2	dimethyl oxalate dimethyl carbonate	78 22	37.0
	Pd/γ-Al_2O_3—NO	120	2	dimethyl oxalate dimethyl carbonate	80 20	21.7
$HCHO + CO + H_2O$	HF	50	2	glycolic acid	94	0.07
$CH_2OCH_2OCH_2O + CO + H_2O$	$RhCl_3$—HI	150	7	glycolic acid acetic and formic acids	39 61	6.4
Paraformaldehyde + H_2 + CO	$Co_2(CO)_8$	120	10	glycolaldehyde methanol	77 23	11.6
	$RhCl(CO)(PPh_3)_2$—NEt_3—PPh_3			glycolaldehyde methanol and carbohydrates	76 24	148.0
Paraformaldehyde + BuOH + H_2 + CO	$Co(OAc)_2(C_5Me_5)$	160	19	monobutyl ether of ethylene glycol dibutyl ether of ethylene glycol methanol	62 6 4	18.8
$H_2C(OMe)_2 + CO + H_2$	$Co_2(CO)_8$	180	20	methyl ether of ethylene glycol dimethyl ether of ethylene glycol methanol and others	46 9 45	3.1

The reaction is performed at atmospheric pressure and a temperature of about 90 °C in the presence of strong acids—HF, H_2SO_4, etc. (selectivity up to 90%). The replacement of methyl formate by formic acid leads to the formation of glycolic acid.

This review considers the method of synthesis of glycolaldehyde (the intermediate in the synthesis of ethylene glycol) by the hydroformylation of formaldehyde:

$$HCHO + CO + H_2 \rightarrow HOCH_2CHO \xrightarrow{H_2} CH_2OH{-}CH_2OH.$$

II. The state of research into formaldehyde hydroformylation processes

Hitherto this reaction has been usually carried out as a homogeneous-catalytic process in solutions of cobalt and rhodium complexes. The subsequent reduction of glycolaldehyde to ethylene glycol was carried out in the same reactor using ruthenium catalysts.[22]

A process involving the hydroformylation of formaldehyde on heterogeneous rhodium catalysts modified by tertiary phosphines immobilised on solid carriers has been patented:[23] at 25 MPa and 120–160 °C, the degree of conversion of formaldehyde into glycolaldehyde in the liquid-phase process is 60–80%. Paraformaldehyde, trioxan, or an aqueous formaldehyde solution can serve as the starting material. In the last case, the selectivity with respect to the target product is low because of the acceleration of the side reaction involving the hydrogenation of glycolaldehyde to methanol. The use of trioxan makes it necessary to carry out the reaction at high temperatures (~300 °C) in order to form monomeric formaldehyde; for the depolymerisation of paraformaldehyde it is sufficient to carry out the reaction at temperatures in the range 90–130 °C,[24] which makes formaldehyde the most suitable reagent.

The high reactivity of formaldehyde and glycolaldehyde leads to many side and secondary reactions, which lower the selectivity of the hydroformylation. Among them, the main reactions are the Cannizzaro–Tishchenko reaction, hydrogenation to methanol and its conversion into higher homologues, and the aldol condensation of formaldehyde to carbohydrates. The last three reactions are catalysed by the components of the catalytic system and the condensation involves the target product (glycolaldehyde) in undesirable reactions. Undesirable side and secondary reactions are accelerated particularly strongly by cobalt catalysts. Thus in the hydroformylation of formaldehyde in the presence of $Co_2(CO)_8$ in dioxan at 120 °C, the maximum selectivity does not exceed 40%; under the same conditions, $RhCl(CO)(PPh_3)_2$ affords glycolaldehyde in 85% yield.[25]

The severe hydroformylation conditions (pressure 15.0–25.0 MPa, temperature 150–170 °C), the low selectivity, and the low rate of reaction in the presence of cobalt catalysts (turnover number 11.6 s^{-1} [26] compared with 148.0 s^{-1} for the rhodium system[27]) made it necessary to give preference to rhodium catalysts. The patent and scientific publications in recent years have been concerned predominantly with processes occurring in solutions of rhodium complexes.

Satisfactory parameters (selectivity up to 95%, degree of conversion of formaldehyde more than 95%, catalyst turnover number about 150 × 10^3 s^{-1}) are attained when promoting agents are introduced into the phosphine–rhodium catalytic system: acids of organic[28] and inorganic[29] origin, organometallic compounds or metal salts,[30–35] and bases.[36,37]

The technological formulation of the synthesis of ethylene glycol by the hydroformylation of formaldehyde is at present in the research and development stage; in the versions proposed, either a single-stage process, combining the hydroformylation of formaldehyde and the hydrogenation of glycolaldehyde in a single reactor,[38] or a two-stage process,[39] in which the catalyst of the first stage is a rhodium complex (in solution, in the form of a suspension, or deposited on a solid carrier), are used. It has been proposed that the process be carried out with a low degree of conversion of formaldehyde[40] in order to reduce the amount of condensation products.

Rhodium catalysts modified with PAr_3 are most often used; they are deactivated, as in the hydroformylation of olefins,[41,42] by the transformation of the phosphine ligand resulting from the *ortho*-metallation of the aromatic substituent.[43] There is no information about the regeneration of such catalysts.

The catalyst can be returned to the cycle when a phosphine amide ligand is used. The following solvent system is employed for this purpose: a low-boiling solvent (acetonitrile), a non-polar high-boiling solvent (*m*-xylene), and a small amount of a second low-boiling solvent (diethyl ether) to decompose the acetonitrile–methanol azeotrope. The most complete regeneration is attained when the ligand is 3-(diphenylphosphino)-*N*-methyl-*N*-oxadecylpropionamide $PPh_2(CH_2)_2C(O)N(CH_3)(C_{18}H_{37})$. A selectivity with respect to glycolaldehyde up to 93–99% is then ensured; the degree of conversion of formaldehyde after the first cycle is reduced by 13% and the residual rhodium content in glycolaldehyde is 26 p.p.m.[44,45]

Glycolaldehyde may be hydrogenated to ethylene glycol in the presence of heterogeneous hydrogenation catalysts: Raney nickel (100% conversion of formaldehyde for 49% selectivity with respect to ethylene glycol is achieved at 110 °C and 7.0 MPa), palladium on charcoal (70 °C, 70 MPa, 100% conversion, 73% selectivity), etc.[46,47] Methods for the hydrogenation of glycolaldehyde to ethylene glycol in quantitative yields have been patented.[48,49]

There exists an example of the selective homogeneous hydrogenation of glycolaldehyde in a static system in solution of $Rh(acac)CO_2$ in *m*-xylene, tetraglyme, or dioxan containing PPh_3: the yield of ethylene glycol is 90.2 mole % at 80 °C, a pressure of 10 MPa, and a $CO:H_2$ ratio of 1:1.[50]

The catalytic method for the hydroformylation of formaldehyde which have been described can be arbitrarily divided into two groups: (a) with participation of carboxylic acid *NN*-dialkylamides in the coordination sphere of rhodium; (b) based on the activation of the catalytic system with the aid of solvents or promoting agents which exhibit a very pronounced basicity ensuring the ionisation of the catalytic complex.

III. Hydroformylation of formaldehyde in solution in amides

The study of the characteristic features of the catalytic hydroformylation of formaldehyde has shown[51] that, in contrast to the reaction with olefins, high rates of formation of glycolaldehyde in the presence of rhodium complexes are attained only when carboxylic acid *NN*-dialkylamides are used as solvents. Only methanol is formed in other solvents (Table 2).

Best results have been obtained in dimethylacetamide using chlorine-containing triphenylphosphine rhodium complexes, especially $RhCl(CO)(PPh_3)_2$, as precursors of the catalyst. The inhibition of the reaction by glycolaldehyde has been noted.[51]

Among other features distinguishing this reaction from the hydroformylation of olefins, the presence of chlorine in the coordination sphere of the active rhodium species and the independence of the rate and selectivity of the reaction of the basicity of the ligand are important. The exclusion of the ligand PR_3 from the catalytic system renders it inactive, which is also uncharacteristic of the hydroformylation of olefins.

The kinetic study of the reaction in the presence of $RhCl(CO)(PPh_3)_2$—the catalyst precursor—in dimethylformamide (DMF) showed that [25,52] the introduction of $Et_3N.HCl$ or Et_3N

into the reaction mixture does not alter the initial rate of hydroformylation. Since the hydroformylation of olefins in the presence of $HRh(CO)(PPh_3)_3$ proceeds at higher rates than in the presence of $RhCl(CO)(PPh_3)_2$ and the catalytic activity of the latter is attributed to the reaction[53,54]

$$RhCl(CO)(PPh_3)_2 + Et_3N + H_2 \rightleftarrows HRh(CO)(PPh_3)_2 + Et_3N \cdot HCl,$$
$$RhCl(CO)(PPh_3)_2 + H_2 \rightleftarrows HRh(CO)(PPh_3)_2 + HCl,$$

the addition of $Et_3N.HCl$ should reduce the rate of reaction, while the addition of Et_3N or the use of $HRh(CO)(PPh_3)_3$ from the very beginning should increase it. The absence of these effects as well as the absence of an induction period when $RhCl(CO)(PPh_3)_2$ is used and also the detection of this complex among the hydroformylation products permitted the conclusion that chlorine enters into the composition of the catalytically active complex.

Table 2. Hydroformylation of formaldehyde in the presence of various catalyst precursors and solvents.[51]

Catalyst precursor	Solvent	Yield, %	
		of glycolaldehyde	of methanol
$HRh(CO)(PPh_3)_3$	acetic acid	0.0	18.6
	acetone	0.0	42.0
	acetonitrile	2.8	43.0
	benzene	0.0	19.7
	1,4-dioxan	0.0	31.7
	pyridine	2.8	4.4
	dimethylacetamide	5.6	4.1
	dimethylformamide	12.3	4.7
$RhCl(CO)(PPh_3)_2$*	"	39.8	2.3
	formamide	0.0	0.0
	methylformamide	0.0	0.0
	methylphenylformamide	0.0	0.0
	dimethylacetamide	49.7	1.2
$Rh_4(CO)_{12}$	dimethylformamide	0.0	0.0
$RhCl(CO)_2(PPh_3)$	"	19.6	0.4
$Rh(C_8H_{12})(PPh_3)_2 \cdot BPh_4$	"	3.8	26.7

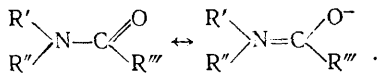
Note. Reaction conditions: [Rh] = 5×10^{-3} M, [HCHO] = 2 M, $CO:H_2$ = 1:1, temperature 110 °C, pressure 8 MPa, reaction time 3 h, 100 ml of solvent.
*[HCHO] = 1 M, pressure 13 MPa.

Taking the above into account, the mechanism of the hydroformylation of formaldehyde must provide for the presence of Cl in the intermediates; overall, it resembles the familiar mechanism of the hydroformylation of olefins:[25]

$$RhCl(CO)(PPh_3)_2 \overset{k_1}{\rightleftarrows} RhCl(CO)(PPh_3) + PPh_3,$$
$$RhCl(CO)(PPh_3) + H_2 \overset{k_2}{\rightleftarrows} RhH_2Cl(CO)(Ph_3P),$$
$$RhH_2Cl(CO)(PPh_3) + HCHO \overset{k_3}{\rightleftarrows} RhHCl(CO)(PPh_3)(CH_2OH),$$
$$RhHCl(CO)(PPh_3)(CH_2OH) + CO \overset{k_4}{\rightleftarrows} \underset{(I)}{RhHCl(CO)(PPh_3)(COCH_2OH)},$$
$$(I) \overset{k_5}{\rightleftarrows} RhCl(CO)(PPh_3) + HOCH_2CHO.$$

On the assumption that the initial rate of reaction is $v_0 = k_5[I]$ when $RhCl(CO)(PPh_3)_2$ with an excess of PPh_3 in solution in a dimethylamide is used, the rate constants for the individual stages (k_1, k_2, k_3, and k_4) were determined and it was shown that the equation derived, namely

$$v_0 = {}^1/_2 k_1 k_2 k_3 k_4 k_5 P_{H_2} P_{CO} [HCHO]_0 \left\{ \left(1 + \frac{4[Rh]_0}{k_1 (1+X)} \right)^{1/2} - 1 \right\}, \quad (1)$$

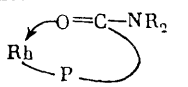


where

$$X = k_2 P_{H_2} + k_2 k_3 P_{H_2} [HCHO]_0 + k_2 k_3 P_{H_2} P_{CO} [HCHO]_0,$$

describes satisfactorily the experimental kinetics.[52] The activation energy for the reaction is 18.3 kcal mol^{-1}.

It is noteworthy that the proposed mechanism does not provide for the participation in the reaction of the chlororhodium dicarbonyl complex with PPh_3, namely $RhCl(CO)_2(PPh_3)$, since such species were incapable of activating H_2 in the oxidative addition reaction in the first stage. At the same time, it is known that the strength of the Rh–CO bond in chlororhodium monocarbonyl complexes of this kind is high and the mobility of the CO group is therefore low.[54] The hydroformylation conditions favour the stabilisation of the dicarbonyl derivative,[55] which may be formed in the reaction with CO or as a result of the decarbonylation of the amide or formaldehyde.[55,56] Such a derivative is characterised by the lability of the carbonyl ligand.[54,55]



The inhibition of the hydroformylation of formaldehyde by an excess of the phosphine ligand[46,51] confirms a dissociative mechanism analogous to that of the hydroformylation of olefins. Here *NN*-dialkylamides are regarded as electron-donating ligands. A specific feature of such molecules is the presence of resonance structures:

There are numerous data supporting the coordination interaction of the amide with the transition metal. In the vast majority of cases, the coordination is to the oxygen atom of the carbonyl group of the amide[57,58] but there are data also for other types of coordination.[56,59] The possibility of rotation about the C–N bond makes it possible to explain the absence of the activating influence of asymmetrically substituted amides (for example *N*-methyl-*N*-phenylformamide—see Table 2) on the hydroformylation of formaldehyde by the steric hindrance to the coordination.[51]

The coordination interaction of the amide with rhodium has been confirmed as a result of a study[45] in which the hydroformylation of formaldehyde was investigated (130 °C, pressure of 1:1 CO + H_2 mixture 12.9 MPa) in the presence of two different rhodium catalysts: $RhCl(CO)(PPh_3)_2$ (Spencer's catalyst) and $RhCl(CO)[PPh_2(CH_2)_2.(CO)N(CH_3)_2]_2$. When acetonitrile is used as the solvent, the degree of conversion of formaldehyde after 3 h in the presence of a rhodium catalyst with the *NN*-dimethyl-3-(diphenylphosphino)-propionamide ligand was 62% for a selectivity with respect to glycolaldehyde of 75% (the yield of methanol was 2%), i.e. higher parameters were attained than in the presence of $RhCl(CO)(PPh_3)_2$.

On the other hand, when an *NN*-dialkylamide was used as the solvent, no differences were observed between the catalytic activities of Spencer's catalyst and the catalyst with the *NN*-dimethyl-3-(diphenylphosphino)propionamide ligand, which indicates the similarity of the catalytic systems. It has been suggested[51,60] that the phosphineamiderhodium catalyst contains the Rh–amide coordinate bond:

The chelate effect in this complex apparently decreases the concentration of the amide groups in the reaction medium.

The hydroformylation of formaldehyde under mild conditions (80 °C, 5.0 MPa) with a conversion close to 100% and a selectivity up to 64% proved to be possible when the dimeric rhodium thiolate complex $Rh_2(\mu\text{-}S\text{-t-Bu})_2(PPh_3)_2$ (A) was used as the precursor of the catalyst with an excess of PPh_3 in solution in *NN*-dialkylamides.[61] After the reaction had been carried out, the complex was isolated unchanged. The complex $Rh_2(\mu\text{-}S\text{-t-Bu})_2(CO)_4$ (B), which has no phosphine ligands, was inactive, as in the hydroformylation of olefins.[62] An excess of the ligand hinders the transformation (A) → (B) and thereby prevents the deactivation of the catalyst. The replacement of the PPh_3 ligands by the more electron-donating PMe_3 ligands promotes the formation of methanol.

In the presence of $RhCl(CO)(PPh_3)_2$, the selectivity with respect to glycolaldehyde can be increased by carrying out the hydroformylation of formaldehyde in pyridine (selectivity 98%, conversion 83.7%, pressure 9.0 MPa, H_2:CO = 2:1),[48] while in the presence of the complex (A) the use of this solvent did not allow the attainment of such high parameters.[61] The employment of the catalyst precursor (A) produces best results in *NN*-dialkylamides and the reaction then proceeds under milder conditions and at higher rates than in the case when Spencer's catalyst is used. Parameters of the hydroformylation of formaldehyde analogous to those obtained using Spencer's catalyst in DMF [51] are attained in the given instance at a pressure of 1.5 MPa, while the use of hexamethylphosphoramide makes it possible to avoid hydrogenation to methanol. Since the observed selectivity and activity are not the same as those obtained in the presence of $RhCl(CO)(PPh_3)_2$ and are attained under milder conditions, while the dinuclear rhodium thiolate complex remains unchanged after the reaction, it has been suggested that the catalysis is affected by another active species of unknown nature.

It has been established that, in the hydroformylation of olefins in the presence of the rhodium complex (A), the dinuclear carbonyl phosphine rhodium thiolate species is active.[62]

The selective hydroformylation of formaldehyde in solution in DMF using $Rh_4(CO)_{12}$ modified with PPh_3 and promoted with HI as the catalyst precursor has been reported.[63]

IV. Hydroformylation in the presence of basic promoting agents or solvents

Another group of catalytic systems used in formaldehyde hydroformylation reactions includes a basic promoting agent, for example, amines or highly basic solvents, which makes it possible to eliminate amides from the composition of the catalytic solution. Table 3 presents data indicating the influence of the nature of the solvent on the yield of the formaldehyde hydroformylation products.[43] The use of pyridine and its derivatives increases significantly the activity and selectivity of the process.

In the hydroformylation in the presence of rhodium complexes promoted by organic bases or alkalis,[27,37,64] the active catalytic system is formed from neutral or cationic rhodium complexes both containing and not containing chlorine, while the employment of amide or highly basic solvents is not obligatory in this instance (Table 4). Thus the addition of a small amount of triethylamine to the $RhCl(CO)(PPh_3)_2$ system in tetraglyme (Table 4) made it possible to increase the degree of conversion of formaldehyde in the hydroformylation reaction almost from zero to 90% for a selectivity with respect to glycolaldehyde of 76%.

Table 3. The influence of the nature of the solvent on the hydroformylation of formaldehyde.[43]

Solvent	Yield, %		
	glycol-aldehyde	ethylene glycol	methanol
γ-Picoline	49.4	0.3	0.4
β-Picoline	43.0	0.3	0.2
Pyridine	42.9	0.4	0.2
4-Pentylpyridine	39.7	0.4	0.4
3,5-Diethylpyridine	35.1	0.1	0.1
Triethylamine	9.4	0.0	0.4
Dimethylformamide	4.3	0.0	0.1
Dioxan	0.8	0.0	0.1
Dimethyl sulphoxide	7.4	0.0	0.2
Acetone	~0	~0	0.1

Note. $[CH_2O]$ = 19.1 mM, $[RhCl(CO)(PPh_3)_2]$ = 0.05 mM, temperature 70 °C, pressure of 1:1 CO + H_2 mixture 5 MPa, reaction time 3 h.

Table 4. Promotion of the rhodium catalysts $RhCl(CO)(PPh_3)_2$ + $n PPh_3$ by bases.[27]

n	Solvent	Base	Concentration of base, M	Reaction time, min	Conversion of CH_2O, %	Selectivity, %		
						glycol-aldehyde	methanol	condensation products
0	tetraglyme	—		30	traces			
0	»	NEt_3	$1\cdot10^{-2}$	30	84	71	6	
0	»	NEt_3	$2\cdot10^{-2}$	30	90	76	6	
8	»	NaOAc	$1.8\cdot10^{-2}$	15	94	14	11	
30	*NN*-dubutyl-formamide	KOH	$5\cdot10^{-3}$	60	75	56	20	
30	»	KOH *	$2.5\cdot10^{-2}$	30	62	2	10	
30**	*NN*-dimethyl-acetamide	NEt_3	$0.84\cdot10^{-2}$	30	43	86	5	9
30**	»	NEt_3	$1.8\cdot10^{-2}$	30	95	71	2	27
30**	»	NEt_3	$45\cdot10^{-2}$	15	95	17	6	77

Note. Reaction conditions: $[Rh] = 5 \times 10^{-3}$ M, $[CH_2O]$ = 2 M, $CO:H_2$ = 1:1, 17.5 MPa, 110 °C.
*The reaction is carried out in the presence of the 18-crown-6 ether to improve the dissolution of KOH.
**Pressure 21.0 MPa.

When the formaldehyde hydroformylation reaction was carried out in the presence of $HRh(CO)_2(PPh_3)_2$, it was established that the catalytic system includes, together with $HRh(CO)_2(PPh_3)_2$, also the anionic species $[Rh(CO)_4]^-$ and $[Rh(CO)_2(PPh_3)_2]^-$.[27] It was suggested that the amine additive serves as a bifunctional promoting agent for the catalytic system. By deprotonating the rhodium carbonyl hydride, it gives rise to an anionic species, to which catalytic activity is attributed:

$$HRh(CO)_2(PPh_3)_2 \rightleftarrows [Rh(CO)_2(PPh_3)_2]^- .$$

Furthermore, the amine serves as a source of protons, which are essential for the formation of the hydroxymethyl complex:

$$[R_3NH]^+ + CH_2O + [Rh(CO)_3(PPh_3)]^- \rightarrow HOCH_2Rh(CO)_3(PPh_3) + R_3N.$$

Being strong bases, the anionic rhodium complexes afford hydrides on interaction with weak acids (H_2, ROH).[65] The formation of the anionic rhodium complexes also in the absence of amine promoting agents can apparently be explained by the reversibility of this reaction:

$$[Rh(CO)_x(PPh_3)_{4-x}]^- + MeOH \rightleftarrows HRh(CO)_x(PPh_3)_{4-x} + [MeO]^-.$$

The activity of $[Rh(CO)_2(PPh_3)_2]^-$ and the inertness of $[Rh(CO)_4]^-$ have been demonstrated by special experiments.[27] However, it is still not understood at which stage the activity of PPh_3 is manifested.

According to the existing ideas, the anionic precursors of the catalyst react with formaldehyde to form a hydroxymethyl complex which catalyses in its turn the hydrogenation, via the elimination of methanol, after interaction with H_2 or H^+:

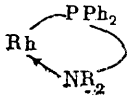
Scheme 1

$$CH_2O + [Rh(CO)_2(PPh_3)_2]^- + H^+ \rightarrow HOCH_2Rh(CO)_2(PPh_3)_2$$

$$\downarrow -CO \qquad\qquad \downarrow H^+$$

$$HOCH_2Rh(CO)(PPh_3)_2 \qquad CH_3OH + [Rh(CO)_2(PPh_3)_2]^+$$

$$\downarrow H_2 \qquad\qquad \downarrow H_2$$



$$CH_3OH + HRh(CO)_2(PPh_3)_3 \qquad H^+ + HRh(CO)_2(PPh_3)_2 .$$

Experiment shows that both pathways can be followed, since the yield of methanol increases in the presence of an excess of the proton-donating reagent or with increase in the H_2:CO ratio.[27]

The effect of the amide in the presence of Spencer's catalyst is analogous to the effect of amines. The mechanism of its action is determined by its weak electron-donating properties.[27]

In the presence of both organic and inorganic basic promoting agents, the rate of hydroformylation of formaldehyde increases, but its condensation is at the same time accelerated sharply, which impairs the process selectivity (Table 4). Apart from methanol, trioses, tetroses, pentoses, and hexoses, have been identified among the side products, the rate of their formation increasing with increase in temperature and in the basicity of the medium. In addition, glyceraldehyde, 1,3-dihydroxypropanone, erythrose, 1,3-dihydroxybutanone, etc. have been detected in systems of this kind.[66]

In contrast to the above, the use of phosphineaminerhodium complexes with ligands of the type $PPh_2(CH_2)_2N(CH_3)_2$ [45] in acetone lowers the content of side products to 9%, which can be explained by the close proximity of the amino-group to the metal complex-forming atom and the chelate effect:

There is no information about the contribution of the condensation reaction of formaldehyde in its hydroformylation to glycolaldehyde. The only mention is in a communication[67] where the hydroformylation of $[^{13}C]$-CH_2O using a polynuclear rhodium complex in amide solvents in the presence of dimethylimidazole or *N*-methylpyrrolidinone is described. The results of the analysis of the positions of the labels in the products permitted the conclusion that under these conditions the dimerisation of formaldehyde to glycolaldehyde does not occur.

It has also been postulated that the catalytically active mononuclear species participating in the hydrogenation of CO to ethylene glycol are anionic in character. In tetraglyme, in the presence of the $Rh(acac)(CO)_2$ catalyst precursor promoted with *N*-methylimidazole (*N*-MI) (the latter is taken in a large excess),[68] whereupon the reaction is believed to proceed via the intermediate formation of formaldehyde and its hydroformylation, the catalyst is the mononuclear anionic rhodium complex formed when rhodium hydride is acted upon by a base:

$$HRh(CO)_3(N\text{-}MI) \rightarrow HRh(CO)_4 \rightarrow [N\text{-}MI]^+[Rh(CO)_4]^-.$$

The fact that the hydrogenation of CO to ethylene glycol, proceeding via the hydroformylation of formaldehyde, is catalysed by polynuclear complexes has been confirmed.[69] The anionic nature of such clusters is also determined, according to the authors, by the action of basic additives or solvents.

On the basis of the idea that the species active in the catalysis of the hydroformylation of formaldehyde are anionic in character and, as the function of the basic promoting agents and polar solvents consists in reducing the oxidised rhodium precursors to low-valence catalytically active anions, Marchionna and Longoni[70] used anionic rhodium carbonyl complexes as direct catalyst precursors. Because of this, they were able to exclude completely basic promoting agents and solvents from the composition of the catalytic system, ensuring nevertheless a high degree of conversion of formaldehyde and a high selectivity of the formation of glycolaldehyde. The $[Rh_5(CO)_{15}]^- - [Rh(CO)_2Cl_2]^- - PPh_3$ catalytic system (with a composition of 1:5:10) at 110 °C, 12 MPa, and with the ratio $CO:H_2 = 1:1$ makes it possible to obtain glycolaldehyde in 87.9% yield in acetone, while the yield of methanol is 9.4%.

It had been shown earlier[63] that selective hydroformylation is possible when one uses the $Rh_4(CO)_{12} - PPh_3 - HI$ catalytic system in which the postulated catalytically active species $[Rh_5(CO)_{15-x}(PPh_3)_x]^-$ with $x = 1,2$ and $[Rh(CO)_2Cl_2]^-$ were identified by IR spectroscopy. In the presence of PPh_3, the complex $[Rh_5(CO)_{15}]^-$ produces $[Rh_5(CO)_{15-x}(PPh_3)_x]^-$.[70] Its combination with $[Rh(CO)_2Cl_2]^-$ leads to the formation of a system analogous to that generated from $Rh_4(CO)_{12} - PPh_3 - HI$.

It has been suggested that each of the two anionic species $[Rh_5(CO)_{15-x}(PPh_3)_x]^-$ and $[Rh(CO)_2Cl_2]^-$ participates in the catalytic cycle, accelerating different hydroformylation stages.

The increased activity of the first of these complexes in the hydroformylation of formaldehyde to methanol provided grounds for the hypothesis that it has an activating effect on H_2 and CH_2O. According to the authors,[70] the anion $[Rh(CO_2)Cl_2]^-$, to which an enhanced activity is attributed in the migration insertion of carbon monoxide with formation of a hydroxyacyl intermediate,[71] is responsible for the high selectivity of the formation of glycolaldehyde. The combination of such or similar species in optimum proportions can ensure a fairly high rate of hydroformylation of formaldehyde with a satisfactory selectivity with respect to glycolaldehyde.

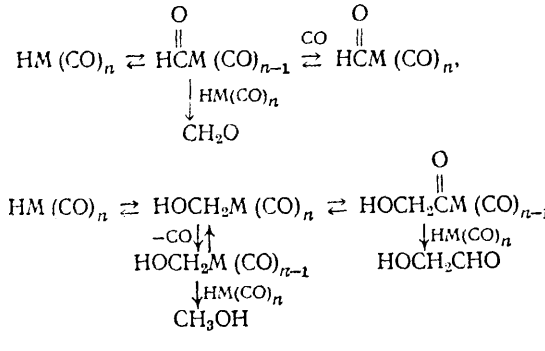
A two-component Co–Rh catalytic heterometallic anionic system has been described.[72] Using mixtures of $Rh_4(CO)_{12}$ and $CoCl_2.6H_2O$ or the mixed cluster $Co_2Rh_2(CO)_{12}$ as the catalyst precursors in DMF, it was possible to achieve a selectivity with respect to glycolaldehyde up to 65%. At the same time, the formation of ethylene glycol was observed. The experiments were performed at 110 °C and a pressure of 10–12 MPa. It was established that at least two types of catalytically active species are generated in the system: species of one type catalyse the formation of glycolaldehyde, while others catalyse its hydrogenation as well as the hydrogenation of CH_2O to ethylene glycol and methanol respectively. The identified structure of the carbonyl complexes before and after the

reaction indicates the reduction of the cobalt and rhodium carbonyls to $[Co(CO)_4]^-$ and $[Rh(CO)_4]^-$ respectively:

$$5Co_2Rh_2(CO)_{12} \rightarrow 2[Rh_5(CO)_{15}]^- + 4Co^{2+} + 6[Co(CO)_4]^- + 6CO,$$
$$5Rh_4(CO)_{12} + 2H_2O + 4DMF + 2CO \rightarrow 4[Rh_5(CO)_{15}]^- + 4DMFH^+ + 2CO_2,$$
$$[Rh_5(CO)_{15}]^- + Cl^- \rightleftarrows [Rh_5(CO)_{14}Cl]^{2-} + CO,$$
$$[Rh_5(CO)_{15}]^- + 10Cl^- + 2Co^{2+} + 3CO \rightarrow 5[Rh(CO)_2Cl_2]^- + 2[Co(CO)_4]^-.$$

The nature of the species active in hydroformylation was not established, but it has been suggested that the monometallic rhodium anion $[Rh(CO)_4]^-$ plays this role.

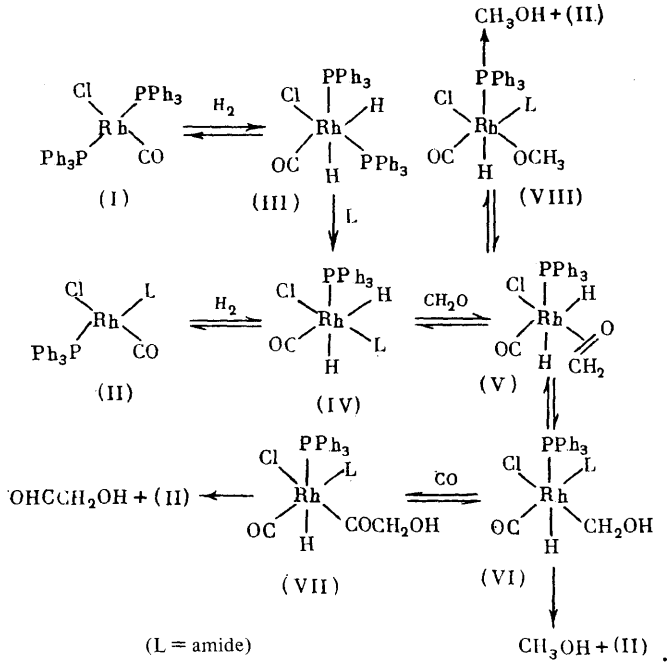
One should apparently not rule out also the possible activity of mixed Co–Rh carbonyls. The formation of an equilibrium mixture of the Co–Rh clusters $Co_2Rh_2(CO)_{12}$ and $Co_3Rh(CO)_{12}$ and the complexes $CoRh(CO)_8$ and $CoRh(CO)_7$ from $Co_2(CO)_8$ and $Rh_4(CO)_{12}$ under CO pressure at 80–90 °C in solutions in dioxan has been reported.[73]



A gradual deactivation of the Co–Rh catalytic system is attributed to the reduction of $[Co(CO)_4]^-$ and $[Rh(CO)_4]^-$. The highest selectivity is observed in the system containing cobalt(II) compounds, which is attributed to their ability to oxidise rhodium complexes to anionic carbonyls and to serve as the buffer for the stabilisation of the active rhodium, the formal oxidation state of which is between +1 and −0.2.

An alternative explanation consists in the cooperative action of the cobalt and rhodium complexes in different oxidation states, analogous to the situation arising in the catalytic hydrogenation of CO to ethylene glycol in the presence of ruthenium carbonyls.[74,75]

V. The chemistry of coordinated formaldehyde and the hydroformylation mechanism

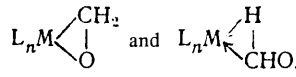


It is believed that the mechanism of the hydroformylation of formaldehyde is on the whole analogous to the known mechanism of the hydroformylation of olefins. In particular, the reaction is determined by the polar character of formaldehyde. It has been suggested that the formation of formaldehyde is an intermediate stage in the homogeneous-catalytic hydrogenation of CO to methanol, methyl formate, ethylene glycol, and other polyhydric alcohols in the presence of transition metal complexes (Scheme 2); the hydroformylation of CH_2O determines the content of ethylene glycol in the products:[4,76]

Scheme 2

Spencer[51] proposed a mechanism for the hydroformylation of formaldehyde in which provision is made for catalysis by a chlororhodium complex in the presence of an *NN*-dialkylamide:

Scheme 3

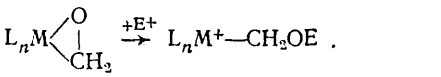


According to this Scheme, the dialkylamide should influence the stages involving the formation of the products (IV)–(VII). The absence of a directing effect of the amide is explained by its displacement by formaldehyde [the reaction (IV) ⇄ (V)]. Evidently this stage represents the interaction of formaldehyde with a solution of the metal complex. Such reactions are known for many neutral or cationic transition metal complexes.[77,78] The reactions of anionic complexes with CH_2O have not been described, which must be borne in mind in connection with the postulated mechanism of their catalytic action.[22,70]

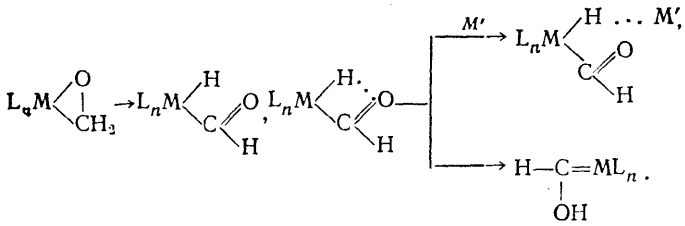
Metal complexes are also capable of interacting with a suspension of paraformaldehyde,[77] gaseous formaldehyde,[52] or an aqueous formalin solution;[53] when trioxan is used, higher temperatures are required for its degradation.[24] In most cases, the complex with the η^2-CH_2O ligand (a π-complex) or a metal carbonyl are formed under very mild conditions.[79,80] It has been established that the complex with the η^2-CH_2O ligand is the most probable precursor in all subsequent reactions of the coordinated formaldehyde,[77] its formation being promoted by the presence of the PR_3 ligands, which are readily substituted in the interaction with CH_2O. As a result of the ligand exchange with CH_2O, stable complexes of this type have been obtained. The first such complex $(CO)_2(PPh_3)_2Os(CH_2O)$ was described in 1979.[81] The complexes $(CO)_2FeL_2(CH_2O)$,[80] $Cp_2V(CH_2O)$,[82] $CpRe(CO)_2(CH_2O)$,[83] $Cp_2Mn(CH_2O)$,[84] and the cationic complex $CpRe(NO)(PPh_3)(CH_2O)^+$ [85] have also been obtained. There are data concerning the bridge type coordination of the μ-CH_2O ligand, which are of interest in connection with the hypothesis that polynuclear and tetrametallic complexes of the type

$$(\eta^5\text{-}C_5H_5)_2Zr(Cl)(\mu\text{-}CH_2O)(Cl)Zr(\eta^5\text{-}C_5H_5)_2$$

are active.[76,86]

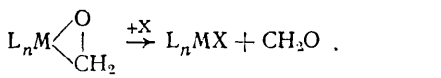


The interaction of formaldehyde with ML_n can lead to the bidentate binding of CH_2O of two types:[81,83,87,88]

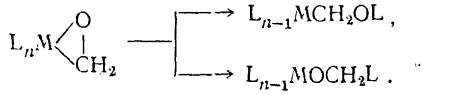


A characteristic feature is the weakening of the C=O bond in such compounds compared with the bond in the non-coordinated formaldehyde, which is manifested by the ν(CO) stretching vibration frequency.

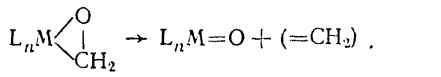
The reactions of the coordinated formaldehyde η^2-CH_2O in the transition metal complex are summarised below:[77,89]



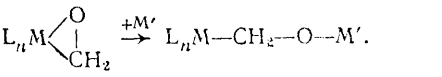
(1) attack on the oxygen atom of the coordinated formaldehyde:[80,82]



(2) Oxidative addition with formation of a formyl derivative:[81]



(3) Displacement of formaldehyde from the coordination sphere:[82]



(4) Insertion of formaldehyde in an M–H [82] or M–C [90] bond:

(5) Dissociation of the C=O bond of formaldehyde with its deoxygenation:[89]

(6) Ditto with formation of the bridging μ-CH_2O form:[86,89]

The mode of reaction and its rate are determined by the nature of the metal, the ligand environment, and the reaction conditions.

Certain other, perhaps unexpected, reactions have also been described. Thus the interaction of the cation $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3).(\eta^2\text{-}CH_2O)]^+$ with PR_3 (R = Rh or Me) at 25 °C led to the formation of the adduct[91]

$$[(\eta^5\text{-}C_5H_5)\,Re\,(NO)\,(PPh_3)\,(OCH_2PR_3)]^+.$$

instead of the expected substitution of the coordinated CH_2O by PR_3.

Reactions (1)–(4) should apparently be assigned to the hydroformylation mechanism proper.

A metal characterised by appropriate oxophilic properties can combine with formaldehyde oxidatively with participation of the C=O or C–H bonds.

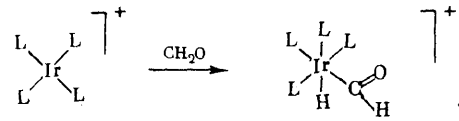
The last reaction, leading to the formation of the formyl complex, is of interest in connection with the mechanism, postulated by Keim et al.,[92] of the formation of ethylene glycol in the presence of solutions of cobalt carbonyls in the hydrogenation of CO:

$$(CO)_n\,Co{-}CHO \xrightarrow{HCo(CO)_n} (CO)_n\,Co{-}CH_2O{-}Co\,(CO)_n \xrightarrow{CO}$$
$$\rightarrow (CO)_n\,Co{-}CO{-}CH_2O{-}Co\,(CO)_n \xrightarrow{H_2} CH_2OH{-}CH_2OH.$$

The key stage is that of the interaction of the formyl complex, formed from CO and H_2, with the carbonyl hydride. In addition, it may prove to be the key stage in the formation of active carbonyl derivatives of the metal in the carbonylation of metal complexes by formaldehyde.

The decarbonylation of formaldehyde by metal complexes proceeds via an oxidative addition stage with formation of a formyl complex.[77,93] The equilibrium

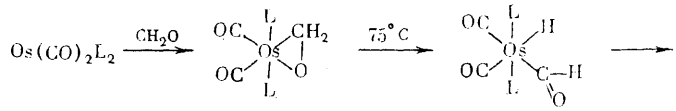
$$H_yM\,(Co)_x \rightleftarrows H_{y-1}M\,(Co)_{x-1}\,(CHO)$$



explains the relative instability of the formyl intermediates.[93]

It has recently been reported that nickel complexes are capable of rapidly decarbonylating formaldehyde via the stoichiometric reaction[89]

$$Ni\,(PR_3)_4 + CH_2O \rightarrow Ni\,(PR_3)_3\,(CO) + H_2.$$



The presence of the rigid bulky np_3 ligand {np_3 = tris[2-diphenylphosphino)ethylamine]} in the coordination sphere makes it possible to alter the formaldehyde reaction pathway and the decarbonylation reaction may become catalytic.[79]

Relatively stable formyl complexes are obtained by the oxidative addition of formaldehyde to cationic or neutral square planar iridium(I) complexes:[80]

Many mono- and poly-nuclear, cationic, neutral, and anionic formyl complexes have been described.[77,78,94] It has been shown for some of them that the M–CHO fragment is an effective hydride donor[91,95] and that it can be stabilised by an electrophile.[96]

The rearrangement $(\eta^2\text{-}CH_2O)M \rightarrow HM{-}CHO \rightarrow MCO$ has been observed for the osmium carbonyl complex:[81]

The main reaction of the coordinated formaldehyde in the hydroformylation process is reaction (4) (L = H) with formation of a hydroxymethyl derivative, which is a precursor of glycolaldehyde: the methoxy-intermediate controls the formation of methyl formate, both affording methanol after reductive elimination.

The insertion of formaldehyde in the M–H bond in the hydroformylation process with formation of the M–O and M–C bonds should determine the ratio of the methyl formate and

glycolaldehyde formed. However, there also exists the view that the presence of a compound with the M–O bond is not an obligatory condition for the formation of formate, since it can be obtained via the reaction[97]

$$HO-CH_2M(CO)_n + RCH_2OH \rightarrow RCH_2\overset{O}{\overset{\|}{O}}CH + HM(CO)_n.$$

Examples of the methoxy-complexes described in the literature are fairly rare, one of them being $Cp_2W(CH_3)(OCH_3)$.[98]

The formation of the methoxy-derivative from the zirconium carbonyl complex has been observed in its reaction with hydrogen, which proceeds tentatively via the intermediate hydroformyl derivative $(\eta^5\text{-}C_5Me_5)_2Zr(H)(OCH)_3$.[99] The hydride donating capacity of the formyl derivative of Re^+ made it possible to obtain a 52% yield of the methoxy-complex from the $\eta^2\text{-}CH_2O$ cation:[91]

$$[CpRe(NO)(PPh_3)(\eta^2\text{-}CH_2O)]^+ + CpRe(NO)(PPh_3)(CHO) \rightarrow$$
$$\rightarrow CpRe(NO)(PPh_3)(OCH_3) + [CpRe(NO)(PPh_3)(CO)]^+.$$

The interaction of this methoxy-complex with $[Ph_3C]^+[PF_6]^-$ in CH_2Cl_2 results in the reformation of the initial complex.

The insertion of formaldehyde in the M–H bond in octaethylporphyrinrhodium hydride led to the formation of a hydroxymethyl derivative:[100] $Rh-H + CH_2O \rightarrow Rh-CH_2-OH$.

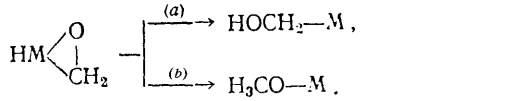
There exist numerous examples of similar complexes with different metals.[77,78]

Apparently both types of insertion, with formation of both M–C and M–O bonds, are possible under the conditions of the catalytic reactions of the carbonyl group in solutions of metal complexes.

The stoichiometric hydroformylation of formaldehyde has been carried out using $HCo(CO)_4$ as the source of hydrogen under the conditions of an excess of CO (the reaction was carried out at 0 °C and a pressure of 1 atm in CH_2Cl_2):[101]

$$2\,HCo(CO)_4 + CH_2O \xrightarrow{CO} HOCH_2CHO + Co_2(CO)_8.$$

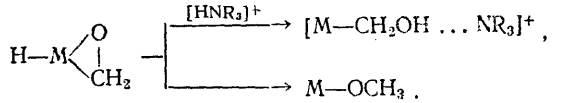
The yield with respect to the $HCo(CO)_4$ which reacted amounted to 60–90%. There was no methyl formate among the reaction products, which indicates the addition of formaldehyde to the carbonyl hydride complex with formation of a Co–C bond.



The possibility of the direct interaction of aldehydes with $HCo(CO)_4$ involving coordination via the oxygen atom of the carbonyl group has been noted;[97] the conversion of aldehydes into alcohols takes place in this way. The catalytic hydroformylation of epoxides presupposes the formation of the Co–C bond; both Co–C and Co–O bonds can participate in the reduction of CO.

The formation of methyl formates (Co–O) (yield up to 40%) in the complete absence of hydroxyaldehydes (Co–C) has been observed in the catalytic hydroformylation of aldehydes in the presence of cobalt carbonyls modified with PR_3.[102] Hydroxyaldehydes are also not formed under the conditions of the hydroformylation of olefins in the presence of cobalt or rhodium catalysts. The principal products of the secondary reactions of aldehydes in oxo synthesis are alkyl formates.[6,103]

In this connection one should note that, in contrast to other aliphatic aldehydes, formaldehyde is capable of undergoing π-type coordination ($\eta^2\text{-}CH_2O$). Coordination via the oxygen atom is characteristic of other aldehydes and π-type coordination is not observed.[104]



Methyl formate is formed in trace amounts in the catalytic hydroformylation of formaldehyde, the selectivity with respect to the target product (in the absence of condensation) being determined by the glycolaldehyde/methanol ratio and not by the glycolaldehyde/methyl formate ratio. The appreciable yield of methyl formate observed in the study of Marchionna and Longoni[72] can be explained by the interaction of formaldehyde with CO and the Cannizzaro–Tishchenko reaction.

It is apparently so far impossible to identify the precursor of methanol (the hydroxymethyl or methoxy-intermediate), but the majority of investigators incline to the view that the formation of methanol via a methoxy-derivative is unlikely, i.e. that pathway (*b*) does not play a significant role under the reaction conditions:

This can be accounted for by several causes. In particular, by thermodynamic control for certain metals. Thus it has been shown that the Ir–O bond in iridium complexes is weaker than the Ir–C bond.[105]

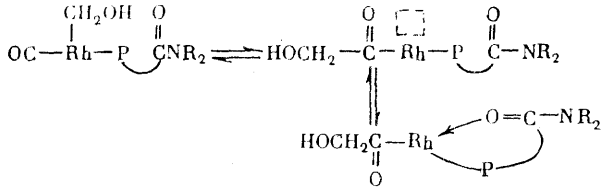
In addition it has been suggested[27] that the suppression of pathway (*b*) is due to the use of basic promoting agents and polar media which promote the hydroxymethyl hydrogen transfer:

and also to the nucleophilic character of the attack on the active anionic metal carbonyl species in their interaction with CH_2O:[27]

$$[Rh(CO)_2(PPh_3)_2]^- \overset{CH_2O,H^+}{\rightleftharpoons} HOCH_2Rh(CO)_2(PPh_3)_2.$$

The promotion of rhodium catalysts by acids also drives the reaction towards the formation of the M–C bond:[3,63]

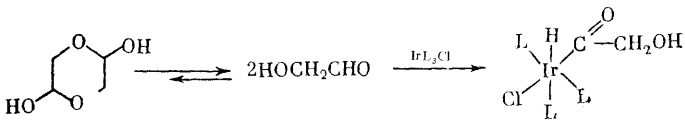
$$CH_2O + HI \rightarrow ICH_2OH,$$
$$ICH_2OH + M \rightarrow HOCH_2MI.$$



In most cases, it is impossible to state unambiguously how formaldehyde is converted into the hydroxymethyl intermediate: via insertion in the M–H bond, as a result of oxidative addition, or via a bimolecular mechanism.

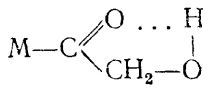
The migration insertion of CO in hydroxymethylcarbonyl complexes leads to the formation of a hydroxyacyl intermediate (see Scheme 3). This reaction has been achieved recently for the octaethylporphyrin (OEP) complex of rhodium:[106]

$$(OEP)Rh(CH_2OH) \xrightarrow{CO} (OEP)RhCOCH_2OH.$$



In contrast to alkylmetal carbonyl complexes, the carbonylation of the hydroxyalkyl derivatives proceeds with difficulty.[107,108] It has been suggested that this reaction is accelerated in the presence of electron-donating solvents, in particular amides, and in the presence of basic ligands. This hypothesis is based on the analogy with the migration insertion of CO in alkylmetal complexes with formation of acyl derivatives, which is promoted by alkali metal cations, amide solvents, basic promoting agents, and basic ligands.[4,76,109] For example, in the reaction involving the formation of acylmanganese complexes from the alkyl complexes, a significant increase in the rate was observed after the replacement of the solvent (mesitylene) by DMF.[76] The $HOCH_2CH_2OH$:CH_3OH ratio in the products must be determined by the ratio of the rates of insertion of CO and of the

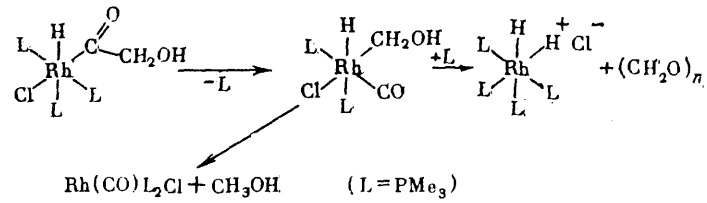
reductive elimination of CH_3OH from the common intermediate for these compounds. It is believed that the rate of the migration insertion with formation of a hydroxyacyl complex can greatly exceed the rate of the irreversible stage involving the reductive elimination of ethanol only in highly electron-donating solvents;[76] the participation of an electron-donating ligand in the reactions of compounds (IV)–(VII) (see Scheme 3) has therefore been postulated. A characteristic feature of the phosphine amide ligand is, according to Jacobson,[45] the acceleration of the reaction (VI) → (VII) as a consequence of the nucleophilic attack on the coordinatively-unsaturated organometallic centre:



Whereas hydromethyl complexes are relatively well known, the hydroxyacyl complexes have been studied to a much smaller extent.

Apart from the octaethylporphyrinrhodium complex,[106] the hydroxyacyliron complex $Fe(COCH_2OH)[P(OMe)_3]_2$ has been described.[110] Data are available concerning the stabilisation of the hydroxyacyl complexes by chelating ligands.[111] The hydroxyacyl-iridium and hydroxyacylrhodium hydride complexes have been recently characterised. They were obtained by the oxidative addition of glycolaldehyde to square-planar iridium(I) and rhodium(I) complexes:[105]

The hydroxyacylrhodium complex is formed in 92% yield from the glycolaldehyde dimer (2,5-dihydroxy-1,4-dioxan) at 25 °C; it is stable in the solid state, decomposing slowly in solution.

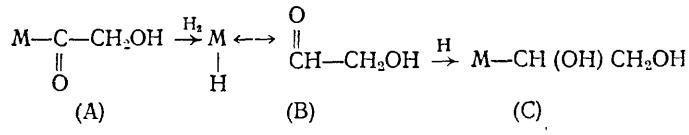


An important structural feature of such complexes proved to be the presence of an intramolecular hydrogen bond C=O...H–O, which leads to the formation of a five-membered ring:[105]

This was demonstrated by IR spectroscopy, showing a lack of dependence of ν_{OH} on the concentration of the complex in C_6D_6.

Since the $M-CH_2OH$ complexes show a greater tendency towards the migration insertion of CO than their analogues $M-CH_2OR$, it has been suggested that the presence of the intramolecular hydrogen bond is a general phenomenon for the α-hydroxyacyl complexes.

The reactions observed in the study of the thermal decomposition of the hydroxyacylrhodium complex[105] may serve as models of the reactions (V) → (IV), (VI) → CH_3OH + (II), and (VII) → (VI) (see Scheme 3). It has been established that the hydroxyacylrhodium complex undergoes on heating a reaction which is the reverse of the migration insertion of CO with formation of $Rh(CO)L_2Cl$ and CH_3OH from the hydroxymethyl intermediate. β-Elimination results in the formation of formaldehyde and a hydride, the reaction being the dominant one:



In addition, the elimination of glycolaldehyde was observed.

The fact that the introduction of the electron-donating ligand (PMe_3) inhibits the decomposition of the hydroxyacyl complex can apparently be associated with its activating effect in hydroformylation. The reversible formation of the hydroxyacyl complex via the oxidative addition of glycolaldehyde is consistent with Spencer's hypothesis of the reaction equilibrium (VII) ⇄ (II) (not shown in the Scheme), by means of which he explains the inhibition of the hydroformylation by the excess glycolaldehyde. A probable cause of this phenomenon may be the blocking of the coordination centres by the bidentate ligand $HOCH_2CHO$.[4] The reversibility of this stage distinguishes the mechanism considered from the mechanism of the hydroformylation of olefins, in which the reversible reductive elimination of the aldehyde has been demonstrated.

An alternative mechanism of the elimination of glycolaldehyde from the hydroxyacyl complex may involve intermolecular reductive elimination with participation of carbonyl hydride complexes. An analogous mechanism is known for the hydroformylation of olefins.[4,112,113]

The reactions

are of key importance in the formation of ethylene glycol.[114] The intermediate (C) may serve as a source of ethylene glycol or can enter into the chain propagation reaction under the influence of CO. The reduction of compound (B) can lead to the formation of ethylene glycol via the intermediate (C) or via the *O*-bonded alkoxy-complex. The latter does not participate in the chain propagation reaction.

The (A) → (B) → (C) chain of reactions has been investigated for the methoxyacetyliron complex $Cp(CO)_2Fe-C(O)-CH_2OCH_3$.[114]

As stated above, the selective hydrogenation of glycolaldehyde to ethylene glycol under the conditions of a homogeneous-catalytic reaction has been demonstrated in a solution of $Rh(acac)(CO)_2$.[50]

The intermediate transition metal complexes, which are believed to be formed in a hydroformylation of formaldehyde, can be distinguished by means of their spectral characteristics (Table 5).

VI. Conclusion

The formaldehyde hydroformylation reaction is of interest not only as a method of synthesis of glycolaldehyde and ethylene glycol but also as the postulated intermediate stage in the homogeneous-catalytic hydrogenation of CO to methyl formate, ethylene glycol, and other polyhydric alcohols. The formation of ethylene glycol from CO to H_2 requires severe conditions, probably because of the thermodynamic difficulties in the formaldehyde formation stage.

The absence of this energetically difficult stage in the synthesis of ethylene glycol by the hydroformylation of formaldehyde makes it possible to carry out the reaction under mild conditions: 8–10 MPa using mononuclear precursors of the rhodium catalyst and 1.5 MPa in the presence of the dinuclear rhodium complex.

The hydroformylation of formaldehyde differs from the analogous hydroformylation of olefins by a multiplicity of features due to the characteristics of the structure of the substrate molecule and the ability of formaldehyde to be coordinated in different ways to the transition metal complex. The formaldehyde hydroformylation mechanism postulated by analogy with the hydroformylation of olefins does not take into account all the experimentally observed features of this reaction and requires certain modifications.

The synthesis of organochlorine compounds from one-carbon molecules

Yu A Treger, V N Rozanov
GOSNIIKhLORPROEKT (State Chlorine Research Project), Moscow

ABSTRACT. Studies on the synthesis of organochlorine compounds from one-carbon molecules are surveyed. The thermodynamics, kinetics, and mechanisms of the direct and oxidative chlorination of methane, the esterification of methanol by hydrogen chloride, the hydrochlorination of acetylene, the hydrodechlorination of carbon tetrachloride, and the carbonylation of chloromethanes, the catalysts employed, and the practical applications of these reactions are examined.
The bibliography includes 143 references.

I. Introduction

The great importance of organochlorine compounds in modern chemistry and technology is determined by their extensive and rapidly growing applications. By virtue of a wide variety of physical and chemical properties, they are used in virtually all branches of industry, agriculture, and domestic technology.[1]

Poly(vinyl chloride) is "plastic number two" (after polyethylene) and chloromethanes serve as the raw materials in the manufacture of organosilicon products, fluorinated plastics, and Freons. Chloromethanes have also found extensive applications as highly effective solvents, for example, in the manufacture of cine-film and of synthetic fibre. The use of carboxylic acid chlorides for the modification of polymers is extremely promising.

Methods have now been developed for the synthesis of these organochlorine compounds from one-carbon molecules. A cheap and readily available raw material is especially necessary bearing in mind the large-scale requirements for these compounds.

We shall examine the following one-carbon substances used for the synthesis of organochlorine compounds: natural gas, methanol synthesised from carbon monoxide and hydrogen, which are in their turn obtained from natural gas, acetylene, which is a methane pyrolysis product or is obtained from calcium carbide, and carbon monoxide obtained from natural gas or coal. In fact the main starting material in all cases is natural gas or coal.

II. Direct chlorination of methane and its chloro-derivatives

The chlorination of methane and its chloro-derivatives by molecular chlorine is one of the most thoroughly investigated reactions, which has in addition found extensive practical applications.[2–4]

The chlorination of methane yields as a rule the entire range of chloromethanes:

$$CH_4 \xrightarrow[-HCl]{Cl_2} CH_3Cl \xrightarrow[-HCl]{Cl_2} CH_2Cl_2 \xrightarrow[-HCl]{Cl_2} CHCl_3 \xrightarrow[-HCl]{Cl_2} CCl_4.$$

Over a wide temperature range, the formation reactions of all chloromethanes are virtually irreversible, the heat of each successive substitution of a hydrogen atom by a chlorine atom in methane amounting to 100–102 kJ mol^{-1}.[2,3] The main advances achieved in the study of this process have been described in reviews.[2,3,5–7] Problems associated with the variation of the ratio of the products obtained towards the preferential formation of one of them, the removal of a large amount of heat of reaction at a high rate of the process, the formation of chlorohydrocarbons of the ethane–ethylene series on chlorination of methane, and the utilisation of the hydrogen chloride evolved in a large amount during the reaction are examined below.

Table 1. The ratios of the rate constants for the chlorination of methane and chloromethanes.

Figs.1–3 illustrate the molar proportions of the products of the chlorination of methane as a function of the chlorine : methane ratio, obtained experimentally in the gas-phase chlorination in a hollow container[8] and in a fluidised catalyst bed.[9] Table 1 presents the ratios of the rate constants for the chlorination of methane and chloromethanes obtained by different investigators by chlorination in a hollow container and on a catalyst.

Figs. 1–3 and Table 1 show that the composition of the chloromethanes obtained can change on chlorination of methane in a fluidised bed of a solid material. Whereas the presence of quartz sand has little influence on the reactivity of methane and chloromethanes,[9,11,12] in the presence of activated charcoal the composition of chloromethanes shifts sharply towards the preferential formation of tetrachloromethane.[9,13]

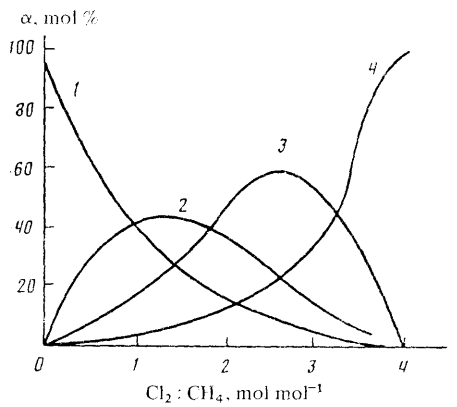

Figure 1. Free volume chlorination of methane:[8] *1*) CH_3Cl; *2*) CH_2Cl_2; *3*) $CHCl_3$; *4*) CCl_4; α—composition of reaction products.

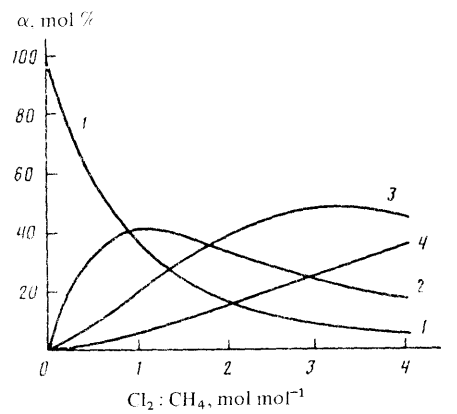

Figure 2. Chlorination of methane on quartz sand.[9]

In terms of absolute magnitude, the rate constants for the chlorination of methane and chloromethane in a fluidised quartz sand bed at 573 K are higher only by a factor of 1.5–2.6 than in a hollow container, while in the presence of activated charcoal the chlorination takes place at a much higher rate (Table 2).

Table 2. The ratios of the rate constants for chlorination in space[10] and on a catalyst[9] (the rate constants in bulk are quoted after Treger[1]).

Catalyst	*T*, K	Relative chlorination rate constants			
		CH_4	CH_3Cl	CH_2Cl_2	$CHCl_3$

»	673	0.6	3.4	3.4	5.0
Kaolin	573	6.3	7.2	6.8	5.5
»	573	1.7	6.5	7.2	11.6
Activated charcoal	573	6.3	18.1	55.7	142
ditto	673	0.95	11.9	26.0	83.7

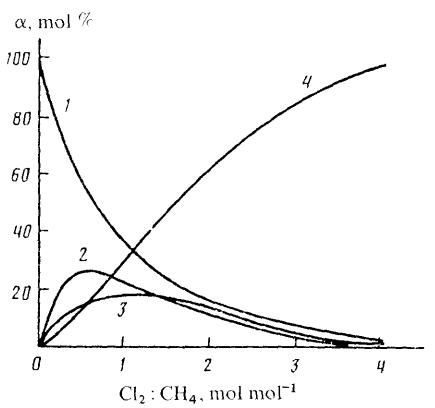

Figure 3. Chlorination of methane on activated charcoal.[9]

The heats and energies of activation for the adsorption of methane and its chloro-derivatives obtained by Belenko[15] enabled the author to put forward a mechanism for the catalytic participation of activated charcoal, kaolin, and sand in the chlorination process involving weak chemisorption of methane and chloromethanes on the surfaces of these catalysts. For activated charcoal, the activity series of methane and chloromethanes agree fully with the series based on their heats of adsorption (10.0 kJ mol^{-1} for CH_4, 29.5 kJ mol^{-1} for CH_3Cl, 43.5 kJ mol^{-1} for CH_2Cl_2, and 38.5 kJ mol^{-1} for $CHCl_3$).

It has been shown that the interaction of methane with a chlorinated carbon surface entails the substitution of chlorine atoms by CH_3 groups:[16]

$$\equiv C{-}Cl + CH_4 \rightarrow \equiv C{-}CH_3 + HCl.$$

The reaction takes place at temperatures above 470 K and at 770 K the chlorine atoms are adsorbed on the surface of technical carbon and are fully substituted, while those on the surface of activated charcoal are 78% substituted. It may be that the adsorbed CH_3 groups are rapidly chlorinated to CCl_3, which in fact explains the increased yield of tetrachloromethane when methane is chlorinated on activated charcoal.

On the other hand, one must note the fairly considerable scatter of the relative rate constants obtained by different investigators under the same chlorination conditions in a hollow container or in a fluidised catalyst bed (Table 1). The possible causes of this may be experimental difficulties [the necessity to maintain an isothermal regime under the conditions of an appreciable heat evolution and a high rate of reaction, failure to take into account the initiation of the reaction by light, different surface to volume ratios (S/V) for the reactor, and the deposition of carbon on the reactor walls or on the catalyst employed as a result of the decomposition of the chloromethanes]. It has been shown that the deposition of carbon on the catalyst increases the yield of tetrachloromethane.[17] Hence it is necessary to "condition" (coat with carbon) the walls in order to obtain reproducible results.[7]

The composition of the chloromethanes obtained on chlorination of methane can vary markedly depending on the gas flow regime in the reactor employed. Calculations have shown that on passing from the ideal displacement to the ideal mixing regime, the yield of the more chlorinated products increases.[18] Comparison of the results of the chlorination of methane in an isothermal ideal displacement reactor and in an industrial reactor showed that in the latter the yield of trichloromethane and tetrachloromethane is higher as a result of the reverse mixing.[19]

In the chlorination of methane in a hollow container,[10] the activation energy and the pre-exponential factor in the Arrhenius equation for the substitution of each successive hydrogen atom decrease steadily, since an increase in the number of chlorine atoms results in a decrease of the C–H bond energy in the chloromethane molecule but at the same time the attack by a chlorine atom on the hydrogen atom becomes more difficult. This behaviour is not observed in chlorination on catalysts.[9,14]

It is notable that the rate of chlorination both in a hollow container[10] and on a fluidised catalyst bed[9,11,12] depends on the concentrations of the initial reactants with an exponent of unity, which corresponds to the identical character of the chain termination reactions.

Different kinetics of the chlorination of methane in the presence of porous fillers of different nature have been obtained on a flow-circulation apparatus.[20] For the gas-phase reaction in the absence of fillers, the reaction orders with respect to the reactants were found to be unity and the activation energy was 121.3 ± 8.4 kJ mol^{-1}. The rate of reaction proved to be twice as high as in the study of Arai et al.[10] On the other hand, as will be seen in the discussion of the mechanism of the chlorination of methane, the first order reactions with respect to the reactants indicate chain termination on the wall, which should be more characteristic of the reaction in the presence of fillers.

The gas-phase chlorination of methane is initiated as a result of the effect of temperature, the catalytic effect of various solid materials or vessel walls, the effect of radiation and light, and various homogeneous catalysts. Because of its simplicity, the thermal chlorination of methane is used in virtually all industrial manufacturing processes.

The initiating influence of the surface consists in reducing the activation energy for the dissociation of the chlorine molecule by the heat of adsorption of the chlorine atom:[21]

$$\begin{array}{l} Cl_2 + 2S = 2SCl, \quad E_1 = \Delta H - 2q_{ClS}, \\ SCl = S + Cl^{\cdot}, \qquad E_2 = q_{ClS}, \end{array} \tag{1}$$

$$Cl_2 + S = SCl + Cl^{\cdot}, E_3 = \Delta H - q_{ClS}. \tag{2}$$

The activation energy for the formation of a chlorine atom in the gas phase, based on the activation energy for the gas-phase decomposition of a chlorine molecule into atoms of 238.5 kJ mol^{-1} and the heat of adsorption of a chlorine atom on glass amounting to 67 kJ mol^{-1}, is $238.5-67 \simeq 172$ kJ mol^{-1}. Gorokhovatskii[22] proposed relations for reactions (1) and (2) linking the heat of dissociation of the adsorbed chlorine molecules ($Q_{Cl_2\,ads}$) to the heat of dissociation of chlorine in space (Q_{Cl_2}) and to the heats of adsorption of molecular (q_{Cl_2}) and atomic (q_{Cl}) chlorine, from which it is seen that Q_{Cl_2ads} must be less than Q_{Cl_2}, because q_{Cl} is always greater than q_{Cl_2}:

$$Q_{Cl_2\,ads} = Q_{Cl_2} + q_{Cl_2} - 2q_{Cl},$$
$$Q_{Cl_2\,ads} = Q_{Cl_2} + q_{Cl_2} - q_{Cl}.$$

It has been shown[23] that the heterogeneous two-stage dissociation of chlorine in the above scheme is kinetically more favourable than the heterogeneous one-stage or gas-phase dissociation for $E_3 < 170$ kJ mol^{-1} and its rate is a maximum for $E_3 \simeq 70$ kJ mol^{-1} and $E_2 \simeq 170$ kJ mol^{-1}. The rate of dissociation via the two-stage scheme is then higher by 10–11 orders of magnitude than the rate of the gas-phase dissociation. This indicates the enormous role of the wall and of the ratio of the surface area of the reactor to its volume in the study of gas-phase radical-chain reactions. In an industrial reactor, it is essential to take into account this factor for the successful performance of the process.

The experimental Arrhenius parameters for the elementary stages of the chain propagation in the chlorination of methane are available.[7,24,25] Calculated and experimental data have been published by Bell et al.[25] The energy parameters of the chain termination stages are given in Kondrat'ev's handbook;[24] the activation energies for these reactions are zero. The process kinetics vary as a function of the dominant type of chain termination.[26]

Theoretically, it is to be expected that, on chlorination, for example, in an industrial reactor, the dominant type of chain termination varies as chlorine is consumed and there is a corresponding change in the chlorine : methane ratio, from quadratic termination by chlorine atoms, through cross-termination between alkyl radicals and chlorine atoms, to quadratic termination by alkyl (or halogenoalkyl) radicals. The process kinetics should vary accordingly.

Variable reaction orders with respect to the reactants have been established experimentally, for example, in the study of the kinetics and mechanism of the vapour-phase chlorination of trichloromethane.[27,28] For the ratio of trichloromethane and chlorine concentrations $[CHCl_3]:[Cl_2] = 10:1$ and temperatures in the range 643–696 K, the rate of chlorination of trichloromethane is described by the equation

$$w = k[Cl_2] \cdot [CHCl_3]^{0.5}.$$

When trichloromethane is chlorinated in an excess of chlorine with $[CHCl_3]:[Cl_2] = 1:7$, the dependence of the rate of reaction on the reactant concentrations is described by a different equation:

$$w = \frac{k}{B^{0.5}}[Cl_2]^{0.5}\,[CHCl_3],$$

where B is the adsorption coefficient.

In studies[20,29] of the chlorination of methane in the presence of adsorbents (including adsorbents impregnated with LiCl or $K_2S_2O_4-K_2S_2O_7$), different reaction orders were also obtained depending on the ratio of the amounts of chlorine and methane in the reaction mixture. Thus, for $p_{Cl_2}/p_{CH_4} < 1$, the order with respect to chlorine was unity and that with respect to methane was 0.5, which corresponds to cross termination of the chain. For $p_{Cl_2}/p_{CH_4} > 3$, the reaction orders with respect to chlorine and methane were respectively 0.5 and 1, which indicates quadratic termination by chlorine atoms. In the transitional range of the above ratios, the reaction orders with respect to chlorine and methane had intermediate values, for example, 0.8 and 0.6 respectively.

In the chlorination of methane in a fluidised catalyst bed, the chain initiation and termination take place preferentially on the wall and a direct dependence of the reaction rates on the chlorine and methane concentration was therefore obtained.[7,10,24] Many investigators believe that the solid materials used for the chlorination of methane, other than activated charcoal, are not catalysts but constitute an "expanded wall", functioning simultaneously as a heat exchanger. Rozlovskii and Treger[30] question the catalytic function of the catalyst (with the exception of activated charcoal) in a fluidised bed reactor on the grounds that, under the conditions of the high-temperature chlorination, equilibrium in the dissociation of chlorine is always attained. It has been concluded[31] that the rates of chlorination of methane attained in a hollow container[8,10] are close to those found in a fluidised catalyst bed.[9,10] The rate proved to be higher by an order of magnitude only on activated charcoal. All these features indicate a weak non-specific catalytic effect of the majority of catalysts used for chlorination. This effect is manifested in the chain initiation and subsequent chlorination stages as a result of the stronger adsorption of chloromethanes compared with methane.

There is no unanimous view concerning the mechanism of the catalytic action of salts; the acceleration of the chlorination of methane by systems based on transition metal chlorides is sometimes attributed to their ability to generate atomic chlorine as a result of their decomposition at a lower temperature than that required for the dissociation of chlorine molecules. A mechanism including a stage in which copper chloride undergoes thermal dissociation has been adopted for the chlorination of methane by a melt of copper and zinc chlorides.[32]

Another version of the catalytic action consists in the polarisation of the adsorbed chlorine molecule and subsequent ionic chlorination. This mechanism has been considered in greater detail by Shatalov.[33] The heterogeneous mechanism is supported by the absence of an inhibiting effect by oxygen. In gas-phase chlorination, oxygen is known to inhibit the reaction as a result of the formation of the relatively inactive $\dot{R}O_2$ radicals. Depending on the thermal stability of the peroxy-radicals, inhibition is shown up to a specific temperature.

It has been established[14,29] that the presence of transition metal chlorides in the salt composition is obligatory for catalytic chlorination. On the other hand, according to the estimate by Aglulin,[14] the rate of chlorination in the presence of metal chlorides on a carrier (at temperatures below 673 K and for $p_{O_2} \to 0$) is approximately 5 times lower than on a clean carrier. Thus metal chlorides proved in this instance to be less active than the carrier, apparently as a result of the greater affinity of metal chlorides for atomic chlorine.

In contrast to lithium chloride and potassium pyrosulphate (see above), in the presence of which variable reactions orders with respect to chlorine and methane have been observed, for other salt systems ($CuCl_2-KCl$, $CuCl_2-KCl-LaCl_3$, $FeCl_3-KCl$, CsCl, LiF, and $LiCl-KCl$), the order of the methane chlorination reaction is unity with respect to methane and is close to 1/2 with respect to chlorine over the entire range of conditions investigated up to extremely low partial pressures of chlorine ($\sim 10^{-3}$ kPa),[29] which indicates the attainment of equilibrium in the chlorine dissociation stage even under these conditions. The authors[29] also concluded that the reactivities of chlorine atoms on the surface and in space are similar.

On comparing the experimental data and the results of calculations based on the known rate constants for the elementary stages in the chlorination of methyl chloride, Lebedev et al.[35] concluded that the photochemical and radiation-chemical chlorination of methane has no significant advantages as regards selectivity (with respect to individual chloromethanes) over the thermal chlorination. The use of catalysts also does not change the ratios of the chloromethanes obtained. The latter claim is insufficiently well founded especially in relation to activated charcoal as the catalyst.

The ratios of the rate constants for the consecutive-parallel reactions in the photochemical chlorination of chloromethane and dichloromethane have been determined in a bubbler apparatus at temperatures in the range 263–308 K.[36] It was shown that the selectivity of the chlorination is described satisfactorily on the assumption that the reaction is of first order with respect to the compounds chlorinated. The relative constants are almost independent of temperature, the presence of inhibitors, and the intensity of irradiation, but are influenced by the composition of the reaction medium. The last finding is interpreted by the authors as due to the influence of the polarity of the medium on the rate of the rate-limiting stage in chain propagation. In the liquid-phase initiated chlorination of trichloromethane, the order of the reaction was found to be zero with respect to trichloromethane, unity with respect to chlorine, and 0.5 with respect to the initiator (azobisisobutyronitrile). The activation energy was 157 $\pm$ 12 kJ mol^{-1}. The difference between the orders of the chlorination reaction with respect to trichloromethane when different methods are used is apparently associated with the change in the character of chain termination.

In the study of the kinetics of the liquid-phase chlorination of methane in the temperature range 150–293 K in dichlorodifluoromethane, the following kientic equations were obtained for 293 K:[37]

$$w_{Cl_2} = k_1 \cdot In^{0.6\pm0.1}[Cl_2] \quad \text{when } [CH_4]:[Cl_2] > 300,$$
$$w_{Cl_2} = k_2 \cdot In^{0.6\pm0.1} \cdot [CH_4] \quad \text{when } [CH_4]:[Cl_2] < 10,$$

where *In* is the intensity of the adsorbed light.

Estimation of the rate constants for the elementary stages under the conditions for the first equation showed that the rate constant for the interaction of methyl radicals with chlorine molecules is six times smaller than the value calculated from literature data, while the rate constant for the reaction of atomic chlorine with methane is smaller by two orders of magnitude compared with the literature data. Such appreciable differences are associated mainly with the decrease in the pre-exponential factor, since the activation energy obtained for this stage (12.5 $\pm$ 2.5 kJ mol^{-1}) is almost identical with the value known for the gas phase.

In our view, examination of the chemical engineering problems arising in the direct chlorination of methane and chloromethanes requires the differentiation of the following factors.

In the first place there is the problem of the removal of a large amount of heat of reaction which in the existing methane chlorination processes in hollow adiabatic reactors is solved by the recirculation of a large amount of methane. At the same time, the excess methane is used to overcome the upper limit to the susceptibility to explosion of chlorine–methane mixtures.

The above problem can be solved effectively by using a fluidised catalyst bed or by carrying out the process in the liquid phase. The presence of a liquid and a solid simultaneously prevent explosion and make it possible thereby to work with concentrated mixtures of chlorine and methane or chloromethane.

Another task is to increase the process selectivity with respect to the individual intermediates in the chlorination reaction, in the first place with respect to trichloromethane. This problem is especially acute at the present time in connection with the signing in September 1987 in Montreal of the Protocol on chlorofluorocarbons, according to which it is necessary to reduce and then stop the manufacture of Freons which decompose the ozone layer, especially Freons 11 and 12 obtained from tetrachloromethane. One of the most realistic ways of converting the Freon 11 and 12 industries is to switch them to the manufacture of Freon 22 from trichloromethane.

The increase in the yield of trichloromethane and the decrease in the yield of tetrachloromethane in chloromethane manufacturing processes is therefore at present of extremely great current interest. In the industrial manufacture of chloromethanes by the chlorination of methane at a temperature of about 773 K, with a chlorine content in the initial mixture of 20–25%, and for the recycling of the entire chloromethane formed, the trichloromethane : tetrachloromethane weight ratio in the reaction products is about 5. In the chlorination of methane on a fluidised coke bed,[17] the ratio was 3, the reaction temperature was 648 K, and the chlorine : methane molar ratio was 1.3.

A high selectivity with respect to trichloromethane $CHCl_3 : CCl_4 = 5–7:1$) was obtained in the liquid-phase chlorination of chloromethane;[38] the reaction temperature was 333–343 K, the $CH_3Cl : Cl_2$ ratio was approximately unity, and the initiator employed was azobisisobutyronitrile.

The selectivity with respect to trichloromethane increases with decrease in the degree of conversion of chloromethane or dichloromethane during a pass, which necessitates the corresponding increase in the extent to which they are recycled. In this case, it is economical to carry out the process by combining the chlorination reaction with fractionation. Yet another problem to which little attention has been devoted in the literature but which is of interest from both theoretical and practical points of view is that of the formation of admixtures of chlorohydrocarbons of the ethane–ethylene series in the chlorination of methane. Some of these admixtures have a boiling point close to that of one of the chloromethanes (for example, 1,1-dichloroethane, *cis*-1,2-dichloroethylene, and trichloromethane), while others form an azeotrope with a boiling point close to that of the main substance (1,2-dichloroethane and tetrachloromethane). Periodic processes leading to the loss of the product, additional consumption of materials and other resources, and the formation of a large amount of waste are usually employed to remove these impurities from chloromethanes. Thus, it has been suggested that dichloromethane be purified by treatment with potassium permanganate solution; trichloromethane is nowadays purified by treatment with oleum and is then neutralised with a solution of caustic soda and dried. In view of the impossibility of separating 1,2-dichloroethane, tetrachloromethane is not isolated at all as a commercial product in the industrial manufacture of chloromethanes by the chlorination of methane. It is noteworthy that the requirements specified by the USSR state standards (GOS) as regards the contents of individual impurities are fairly stringent: the amount of 1,1-dichloroethane in trichloromethane and of 1,2-dichloroethane in tetrachloromethane must be not more than 0.002%. The concentration of the impurities formed in the industrial manufacture of chloromethanes by the chlorination of methane in a hollow reactor has been quoted by Nikitenko et al.[39]

Evidently the C_2 chloro-derivatives are formed as a result of the recombination of radicals since the initial methane is freed from homologues, including ethane. The ways which should be employed to rule out the formation of impurities are also indicated: firstly, one can attempt to prevent the quadratic termination by hydrocarbon radicals and secondly it is desirable to increase the chain length.

The influence of temperature and of the dilution of the initial mixture by an inert gas on the formation of C_2 chlorohydrocarbons in the volume chlorination of methane has been investigated.[40] A decrease in temperature alters the composition and amount of the impurities formed, one of the causes of which is apparently an increase in chain length and a decrease in the degree of decomposition of the chloromethanes. However, a significant decrease in the amount of impurities to the required level could not be achieved.

As already stated, in the chlorination of methane in a fluidised catalyst bed chain termination takes place on the surface of the solid material ("wall"). As a result, the chloromethanes obtained in this way contain virtually no impurities.[41] However, despite the evident advantages of the fluidised bed such as high productivity, the possibility of working with virtually any chlorine : methane ratio, and the excellent quality of the chloromethanes obtained, the chlorination of methane in a fluidised catalyst bed has not so far actually found application in industrial practice. Two small industrial plants of the Japanese company Asahi Glass[42] and the Indian Company Standard Alkali[43] are known.

The use of a fluidised bed is desirable for exhaustive chlorination but for the preferential yield of chlorination intermediates it has not so far been possible to use this method in industrial practice. The point is that chloromethanes decompose during the chlorination of methane and carbon is deposited on the catalyst. According to Shatalov's data,[17] under these conditions the yield of tetrachloromethane on the carbon-coated silica gel or on coke with a specific surface of 1–3 $m^2 g^{-1}$ increases to the same level as on activated charcoal with a specific surface of 1000–2000 $m^2 g^{-1}$.

The use of an inert solid (quartz sand) made it possible to increase the duration of the operation of the apparatus to 1500 h,[44] while pumice became blocked with the decomposition and charring products after 20 h. Even the use of an inert solid does not fully guarantee the absence of carbon deposition, since adiabatic heating of an equimolar mixture of chlorine and methane results in a temperature rise of more than 1000 °C and any breakdowns in the structure of the fluidised bed in the form of bubbles or thickened regions[45] can lead to local overheating and decomposition of chloromethanes. On the Asahi Glass apparatus[42] provision is made for the supply of oxygen to burn off the carbonaceous deposits. Yet another disadvantage of the fluidised bed is that, with increase in diameter on passing to industrial apparatus, an increase in the yield of tetrachloromethane is also to be expected as a result of the approach of the operating regime of the reactor to the ideal mixing model.

III. Decomposition of chloromethanes

In connection with the great influence of the decomposition of chloromethanes on the stable course of the chlorination process in a fluidised catalyst bed and also in a hollow reactor, where abrupt process terminations with an abundant release of carbon also occur, it is useful to examine the kinetics and mechanisms of these reactions. Studies by Shilov and Sabirova[46-48] have made a great contribution to the investigation of the chloromethane decomposition reactions. According to data obtained in a vacuum flow apparatus for short contact times, chloromethane decomposes at 1116 and 1147 K to hydrogen chloride, methane, acetylene, and a small amount of hydrogen, the amount of methane being three times smaller than that of HCl.[47] The activation energy for the decomposition (358 kJ mol^{-1}) is close to the bond energy. The authors suggest the following mechanism of the decomposition process:

$$CH_3Cl \rightarrow \dot{C}H_3 + Cl^{\cdot},$$
$$\dot{C}H_3 + CH_3Cl \rightarrow CH_4 + \dot{C}H_2Cl,$$
$$Cl^{\cdot} + CH_3Cl \rightarrow HCl + \dot{C}H_2Cl,$$
$$\dot{C}H_2Cl + \dot{C}H_2Cl \rightarrow CH_2Cl{-}CH_2Cl \rightarrow HCl + CH_2{=}CHCl,$$
$$CH_2{=}CHCl \rightarrow HCl + CH{\equiv}CH.$$

The thermal decomposition of tetrachloromethane[47] (827–874 K) results in the formation of chlorine, hexachloroethane, and tetrachloroethylene. The activation energy for the decomposition is 230 kJ mol^{-1}. The proposed mechanism is based on experimental data showing that hexachloroethane is an intermediate:

$$CCl_4 \rightarrow \dot{C}Cl_3 + Cl^{\cdot},$$
$$Cl^{\cdot} + CCl_4 \rightarrow Cl_2 + \dot{C}Cl_3,$$
$$\dot{C}Cl_3 + \dot{C}Cl_3 \rightarrow C_2Cl_6,$$
$$C_2Cl_6 \rightarrow C_2Cl_4 + Cl_2.$$

The thermal decomposition of tetrachloromethane to tetrachloroethylene, i.e. $2CCl_4 \rightleftarrows C_2Cl_4 + 2Cl_2$, is used in the industrial manufacture of perchlorocarbons by the exhaustive destructive chlorination of C_1–C_3 hydrocarbons and their chloroderivatives in order to obtain tetrachloroethylene and tetrachloromethane in variable proportions. The process is carried out in a hollow reactor at temperatures in the range 833–873 K or in a fluidised sand bed at 773–823 K.

Despite the fact that the C–Cl bond energy in trichloromethane is higher than in tetrachloromethane, the rate of decomposition of the latter at 832 K is 15 times smaller than that of trichloromethane.[44] This is explained[44] by the biradical decomposition of trichloromethane ($CHCl_3 \rightarrow HCl + :CCl_2$), after which the following reactions can occur:

$$:CCl_2 + CHCl_3 \rightarrow HCl + C_2Cl_4 \text{ or}$$
$$:CCl_2 + CHCl_3 \rightarrow CHCl_2CCl_3 \rightarrow HCl + C_2Cl_4,$$
$$:CCl_2 + CHCl_3 \rightarrow \dot{C}Cl_3 + \dot{C}HCl_2,$$
$$2\dot{C}Cl_3 \rightarrow C_2Cl_6.$$

The temperature dependence of the rate constant is described by the equation $k = 2.61 \times 10^{11} \exp(-197\,000/RT)$ s^{-1}.

Another expression has been quoted[49] for the trichloromethane decomposition rate constant: $k = 6.3 \times 10^8 \exp(-157\,000/RT)$ s^{-1}, but the values of the constant at temperatures in the range 750–850 K differ little from those of Shilov and Sabirova.[48] A radical mechanism has been proposed for the decomposition process: $CHCl_3 \rightarrow \dot{C}HCl_2 + Cl^{\cdot}$. The main decomposition products are HCl and C_2Cl_4, as well as C_2Cl_6, C_2HCl_5, etc.

The study of the thermal decomposition of trichloromethane with the aid of shock waves[50] has confirmed the formation of the $:CCl_2$ biradicals and hydrogen chloride.

In the thermal decomposition of dichloromethane (806 K), CH_3Cl, $CHCl{=}CCl_2$, C_2Cl_4, $CHCl_3$, CCl_4, and *cis*- and *trans*-$CHCl{=}CHCl$ were detected.[51] The activation energy for the decomposition is 184 kJ mol^{-1}. The authors[51] propose a degenerate-branched mechanism involving the formation of an intermediate (dichloroethylene), chain propagation with the aid of $Cl^{\cdot}$ atoms and the radicals $\dot{C}H_2Cl$, and the chain branching reaction $CHCl{=}CHCl \rightarrow \dot{C}_2H_2Cl + Cl^{\cdot}$.

It must be recognised that the biradical decomposition of dichloromethane is nevertheless more probable. The formation of biradicals (or carbenes) in the decomposition of dichloromethane and trichloromethane was demonstrated in an early study by Semenov.[26]

The decomposition of dichloromethane was not observed in the temperature range 673–753 K in a gradient-free quartz reactor with a stirrer which had been coated with carbon beforehand.[52]

The heterogeneous thermal decomposition of tetrachloromethane[53] as well as trichloromethane and dichloromethane[54] has been studied at temperatures in the range 773–873 K on a quartz fibre (S_{sp} = 0.26 m^2 g^{-1}) and on carbon black (S_{sp} = 100 m^2 g^{-1}) both of which had been coated beforehand with a layer of pyrolytic carbon obtained as a result of the decomposition of toluene.

The ratios of the rate constants (in g cm^{-2} s^{-1} Pa^{-1}) for the pyrolysis of tetrachloromethane, trichloromethane, and dichloromethane at 773 K are 1:80.6:15.7. The rate of formation of pyrolytic carbon on quartz in the decomposition of dichloromethane is given by the equation $w = 7.7 \times 10^{-4} p \exp(-163\,000/RT)$, while in the decomposition of trichloromethane the equation is $w = 2.1 \times 10^{-3} p \exp(-159\,000/RT)$.

The decomposition of chloromethanes on the surface of pyrolytic carbon at a low pressure in the temperature range 850–1280 K has been investigated.[55] While CH_3Cl is stable under the conditions investigated, the decomposition of CH_2Cl_2 and CCl_4 over clean silicon dioxide surface takes place initially with appreciable self-acceleration as a result of the formation of soot on the reactor walls and then the rate of the decomposition reaction remains constant but twice as high as the rate of the homogeneous pyrolysis under the same conditions.

An analogous increase in the rate of reaction during the initial period in the decomposition of dichloromethane on alumina (S_{sp} = 10 m^2 g^{-1}) was noted by Kovaleva et al.[56] The rate of decomposition then begins to fall. Simultaneously with the change in the degree of deposition of carbon, the specific surface of the decomposition catalyst initially increases and then falls.

The rate of the catalytic decomposition of dichloromethane depends on its concentration (with an exponent of unity) and has an activation energy of 105 kJ mol^{-1}.[57] Only carbon and hydrogen chloride were detected among the catalytic decomposition products[57] in accordance with the proposed reaction mechanism:

$$CH_2Cl_2 \rightarrow CHCl_{ads} + HCl,$$
$$CHCl_{ads} \rightarrow C + HCl$$

The study of the decomposition of chloromethanes in a fluidised activated charcoal bed was undertaken by Shatalov et al.[58] The qualitative results obtained agree with the decomposition reaction mechanisms proposed by Shilov and Sabirova.[46-48] The decomposition of mixtures of various chloromethanes and mixtures of methane with chloromethanes has also been studied.[58] For example, it has been noted that, in the presence of CH_4, the degree

of decomposition of tetrachloromethane increases, apparently as a result of the binding of chlorine.

A thermodynamic analysis of the reversible reactions in the formation of chloromethane has been carried out:[59]

$$CH_4 + CCl_4 \rightleftarrows CH_3Cl + CHCl_3,$$
$$CH_4 + CHCl_3 \rightleftarrows CH_3Cl + CH_2Cl_2,$$
$$CH_3Cl + CCl_4 \rightleftarrows CH_2Cl_2 + CHCl_3.$$

The highest equilibrium constant was obtained for the first reaction.

The study of the interaction of tetrachloromethane and methane showed that the experimental data are in satisfactory agreement with calculations based on the known constants for the elementary stages.[60] The exchange reaction has an order of 1.5 (0.5 with respect to CCl_4 and 1 with respect to CH_4) and the effective calculated rate constant given by

$$k = 10^{14.94} \exp(-205\,600/RT)\ \text{cm}^{1.5}\ \text{mol}^{-0.5}\ \text{s}^{-1}.$$

Thus the thermal stabilities of chloromethanes increase in the sequence $CHCl_3 < CH_2Cl_2 < CCl_4 < CH_3Cl$, and the pyrolytic carbon formed in the decomposition process can accelerate further decomposition. Apparently a proportion of the C_2 chlorohydrocarbon impurities are obtained from the radicals and biradicals formed on decomposition of chloromethanes.

IV. Benson's process

It is of interest that "undesirable" (in the synthesis of chloromethanes) reactions involving the decomposition of chloromethanes and the recombination of radicals have been used by Benson to develop a process for the preparation of hydrocarbons by the high-temperature interaction of chlorine with methane.[61] The process is carried out at atmospheric pressure, high temperatures (973–1983 K), methane : chlorine ratios ranging from 1:1 to 10:1, and short contact times counted in milliseconds. The combustion of a mixture of methane with chlorine results in the formation of ethane at temperatures of about 1000 K or of ethylene and hydrogen at temperatures of about 2000 K.

The method consists in chlorinating methane to chloromethane, the pyrolysis of chloromethane, and the formation of C_2 hydrocarbons as a result of the recombination of hydrocarbon radicals.[62]

The thermal reaction of a mixture of chlorine and methane has been investigated[63,64] at temperatures in the range 1081–1273 K, at pressures in the range 150–577 mm Hg, for a chlorine content in the mixture with methane of 0.42–1.2%, and for contact times of 0.8–1.6 s. The carbon-containing products are CH_3Cl, C_2H_4, C_2H_6, C_2H_2, and C_3H_6. The fraction of the non-chlorinated unsaturated hydrocarbons increases with increase in temperature and reaches 77% at 1273 K. The following radical process mechanism, divided into several stages, has been proposed:

I. Initial ethane

Initiation:

$$CH_4 \rightarrow \dot{C}H_3 + H^{\cdot},$$
$$Cl_2 + M \rightarrow 2\,Cl^{\cdot} + M.$$

Chain transfer:

$$H^{\cdot} + CH_4 \rightarrow H_2 + \dot{C}H_3,$$
$$H^{\cdot} + Cl_2 \rightarrow HCl + Cl^{\cdot}.$$

Chain propagation:

$$\dot{C}H_3 + Cl_2 \rightarrow CH_3Cl + Cl^{\cdot},$$
$$Cl^{\cdot} + CH_4 \rightarrow HCl + \dot{C}H_3.$$

Chain termination:

$$2\,\dot{C}H_3 \rightarrow C_2H_6. \qquad (3)$$

Chain termination is also possible (to a lesser extent) via the reaction:

$$\dot{C}H_3 + Cl^{\cdot} \rightarrow CH_3Cl,$$
$$\dot{C}H_3 + H^{\cdot} \rightarrow CH_4. \qquad (4)$$

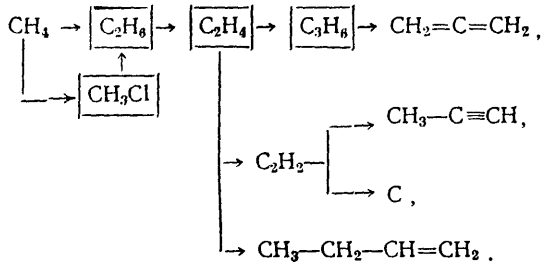
The first stage can be characterised by the overall equations:

$$2\,CH_4 + Cl_2 \rightarrow C_2H_6 + 2HCl,$$
$$CH_4 + Cl_2 \rightarrow CH_3Cl + HCl.$$

II. Second stage

$$\dot{C}H_2Cl + RH \rightleftarrows CH_3Cl + R^{\cdot},$$
$$\dot{C}H_2Cl + Cl_2 \rightarrow CH_2Cl_2 + Cl^{\cdot},$$
$$\dot{C}_2H_5 \rightarrow C_2H_4 + H^{\cdot},$$
$$\dot{C}_2H_5 + RH \rightleftarrows C_2H_6 + R^{\cdot},$$
$$\dot{C}_2H_5 + Cl_2 \rightarrow C_2H_5Cl + Cl^{\cdot},$$
$$\dot{C}H_3 + \dot{C}H_2Cl \rightarrow C_2H_5Cl, \qquad (5)$$
$$2\,\dot{C}H_2Cl \rightarrow CH_2Cl{-}CH_2Cl. \qquad (6)$$

The concentration of the $CH_2Cl^{\cdot}$ radicals is negligible compared with the $CH_3^{\cdot}$ concentration so that the chain termination via reactions (5) and (6) is insignificant compared with the termination via reaction (3).



III. Third stage

$$\dot{C}H_3 + C_2H_4 \rightleftarrows CH_3{-}CH_2{-}\dot{C}H_2,$$
$$\dot{C}_2H_5 + C_2H_4 \rightarrow CH_3{-}CH_2{-}CH_2{-}\dot{C}H_2,$$
$$CH_3{-}CH_2{-}\dot{C}H_2 \rightarrow CH_3{-}CH{=}CH_2 + H^{\cdot},$$
$$CH_3{-}CH_2{-}CH_2{-}\dot{C}H_2 \rightarrow CH_3{-}CH_2{-}CH{=}CH_2 + H^{\cdot},$$
$$R^{\cdot} + C_2H_4 \rightarrow RH + \dot{C}_2H_3,$$
$$\dot{C}_2H_3 \rightarrow C_2H_2 + H^{\cdot}.$$

IV. Fourth stage

$$\dot{C}H_3 + C_2H_2 \rightleftarrows CH_3{-}CH{=}\dot{C}H,$$
$$R^{\cdot} + CH_3{-}CH{=}CH_2 \rightarrow RH + \dot{C}H_2{-}CH{=}CH,$$
$$R^{\cdot} + C_2H_2 \rightarrow RH + CH{\equiv}C^{\cdot},$$
$$CH_3{-}CH{=}\dot{C}H \rightarrow CH_3{-}C{\equiv}CH + H^{\cdot},$$
$$CH{\equiv}C^{\cdot} \rightarrow 2C + H^{\cdot},$$
$$\dot{C}H_2{-}CH{=}CH_2 \rightarrow CH_2{=}C{=}CH_2 + H^{\cdot}.$$

Under the conditions indicated, Benson's process can be summarised by means of the scheme presented below, the main products being ethane, ethylene, chloromethane, and propene, while the rest are present as impurities:

In our view, in the scheme for the initial stage it is necessary to make provision for the decomposition of methyl chloride, i.e. the reaction which is the reverse of reaction (4), as a result of which the $\dot{C}H_3$ and $Cl^{\cdot}$ radicals are returned to the reaction sphere and virtually the only possible termination involves the recombination of the $\dot{C}H_3$ radicals. Benson's process is based on the ease of dissociation of chlorine and the lower thermal stability of methyl chloride compared with methane.

V. Oxidative chlorination of methane and its chloro-derivatives

One of the deficiencies of the processes involving the direct chlorination of methane and its chloro-derivatives, not mentioned above, is the conversion of half of the chlorine used into hydrogen chloride. The necessity to utilise increasing amounts of the latter has been the cause of the development of a method for the oxidative chlorination of methane, where the chlorinating agent is a mixture of hydrogen chloride and oxygen.

The oxidative chlorination of methane is based on the oxidation of hydrogen chloride by oxygen to chlorine, which is usually carried out in the gas phase copper chloride-containing catalysts.

From the results of kinetic studies of the oxidative chlorination of methane, it has been concluded[14,23,65] that the oxidation of hydrogen chloride (also called the Deacon reaction) takes place at the same rate both in the presence and absence of methane, i.e. regardless of its subsequent chlorination. The oxidation of hydrogen chloride to chlorine is a reversible reaction, which usually occurs at temperatures in the range 623–723 K, the equilibrium constant K_e decreasing appreciably with increase in temperature. When the Deacon reaction and the methane chlorination reaction take place simultaneously, the equilibrium in the first reaction is displaced as a result of the consumption of chlorine, as can be seen from the data presented below:[2]

$$2n\,HCl + n/2O_2 \rightleftarrows n\,Cl_2 + n\,H_2O,\quad K_e(700\ K)\,8.3,$$
$$CH_4 + n\,Cl_2 \rightarrow CH_{4-n}Cl_n + n\,HCl$$
$$CH_4 + n\,HCl + n/2\,O_2 \rightarrow CH_{4-n}Cl_n + n\,H_2O,$$
$$K_e(700\ K)\,9.1\cdot10^{8} - 9.8\cdot10^{33}.$$

A number of recent publications have been devoted to the gas-phase heterogeneous-catalytic oxidative chlorination of hydrocarbons and their chloro-derivatives.[2,23,66]† The problem of the oxidative chlorination of methane will therefore be considered here in a more concise form.

Since, as can be seen from the above, the methane chlorination reaction at temperatures at which the Deacon reaction is carried out can proceed without the participation of a catalyst, the main task in the development of a process for the oxidative chlorination of methane is the selection of a catalytic system for the first stage.

Despite a number of advances achieved on these lines, copper(II) chloride, proposed as the catalyst for the oxidation of hydrogen chloride already in the past century, still remains the main component of catalysts for the Deacon and oxidative chlorination reactions.[67] Catalytic systems based on palladium, chromium, and iron chlorides proved to be less active.[68] Platinum(II)–platinum(IV) chloride complexes have been recently proposed as well as the complex $K_4Ru_2OCl_{10}$; being deposited on alumina or silicon dioxide, they catalyse the oxidative chlorination of methane in aqueous solutions or in the gas phase.[69,70] The catalysts obtained proved to be more active than catalysts based on copper and potassium chlorides. Our studies on catalysts which Tret'yakov et al.[69,70] prepared by adding a ruthenium complex to copper and potassium chlorides on α-alumina confirmed the higher activity of the ruthenium-containing catalyst. However, the addition of a lanthanide chloride[71] proved to be more effective.

It is noteworthy that catalysts for the oxidative chlorination of methane based on copper, alkali metal, and alkaline earth metal chlorides on a porous carrier constitute an extremely unusual system; apart from the traditional questions of activity, selectivity, and stability, problems associated with the volatility of copper chlorides in the formation of a melt of catalytically active salts under the reaction conditions arise here.

The addition of alkali metal chlorides to copper chloride diminishes the volatility of the latter.[72] The greatest decrease in volatility is observed when rubidium chloride is added, but, as regards the combination of efficiency with availability, preference was given to potassium chloride. The dependence of the volatility of copper chlorides and of the activity of the catalyst on the ratio $KCl:CuCl_2$ is illustrated in Fig.4. The equimolar ratio has been recognised as optimal in terms of the combination of activity and stability. The influence of the nature of the alkali metal (lithium, sodium, potassium, and caesium) and of the potassium : copper ratio in catalytic systems on the kinetic parameters of the hydrogen chloride oxidation reaction has been examined in detail.[23] The changes in these parameters are attributed to the formation of copper and alkali metal chlorides. It is most likely that this is also the cause of the decrease in the volatility of copper chlorides.

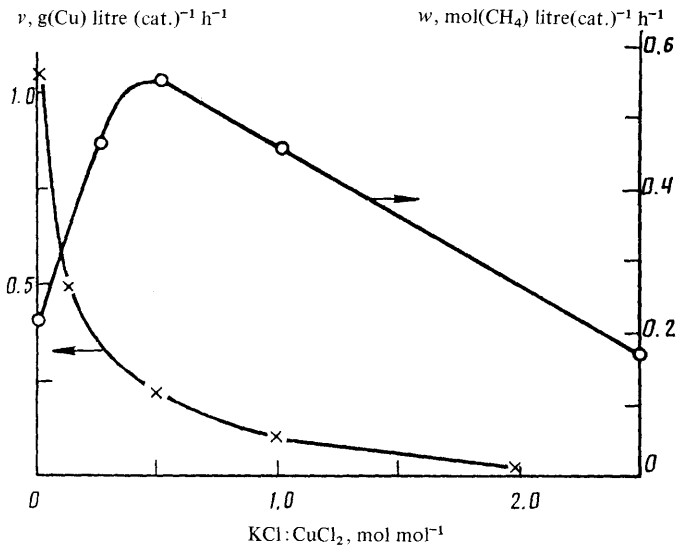


Figure 4. Dependence of the activity and stability of the catalysts for the oxidative chlorination of methane on the $KCl:CuCl_2$ ratio;[14,72] w—rate of overall conversion of methane at 648 K; r—rate of volatilisation of copper chlorides at 723 K.

†Yu A Treger, V N Rozanov, M R Flid, L M Kartashov, *Uspekhi Khim.*, 1988, **57** 577 [*Russ. Chem. Rev.*, 1988(4)]

The influence of potassium chloride on the activity of the catalyst based on copper chloride in the oxidative chlorination of methane has been investigated in detail in a recently published study.[73] The maximum activity was observed for the ratio potassium : copper = 1, the composition of the chloromethanes obtained varying as a function of the presence or absence of potassium chloride.

The attempts to bind copper in the spinel structure ($CuAl_2O_4$, $CuCr_2O_4$) in order to eliminate the volatility were unsuccessful, since, under the conditions of an excess of hydrogen chloride at an elevated temperature, these compounds gradually decompose with segregation of copper chloride as the active component of the catalyst.[68,74]

A melt of the active mass of the copper and potassium chlorides, on carriers of different chemical nature and with different specific surfaces, forms in the extensive pore system of the carrier isolated inclusions with a thickness equivalent to 10–200 molecular layers.[75,76]

The interaction of the salts with the carrier, the surface migration of the salt phases, and the change in the structure and surface area of the salt clusters have been demonstrated by electron microscopy and also by studying adsorption in conjunction with X-ray diffraction and differential thermal analysis.[77]

Porous substances with a wide range of specific surfaces are used as carriers for the catalysts of the oxidative chlorination of methane.[66] However, the choice of the carrier is fairly specific. For example, when the process is carried out in a fluidised catalyst bed, the use of carriers with a large specific surface proved preferable, since this ensures excellent fluidisation without bubbles and lumps.[78] However, on these catalysts the process selectivity, characterised by the degree of conversion of methane into chloromethanes relative to the overall conversion into chloromethanes and carbon oxides, is lower than in the case where inert carriers with a limited specific surface are used. At the same time, the catalysts on carriers with a limited specific surface in a fluidised bed form lumps probably owing to the partial emergence of the melt onto the surface. As a result, carriers with an average specific surface of 10–60 $m^2\ g^{-1}$ proved optimal.[78]

In the stationary catalyst bed, one can use carriers with a specific surface less than 10 $m^2\ g^{-1}$, but when it is reduced to 1 $m^2\ g^{-1}$ and less, the corrosion of the metallic walls of the reactor at the sites of contact intensifies sharply, which is also most probably associated with the presence of the melt.[79] Under these conditions, iron chloride, a corrosion product, enters the catalyst and increases the rate of the extensive oxidation of methane and chloromethanes to carbon oxides, while nickel and chromium chlorides hardly affect the activity and selectivity of the catalyst.[80]

Communications have been published recently concerning the possibility of carrying out the oxidative chlorination of methane at relatively low temperatures (less than 473 K) by using colloidal silicon dioxide as the carrier.[81]

The kinetics and mechanism of the oxidative chlorination of methane on traditional catalysts with copper chlorides have been described in greatest detail in Refs. 14, 23, 65, and 82. It was shown that the oxidation of HCl proceeds throughout the bulk of the salt melt with participation of copper chloride. The rate of the Deacon reaction is independent of the partial pressure of hydrogen chloride when it is above 0.04 atm, its observed reaction order with respect to oxygen is 0.5, and, when account is taken of the inhibiting effect of chlorine, it is unity. The observed activation energy on the catalyst containing an equimolar mixture of copper and potassium chlorides is 129 kJ mol^{-1}.

The process mechanism put forward by Slama and Kodajs[83] in connection with the observed second order of the oxygen absorption reaction with respect to Cu^+ assumes the following form:

$$2\,CuCl_2 \overset{\text{fast}}{\rightleftarrows} 2CuCl + Cl_2,$$
$$2\,CuCl + O_2 \xrightarrow{\text{slow}} Cu_2O_2Cl_2,$$
$$Cu_2O_2Cl_2 + 4HCl \xrightarrow{\text{fast}} 2CuCl_2 + Cl_2 + 2\,H_2O.$$

The following kinetic equation corresponds to this mechanism:

$$w = 4kK\,[CuCl_2]^2\ p_{O_2}/p_{Cl_2} = k'p_{O_2}/p_{Cl_2},$$

where k is the rate constant, K the equilibrium constant, and $k' = 4kK[CuCl_2]^2$.

The above mechanism may serve as an illustration of one of the first theories of catalysis, which explains the mechanism of the catalytic reaction by the formation of intermediate compounds which are then converted into the reaction products with regeneration of the initial catalysts. All the stages of the mechanism have been investigated separately and can proceed as independent reactions.[84,85]

On the basis of the results of the study of the adsorption of oxygen, Ruthven and Kenney[86] believe that the rate of the Deacon reaction is determined by the rate of oxidation of CuCl to $CuCl_2$ and is described by the equation

$$w = 4k\gamma^2K^2a^2p_{O_2}\{\gamma K + (p_{Cl_2})^{1/2}\}^2,$$

where K is the equilibrium constant of the thermal dissociation of copper chloride, a the mole fraction of copper in the melt, γ the ratio of the activity coefficients of Cu^{2+} and Cu^+, and k the rate constant for the absorption of oxygen.

When $(p_{Cl_2})^{1/2} \gg \gamma/K$, the familiar equation

$$w = k''p_{O_2}/p_{Cl_2},\ \text{where}\ k'' = 4k\gamma^2K^2a^2,$$

holds. Two probable mechanisms of the HCl oxidation reaction have been examined.[23] The author took into account primarily data (including his own) concerning the complex-forming properties of copper, which influence both the stage involving the formation of the active form of the catalyst and the stage in which the reactants are activated in the oxidation-reduction reaction. It is notable that the formation of complexes between copper and potassium chlorides, namely $KCuCl_3$, K_2CuCl_4, K_2CuCl_3, and $K_2Cu_2Cl_6$, has been noted by many investigators.[83–87]

The first mechanism is based on the fact that chlorine is formed in the copper(II) chloride decomposition stage, the copper(II) chloride being regenerated by reaction with oxygen and then with hydrogen chloride. In the second mechanism, chlorine is evolved in the stage involving the interaction of oxygen with copper(II) chloride which is promoted by the formation of complexes with HCl and KCl.

Subject to certain assumptions, the equations corresponding to both mechanisms simplify and are converted into

$$w = k'''(p_{O_2}/p_{Cl_2}).$$

Gel'bshtein[23] gave preference to the first mechanism.

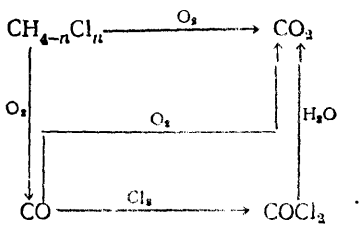
The kinetics of the formation of chloromethanes proved to be the same both in the oxidative chlorination reaction and in the direct chlorination reaction in the presence of the $CuCl_2-KCl$ system.[14,65,82] Both reactions are characterised by the first kinetic order with respect to methane, a fractional order with respect to

chlorine, and virtually identical activation energies (113 kJ mol^{-1}). The rates of the oxidative chlorination and chlorination can be described with the same accuracy by an equation of the fractional-rational type:

$$w = \frac{kp_{CH_4} \cdot p_{Cl_2}}{1 + ap_{Cl_2} + bp_{O_2}},$$

where a and b are adsorption coefficients. Or they can be described by the equation

$$w = kp_{CH_4}\, p_{Cl_2}^{0.6}\, p_{O_2}^{-n},$$



where n varies from 0.25 to 0 as the temperature increases.

It is of interest that the rate of chlorination is independent of the presence of copper in the salt composition, i.e. the presence of variable-valence metal cations in the centres on which chlorination takes place is not obligatory. It has been suggested[14,65,82] that the chlorination of methane at temperatures below 425 °C takes place on the surface of the melt preferentially as a result of the interaction with a polyhalide complex of the type ZCl_3 formed when molecular chlorine is chemisorbed by metal chlorides. An increase in temperature increases the contribution of the reaction involving the thermal volume chlorination by free chlorine.

Subsequently, evidence in support of the catalytic or heterogeneous-homogeneous chain mechanism of the chlorination of methane in the presence of oxidative chlorination catalysts was re-examined by Aglulin.[29] It was established that in a flow-circulation apparatus there is a possibility of additional chlorination in the free volume as a result of the contamination of the glass surface by volatile catalytic compounds (copper and iron chlorides) and also under the influence of light. The reduction of the distorting factors to a minimum enabled the authors[29] to support the heterogeneous-homogeneous mechanism of chlorination under the conditions of the oxidative methane chlorination reaction.

The use of semiconductor detectors, mass-spectrometric and molecular beam methods made it possible to develop these ideas.[88] On interaction with molecular chlorine, the carrier or catalyst generates atomic chlorine in space and subsequent chlorination proceeds via the usual chain mechanism.

The kinetics of the side reactions in the oxidation of methane and its chloro-derivatives have been established.[82] The mechanism of the formation of carbon oxides assumes the following form:

The rates of formation of carbon oxides are described by the following equations at $p_{Cl_2} > 0.01$ atm:

$$w_{CO} = \frac{k_i^{CO}\, p_i\, p_{O_2}\, p_{HCl}}{1 + Kp_{HCl}},$$

$$w_{CO_2} = \frac{k_i^{CO_2} p_i p_{O_2}}{1 + Kp_{HCl}},$$

where k_i and p_i are the rate constants and partial pressures of methane and chloromethanes respectively and K is the equilibrium constant for the absorption of hydrogen chloride.

At $p_{Cl_2} < 0.01$ atm, the rates of formation of carbon oxides depend also on $p_{Cl_2}^{0.5}$. The ratios of the rates of oxidation of methane and chloromethanes are CH_3Cl:CH_2Cl_2:$CHCl_3$:CH_4:CCl_4 = 1:0.5:0.33:0.18:0.033.

The mechanism of the extensive oxidation reactions has been hardly investigated. It is believed[89] that the oxidation reactions of hydrogen chloride and the reactions leading to the extensive oxidation of methane and chloromethanes are catalytic and that chlorination takes place mainly as a homogeneous process.

The view has been expressed[90] that the chlorination of methane occurs on the surface of the melt of copper chlorides. This is justified by the different selectivities in the formation of chloromethanes in catalytic and thermal chlorination processes and by the considerable difference between the rate of evolution of chlorine from the melt and the rate of chlorination. However, the activation energies obtained for the catalytic chlorination of methane (176 kJ mol^{-1}) and the oxidative chlorination of methane (172 kJ mol^{-1}) do not agree with the known values for the energy barriers in the gas-phase chlorination of methane (139 kJ mol^{-1}) and the oxidation of hydrogen chloride (126 kJ mol^{-1}), which can be associated with the change in the activity of the catalyst.

In conclusion one should note that the oxidative chlorination of methane has not been achieved on an industrial scale anywhere in the world. By virtue of the large amount of experimental and design studies, a balanced (with respect to chlorine) industrial manufacture of chloromethanes has been planned and is being established in the USSR, where the entire hydrogen chloride formed in the direct methane chlorination stage is processed in the oxidation chlorination stage. The report[91] concerning the construction of a plant for the preparation of chloromethanes by the oxidative chlorination of methane in fused salts was not confirmed—apparently technological difficulties arose.

VI. Interaction of methanol with hydrogen chloride

The heat of the reaction

$$CH_3OH + HCl \rightarrow CH_3Cl + H_2O$$

is low (32.9 kJ mol^{-1}). Dimethyl ether is formed as a side product:

$$2\,CH_3OH \rightarrow (CH_3)_2O + H_2O.$$

Dimethyl ether also interacts with hydrogen chloride:

$$(CH_3)_2O + 2HCl \rightarrow 2\,CH_3Cl + H_2O.$$

As a result, the selectivity in the formation of chloromethane is usually high and amounts to more than 99%.

Chloromethane can be synthesised from methanol and hydrogen chloride in both liquid and gas phases. Under laboratory conditions, chloromethane is obtained by refluxing methanol with hydrochloric acid without a catalyst. The kinetics of the reaction of hydrogen chloride with methanol at 363 K have been investigated.[92] When the initial hydrogen chloride concentration is varied from 0.115 to 1.623 M, the relative equilibrium degree of conversion of methanol changes only slightly—from 96.5 to 96.1%. The same method of synthesis has been proposed also for use in industry.[93,94] The process temperature is 343–423 K. Zinc chloride is usually employed as the catalyst of the liquid-phase process and a quaternary ammonium halide has been proposed for this purpose recently.[95]

However the majority of companies prefer to carry out the reaction of methanol with hydrogen chloride in the gas phase in the presence of a catalyst in the industrial manufacturing process.[4] Chloromethane is obtained in the USSR by the same method. The reaction is usually carried out in an excess of hydrogen chloride (about 30%), which suppresses the formation of dimethyl ether as the side product; the degree of conversion of methanol under these conditions is about 99%.

A comparative study of the catalytic activities of various salts (zinc, magnesium, calcium, strontium, barium, manganese, cobalt, nickel, copper, cadmium, bismuth, and mercury chlorides) in the reaction of methanol with hydrogen chloride has been carried out in a study for a dissertation.[96] It was shown that zinc chloride exhibits the highest catalytic activity. Comparative tests of various carriers (alumina, activated charcoal, silica gel) for the catalytically active zinc chloride mass led to the selection of activated alumina. The catalytic activity of pure alumina has also been studied.

The rate of reaction of methanol with hydrogen chloride is described by the equation

$$w_1 = k_1\, p_{CH_3OH}\, p_{HCl}.$$

The activation energy for the reaction in the presence of the catalyst containing 60% of zinc chloride on alumina is 36.5 kJ mol^{-1} and that on pure alumina is 51.5 kJ mol^{-1}, the pre-exponential factors being respectively 2.2×10^8 and 1.5×10^8 litre litre(cat.)$^{-1}$ h^{-1} atom^{-2}.

The kinetic equation for the side reaction involving the formation of dimethyl ether is

$$w_2 = k_2\, p^2_{CH_3OH}.$$

The activation energies for the side reactions in the presence of the same catalysts (60% $ZnCl_2/Al_2O_3$ and Al_2O_3) are 192 and 96 kJ mol^{-1} and the pre-exponential factors at 10^{19} and 2.5×10^{12} litre litre(cat.)$^{-1}$ h^{-1} atm^{-2} respectively.

The kinetics of the reaction of dimethyl ether with hydrogen chloride have also been studied.[96] It was found that the rate of reaction depends on the partial pressures of dimethyl ether and hydrogen chloride with an exponent of unity. It is suggested that the last reaction takes place consecutively—via a stage involving the interaction of dimethyl ether with one hydrogen chloride molecule:

$$w_0 = k\, p^0_{HCl}\, p^0_{CH_3OH}/\{1 + (K_{HCl}\, p^0_{HCl})^{1/4}\}^2,$$

and the methanol formed then reacts with another HCl molecule. Here we have $k_3 < k_1$.

Various possible mechanisms of the main reaction have been examined.[96] It has been suggested that a ternary complex of the metal chloride with methanol and HCl is formed as an intermediate[97] and then decomposes into the reaction products.

A correlation-regression analysis has been carried out[98-100] for the heterogeneous-catalytic reaction involving the synthesis of chloromethane from methanol and hydrogen chloride. Out of the 16 kinetic equations for the initial rate of reaction at temperatures in the range 423–473 K, the following equation was selected after resorting to IR spectroscopic data:

$$w_0 = k\; p^0_{HCl}\; p^0_{CH_3OH}/\{1 + (K_{HCl}\; p^0_{HCl})^{1/2}\}^2,$$

where p^0_{HCl} and $p^0_{CH_3OH}$ are the initial partial pressures of hydrogen chloride in methanol and K_{HCl} is the adsorption constant for hydrogen chloride.[99] It is suggested that the reaction takes place on the surface between the hydrogen chloride dissociatively adsorbed on activated charcoal and methanol from the gas phase.[100]

In a study of the kinetics of the reaction of hydrogen chloride with methanol over alumina,[101] it was found that the rate of reaction depends on the partial pressure of HCl with an exponent of unity and is independent of the partial pressure of methanol. The differential rate constant is proportional to the specific surface of the catalyst and is independent of its crystalline modification. Ageing of the catalyst takes place as a result of the deposition of carbon, its activity diminishing exponentially as a function of time.

Studies by Svetlanov[96] made it possible to develop and apply in an industrial process a stronger and more stable catalyst containing 35–38 wt.% of zinc chloride on active γ-alumina instead of the previously employed catalyst (zinc chloride on activated charcoal). The reaction kinetics were revised for the recommended catalyst and a mathematical model of the process was set up, which made it possible to design and recommend a two-compartment adiabatic reactor instead of the tubular reactor currently used.

An analogous catalyst ($ZnCl_2/Al_2O_3$) has been proposed in a patent.[102]

Nevertheless, even this improved catalyst, used nowadays in the industrial manufacture in the USSR,[103] has an appreciably shorter useful life (approximately half a year) compared with the useful life of catalysts of the best foreign companies (1–2 years). This stimulated further research into factors influencing the stability of the catalyst of the synthesis of chloromethane. One of the causes of the decrease in the activity of the catalyst with time is the volatilisation of its active component—zinc chloride.[104] It has been established that the carrier greatly retards the desorption of zinc chloride and that a limiting degree of desorption of zinc chloride corresponds to each temperature. The thermal desorption of zinc chloride from the carrier surface increases by a factor of 3–4 in the presence of reactants, in the first place methanol. Modifying additives have made it possible to reduce by a factor of 2–3 the loss of the active component.[104]

The gradual decrease in the rate of sublimation of zinc chloride as a function of time occurs, according to Grinberg et al.,[105] initially as a result of the slow establishment of the capillary equilibrium within the carrier pores and then as a result of the strengthening of the bond between the salt and the carrier surface.

In contrast to the above view,[105] according to which the surface of the catalyst working above the melting point of zinc chloride is the surface of melt menisci, fusion structures were not discovered in the study of Glazunova et al.[106] Apart from $ZnCl_2$, variable-composition zinc hydroxide chlorides as well as the structures resulting from the insertion of zinc into the spinel-type aluminium oxide lattice were detected by X-ray diffraction and thermal analyses.

Another factor influencing the stability of the operation of the catalyst of the synthesis of chloromethane is the deposition of carbon on its surface during the reaction. It has been observed[107] that the decrease in the specific surface of catalyst on deposition of carbon is associated with the reduction of the fraction of pores with effective dimensions less that 20 Å. A relation between the degree of deposition of carbon, on the one hand, and the surface acidity and the irreversible adsorption of methanol, on the other, has been demonstrated.

It is noteworthy that γ-alumina without salts is normally employed abroad in the manufacture of chloromethane from methanol and hydrogen chloride. Salt-free catalysts are used at a somewhat higher temperature, apparently in order to block the highly acid centres which are responsible for the deposition of carbon on the

catalyst and it is recommended that a small amout (0.05–2.0 wt.%) of an alkali metal oxide be introduced into the γ-alumina.[108]

It has been suggested that the reaction of methanol with hydrogen chloride be carried out in the presence of a natural or synthetic ion-exchange zeolite.[109] Chlorine-containing hydrogen chloride reacts with methanol in the gas phase and in the presence of alumina containing <0.5 wt.% of iron (as iron oxide).[110] A mixture obtained by chlorinating methane and containing methane, chloromethanes, nitrogen, and a small amount of chlorine is used in certain cases.[95,102]

In view of the difficulty of applying the oxidative chlorination of methane on an industrial scale, the reaction of methanol with hydrogen chloride has found extensive application abroad, as an HCl-consuming stage, in the industrial manufacture of chloromethanes from methanol and chlorine.[4] Chloromethane is chlorinated in the gas or liquid phase to di-, tri-, and tetrachloromethanes and the hydrogen chloride formed is used to synthesise chloromethanes from methanol. Although methanol is in fact more expensive than methane, the solution of the problem of the utilisation of hydrogen chloride by a relatively simple procedure compensates for the increased cost of the raw material.

VII. Hydrodechlorination of tetrachloromethane

The hydrodechlorination of tetrachloromethane has assumed major importance recently in connection with the positive imbalance which has arisen in the manufacture and consumption of tetrachloromethane. The large excess of tetrachloromethane is caused, firstly, by the cessation of its use as the raw material for the manufacture of Freons 11 and 12, which decompose the ozone layer; secondly, there has been a continuous growth of the processing of waste from organochlorine industries by exhaustive chlorination to perchlorocarbons (CCl_4 and C_2Cl_4). The presence of the stage involving the selective hydrodechlorination of tetrachloromethane to $CHCl_3$, CH_2Cl_2, and CH_3Cl combined with the direct chlorination of methane makes it possible to obtain chloromethanes in any required proportions.

Various methods are known for the reduction of tetrachloromethanes. For example, chloroform can be obtained by the slow (3–4 days) reduction of CCl_4 with iron and hydrochloric acid at 288 K or by treatment with zinc dust and a 50% NH_4Cl solution at 323–333 K and also by treatment with water, zinc, and nickel.[111]

Various methods for the reduction of organochlorine compounds have been examined in reviews.[112,113] In the electrochemical reduction,[114] two electrons are consumed in the dissociation of the carbon–chlorine bond, the half-wave potential being independent of the pH of the medium and the reactions being reversible overall. There is a linear relation between the half-wave potentials for the reactions

$$RCl + 2e + H^+ \rightarrow RH + Cl^-$$

and the R–Cl bond dissociation energies. With an increase in the number of chlorine atoms in the molecule, the reduction is facilitated as a result of the shift of the half-wave potential in the positive direction. Thus the half-wave potentials (relative to the saturated calomel electrode) for chloromethanes are respectively −3.23, −2.33, −1.67, and −0.78 V. The reduction of tetrachloromethane yields mainly di- and tri-chloromethanes. A publication[115] has also been devoted to the study of the adsorption and dehalogenation of chloromethanes on a platinised platinum electrode.

In a number of studies, the CCl_3 group has been reduced to $CHCl_2$ with the aid of hydrogen donors. Thus it has been shown[116] that the reduction by treatment with $(CH_3)_2C_6H_4$ or $(C_2H_5)SiH$ with participation of $Fe(CO)_5$ takes place selectively as far as the $CHCl_2$ group. Mercaptans, n- and t-C_4H_9SH, and $C_6H_5CH_2SH$ have been used[117] to reduce the CCl_3 group in the presence of the metal carbonyls $Mo(CO)_6$, $W(CO)_6$, $Mn_2(CO)_{10}$, $Re_2(CO)_{10}$, and $Fe(CO)_5$. The $Re_2(CO)_{10}-(C_2H_5)_3SiH$ system has been used for the same purposes.[118] The reduction of CCl_4 by isopropyl alcohol initiated with iron, molybdenum, and manganese carbonyls has been described.[119] The reaction of tetrachloromethane with alcohols, catalysed by metal complexes,[120,121] in particular dichlorotris-(triphenylphosphine)ruthenium(II) $RuCl_2(PPh_3)_3$ and also by rhodium, ruthenium, and iridium complexes immobilised on polystyrene,[122] has been investigated:

$$R^1R^2CHOH + CCl_4 \rightarrow R^1R^2CO + CHCl_3 + HCl$$

Strunkina and Brainina[123] used the zirconium and hafnium hydride complexes Cp_3ZrH, Cp_3HfH, and Cp_2ZrClH for the reduction of CCl_4. A review has been devoted[124] to new redox catalysts for the homolytic reduction of trichloromethyl compounds to dichloromethyl compounds.

However, the hydrodechlorination of tetrachloromethane with the aid of hydrogen donors is relatively unpromising from the practical point of view; in the industrial process, it is necessary to use hydrogen as the reductant. Few studies have been carried out on these lines.

The gas-phase hydrodechlorination of tetrachloromethane on the Pt/Al_2O_3 catalyst has been investigated at temperatures in the range 285–396 K.[125] The reaction products are methane, trichloromethane, and hydrogen chloride, trichloromethane being inactive in the hydrogenation reaction even when it is added to the initial mixture. The authors proposed a radical reaction mechanism in which hydrogen and tetrachloromethane dissociate on platinum and then two parallel reactions take place: CCl_3 interacts with H_2 or absorbs atomic hydrogen, affording tri-chloromethane. In the alternative reaction, CCl_3 is readsorbed on platinum and is not desorbed until it is converted into CH_3 and three molecules of hydrogen chloride. The reaction of the CH_3 radical with hydrogen gives rise to methane.

The hydrodechlorination of CCl_4 by hydrogen has been investigated[126] at 643 K over the nickel-containing zeolites NiNaY, NiCuNaY, NiCrNaY, NiCoNaY, and CuNaY. The amount of nickel was 30 wt.%.

In the reaction of tetrachloromethane with hydrogen on palladium membrane catalysts, the formation of tetrachloroethylene and hexachlorobuta-1,3-diene has been observed.[127]

A study of the interaction of tetrachloromethane with hydrogen by the pulse compression method in a free-piston apparatus with characteristic process times of 10^{-3} s showed that the reaction occurs in two regions.[128] At 1150 K (degree of conversion up to 20%), the process is relatively slow. By regulating the composition of the initial mixture and the process temperature, it is possible to obtain a 16% yield of trichloromethane with a selectivity close to 100%. In a certain temperature range, under the conditions corresponding to the self-inflammation of the mixture, the reaction can be directed to the preferential formation of tetrachloroethylene.

The gas-phase hydrodechlorination of tetrachloromethane over the palladium catalyst has two characteristic features according to Zanaveskin:[129] firstly, the reaction does not stop at an intermediate stage but proceeds as far as the formation of methane and, secondly, the catalyst is rapidly deactivated.

In order to maintain the stable operation of the catalyst (platinum on alumina) in the hydrodechlorination of trichloromethane to dichloromethane, it has been recommended[130] that water, which according to the authors promotes the removal of chlorine from alumina, preventing excess acidity and the associated rapid deposition of carbon, be added to the initial mixture. The addition of a small amount of H_2S lowers the initial activity of the catalyst but increases its stability.

The hydrodechlorination of tetrachloromethane has been studied[131] on palladium catalysts in the liquid phase at temperatures in the range 313–343 K. On palladium acetates with added acetic acid and using C_7–C_{12} paraffins, ethyl methyl ketone dimethylformamide, dioxan, and benzyl alcohol as the solvents, the only reaction product proved to be methane. By carrying out the reaction in isopropyl and t-butyl alcohols as solvents, it was possible to obtain trichloromethane and chloromethane as the main products, the yield of methane varying from trace amounts to 5%. The catalyst containing 4% of palladium on charcoal proved to be more active (approximately by a factor of 20). However, the activities of both catalysts fall appreciably during the experiment (5 h). Only the catalyst containing 0.1% of palladium and 1% of KOH on γ-alumina retains its activity during the experiment.

It has been found[132] that the palladium–cobalt catalysts on activated graphite are more active in the reactions involving liquid-phase hydrogenation with hydrogen than any non-prefused metals.

By passing the vapours of chloromethanes over metals (Ni, Co, Cu, Fe, Rh, Pd) or alloys (Ni–Cu, Ni–Pd), either in a pure form or in a mixture with hydrogen or H_2 + CO, it has been observed[133] that metals which are active in the Fischer–Tropsch reactions afford higher hydrocarbons both in the absence and in the presence of carbon monoxide.

VIII. Carbonylation of chlorohydrocarbons

The method of synthesis of carboxylic acid chlorides by carbonylating chlorohydrocarbons has been known for a long time.[134] It is best to use nickel carbonyl as the catalyst, but cobalt, iron, palladium, and rhodium compounds can also be used.[135] The following reaction mechanism has been proposed:

$$RX + Ni(CO)_4 \rightarrow RNi(CO)_2X + 2CO,$$
$$RNi(CO)_2X + CO \rightarrow RCONi(CO)_2X,$$
$$RCONi(CO)_2X + 2CO \rightarrow RCOX + Ni(CO)_4.$$

The process takes place at temperatures in the range 200–300 °C and pressures in the range 600–1000 atm; in the presence of tertiary amines or alkoxides in amounts equimolecular with the initial halide in the presence of the $NaCo(CO)_4$ catalyst, it is possible to attain a yield of 80% at 0–100 °C without using high pressure.[135]

The development of metal complex catalysis permitted the creation of catalytic systems, with the aid of which it is possible to obtain acetyl chloride by carbonylating methyl chloride:

$$CH_3Cl + CO \rightarrow CH_3COCl.$$

Table 3 presents examples illustrating the conditions in this reaction.

In the vapour-phase carbonylation of methyl chloride in the presence of catalysts—transition metal compounds deposited on activated charcoal—acetic acid with an admixture of methyl acetate is formed on treatment with water.[141]

The authors of a patent[142] describe a process leading to the formation of halogenoacetic acid halides from polyhalogenomethanes by a reaction with carbon monoxide in the presence of platinum and palladium catalysts. Most attention has been devoted to the synthesis of chloroacetyl chlorides by the reaction of polychloromethanes with carbon monoxide in the presence of palladium chloride at 20–250 °C and a carbon monoxide pressure of 30–300 atm:

$$CX_nH_{4-n} + CO \xrightarrow{PdCl} CX_{n-1}H_{4-n}C(=O)X$$
X=F, Cl, Br; $n = 2 - 4$.

The process is applicable to any polychloromethane having two or more halogen atoms of the same or different types.

Table 3. Carbonylation of methyl chloride with formation of acetyl chloride.

Catalytic system	Solvent	T, °C	Patm	t^*_{CO}, min	Yield, %	Refs.
$RhCl_3$, CH_3I, Bu_3P, Bu_3PO	toluene	150	20	120	45.5	[136]
$RhCl(CO)(PPh_3)_2$, CH_3I, Bu_3P	»	130	20	30	25	[137]
$RhCl_3$, $CrCl_3$, CH_3I, $(C_6H_5)_3PO$, $(C_6H_5)_3PCH_3I$	n-heptane	180	82.5	35	56	[138]
Ditto	»	180	75	60	54	[138]
$RhCl_3$, $[Re(CO)_5]_2$, $(C_4H_9)_3PCH_3I$, $(C_6H_5)_3PCH_3I$, CH_3I	»	180	75	35	62.8	[139]
$RhCl_3$, Li (CH_3COO), CH_3I, CH_3COOH, $(CH_3CO)_2O$	—	180	82.5	60	51.6	[140]

* t_{CO} is the time during which CO is passed through the system.

Any platinum or palladium group metals (Ru, Rh, Os, Ir, Pt, and Pd) or their compounds such as salts (nitrates, chlorides, bromides, benzoates, or acetates), oxides, or complexes with organic compounds for example, acetylacetonates) can be used as catalysts. Palladium halides ($PdCl_2$ or $PdBr_2$), which are relatively cheap and entirely effective, are preferred. It is recommended that other transition metal halides (Cu, Ni, Fe, and Co) be used as promoting agents. Inert organic solvents (hexane, octane, decane, benzene, toluene, etc.), are employed in the reaction, anhydrous solvents being preferred.

The use of phase transfer catalysts increases the activity of the catalytic system in reactions involving the cabonylation of organic halides.[143]

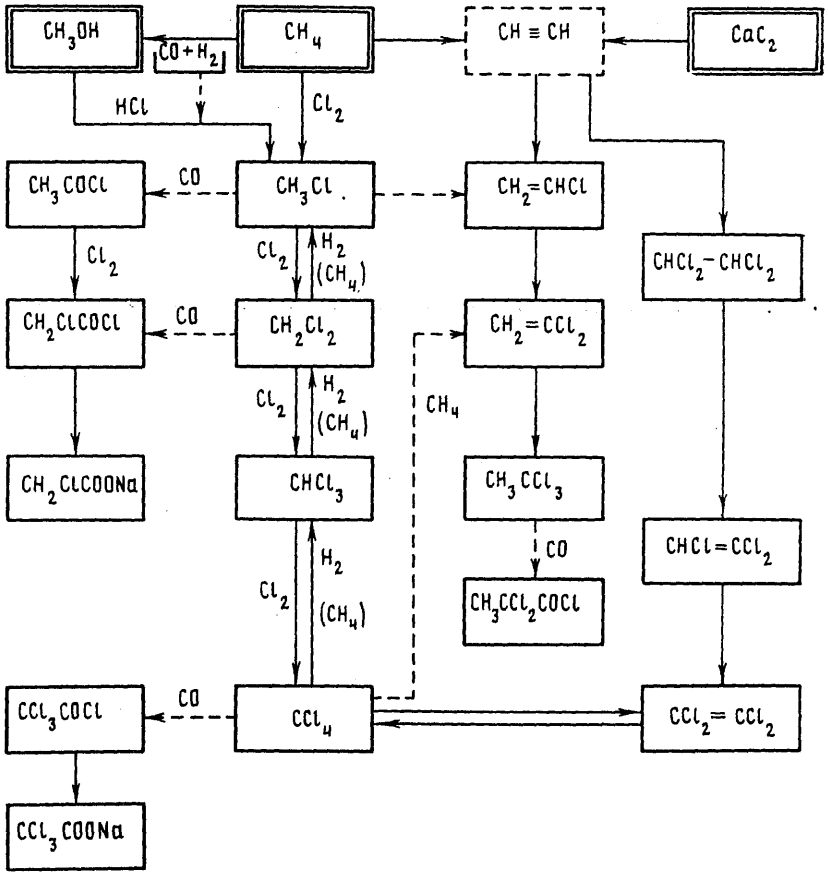

Figure 5. Schematic illustration of the synthesis of organochlorine compounds from one-carbon molecules.

The employment of one-carbon compounds such as methane, methanol, and carbon monoxide as starting material makes it possible to manufacture organochlorine compounds on an industrial scale both at the present time and probably in the future. The scheme presented in Fig. 5 illustrates the conversion of the one-carbon compounds into organochlorine compounds, the continuous lines indicating the reactions achieved in industry and the dashed lines the reactions so far attained only in the laboratory. The time when the latter will also become industrial processes is apparently not distant either.

Thermodynamics of ionic micelles

A I Rusanov
Leningrad State University

ABSTRACT. The present state of the thermodynamics of ionic micellar systems is examined and the principal characteristics of these systems are discussed: the charge and activity coefficients of the micelles, the concentration of the monomers and the degree of binding of the counterions, and the dependence of the critical micelle formation concentration on the length of the hydrocarbon chain of the surfactant and on the added electrolytes. The thermodynamics of the micellar cell and the methods for the calculation of the electrostatic contribution to its energy are described.

The bibliography includes 107 references.

I. Introduction

The formation of surfactant micelles is one of the most interesting phenomena in the physical chemistry of solutions. It is characteristic of colloidal surfactants in the molecules of which hydrophilic (polar, including ionogenic) and lipophilic (hydrophobic) groups (hydrocarbon or fluorocarbon chains usually play the function of such groups) are well balanced. The micelles are molecular or ionic aggregates whose size is about 3–100 nm and which arise after the attainment of the critical concentration for micelle formation (CCM). Micelles are formed over a fairly narrow concentration range. It appeared natural to explain the results of the first observations[1–5] by the fact that micelles are formed under the influence of the attractive forces between surfactant molecules. However, this is true only of micelles in non-polar media. The true cause of micelle formation in aqueous solutions is the hydrophobic effect—the tendency of water to liquidate internal cavities and to expel hydrophobic bodies (especially hydrocarbon groups), which is due to the intermolecular interactions and the structure of water. Treatment of micelle formation as the water aggregation process[6] was the first step in the elucidation of the hydrophobic effect, numerous manifestations of which (the formation of adsorption layers, membranes, vesicles, etc.) play an important role in the self-organisation processes in molecular systems. Micelles may be formed only above a temperature characteristic of its surfactant, called the Krafft point (crystallisation takes place below this temperature). In the equilibrium micellar solution, there is a stable distribution of micelles with respect to size, shape, and composition with an extremely sharp maximum, which is a feature in terms of which micellar systems resemble monodisperse systems.

The first advances in the theory of micelle formation[3–6] were associated with the application of the Law of Mass Action. In this approach (it can be called quasi-chemical), the surfactant aggregation process is regarded as a reversible chemical reaction of the type

$$\sum_i n_i A_i \rightleftarrows M, \qquad (1)$$

where n is the aggregation number, i.e. the number of molecules or ions of the given kind involved in the formation of a single micelle, A and i are the symbol and number of the micelle component, and M is the symbol for the micelle. The lifetime of the surfactant molecule in the micelle can be of the order of 10^{-7} s[7,8] and the half-life of the micelle is between 10^{-3} and 1 s,[9–11] so that reaction (1) should be assigned to the class of fast reactions. The aggregation numbers n_i, which play the role of stoichiometric coefficients in Eqn. (1), are not strictly speaking constant (they increase with increasing surfactant concentration), but in the region of the CCM their variation can be neglected. The observed sharp transition to micelle formation can then be readily accounted for on the basis of the Law of Mass Action by the large aggregation number (several tens and more).

Micelle formation resembles not only a chemical reaction but also a process involving the segregation of a new phase. If this is the pure surfactant phase, then the addition of the latter to the system should not alter its state. In order to justify the phase treatment of micelles, the phase rule and the apparent identity of the Krafft point and the triple point have been resorted to,[12,13] but these arguments proved to be erroneous†.[14–17] Furthermore, direct measurements of the surface tension of a micellar solution and of the activity coefficients of the surfactants[18,19] established that the parameters of state vary steadily with concentration, as in the usual solution, even above the CCM. However, the functions of state of molecular (ionic) and micellar solutions are different and the transition through the CCM can therefore be interpreted as a second order phase transition.[20] The concept of the macroscopic phase is inapplicable to an individual micelle, but it can be regarded as a kind of microphase and, using the concept of the thermodynamics of curved surfaces,[21] a definite pressure and surface tension can be attributed to it. It is significant that this microphase has no macroscopic analogue, because a micellar solution can exist under experimental conditions

† The phase rule cannot be extended automatically to disperse systems and the difference between the Krafft point and the triple point became evident after a more detailed investigation of phase diagrams.

in equilibrium with the solid or liquid crystals surfactant phases and micelles are evidently not nuclei of these phases.

In quasi-chemical and phase approaches, there is a tendency to describe the micelle as a molecule or as a phase respectively. However, the micelle occupies an intermediate position between them. Whereas in the thermodynamic description of the molecule as a component of the solution attention is concentrated usually on the external energy while in the description of the phase the internal energy is exclusively concentrated upon; for the micelle both are equally important. The quasi-chemical approach is useful when its external degrees of freedom are examined and many important properties of the micellar solution can be described on the hypothesis that the micelle is an unmodified entity. On the other hand, in the analysis of the internal state of the micelle (in the language of the quasi-chemical approach, this can mean, in particular, the calculation of the Law of Mass Action constant), the phase approach is entirely appropriate because the micelle is regarded as a microphase. The combination of both approaches makes it possible to describe rationally the thermodynamics of the micellar solution[22] and below we shall follow this recipe.

Micelles are of very considerable practical interest. It is sufficient to recall their wide-scale employment in micellar catalysis, emulsion polymerisation, and other fields of the solubilisation phenomenon, i.e. the dissolution by the micellar solution of substances which are sparingly soluble in an aqueous medium in the absence of micelles. Extensive experimental data on micelles (data for the CCM, the aggregation numbers, the diffusion coefficient, the size, charge, geometrical shape, and degree of dissociation of micelles, etc.) have been published in a series of reviews.[13,23-33] There are more data about ionic micelles with which the study of micelle formation began. The critical concentration for micelle formation from ionic surfactants is 1–2 orders of magnitude higher than for non-ionic surfactants and the number of parameters characterising micelles is greater than for molecular substances (the electrical parameters are added). The interpretation of the experimental results, which depend greatly also on the purity of the surfactant, is also correspondingly more complex. On the one hand, the theory of ionic micelles is based on the general theory of micelle formation in aqueous solutions, including the analysis of the hydrophobic effect, and, on the other, its task is to estimate the contribution of electrostatic interactions to the micelle formation process. This task, which has been recognised at least since 1956,[34] has been considered in a series of studies.[13,35-55] In its development, the theory of ionic micelles was based on the advances in the general theory of solutions of charged colloidal particles[56] and the theory of electrolyte solutions in relation to reacting mixtures[57-62] and polyelectrolytes.[63-69] Considerable progress in the thermodynamic theory of ionic micellar systems was attained in the 1980's. This can be explained by at least two causes: the rapid improvement of the computer techniques and the introduction of new experimental research methods. Wide-scale prospects have arisen, for example, from the direct measurement of the electrical potential of the surface of the micelle, essential for thermodynamic calculations, by the fluoroescent probe method[70] (previously only its charge was determined).

This review considers mainly ionic micelles—more precisely their specific properties which distinguish ionic surfactant micelles from all others. On the other hand, certain results are applicable also to the micelles of non-dissociating surfactants, in particular to zwitter-ionic surfactant micelles (lecithin, betaines, etc.), in the molecules of which the opposite charges of the dipole are separated by a considerable distance (for example, by several CH_2 groups).

II. The micellar system as an electrolyte solution

1. The aggregation number and charge of the micelle. Degree of binding of counterions

The quasi-chemical approach presupposes that the micellar system is single-phase, i.e. is a solution, and that any ionic micelle is no more than a large multicharged ion. Its size is determined by the size and aggregation number of the surface-active ion (or ions) and its charge is determined by the aggregation number and degree of binding of counterions. In a specific concentration range above the CCM (usually within the limits of variation of the concentration by 1–2 orders of magnitude) micelles are spherical in shape. The volume of the hydrocarbon core of the micelle is calculated as the volume of a sphere whose radius is equal to the length of the extended largest hydrocarbon group in the surfactant molecule and the aggregation number is found by dividing this volume by the overall volume of the groups of the surfactant molecule forming part of the core (if necessary, account is taken of the additional packing conditions[26,71-75]). Under the usual conditions, the maximum length (l_{max}, m) and volume (V, m^3) of the linear aliphatic group is determined from the formulae[26]

$$l_{max} = (1.5 + 1.265n_C)\cdot 10^{-10},$$
$$V = (27.4 + 26.9n_C)\cdot 10^{-30}. \quad (2)$$

where n_C is the number of carbon atoms in the group. Accordingly, when the surfactant molecule contains only one such group, the aggregation number n is defined as follows:

$$n = 4\pi l_{max}^3/3V = 4\pi(1.5 + 1.265n_C)^3/(27.4 + 26.9n_C). \quad (3)$$

It is seen from Eqn. (3) that n is an increasing function of n_C. For $n_C = 12$, we obtain $l_{max} = 1.67$ nm, $V = 0.350$ nm^3, and $n = 55.5$ from Eqns. (2) and (3). We may note that the theoretical value of the aggregation number cannot be regarded as either minimal or maximal. If the hydrocarbon chain is not fully uncoiled, then the aggregation number may be less. If a proportion of the chains are not wholly incorporated in the core and continue to remain in contact with water (this possibility is indicated by data for the permeation of water into the interior of micelles[76-83]), then the aggregation number can be actually greater. For the most thoroughly investigated ionic surfactant—sodium dodecyl sulphate (SDS)—n = 60–70 and above has been obtained in many experiments, but, in the assessment of the experimental results, the question of the possible admixtures increasing the aggregation number always arises. An unusually low aggregation number (n = 27) of thoroughly purified SDS has been reported.[84]

For a specified aggregation number, the charge of the micelle is determined by the degree of binding of counterions. The very concept of binding has many meanings.[41] It can be understood as the recombination of ions (binding via chemical forces) or as simple electrostatic attraction, which depends on distance. Even if the degree of dissociation of the micelle is known and the radial statistical distribution of the counterions has been found, one cannot state what proportion of such counterions can be regarded as bound. It is assumed arbitrarily, for example, that the counterions in the first coordination sphere can be regarded as bound.[39] The ambiguity of the concept of binding is manifested also in the interpretation of experimental data, which creates a considerable scatter in the degrees of dissociation of counterions (from 0.46 to 0.86 for SDS[85]). Since this concept originates from the idea of the micelle as a kinetic entity, it is logical to make an attempt to base the concept of the degree of binding on kinetic considerations. Although this approach

does not in fact permit the determination of the exact value of the degree of binding, it does create the possibility of discovering its dependence on the parameters of state.

The critical concentrations for the micelle formations for the majority of ionic surfactants are so low that, in the absence of micelle formation, the average energy of the Coulombic interaction of a pair of ions (u_{ik}), given by

$$u_{ik} = z_i z_k e^2/(4\pi\varepsilon_0\varepsilon\bar{r}) \tag{4}$$

[$z_i e$ and $z_k e$ are the charges of ions of the ith and kth kinds respectively, u is the elementary charge, $\bar{r}$ the average interionic distance, ε_0 the electrical constant (permittivity) and ε the dielectric constant], is less than the average energy of thermal motion. Thus, for an aqueous SDS solution at 25 °C, we have CCM = c_m = 8.1 M, $\bar{r} = (2c_m)^{-1/3} \simeq 46.8 \times 10^{-16}$ m, and, when $\varepsilon = 80$, we have the ratio $u_{ik}/kT \simeq 0.15$ (k is the Boltzmann constant and T the absolute temperature). Under these conditions, the binding of oppositely charged ions is impossible. In the presence of micelles, the situation changes. Suppose that the aggregation number is n, whence the energy of the interaction of the primary core of the micelle with an individual ion is greater by the factor n than the value calculated using Eqn. (4) and, whereas this energy is an order of magnitude smaller than kT for $n = 1$, when $n = 100$ it is already an order of magnitude greater than kT. Such a micellar core will bind the counterions. In the general case, the degree of binding is

$$\beta = -\sum_k n_k z_k \Big/ \sum_i n_i z_i > 0,$$

where n_i and n_k are the aggregation numbers of the surface-active ions and counterions respectively (the minus sign is due to the different signs of z_i and z_k). The charge on the micelle is given by the expression

$$q_M = e\left(\sum_i n_i z_i + \sum_k n_k z_k\right) = e(1-\beta)\sum_i n_i z_i, \tag{5}$$

and a sufficient condition for the absence of binding of counterions by the micelle is

$$e^2(1-\beta)|z_k|\sum_i n_i|z_i|/(4\pi\varepsilon_0\varepsilon\bar{r}kT) \lesssim 1, \tag{6}$$

where $z_k e$ is the greatest of the charges on the counterions (ions with a large charge interact more strongly with the core of the micelle and are the first to be bound).

Eqn. (6) must hold for a certain parameter $\beta < 1$, which indicates the presence of a charge on the ionic micelle. Thus, for SDS, condition (6) holds in the vicinity of the CCM for $\beta \geqslant 0.87$, which means that the real value of β is less than 0.87. If it is assumed that a certain constant value of b on the left-hand side of Eqn. (6) corresponds to the equilibrium degree of binding, then the expression

$$\beta = 1 - 4\pi b\varepsilon_0\varepsilon\bar{r}kT \Big/ \left(e^2|z_k|\sum_i n_i|z_i|\right) \tag{7}$$

makes it possible to determine β as the parameter of state, namely as a function of temperature, concentration, aggregation numbers, and ionic charges. The temperature dependence of β is expressed both explicitly and in terms of the slowly varying functions $\bar{r}(T)$ and $\varepsilon(T)$. As can be seen from Eqn. (7), β diminishes with increase in temperature but in the accessible temperature range this variation is fairly slight.

The concentration dependence of β is manifested mainly in terms of the quantity $\bar{r}$ (and at high concentrations also in terms of ε).

In the presence of micelles, we have

$$\bar{r} = \left(\sum_i c_{i1} + c_M\right)^{-1/3}, \tag{8}$$

where $\sum_i c_{i1}$ is the overall volume concentration of the monomeric ions of both signs and c_M is the concentration of micelles. Above the CCM, both these quantities depend only slightly on the overall surfactant concentration: c_{i1} varies slightly, because the substance is consumed mainly in the formation of micelles and c_M varies slightly because of the large aggregation number. This leads to a very weak dependence of β on the overall surfactant concentration. Thus at concentrations above the CCM for a uni-univalent electrolyte, where the aggregation number of the surface-active ion is n, the doubling of the concentration of the species requires an increase in the overall surfactant concentration by the factor $2n$, i.e. by 2–3 orders of magnitude; under these conditions, r diminishes only by 20% and β even less.

As can be seen from Eqn. (7), the degree of binding is greater the higher the valence of the counterion and the higher the primary charge on the micelle (in particular the larger the micelle). The size of the micelle, its aggregation number, and its primary charge increase, as we have seen, with increase in the length of the hydrocarbon chain in the homologous series of surfactants. However, this entails a decrease in the CCM and an increase in $\bar{r}$, so that the numerator and denominator in Eqn. (7) change in the same direction. Experiment shows[86] that the degree of binding β is independent of the length of the hydrocarbon chain in the range accessible to study. Measurements of the activity and self-diffusion coefficients as well as NMR data[41] confirm the qualitative relations which follow from Eqn. (7): for spherical micelles, β is almost independent of temperature and surfactant concentration and also of the concentration of an extraneous electrolyte, but it does increase on passing to cylindrical micelles, which is always accompanied by an increase in their size.[86] The approximate constancy of β and aggregation numbers makes the micelle resemble a chemical compound and gives rise to the possibility of a quasi-chemical approach to the description of micelle formation.

2. The chemical potential and the activity coefficient of micelles

Statistical mechanics yields the following expression for the chemical potential of the molecules or ions of the solute:

$$\mu_i = \mu_i^0 + w_i + kT\ln a_i\lambda_i^3 \equiv g_i^0 + kT\ln a_i\lambda_i^3, \tag{9}$$

where μ^0 is the contribution of internal degrees of freedom, w the work of introducing one molecule (ion) through a vacuum into the solvent, $a \equiv cf$ the activity (c is the concentration and f the activity coefficient), λ the average de Broglie wavelength for a single molecule (ion), g^0 the partial Gibbs free energy for a molecule (ion) in the solvent with the centre of gravity at rest, and the subscript i characterises the kind of species. The work of introducing a species w depends on the charge q of the species:[87]

$$w(q) = w(0) + q\varphi - qP_0/\varepsilon_0 - (q^2/8\pi\varepsilon_0 r)\cdot(1 - 1/\varepsilon + \varkappa/r). \tag{10}$$

where $w(0)$ is the work of introducing the species in the absence of charge, φ the electrical potential of the bulk phase, P_0 the excess polarisation of the solvent at a neutral species (the constant part of polarisation which is independent of the charge), $\varkappa q/8\pi r^2$ the induced part of polarisation, and r the radius of the species. Since not one ion but a neutral combination of ions (a molecule) is in fact introduced into the solvent, the second term on the right-hand side of

Eqn. (10) is insignificant. The remaining part $w(q)$, called the chemical work of solvation of the ion, depends appreciably on the nature of the latter.

By analogy with Eqn. (9), we shall formulate an expression for the chemical potential of the micelle:

$$\mu_M = G^0_M + kT \ln a_M \lambda^3_M, \quad (11)$$

where G^0_M is the Gibbs free energy of the micelle with its centre of gravity at rest in the specified solvent, $a_M \equiv c_M f_M$ the activity of the micelle (c_M is the volume concentration of micelles and f_M the micellar activity coefficient), and λ_M the average de Broglie wave length of an individual micelle:

$$\lambda_M \equiv h\,(2\pi m_M kT)^{-1/2}, \quad (12)$$

where $m_M \equiv \sum_i n_i m_i$ is the mass of the micelle and m_i the mass of an individual ion (molecule).

The formulation of the chemical potential μ in terms of its standard value μ_s, corresponding to a selected concentration c_s, is very widely used in physical chemistry. For solutions of colloidal surfactants, c_s = 1 M is generally adopted and the following expression is used:

$$\mu = \mu^*_s + kT \ln c' f,$$

where

$$\mu^*_s \equiv \mu_s - kT \ln f_s = g^0 + kT \ln c_s \lambda^3, \quad (13)$$

where c' is a dimensionless quantity numerically equal to the molarity and μ^*_s the chemical potential in the hypothetical ideal unimolar solution. In the treatment of the activity coefficient f, it is necessary to distinguish two cases where the micelles ar segregated and not segregated as an individual component. If the surfactant is a strong electrolyte dissociating via the reaction

$$A = \sum_i \nu_i A_i, \quad (14)$$

where ν_i are stoichiometric coefficients, then its average activity coefficient $f_\pm$ is usually defined by the identity

$$\ln f_\pm \equiv \sum_i (\nu_i/\nu) \ln f_i \quad (15)$$

(the terms f_i are the activity coefficients of the individual ions and $\nu = \sum_i \nu_i$ is the total number of ions formed on dissociation of one surfactant molecule). When the micelle is differentiated as a single ion, the same surfactant dissociation reaction assumes the form

$$A = \sum_i \nu_i (1 - \alpha_i) A_i + (\nu_j \alpha_j / n_j) M, \quad (16)$$

where $\alpha_i = n_i c_M / \nu_i c$ is the degree of micellar aggregation of the ith ion (c_M is the concentration of micelles and c the overall concentration of the surfactant) and the subscript j can be assigned to any ion. By analogy with Eqn. (15), one can write for the mean activity coefficient

$$\ln f^*_\pm \equiv \sum_i (\nu_i/\nu^*)(1 - \alpha_i) \ln f_i + (\nu_j \alpha_j / \nu^* n_j) \ln f_M,$$
$$\nu^* \equiv \nu - \sum_i \nu_i \alpha_i + \nu_j \alpha_j / n_j. \quad (17)$$

The number of ions ν^* formed on dissociation of one molecule is now less than ν and the activity coefficients in Eqn. (17) have a different significance than in Eqn. (15). On the other hand, if the activity coefficients of the individual ions f_i defined by Eqns. (15) and (17) are set equal to one another, then Eqn. (15) yields the mean activity coefficient of the surfactant in the monomeric form. In fact, the micellar solution can be formally regarded as a solution of two electrolytes where the molecules of the first are identical with those of the surfactant and yield on dissociation ν monomeric ions, while those of the second are neutral micelles which split off counterions on dissociation. The mean activity coefficient of the first electrolyte is in fact the quantity $f_\pm$ defined by Eqn. (15) when the real activity coefficients f_i of the individual ions are substituted in it. However, this is not the quantity determined experimentally in accordance with the stoichiometry of Eqn. (14): according to Eqn. (17), the coefficients f_i refer to the real concentrations of the ions $c\nu_i(1-\alpha_i)$, while the experimental values usually refer to the stoichiometric concentrations $c\nu_i$. This increases each ionic coefficient by the factor $1-\alpha_i$ and, if the additional contribution of the micelles themselves is affected [in the region of existence of spherical micelles, the coefficient $\nu_j\alpha_j/n_j$ in Eqns. (16) and (17) is very small], the experimental mean activity coefficient of the surfactant in the micellar solution $f^e_\pm$ satisfies the condition

$$f^e_\pm = \prod_i [(1 - \alpha_i) f_i]^{\nu_i/\nu} \quad (18)$$

For a 1–1 electrolyte, Eqn. (18) can be written in the form[52]

$$f^e_\pm = [(1 - \alpha)(1 - \alpha\beta) f_1 f_2]^{1/2}, \quad (19)$$

where $\alpha \equiv \alpha_1$, $\beta \equiv \alpha_2/\alpha$ is the counterion binding coefficient, the subscript 1 corresponds to the surface-active ion, and 2 corresponds to the counterion.

It has been shown[52,53] that the Guggenheim–Pitzer method,[57,66,88] usually used for concentrated solutions of simple electrolytes, is applicable to the description of the activity coefficients in a micellar system. The expressions for the activity coefficients of ions and micelles of a 1 : 1 electrolyte assume the form

$$\ln f_1 = \ln f_{1D} + B_{1\gamma}(1 - \alpha\beta)\, c,$$
$$\ln f_2 = \ln f_{2D} + B_{1\gamma}(1 - \alpha)\, c + B_{n\gamma}\alpha c/n,$$
$$\ln f_M = n^2\delta^2 (1 - \beta)^2 \ln f_{MD} + B_{n\gamma}(1 - \alpha\beta)\, c, \quad (20)$$

where the terms B_{ik} are the parameters of specific ionic interactions (the surfactant concentration c is expressed on the molal scale) and f_{iD} is the Debye component of the activity coefficient specified by standard expressions of the theory of electrolyte solutions:

$$\ln f_{iD} = -A_\gamma I^{1/2}/(1 + b_i I^{1/2}), \quad (21)$$

$$I \equiv [2 - \alpha - \alpha\beta + n\delta^2 (1 - \beta)^2 \alpha]\, c/2, \quad (22)$$

where I is the ionic strength, A_γ and b_i are constants (it is often assumed that $b_1 = b_2 = b_M = 1$) and δ is the so called micelle charge shielding factor— is actually an adjustable parameter for the description of micelles within the framework of the Debye–Hückel theory (the values $\beta = 0.77$ and $\delta = 0.52$ were used by Burchfield and Woolley[52]). It follows from Eqn. (22) that, with a specified overall surfactant concentration, the ionic strength of the solution increases with increase in the content of micelles if $n > (1 + \beta)/\delta^2(1 - \beta)^2$, whilst otherwise it decreases. Comparison of the quantities obtained on substituting the parameters defined by formula (20) in Eqn. (19) with the experimental values of the mean activity coefficients both above and below the CCM[19,85,89] (it is also possible to compare the osmotic coefficients[52]) permits the determination of the coefficients $B_{1\gamma}$ and $B_{n\gamma}$ (in particular,

$B_{1\gamma} = B_{n\gamma} = 0$ has been found for SDS[52]) and hence one can calculate various thermodynamic characteristics of micelle formation.[52-55]

3. The micellar equilibrium. Expression for the law of mass action constant

The equilibrium condition

$$\sum_i n_i\mu_i = \mu_M. \qquad (23)$$

corresponds to the chemical reaction (1). It can be shown (see, for example, Kuni and Rusanov[90]) that condition (23) is strictly applicable only to the aggregation equilibrium. The entire difference consists in the fact that, at chemical equilibrium, the quantities n_i are strictly constant (they are stoichiometric coefficients), whilst at aggregation equilibrium they are generally speaking variable, since the average aggregation numbers depend on the parameters of state. On the other hand, if one uses not the average numbers but the distribution of the micelles with respect to size, then for each size one can assume that the numbers n_i are constant (determining the type of molecular or ionic aggregate) and one can consider the micellar equilibrium similarly to a multistep chemical equilibrium with participation of many intermediates (see the relevant reviews[91,92]). Condition (23) then makes it possible to find the equilibrium distribution of micelles with respect to size.[22] Within the framework of the monodisperse approach, the numbers n_i are variable but their dependence on the surfactant concentration is weak, so that over a limited concentration range, for example, in the region of existence of spherical micelles, the numbers can be regarded as approximately constant.

Substitution of Eqns. (9) and (11) in Eqn. (23) leads to the relation

$$a_M \Big/ \prod_i a_{i1}^{n_i} = \left(\prod_i \lambda_i^{3n_i}/\lambda_M^3\right) \exp\left[\left(\sum_i n_i g_i^0 - G_M^0\right)\Big/kT\right] \equiv K_a. \qquad (24)$$

For a specified temperature, pressure, solvent composition, and aggregation numbers, the right-hand side of Eqn. (24) is constant. the equation expresses the Law of Mass Action for the micelle formation process in terms of activities. If one goes over to the traditional formulation of the Law of Mass Action with a constant K_c, which is strictly speaking not constant and depends on the concentration, then Eqn. (24) becomes

$$c_M \Big/ \prod_i c_{i1}^{n_i} = K_a \prod_i f_{i1}^{n_i}/f_M \equiv K_c. \qquad (25)$$

The presence of the second subscript 1 in Eqn. (24) and (25) emphasises the fact that the activities, concentrations, and activity coefficients refer to monomeric ions and molecules in solution.

In Eqns. (24) and (25), the constants K_a and K_c are dimensional. In order to go over to dimensionless constants, we introduce, as in Eqn. (13), a standard concentration c_s, divide both sides of Eqn. (25) by $c_s/\prod_i c_s^{n_i}$, and put c_s = 1 M. Eqn. (25) then retains its form subject to the condition that all the concentrations are expressed on molar scale (in reality these are dimensionless quantities numerically equal to the molarities) and the constant K_a, which is now dimensionless, is defined by the expression

$$K_a \equiv \left(\prod_i c_s^{n_i}\lambda_i^{3n_i}/c_s\lambda_M^3\right) \exp\left[\left(\sum_i n_i g_i^0 - G_M^0\right)\Big/kT\right]. \qquad (26)$$

Since the quantities λ refer not to a mole but to an individual species, on substitution of the standard concentration c_s = 1 M in Eqn. (26), it must be expressed in terms of the number of species per unit volume (the Avogadro number in 1 dm^3). According to Eqn. (25), the quantities K_a and K_c differ from one another by a multiplier which includes the activity coefficients. Having determined this multiplier as described in the previous subsection, for example, with the aid of Eqns. (20), and knowing the value of K_c (usually determined from the CCM), it is possible to find the constant K_a.

Expressing the concentration of ions and micelles in terms of the overall surfactant concentration c taking into account the degrees of aggregation α_i and the stoichiometric coefficients ν_i (the subscript 1 is assigned to the surface-active ion), we obtain from Eqn. (25)

$$\ln K_c = \ln(\alpha_1\nu_1/n_1) + (1-n)\ln c - \sum_i n_i \ln \nu_i - \sum_i n_i \ln(1-\alpha_i) \qquad (27)$$

Since the overall aggregation number $n \equiv \sum_i n_i$ is large, the first term on the right-hand side of Eqn. (27) is small compared with the second. Near the CCM, where the degree of aggregation is several per cent, the last term is also small and both these terms may be neglected. The third term automatically becomes zero if the surfactant molecule gives rise to one ion of each kind on dissociation.

The first successes of the micelle formation theory[3-6] were associated with the application of the Law of Mass Action in its traditional form [Eqn. (25)] on the assumption that K_c = const. The activity coefficients are neglected also in modern theory (see, for example, Mijnlieff[93]). This is to some extent justified by the fact that, firstly, when one is dealing with small concentrations, the activity coefficients are close to unity and, secondly, the interaction of the dissolved species with one another, leading to the activity coefficients differing from unity, is in the case of micelle formation a preliminary and not a decisive factor (micelle formation is caused by the hydrophobic effect).

The quantity $-kT \ln K_\alpha$ yields the standard Gibbs free energy of micelle formation per micelle and the quantity

$$\Delta G_a = -(RT/n_1)\ln K_a \qquad (28)$$

is calculated per gram-ion of the surface-active ion with an aggregation number n_1. When K_a is replaced by K_c, the standard Gibbs free energy of micelle formation is defined as follows:

$$\Delta G_c = -(RT/n_1)\ln K_c \simeq (RTn/n_1)\ln c_m + RT\sum_i (n_i/n_1)\ln \nu_i, \qquad (29)$$

where c_m is the CCM. For 1–1 electrolytes, we have

$$\Delta G_c \simeq RT(1+\beta)\ln c_m. \qquad (30)$$

This is perhaps the most familiar relation of the thermodynamics of micelle formation. Some workers express the CCM in terms of the mole fraction x_m in the calculation of ΔG_c, but, since at low concentrations $x_m \simeq c_m/c_0$ (c_0 is the solvent concentration), in practice this means a change in ΔG_c by the constant quantity $RT(1+\beta)\ln c_0$. The different physical significance of the Gibbs free energy in Eqns. (28) and (29) must be emphasised. Whereas ΔG_a is the isothermal-isobaric work of formation of micelles from one mole of the surfactant in a unimolar ideal solution, ΔG_c is the same work subject to the condition that the unimolar solution is not ideal but is characterised by activity coefficients which correspond to the CCM in the real solution. It is seen from Eqn. (25) that, in contrast to K_a, K_c depends on the concentration and ΔG_c is therefore strictly speaking not a standard quantity.

The use of the stoichiometrically mean activity

$$a_{\pm}^{e} = \sum_{i} a_{i1}^{\nu_i/\nu} = f_{\pm}^{e} c \tag{31}$$

in Eqn. (24) leads to the expression

$$\ln K_a \cong -(n_1\nu/\nu_1)\ln a_{\pm} + \sum_{i\geqslant 2}(n_1\nu_i/\nu_1 - n_i)\ln a_{i1} \tag{32}$$

(the term $\ln a_M$ is neglected), whose substitution in Eqn. (28) affords

$$\Delta G_a/RT \cong (\nu/\nu_1)\ln a_{\pm} + \sum_{i\geqslant 2}(n_t/n_1 - \nu_i/\nu_1)\ln a_{i1}. \tag{33}$$

The concept of the critical activity for micelle formation $a_{\pm m}^{\nu}$, corresponding to the CCM, was used by Nakagaki and Handa[94] and the following formula was proposed for the calculation of ΔG_a:

$$\Delta G_a/RT \simeq (\nu/\nu_1)\ln a_{\pm}, \tag{34}$$

However, as can be seen from Eqns. (33) and (34), it is fairly approximate.

The coefficients of $\ln a_{i1}$ in Eqn. (33) (for a 1-1 electrolyte, these are the β-1 coefficients) must be zero for an electrically neutral micelle. An approximate electroneutrality is attained either at the concentration several orders of magnitude higher than the CCM (but it is then not permissible to neglect the term $\ln a_M$) or in the presence of an excess of an extraneous electrolyte. Nevertheless, it has been shown[94] that the use of Eqn. (34) yields somewhat better results than those obtained from Eqn. (29).

4. Dependence of the critical concentration for micelle formation on the length of the hydrocarbon chain of the surfactant molecule

We shall characterise the length of the hydrocarbon chain by the number of carbon atoms n_c. Since micelle formation is caused by the hydrophobic effect, the derivative $\partial\Delta G_a/\partial n_c$ (the hydrophobic effect per chain unit) must be approximately constant for a sufficiently long chain and the same for different surfactants. Near the CCM, a similar rule should hold also for the derivative $\partial\Delta G_c/\partial n_c$ and, according to Eqn. (29), also for the derivative $\partial \ln c_m/\partial n_c$, and the absolute value of the latter for surfactants which do not generate ions ($n = n_1$) should be greater by the factor n/n_1 (by the factor $1 + \beta$, i.e. 1.5-2, for a 1-1 electrolyte) than for ionic surfactants. In fact, experiment shows that the slopes of the $\lg c_m$-n_c curves for non-ionic and zwitter-ionic surfactants are almost the same and close to -0.5 (the slope is -0.517 for alkyl hexaethylene glycol ethers and -0.49 for n-alkylbetaines[94]). Although the $\lg c_m$-n_c relations do remain linear for ionic surfactants, their slope is appreciably smaller: it amounts to -0.29 for alkyltrimethylammonium bromides, -0.30 for sodium alkyl sulphates, -0.28 for sodium alkanecarboxylates,[95] and -0.25 for sodium alkyl phosphates[94] (the smaller slope, in absolute magnitude, for sodium alkyl phosphates is evidently associated with the higher value of β induced by the presence of the doubly charged ion). There exist analogous data also for other homologous series of ionic surfactants.[96]

Since the activity coefficients of non-ionic and zwitter-ionic surfactants at the CCM are virtually unity, the above slope (about -0.5) is characteristic also of the linear relation between $\lg a_m$ and n_c, where a_m is the critical activity for micelle formation. An analogous approach to ionic surfactants with $a_m \equiv a_{\pm m}^{\nu}$[94] made it possible to establish the following values of the derivatives $\partial \lg a_{\pm m}^{\nu}/\partial n_c$ for the above four homologous series: -0.54, -0.58, -0.52, and -0.50 respectively. The closeness of these values to -0.5, which is characteristic of other types of surfactants, confirms that the nature of the micelle formation is the same.

5. The influence of added electrolytes on the CCM

To make the treatment concrete, we shall consider cases where the extraneous electrolyte and the surfactant have a common ion which is a counterion for the micelle. In the presence of an excess of counterions, the micelle is almost electrically neutral, the second term on the right-hand sides of Eqns. (32) and (33) disappears, and condition (34) holds to a high degree of approximation. From Eqn. (32), we have

$$\ln a_{\pm}^{\nu} \simeq -(\nu_1/n_1)\ln K_a \equiv \text{const}. \tag{35}$$

Suppose that the surfactant yields on dissociation only two kinds of ions ($i = 1, 2$, the subscript 1 corresponding to the surface-active ion and 2 to the counterion). On passing from the mean activities to the concentrations of the monomeric ions c_{11} and c_{21} in Eqn. (35), we obtain

$$\nu_1 \ln c_{11} + \nu_2 \ln c_{21} + \nu \ln f_{\pm} \cong -(\nu_1/n_1)\ln K_a. \tag{36}$$

We apply this condition to the CCM. Substitution of $c_{11} \simeq c_m\nu_1$ and $c_{21} \simeq c_m\nu_2 + c'\nu_2'$ (the quantities referring to the extraneous electrolyte are designated by a prime) leads to the expression

$$\ln c_m + (\nu/\nu_1)\ln f_{\pm} \simeq -(\nu_2/\nu_1)\ln(c_m\nu_2 + c'\nu_2') - (1/\nu_1)\ln K_a - \ln\nu_1. \tag{37}$$

Eqn. (37) indicates the dependence of the CCM for an ionic surfactant on the concentration of the extraneous electrolyte in the presence of a common ion. The left-hand side of Eqn. (37) is a linear function of $\ln(c_m\nu_2 + c'\nu_2')$, the slope of the straight line being determined by the coefficient $-\nu_2/\nu_1$. When Eqn. (37) was tested experimentally, the slopes of the linear relation proved to be -0.9 for SDS and potassium dodecanoate and -1.8 for sodium dodecyl phosphate[94] against the theoretical values of -1 and -2. Although a discrepancy, associated with some inaccuracy of Eqn. (37) itself, does exist, the ratio of the quantities obtained is as expected: in the presence of a doubly charged surface-active ion (dodecyl phosphate), the slope is twice as steep. We may note that, if no account is taken of the activity coefficient (as is usually in fact done), the dependence of $\ln c_m$ on $\ln(c_m\nu_2 + c'\nu_2')$, whilst remaining linear, ceases to correspond to the expected relation associated with the difference between the ionic charges. Thus the slope becomes -0.67 for SDS, -0.6 for potassium dodecanoate, and -0.9 for sodium dodecyl phosphate.[94]

6. Concentration of monomeric ions

The results of kinetic studies,[10] of direct measurements of activities by an e.m.f. method,[19] and of the determination of the self-diffusion coefficients[86,97] show that above the CCM the activity and concentration of the monomeric surface-active ions diminished after the addition of the surfactant to the solution. This finding, which appears at first sight to be improbable, is in reality thermodynamically legitimate and its prediction dates back to as early as 1935.[5] This theory has been formulated[41] within the framework of the electrostatic model, but, for the understanding of the essential feature of the problem, the general considerations associated with the Law of Mass Action are sufficient. As already mentioned in the Introduction, above the CCM the chemical potential and hence the mean activity of surfactants increase only slightly with increasing content of the surfactant in solution. This is consistent with the requirement for the thermodynamic stability of the solution but says nothing about the behaviour of the activities of

individual ions. We shall turn initially to the electroneutrality condition for a micellar solution:

$$c_M z_M = -\sum_i c_{i1} z_i, \tag{38}$$

where z_i is the charge of the monomeric ions and $z_M \equiv \sum_i n_i z_i$ is the charge of the micelle (the number of elementary charges). The overall charge of the micelles appears on the left-hand side of Eqn. (38), while the charge of the rest of the solution (we shall speak of the 'charge of the solution') is on the right-hand side. Surface-active ions predominate in the micelles and counterions predominate in the solution, so that the charges of the micelles and the solution have the opposite signs. However, condition (38) does not express this trivial fact alone. Since the number of micelles increases after the addition of the surfactant, there is a corresponding increase (in absolute magnitude) also in the charge of the solution and this means that the concentration of the monomeric counterions in the solution increases faster than the concentration of the monomeric surface-active ions. In order that the mean activity of the surfactant should increase with increase in its content, it is essential that the activity of at least one of the ions should increase and this ion is evidently the counterion.

In order to discover something about the surface-active ions, we turn to the Law of Mass Action in the form of Eqn. (24). Having first formulated the electroneutrality condition [Eqn. (38)] in terms of the activities, i.e.

$$a_M z_M / f_M = -\sum_i a_{i1} z_i / f_i, \tag{39}$$

and having eliminated a_M from Eqns. (24) and (39), we obtain

$$f_M \sum_i a_{i1} z_i / f_i = -z_M K_a \prod_i a_{i1}^{n_i} \tag{40}$$

or

$$\sum_i c_{i1} z_i = -z_M K_c \prod_i c_{i1}^{n_i}. \tag{41}$$

The activities of the monomeric ions a_{i1} appear on both sides of Eqn. (40), but, whereas the left-hand side depends only slightly on these quantities, on the right-hand side, where there are power functions with large power exponents, such dependence is very marked. Clearly Eqn. (40) cannot hold if all the activities vary in the same direction, i.e. if they all increase with increase in the overall surfactant concentration. A compensation effect on the right-hand side of Eqn. (40) is necessary—some of the activities must increase whilst others must decrease and, since we know that the activity of the counterions increases, then the activity of the surface-active ions must in fact decrease. Analogous reasoning is possible also in terms of Eqn. (41) for the concentration of the monomeric ions, assuming that the quantity K_c is a weak function of concentrations (with activity coefficients close to unity). Thus the conclusion that the concentrations and activities of the monomeric surface-active ions decrease above the CCM can be regarded as thermodynamically justified.

The foregoing can be illustrated by the simplest specific example. Assuming to a very rough approximation that

$$K_c = (n_1 + n_2) \ln c_m = \text{const},$$

and adopting $c_m = 8.3 \times 10^{-3}$, $n_1 = 65$, and $n_2 = 39$ (for $\beta = 0.6$[86]) for SDS, we obtain from Eqn. (41) the equation

$$\ln (c_2 - c_1) = 520.74 + 65 \ln c_1 + 39 \ln c_2, \tag{42}$$

from which it is possible to calculate the concentrations of the monomeric dodecyl sulphate ion (c_1), the monomeric sodium ion (c_2), and the micelles (c_M) as a function of the overall surfactant concentrations $c = c_1 + \nu_1 c_M = c_2 + \nu_2 c_M$. It is seen from Table 1 that the functions $c_2(c)$ and $c_M(c)$ increase monotonically over the entire concentration range, whereas the function $c_1(c)$ has a maximum near the CCM.

Table 1. The concentrations (10^{-3} M) of monomeric ions and micelles in aqueous sodium dodecyl sulphate solution calculated from Eqn. (42).

c	c_1	c_2	c_M
6.01	5.98	5.99	$3.85 \cdot 10^{-4}$
6.33	6.09	6.19	$3.85 \cdot 10^{-3}$
6.82	6.40	6.56	$6.46 \cdot 10^{-3}$
8.4	5.91	6.91	$3.85 \cdot 10^{-2}$
17.7	4.85	10	0.20
248	1.27	10^2	3.80

III. Thermodynamics of the micellar cell

The Gibbs free energy of the micelle G_M^0 with the centre of gravity at rest plays an important role in Eqns. (24) and (26) for the Law of Mass Action constant. We shall now proceed to its analysis. The quantity G_M^0 includes the work of introducing the micelle into the solution to which the energy changes not only in the micelle itself but also in the surrounding solution contribute. We shall therefore define the concept of the micellar cell as the combination of the micelle and its environment. In principle, the entire micellar solution, containing, apart from the differentiated micelle at rest, also other (moving) micelles, can be included in the micellar cell. The micellar cell is electrically neutral and represents an autonomous thermodynamic system which can be regarded as a two-phase system. The hydrocarbon (fluorocarbon) core of the micelle is usually regarded as the internal phase (α) while the solution surrounding the micelle is treated as the external phase (β), an interfacial tension σ being attributed to the interface between them containing the electrical double layer (EDL). The interfacial tension satisfies, as usual, the Laplace equation

$$p^\alpha - p^\beta = \sigma (c_1 + c_2), \tag{43}$$

where p is the pressure and c_1 and c_2 are the principal curvatures of the selected interface. We may note that in general the applicability of the macroscopic condition (43) to small objects such as micelles is not open to doubt only for spherical micelles (the mechanics of spherical micelles have been described in detail[98]). For micelles of more complex shape, there is a possibility of the appearance of anisotropy in the interfacial tension and of effects which are non-linear in terms of curvature. In the most general case, the Laplace equation can be replaced by the equation

$$p^\alpha - p^\beta = \sigma_1 c_1 + \sigma_2 c_2 + C_1 c_1^2 + C_2 c_2^2, \tag{44}$$

where σ_1 and σ_2 are the interfacial tensions along the principal

directions and C_1 and C_2 are certain coefficients. If the micelles are spherical ($\sigma_1 = \sigma_2$, $c_1 = c_2$, and $C_1 = C_2$), it is possible to eliminate the quadratic terms by selecting a special position on the interface, which Gibbs called the tension surface. The case of a cylindrical ($c_2 = 0$) micelle with spheroidal ends (in the mechanics of a cylindrical micelle, the interfacial tension is usually assumed to be isotropic)[99] is also favourable in this respect. However, in the very widely used ellipsoidal micelle model, the neglect of the quadratic terms in Eqn. (44) is hardly permissible.

1. Fundamental equations for the Gibbs free energy

For computational purposes, it is essential that the micelle at rest considered should be characterised by the same aggregation number as the moving micelles in the solution. However, the existence of the micelle in the state at rest cannot fail to affect its chemical potential and hence the fixation of the micelle displaces it from equilibrium with the solution. In studying the thermodynamics of a micellar cell, one should therefore make provision for the case where the micelle proper is not in diffusional equilibrium with the solution [the thermal and mechanical equilibria, defined by Eqn. (44), can be regarded as attained] and in essence plays the role of only a source of an external field in relation to its environment. In this case, the components of the micelle are formally segregated in a special group although they do consist of the same species as the solution. When account is taken of this factor, the joint formulation of the First and Second Laws of Thermodynamics leads to the following fundamental equations for the Gibbs free energy G of the micellar cell:

$$dG = -SdT + Vdp^{\beta} + \sum_i \mu_i dN_i + \sum_i \mu_i^0 dn_i, \tag{45}$$

$$G = -(p^{\alpha} - p^{\beta})V_M + \sigma A + \sum_i \mu_i N_i + \sum_i \mu_i^0 n_i, \tag{46}$$

where S is the entropy, T the temperature, and V the volume of the micellar cell, μ_i and μ_i^0 are the chemical potentials respectively in solution and in the micelle with the centre of gravity at rest, N_i is the number of species of the ith kind in the solution, n_i their aggregation number, A the area of the micelle interface, and V_M the volume which the interface encloses.

If the micelle is spherical, then condition (43) converts Eqn. (46) into the form

$$G = \sigma A/3 + \sum_i \mu_i N_i + \sum_i \mu_i^0 n_i. \tag{47}$$

Yet another equation (of the Gibbs–Duhem type) follows from a comparison of Eqn.s (47) and (45):[22]

$$d(\sigma A/3) = -SdT + Vdp^{\beta} - \sum_i N_i d\mu_i - \sum_i n_i d\mu_i^0. \tag{48}$$

Eqns. (45)–(48) refer to the micellar cell. We define the Gibbs free energy of the micelle proper by the equations

$$G_M^0 = G - \sum_i \mu_i N_i = \sigma A/3 + \sum_i \mu_i^0 n_i, \tag{49}$$

$$dG_M^0 = -SdT + Vdp^{\beta} - \sum_i N_i d\mu_i + \sum_i \mu_i^0 dn_i. \tag{50}$$

On subtracting the Gibbs–Duhem equation (51) for the solution (phase β)

$$0 = -S^{\beta}dT + V^{\beta}dp^{\beta} - \sum_i N_i^{\beta} d\mu_i \tag{51}$$

from Eqns. (50) and (48), we obtain the fundamental equations in terms of excess quantities:

$$dG_M^0 = -\bar{S}_M^0 dT + V_M dp^{\beta} - \sum_i \bar{N}_i d\mu_i + \sum_i \mu_i^0 dn_i, \tag{52}$$

$$d(\sigma A/3) = -\bar{S}_M^0 dT + V_M dp^{\beta} - \sum_i \bar{N}_i d\mu_i - \sum_i n_i d\mu_i^0, \tag{53}$$

where $\bar{S}_M^0 \equiv S - S^{\beta} = S_M^0 + \bar{S}$ includes the entropy of the micelle S_M^0 and the excess entropy $\bar{S}$ contributed by the solution and $\bar{N}_i$ is the excess number of species of the ith kind at the surface of the micelle. By analogy with $\bar{S}_M^0$, it is possible to introduce a quantity G_M^0 intermediate between G[Eqn. (47)] and G_M^0 [Eqn. (49)]:

$$\bar{G}_M^0 = G_M^0 + \bar{G} = \sigma A/3 + \sum_i \mu_i \bar{N}_i + \sum_i \mu_i^0 n_i \tag{54}$$

and to formulate the fundamental equation

$$d\bar{G}_M^0 = -\bar{S}_M^0 dT + V_M dp^{\beta} + \sum_i \mu_i d\bar{N}_i + \sum_i \mu_i^0 dn_i. \tag{55}$$

The excess quantities $\bar{G}$, $\bar{S}$, and $\bar{N}_i$ are associated with the fact that the structure of the solution changes near the micelle. Statistical mechanics yields the following useful relations for the quantity $\bar{N}_i$:

$$(\bar{N}_i + \delta_{iM})/kT = \partial \ln c_M/\partial \mu_i = \partial c_i/c_M \partial \mu_M, \tag{56}$$

where c is the concentration and δ_{iM} the Kronecker symbol (the case $i = M$ corresponds to the distribution of mobile micelles in the field of th micelle at rest).

The fundamental equations for the internal energy ($U = G + TS - p^{\beta}V$), the [Helmholtz] free energy ($F = G - p^{\beta}V$), the enthalpy ($H = G + TS$), and the grand thermodynamic potential

$$\left(\Omega = G - p^{\beta}V - \sum_i \mu_i N_i\right)$$

of the micellar cell, can be readily obtained from the above equations for the Gibbs free energy.

2. Thermodynamics of the charging of the micellar cell

A characteristic feature of the ionic micellar cell is the presence of the ionic EDL and of a Coulombic contribution to the Gibbs free energy. There exist different methods for estimating the contribution. The commonest is the artificial procedure, proposed by Debye, involving the imaginary charging of the ion (for a more detailed description, see Deryagin[56]). If for a specified number of ions the charges of the latter $e\xi_i$ can be varied smoothly (from zero to ez_i), new variables ξ_i appear in eqns. (45), (48), (50), (52), (53) and (55) together with the additional term (on the right-hand side)

$$e\sum_i (N_i + n_i)\varphi_i d\xi_i, \tag{57}$$

where φ_i is the average electrical potential generated by all the ions in the system with the exception of one ion of the ith kind. In an inhomogeneous system, like the micellar cell, we have

$$\varphi_i = (N_i + n_i)^{-1} \int\int\int \varphi_i(\mathbf{r})\, c_i(\mathbf{r})\, d\mathbf{r}, \tag{58}$$

where $\varphi_i(\mathbf{r})$ is the average force potential generated by all the ions except one ion of the ith kind at the point $\mathbf{r}$ in space and $c_i(\mathbf{r})$ is the local concentration of ions of the ith kind; the integration is carried out over the entire volume of the system.

A similar additional term [formula (57)] appears in the fundamental equations for the energy, the [Helmholtz] free energy, the

enthalpy, and the grand thermodynamic potential. The work of charging the micellar cell is found by integrating Eqns. (45), (52), and others for fixed characteristic variables:

$$(\Delta G^{el})_{T,p\beta,N_i,n_i} = (\Delta G^{el}_{M})_{T,p\beta,\mu_i,n_i} =$$
$$= (\Delta U^{el})_{S,V,N_i,n_i} = (\Delta F^{el})_{T,V,N_i,n_i} =$$
$$= (\Delta H^{el})_{S,p\beta,N_i,n_i} = (\Delta\Omega^{el})_{T,V,\mu_i,n_i} =$$
$$= e\sum_i (N_i + n_i)\int_0^{z_i} \varphi_i d\xi_i. \qquad (59)$$

Here the symbol Δ denotes the change in the corresponding thermodynamic function and the superscript *el* shows that the change is due to the appearance of electrical charges. A chain of equations (59) naturally does not imply that the electrical contributions to different thermodynamic functions are always the same: they are the same under different external conditions and therefore differ under the same conditions. Thus under isothermal conditions we have

$$\Delta U = \Delta F + T\Delta S \qquad (60)$$

and, whereas ΔF is specified by Eqn. (59), ΔU now has a different value. Here it is appropriate to point out a common error in the use of Eqn. (60) for the calculation of the electrostatic contribution to the [Helmholtz] free energy: it is assumed that the Coulombic energy (apparently the very term provokes an error) is always ΔU and ΔF is found by substituting ΔU in Eqn. (60). Nevertheless, the Coulombic energy [the right-hand side of Eqn. (59)] is equal to the energy change ΔU only for an isentropic charging process, while Eqn. (60) is isothermal and one cannot substitute in it ΔU defined by Eqn. (59). When Eqn. (60) is used correctly, the Coulombic energy is set equal not to ΔU but to ΔF and substitution of ΔF, defined by Eqn. (59), makes it possible to calculate by this formula the unknown value of ΔU for the isothermal charging process (naturally provided that ΔS is known).

An analogous comment can also be made concerning the Gibbs–Helmholtz equation:

$$\Delta U = d(\Delta F/T)/d(1/T), \qquad (61)$$

which follows from Eqn. (60), provided that account is taken of the thermodynamic relation

$$\Delta S = -\partial\Delta F/\partial T. \qquad (62)$$

Integration of Eqn. (61) yields

$$\Delta F = T\int_0^{1/T} \Delta U d(1/T). \qquad (63)$$

The use of Eqn. (63) for the calculation of the electrostatic contribution to the [Helmholtz] free energy (see, for example, the study of Jönsson and Wennerström[42]) would be significant if the isothermal contribution to the energy were known [as in the initial formula (60), ΔU in Eqns. (61) and (63) refers to an isothermal process], but Eqn. (59) does not allow the determination of these contributions. Thus it must be recognised that Eqns. (60) and (63) are relatively unsuitable for the calculation of the electrostatic [Helmholtz] free energy ΔF^{el} (for condensed phases, $\Delta F^{el} \simeq \Delta G^{el}$). Furthermore, there is no need for them, since the quantities ΔF^{el} and ΔG^{el} can be determined directly from Eqn. (59).

Eqns. (59) yield the total change in the thermodynamic functions during the charging process with allowance for all possible concomitant phenomana (solvent polarisation, changes in the steric structure of the system, etc.). If the distribution in space of all the charged species, and not only the micelle ions (we recall that a micelle is in a state of rest), had been kept unchanged during such a process, then, by virtue of the linear relation between φ_i and ξ_i, the right-hand side of Eqn. (59) would have been determined by the elementary electrostatic relation

$$e\sum_i (N_i + n_i)\int_0^{z_i} \varphi_i d\xi_i = (e/2)\sum_i (N_i + n_i)\varphi_i z_i =$$
$$= (1/2)\iiint \sum_i \varphi_i(\mathbf{r})\rho_i(\mathbf{r})\,d\mathbf{r}, \qquad (64)$$

in which Eqn. (58) and the quantity $\rho_i(\mathbf{r}) = ez_i c_i(\mathbf{r})$—the local charge density generated by ions of the ith kind—are used. In fact, however, the positions of the ions change during the charging process and the linear relation between φ_i and ξ_i is lost. There are also other difficulties which preclude the calculation of the right-hand side of Eqn. (59) in a general form. A number of artificial procedures and approximations, to which we shall now turn, make it possible to obtain simpler expressions for the electrostatic component of the thermodynamic functions (to make the treatment concrete, we shall consider the Gibbs free energy).

3. A two-stage charging process

We imagine that the charging process is divided into two stages. We assume that initially, before charging, an amount of work ΔG_0 was performed under isothermal-isobaric conditions to achieve a reversible rearrangement of the system to the situation which corresponds to the final state of equilibrium in the presence of charges on the species. In the second stage, the charging of the species takes place for their specified distribution in space. The work of the second stage is defined by Eqn. (64) and one can then write

$$\Delta G^{el} = \Delta G_0 + (1/2)\iiint \sum_i \varphi_i(\mathbf{r})\rho_i(\mathbf{r})\,d\mathbf{r} \qquad (65)$$

(here and henceforth the subscripts to ΔG^{el} will be omitted).

For a spherical micelle, the use of Eqn. (47) and the change to spherical coordinates permit the formulation

$$\Delta G^{el} = \Delta(\sigma A/3)^{el} + \sum_i N_i \Delta\mu_i^{el} + \sum_i n_i (\Delta\mu_i^0)^{el} \qquad (66)$$

or, when account is taken of Eqn. (65),

$$\Delta G^{el} = \Delta(\sigma A/3)_0 + \sum_i N_i(\Delta\mu_i)_0 + \sum_i n_i(\Delta\mu_i^0)_0 +$$
$$+ 2\pi\int_0^R \sum_i \varphi_i(r)\rho_i(r)\,r^2 dr, \qquad (67)$$

where R is the radius of the micellar cell in its "charged" state (for $r = R$, there exists a virtually homogeneous phase β). The quantity

$$(\Delta\mu_i)_0 = (4\pi/N_i)\int_0^R \Delta\mu_i(r)\,c_i(r)\,r^2 dr \qquad (68)$$

has the significance of the average change in the chemical potential of the species of the ith kind, since in the first stage the rearrangement links the system to a non-equilibrium state (for this reason, $\Delta G_0 > 0$), while the chemical potential has different values at different points.

According to Eqn. (13),

$$\Delta\mu_i(r) = kT\ln[c_i(r)/c_{i0}(r)] + kT\Delta\ln f_{i0}(r), \qquad (69)$$

where the subscript 0 indicates the absence of charge. Whereas the concentration components of $\Delta\mu_i(\mathbf{r})$ and $\Delta\mu_i^{el}$ at the specified point

in space are the same, the force components are significantly different. Unspecified dispersion forces, whose overall balance is relatively insensitive to the position of the species in solution, contribute to the quantities $\Delta \ln f_{i0}(r)$ and $\Delta(\sigma A/3)_0$, while the main force contribution to the quantities $\Delta\mu_i^{el}$ and $\Delta(\sigma A/3)^{el}$ comes from the strong Coulombic interactions (one can easily imagine that $\Delta\mu_i^{el} > 0$ and $\Delta(\sigma A/3)^{el} < 0$). The approximation

$$|kT\,\Delta \ln f_{i0}(r)| \ll \Delta\mu_i^{el},\ |\Delta(\sigma A/3)_0| \ll |\Delta(\sigma A/3)^{el}|, \tag{70}$$

is suggested, and, when it is valid, Eqn. (67) reduces to the form

$$\Delta G^{el} \cong 4\pi kT \sum_i \int_0^R c_i(r) \ln [c_i(r)/c_{i0}(r)]\, r^2 dr + 2\pi \int_0^R \sum_i \varphi_i(r)\rho_i(r)\, r^2 dr. \tag{71}$$

4. The average field approximation

In order to evaluate the integral in Eqn. (71), one must know the functions $\varphi_i(r)$ and $\rho_i(r)$, the determination of which constitutes an extremely complex electrostatic problem. Even for homogeneous solution, it cannot be regarded as solved. In the modern versions of the Debye–Hückel theory, the quantity φ_i is calculated for low concentrations as the potential generated by the ionic atmosphere around the specified ion with the centre of gravity at rest. Account is thereby taken approximately of the two-particle correlations of the ions in the solution. However, the system which we shall be examining is much more complex. At the centre of the micellar cell, we have the micelle with the centre of gravity at rest, which generates a field in which the ions of the micellar cell, forming the ionic atmosphere of the micelle, move. If one imagines that one of these ions has been stopped and the potential generated by the ionic cloud is sought, then in essence this implies allowance for three-particle correlations with participation of the micelle. Here a reasonable approximation involves the neglect of the correlations of the ions in the strong field of the micelle, i.e. the neglect of the perturbation of the ionic atmosphere of the micelle arising as a result of the arrest of one of the ions. In terms of this approximation, the potential $\varphi_i(r)$ is replaced by the average potential $\varphi(r)$ generated by all the ions of the micellar cell without exception. The potential $\varphi(r)$ "no longer senses" the individual components of the system and in the summation with respect to i is taken outside the summation sign.

In terms of the approximation indicated, Eqn. (59) for ΔG^{el} assumes the form

$$\Delta G^{el} \approx 4\pi e \sum_i \int_0^{z_i} d\xi_i \int_0^R \varphi(r)\, c_i(r)\, r^2 dr = = 4\pi \int_0^1 (d\lambda/\lambda) \int_0^R \varphi(r,\lambda)\,\rho(r,\lambda)\, r^2 dr, \tag{72}$$

where $\lambda \equiv \xi_i/z_i$ is the Debye parameter of the "switching on" of the charge ($0 \leqslant l \leqslant 1$) and $\rho(r,\lambda) \equiv \sum \xi_i c_i(r,\lambda)$ is the variable charge density. The formulation of Eqn. (71) is simplified correspondingly:

$$\Delta G^{el} \cong 4\pi kT \sum_i \int_0^R c_i(r) \ln [c_i(r)/c_{i0}(r)]\, r^2 dr + 2\pi \int_0^R \varphi(r)\rho(r)\, r^2 dr, \tag{73}$$

where $c_i(r)$, $\varphi(r)$, and $\rho(r)$ correspond to $\lambda = 1$. As can be seen from Eqn. (73), by virtue of the electroneutrality of the micellar cell, the potential $\varphi(r)$ is determined to within an arbitrary constant—it is usually reckoned from the value of φ^β in the bulk phase β. We may note that the transition to the average potential immediately converts ΔG^{el} into an excess quantity, since in the bulk phase the integrand expression now becomes zero. For this reason, one can put $R = \infty$ in Eqns. (72) and (73).

5. The switching on of the hydrophobic interaction

Eqns. (72) and (73) have been derived by the method involving the imaginary charging of ions in the presence of a complete micelle. Since micelles exist by virtue of the hydrophobic effect, one may say that we have "switched on" the charge for a constant hydrophobic interaction. Conversely, we shall now try to achieve the imaginary "switching on" of the hydrophobic interaction for a constant ionic charge so that the ions gradually pass from the solution to the micelle. Although the charges of the ions themselves remain unchanged in this process, the charge on the micelle gradually increases and the same work which we calculated by the ion charging method is expended on the formation of the EDL.

If the assembly of the micelle from the ions of the solution proceeds with a constant overall number of ions, then, according to Eqn. (45),

$$(dG)_{T,p^\beta,N_i+n_i} = \sum_i (\mu_i^0 - \mu_i)\, dn_i, \tag{74}$$

and if it takes place for constant chemical potentials of the solution, then, according to Eqn. (50),

$$(dG_M^0)_{T,p^\beta,\mu_i} = \sum_i \mu_i^0 dn_i. \tag{75}$$

In terms of the average field potential, where the electrical component of the electrochemical potential is represented approximately by the term $ez_i\varphi$, the electrostatic contributions on the right-hand sides of Eqns. (74) and (75) are the same, since the bulk phase β, to which μ_i refers, does not participate in these contributions by virtue of its electroneutrality. Assuming now that

$$\sum_i (\mu_i^0 - \mu_i)^{el} dn_i \simeq \sum_i (\mu_i^0)^{el} dn_i \simeq \approx e \sum_i z_i \varphi_M dn_i = \varphi_M dq_M, \tag{76}$$

where φ_M and q_M are respectively the average potential and the charge of the micelle, we obtain, after integrating Eqns. (74) and (75),

$$(\Delta G^{el})_{T,p^\beta,N_i+n_i} = (\Delta G_M^{el})_{T,p^\beta,\mu_i} = = (\Delta U^{el})_{S,V,N_i+n_i} = (\Delta F^{el})_{T,V,N_i+n_i} = = (\Delta H^{el})_{S,p^\beta,N_i+n_i} = (\Delta\Omega^{el})_{T,V,\mu_i} \cong \int_0^{q_M} \varphi_M dq_M. \tag{77}$$

An expression of this type for the [Helmholtz] free energy of a charged colloidal particle was proposed previously by Deryagin.[56,100] If the micelle has a single-layer charge and φ_M is identical with the potential φ_l of the surface of a micelle with a radius l, then the right-hand side of Eqn. (77) can be transformed into[56]

$$\int_0^{q_M} \varphi_1 dq_M = (1/2) \int_l^\infty \varepsilon\, (r d\varphi/dr)^2 dr - 4\pi \int_0^\rho d\rho \int_l^\infty \varphi(r)\, r^2 dr. \tag{78}$$

In the general case of a complex charge structure of the micelle, we have

$$\varphi_M = (1/q_M) \int_l^{l+\delta} \varphi(r)\,\rho(r)\, r^2 dr, \tag{79}$$

where δ is the thickness of the charged layer. For a two-layer charge on spheres with radii l and $l + \delta$, one can write for the

average potential of the micelle

$$\varphi_M = (\varphi_1 q_1 + \varphi_2 q_2)/(q_1 + q_2), \quad (80)$$

where the subscripts 1 and 2 refer to the coordinates l and $l + \delta$ respectively.

IV. Model calculations of the electrostatic contribution to the Gibbs free energy of the micellar cell

Eqns. (72), (73), and (77) provide three ways of calculating the electrostatic contribution to the Gibbs free energy of the micellar cell, but, in order to be able to use them, one must know the functions $\varphi(r)$ and $\rho(r)$. The relation between them is given by the Poisson equation, which assumes the following form for a spherically symmetrical system:

$$(\varepsilon_0/r^2)\, d(r^2 \varepsilon d\varphi/dr)/dr = -\rho = -e \sum_i z_i c_i, \quad (81)$$

where $\varepsilon = \varepsilon(r)$ is the dielectric constant and ε_0 the electrical constant (permittivity). However, the functions $\varphi(r)$ and $\rho(r)$ themselves are not then determined. In order to find them, one must have at least one other relation or one must specify the functions $c_i = c_i(r)$ and hence $\rho(r)$ in an explicit form. This is done in model approaches to the consideration of which we shall now proceed.

1. Static models

In static models, the distribution of ions in space is assumed to be specified and constant. In this case Eqns. (72) and (73) become identical:

$$\Delta G^{el} \simeq 2\pi \int_0^R \varphi(r)\, \rho(r)\, r^2 dr, \quad (82)$$

and, bearing in mind the proportionality between the charge and potential characteristic of static models, Eqn. (77) can be written in the form

$$\Delta G^{el} \cong \varphi_M q_M/2, \quad (83)$$

which is equivalent to Eqn. (82).

As an example, we shall consider the spherical condenser model. If the charges are distributed in the form of two oppositely charged thin concentric layers with radii l and $l + \delta$, it follows from Eqns. (82) and (83) that

$$\Delta G^{el} \cong (q_1^2/8\pi\varepsilon_0\varepsilon)\,[1/l - 1/(l+\delta)], \quad (84)$$

where q_1 is the charge of the primary plate. For ionic micelles, Eqn. (84) is naturally too rough, but it can constitute a satisfactory approximation for non-ionic micelles with a dipolar EDL. Then $q_1 = \sum_i n_i D_i/\delta_i$, where D_i and δ_i are the dipole moment and the distance between the centres of the opposite charges of the dipole of the ith kind respectively. The spherical condenser model is satisfactorily applicable to zwitter-ionic surfactants. The opposite charges in their molecules are separated from one other and a distinct spherical condenser is created in the micelles with an energy close to that of ionic micelles.

The determination of the effective dielectric constant in the dipolar ELD constitutes an interesting problem. Water molecules naturally cannot become wedged between the charges of the same dipole but they can enter the EDL—can be located between the dipoles. Their presence influences the capacitance of the dipolar condenser, so that the dielectric constant ε retains its significance. The attempt to estimate this quantity by the spectral probe method, i.e. by introducing into the micelles small amounts of added substances (for example, dodecypyridinium iodide), whose spectra are sensitive to the polarity of the medium, led to the following values of ε:- $\varepsilon = 46$ for octyl β-D-glucoside $C_8H_{17}OCHC_5H_{10}O_5$, $\varepsilon = 36$ for the dodecyl ether of tricosaethylene glycol $C_{12}H_{25}.(OCH_2CH_2)_{23}OH$, and $\varepsilon = 37$ for *N*-dodecylbetaine $C_{12}H_{25}N^+.(CH_3)_2CH_2COO^-$.[82]

When applied to an ionic micelle, Eqn. (84) corresponds to the model with total binding of the counterions ($\beta = 1$). We obtain $\Delta G^{el}/nkT \simeq 2.2$ for SDS with $n = 56$, $T = 293$ K, $\varepsilon = 80$, $l = 1.97$ nm, and $\delta = 0.55$ nm (diameter of the hydrated sodium ion). The opposite case is represented by the model in which there is no binding of the counterions ($\beta = 0$). With the aid of this simplest and most approximate for the models, which, however, is used for calculations (see, for example, Eriksson et al.[101]) we obtain $\Delta G^{el}/nkT \simeq 10.2$ for SDS having assumed that $\delta = \infty$ in Eqn. (84). Since the real distribution of ions in the EDL is intermediate between these cases, the first and second models yield electrostatic contributions to the Gibbs free energy which are respectively too low and too high. More accurate values are obtained using the Boltzmann distribution.

2. The linearised Poisson–Boltzmann equation

As an additional equation relating φ and c_i, which enter into the Poisson equation (81), the Boltzmann formula is normally employed, i.e.

$$c_i(r) = c_i^\beta \exp[-ez_i\varphi(r)/kT], \quad (85)$$

which follows from the equilibrium condition $\mu_i(r) = \text{const.}$ [see Eqn. (9)] for

$$w_i + kT \ln f_i \cong ez_i\varphi.$$

In static mechanics, the Boltzmann formula can be rigorously justified only for low concentrations when the average energy of the Coulombic interaction of the species is much smaller than kT and only the first term of the series expansion of the exponential function on the right-hand side of Eqn. (85) need be retained:

$$c_i(r) = c_i^\beta [1 - ez_i\varphi(r)/kT]. \quad (86)$$

Substitution of Eqn. (86) in Eqn. (81) yields the linearised Poisson–Boltzmann equation

$$(\varepsilon_0/r^2)\, d(r^2 \varepsilon d\varphi/dr)/dr = \varphi e^2 \sum_i c_i^\beta z_i^2/kT, \quad (87)$$

from the solution of which for a specified function $\varepsilon(r)$ it is possible to find the distribution of the potential φ in the micellar cell. It is usually assumed that $\varepsilon = \text{const.}$ and Eqn. (87) is written in the form

$$(1/r^2)\, d(r^2 d\varphi/dr)/dr = \varphi \left[e^2 \sum_i c_i^\beta z_i^2/\varepsilon_0 \varepsilon kT \right] \equiv \varphi/\delta_D^2, \quad (88)$$

where δ_D is the Debye radius. The solution of Eqn. (88) for the micellar cell represents a trivial repetition of the Debye–Hückel theory. The final result depends on the part of the counterions and the part of the space of the micellar cell to which the Boltzmann formula is applied. We shall consider three cases.

Case 1. The Boltzmann formula is applied to the entire space with the exception of the primary core of the micelle with the charge q_1 localised on a sphere with a radius l. Then, according to the Debye–Hückel theory, we have

$$\varphi(r) = \varphi_1 \equiv \varphi(l) = q_1\delta_D/4\pi\varepsilon_0\varepsilon l(l+\delta_D), \quad (89)$$

for $r \leqslant l$ and

$$\varphi(r) = [q_1\delta_D/4\pi\varepsilon_0\varepsilon(l+\delta_D)\,r]\exp[-(r-l)/\delta_D], \quad (90)$$

for $r \geqslant l$;

$$\rho(r) = -\varepsilon_0\varepsilon\varphi(r)/\delta_D^2. \quad (91)$$

The charge q_1 is generated either by the surface-active ions of the micelle alone or jointly by the latter with the bound counterions. the latter situation is apparently a characteristic of spherical micelles in which the packing of the functional groups is least dense compared with micelles of other shapes and leaves room for the permeation of counterions.[102]

It is simplest to use Eqn. (77) for the calculation of ΔG^{el} with $q_M = q_1$ and $\varphi_M = \varphi_1$, for which it is necessary to know only φ_1 determined from Eqn. (89). Since according to Eqn. (89) φ_1 and q_1 are proportional to each other, we obtain

$$\Delta G^{el} \cong \int_0^{q_1} \varphi_1 dq_1 = \varphi_1 q_1/2 = (q_1^2/8\pi\varepsilon_0\varepsilon)\,[1/l - 1/(l+\delta_D)]. \quad (92)$$

From Eqn. (72), the same result can be arrived at by a much longer procedure.[103] The analogy between Eqns. (92) and (84) shows that, in the model described by the linearised Poisson–Boltzmann equation, the diffuse part of the EDL can be effectively reduced to the dense outer plate of a spherical condenser. For SDS ($n = 56$, $l = 1.97$ nm, $\delta_D = 3.33$ nm at the CCM, $T = 293$ K), we obtain $\Delta G^{el}/nkT \simeq 509/\varepsilon$ on the assumption that the counterions are not involved in the generation of the charge ($q_1 = -en$), which yields $\Delta G^{el}/nkT \simeq 6.36$ for $\varepsilon = 80$. On the other hand, if all the bound counterions also contribute to q_1 [$q_1 = -en(1-\beta)$], we have $\Delta G^{el}/nkT \simeq 1$ (evidently this is the smallest value for the given model) for $\beta = 0.6$[86] and $\varepsilon = 80$.

Case 2. The Boltzmann formula is applied starting with a distance $l + \delta_1$ from the centre of the micellar cell, although the primary charge is again on a sphere with a radius l. The parameter δ_1 has the significance of the distance of closest approach of free counterions (the bound counterions can be located on a sphere with a radius l). Evidently Eqn. (90) remains in force but l is replaced by $l + \delta_1$. The electrostatic contribution to the Gibbs free energy is correspondingly given by the expression[45]

$$\Delta G^{el} \simeq (q_1^2/8\pi\varepsilon_0\varepsilon)\,[1/l - 1/(l+\delta_1+\delta_D)], \quad (93)$$

which differs trivially from Eqn. (92) by the shift of the outer plate of the condenser by a distance δ_1.

Case 3. The Boltzmann formula is again applied starting with the distance $l + \delta_1$ but under conditions where the bound counterions can also be located in the second layer of charges. In the two-layer model, $q_M = q_1 + q_2$ and φ_M is specified by Eqn. (80). The surface potential of the micelle (this is now φ_2) is specified by the right-hand side of Eqn. (89) with l replaced by $l + \delta_1$ and q_1 replaced by q_M. We obtain accordingly

$$\varphi_M = q_1^2\delta_1/4\pi\varepsilon_0\varepsilon_1 q_M l(l+\delta_1) + q_M\delta_D/4\pi\varepsilon_0\varepsilon(l+\delta_1)(l+\delta_1+\delta_D), \quad (94)$$

where ε_1 is the effective dielectric constant in the $l \leqslant r \leqslant l + \delta_1$ layer. Hence

$$\Delta G^{el} \simeq \frac{\varphi_M q_M}{2} = \frac{q_1^2}{8\pi\varepsilon_0\varepsilon_1}\left(\frac{1}{l} - \frac{1}{l+\delta_1}\right) + \frac{q_M^2}{8\pi\varepsilon_0\varepsilon}\left(\frac{1}{l+\delta_1} - \frac{1}{l+\delta_1+\delta_D}\right). \quad (95)$$

In this case ΔG^{el} is interpreted as the electrical energy of two condensers with the charges $\pm q_1$ and $\pm q_M$ on their plates. Formulae for more complex micellar structures can be obtained analogously.

3. The non-linearised Poisson–Boltzmann equation

Substitution of Eqn. (85) in Eqn. (81) yields the non-linearised Poisson–Boltzmann equation

$$(\varepsilon_0/r^2)\,d(r^2\varepsilon d\varphi/dr)/dr = -e\sum_i z_i c_i^\beta \exp[-ez_i\varphi/kT]. \quad (96)$$

Sufficiently accurate solutions of this equation can be achieved by numerical methods (the details of the calculations can be found in a number of communications[35,41,67,68,104]), but if one is interested not in the detailed description of the EDL of the micellar cell but only in its energy relations (which in fact control the micelle formation process), then, with the aid of the non-linearised Poisson–Boltzmann equation (96) with ε = const., it is possible to transform Eqn. (73) into a form which does not require the knowledge of the entire function $\varphi(r)$. Since the Boltzmann formula is inapplicable to the central part of the micellar cell, we shall divide the integration region in Eqn. (73) into two parts: from zero to $l + \delta_1$ and from $l + \delta_1$ to R. The contribution to the first integral by the region $r < l + \delta_1$ will be neglected, since the change in concentration in it can be associated solely with the volume charging effect, which we shall assume to be small. The rest of the first integral in eqn. (73) will be formulated using Eqn. (85) as follows (assuming that $R = \infty$):

$$kT\int_{l+\delta_1}^{\infty}\sum_i c_i(r)\ln[c_i(r)/c_i^\beta]\,r^2dr = -\int_{l+\delta_1}^{\infty}\varphi(r)\rho(r)\,r^2dr, \quad (97)$$

after which Eqn. (73) assumes the form

$$\Delta G^{el} \cong 2\pi\int_0^{l+\delta_1}\varphi(r)\rho(r)\,r^2dr - 2\pi\int_{l+\delta_1}^{\infty}\varphi(r)\rho(r)\,r^2dr. \quad (98)$$

The first term will be estimated, in conformity with Eqn. (79), as $\varphi_M q_M/2$, which can be calculated by the following procedure.[41] We multiply both sides of Eqn. (96) by $r^3 d\varphi/dr$ and write their integrals in the form

$$\frac{\varepsilon_0}{2}\int_{r=l+\delta_1}^{r=\infty}\frac{1}{\varepsilon r}d\left(\varepsilon r^2\frac{d\varphi}{dr}\right)^2 = kT\sum_i c_i^\beta\int_{r=l+\delta_1}^{r=\infty} r^3 d[\exp(-ez_i\varphi/kT)]. \quad (99)$$

Integration by parts, taking into account the boundary condition $d\varphi/dr = -q_M/4\pi\varepsilon_0\varepsilon_1(l+\delta_1)^2$ with $r = l + \delta_1$ and $\varphi = 0$, $d\varphi/dr = 0$, $r^2 d\varphi/dr = 0$, and $r^3\varphi = 0$ for $r = \infty$ yields

$$-q_M^2/8\pi\varepsilon_0\varepsilon_1(l+\delta_1) + 2\pi\varepsilon_0\int_{r=l+\delta_1}^{r=\infty}(rd\varphi/dr)^2\,d(\varepsilon r) =$$

$$= -3kT\sum_i\{V_M[c_i(l+\delta_1) - c_i^\beta] + \overline{N}_i\}, \quad (100)$$

where $V_M \equiv (4\pi/3)(l+\delta_1)^3$ and $\overline{N}_i$ is the excess (relative to the bulk phase β) number of ions of the ith kind in the diffuse plate of the

EDL:

$$\bar{N}_i = 4\pi \int_{l+\delta_1}^{\infty} (c_i - c_i^{\beta}) r^2 dr. \quad (101)$$

The relation between the second integral in Eqn. (98) and the integral in Eqn. (100) is found by integration by parts using the Poisson equation (81):

$$2\pi \int_{l+\delta_1}^{\infty} \varphi\rho r^2 dr = -\varphi(l+\delta_1) q_M/2 + 2\pi\varepsilon_0 \int_{l+\delta_1}^{\infty} \varepsilon (rd\varphi/dr)^2 dr. \quad (102)$$

If it is assumed that, when $r > l + \delta_1$, the dielectric constant assumes a constant value, then the integrals in Eqn. (100) and on the right-hand side of Eqn. (102) become identical. On substituting Eqns. (100) and (102) in Eqn. (98), we then obtain

$$\Delta G^{el} \cong \varphi_M q_M/2 + \varphi(l+\delta_1) q_M/2 - q_M^2/8\pi\varepsilon_0\varepsilon_1 (l+\delta_1) + 3kT \sum_i \{V_M [c_i (l+\delta_1) - c_i^{\beta}] + \bar{N}_i\}. \quad (103)$$

In the special case where the micelle has a single-layer charge [$\delta_1 = 0$, $q_M = q_1$, and $\varphi_M = \varphi(l) \equiv \varphi_1$], we have

$$\Delta G^{el} \cong \varphi_1 q_1 - q_1^2/8\pi\varepsilon_0\varepsilon_1 l + 3kT \sum_i \{V_M [c_i(l) - c_i^{\beta}] + \bar{N}_i\}. \quad (104)$$

As an example, we shall consider the calculation of ΔG^{el} by Eqn. (104) for SDS at 20 °C. The numerical solution of Eqn. (96) for $\varepsilon = 79.7$, $n = 56$, $q_1 = 8.9 \times 10^{-18}$ C, and $l = 1.97$ nm yields $ez_1\varphi(l) \simeq 6.5\ kT$.[41] From the electroneutrality condition, we obtain $\bar{N}_2 \simeq 56$ and from the Boltzmann formula we have $c_2(l) - c_2^{\beta} \simeq 5.51$ M for $c_2 = 8.3 \times 10^{-3}$ M (CCM). From Eqn. (104), we then find $\Delta G^{el}/nkT \simeq 5.0$. Using the same initial data, we obtained above 6.36 by Eqn. (92), so that the linearised Poisson–Boltzmann equation yields a result which is too high.

4. A modified non-linearised Poisson–Boltzmann equation

If the dielectric constant in the Poisson–Boltzmann equation is assumed to be a function not of the spatial coordinates but of the electric field, then the very form of the equation changes. Such an equation is referred to as modified.[38,39] Apart from dielectric saturation, the intrinsic volume of the counterions is taken into account in it.

The dependence of the dielectric constant of a polar liquid on the electric field strength E is described by the expression[105]

$$\varepsilon(E) = n_0^2 + [4\pi cD(n_0^2+2)/3.3E] L(0.55(n_0^2+2)DE/kT), \quad (105)$$

where n_0 is the refractive index of the liquid (for long waves), c the number of its molecules per unit volume, D their dipole moment, and $L(x) \equiv \coth x - 1/x$ the Langevin function. For water, the effect of dielectric saturation begins to be manifested as $E = 10^8$ V m^{-1} is approached. At the surface of a micelle, $E = q_M/4\pi\varepsilon_0\varepsilon(l+\delta_1)^2$. If the counterions do not enter into the primary charge sphere, then $q_M = ezn$ and, taking into account Eqn. (2), we have

$$E = ezl_{max}^3/3\varepsilon_0\varepsilon(l+\delta_1)^2 v.$$

For members of a homologous series (excluding the initial members), $l_{max} \simeq l + \delta_1$ and $l_{max}/v \simeq$ const., so that all the micelles of the homologous series are characterised by approximately the same value of E. Its estimation for the specific case of SDS yields $E = 2.6 \times 10^8$ V m^{-1} for $n = 56$ and $\varepsilon = 80$, which means that in reality $\varepsilon < 80$: at the surface of the alkyl sulphate micelle dielectric saturation takes place. The substitution of $E = -\partial\varphi/\partial r \equiv -\varphi$ converts Eqn. (105) into

$$\varepsilon = n_0^2 - aL(-b\varphi')/\varphi', \quad (106)$$

where a and b are coefficients in Eqn. (105). The substitution of Eqn. (106) in Eqn. (81) yields in its turn a modified Poisson equation.

The presence of a strong electric field increases greatly the concentration of counterions at the surface of the micelle. Their intrinsic volume, which is not taken into account in the usual Boltzmann formula, becomes significant under these conditions. A refined Boltzmann formula has been proposed:[38]

$$c_j = c_{j_0} \exp(-z_j e\varphi/kT)/\{1 + (1/N) \times \times \sum_i' c_{oi} [\exp(-z_i e\varphi/kT) - 1]\}, \quad (107)$$

where N is the maximum possible occupation number by hydrated ions and the prime denotes summation with respect to ions having the same sign as that of the ion j (in this model only like ions are treated as hard spheres, while unlike ions are allowed to penetrate one another). The quantity N is assumed to be the same for all the ions; the ion with the maximum charge should be treated with greater precision [from Eqn. (107), it is also seen that N must be referred to unit volume].

Substitution of Eqns. (106) and (107) in Eqn. (96) leads to a modified non-linearised Poisson–Boltzmann equation. Its numerical solution for divalent counterions at a concentration of 1×10^{-3} M[38] shows that the influence of the intrinsic dimensions of the ions on their distribution near the surface of the micelle (in a layer 0.8 nm thick) begins to have an effect at a potential of the primary core of the micelle $\varphi_1 > 100$ mV and increases sharply with increase in the potential. For $\varphi_1 < 100$ mV, the use of the usual (unmodified) non-linearised Poisson–Boltzmann equation does not introduce an error. According to the data of Frahm et al.,[39] the values of φ_1 for sodium alkyl sulphate micelles at 35 °C are $\varphi_1 = -87$ mV for $n_c = 10$, $\varphi_1 = -120$ mV for $n_c = 12$, $\varphi_1 = 155$ mV for $n_c = 14$, and $\varphi_1 = -195$ mV for $n_c = 16$. For SDS at 25 °C in the region of the CCM, $\varphi_1 \simeq -130$ mV, but, since in this case the counterions are singly charged, one may hope that the application of the usual Poisson–Boltzmann equation still does not entail a large error.

If φ_1 has been determined experimentally (for example, by the fluoroescent probe method[39,70]), then the modified non-linearised Poisson–Boltzmann equation makes it possible to calculate the primary charge on the micelle and also the distributions $\varphi(r)$ and $c_i(r)$. Information about the primary charge is especially valuable, since, for a specified aggregation number, this makes it possible to find the number of counterions which have entered the primary plate of the EDL. According to Frahm et al.,[39] the primary charge on the SDS micelle for $n = 55$ and $l = 1.8$ nm is 26.8 ± 1.9 elementary charges, i.e. only half of the charge of the 55 surface-active ions. On the other hand, if it is assumed, as was done above, that $l = 1.97$ nm, then, for the potential $\varphi_1 = 130$ mV, the charge on the micelle is about 32 elementary charges, so that even in the primary plate of the EDL the degree of binding of the counterions reaches 42%. If apart from this one takes into account the additional shielding of the charge by the counterions in a shell 0.5 nm thick adjoining the core, then the degree of binding reaches $\beta = 0.55$ (Frahm et al.[39] obtained $\beta = 0.65$ for $l = 1.8$ nm). Accordingly, one can put forward the following picture of the distribution of the 55 counterions around the core of micelle: 23 enter into the primary layer of the EDL, 7 into the shell adjoining the core, and 25 into the

diffuse part of the EDL. In this case we are dealing with a two-layer charge on the micelle and the quantity ΔG^{el} can be calculated from Eqn. (103). However, the result of the calculation is sensitive to the postulated value of ε_1. The maximum value of $\Delta G^{el}/nkT \simeq 5.5$ is obtained for $\varepsilon_1 = 80$. On the other hand, if, for example, $\varepsilon_1 = 40$, then $\Delta G^{el}/nkT \simeq 4.2$.

The Poisson–Boltzmann equation has been modified[46] with the aid of the semiempirical relation[106]

$$\varepsilon(E) = \varepsilon_\infty + (\varepsilon_0 - \varepsilon_\infty)/(1 + BE^2), \qquad (108)$$

where the subscripts correspond to $E = 0$ and $E = \infty$ ($E_\infty = 6$) and B is a constant. Apart from the revised description of the EDL, Beunen and Ruckenstein[46] formulated the problem of the more accurate calculation of the work of formation of the primary plate of the EDL of the micelle. It is usually assumed that, when the ions are bound to one another, their contribution to the electrostatic energy vanishes. This would be the case if oppositely charged ions did indeed penetrate one another. In fact, they form dipoles, which interact with the surface-active ions of the micelle. The extent of such ion–dipole interaction can be estimated, for example, within the framework of the lattice model (taking into account the interaction of neighbours).[46] The values $\beta = 0.65$ for spherical micelles and $\beta = 0.88$ for cylindrical micelles were obtained by this method for SDS with $l = 2.03$ nm.

V. Conclusion

In terms of the average field approximation, the electrostatic contributions to the Gibbs free energy of the micellar cell and to the standard Gibbs free energy of micelle formation are the same, so that, by estimating ΔG^{el}, we thereby determine also the electrostatic contribution to the Law of Mass Action constant. If one takes into account the fact that the hydrophobic effect amounts to about $-1.5\ kT$ per CH_2 group, then the contribution by $\Delta G^{el}/nkT$ of the order of 4–5 must be recognised as relatively small. It is significant that $\Delta G^{el} > 0$ (while the main contribution by the hydrophobic effect is negative) and, as can be seen from Eqn. (30), this increases CCM (for $\Delta G^{el}/nkT = 4.6$, the critical concentration for micelle formation is 100 times greater than in the absence of the electrostatic contribution). It is necessary to note that the influence of ions on the micelle formation process can be mediated by the hydrophobic effect itself, because the dissolved ions influence the structure of water.[51,81] The marked dependence of the size of the dodecyl sulphate micelles on the nature of the counterion[51] provides an interesting illustration of this finding, although a theory of this phenomenon has not yet been developed.

In estimating the electrostatic contribution to the Gibbs free energy, we considered spherical micelles for which this contribution is a maximum. Analogous calculations can be performed also for cylindrical micelles, but in this case the electrostatic effects are smaller because of the denser packing of the surface-active ions and the greater degree of binding of the counterions. As regards the phenomenon of the polymorphic transformation of the micelles itself (from spherical to cylindrical and from cylindrical to lamellar), we confined ourselves only to a general comment in this review. Some workers (see, for example, Refs. 71 and 75) treat the phenomenon in terms of a purely geometrical aspect taking into account only the shape of the molecules and their packing. In reality, such processes are controlled by energy relations. A rigorous study of polymorphic transformations of micelles, like that of the polymorphic transformations of small crystals, is based on the generalised Gibbs–Curie principle[107] using [as in Eqns. (47) and (49)] the concept of surface tension. For the latter, as for many other thermodynamic quantities, it is also possible to differentiate and calculate in one way or another the electrostatic contribution characteristic of ionic micelles (see, for example, Rusanov[22]). However, a detailed examination of these questions is outside the framework of this review.

Catalytic synthesis of organic compounds by the carbonylation of unsaturated hydrocarbons and alcohols

A L Lapidus, S D Pirozhkov
Zelinskii Institute of Organic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The methods of synthesis of organic compounds by the carbonylation of acetylene, diene, and alkene hydrocarbons as well as alcohols in the presence of homogeneous and heterogeneous catalysts based on Group VIII metals and acid catalysts are examined. Data are presented on the synthesis of unsaturated and saturated mono- and di-carboxylic acids and their esters, lactones, and ketones from hydrocarbons and alcohols as well as the activities, selectivities, and stabilities of the catalytic systems in the carbonylation reaction.
The bibliography includes 256 references.

Contents

I. Introduction 117
II. Carbonylation of unsaturated hydrocarbons 117
III. Carbonylation of alcohols and esters 128

I. Introduction

During recent years, the world industrial output based on the use of carbon monoxide has expanded significantly. The synthesis of methanol and of liquid hydrocarbons from CO and H_2 (the synthesis gas), the hydroformylation of olefins, and the carbonylation of methanol with formation of acetic acid may be regarded as some of the processes carried out on a large scale.

The development of processes based on the use of carbon monoxide is associated with many factors. The principal of these is the necessity to employ new alternative sources of raw materials. Since the 1940s, petroleum has been the principal source of raw materials for the chemical industry, which led to the creation of an independent branch of industry—petrochemistry. However, in recent years a tendency has arisen towards a decrease in the rate of extraction of petroleum, the principal petroleum deposits tend to become exhausted, and there is a trend towards a shift of the main centres of petroleum extraction in the USSR to the regions of the North, the North West, and the Far West. These factors led to the increase in the cost of prospecting for and the extraction and transport of petroleum and hence has necessitated the search for new ways of replacing it. Since the USSR has enormous resources in coal, shale, and natural gas, the intensification of their chemical processing in order to obtain valuable organic compounds, which are nowadays produced on the basis of petroleum, is extremely promising.

In particular, carboxylic acids, hydroxyacids, acid anhydrides, lactones, alcohols, ethers and esters, and aldehydes and ketones can be obtained via carbonylation. Many of these reactions have been fairly thoroughly investigated but so far sufficiently active, selective, and stable catalytic systems, which would permit the introduction of promising processes into industry, have not been created in many instances.

The present review includes data on the latest advances in the catalytic syntheses of oxygen-containing compounds by the catalytic carbonylation of acetylene, dienes, olefins, and alcohols in the presence of homogeneous and heterogeneous catalysts based on Group VIII metals or acid catalysts.

II. Carbonylation of unsaturated hydrocarbons

A wide variety of carbonyl-containing products of practical value are obtained by the carbonylation of unsaturated compounds containing triple, double, or conjugated bonds. The interest in this reaction has grown particularly in recent years in connection with the necessity to create new technological methods for the synthesis of valuable chemical products on the basis of natural gas and coal from which mixtures of carbon monoxide and hydrogen can be readily obtained.

A series of monographs and reviews have been devoted to the carbonylation reactions of unsaturated compounds.[1-3] Below we shall therefore examine only the publications of recent years as well as problems of a general character.

The possibility of obtaining acetylene hydrocarbons from a non-petroleum raw material leads to good prospects for the application of processes involving the carbonylation of these substrates.

1. Carbonylation of acetylene hydrocarbons

The carbonylation of acetylene hydrocarbons usually leads to the formation of acrylic acid, its derivatives, and esters:[4-20]

$$R{-}C{\equiv}CH + CO{-}\begin{cases}\xrightarrow{H_2O} CH_2{=}C(R)COOH\\ \xrightarrow{R'OH} CH_2{=}C(R)\,COOR'.\end{cases}$$

For example, mixtures of maleic and fumaric acids have been obtained in 35–40% yield by the carbonylation of acetylene in the presence of H_2PdBr_6.[4] The reaction is carried out at atmospheric pressure and a temperature in the range 35–40 °C by passing a 4:1 mixture of CO and C_2H_2 through a hydrochloric acid solution. The maleic acid formed together with fumaric acid then isomerises fully to fumaric acid. When $PdBr_2$ mixed with oxidants [$FeCl_3.6H_2O$, $Fe_2(SO_4)_3.9H_2O$, O_2] is used as the catalyst, a mixture of fumaric and maleic acids and maleic anhydride is obtained from acetylene and its homologues.[5] The anhydride of phenylmaleic acid has been obtained from phenylacetylene under these conditions.

The carbonylation of acetylene and some of its homologues in the presence of palladium catalysts in the liquid phase containing HCl and HBr takes place with formation of acrylic acid and its esters and β-chloroacrylic acid and its esters. It has been studied in detail in a number of investigations.[6-12] *trans*-β-Chloroacrylic acid has been obtained in 62.5% yield from a 4:1 C_2H_2-CO mixture in HCl solution in the presence of $PdCl_2-HgCl_2$ with added NH_4Cl and $FeCl_3$ at 80.5 °C and atmospheric pressure.[6] Vinyl chloride and small amounts of acetaldehydes are formed as side products.

The carbonylation of acetylene also takes place in the presence of the $PdBr_2-HBr-$oxidant$-BuOH$ system with added PPh_3. $FeCl_3$, O_2, and quinone are used as oxidants.[7,8] In order to increase its rate, the reaction is carried out in carboxylic acid amides.[8]

The rate of carbonylation of acetylene (70 °C, atmospheric pressure) is described by the following equation when the $PdBr_2-P(OPh)_3-HBr.ROH$ catalytic system is used:[9]

$$r = k_1 p_{CO} p_{C_2H_2} / [H^+] \times (1 + k_2 p_{CO} p_{C_2H_2} + k_3 p_{C_2H_2}),$$

where k_1, k_2, and k_3 are constants and p_{CO} and $p_{C_2H_2}$ are the current partial pressures of carbon monoxide and acetylene respectively.

In the presence of the $PdI_2-LiI-HCl-ROH$ catalyst, the kinetics of the carbonylation of acetylene are described by a more complex equation.

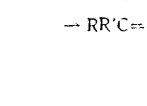
The "alkoxide" reaction mechanism has been proposed:[9]

$$PdX_2 \underset{HX}{\overset{ROH}{\rightleftharpoons}} XPdOR \xrightarrow{CO} XPdCOOR \xrightarrow{C_2H_2} XPdCH{=}CHCOOR - \begin{cases} \xrightarrow{H^+} CH_2{=}CHCOOR + PdX_2, \\ \xrightarrow{CO,ROH} (ROOCCH{=})_2 + HX + Pd(0). \end{cases}$$

The activity of complexes of the type $Pd\{P(OR)_3\}X_2$ in the carbonylation of acetylene in hydrochloric acid and 1-butanol diminishes in the sequences $Cl^- > Br^- > I^- > SCN^-$ and $P(OCH_3)_3 > P(OC_2H_5)_3 > P(O\text{-iso-}C_3H_7)_3$. When the reaction is carried out in hydrobromic acid, the opposite sequences are observed. The addition of LiI to the reaction medium appreciably increases the activity of the catalytic system. Palladium complexes with ligands in the *trans*-positions possess a higher activity. The main product of the carbonylation of acetylene is the monoester of acrylic acid. The formation of dicarboxylic acid diesters is hardly observed.[10,11]

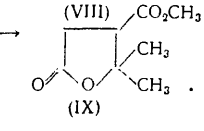
Quinone is an effective oxidant when the $PdI_2-LiI-HCl-BuOH$ catalytic system is used for the carbonylation of acetylene with formation of acrylic, propionic, maleic, fumaric, and succinic acid esters. The Pd^+ ion is then responsible for the catalysis. The activity of the complexes $MPdI_2.2H_2O$ (where M = Li or Cs) is significantly higher than that of the complexes $[Pd(CO)Cl]_n$ and $Cs[Pd(CO)Cl_2]$.[8]

The carbonylation of methylacetylene in the presence of a catalytic system containing $PdCl_2$ and HI in methanol and acetone at 50 °C and a pressure of 24 atm afforded methyl methacrylate and methyl crotonate in overall yields of 97.0 and 2.0% respectively.[12,14] The reaction takes place effectively not only in alcohol but also in other oxygen-containing compounds, for example, methyl and ethyl acetates, ethyl methyl ketone, tetrahydrofuran (THF), dioxan, and acetone.



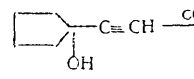
The carbonylation of acetylene, methylacetylene, phenylacetylene, and other alkyl- or aryl-acetylenes can be achieved in the presence of a wide range of palladium complex catalysts containing various ligands.[15,16] Thus acetylene reacts readily with CO and O_2 in the presence of PdX_2, where X = Cl, Br, or I, at temperatures in the range 0–70 °C and atmospheric pressure with added thiourea.

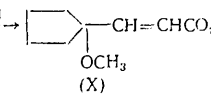
Methyl maleate with a small admixture of fumaric acid ester as well as the diesters of *cis,cis*-, *cis,trans*-, and *trans,trans*-muconic acids are mainly formed in methanol and acetone at 15 °C from CO, C_2H_2, and O_2 in proportions of 1:1:0.1 in the presence of $PdCl_2$ and thiourea.[15]

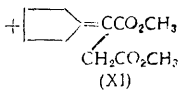


Maleic and fumaric acid esters are obtained from acetylene, CO, and O_2 at 20 °C and atmospheric pressure in the presence of $PdCl_2$ and ethanol with the following aminoacids as additives: DL-threonine, L-glutamic acid, DL-lysine.HCl, *N*-methylglycine, L-α-alanine, DL-β-phenyl-α-alanine, and DL-serine.[16]

Nickel catalysts are also effective in the carbonylation of acetylene. Ethyl 3,4-diacetoxy-2-methylenebutyrate, whose hydrolysis affords the valuable antibacterial preparation methyl βγ-dihydroxy-α-methylenebutyrate, is formed from 1,2-diacetoxybut-3-yne in solution in an alcohol–acetic acid (or an alcohol–benzene) mixture in the presence of nickel carbonyl under mild conditions (70 °C, atmospheric pressure).[17]







Derivatives of alkylidenesuccinic acids have been synthesised from acetylene alcohols having the general formula $RR'C(OH)C{\equiv}CH$ and carbon monoxide by carbonylation under pressure in the presence of palladium black and HI in benzene or in the presence of $CO_2(CO)_8$ with various additives.[18] The reaction proceeds in accordance with the mechanism

$$RR'C(OH)C{\equiv}CH + CO \rightarrow \underset{(I)}{[RR'C{=}C{=}CHCOOH]} \xrightarrow{CO,H_2O} \underset{(II)}{RR'C{=}C(COOH)CH_2COOH} \rightarrow RR'C{=}\underset{(III)}{\text{  }}.$$

The carbonylation of the alcohols (Ib) and (Ic) proceeds specifically. Thus a mixture of the aliphatic unsaturated methoxyacids (VI), (VII), and (VIII) as well as the lactone (IX) have been obtained from compound (Ib):

$$\underset{(Ib)}{(CH_3)_2C(OH)C{\equiv}CH} \begin{cases} \rightarrow (CH_3)_2C{=}C(CO_2CH_3)CH_2CO_2CH_3, \ (VI) \\ \rightarrow (CH_3)_2C(OCH_3)CH{=}CHCO_2CH_3, \ (VII) \\ \rightarrow (CH_3)_2C(OCH_3)C(CO_2CH_3){=}CHCO_2CH_3, \ (VIII) \\ \rightarrow \underset{(IX)}{\text{  }}. \end{cases}$$

The carbonylation of the alcohol (Ic) results in the formation of a mixture of the methoxymonoester (X) and the diester (XI):

$$\underset{(Ic)}{\text{  }} \xrightarrow{CO,CH_3OH} \underset{(X)}{\text{  }} + \underset{(XI)}{\text{  }}.$$

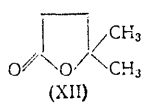
Acetylene alcohols having the formula (I), where R = R′ = H (Ia), R = R′ = CH_3 (Ib), R + R′ = $(-CH_2)_4$ (Ic), or R = CH_3 and R′ = C_6H_5 (Id) have been converted into the anhydrides of the corresponding dicarboxylic acids (II) (Table 1) on interaction with CO under a pressure of 100 atm in benzene in the presence of palladium black and HI.

On refluxing with water, the anhydrides (IIIb–d) are converted into the corresponding acids (IIb–d).

The carbonylation of compound (Ia) in methanol leads to the formation of dimethyl itaconate (IV) and dimethyl aconitate (V) in proportions of 6:1 in an overall yield of 35%. The reaction

proceeds in accordance with the mechanism

$$HC{\equiv}CCH_2OH \xrightarrow[-H_2O]{CO,CH_3OH} [CH_2{=}C{=}CHCO_2CH_3] \xrightarrow{CO,CH_3OH} CH_2{=}C(CO_2CH_3)CH_2CO_2CH_3 \quad (IV)$$



$$HC{\equiv}CCH_2OH \xrightarrow{CO,CH_3OH} CH_3O_2CCH{=}C(CO_2CH_3)CH_2OCH_3 \xrightarrow{CO} CH_3CO_2CH{=}C(CO_2CH_3)CH_2CO_2CH_3 \quad (V)$$

Table 1. Carbonylation of acetylene alcohols in benzene in the presence of palladium black and HI.[18]

Acetylene alcohol	T, °C	p_{CO}, atm	t, h	Reaction product	Yield of reaction product, %
(Ia)	30	20	1.5	tar	—
(Ib)	50	20	3.0	(IIIb)	45
(Ic)	70	50	5.0	(IIIc)	36
(Id)	30	50	2.0	(IIId)	51

The carbonylation of the alcohol (Ib) in the presence of $Co_2(CO)_8$ with various additives (see Table 2) affords tetraconic anhydride (IIb) and the diester (VII). 5,5-Dimethyl-$\Delta^{3,4}$-dihydrofuran-2-one (XII) was also obtained in small amounts:[18]

$$(CH_3)_2C(OH)C{\equiv}CH \xrightarrow{CO,H_2O} (CH_3)_2C(OH)CH{=}CHCOOH \rightarrow$$

(XII)

Table 2. Carbonylation of ethynyldimethylmethanol (Ib) in the presence of cobalt catalysts (150 °C, 100 atm CO).[18]

Catalytic system	Overall yield of compounds (IIb), (VII), and (XII), %	Relative yields, %		
		(IIb)	(VII)	(XII)
$Co_2(CO)_8+HI+CH_3OH$	53.4	42.1	50.4	7.5
$Co_2(CO)_8+HI+Py+CH_3OH$	49.2	25.6	32.3	42.1
$Co_2(CO)_8+C_6H_6$	15.3	—	—	100.0
80.7% CoNaY (SiO_2/Al_2O_3=4.4)	58.3	28.8	47.9	23.3

Butyl acrylate and propionate, the diesters of maleic and fumaric acids, and also crotonic acid esters can be obtained by carbonylating acetylene in the presence of $Pd(NH_3)_nX_2$ (where n = 2 or 4 and X = Cl or I) and HCl at 70 °C and atmospheric pressure in the liquid phase.[19,20] A 1 : 1 mixture of CO and C_2H_2 is used in the reaction. Palladium is regenerated by treating the reaction solution with a stream of dry NH_3 and subsequently isolating the palladium complex by filtration. Under the conditions indicated, the overall rate of formation of the carbonylation products is 1.45 mol litre^{-1} h^{-1}.[19]

Thus a wide variety of mono-, di-, and tri-carboxylic acids, their esters and anhydrides, lactones, and cyclic compounds can be obtained by carbonylating acetylene compounds and their homologues. However, the industrial application of these processes is prevented in the first place by the insufficient activity and selectivity of the proposed catalytic systems.

We may also note that complexes based on Group VIII noble metals are very costly, while nickel complexes are extremely toxic and volatile. In addition, the use of homogeneous complex systems requires the creation of complex regeneration schemes.

2. Carbonylation of dienes

When dienes interact with carbon monoxide in aqueous or alcoholic media, unsaturated monocarboxylic acids, saturated dicarboxylic acids, or their esters, lactones, and mono- and polyketones are formed.[1-3,21] Butadiene and its oligomers, allene, keten, the di- and tri-oligomers of cyclopentadiene are most often used as substrates in this reaction.

The carbonylation of the simplest diene (buta-1,3-diene) in methyl or ethyl formate takes place under mild conditions (120 °C, 30 atm) mainly with formation of the pent-3-enoic acid ester.[22] Pent-3-enoic acid itself is formed in small amounts. Cobalt carbonyl with added isoquinoline is used as the catalyst. The process selectivity increases after the introduction of amines with pK_a = 3–11 into the reaction zone as cocatalysts and also on raising the reaction temperature to 140 °C and the CO pressure to ~900 atm.[23] The presence of admixtures of acetylene hydrocarbons in buta-1,3-diene lowers the efficiency of the process. In the presence of $Co_2(CO)_8$ and pyridine, methyl pent-3-enoate can be obtained in 78% yield from buta-1,3-diene containing about 5% of vinylacetylene, CO, and methanol at 135 °C and a pressure of 900 atm. A decrease in the vinylacetylene content to 0.1% increases the yield of the product to 98%.

In the presence of the $Pd(OAc)_2-Ph_2P(CH_2)_2.PPh_2$ catalytic system (110 °C, 50 atm), a mixture of the isopropyl esters of pent-3-enoic and nona-3,8-dienoic acids is formed from buta-1,3-diene, CO, and isopropyl alcohol in 26.0 and 13.5% yields respectively.[24] The use of C_1–C_{12} aliphatic alcohols makes it possible to regenerate the palladium to the extent of 90%.

The selectivity of the carbonylation of buta-1,3-diene with formation of pen-3-enoate esters increases after the introduction of a mixture of pyridine and isoquinoline into the reaction zone together with $Co_2(CO)_8$. Under these conditions, mainly only the target product is formed from the butadiene at 100–140 °C. Side compounds—4-vinylcyclohexene, dibutyl ketone, methyl α-methylglutarate, and butenals—are formed in insignificant amounts.[25]

A method has been proposed for the synthesis of the phenyl esters of pent-3-enoic and pent-2-enoic acids by carbonylating buta-1,3-diene with carbon monoxide in the presence of compounds having the formula $HX.C_6RR^1R^2R^3R^4$, where X = O or S and R – R^4 = H, alkyl, alkoxy-group ($\leqslant C_6$), cycloalkyl, cycloalkoxy-group (C_3–C_{12}), aryl, and aryloxy-group (C_6–C_{12}), in the presence of $Co_2(CO)_8$ and nitrogen-containing bases with pK_a = 3–10, namely pyridine, γ-picoline, isoquinoline, or their mixtures.[26] The carbonylation of the butadiene is accompanied by dimerisation, which results in the formation of a nona-3,8-dienoate ester:

$$2CH_2{=}CHCH{=}CH_2 + CO + ROH \rightarrow CH_2{=}CH(CH_2)_3CH{=}CHCH_2COOR .$$

It has been suggested that the coupled dimerisation and carbonylation reactions be carried out in the presence of palladium salts or complexes together with sodium, lithium, and potassium acetates.

The catalytic systems are stabilised by arsines, stibines, or phosphines in aliphatic, cyclic or aromatic alcohols and heterocyclic compounds containing oxygen, sulphur, and nitrogen atoms: THF, tetrahydropyran, dioxan, lactones, diketones, tetrahydrothiophen, dibenzothiophen, benzo-1,3-dioxole, etc. Thus isopropyl nona-3,8-dienoate was formed in 85% yield from butadiene, CO, and isopropyl alcohol in the presence of $Pd(OAc)_2$ and PPh_3 at 110 °C and a CO pressure of 50 atm after 18 h.[27]

Allene is carbonylated in the presence of $(Et_2NH)_2NiI_2$ and Et_2NH under mild conditions (20 °C, 5–10 atm CO).[28] For the $(Et_2NH)_2\ NiI_2 : CH_2=C=CH_2 = 1:2$ ratio, a mixture of $Et_2NC(O).C(=CH_2)CH_2NEt_2$ and $Et_2NC(O)C(=CH_2)CH_2C(=CH_2)CH_2NEt_2$ is formed in 48 and 12% yields in solution in a THF–ether mixture. For the equimolar reactant ratio, the yields of these products are 57 and 0.9% respectively. They are formed from allene, Et_2NH, and CO via the intermediate $Et_2NC(O).(=CH_2)CH_2NiI(Et_2NH)_n$.[28] Alkyl esters of malonic acid, which are used in the industrial synthesis of malonic and barbituric acids and medicinal drugs, are obtained by the interaction of keten $CH_2=C=O$ with CO in nitrous acid esters RONO in the presence of phosphine-containing complexes L_2MX_2 (where M = Pt, Pd, Rh, Ru, or Ir and X = Cl, Br, or I), tin halides, and quaternary ammonium salts $R'_4N.X$.[29]

A process has been developed for the syntheis of formylvaleric acid by carbonylating buta-1,3-diene with subsequent hydroformylation of the pent-3-enoic acid ester formed in accordance with the scheme[30]

$$CH_2=CHCH=CH_2 + CO + ROH \rightarrow CH_2=CHCH_2CH_2COOR \rightarrow \xrightarrow{CO,\ H_2} HCOCH_2CH_2CH_2CH_2COOR\ .$$

The first stage is carried out at 135 °C and a CO pressure of 900 atm and the second stage is performed at 120 °C and a pressure of 200 atm. The methyl formylvalerate formed is used in the manufacture of plasticising agents, ε-caprolactam, ε-caprolactone, hexanediol, and adipic acid.

The selective carbonylation of dienes, in particular buta-1,3-diene,[31] can be achieved in a two-phase system consisting of a layer of a polar liquid (water, MeCN, DMF, DMSO, $MeNO_2$, *N*-methylpyrrolidinone, and C_1-C_4 alcohols) and a layer of a non-polar liquid with a dielectric constant $\varepsilon < 2.3$ (pentane, isopentane, hexane, iso-octane, cyclo-octane, tetradecane, etc.). The non-polar solvents then contain the reaction products and the layer of polar liquids contains the components of the catalytic system which are returned to the process. The catalysts are palladium and its compounds. Palladium catalysts on carriers promoted by nitrogen, phosphorus, and arsenic compounds and quaternary ammonium compounds, containing substances capable of generating hydrogen halides in the course of the reaction. Thus, ethyl esters of pentenoic acid (in 61.0% yield) as well as a mixture of diethyl α-methylglutarate and ethyl nona-3,8-dienoate are formed from buta-1,3-diene, CO, and ethanol in the presence of $(C_3H_4)_2PdCl_2$, Bu_4NCl, and 1-chlorobut-2-ene (source of HCl) at 120 °C and a pressure of 196 atm. After the treatment of the products with a mixture of hexane and methanol, the components of the catalytic system are extracted from the methanol phase and the reaction products are extracted from the hexane phase.

The esters of nona-3,8-dienoic acid are obtained selectively from butadiene in the presence of palladium complexes with phosphines and of a thiol as a stabiliser.[32] Thus methyl nona-3,8-dienoate has been obtained in 75% yield from buta-1,3-diene, CO, and methanol in the presence of the complex $Pd(OAc)_2.[P(iso\text{-}Pr)_3]_2$ with added $P(iso\text{-}Pr)_3$ and BuSh (stabiliser) at 100 °C and a pressure of 52.5 atm. Palladium black is not formed during the reaction, which indicates the stability of the catalytic complex.

Esters of but-2-ene-1,2-dicarboxylic acid have been obtained from butadiene under oxidative carbonylation conditions. The reaction is carried out in the presence of O_2, alkoxycycloalkenes, and alcohols. For example, treatment of butadiene with a mixture of carbon monoxide (7 atm) and O_2 (7 atm) in methanol and 1-methoxycyclohexene in the presence of $PdCl_2$, $CuCl_2$, and LiCl at 100 °C and a pressure of 126 atm gave rise after 2 h to dimethyl hex-3-enedioate in 84% yield for a diene conversion of 43%.[33,34]

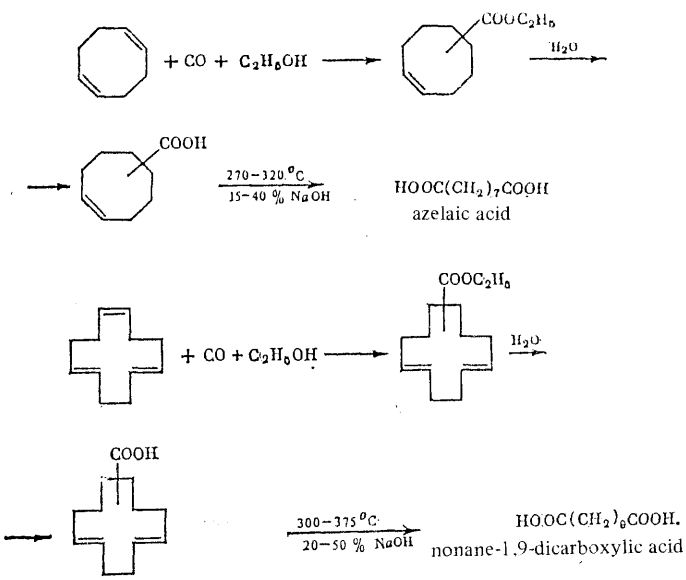
Pent-3-enoic acid esters were obtained from butadiene, CO, and O_2 in the presence of $PdCl_2-CuCl_2$ as well as the additives PrCOONa and $HC(OMe)_3$. Thus *trans*-$(PhCH_2OOCCH_2CH=)_2$ is formed in ~80% yield in $PhCH_2OH$ at a CO pressure of 144 atm and a temperature of 60 °C.[35]

Pent-3-enoic acid diesters are obtained also without access of water and air in the presence of $PdCl_2$, $CuCl_2$, and alkali earth metal salts. The interaction of butadiene with CO in solution in anhydrous $CuCl_2$ in $PhCH_2OH$, NaOOCPr, and $HC(OMe)_3$ in the presence of $PdCl_2$ at 60 °C and a pressure of 3 atm resulted in the formation of the diester *trans*-$PhOOCCH_2CH=CHCH_2COOPh$.[36] This diester is hydrolysed to the unsaturated acid, which is then hydrogenated to adipic acid over a palladium catalyst.[36]

The selectivity of the conversion of butadiene into adipic acid diesters increases when mixtures of two bases of the pyridine and quinoline series, substituted by C_1-C_6 alkyls or alkenyls or by C_7-C_{10} alkylaryls or arylalkyls, are used as cocatalysts with $Co_2(CO)_8$. In the presence of the $Co_2(CO)_8$–pyridine–isoquinoline system butadiene interacts with CO and MeOH to form dimethyl adipate with a selectivity of 72.5% for a 100% conversion of the diene. When the $Co_2(CO)_8$–pyridine–γ-picoline catalytic system is used, the selectivity of the reaction with respect to the target product is 77.5%.[37]

A convenient technology has been proposed for the synthesis of adipic acid diesters via a two-stage scheme, where the first stage involves the preparation of the pent-3-enoic acid ester with utilisation of all the reaction side products and the regeneration of cobalt.[38–41] The catalyst is the $Co_2(CO)_8$, $HCo(CO)_4$ + pyridine (*N*-methylpyridine or *N*-methyldihydropyridine) system.

The synthesis of dimethyl butane-1,4-dicarboxylate from butadiene was improved by introducing the step involving the cooling to −5 °C of the products obtained in the first stage in the alcoholic phase (MeOH). This results in the formation of two phases: the reaction product (methyl pent-4-enoate) collects in the upper phase, while the lower, aqueous alcoholic phase contains up to about 98% of the cobalt catalyst, which is used in the second carbonylation stage.[41]



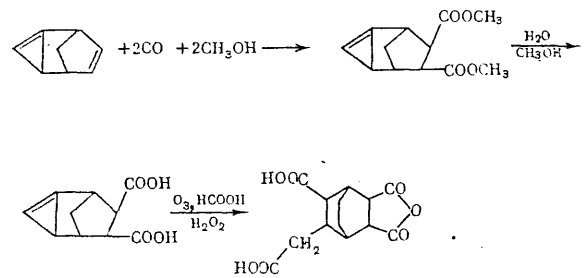
It has been shown[42] that the efficiency of the $Pd(OAc)_2-X_2$ (where X = phosphine) catalytic system in solution in amines [quinoline, lutidine, *NN*-diethylaniline, and 3,5-lutidine ($pK_a < 7$)] in the carbonylation of butadiene by carbon monoxide in an alcoholic phase (110 °C, 48 atm CO) with formation of the nona-3,8-dienoic acid ester increases with increasing basicity of the phosphines in the sequence $P(OPh)_3 < P(p\text{-}ClPh)_3 < PPh_3 < P(p\text{-}MePh)_3 < P(p\text{-}Bu)_3$. In the presence of tertiary amines with $pK_a > 7$ (*N*-methylmorpholine, *NN'*-dimethylpyridine, *NN'*-dimethylpiperazine, *N*-methylimidazole, etc.), the yield of the target products falls from 60–70 to 6–7%. The activity of the $Pd(OAc)_2$ $(PPh_3)_2$ catalytic system in amines with $pK_a < 7$ hardly changes after 32 cycles of its use, while the selectivity diminishes by 20%.

The structure and basicity of the ligands influence strongly the carbonylation of butadiene. For "strong" ligands ($pK_a < 6$), a ligand/Pd = 1–3 ratio is desirable, while for "weak" ligands ($pK_a < 6$) the ratio should be 4–100. Methyl nona-3,8-dienoate can be obtained in 60% yield from butadiene, CO, and methanol in the presence of $Pd(OAc)_2$, n-Bu_3P, and $(CNCC_2H_4)_3P$ at 90 °C and a CO pressure of 35 atm in the first stage for 2 h and at 110 °C in the second stage for 4 h.[43]

A continuous method has been developed for the synthesis of dialkyl adipates from butadiene, CO, and alcohols in the presence of the $Co_2(CO)_8$–pyridine–isoquinoline catalytic system with added hexane.[44] The first stage is carried out at 130 °C and a CO pressure of 300 atm, while the second stage is performed at 185 °C and 300 atm. The selectivity with respect to dimethyl adipate reaches 72.5%. In the absence of hexane, the selectivity is 66.4%.

Studies on the carbonylation of cyclic dienes (cyclo-octa-1,5-diene and cyclo-dodeca-1,5,9-triene), obtained from butadiene in the presence of nickel catalysts, are of great theoretical and practical interest.

A method has been proposed[45,46] for the preparation of azelaic acid from cyclo-octa-1,5-diene and of nonane-1,9-dicarboxylic acid from cyclododeca-1,5,9-triene by carbonylating dienes with formation of the corresponding unsaturated monocarboxylic acid esters and subsequent ring opening by refluxing in aqueous NaOH solutions.



Cyclo-octa-1,5-diene is carbonylated in the presence of Rh(OAc).$(CO)(PPh_3)_2$ or Rh_2O using a 2 : 1–2 mixture of CO and H_2 at 70–85 °C and a pressure of 55–80 atm,[45] while cyclododeca-1,5,9-triene is carbonylated at 50–60 °C and a pressure of 250 to 300 atm.[46]

Ethyl cyclo-oct-4-ene-1-carboxylate has been obtained in yields up to 85–90% by carbonylating cyclo-octa-1,5-diene in the presence of $PdCl_2(PPh_3)_2$ and $AlCl_3$ in ethanol at 105–108 °C and a pressure of 100 atm.[47]

Cyclic di-, tri-, and tetra-carboxylic acids or their anhydrides, which are widely used in the industrial manufacture of plasticising agents, hardening agents for epoxy-resins, water-soluble polyester resins, and inks and dyes for printing and coatings, were obtained by carbonylating di- and tri-cyclopentadienes.[48–51]

The esters of dicyclopentadienedicarboxylic acids are obtained in high yields from dicyclopentadiene, CO, and alcohol in the presence of $Co_2(CO)_8$ and a pyridine base (pyridine, picoline, etc.). The process is carried out at a CO pressure of 20–40 atm in two stages: the first takes place at 100–120 °C and the second at 140–160 °C.[48] Dimethyldicyclopentenedicarboxylate is obtained by carboxylating dicyclopentadiene in the presence of $PdCl_2$, $CuCl_2$, and CH_3OH. It is then hydrolysed to the free acid, ozonised in formic acid, and oxidised to a tetracarboxylic acid and then further to the anhydride in accordance with the scheme[49]

The so called "tarry" carboxylic acids are obtained by carbonylating cyclopentadiene trimers and tetramers.[50] As in the carbonylation of dicyclopentadiene, which has the norbornadiene structure, in the presence of the $Co_2(CO)_8$ + pyridine catalytic system (50 atm CO, 80–140 °C) in methanol, methyl tricyclodecenecarboxylate and dimethyltricyclodecanedicarboxylate in porportions of 90 : 8 are obtained in an overall yield of ~80%.

The alkoxycarbonylation of butadiene is performed in isopropyl alcohol in the presence of $PdCl_2$ with added quaternary nitrogen-, phosphorus-, and arsenic-containing salts.[51] Extraction by saturated hydrocarbons to which the same quaternary salts have been added makes it possible to separate selectively methyl pent-3-enoate from the palladium catalyst present in the alcoholic layer. This ensures the stability of the catalytic system employed. The process takes place with a selectivity of 93.2%. The efficiency of the carbonylation of the cyclopentadiene trimer increases if some of the cyclopentadiene trimers or tetramers are hydrogenated in a preliminary step. The carbonylation of the partly hydrogenated cyclopentadiene trimer in the presence of NiI_2–H_2O (220 °C, 80 atm) yielded "tarry" carboxylic acids with a softening temperature of 42 °C.

In the carbonylation of buta-1,3-diene in the presence of $PdCl_2$ with addition of quaternary nitrogen-, phosphorus-, and arsenic-containing salts, 99% of the palladium passes to the isopropyl phase after the introduction into the reaction mixture of n-octane and Bu_4NCl. The specific activity of the catalytic system increases somewhat when it is reused. Analogous results have been obtained also in the carbonylation of butadiene in the presence of bis(π-allylpalladium dichloride) with the addition of the same salts and hydrogen halides.[52,53]

It has been suggested[54–56] that the products of the alkoxycarbonylation of dienes (including butadiene) in the presence of the $Co_2(CO)_8$–isoquinoline system be separated by distillation with subsequent refluxing of the separated product in benzene. The benzene layer is next treated with sulphuric acid and then with a Na_2CO_3 solution. The degree of extraction of cobalt is 99%.[52] Cobalt may be isolated from the reaction products also by treatment with air.[53]

3. Carbonylation of olefins

The interaction of olefins with CO and H_2O leads to the formation of unsaturated carboxylic acids having linear or branched structures. When water is replaced by alcohol, carboxylic acid esters are obtained. The structure of the acids formed depends primarily on the nature of the catalyst used and also on the conditions under which they are employed. In the presence of catalysts based on Group VIII metals, mainly mixtures of linear and branched α-methyl-substituted carboxylic acids are formed. When acid catalysts are used, the products are mainly branched αα-dialkyl-substituted carboxylic acids.

(a) Carbonylation of olefins in the presence of Group VIII metals and their complexes. When ethylene is carbonylated in the presence of metal complexes, propionic acid is formed.[58] The advantages of this method are its single-stage nature, high selectivity, and relative mild process conditions. Propionic acid is an important product used for the preparation of artificial fibres, the conservation of agricultural feed, and the manufacture of medicinal drugs and perfumes.

The synthesis of propionic acid by the carbonylation of ethylene has been achieved with a yield of 95% on the $Ni(OCOC_2H_5)_2$ catalyst at 285 °C and a pressure of 235 atm.[57] Nickel in the form of the carbonyl is extracted from the reaction mixture by treating it at 70–80 °C with an inert gas containing 3–10% of O_2. The acid obtained is used in the bread-baking industry.[58]

Effective catalysts based on mixtures of nickel and molybdenum or nickel and tungsten compounds have been proposed for the synthesis of propionic acid from C_2H_4, CO, and H_2O.[59] The reaction is carried out in the presence of iodine-containing promoting agents as well as amines or phosphines. Propionic acid has been obtained in 48.9% yield from ethylene (28 atm) and CO (28 atm) with added H_2 (3.5 atm) in the presence of $NiI_2.6H_2O$, $Mo(CO)_6$, and EtI at 175 °C in aqueous propionic acid. In the presence of NiI_2, $Mo(CO)_6$, and PPh_3, propionic acid is also formed in 56% yield from C_2H_4, CO, and H_2O.[60]

Together with heterogeneous palladium catalysts, homogeneous palladium systems are also effective in the carbonylation of C_2–C_4 olefins.[61–66] The $Pd(OAc)_2$, $Pd(OAc)_2(PPh_3)_2$, and Pd[poly-(2-vinylpyridine)]$_2Cl_2$ catalytic systems are active and selective in the carbonylation of ethylene (170 °C, 100 atm, C_2H_4/CO = 1). Propionic acid is formed in 65–70% yield.[61]

The reaction is carried out in acetic or propionic acid with the addition of Group I–III, VI, and VIII metals salts to the $Rh-Ru_3(CO)_{12}$ cluster and complexes based on it. The maximum yield of methyl esters of butyric acid is observed in the hexane–methanol–water mixture at 180 °C, an initial pressure of 28 atm, and a water concentration of 46.2 vol. %. The addition of $MoCl_6$ to the catalyst induces an increase in the activity of the system. It has been shown by UV spectroscopy that the change in activity is apparently associated with the formation of the $[Ru_3(CO)_{12-n}]Cl^{n-}$ anion stabilised by a M^{n+} metal ion.[62]

The carbonylation of olefins can occur in the presence of palladium catalysts obtained by the impregnation of zeolites or by ion exchange involving them.[61,63,64] High-silica zeolites, containing 0.5–1.0% of palladium, exhibit a high activity and selectivity in this reaction. Propionic acid has been obtained with a selectivity of 75–95% by carbonylating ethylene in aqueous acetic or propionic acid (140–190 °C, 20–80 atm). Partial hydration of ethylene results in the formation, together with propionic acid, of ethanol, from which ethyl acetate, ethyl propionate, and diethyl ketone are obtained with participation of ethylene. The optimum ethylene carbonylation conditions are created at a temperature of 170 °C and a pressure of 60 atm. Preliminary treatment of the Pd/NaM catalyst with air (350 °C, 5 h) and hydrogen (300 °C, 5 h) in succession increases the selectivity in the formation of propionic acid. The introduction of platinum instead of palladium into the zeolite increases sharply the degree of hydration of ethylene. Palladium-zeolite catalysts with a modulus $SiO_2/Al_2O_3 \geqslant 10$ are stable under the carbonylation conditions. In the presence of 1.2 wt. % of Pd/HSZ-1† (modulus = 47), propionic, butyric, and valeric acids have been obtained from CO and H_2O as well as C_2H_4, C_3H_6, and C_4H_8 respectively (170 °C, initial pressure 60 atm, 3 h). The degree of conversion then reached 98% and the overall selectivity in the formation of these three acids was 90–98%.[64]

The synthesis of cycloalkanecarboxylic acids from cyclo-olefins, CO, and H_2O is also of practical importance. These acids are used to synthesise medicinal drugs and preparations. Homogeneous palladium catalysts are active in the carbonylation of cyclopentene, cyclohexene, a 60 : 14 : 13 : 13 mixture of 1-methyl-, 3-methyl-, and 4-methyl-cyclopentenes and cyclohexene, as well as 1-methylcyclo-hexene, 4-methyl-cyclohexene, and 1-ethylcyclohexene with formation of the corresponding carboxylic acids.[65] The efficiency of the catalyst decreases in the sequence $Pd_3(CO)_3(PPh_3) > Pd(PPh_3)_2.(OAc)_2 > Pd(PPh_3)_2Cl_2 > Pd(OAc)_2 > PdCl_2$.

The carbonylation of cyclo-olefins in the presence of $Pd(PPh_3)_2Cl_2$ takes place most effectively in acetic acid. Mainly 2-methyl- and 3-methylcyclopentanecarboxylic acids are formed from a mixture of 1-, 3-, and 4-methylcyclopentenes. The formation of 1-methyl-cyclopentane-1-carboxylic acid is prevented by steric hindrance. A temperature of 150 °C and a CO pressure of 50–100 atm are optimal for the carbonylation of cyclo-olefins. Under these conditions, the yield of cyclic carboxylic acid is 80–90%.[65]

Acetals have been synthesised in high yields from olefins, CO, and H_2 in an alcoholic medium in the presence of cobalt carbonyl and added quaternary ammonium compounds. Thus the dimethyl acetal of tridecanal has been obtained with 90% selectivity and 10% conversion from dodec-1-ene and 1 : 1 mixture of CO and H_2 under pressure at 110 °C in methanol containing $Co_2(CO)_8$ and $PhCH_2M^+Me_3MeO^-$.[66]

The esters of branched carboxylic acids have been synthesised by carbonylating β-alkyl-α-olefins:[67] 2-ethylpent-1-ene, hex-1-ene, hept-1-ene, 2-butyloct-1-ene, 2-hexyldec-1-ene, 2-octyldec-1-ene, 2-hexyl-decyleicos-1-ene, or 3-propylhex-1-ene. The reactions were carried out at 180–200 °C and a pressure of CO with added H_2 of 50 to 250 atm in the presence of cobalt catalysts as well as nickel-containing compounds and pyridine bases as promoting agents. In the carbonylation of 2-ethyl-hex-1-ene in the presence of cobalt laurate and γ-picoline (185 °C, 180 atm) by carbon monoxide with added H_2 (3.5 atm) in methanol, the degree of conversion of the olefin was 90% and the selectivity with respect to methyl esters of nonanoic acids was 38%. The contents of the methyl esters of various acids in the mixture were 49.5% of the 4-methyloctanoate, 17% of the 6-methyloctanoate, and 18.5% of the 3-ethylheptanoate. The branched carboxylic acids obtained are widely used in the

†HSZ = high-silica zeolite.

synthesis of alcohols, amines, surfactants, emulsifying agents, plasticising agents, and components of synthesit lubricants.

A mixture of carboxylic acid esters has been obtained under analogous conditions from olefins, CO, and alcohols in the presence of the cobalt carbonyl–pyridine (alkylpyridine) catalytic system.[68] Their hydrogenation in the presence of a copper–chromium catalyst (250–350 atm, 180–220 °C) leads to the formation of alcohols which are intermediates in the synthesis of surfactants. Thus the carbonylation of a mixture of n-undecene, n-dodecene, and n-tridecene in methanol in the presence of cobalt carbonyl and γ-picoline yields a mixture of the methyl esters of C_{12}–C_{14} acids, which are hydrogenated to the corresponding C_{12}–C_{14} alcohols.[68]

The esters of linear saturated carboxylic acids are synthesised by carbonylating α-olefins and the esters of unsaturated carboxylic acids or the acids themselves are synthesised from dienes and acetylenes in the presence of palladium complexes $(R_3P)_2PdXR'$ (where R = alkyl, hydroxyalkyl, cycloalkyl, dialkylamine, thioalkyl, thioaryl, substituted or unsubstituted aryls, and piperidine or pyrrolidine groups and R′ = H, Cl, Br, C_1–C_5 alkyl, C_2–C_4 acyl, or arylalkyls up to C_{12}) and promoting agents—Ti, Tl, Ni, Fe, Cu, Mn, Cr, Pd, Zn, Co, or Sn chlorides. The interaction of hex-1-ene with CO (700 atm, 90 °C) in the presence of $PdCl_2(PPh_3)_2$ and $SnCl_2.2H_2O$ in ethanol results in the formation of C_7 acid esters consisting of 77% of the linear isomer.[69,70] The degree of conversion of hex-1-ene reaches 86%. C_7 acids, including 90% of oenanthic acid, are obtained in aqueous acetone (90 °C, 100 atm) from hex-1-ene in the presence of the $(PPh_3)_2PdCl_2.NH_2(CH_2)_2NH_2$ complex systems.[69,70]

Esters of linear carboxylic acids have been synthesised with a high selectivity under mild conditions in the presence of palladium complexes containing sterically hindered ligands.[71] Thus the esters of isopropanethiol with linear and α-methyl-substituted branched C_7 acids have been obtained in 78.8 and 7.1% yields respectively from hex-1-ene, CO, and alcohol in the presence of $Pd(OAc)_2$ and $(iso\text{-}Pr)_3P$ in solution in the $THF-(CH_3)_3CSH$ mixture (100 °C, 50 atm).

The isomeric composition of the esters formed in the methoxycarbonylation of hex-1-ene in the presence of $Co_2(CO)_8$ depends greatly on the nature of the medium, which also influences the rates of isomerisation and carbonylation of the olefin. For a methanol : hex-1-ene molar ratio of 10, the rates of isomerisation and carbonylation of hex-1-ene in pyridine are comparable (175–190 °C, 200–300 atm). In toluene, the rate of isomerisation of olefin is higher than the rate of its carbonylation, as a result of which esters of branched acids predominate in the products of the synthesis. The selectivity in the formation of the oenanthic acid ester increases with decrease in temperature and with increase in the CO pressure.[72]

Carboxylic acid esters are obtained[73,74] from α-olefins up to C_{12}–C_{13} in the presence of catalytic systems based on cobalt: $HCo(CO)_4$, $Co_2(CO)_8$, $Co_4(CO)_{12}$, or $Co(CO)_3A_3$, where A = Bu_3P, $(C_{10}H_{21})_3P$, $(PhCH_2)_3P$, pyridine, picoline, or an alkylpyridine. Phosphine, phosphine oxides, and phosphites having the general formula $RR'PHO$, RR^1POR^2, and $RR^1POC(OH)R^2R^3$, where R, R′, R^1, R^2, and R^3 are C_1–C_{20} alkyls, are also used as ligands. Thus a mixture of C_{13} aldehydes and carboxylic acids in proportions of 10 : 1 has been obtained from dec-1-ene in the presence of $Co_2(CO)_8$ and $(C_8H_{17})_2POH$ (150 °C, 70 atm, H_2/CO = 1) for an overall degree of conversion of the olefin of 97%.[74]

Olefins can be carbonylated in a tubular reactor at 180 °C and a pressure of 170 atm in the presence of cobalt naphthenate.[75] The olefin is fully converted into carboxylic acid esters. When a mixture of CO with 5–10% of H_2 was used, the methyl esters of C_{13} acids were obtained in 97% yield from dodec-1-ene. They included 74% of the linear acid ester and the degree of conversion of the olefin was 63%.

Nickel complexes with tertiary amines, promoted by iodine compounds, are also effective catalysts of the carbonylation of α-olefins.[76] Thus the carbonylation of hexadec-1-ene in the presence of the $NiI_2-Py-HI$ system in an aqueous medium (88 atm CO, 200 °C) results in the formation of a mixture of C_{17} acids (yield 94%) containing 31.0% of acids with a linear structure. The remaining acids (47.0, 13.0, and 9.0%) contain methyl, ethyl, and propyl groups in the α-position, relative to the carboxy-group. Mixtures of saturated and unsaturated carboxylic acids, which can be used as surfactants after hydrogenation, have been obtained from cracking olefins.

Carboxylic acid esters are also synthesised by carbonylating olefins in the presence of mixtures of nickel and molybdenum or nickel and tungsten compounds, a halogen promoting agent, and a phosphorus- or nitrogen-containing base.[77] Treatment of ethylene with carbon monoxide in a medium consisting of a mixture of methanol and ethyl propionate in the presence of the $NiI_2-Mo(CO)_6-EtI$ system and PPh_3 (150–200 °C, 10–100 atm CO) affords methyl propionate in a high yield.

The selective synthesis of carboxylic acids or their esters has been achieved by carbonylating olefins in the presence of copper compounds with palladium, rhodium, ruthenium, iridium, or cobalt compounds in protic hydrogen halide acids.[78] The interaction of dec-1-ene with CO and methanol in the presence of $PdCl_2$, $CuCl_2$, and HCl under mild conditions results in the selective formation of methyl undecanoate.

Olefins are carbonylated in alcohols or phenols also under mild conditions (70–120 °C, 1–40 atm CO) in the presence of palladium complexes, phosphines, and peroxide compounds (H_2O_2, peracids). The presence of peroxides facilitates the coordination of the substrates to the palladium complexes and also promotes the oxidation of phosphines.[79]

The selectivity of the propene carbonylation process and the activity of Ru–Fe carbonyl clusters increase after the addition of $CuCl_2$ to the catalytic system. The main reaction products are methyl butyrate and butyric acid.[80]

Not only acids and their esters but also ketones can be obtained from olefins and CO. Diethyl ketone was formed from a mixture of C_2H_4, CO, and H_2O in the presence of the catalyst formed as a result of the rapid thermal decomposition of $Co_2(CO)_8$ on a carbon carrier at 150 °C and atmospheric pressure.[81]

Ketones have also been synthesised by carbonylating higher olefins (C_3–C_{20}) in a mixture with ethylene in the presence of H_2 on rhodium or cobalt catalysts at 150–250 °C and a pressure of 150 to 350 atm in various solvents, especially butanol.[82] The molar ratio of the catalyst and the mixture of ethylene with a higher olefin must be between 100 and 10 000 and that of the alcohol and the olefin must be between 0.3 and 2.0. Thus the interaction of ethylene and propene with CO in butanol at a pressure of 120 atm leads to the formation of a mixture of the ketones $EtCOCHMe_2$, PrCOEt, $(MeCH)_2CO$, $PrCOCHMe_2$, and Pr_2CO.

Ketones are also obtained by the reaction of olefins with CO and H_2O in the presence of cobalt carbonyl compounds and phosphines. For example, the reaction of C_3H_6 with CO and H_2O in the presence of $Co_2(CO)_8$ and $Ph_2PCH_2PPh_2$ at 165 °C and a pressure of 100 atm led to the formation of a mixture of the ketones Pr_2CO, $(Me_2CH)_2CO$, n-$PrCOCHMe_2$, and $PrCHO + Me_2CHCHO$.[83]

Homogeneous palladium catalysts deposited on polymers are active in the carbonylation of α-olefins. Thus the catalyst in the presence of which ethyl hexanoate was formed from pent-1-ene, styrene, and CO (120 °C, 28 atm CO) with 94% selectivity for an olefin conversion of 26.3% has been obtained from a copolymer of styrene with 1% of divinylbenzene (after bromination and treatment with $LiPPh_2$ in THF) by its interaction with $(PhCN)_2PdCl_2$.[84]

Palladium–anion exchanger catalysts, containing 0.4–0.75% of palladium on the Soviet produced anion-exchange resins AN-221, AN-251, and AN-511, possess a high activity, selectivity, and stability in the carbonylation of hex-1-ene.[85,86] Such catalysts can be used repeatedly (up to 10 times), retaining 0.35–0.4% of Pd under these conditions. Catalysts with a higher palladium content are less stable. Under optimum conditions (170 °C, 100 atm CO), C_7 acids are formed in an overall yield of 75–95%, the selectivity in the formation of oenanthic acid amounting to 50–60%.[86]

When $SnCl_2.2H_2O$ is added to palladium–anion exchanger catalysts (0.4% Pd/AN-221, 0.75% Pd/AN-511, and 0.4% Pd/AN-251) (atomic ratio Sn/Pd = 5–30), the selectivity in the formation of oenanthic acid increases to 94.5% with a simultaneous decrease the degree of conversion of the olefin to 30–35%.[86]

It has been suggested that the bimetallic complexes of $SnCl_2$ with chromium, molybdenum, or tungsten carbonyls can be used as catalysts of the carbonylation of olefins with formation of carboxylic acid esters (molar ratio 1–1.5 : 1, temperature 150–200 °C, CO pressure 250–300 atm).[87] These catalysts are less toxic than the nickel catalysts.

The carbonylation of isobutene or isobutyl alcohol in the presence of the $Rh(PR_3)_2X_2$ system, where X = Cl, Br, I, or another univalent anion and R = alkyl, aryl, or cycloalkyl, results in the selective formation of isovaleric acid. Such a reaction occurs, for example, in the interaction of iso-C_4H_8 with CO and H_2O at 18 to 20 °C and atmospheric pressure in the presence of $RhCl_2.[P(C_6H_{11})_3]_2$.[88] Palladium complexes with aminophosphine and phosphine ligands have been proposed as catalysts for the synthesis of isobutyric acid from propene, CO, and H_2O.[89] The process takes place selectively at 75–150 °C and a pressure of 20–350 atm. Isobutyric acid is formed in 79.5% yield from C_3H_6, CO, and H_2O in the presence of $Pd(OAc)_2$ and $(Me_2N)_3P$ in acetic acid and 38% HCl (110 °C, 315 atm).

The carbonylation of propene with formation of isobutyric acid and small amounts of n-butyric acid as well as a certain amount of $(CH_3)_2CHCl$ has been achieved on the $Pd(OAc)_2-Ph_3As-HCl$ catalyst at 75–150 °C and a CO pressure of 20–50 atm.[90]

The addition of n-Pr_3N to $Co_4(CO)_{12}$ increases the activity of the system in the hydrosilylation of α-olefins by a factor of 70 compared with the activity of $Co_2(CO)_8$.[91]

Isobutyric acid esters are obtained by carbonylating C_3H_6 in the presence of $Pd(PPh_3)_4$, PPh_3, and CF_3SO_3H (105 °C, 138 atm) in alcohol.[92]

Carboxylic acids and their esters are formed from C_{10}–C_{20} olefins or their mixtures in the presence of the $Co_2(CO)_8$–pyridine (or alkylpyridine) catalyst in C_2–C_{20} carboxylic acid at a pressure of 200 atm and a temperature of 150–200 °C.[93,94] The carbonylation is carried out in two stages. Initially the reaction is performed at 220 °C and the yield is then about 90%. The second stage, in which the yield of acids from the olefins is 10–12%, is performed at 180–190 °C. The fraction of linear acids formed in the first and second stages is 70–75% and 40–70% respectively. Water is added continuously to the reaction zone in order to increase the selectivity in the formation of linear carboxylic acids. In the carbonylation of a mixture of olefins, the contents of α-olefins in the first and second stages were 90 and 10.8% respectively. The carboxylic acids obtained are used in the manufacture of plastics, lubricants, and surfactants.

The carbonylation of π-olefins has been investigated[95–98] in the presence of homogeneous palladium catalysts at a low pressure of CO or the synthesis gas. The carbonylation of hept-1-ene on the $PdCl_2(PPh_3)_2-SnCl_2$ catalytic system in dioxan (185 °C, 20 atm, CO/H_2 = 1) takes place quantitatively with a selectivity of 85% in the formation of octanoic acid.[95]

In the carbonylation of non-1-ene in the presence of the $PdCl_2.(PPh_3)_2-PPh_3$ system in aqueous acetone (volume ratio acetone : water = 1 : 27, molar ratio olefin : Pd = 117, 13 atm, 90 °C, 6 h), the selectivity in the formation of capric acid increases to 88% with increase in the PPh_3/Pd ratio to 15. In the absence of PPh_3, the selectivity remains unchanged as the pressure is raised from 3 to 24 atm. The carbonylation products are a mixture of capric and α-methylpelargonic acid as well as a small amount (~4%) of α-ethylcaprylic acid.

The selectivity in the formation of linear acid increases when the CO pressure is reduced to 3 atm for the molar ratio PPh_3/Pd = 4.5.[96] With increase in the water concentration in acetone, the overall yield of carboxylic acid diminishes and the carbonylation process ceases with the volume ratio acetone : water = 3.

The influence of CO pressure on the carbonylation of non-1-ene is different in solution in the acetone–methanol mixture in the presence of the same $PdCl_2(PPh_3)_2$ catalytic system. With increase in the CO pressure from 7 to 24 atm and also with increase in the PPh_3/Pd ratio, the yield of methyl caprate also rises.[97]

The selectivity in the formation of octanoic acid from hept-1-ene in the presence of $PdCl_2(PPh_3).PR_3$ (where R = aryl or alkyl) in dioxan increases with increasing basicity of the phosphine ligand.[98]

The methyl esters of C_{12}–C_{17} carboxylic acids are obtained by carbonylating C_{11}–C_{16} olefins in methanol in the presence of the $Co_2(CO)_8$–pyridine–isoquinoline catalytic system at 140 °C and a CO pressure of 250–300 atm.[99] Thus methyl dodecanoate has been obtained with a selectivity of 93% from undec-1-ene, CO, and CH_3OH (140 °C, 300 atm). Cobalt carbonyl compounds are removed from the reaction products by oxidising them with oxygen or air in the liquid phase at a pressure of 3 atm and a temperature of 50 °C.

Higher C_{10}–C_{20} carboxylic acids are obtained by carbonylating C_9–C_{19} olefins under the same conditions using the catalysts described by Katsnel'son and Bel'nik.[99] The processes are carried out in a solvent with vigorous stirring of the reaction mixture.[100]

The synthesis of cinnamic acid esters by the oxidative carbonylation of styrene has been described:[101–106]

The catalysts used are 2% Pd/C[101,102] as well as Pd, Pt, Rh, Ir, Ru, and Os compounds or their mixtures with Cu^{2+} and Fe^{2+}.[103,104] Tertiary amines or bases—alkali or alkaline earth metal salts of organic or inorganic acids—are also used as additives. Aluminium powder[105] and aliphatic polyamines—ethylenediamine, piperazine, etc.[106]—can be added to compounds of the platinum group metals.

Cinnamic acid esters, which are widely used in the manufacture of medicinal drugs and perfumes, plant protecting agents, and light-sensitive resins, are obtained from styrene at CO and O_2 partial pressures ⩽18 atm and ⩽7 atm respectively in alcohol at 120 to 170 °C.[105] The yield of the target products is between 26 and

82.4% for a degree of conversion of styrene from 35 to 75.8%. La, Nd, Ce, Eu, V, and Pr oxides and acetates are effective process cocatalysts. The Pd : Cu (or Pd : Fe) atomic ratios range from 1 : 10 to 1 : 30, while the Cu : Ln (or Fe : Mn) atomic ratios are between 1 : 0.1 and 1 : 50.[105]

The carbonylation of styrene in the presence of the complex $PdCl_2.(PPh_3)_2$ in dioxan results in the formation of α-phenylpropionic acid with a selectivity of 99% for a degree of conversion of the olefin amounting to 93%. The replacement of carbon monoxide by the synthesis gas does not alter the overall yield of carboxylic acids but it does induce an increase in the process selectivity in the direction of the formation of β-phenylpropionic acid.[107]

An improved method has been proposed for the carbonylation of α-olefins, which makes it possible to obtain carboxylic acids or their ester with an increased content of linear products at 80–120 °C.[108] For this purpose, one uses palladium–sulphonic acid catalysts with phosphines, containing added perfluorosulphonic acids (CF_3SO_3H, $C_2H_5SO_3H$, $C_4H_9SO_3H$, and $C_8H_{17}SO_3H$) and polymeric perfluorosulphonic acids having molecular weights in excess of 5000, as promoting agents. Thus the carbonylation of propene in methanol in the presence of $Pd(PPh_3)_4$, PPh_3, and the additive CF_3SO_3H (molar ratio Pd/CF_3SO_3H = 1/2, 105°, 138 atm, CO, 2 h) results in the formation of methyl esters of butyric acids in 53.4% yield. The selectivity in the formation of the n-butyric acid ester is 69.2%. An increase in the amount of the CF_3SO_3H additive increases the degree of conversion of propene into butyric acid esters to 92.5%.

α-Olefins or diolefins are hydrocarboxylated under mild conditions in the presence of $PdCl_2-CuCl_2$ and O_2 in alcohol to which gaseous HCl has been added.[109] Mainly esters of branched carboxylic acids are formed. Olefins with an inner double bond afford carboxylic acid esters branched at the carbon atom which is closer to the end of the carbon chain. Thus $CH_3O_2CCH(CH_3)(CH_2)_4CH(CH_3)CO_2CH_3$ is formed quantitatively from octa-1,7-diene. Cyclic olefins also readily enter into the carbonylation reaction .[109]

Catalytic systems based on $Co_2(CO)_8$ and alkylpyridines (with the exception of pyridines having an *ortho*-substituent) capable of carbonylating selectively olefins with an inner double bond (for example, dodecenes) to form linear carboxylic acids have been devised.[110,111] Under the reaction conditions (180 °C, ratio of promoting agent and catalyst 10 : 1, 180 atm CO), the initial olefins with an inner double bond isomerise to α-olefins, which are in fact carbonylated. The initial α-olefins are obtained by the dehydrochlorination of the chlorinated paraffins. The process can be carried out in the presence of paraffins (up to 75%) and carbon monoxide containing up to 10% of H_2. The cobalt catalyst is normally employed as the acetate, naphthenate, 2-ethylhexanoate, or stearate, which are converted into cobalt carbonyl, while the promoting agents are β- or γ-picolines, 3,4- or 3,5-lutidines, or ethylpyridines in an amount of 3–25 moles per mole of the cobalt compound. Thus the carbonylation of a mixture of dodecenes in the presence of cobalt naphthenate and γ-picoline (molar ratio 1 : 10) in methanol (180 °C, 180 atm CO, 2% H_2 in CO) leads to the formation of a mixture of methyl esters of tridecanoic acids in 60% yield and a selectivity with respect to the linear isomer of 74%. Cobalt carbonyl is removed from the reaction products by treatment with air at 40–60 °C, cobalt oxides being isolated and returned to the cycle. The process is carried out under continuous conditions.[111]

The selective hydromethoxycarbonylation of higher olefins takes place with a high molar ratio of alkylpyridines and the cobalt catalyst (10–100). Otherwise there is a sharp increase in the yield of branched carboxylic acid esters. The productivity of the catalytic systems described above is 300–500 g of the ester per litre of the reaction solution per hour. Calculations have demonstrated the economic efficiency of the given method of synthesis of esters and acids having a linear structure.[112]

In order to reduce the yield of high-boiling products, it has been suggested either to remove water from the initial reactants by azeotropic distillation[113] or to replace the large amount of alkylpyridines by high-boiling residues isolated after distilling off the reaction products.[114] It has been suggested that the selective methoxycarbonylation of α-olefins and alkylenenitriles be carried out in the presence of cobalt catalysts with added ruthenium compounds and tertiary nitrogen-containing bases.[115] Hex-1-ene is selectively converted into methyl oenanthate in methanol in the presence of $Co_2(CO)_8$, isoquinoline, and $Ru_3(CO)_{12}$.

Dialkyl ketones can be obtained from ethylene (or propene), CO, and H_2 in the presence of the $Pd(OAc)_2-PPh_3$ catalytic system under mild conditions (30–70 °C, 1 atm) in aqueous trifluoroacetic acid.[116] Butyric acid, butyraldehyde, paraffins, and CO_2 are formed in small amounts. The rate of reaction and the isomeric composition of dialkyl ketones depend on the concentration of water in the reaction mixture. For a water content less than 5 vol. %, a mixture of 2,4-dimethyl-3-pentanone, 2-methyl-3-hexanone, and 4-heptanone is formed in proportions of 1 : 2 : 1. At a water concentration of 25–30 vol. %, the above ratios change to 1 : 5 : 1. It has been suggested that the ketones are synthesised via the intermediate formation of the Pd–H hydride complexes, formed as a result of the heterolytic capture of hydrogen by the palladium complex.

A method has been proposed for the carbonylation of olefinic compounds under mild conditions in the presence of a cobalt catalyst and disubstituted phosphines RR′ – PH as promoting agents.[117] The catalytic system is separated from the reaction products (acids or esters) by distilling off the latter.

Pent-3-enoic acid esters, which are intermediates in the synthesis of adipic acid diesters, are synthesised from butadiene, CO, and alcohols in the presence of $Co_2(CO)_8$ promoted by pyridine, quinoline, isoquinoline, both unsubstituted and substituted C_1-C_6 alkyls or alkenyls, aryls, and C_7-C_{10} arylalkyls or alkylaryls.[118] The process is carried out in the presence of the polymerisation inhibitors Ph_2NH, (Ph)(Me)NH, *NN′*-tetraethyl-*p*-phenylenediamine, *NN′*-di-β-naphthyl-*p*-phenylenediamine, benzoquinone, anthraquinone, or chloramine. Thus methyl pent-3-enoate is formed with a selectivity of 98.5% from butadiene, CO, and methanol in the presence of $Co_2(CO)_8$, pyridine, and *NN′*-di-β-naphthyl-*p*-phenylenediamine (120 °C, 300 atm CO, 1.5 h). The degree of conversion of the diolefin reaches 99.5%.

In the presence of the $PdCl_2$ catalyst, the carbonylation of a disubstituted but-2-ene proceeds with formation of the diester of an unsaturated C_6 dicarboxylic acid:

$$RCH_2CH{=}CHCH_2R + CO \rightarrow RCOCH_2CH{=}CHCH_2COR\ ;$$
$$R = OAc,\ OMe,\ OH \text{ or } Cl.$$

The selectivity of the reaction increases in the presence of polar and non-basic solvents.[119]

Dicarboxylic acid esters are obtained by treating unsaturated C_5-C_{15} carboxylic acids with carbon monoxide in the presence of C_1-C_3 alcohols using as the catalyst cobalt carbonyl with added water (up to 50% of the alcohol) and alkanes to separate the reaction products from the catalyst. Thus the interaction of the methyl ester of tricyclo[5.2.1.$0^{2,6}$]dec-3(or 4)-ene-8(or 9)-carboxylic

acid with CO (100 atm, 160 °C) in the presence of $Co_2(CO)_8$ in aqueous methanol with added cyclohexane results in the formation of dimethyl ester of tricyclodecanedicarboxylic acid in 79.3% yield.[120]

Together with olefins, other unsaturated compounds enter into the carbonylation reaction. A series of processes involving the carbonylation of unsaturated alcohols with formation of lactones[121] in the presence of $PdCl_2$, CO, O_2, and concentrated HCl in dry THF at room temperature and atmospheric pressure have been described. For example, but-3-enol is converted in 60% yield into α-methyl-γ-butyrolactone, while 2-methylbut-3-en-1-ol is converted into a 2:1 mixture of *trans*- and *cis*-2,3-dimethyl-γ-lactones. Pent-4-en-1-ol is converted into α-methyl-δ-valerolactone in 75% yield. In the presence of $Co_2(CO)_8$, the corresponding lactones are formed from saturated alcohols in yields ranging from 3 to 51%. The process takes place under fairly severe conditions—at 240 °C and a CO pressure of 900 atm.

Succinic acid diesters have been obtained by carbonylating acrylic acid esters in the presence of cobalt-containing catalysts and pyridines. Thus the interaction of methyl acrylate with CO and methanol in the presence of $Co_2(CO)_8$–Py in toluene (130 °C, 120–130 atm CO) affords dimethyl succinate in 94.2% yield. Dibutyl and dicyclohexyl succinates are obtained analogously in 91.2 and 90.0% yields respectively.[122]

In the methoxycarbonylation of 3-(β-cyanoethoxy)propene (110–120 °C, 200 atm CO) in the presence of $Co_2(CO)_8$, the addition of pyridine and CH_3ONa does not affect the rate of reaction or lower it.[123] The selectivity in the formation of methyl 4-(β-cyanoethoxy)butyrate then increases from 52 to 60–70%, while the selectivity in the formation of methyl 3-(β-cyanoethoxy)-isobutyrate rises from 1.7 to 3.3%. The addition of $PdCl_2$ to $Co_2(CO)_8$ in the absence of pyridine increases the rate of reaction by a factor of 10, while in its presence the increase is by a factor of 15–17. The addition of $PdCl_2$ has a similar effect on the carbonylation of propene in the presence of pyridine (140–160 °C, 200 atm CO). The introduction of up to 7.5% of H_2 into carbon monoxide acts effectively on the carbonylation process. The addition of $PdCl_2$ to $Co_2(CO)_8$ also influences the carbonylation of acetonitrile [140 °C, 200 atm CO, $Co_2(CO)_8$–pyridine mixture in proportions of 1:2]: an increase in the degree of conversion of acetonitrile from 28 to 80% is observed with the simultaneous rise in the yields of methyl γ- β-, and α-cyanobutyrates from 18.0, 3.4, and 4.9% to 52.0, 8.8, and 17.0% respectively.[123]

The carbonylation of CN-containing olefinic hydrocarbons with formation of the esters of the corresponding carboxylic acids has been described.[124–128] The esters are used for the synthesis of aminoacids, which have found extensive application in industry, agriculture, medicine, and biology. Complexes based on cobalt, palladium, and ruthenium are effective catalysts. Thus the carbonylation of acetonitrile in the presence of cobalt or ruthenium carbonyls and polyamines [poly(vinylpyrrolidinone)] as ligands leads to the formation of methyl α-cyanopropionate in 55.4% yield.[124]

The cobalt catalysts are promoted by γ-picoline oxide[125] and also by the oxides of various substituted pyridines.[126] The substituents can be not only alkyl or hydroxyalkyl groups but also the $(CH_2)_nCN$, $(CH_2)_mOR$, $(CH_2)_fCOOH$, or $(CH_2)_pCOOR$ groups.[125] Not only pyridine oxides but also phosphine oxides, sulphide oxides (sulphoxides?), or sulphones are effective ligands.[126] Unsaturated compounds are carbonylated in nitriles or dinitriles. The carbonylation of acetonitrile (97.5 °C, 70 atm, CO/H_2 = 1) in the presence of $Co_2(CO)_8$ and γ-picoline oxide in adipodinitrile with added CH_3OH resulted in a degree of conversion of 84.4%, the mixture of products consisting of 97.5% of methyl γ-cyanopropionate.[127,128] The catalytic system is extracted from the reaction mixture with a fourfold excess of C_5–C_8 alkanes and is returned to the reaction cycle.

A method has been proposed for the selective synthesis of isobutyric acid by carbonylating propene in the presence of a catalytic system containing palladium(II) compounds as well as arsenic compounds in the inorganic aicds HBr, HCl, H_2SO_4, HI, H_3PO_4, or HBF_4.[129] When propene is carbonylated in an autoclave with glass-lined walls (105 °C, 60 atm CO, 1.5 h) in the presence of $Pd(OAc)_2$, $AsPh_3$, and HCl (molar ratios 1:40:90) in aqueous isobutyric acid, isobutyric acid is formed with a selectivity of 74.9% for a 100% conversion of the olefin.

δ-Cyanovaleric acid esters are obtained in 75% yield by carbonylating 3-cyanobut-1-ene in alcohol and acetone (160 °C, 200 atm CO) in the presence of the $Co_2(CO)_8$–pyridine catalytic system.[130]

The carbonylation of acetonitrile in the presence of $Co_2(CO)_8$ with formation of methyl α-cyano-α-methylacetate and β-cyanopropionate (120–140 °C, 260–300 atm, CO/H_2 = 8–10) has been described.[131] Their hydrolysis affords respectively methylmalonic and succinic acids. The cyanoethylation of methyl α-cyano-α-methylacetate gives rise to $NCC(COOCH_3)(CH_3)CH_2CH_2CN$, which is hydrolysed to α-methylglutaric acid. The hydrogenation of the β-cyanopropionic acid ester results in the formation of α-pyrrolidinone in 95–98% yield. The reactions proceed in accordance with the following schemes:

$$NCCH{=}CH_2 + CO + CH_3OH \xrightarrow{Co_2(CO)_8,\ H_2} \begin{cases} \longrightarrow NCCH(CH_3)COOCH_3 \xrightarrow{H_2O} NH_3 + \\ \quad + HOOCCH(CH_3)COOH + CH_3OH + CO_2, \\ \quad \alpha\text{-methylmalonic acid} \\ \longrightarrow NCCH_2CH_2COOCH_3 \xrightarrow{H_2O} NH_3 + \\ \quad + HOOCCH_2CH_2COOH + CH_3OH; \\ \quad \text{succinic acid} \end{cases}$$

$$NCCH(CH_3)COOCH_3 + NCCH{=}CH_2 \rightarrow NCC(COOCH_3)(CH_3)CH_2CH_2CN \xrightarrow{H_2O} \rightarrow 2NH_3 + 2CO_2 + HOOCCH(CH_3)CH_2CH_2COOH;$$

α-methylglutaric acid

$$NCCH_2CH_2COOCH_3 \xrightarrow[150-300^\circ C\ 2-21\ atm]{H_2,\ NH_3} \underset{\text{α-pyrrolidinone}}{\overset{H_2C-CH_2}{\underset{CO}{H_2C\quad NH}}}$$

Methyl 5-cyanovalerate has been obtained with a selectivity of 92% for a conversion of the initial compound of 92% by carbonylating *cis*-pent-2-enylnitrile in the presence of $Co_2(CO)_8$ (180 °C, 310 atm) in a mixture of tetramethylene sulphone and methanol.[132]

α-Acyloxypropionic acids, whose hydrolysis affords lactic acid, are formed from the vinyl esters of carboxylic acids in the presence of $Pd(PR_3)_4$ in an excess of PR_3 (R is an aromatic group).[133] A characteristic feature of the process is a rigorously specified amount of water necessary for the formation of the product, its concentration in the mixture amounting to about 1.0 wt.%. The carbonylation of vinyl acetate (150 °C, 49 atm CO, H_2O concentration 0.9%) in the presence of $[(CH_2{=}CHCH_2)PdCl]_2$ and PPh_3 in butyric acid results in the formation of α-acetoxypropionic acid with a selectivity of 67% for 96% conversion of vinyl acetate.[133]

The carbonylation of alkenyl alkyl carbonates in the presence of palladium complexes leads to the formation of the alkyl esters of βγ-unsaturated carboxylic acids.[134] The reaction takes place in accordance with the equation

$$R^1R^2C{=}CR^3CR^4R^5OC(O)OR \xrightarrow[-CO_2]{CO} R^1R^2C{=}CR^3CR^4R^5COOR\ .$$

The catalysts employed are $Pd(PPh_3)_2(OAc)_2$ and $Pd(PPh_3)_2Cl_2$ in an inert solvent (alcohol, THF) or in its absence. The interaction of methyl 2-propenyl carbonate with carbon monoxide (100 °C, 70 atm CO) in the presence of $Pd(OAc)_2$ and PPh_3 affords a quantitative yield of methyl but-3-enoate.[134]

An analogous procedure is used to obtain methyl pent-3-enoate from but-2-enyl methyl carbonate, ethyl hept-3-enoate from ethyl hex-2-enyl carbonate and methyl 4,8-dimethylnona-3,7-dienoate from butadiene.[124]

Effective methods have been proposed for the carbonylation and regeneration of cobalt–pyridine catalysts used for the synthesis of polyol esters of carboxylic acids from C_3–C_{30} α-olefins (180–185 °C, 200 atm CO).[135–137]

The $Co_2(CO)_8$–isoquinoline complex in an aromatic hydrocarbon and alcohol is used successfully for the synthesis of methyl pent-3-enoate from butadiene.[138,139] Thus methyl pent-3-enoate has been obtained in a high yield from butadiene and carbon monoxide (containing 3% of H_2) in a mixture of benzene, isoquinoline, and methanol (123 °C, 300 atm CO) in the presence of $Co_2(CO)_8$. The catalyst is regenerated by the stepwise distillation of benzene, isoquinoline, methanol, and methyl pent-3-enoate from the reaction mixture. After treating the residue with aqueous solutions of inorganic acids (HCl, HNO_3, H_2SO_4—5% excess relative to cobalt), cobalt carbonate is precipitated with an aqueous Na_2CO_3 solution.

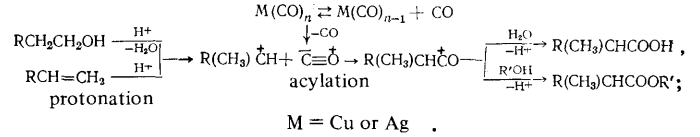
A method has been proposed for the synthesis of dicarboxylic acid esters, including adipic acid ester, by carbonylating unsaturated acid esters[140,141] under conditions analogous to those described in patents.[138,139] The carbonylation of methyl but-2-enoate in methanol and isoquinoline in the presence of $Co_2(CO)_8$ (160 °C, 200 atm, CO containing 0.7% of H_2) gives rise to a 77.9% yield of unsaturated acid esters consisting of 77% of $(CH_2)_3(COOMe)_2$, 18% of the $MeOCOCH_2CH(Me)COOMe$–$MeOCOCH(Et)COOMe$ mixture and 5% of $C_7H_{17}COOMe$. The esters of other dicarboxylic acids, mainly with a linear structure, are obtained similarly in a high yield.[141] Dimethyl adipate has been obtained in 81.8% yield from methyl pent-3-enoate, CO, and methanol, the content of the pentanoic acid ester in mixture not exceeding 3.8%.[142]

The carbonylation of methyl pent-3-enoate in aromatic hydrocarbons under conditions such that the ratio of the tertiary nitrogen-containing base and the cobalt compound is between 2 and 25 leads to the formation of dimethyl adipate in 96.3% yield.[143] Dimethyl adipate has been synthesised in 70.5% yield from methyl pent-3-enoate by the method involving carbonylation in the presence of CoS and tertiary amines (185 °C, 200 atm CO). CoS is then readily isolated and can be reused.[144]

A method has been proposed for the synthesis of succinic acid esters from C_2H_4, CO, and alcohol in the presence of platinum group metal complexes with added iron, copper, and cobalt salts and aminoacids such as glycine, alanine, valine, phenylalanine, etc.[145] For example, dimethyl succinate is formed from a 1 : 1 mixture of C_2H_4 and CO at an overall pressure of 80 atm ($PdCl_2$, glycine, 100 °C) in methanol. Double carbonylation of ethylene takes place during the reaction:[146]

$$CH_2{=}CH_2 + 2CO + 2CH_3OH \rightarrow \begin{matrix} CH_2COOCH_3 \\ | \\ CH_2COOCH_3 \end{matrix}.$$

(b) Carbonylation of olefins in the presence of acid catalysts. The use of organic or inorganic acids or acid complexes as catalysts makes it possible to obtain products branched in the α-position relative to the functional group by carbonylating unsaturated compounds (olefins, dienes).[1,3] The carbonylation is usually carried out at temperatures in the range 20–125 °C and CO pressures up to 200 atm. The catalysts are H_2SO_4, HF, H_3PO_4, $AlCl_3$, SbF_5, HSO_2Cl, FSO_2Cl, BF_3, $BF_3.n\,ROH$, $BF_3.n\,H_2O$, $BF_3.n\,RCOOH$ (n = 1 or 2), etc.[147–153]



C_{20}–C_{24} α-olefins or their mixtures are carbonylated in concentrated H_2SO_4 at 10–35 °C and a CO pressure of 35–140 atm.[147] Before being supplied to the reactor, the olefins are fused, but the temperature in the reactor is maintained below the melting point of the olefin, which makes it possible to increase the contact time between the olefin and the catalyst and to raise the process selectivity. Thus, when eicos-1-ene heated to 45 °C under a CO pressure of 94 atm is added gradually to vigorously stirred concentrated H_2SO_4, a C_{21} acid is formed in 82.1% yield.

For the molar ratios of H_2SO_4, ethyl formate, and 1-hexanol of 10 : 4 : 1, the overall yields of the ethyl esters and acids in the synthesis products are influenced by the temperature, reactant ratio, and the H_2SO_4 concentration. Mainly ethyl esters of 1-methylcyclopentanecarboxylic and cyclohexanecarboxylic acids are formed from cyclohexanol.[150] The overall yield of the esters and acids obtained in proportions of 2–3 : 1 was 65–75%.

The carbonylation of branched and linear olefins (2-methylbut-2-ene, 2-methyl-pent-2-ene, mixtures of di- and tri-isobutenes, and also hex-1-ene and hept-1-ene) in the presence of BF_3–H_2O and ethyl formate at atmospheric pressure and a temperature of 20–90 °C results in the formation of the ethyl esters of the corresponding acids and directly the acids themselves in an overall yield ranging from 50 to 90%. At the optimum carbonylation temperature of 50 °C, the maximum yields of the ethyl esters of the acids and of the acids themselves obtained from hex-1-ene and hept-1-ene were 51 and 50% respectively.[151]

The corresponding carboxylic acids have been obtained in yields of 45–85% by the carbonylation of C_6–C_{12} iso- and n-olefins with carbon monoxide at 30 °C and atmospheric pressure in the presence of the 97% H_2SO_4 + Ag_2O (or Cu_2O) and $(BF_3.H_2O)(BF_3.H_3PO_4)$ + Cu_2O catalytic systems.[152]

The mechanism of the carbonylation of olefins and alcohols in the presence of the above catalysts has been investigated.[153] The activity of the catalysts increases with increase in their Hammett acidity (H_0): $BF_3.H_2O$ (−11.40) > H_2SO_4 (−10.65) > $(BF_3.H_2O)$. $(BF_3.H_3PO_4)$ (−10.00) > H_3PO_4 (−5.18). The reactivity of olefins with the normal structure is lower than that of branched olefins and the selectivity in the formation of carboxylic acids or their esters is higher for linear α-olefins. The reactivity of alcohols increases on passing from primary to secondary and then to tertiary alcohols. The yields of carboxylic acids are maximum at the optimum rates of the stages involving the protonation of the substrates and the addition of CO to the carbonium ions formed (the acylation stage). This conclusion is valid also when the carbonylation of olefins and alcohols is carried out in the presence of the H_2SO_4, $BF_3.H_2O$, and $(BF_3.H_2O)(BF_3.H_3PO_4)$ catalysts with added Cu_2O and Ag_2O. The carbonylation proceeds in accordance with the scheme:

The protonation of the substrates is ensured by the presence of the acid component and CO is activated by the intermediate formation of Cu(I) or Ag(I) carbonyls during the process. When

ethyl formate is used as the carbonylating agent, carbon monoxide is activated in the stage involving the decomposition of ethyl formate with formation of CO *in situ*.

The carbonylation of propene in the presence of $BF_3.CH_3OH$ (50 °C, 60 atm) results in the formation of mainly methyl isobutyrate with a small amount of methyl dimethylvalerate and methyl neodecanoate.[154] The complex $BF_3.CH_3OH$ with added Cu_2O or Ag_2O is an effective catalyst of this process. When diisobutene is carbonylated by carbon monoxide under pressure, the esters of C_6–C_{11} acids are formed in high yields.[155] Methyl isobutyrate is formed analogously from C_3H_6, CO, and H_2O in the presence of $BF_3.(CH_3)_2CHCOOCH_3$, $BF_3.CH_3OH$, and $BF_3.H_2O$.[156]

One of the most important target products of the carbonylation of olefins in the presence of acid catalysts is isobutyric acid or its esters—the intermediates in the synthesis of acrylic acid or methyl methacrylate.

When a mixture of methanol, methyl isobutyrate, and Cu_2O is used in molar proportions of 31.2 : 97.5 : 1 in the presence of BF_3 (50 °C, 49 atm CO) with subsequent supply of propene into the reactor, methyl isobutyrate is obtained in 99% yield.[157]

Propene is carbonylated in the presence of a 15-fold excess of HF (30 °C, 340 atm CO, 30 min), after which HF is distilled off and directed to the carbonylation stage.[158,159] The isobutyric acid fluoride obtained is hydrolysed (with an acid fluoride : water molar ratio of 1 : 0.2–0.4) at −40 °C in the presence of NaF as the HF acceptor. $NaHF_2$ is separated by centrifugation from the resulting equilibrium mixture of the isobutyric acid anhydride, its fluoride, and $NaHF_2$. The acid fluoride is returned to the hydrolysis stage and $NaHF_2$ is decomposed into NaF and HF, which are directed respectively to the hydrolysis and carbonylation stages. The selectivity in the formation of isobutyric acid anhydride is close to 100%.

Isobutyric acid fluoride is obtained by carbonylating isopropyl chloride in the presence of an excess of HF (20–80 °C, 50 atm CO), after which the product is hydrolysed with water to form isobutyric acid:[160]

$$(CH_3)_2CHCl + CO \rightarrow (CH_3)_2CHCOF \xrightarrow{H_2O} (CH_3)_2CHCOOH + HF.$$

A continuous method has been developed for the synthesis of acid fluorides, in particular isobutyryl fluoride, from C_3H_6, CO, and HF via their effective mixing in a turbulent mixer (30–80 °C, 196 atm CO).[161] The degree of conversion of C_3H_6 reaches 100% and the selectivity in the formation of isobutyryl fluoride is about 90%.

Isobutyric acid can be obtained in 98% yield by the isomerisation of isopropyl formate in the presence of HF:[162]

$$HCOOCH(CH_3)_2 \xrightarrow{CO,\ HF} (CH_3)_2CHCOOH.$$

A method has been proposed for the synthesis of isobutyric acid and its esters by carbonylating propene in an autoclave with a high-speed stirrer in the presence of not more than 2 mol % of alcohol or water in the reaction mixture.[163] The molar ratios H_2O (alcohol) : C_3H_6 : HF : CO = 0.96 : 1 : 10 : 1.5. The process is carried out under continuous conditions at 100–140 °C and a pressure of 80–140 atm. It takes place in the liquid phase and the reaction products (isobutyric acid fluoride and isopropyl isobutyrate) are readily isolated and the mixture is expanded to give a pressure of 1–4 atm. HF, isopropyl fluoride, isopropyl alcohol, and diisopropyl ether are then transferred to the gas phase and are returned to the process. Isobutyric acid fluoride and isopropyl isobutyrate are hydrolysed, HF and isopropyl alcohol are returned to the cycle, and isobutyric acid is purified further by double fractionation. The overall yield of the acid exceeds 90% and the selectivity in its formation is 93%.

An improved version of this process has also been proposed.[164] The reaction is carried out at 70 °C and 120 atm CO, the residence time of propene in the reactor amounting to 5 min. For a molar ratio C_3H_6 : HF = 1 : 20, the yield and selectivity in the formation of isobutyric acid fluoride reach respectively 95 and 96.5%. A characteristic feature of this process is that the carbonylation of C_3H_6 or iso-BrF are carried out in a polyhalogenoalkane (it is best to use 1,1,2,2-tetrachloroethane) with formation of a two-phase system with HF. A method has been proposed for the preparation of isobutyric acid fluoride by passing a mixture of HF, CO, and C_3H_6 (in molar proportions of 40 : 13 : 1) through a tubular reactor (35.7 atm, 20 °C) with a contact time of 1–2 min.[165–167] The yield of isobutyric acid fluoride is then 90%.

Carboxylic acids can be obtained by carbonylating olefins in the presence of the $HF : BF_3 : H_2O$ = 5.1 : 1 : 1.1 catalytic system at 60 °C and a pressure of 7.5 atm.[168]

Contact between the reactants is achieved by means of a stirrer rotating at 1000 rev min^{-1}. This method is suitable for the carbonylation of alcohols. Under the conditions indicated, trimethylacetic acid is formed in 88% yield from isobutyl alcohol after 45 min.

The reaction of C_3H_6, CO_2, and CH_3OH in the presence of $RuCl_2(PPh_3)_2$ (CO_2 pressure 45 atm at 20 °C, reaction temperature 215 °C, 20 h) in acetone results in the formation of a 1 : 1 mixture of methyl isobutyrate and methyl butyrate in 32% yield:[169]

$$C_3H_6 + CO_2 + CH_3OH \rightarrow \begin{cases} (CH_3)_2CHCOOCH_3, \\ CH_3CH_2CH_2COOCH_3. \end{cases}$$

Aromatic hydrocarbons have been carbonylated on the HF–BF_3 catalyst with formation of aldehydes.[170] Ethylbenzene, cumene, xylene, mesitylene, diisopropylbenzene, biphenyl, naphthalene, bibenzyl, isobutylbenzene, tetralin, and toluene can be carbonylated by this method. Under mild conditions (20 °C, 10–15 atm), *p*-toluic aldehyde was obtained selectively in 98% yield from toluene and CO in the presence of the HF–BF_3 catalytic system in apparatus made of copper alloys. A non-specific method of carrying out the process has been developed.

Carboxylic acids branched in the αα-positions, obtained by the method described above, have found extensive applications in the preparation of synthetic lubricants distinguished by high chemical and thermal stabilities,[171] as detergents, corrosion inhibitors,[172] insecticides, perfumes, preservatives, and antifungal preparations.[173]

III. Carbonylation of alcohols

Many valuable chemical products, which have found extensive applications in industry, agriculture, and medicine, can be obtained by carbonylating alcohols. A wide variety of compounds have been obtained from the simplest alcohol (methanol) depending on the process conditions and the catalyst used:

$$CH_3OH \rightarrow \begin{cases} \xrightarrow{CO,H_2} CH_3CHO,\ CH_3CH_2OH,\ HO(CH_2)_nCH_3,\ HO(CH_2)_nOH, \\ \xrightarrow{CO} CH_3COOH,\ CH_3COOCH_3,\ (CH_3)_2O, \\ \xrightarrow{CO} HCOOCH_3 \rightarrow HCOOH. \end{cases}$$

The likely usefulness of the processes involving the carbonylation of alcohols is confirmed by the widespread industrial use of the method of synthesis of acetic acids from methanol in the presence of a rhodium catalyst developed by the Monsanto Company:[1,3]

$$CH_3OH + CO \rightarrow CH_3COOH .$$

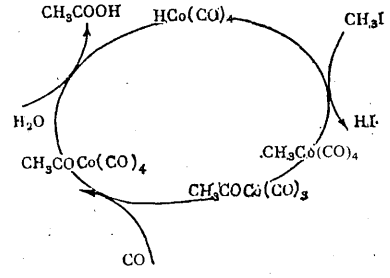
In the future, it will be possible to synthesise glycols (ethylene glycol) from CO and H_2, to prepare ethanol by introducing an extra CH_2 group into methanol, etc. The number of publications concerned with the study of the reactions involving the conversion of alcohols, acids, esters, and olefins into higher homologues by the interaction of the latter with CO and H_2 has been increasing. The prospects for the employment of alcohol carbonylation reactions can be inferred from the relevant publications.[174-180]

The available information about the carbonylation of methanol and some of its homologues and derivatives under the conditions of homogeneous and heterogeneous catalysis will be examine below.

In recent year, much attention has been devoted not only to the creation of catalysts but also to the elucidation of the mechanisms of the alcohol carbonylation reactions.[179,180] The most effective catalysts of the carbonylation of methanol with formation of acetic acid are rhodium complexes. Cobalt compounds are less selective and less active. Rhodium complexes with monodentate ligands are less active than those with bidentate ligands. The bidentate complexes exhibit a reduced activity in the initial stage of the process. The identical rates of carbonylation attained when $RhCl_3$ and phosphine complexes of Rh^+ are used indicate the similarity of the nature of the catalytically active species formed from the above compounds during the process.[180]

It has been suggested that rhodium complexes are more selective than catalytic systems based on iridium.[181] Selectivity in the formation of acetic acid on carbonylation of methanol in the presence of rhodium systems approaches 99%. When iridium catalysts are used, the selectivity does not exceed 90%, which is associated with the occurrence of side reactions involving the formation of methane:

$$CH_3OH + CO \rightarrow CH_4 + CO_2 ,$$
$$CH_3OH + H_2 \rightarrow CH_4 + H_2O .$$



Their contribution increases at high carbon monoxide pressures and for a low water content in the system. An increase in the I^- and H_2O concentrations promotes the water gas conversion reaction:

$$CO + H_2O \rightarrow CO_2 + H_2 .$$

In the presence of a rhodium catalyst, the degree of conversion of CO via this reaction hardly exceeds 10%.

When rhodium and iridium catalysts are used, the CH_3I promoting agent plays an especially important role. The rate of carbonylation of methanol is proportional to the CH_3I and rhodium concentrations and is independent of the concentrations of methanol, carbon monoxide, and acetic acid. For the iridium complexes, the rate of reaction is described by a more complex relation and is determined to a large extent by the composition of the catalytic system and the process conditions. The rate-limiting stage of the process in the presence of the rhodium and iridium catalysts is the oxidative addition of CH_3I to the catalytically active species $[Rh(CO)_2I_2]^-$ and $[Ir(CO)_2I_2]^-$ respectively.[181]

Cobalt catalysts are less selective in the carbonylation of methanol because the cobalt carbonyl hydride $HCo(CO)_4$, responsible for catalysis, catalyses in addition also side reactions: the conversion of methanol into ethanol by the addition of the CH_2 group, the water gas reaction, esterification, etc., which reduces sharply the process selectivity.[181] The catalytic cycle in the methanol carbonylation process in the presence of a cobalt catalyst is presented schematically below:[182]

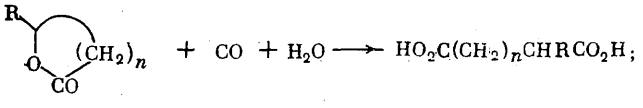
In the carbonylation reactions of alcohols and esters, Ru, Ni, Pd, Pt, Fe, and Cu compounds also exhibit activity.[182]

The use of CH_3Br instead of CH_3I as the agent promoting the rhodium catalyst reduces the rate of carbonylation of methanol with formation of acetic acids by a factor of ~ 10.[181]

A coupled process involving the carbonylation of mixtures of methanol and ethylene with formation of a mixture of acetic and propionic acids has been patented.[183] The process is carried out in the presence of an industrial catalytic system which inlcudes $RhCl_3$, HI, and CH_3I. The reaction takes place at 185 °C and a CO pressure of 2 atm. The rate of formation of acetic acid is described by the equation

$$r = 5 \cdot 10^{10} e^{-7630/T} [Rh] [I^-] \text{ mol AcOH litre}^{-1} \text{ h}^{-1},$$

where [RH] and $[I^-]$ are the concentrations of rhodium and I^- in solution.



Cobalt and iron clusters having the general formulae $M[FeCo_3.(CO)_{12}]$ or $M[CoFe_3(CO)_{13}]$, where M is a hydrogen atom, an alkali or alkaline earth metal cation, the residue of a nitrogen-containing C_3–C_9 heterocyclic compound, $[(Ph_3P)_2N]^+$, or the cation of a quaternary nitrogen-, phosphorus-, or arsenic-containing base, are used as catalysts of the carbonylation of methanol with formation of methyl acetate.[184] The process takes place in the presence of an iodine-containing promoting agent. The catalyst can also be formed *in situ* from cobalt and iron carbonyls in the presence of M^+. The method makes it possible to obtain acetaldehyde with a high degree of selectivity for the ratio $H_2:CO = 1:1$ at 140–200 °C. For the molar ratio $H_2:CO = 1.5$–3 and a temperature of 200–220 °C, ethanol is formed. The carbonylation of methanol in the presence of $Bu_4N.[FeCo_3(CO)_{12}]$ and CH_3I [molar ratio MeI/(Fe + CO) = 4], at a pressure of 270 atm of the 1:1 CO + H_2 mixture, and at a temperature of 180 °C leads to the formation of acetaldehyde and the aldehyde acetal in 62 and 18% yields respectively.[184]

The complexes $R_2Mg[Fe(CO)_{12}C_5H_5]_2$ and $R_4Mg[Co(CO)_3PBu_3]_2$ are effective carbonylation and hydroformylation catalysts, in the presence of which methanol is converted into methyl acetate in 37% yield (120 °C, 56 atm CO).[185]

In order to lower the alkyl halide concentration (to 0.3 M) and thus weaken the corrosive properties of the medium, it is recommended that the carbonylation of methanol to form acetic acid or methyl acetate be carried out with the addition of phosphonium salts of the type $(CH_3)(C_6H_5)_3P^+I^-$ to the system.[186]

Acetic acid is obtained in 88.2% yield by carbonylating methanol with carbon monoxide at a pressure of 10 atm and a temperature of 200 °C in the presence of the catalyst prepared from five parts (by weight) of graphite, one part of $RhCl_3$, and one part of $IrCl_3$.[187] Acetic acid is also formed from the 1 : 1 CO + H_2 mixture in the presence of cobalt and ruthenium carbonyls and amines, phosphines, arsines, stibines, bismuthines, and halogen-containing compounds used as promoting agents. Thus the interaction of CO with H_2 in an autoclave (280 atm, 220 °C) in the presence of $Ru_3(CO)_{12}$, $Co_2(CO)_8$, PPh_3, and $[CH_3(CH_2)_6]Ph_3P^+Br^-$ in an acid medium leads to the formation of a mixture of acetic acid, methyl acetate, ethyl acetate, and C_1–C_3 alcohols (74.5, 1.5, 15.5, and 8.5 wt.% respectively). In aprotic dipolar solvents (ethers, esters, polyesters, sulphones, or amides), mainly acetic acid with an admixture of propionic acid is formed from CO and H_2 in the presence of a soluble hafnium compound.[189]

Dicarboxylic acids are readily formed on carbonylation of lactones under mild conditions (40 atm CO, 180 °C):[190,191]

$n = 2$–4.

The carbonylation of γ-valerolactone in the presence of $RhCl_3.3H_2O$, CH_3I, and water in caproic acid afforded a mixture of 2-methylglutaric and adipic acids in 65.2 and 20.3% yields respectively.[190]

Dicarboxylic acids are formed with a high selectivity on carbonylation of glycols whose OH groups are not at neighbouring carbon atoms. Thus the interaction of butane-1,4-diol in acetic acid in the presence of $[Rh(PPh_3)(CO)Cl]_2$ and CH_3I (175 °C, 49 atm CO) results in the formation of adipic acid in 74.0% yield. An aromatic glycol (recorcinol) and *p*-phenylene diiodide gave rise to isphthalic and terephthalic acids in an overall yield of 15.0%.[192]

The Rh–Fe, Rh–Mn, Rh–Mn–Cl, Rh–Ru, and Rh–Cr bimetallic catalysts exhibit an appreciable activity in the synthesis of acetic acid from CO and H_2.[193] Acetic acid is also formed selectively in the carbonylation of methanol in the presence of the Rh–RM(Z).$[(O)_nR^1].(O)_mR^2$ complexes (where M = P, As, or Sb, Z = O, S, or Se, and R = H or alkyl; for $n = m = 0.1$, we have $R^1 = R^2 = OH$ and, when $n = m = 0$, MR^1R^2 represents a heterocycle), $RhCl_3$, CH_3I, and Ph_3PO.[194] The carbonylation of a mixture of methyl acetate and methanol, whose composition ranges from 1 : 1 to 3 : 1, with a mixture of CO and H_2 (from 1 to 40% H_2) in the liquid phase in the presence of rhodium compounds, alkyl iodides, phosphines, and also chromium or zirconium compounds results in the formation of acetic anhydride and acetic acid.[195] Under pressure (31.5 atm of CO, 1.5 atm of H_2, 180 °C) and in the presence of $RhCl_3.3H_2O$, CH_3I, $Bu_3P^+(Me).I^-$, and $Cr(CO)_6$, the above reaction takes place significantly less effectively.

Carboxylic acids having the general formula RCOOH (where R = C_1–C_{17} alkyl, Ph, or $PhCH_2$) are obtained by carbonylating the corresponding alcohols in the presence of a homogeneous catalyst containing molybdenum (or tungsten) compounds of an alkali metal as well as a promoting agent—inorganic or organic Br^- or I^- compounds.[196] The process can be carried out also under heterogeneous conditions on catalysts containing the above components (up to 10 wt.%) deposited on Al_2O_3, SiO_2, ZrO_2, clays, etc. In the carbonylation of methanol in acetic acid in the presence of NiI_2, $Mo(CO)_6$, LiI, and CH_3I (200 °C, 4.9 atm H_2, 37 atm CO), acetic acid is formed with a selectivity of 100%. The rate of its formation is 12.3 mol litre^{-1} h^{-1}.

Acetic and pripionic acids are formed jointly on γ-irradiation of methane mixed with CO and CO_2.[197,198] A mixture of acetic acid and methyl acetate is formed from methanol and a mixture of CO and H_2 (160 °C, 250 atm CO) in the presence of $Co_2(CO)_8$, NaI, and EtI.[199]

Ruthenium promoted with halogen-containing compounds is an effective catalyst of the carbonylation of alcohols. Thus the carbonylation of methanol in the presence of Ru/C and CH_3I affords a mixture of acetic acid and methyl acetate in 92.2 and 4.6% yields respectively.[200] The same products are obtained by carbonylating methanol with a mixture of CO and H_2 (80–98% CO) in the presence of a cobalt catalyst, a compound capable of generating I^-, and covalently bound iodine (1–30% of the amount of I^-).[201] Ammonium salts, alkali and alkaline earth metal salts, and phosphonium compounds are used as sources of I^-. Other promoting agents are X_2, HX, RX (where X = Cl, Br, or I), $CoBr_2$, CoI_2, CH_3I, I_2, HI, or $Co_2(CO)_8$. Thus a mixture of 10.5% of acetic acid and 80.5% of methyl acetate is formed in an overall yield of 91% from methanol and a mixture of CO and H_2 (95 and 5 atm respectively) at a pressure of 140 atm and a temperature of 160 °C in the presence of $Co_2(CO)_8$, NaI, and EtI.

Molybdenum deposited in an amount of 2.5 wt.% on activated carbon (gas carbon black) catalyses the carbonylation of methanol and dimethyl ether with formation of methyl acetate and the carbonylation of methyl acetate to form acetic anhydride.[101] Catalysts containing nickel on carbon, SiO_2, and Al_2O_3 as well as molybdenum on SiO_2 and Al_2O_3 are less active. Acetic anhydride is formed in 15% yield and a selectivity of 83% in the carbonylation of methyl acetate (250 °C, 46 atm CO) in the presence of 2.5 wt.% Mo/C and CH_3I.

Catalysts containing between 0.001 and 15 parts by weight of B_2O_3, P_2O_5 or $x B_2O_3.y P_2O_5$ (where $x = 0.05$–0.95 and $y = 0.05$ to 0.95), deposited on activated carbon, exhibit activity in the carbonylation of methanol with formation of methyl acetate.[203]

The study of the kinetics of the carbonylation of methanol[204] in acetic acid showed that the reaction is of first order with respect to methanol. In an aqueous medium, the order with respect to methanol is 0.75. The reaction mechanism involves the formation of CH_3I on interaction of CH_3OH with HI and its subsequent oxidative addition to the complex $[Rh(CO)_2I_2]^-$. This results in the appearance of the complex $[CH_3Rh(CO)_2I_3]^-$, subsequently converted into $[(CH_3CO)Rh(CO)_2I_3]^-$, which decomposes into CH_3COI and $[Rh(CO)_2I_2]^-$. The effectiveness of the solvents is determined by the solubility of CH_3I in them. Thus, an increase in the concentration of methanol in water increases the solubility of CH_3I, which leads to an increase in the rate of carbonylation. In acetic acid, an increase in the concentration of methanol does not affect the solubility of CH_3I.[204]

Acetaldehyde is formed in the vapour-phase carbonylation of methanol in the presence of CH_3I and the Co/C catalyst promoted with palladium salts and alkali metals (after their reduction). The process is carried out in a flow apparatus (180–240 °C, 10–65 atm, $CO/H_2 = 1$). The promoting effect of palladium salts and alkali metals is associated with the intensification of the hydrogenating function of the cobalt catalysts.[205]

Modification of the nickel catalysts with palladium or copper chlorides or nitrates increases the effectiveness of the synthesis of acetic acid and methyl acetate via the vapour-phase carbonylation of methanol. Cl_2, Br_2, or I_2 or their volatile compounds are used as

promoting agents in an amount of 0.05–0.4 of a mole per mole of methanol. The vapour-phase carbonylation of methanol (300 °C, 1 atm, a mixture of CO and CH_3I in molar proportions of 30.1 : 8.6 : 1) in the presence of a catalyst containing 8.7% Ni and 0.03% Pd on activated carbon produces a mixture of acetic acid and methyl acetate in an overall yield of 80%. The degree of conversion of methanol is 65% and the productivity reaches 0.3 kg (AcOH + AcOMe) (litre cat.)$^{-1}$ h^{-1}. The catalysts retain their stability for two weeks of continuous operation.[206] Methanol can be converted into methyl acetate on a palladium catalyst (0.1–1% Pd) deposited on a dealuminated and decationated mordenite in a flow system. The degree of conversion of methanol at 250 °C, a pressure of 1 atm, and a space velocity of 0.4 h^{-1} in the presence of added 10% CH_3I in methanol is 49.1%.[207]

Methanol can be carbonylated to acetic acid and methyl acetate in the presence of effective homogeneous systems containing Group VIII metal compounds. The compounds RX (where R = H or C_1–C_3 alkyls and X = Cl, Br, or I) as well as Group IA and IIA metals, transition metal iodides (or carboxylates), and nitrogen-containing bases are used as promoting agents. Such a reaction takes place, for example, in an autoclave in the presence of $Pd(OAc)_2$, 2,2′-bipyridyl, MeOAc, H_2O, MeI, and NaI (178 °C, 1110 atm), a mixture of acetic acid and methyl acetate being formed at a rate of 0.14 kg litre^{-1} h^{-1}.[208]

Heterogeneous rhodium catalysts on carriers, including faujasites, exhibit a higher activity when they are obtained from $RhCl_3$ than the catalysts obtained from the complex $[Rh(NH_3)_5Cl]Cl_2$. In more active catalysts, the metal is distributed on the surface of the carrier more uniformly and the rhodium particle size is about 9 Å.[209]

Among the catalysts based on Ni, Co, and Fe which have been investigated,[210] the highest activity in the carbonylation of methanol was shown by nickel catalysts on activated carbon. The use of other carriers (γ-Al_2O_3, SiO_2, carbon blacks, and graphite) yielded worse results. In the presence of the iron and cobalt catalysts on activated carbon, the main carbonylation product was dimethyl ether and the yield of acetic acid and methyl acetate did not exceed 11%. At 300 °C, a pressure of 11 atm, and for the molar ratios CO : MeOH : MeI = 20 : 19 : 1, acetic acid and methyl acetate were obtained from methanol in 69.1 and 21.6% yields respectively in the presence of 2.5% Ni/C. The degree of conversion of methanol was 69.1%. The primary reaction products are Me_2O and AcOMe, acetic acid being formed on their subsequent carbonylation.

The selective synthesis of methyl acetate is carried out by the liquid-phase carbonylation of methanol in the presence of the Ru–Co - onium salt (0.25 : 1 : 10–50) catalyst in 1,4- or 1,3-dioxans. The interaction of methanol with CO in the presence of $Rh(OH)_4$, $Co_2(CO)_8$, and Bu_4PBr^- in 1,4-dioxan (180 °C, 245 atm) affords methyl acetate in 83% yield. Ethyl acetate is formed as a side product in 9% yield. The degree of conversion of methanol reaches 95%.[211]

The selective synthesis of methyl acetate from methanol also takes place in the presence of Group VIII metal compounds mixed with pentachlorobenzenethiol or its salts. Thus the carbonylation of methanol in the presence of the $RhCl_3$–C_6Cl_5SH system (175 °C, 50 atm CO) gives rise preferentially to the formation of methyl acetate.[212] When nickel compounds, a phosphine promoting agent, and methyl iodide are used, a mixture of acetic acid and methyl acetate is obtained from methanol. For example, the carbonylation of methanol in the presence of NiI_2, PPh_3, and MeI (28 atm, 150 °C) makes it possible to obtain a mixture of acetic acid and methyl acetate in 73.0 and 25.3% yields respectively.[213]

The selectivity in the formation of methyl acetate in the vapour-phase carbonylation of methanol on the Rh/NaX catalyst falls when the concentration of the rhodium introduced by the method involving the ion exchange of the $[Rh(NH_3)_5Cl]^{2+}$ cations, increases from 0.4 to 4%.[214] The reaction selectivity also falls (approximately by a factor of 4) if the rhodium catalyst is subjected to a preliminary heat treatment in air at 200 °C but remains unchanged if the heat treatment is performed at a higher temperature, up to 422 °C. Heat treatment in H_2 or CO at 320–350 °C deactivates the catalyst to a lesser extent than heat treatment in air. The treatment in CO does not affect the yield of dimethyl ether, while the treatment in H_2 increases it by approximately a factor of 1.5 compared with the heat treatment in air.

Catalysts for the homogeneous carbonylation of methanol having the general formula $R_pM[M'(CO)_mL_n]_2$ (where R is a nitrogen-containing base capable of being coordinated to Group IIA metals, M is a Group IIA metal, M′ is a Group VIB, VIIB, or VIII transition metal, L is a polyfunctional ligand capable of being coordinted to the transition metal, p = 1–4, m = 1–5, n = 0–4, and n + m = 5) have been prepared. The carbonylation of methanol in the presence of $(THF)_4.Mg[Co(CO)_3PBu_3]_2$ and CH_3I in benzene (120 °C, 56 atm CO) affords methyl acetate in 37% yield. Dimethyl ether is hardly formed.[215]

The carbonylation of dimethyl ether with formation of methyl acetate is carried out in the presence of palladium compounds, an iodine-containing promoting agent, and a tertiary amide or alkali or alkaline earth metal salts of a carboxylic acid.[216] The process, which is performed at a CO partial pressure of 30–150 atm and 180–220 °C, is distinguished by high selectivity.

The kinetics of the carbonylation of isopropyl alcohol with formation of isobutyric or n-butyric acid in the presence of the $RhCl_3$–HI catalytic system have been investigated.[217] The rate of carbonylation at 170 °C in an acetic acid–water mixture falls with increase in pressure. The reaction is of first order with respect to Rh, while the order with respect to HI is less than unity. Only the anionic species $[Rh(CO)_2I_2]^-$ have been detected spectroscopically. With increase in pressure from 14.6 to 205 atm, the isobutyric acid/n-butyric acid ratio increases from 0.7 to 1.6. The ratio is independent of the concentrations [Rh] and [HI]. The addition of propene to the mixture tends to increase the content of the n-isomer while the addition of an iodide slightly accelerates the reaction but does not affect the isobutyric acid/n-butyric acid ratio.

On treatment with the synthesis gas in the presence of a rhodium compound, a Group II metal iodide, and a Group VIII metal iodide (or bromide), ethers and esters are converted into mixtures of carboxylic acids or their esters, in which the alkyl group contains one CH_2 group more. Thus the interaction of methyl acetate with the synthesis gas in the presence of $RhCl_3$, $RuCl_3$, and ZnI_2 in 15-crown-5-(or 18-crown-6-) ethers results in the formation of ethyl acetate and acetic acid among other products.[218]

The reductive carbonylation of methanol in the presence of salts containing the anion $[FeCo_3(CO)_{12}]^-$ at 220 °C leads to the formation of ethanol in 73% yield. The reaction proceeds via stages involving the formation of acetaldehyde and methyl acetate. Under optimum conditions, the yield of acetaldehyde reaches 80–82%.[219]

Active nickel catalysts have been proposed for the synthesis of acetic acid by the isomerisation of methyl formate in the presence of iodine-containing promoting agents as well as compounds having the formula VR^1R^2, where V = N, P, Sb, As, or Bi and R, R^1, and R^2 = H, C_1–C_{10} alkyl, cycloalkyl, or aryl.[220] The reaction is carried out at 170–190 °C at normal or elevated pressures.

An effective method has been developed for the synthesis of esters from polyhydric alcohols, hex-1-ene and carbon monoxide in the presence of a cobalt catalyst and γ-picoline as the promoting agent. The catalyst is prepared from cobalt octanoate, γ-picoline, H_2O and CO in a separate apparatus (170 °C, 200 atm). The synthesis is carried out in apparatus of the bubbler type and the CO can contain up to 5 vol.% H_2. The esters obtained, for example, pentaerythritol tetraheptanoate, are used as components of a lubricating oil, plasticisers, and surfactants.[221-224] The initial polyhydric alcohols may be di- and tri-pentaerythritols, pentaerythritol, tris- or tetrakis-(hydroxymethyl)propanes, etc. and the olefins may be, apart from hex-1-ene, also but-1-ene, pent-1-ene, dec-1-ene, dodec-1-ene, etc. A method has been developed for the purification of the final product involving the removal of the cobalt impurities by treatment with aqueous solutions of alkali or alkaline earth metal oxides, carbonates, or bicarbonates at 120–140 °C.[221]

In the synthesis of aliphatic esters from alcohols and CO on an industrial scale, it is essential to use lower temperatures and pressures than is provided for in the majority of the patented processes. By carrying out the process in the presence of traces of H_2 and by using a complex of pyridine with cobalt carbonyl in proportions of 2:1 as the catalyst, it is possible to reduce the reaction temperature from 160–180 °C to 80–100 °C and the pressure from 150–200 to 20 atm.[225]

It has been established[226] that, in order to obtain active and stable deposited rhodium catalysts, the carriers must have definite acid–base properties. The use of oxide carriers with pronounced acid–base properties, such as Al_2O_3 or Al_2O_3–SiO_2, promotes the formation of rhodium complexes of the anionic type $[O \rightarrow Rh(CO)_2Cl]^-$ on the surface. When neutral carriers (SiO_2) are used, rhodium complexes of the type $O \rightarrow Rh(CO)_2Cl$, which are inactive in catalysis, are formed.

A catalyst for the carbonylation of methanol, exhibiting an activity higher by a factor of 50–100 than the usual rhodium catalysts, has been obtained by ion exchange between the NaX zeolite and $[Rh(NH_3)_5Cl]Cl_2$ and subsequent heating to 400 °C in a stream of N_2.[227] It works effectively at temperatures in the range 130–150 °C.

The chlororhodium-phthalocyanine catalyst for the carbonylation of methanol, used together with CH_3I and the sulphonic acids $CH_3C_6H_4SO_3H$, CH_3SO_3H, $PhCH_2SO_3H$, etc., is prepared by treating phthalocyanine or its carboxysulpho-derivatives with rhodium, cobalt, and iridium halides and also phosphorus-, sulphur-, arsenic-, or nitrogen-containing anions.[228] Before use, the catalyst is activated in an atmosphere of CO and H_2 at temperatures in the range 50–100 °C. The carbonylation of methanol in an autoclave (200 °C, 80 atm CO, 80 atm H_2) in the presence of a complex prepared from sodium phthalocyaninetetrasulphonate and $RhCl_3$ afforded a mixture of methyl acetate and acetic acid in 11 and 9% yields respectively.

The addition of lanthanide oxides to the nickel or cobalt catalysts makes it possible to carbonylate methanol with formation of acetic acid and methyl acetate without using halogen-containing promoting agents. The products are formed in high yields at temperatures in the range 130–200 °C and CO pressures from 1 to 50 atm.[229] The catalyst is first reduced in a stream of H_2 at 300–400 °C for 1 h and is then treated with CO (10–80 vol.%) containing N_2, CH_4, or C_2H_6 at 250–300 °C for 1–3 h. A mixture of methyl acetate, acetic acid, and methyl formate has been obtained in yields of 87.0, 8.7, and 0.87% respectively from methanol and carbon monoxide (in proportions by volume of 1:9) at 190 °C and a pressure of 5 atm on a catalyst containing 0.5% Rh and 15% of lanthanum oxide on SiO_2. Catalysts containing platinum (0.8–2.0 wt.%), cerium (15–20%), or lanthanum (10–20%) deposited on Al_2O_3 and TiO_2 are also active in this reaction.[230]

The rhodium ions in the Rh/NaX catalyst obtained by ion exchange are in a state close to their state in a homogeneous catalyst, but the activation energy for the heterogeneous carbonylation of methanol is nevertheless twice as high as for the homogeneous carbonylation.[231] The Rh/NaX catalysts are stable only at temperatures not exceeding 220 °C. The reaction is of zero order with respect to rhodium.

Oxidative carbonylation of fluorinated alcohols with carbon monoxide in the presence of Group IIB elements in the ionic form can result in the formation of the corresponding carbonates. Fluorine-containing carbonates and polycarbonates based on them have found extensive application in the pressing and moulding of plastics. The reaction takes place under mild conditions. Thus the interaction of CF_3CH_2OH with CO bubbling through it at atmospheric pressure and 20 °C in the presence of $Hg(OAc)_2$, 1,2,2,6,6-pentamethylpiperidine, and the sodium salt of dimethyl sulphoxide afforded $(CF_3CH_2O)_2O$ in 90% yield.[232]

But-3-enoic acid is obtained by the liquid-phase carbonylation of allyl alcohol in the presence of the palladium complex $LnPdCl_2$ (where L = nitrile, phosphine, or amine and n = 0 or 2) at 75 to 200 °C and a pressure of 35–140 atm.[233] Thus the carbonylation of allyl alcohol in acetic acid ($PdCl_2$, 80 °C, 90 atm CO) produces but-3-enoic acid in 64% yield. In acetonitrile, the yield falls to 40%. But-3-enoic acid is a valuable intermediate in the synthesis of γ-butyrolactone and 2-pyrrolidinone.

Nickel and cobalt catalysts promoted with compounds of Group IV elements (Si, Ge, and Sn), Group IA and IIA elements (Li, Ca, and Sr), as well as nitrogen-containing bases showed a high effectiveness in the synthesis of acetic acid from methanol. The promoting agents are iodine-containing compounds and aluminium, zinc, copper, lanthanum, and cerium iodides or bromides. Thus the carbonylation of methanol in acetic acid in the presence of nickel powder, SnI_4, 2,4-dimethylpyridine, CH_3I, and LiOAc (195 °C, 20 atm CO, and 3 atm H_2) gave rise to acetic acid in 97.6% yield.[234] The use of compounds (cobalt and nickel) with added alkyl- or arylphosphines and iodine-containing promoting agents as catalysts makes it possible to carry out the liquid-phase carbonylation of methanol. Thus the carbonylation of methanol (350 atm CO, 200 °C) in the presence of $Co(AcO)_2.4H_2O$, HI, and Bu_3P in an aqueous medium results in the formation of a mixture of methyl acetate and acetic acid in an overall yield of 91.0%.[235] Methyl acetate is formed selectively in the carbonylation of methanol (125 atm, 120 °C) in the presence of $Mn_2(CO)_{10}$ and CH_3I.[236]

The treatment of esters of mono- or di-carboxylic acids with the synthesis gas in the presence of homogeneous cobalt and rhodium compounds as well as LiI or LiBr results in the formation of aldehydes, carboxylic acids and their esters. Thus the interaction of methyl acetate with the synthesis gas (CO/H_2 = 1, 180 °C, 210 atm) in the presence of $Co(AcO)_2.4H_2O$, $Rh(acac)(CO)_2$, and LiI produced a mixture of MeCHO, HOAc, and AcOEt, the selectivity in the formation of acetaldehyde amounting to 86%.[237]

Lower carboxylic acids are obtained by the carbonylation of alcohols in the presence of nickel complexes and iodine-containing promoting agents. Acetic acid has been formed in a high yield in the interaction of methanol with CO (150 °C, 21 atm CO) in the presence of $(Ph_3P)_2Ni(CO)_2$, PPh_3, and CH_3I.[239] In order to reduce the corrosion of the apparatus by iodine-containing compounds, it is

recommended that alcohols be carbonylated with formation of acids and their esters in solution in aryl acetates.[240]

A method has been developed for the transesterification and carbonylation of the esters of lower aliphatic C_1–C_5 carboxylic acids and C_1–C_4 alcohols by carbon monoxide and phenols in the presence of Group VIII metal compounds with added iodine compounds as promoting agents.[241] The reaction is accelerated by tertiary amines NRR^1R_2 or the compounds $N(COR)R^1R^2$, where R, R^1, and R^2 = H, alkyl, or aryl. Thus the interaction of methyl acetate with CO and phenol (30 atm CO, 180 °C) in acetic acid in the presence of $RhCl_3$ and CH_3I converted half of the initial methyl acetate into acetic acid and phenyl acetate (the degrees of conversion were 97.5 and 96.8% respectively).

The $RhCl_3$–graphite and $RhCl_3$–graphite–I_2 systems, prepared by depositing $RhCl_3$ and I_2 on petroleum or coal coke in a high vacuum or in an inert gas atmosphere at 300 °C, are effective catalysts of the carbonylation of methanol to acetic acid.[242] Thus, by passing an MeOH : CO = 1 : 4 mixture at a space velocity of 45 cm^3 min^{-1} through a glass tube charged with the catalyst (2% $RhCl_3$ + 0.4% I_2)/C (with a specific surface of 10 m^2 g^{-1}) at 200 °C, methyl acetate and acetic acid have been obtained in 35.5 and 8.5% yields.

Carboxylic acids and esters are obtained together on interaction of compounds having the general formula RCO_2R' with the synthesis gas:

$$RCO_2R' + CO + H_2 \begin{cases} \longrightarrow RCOOH + R'COOH, \\ \longrightarrow RCH_2COOR', \\ \longrightarrow R'COOR. \end{cases}$$

The reaction is catalysed by rhodium compounds as well as compounds of other Group VIII metals, phosphines, and alkyl iodides or bromides. Thus treatment of methyl acetate with a 1 : 1 mixture of CO and H_2 in the presence of $RuCl_3$, $RhCl_3$, MeI, and PPh_3 (160 °C) leads to the formation of a mixture of acetic acid and ethyl acetate.[243]

Carboxylic acids and their anhydrides are obtained by carbonylating ethers or esters in the presence of metals or Group VIII metal compounds, Br^-, I^-, or their compounds. Thus a mixture of acetic acid and acetic anhydride can be obtained in a high yield by treating methyl acetate with carbon monoxide in the presence of the rhodium acetate dimer, 1-methylimidazole, and CH_3I at 175 °C.[244]

The interaction of carboxylic acids with the synthesis gas in the presence of rhenium and ruthenium compounds leads to the formation of acid esters. Thus treatment of acetic acid with a 1 : 1 mixture of CO and H_2 in the presence of $Ru_3(CO)_{12}$ and $NaRe(CO)_2$ (240 °C, 245 atm) affords a mixture of methyl and ethyl acetates.[245]

A method has been proposed for the preparation of methyl formate by carbonylating methanol in the presence of sodium methoxide. The introduction of $H_2N(CH_2)_6NH_2$ into the reaction zone increases the degree of conversion of methanol, while the addition of water poisons the catalysts.[246–249] The formation of methyl formate is facilitated in the presence of 0.1–30 wt.% of pyridine and 0.1–28 wt.% of the hydroxylated epoxide oligomer $HO(CH_2CHRO)_nH$ (where n = 2–600 and R = H or Me).[247] The reaction is carried out in the temperature range 60–100 °C. Conditions have been found for the hydrolysis of methyl formate with formation of formic acid in the presence of a strongly acid sulphonic acid cation exchanger based on styrene and divinylbenzene.[248,249] The hydrolysis is carried out at 60–100 °C and the resulting reaction mixture is transferred to a second vat-reactor where the hydrolysis is completed at 100–105 °C.

The interaction of methanol with the synthesis gas (CO/H_2 = 1) in the presence of $Al(acac)_3$ (250 °C, 200 atm) results in the formation of methyl acetate and methyl formate with selectivities of 62.5 and 35.1% respectively. The degree of conversion of methanol is 21%.[250]

Treatment of C_1–C_{20} alkyl, aryl, arylalkyl, and alkylaryl formates with the synthesis gas in the presence of a catalytic system containing rhodium compounds and LiI leads to the formation of the corresponding carboxylic acids. Thus the interaction of methyl formate with a 1 : 1 mixture of CO and H_2 in the presence of the $Rh(CO)_2(acac)_2$–LiI system results in the formation of acetic acid with a selectivity of 95% for a formate conversion of 65%.[251]

The technology of the synthesis of formic acid via methyl formate has been investigated on a scaled-up experimental apparatus. A procedure for the isolation of pure formic acid after the stage involving the hydrolysis of methyl formate and its concentration to 96% has been developed.[252]

The carbonylation of alcohols with formation of branched carboxylic acids proceeds under mild conditions on effective acid catalytic systems.[253–256] Thus trimethylacetic acid has been obtained with a high selectivity in the interaction of isobutyl alcohol with carbon monoxide (7.5 atm) in a liquid-phase reactor with vigorous stirring (1000 rev min^{-1}) at 60 °C in the presence of the $HF : BF_3 : H_2O$ = 5.1 : 1 : 1 catalytic system.[253]

The esters of αα-branched carboxylic acids are obtained in the presence of BF_3 with added copper(I), silver(I), or gold(I) carbonyls, formed in a strongly acid medium under mild conditions (temperature from −20° to +20 °C, 1 atm).[254]

Trimethylacetic acid is obtained selectively by carbonylating isobutyl alcohol in the presence of H_2SO_4 as the catalyst and ethyl formate as the carbonylating agent.[256] The reaction takes place at atmospheric pressure, 40–60 °C, and with molar ratios H_2SO_4 : 1-hexanol : $HCOOC_2H_5$ = 8–10 : 1 : 4. The mild process conditions are due to the formation of activated carbon monoxide on decomposition of ethyl formate in an acid medium and the evolution of ethanol as the esterifying agent.

In conclusion, we shall identify certain problems associated with the catalytic syntheses based on carbon monoxide. Despite the promising nature of many methods and the availability of large resources of carbon monoxode derivatives, there are as yet few industrial processes using this gas. The main causes of this situation are as follows: (1) the complexity and high cost of the majority of catalytic systems known at present; (2) the necessity to used special apparatus resistant to the corrosive action of the catalytic systems; (3) the insufficient number of highly selective and very stable catalysts which can be readily removed from the reaction products.

The introduction into industrial practice in recent years of the synthesis of acetic acid by the carbonylation of methanol can be regarded as one of the greatest advances in the field of carbonylation. Despite major successes achieved in their theoretical study, other processes have not so far found much practical application. Analysis of the extensive literature data presented in the present review shows that in most cases the proposed catalytic systems,

ensuring a high selectivity, are extremely complex and are frequently insufficiently stable. The questions of the repeated use of such systems have not been resolved.

Since virtually all carbonylation processes take place only at elevated pressures, a far-reaching study of their mechanism is difficult. Therefore in most cases the role of each component of the catalytic system is not entirely clear and so far the catalysts are selected empirically.

The present review naturally cannot embrace the entire literature devoted to the catalytic syntheses based on carbon monoxide. It includes only the main studies demonstrating the principal trends in the development of this important branch of science and technology.

The concentration of the research effort on the most promising and most thoroughly developed aspects of the field will apparently permit in the immediate future a significant expansion of the range of processes based on the use of carbon monoxide.

One should note that, among all types of the catalysts of the carbonylation reactions which have been investigated, the homogeneous catalysts exhibit the highest activity and selectivity. However, their separation from the reaction mixture presents certain difficulties. One way of solving this problem is the development of a method for the immobilisation of the soluble catalyst on an insoluble carrier. Such hybrid catalysts, which combine the high activity and selectivity of homogeneous systems with the ease of separation characteristic of heterogeneous catalysts, will probably find extensive application in industry. Another possible solution of the problem of the catalyst involves the carrying out of the reaction in a two-phase liquid–liquid system in which the catalyst and reaction products are dissolved in different phases.

Activation of oxygen by metalloenzymes and their models

N B Kozlova, Yu I Skurlatov
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. Studies on the activation of molecular oxygen by metalloenzymes and their models are surveyed.
The bibliography includes 105 references.

IV. Activation of oxygen by metal-containing enzymes 142

I. Introduction

The description of biological oxidation-reduction processes at the elementary step level is virtually impossible owing to the complexity of the protein objects studied, but the various kinds of model systems which reproduce in a simplified form particular functional features of biological systems can help.

In the present review, we shall confine ourselves to the examination of problems of the modelling of the elementary mechanisms of the action of metalloenzymes catalysing processes with participation of O_2.[1] Attention has been traditionally concentrated on these processes as a consequence of the great importance of O_2 for the vital activity of organisms, in connection with the prospect of using O_2 as an ecologically pure oxidant, and also because of the abundance of processes with participation of O_2 in the environment.

In examining metalloenzyme systems and their models, one must take into account the chemical and biological characteristics of each elementary step. The chemical characteristics are of a general character for many enzyme systems, while the biological characteristics define the specificity of the given system, determined by the structural features of the active centre and of the entire metalloenzyme molecule, and the dynamic properties of macromolecules with their multipoint intermolecular interactions. It would be premature to make any kind of generalisations for complex systems of this kind. On the other hand, the chemical characteristics of the elementary step make it possible to consider from general standpoints the mechanisms of oxidation-reduction reactions in both enzyme and model systems. This postulate constitutes the basis of the review. Its aim is an attempt to represent biological oxidation-reduction processes in terms of the electron transfer step.

The theory of outer-sphere electron transfer has been developed[2] and its quantitative aspect has been applied.[3]

Outer-sphere electron transfer takes place in a collision (unoriented and unstabilised) complex as a consequence of the fluctuations in the dipoles of the medium which equalise the energy levels of the initial and final states:[2,3]

$$A + D^e \rightarrow (A...D^e \longleftrightarrow A^e...D)^{\neq} \rightarrow A + D^e,$$

where A is the electron acceptor and D^e the one-electron donor. The energy of the reorganisation of the solvent in the outer-sphere electron transfer depends quadratically on the number of electrons transferred. By virtue of this, the transfer of two electrons via the outer sphere mechanism is relatively ineffective although it has been detected in many instances. On the other hand, when one speaks of reactions with participation of O_2, in enzyme systems its reduction takes place as a two-electron process with formation of $O_2^{2-}(H_2O_2)$ or effectively as a four-electron process with formation of $O^{2-}(H_2O)$. These reactions occur mostly as a result of the formation of complexes between O_2 and reduced variable valence metal ions—usually copper and iron ions. In general, one may call such reactions inner-sphere electron transfer reactions. Intramolecular electron transfer is sometimes also implied by the inner-sphere transfer:

Such transfer usually takes place either when the molecule contains bridging electron-conducting groups (with a "rigid" molecular structure) or as a result of intramolecular collisions of the donor–acceptor functional groups (flexible dynamic structure).

Consideration of complexes between electron-donating and electron-accepting species led Mulliken to introduce the concept of charge transfer complexes (CTC).[4,5] The studies by one of the authors of the present review have been devoted to the role of such complexes in oxidation-reduction reactions.[6,7] Subsequently oxidation-reduction reactions with participation of O_2 in model and enzyme systems were considered from the standpoint of ideas postulating intramolecular electron transfer as a chemical step in which the products of the final electron transfer are formed on decomposition of the intermediate donor–acceptor complex with *partial* charge transfer (PCTC):

$$A + D^e \rightleftarrows (AD)^e \rightarrow A^e + D,$$

where $(AD)^e$ is a PCTC with one-electron inner-sphere transfer.

The final two-electron process can be represented analogously:

$$A + D^{2e} \rightleftarrows (AD)^{2e} \rightarrow A^{2e} + D.$$

The fundamental difference between the "activated" collision complex and the PCTC consists in the mutual orientation of the donor and acceptor and the distance between them or, more precisely, in the extent of the electron-exchange interaction (V) of the donor–acceptor orbitals. In the outer-sphere case, the reactants approach one another to a distance $\gtrsim 4$ Å and $V < kT$; in the inner-sphere case, the distance between the reacting species is less than the sum of the van der Waals or ionic radii but is greater than the sum of the covalent radii of the atoms in contact, while the energy of the exchange donor–acceptor interaction exceeds the energy of the thermal motion: $kT < V \lesssim 10\ kT$. Evidently, depending on the values of V, the intermolecular transfer can take place either via the "outer-sphere" mechanism or via the "inner-sphere" mechanism [a partial charge transfer (PCT) state is produced]. Intramolecular electron transfer over long distances is the most typical property of biological electron-transport systems.

II. Characteristic features of inner-sphere electron transfer reactions and of intermediate complexes with partial charge transfer

We shall consider the distinctive features of the donor–acceptor PCTC by virtue of which they play an important role in metal complex and especially metalloenzyme catalysis. Their main feature is the existence of a rapidly established (thermal) equilibrium between the ground (N) and electronically excited (E) states. At the present time, complexes of this kind are referred to as examples of redox isomerism. In the ground state, the complex decomposes into the initial reactants, while in the electroncially excited state it decomposes into the electron transfer products:

$$A + D^{e} \rightleftarrows (AD)^{e}_{N} \overset{kT}{\rightleftarrows} (AD)^{e}_{E} \rightarrow A^{e} + D,$$
$$A + D^{2e} \rightleftarrows (AD)^{2e}_{N} \overset{kT}{\rightleftarrows} (AD)^{2e}_{E} \rightarrow A^{2e} + D.$$

As a result, the PCTC can interact with any "third" species and, existing simultaneously in two (ground and electronically excited) states, it can manifest the properties of both the initial reacting species and of the electron transfer products. Such "duality" in the properties of the PCTC has been clearly interpreted in terms of the ideas of Mulliken's resonance theory,[4,5] according to which the PCTC can be represented by a "superposition" of states without charge transfer and with complete charge transfer:

$$(AD)^{e} \equiv (AD^{e} \longleftrightarrow A^{e}D),$$
$$(AD)^{2e} \equiv (AD^{2e} \longleftrightarrow A^{2e}D).$$

Identical contributions of the limiting structures obtain when the energies of the donor–acceptor pair without (i) and with (f) complete charge transfer in the absence of electron-exchange interaction are equal.[6,8] The difference between the energies of these states (ΔH_e) can be estimated from thermodynamic considerations:[5]

$$\Delta H_e \simeq \Delta\sigma^0_{el} + RT \ln (K_{c,i}/K_{c,f}),$$

where $\Delta\sigma_{el}$ is the difference between the redox potentials of the donor and the acceptor and the constants K_c are the stability constants of the hypothetical complexes of the initial and final states. When the values of $K_{c,i}$ and $K_{c,f}$ are similar, the condition $\Delta H_e \simeq \Delta\sigma_{el} \simeq 0$ implies the approximate equality of the redox potentials of the partners involved in the bond:

$$\varphi_0(A/A^{e,2e}) \simeq \varphi_0(D^{e,2e}/D).$$

When the values of $K_{c,i}$ and $K_{c,f}$ or methods for their formation are available, account can be taken also of the contribution by the complex formation effect to ΔH_e.

The thermodynamic factor determines not only the properties of the PCTC (the degree of charge transfer in the ground and electronically excited states depends on ΔH_e) but also the relative probability of the decomposition into the electron transfer products.

The rate of the final electron transfer via the inner-sphere mechanism depends on the nature of the intermediate PCTC and the process thermodynamics. It is possible to differentiate two extreme cases:[8] the rate of the electron transfer is determined either by the rate of formation of the PCTC (as a rule when $\Delta\sigma^0_{el} < 0$) or by the rate of its decomposition into the electron transfer products (usually when $\Delta\sigma^0_{el} > 0$).

Since the properties of the PCTC and the probability of their decomposition into the electron transfer products depend on parameters such as ΔH_e and $\Delta\sigma^0_{el}$, there is a possibility of the operation of several "external" mechanisms whereby these parameters are influenced.

When ionic and highly polar reactants participate in the reactions, the values of $\Delta\sigma^0_{el}$ depend on the polarity of the medium. Solvation effects diminish ΔH_e and correspondingly increase the degree of charge transfer in the donor – acceptor complex. Appreciable changes in the polarity of the medium usually occur at the water–non-polar phase interface, as a result of which effective charge transfer, induced by relatively small movements of the reacting species in a medium with a polarity gradient, are to be expected in precisely such boundary regions.

Another pathway leading to the final electron transfer in PCTC is associated with the effects of the coupling of oxidation-reduction and acid–base reactions. The mechanism whereby a proton is supplied to the acceptor can be various: a proton can be drawn from the aqueous medium or from other proton donors in close proximity. The transition from an ionic to an electrically neutral reaction entails a sharp alteration of $\Delta\sigma^0_{el}$ and ΔH_e. In fact such energy coupling of electron and proton transfer appears as the transfer of a hydrogen atom in a one-electron process or of a hydride ion in a two-electron process. In protein macromolecules, there is an inter-relation between small local changes in the relative disposition of the atoms in the active centre and the change in the structure in the entire macromolecule.[9] As a result of this, there is a possibility of the energy coupling of the structural and electronic-structural characteristics accompanied by a change in V and $\Delta\sigma^0_{el}$. The dynamic conformational properties of the macromolecule thereby determine also its functional possibilities in effecting electron transfer. Any coupling merely "manifests" some property characteristic of the PCTC, while the essential feature of the inner-sphere electron transfer remains unaltered.

The intrinsic concept of an "inner-sphere" process refers usually to electron transfer reactions in the inner coordination spheres of transition metal ions.

In contrast to the intermolecular donor–acceptor (valence) bond, in the case of metal ions the coordinate bond is collective in character. By virtue of this feature, appreciable changes in the geometrical and electronic structures of the complex can occur without appreciable energy expenditure.[11] Two consequences of such collective binding are very important for the occurrence of "true" inner-sphere electron transfer reactions.

The first concerns the dynamic character of the metal–ligand bond: despite the high strength of each bond considered separately, in the absence of steric limitations or chelation the complex ion exists permanently in the state of ligand exchange. This occurs either as a result of conformational instability (the dynamic Jahn–Teller effect)[12] or as a result of transitions between close conformationally excited states of the complex differing in the symmetry of the ligand environment and hence in the electronic-structural characteristics of the central ion.[9] In transition metal ions, there may be three types of conformationally excited states:

(1) For an unchanged coordination number (CN), only the symmetry of the ligand environment changes, which can entail a change in the spin state and population of the *d* orbitals of the central ion.

(2) In conformational excitation, the CN increases by 1 or 2—vacant sites appear in the coordination sphere and are available for the introduction of one or two ligands.

(3) On conformational excitation, the CN diminishes by 1 or 2—the dissociation of the ligands (one or two) takes place.

The second consequence is associated with the possibility of identifying the donor–acceptor bond between the metal ion and the redox ligand as a "valence" bond. Bearing in mind the limitations to the strength of such a bond ($V \lesssim 10\ kT$) and the types of conformationally-excited states of the metal complex ion quoted above, one can infer *a priori* the presence or absence of sites in the coordination sphere of the metal ion potentially vacant and available for the binding of a redox ligand with formation of a coordination PCTC.[9]

Variable-valence metal ions in the oxidised state (M^{2+}) are usually coordinatively unsaturated to the maximum extent. In this case the incorporation of redox ligands—two-electron donors (D^{2-})—in the inner coordination sphere is possible only via the ligand substitution mechanism:

$$LM^{2+} + D^{2+} \overset{-L}{\rightleftarrows} MD \rightleftarrows M^{+} + D^{\cdot-}.$$

On the other hand, in the reduced form, metals frequently have potentially vacant sites for the binding of a redox ligand. The incorporation of the ligand in the inner coordination sphere takes place in this case via a mechanism of the oxidative addition type:

$$LM^{+} + A \rightleftarrows L(MA)^{+} \rightarrow LM^{2+} + A^{\cdot-}.$$

If A is a two-electron acceptor, there is a possibility of an inner-sphere two-electron transfer with formation of the metal ion in the superoxidised state M^{3+}:

$$M^{+} + A \rightleftarrows MA^{+} \rightleftarrows M^{3+} + A^{2-}.$$

An inner-sphere two-electron reaction can take place analogously also in the interaction of the M^{3+} ion with a two-electron donor D^{2-}:

$$M^{3+} + D^{2-} \rightleftarrows MD \rightarrow M^{+} + D.$$

In each of the examples of the one- and two-electron inner-sphere transfer, the intermediate complex exists simultaneously in the ground and electronically excited states, decomposing respectively into the initial reactants or the electron transfer products. In order to have a clear idea about the nature of the PCTC, the initial reactants from which it is formed, and the products into which it decomposes, in describing the PCTC it is convenient to use Mulliken's terminology,[5] defining "limiting structures" as respectively the initial reactants and the products of the final electron transfer. In this case, the intermediate binary PCTC with inner-sphere one- or two-electron transfer can be represented as a "superposition" of structures without and with complete charge transfer:

$$(MA^{+})_{I} = (M^{+}A \leftrightarrow M^{3+}A^{2-}),$$
$$(MA^{+})_{II} = (M^{+}A \leftrightarrow M^{2+}A^{\cdot-}),$$
$$MD = (M^{2+}D^{2-} \leftrightarrow M^{+}D^{\cdot-},$$
$$MD^{+} = (M^{3+}D^{2-} \leftrightarrow M^{+}D).$$

The double arrow between states without charge transfer (initial reactants) and those with full charge transfer (products) reflects here the mixing of these two stages on formation of the PCTC.

Ternary PCTC can include either one or two metal ions. In the former case, inner-sphere electron transfer takes place in the coordination sphere of one metal ion. Such complexes are formed in the interaction of binary PCTC with a redox ligand. Accordingly, four types of ternary complexes can be formed:

$$(DMA^{-})_{I} = (D^{2-}M^{+}A \leftrightarrow D^{\cdot-}M^{2+}A^{2-} \leftrightarrow DM^{+}A^{2-}),$$
$$(DMA^{-})_{II} = (D^{2-}M^{+}A \leftrightarrow D^{\cdot-}M^{+}A^{\cdot-} \leftrightarrow D^{\cdot-}M^{2+}A^{2-} \leftrightarrow DM + A^{2-}),$$
$$(AMD) = (AM^{2+}D^{2-} \leftrightarrow A^{\cdot-}M^{2+}D^{\cdot-} \leftrightarrow A^{\cdot-}MD \leftrightarrow A^{2-}M^{2+}D),$$
$$(AMD^{+}) = (AM^{3+}D^{2-} \leftrightarrow A^{\cdot-}M^{2+}D \leftrightarrow A^{\cdot-}M^{3+}D^{\cdot-} \leftrightarrow A^{2-}M^{3+}D).$$

Their decomposition into particular electron transfer products is determined by the corresponding values of $\Delta\sigma^{0}_{el}$ and can be controlled by the energy coupling effect manifesting particular "limiting" structures.

A second metal ion can also play the role of a redox partner in the binary PCTC with the resulting formation of dinuclear bridged PCTC:

$$M^{+} + (MA^{+})_{II} \rightleftarrows (MAM)^{2+} \rightarrow 2M^{2+} + A^{2-},$$
$$MD + M^{2+} \rightleftarrows (MDM)^{2+} \rightarrow 2M^{+} + D,$$
$$M^{+} + M(A{-}{-}A)^{+}_{I} \rightleftarrows (MA{-}{-}AM)^{2\cdot} \rightarrow 2(MA^{+})_{I} \rightarrow 2M^{3+} + 2A^{2-},$$
$$MD^{+} + MD^{+} \rightleftarrows (MD-DM)^{2+} \rightarrow 2M^{+} + D-D.$$

Dinuclear bridged PCTC can be formed also in the interaction of the initial dinuclear metal complex ion (ion pair) with the corresponding redox ligand:

$$\underset{\text{|———|}}{M^{+}\ldots M^{+}} + A \rightleftarrows \underset{\text{|——|}}{(MAM)^{2+}} \rightarrow \underset{\text{|———|}}{M^{2+}\ldots M^{2+}} + A^{2-},$$
$$\underset{\text{|——|}}{M^{2+}\ldots M^{2+}} + D^{2-} \rightleftarrows \underset{\text{|—|}}{(MDM)^{2+}} \rightarrow \underset{\text{|——|}}{M^{+}\ldots M^{+}} + D.$$

Polynuclear cluster complexes with a strong metal–metal bond can also participate in energy coupling effects:

$$-M^{+}-M^{+} + A \rightleftarrows (-MMA)^{2+} \rightarrow -M^{2+}-M^{2+} + A^{2-},$$
$$-M^{2+}-M^{2+} + D^{2-} \rightleftarrows -M^{+}-M^{+} + D.$$
$$\uparrow$$
$$\rightleftarrows (-MMD)^{2+} \rightleftarrows$$

The above schemes describe in a general form virtually all cases of the formation of molecular and coordination PCTC in oxidation-reduction reactions.

The proposed classification of the PCTC is useful when the nature, properties, and reactivities of the intermediate complexes formed in catalytic redox reactions are considered. In fact, knowing the structural and energy characteristics of the metal ion and the redox ligand, it is possible to predict the possibility of the formation of the PCTC, its reactivity in relation to "third" species, the preferred decomposition channels, and the rate constant for the final electron transfer.[7,10] Ideas about PCTC have proved extremely productive in the analysis of both the general questions and specific examples of the activation of molecular oxygen by variable valence metal ions.[7]

III. The ligand properties of molecular oxygen and the reactivity of metal—oxygen complexes

Molecular oxygen is a redox ligand without unshared electron pairs for the formation of the usual (σ-donor) coordinate bond. By virtue of this factor, the incorporation of O_2 in the coordination sphere of a metal ion is possible only at a potentially vacant site in the conformationally excited complex. A donor-acceptor metal—oxygen bond is formed on partial transfer of one or two electrons from the t_{2g} orbital of a metal ion, which existed initially in the reduced form, to the antibonding orbitals of the O_2 molecule.

This question has been investigated in detail[9,13,14] and we shall consider only the geometrical structure of the metal—oxygen complexes. It follows from symmetry considerations that the combination of the $\pi^*(O_2)$ and $t_{2g}(M^+)$ orbitals can be achieved in two ways—with retention or breakdown of the equivalence of the O atoms. In the former case, the product is only PCTC of the peroxy-type (oxygen acting as a bidentate ligand) with inner-sphere two-electron transfer:

$$(MO_2^+)_I = \left(M^+ \cdots \begin{matrix} O \\ \| \\ O \end{matrix} \longleftrightarrow M^{3+} \begin{matrix} O^- \\ | \\ O^- \end{matrix} \right)$$

The latter case involves a one-electron transfer with formation of a complex of the superoxide type (oxygen acting as a monodentate ligand) with a "linear" structure:

$$(MO_2^+)_{II} = \left(M^+ \cdots \overset{O}{\overset{\|}{O}} \ (^1\Delta) \longleftrightarrow M^{2+} - \overset{O^-}{O} \right).$$

The establishment of singlet oxygen (sp^2-hybridisation of the atomic orbitals) in a complex of the "superoxide" type has been confirmed by the results of quantum-chemical calculations[15] and by direct measurements using IR spectroscopic methods.[16] Together with the singlet oxygen structure, the presence of the superoxide radical has been detected in the complexes with the "linear" structure.[17,18]

Complexes of the "superoxide" type have been isolated in the solid state for Co^{2+} (d^7) and Fe^{2+} (d^6) ions[16] in a planar ligand environment: salicylideneamines, porphyrins, and other macrocyclic ligands. Many such complexes have been characterised in solution by EPR. These are $(OH^-)Ti^{4+}O_2^-$,[19] Mn^{3+}(porphyrin)O_2^-,[20] Co^{3+}(corrin)O_2^{2-}, vitamin B_{12},[21] $Sn^{4+}O_2^-$,[22] etc. Analogous metal—oxygen complexes are formed in the interaction of HO_2 with Ti^{4+} [23] and other d^0 elements (V^{5+}, Zr^{4+}, U^{6+}, Th^{4+}, Mo^{6+}) [23-25] and also in the interaction of vitamin B_{12} in the oxidised form with the O_2^- radical-ion.[26]

The equivalence of the O atoms in the complex with the "linear" structure is attained only on formation of dinuclear μ-peroxo-complexes:

$$(MOM)^{2+} = \left(M^+ \cdots \overset{O \cdots M^+}{\overset{\|}{O}} \longleftrightarrow M^{3+} - \overset{O^- - M^{3+}}{O^-} \right).$$

Complexes of this type are most characterstic of ions with the d^7 electronic configuration (Co^{2+}) [27,28] and also with the d^5 electronic configuration: Mn^{2+}(phthalocyanine) in the presence of pyridine[29] and Ru^{2+} + EDTA in an alkaline medium.[30,31] Analogous complexes are formed in the interaction of Ru^{3+} EDTA with H_2O_2.[31] The formation of dinuclear μ-peroxo-complexes is possible also for M^+ ions with the d^9, d^{10} electronic configuration.

The preferential formation of a particular type of oxygen complex depends on the presence of one or two potentially vacant sites in the coordination sphere of the metal ion and on the value of $\Delta\sigma_{el}^0$ for the corresponding electron transfer reaction.

Although the binding of O_2 in complexes with variable valence metals is of intrinsic interest as regards the study of natural O_2 transferring agents,[14] the question of the activation of O_2 as an oxidant is more significant. The complete or partial reduction of O_2 to reactive products such as HO_2 and OH leads to the activation of O_2. Attention should be drawn to the fact that, the higher the reactivity of the intermediate species, the smaller the chance of its being detected or isolated in the solid state. The "unobserved" oxygen complexes can therefore play a role in the activation of O_2.

From the standpoint of the PCT concept, the reactivity of coordinated oxygen is determined by the nature of the oxygen complex and the possibility of the incorporation of the oxidised substrate in the inner coordination sphere of the metal ion.

In the case of complexes of the "superoxide" type, reactions of three kinds are most characteristic.

1. Outer-sphere electron transfer reactions similar to the reactions of the superoxide radical-ion[32] but occurring much more effectively as a consequence of the increase in the redox potential of the oxygen coordinated to the highly charged central ion:

$$(MO_2^+)_{II} + D^{2-} \rightarrow MO_2 + D^-.$$

(2) Inner-sphere redox reactions for the *cis*-coordination of the oxidised substrate: in this case the incorporation of the substrate in the inner coordination sphere is possible either at a potentially vacant site or via the ligand substitution mechanism in the *cis*-position relative to the coordinated oxygen:

$$(MO_2^+)_{II} + RH \rightleftarrows (MO_2RH)^+ \begin{cases} \longrightarrow M^{3+} + HO_2^- + R' \\ \longrightarrow M^+ + HO_2 + R' \\ \longrightarrow M^+ + H_2O_2 + \text{product}. \end{cases}$$

The latter reaction is of greatest interest, since it entails the two-electron oxidation of the substrate in the inner coordination sphere of the metal ion with formation of hydrogen peroxide as the O_2 reduction product and without the final change in the (reduced) oxidation state of the metal ion. Such a reaction has been discovered in the oxidation of ascorbic acid by copper ions[7,33-36] and in the oxidation of methanol by the complexes $L_2Cu^+O_2$ (L = 2,2'-bipyridyl).[37]

When the substrate has reducing (DH^-) and ligand properties, there is a possibility of the formation of a ternary PCTC and the substrate can be bound to the metal also before the interaction with O_2.

(3) Inner-sphere redox reactions with a second metal ion. These are common in autoxidation processes:

$$(MO_2^+)_{II} + M^+ \xrightarrow{2H^+} 2M^{2+} + H_2O_2.$$

Two M^+ ions may exist also in a "pair":

$$M^+ \ldots M^+ + O_2 \rightleftarrows (M{-}O_2{-}M)^{2+} \begin{cases} \xrightarrow{2H^+} M^{2+}M^{2+} + H_2O_2 \\ \xrightarrow{2H^+} M^{2+}M^{2+} + 2H_2O \end{cases}$$

The reactivity of mononuclear oxygen complexes of the peroxy-type is due to two factors.

(1) The manifestation by such complexes of the reactive properties of metal ions in the superoxidised state as one- and two-electron acceptors. The formation of superoxidised states of the metal ion can be accompanied by the complete or partial oxidation of the coordinated ligands. For example, the autoxidation of the complexes of Fe^{2+} with 1-hydrazinophthalazine,[38] phosphines,[39] and EDTA is accompanied by inner-sphere oxidation of these ligands. The incorporation of a redox ligand in the coordination sphere is possible both in the interaction of M^+ with O_2 and after the binding of O_2 in a complex with the metal. A high reactivity in relation to H^+ and OH^- with the "appearance" of coordinated hydrogen peroxide or the superoxidised metal ion respectively is characteristic of complexes of the peroxy-type.

(2) In complexes with strong two-electron charge transfer, the dissociation of the O—O bond as a result of the stabilisation of O^{2-} with "partial" formation of atomic oxygen may prove to be more favourable than the hydrogen peroxide structure by virtue of the increase in the effective charge on the central metal ion, especially in weakly polar media:[40]

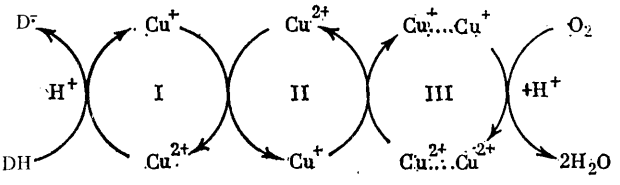
$$(MO_2^+)_I = \left(M^+ \ldots \overset{O}{\underset{O}{\|}} \longleftrightarrow M^{3+}\!\!<\!\!\begin{matrix} O^- \\ | \\ O^- \end{matrix} \longleftrightarrow M^{3+}\!\!:\!\!\begin{matrix} O^{2-} \\ | \\ O \end{matrix} \right).$$

Accordingly, complexes of the peroxy-type with strong charge transfer can exhibit the reactivity characteristic of the superoxidised metal ion and can participate, like atomic oxygen, in substrate hydroxylation and epoxidation reactions.

Among the model hydroxylating systems based on O_2, the Fe^{3+}/Fe^{2+}—EDTA—ascorbic acid (DH_2) system, discovered in 1954 by Udenfriend[41] and catalysing reactions of the type

$$RH + DH_2 + O_2 \rightarrow ROH + D + H_2O$$

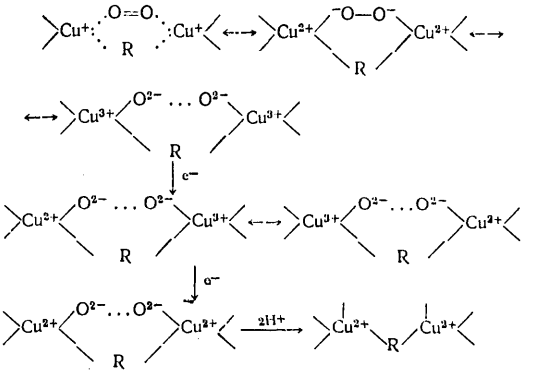
has been most widely investigated. The role of the electron donor in this reaction reduces to regenerating the reduced form of the iron ethylenediaminetetra-acetate complex participating in the activation of O_2 with formation of an oxygen complex of the peroxy-type.



IV. Activation of oxygen by metal-containing enzymes

The biological catalysts and processes involving oxidation by molecular oxygen are widely distributed in nature. Resorting to the ideas and characteristic mechanisms of the activation of O_2 described above, we shall consider metal-containing enzymes—oxidases and oxygenases. The former use oxygen as an electron acceptor and the latter use it as a donor of an O atom.[42]

Oxidases—the catalysts of the four-electron reduction of O_2 to water—have been most thoroughly investigated: laccase, ascorbate oxidase, and cytochrome *c* oxidase. A characteristic feature of all these enzymes is the separation in space of the centres for the transformation of the substrate and reduction of O_2.



Thue "blue oxidases" (laccase, ascorbate oxidase) contain copper ions of three types: EPR-detectable "blue" [type (I)] and "non-blue" [type (II)] Cu^{2+} ions as well as a pair of Cu^{2+} ions [type (III)] which are not detectable by EPR.[43] In these oxidases, there is direct electron transfer between copper ions of types (I) and (II) and between types (II) and (III).[44] In fact, O_2 is not activated in the substrate oxidation process for this group of enzymes. The role of O_2 consists in the regeneration of the oxidised form of the enzyme. The rate of the enzyme reaction is limited by the interaction of the substrate with the "blue" Cu^{2+} ion, while the rate of regeneration of the oxidised form of the oxidase is limited by the interaction of O_2 with the reduced type (III) ions.

The mechanism of the action of laccase and ascorbate oxidase is of the same type and includes the usual cyclic scheme involving the alternate oxidation of the substrate and reduction of O_2:

The reduced enzyme is oxidised via the intermediate formation of a dinuclear μ-peroxo-complex analogous to the complexes of O_2 with the copper-containing O_2 transferring agent (haemocyanine) and ceruloplasmin.[42] The reduction of the bridging hydrogen peroxide in such a complex to water requires the transfer of two additional electrons from the substrate binding centre. Such electron transport takes place via a "non-blue" copper ion in the case of laccase and ascorbate oxidase.

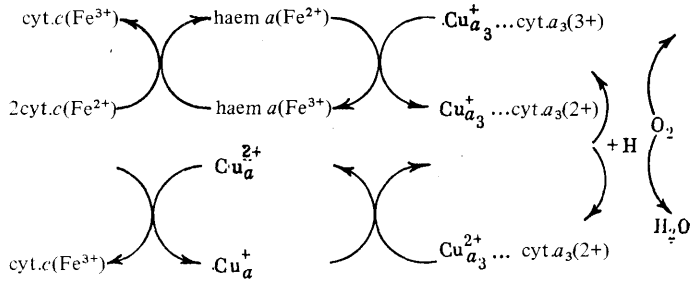
Within the framework of the concept of the PCTC, the mechanism of the four-electron reduction of O_2 in "blue" oxidases can be represented by a sequence of the following inner-sphere reactions of type (III) ions:

R = bridging ligand.

The inner-sphere two-electron oxidation of each copper ion in the dinuclear complex is called upon to play a stabilising role by virtue of the inertness of Cu^{2+} [Cu^{3+}? (Ed. of Translation)] in ligand substitution reactions. In the binding of O_2, the rate of the intermolecular electron transfer from the centre (I) to the centre (III) increases by two orders of magnitude,[42] which apparently in fact ensures the possibility of the four-electron reduction of O_2 before the complex decomposes to H_2O_2 via the μ-peroxo-complex state.

A copper–polymer complex (Cu^{2+}–polyvinylpyridine) is a functional model of ascorbate oxidase:[44,45] in its presence, ascorbate anions are oxidised via a one-electron process and O_2^- radical-ions do not migrate outside the limits of the macromolecular coil because of the high local concentration of copper ions in the metal–polymer complex.

Cytochrome *c* oxidase is an enzyme which plays an important role in respiratory processes, catalysing the oxidation of cytochrome *c*:



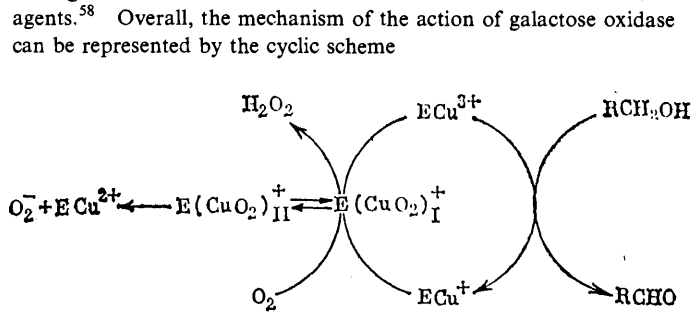
$$4\text{cytochrome } c(2+) + 4H^+ \rightarrow 4\text{cytochrome } c(3+) + H_2O.$$

It has been established by EPR that two magnetically isolated centres enter into the composition of the enzyme—the low-spin cytochrome *a* and Cu_a ($S = 1/2$; $\varphi_0 = 0.25$ V) as well as the $S = 2$ centre due to the antiferromagnetic coupling of cytochrome a_3 ($S = 5/2$) and Cu_{a_3} ($S = 1/2$), separated by a distance of 5 Å ($\varphi_0 = 0.35$ V).[46] These two centres are apparently linked via a bridge comprising a common ligand-oxygen (cytochrome a_3-O-Cu^{2+}), imidazole, or sulphur.[47–52] However, in the study of various synthetic imidazole-bridged dimers, it was demonstrated by measurements of the magnetic susceptibility between 4 and 300 K that the antiferromagnetic coupling does not correspond to that observed in cytochrome *c* oxidase ($-J > 200$ cm^{-1}).[52] It is most likely that in the oxidised enzyme the cytochrome a_3 and Cu_{a_3} centres are linked via oxygen or sulphur atoms.[49] The ligands in Cu_a are cysteine and histidine residues.[53] There is a haem–haem interaction between cytochromes *a* and a_3 accompanied by a change from the high-spin to the low-spin state of iron in cytochrome a_3 as the molecular environment in haem *a* is altered.[54] The study of the partly reduced form of cytochrome *c* oxidase demonstrated the presence of reduced low-spin haem iron, type (I) copper ions in the reduced form, and the high-spin ferrihaem a_3. Both the oxidised and the one-electron reduced enzymes oxidise cytochrome *c* also in the absence of O_2. The two-electron reduction of the oxidised form of cytochrome *c* oxidase converts it into the active form. The subsequent reduction is not significant for the manifestation of catalytic activity.

The activation of the enzyme is apparently associated with the reduction of a dinuclear haem a_3–Cu centre, which results in the possibility of the incorporation of O_2 in the coordination spheres of copper and iron ions as a bridging ligand.

In the functioning of the enzyme, haem *a* and Cu_a are independent electron acceptors on contact with the substrate, while haem a_3 and Cu_{a_3} form jointly a dinuclear O_2 binding centre.[53,55] Experiments with cross-link reactants established that the electron transfer from the haem of ferrocytochrome *c* to the haem *a* of cytochrome *c* oxidase takes place over a long distance and at a constant rate close to the rate of diffusion. The interaction of cytochrome *c* with the Cu_a centre takes place independently but much more slowly than the interaction with haem *a*.[53]

Structural studies have shown that the plane of haem *a* is at right angles to the plane of the phospholipid membrane near the water–non-polar phase interface, i.e. in the region of a dielectric constant gradient in the medium. The "cooperation" with electron transfer as a result of low changes in the polarity of the medium, mentioned previously, is thereby achieved for this enzyme. The "proton cooperation" in the stage involving the reduction of O_2 to water is also significant for the functioning of the enzyme.[55,56] The mechanism of the action of cytochrome *c* oxidase can be represented by a scheme analogous to that presented for ascorbate oxidase:



In the reduction of the bridging oxygen molecule to H_2O, three intermediate compounds are distinguished: $[Fe_{a_3}-O-O-Cu_{a_3}]^{3+}$, $[Fe_{a_3}-O-O-Cu_{a_3}]^{2+}$, and $[Fe_{a_3}-O-O-Cu_{a_3}]^{+}$.[57] These forms can be regarded as dinuclear PCTC.

It follows from the mechanisms of the action of oxidases presented that the metal ion in the oxidised form (Cu^{2+} or Fe^{3+}) participates in the oxidation of the substrate–electron donor (cytochrome *c*) or H atom (ascorbate), while a pair of metal ions in the reduced form, forming a relatively stable intermediate μ-peroxo-complex, participates in the reduction of O_2 to H_2O. The proton cooperation by the medium plays an important role in the subsequent reduction of this complex.

The metalloenzymes catalysing the reduction of O_2 to H_2O_2 contain in the active centre as a rule one "non-blue" copper ion [type (II)]. Certain amino-oxidases, galactose oxidase, and uricase are representatives of this group of "colourless" enzymes. The mechanism of the action of enzymes of this group can be various.

In the case of the galactose oxidase, the catalytic cycle includes the Cu(I) and Cu(III) enzyme forms, i.e. Cu(I) interacts with O_2 via the inner-sphere two-electron transfer mechanism. The formation of oxygen complexes of the peroxy-type is characteristic of copper(I) ions, but in the absence of the substrate they are readily transformed into complexes of the superoxide type.[58] The copper(II) formed on dissociation of this form of the enzyme is catalytically inactive. The inactive Cu(II) and the active Cu(III) forms of the enzyme can undergo interconversions under the influence of one-electron redox agents.[58] Overall, the mechanism of the action of galactose oxidase can be represented by the cyclic scheme

E = protein ligand

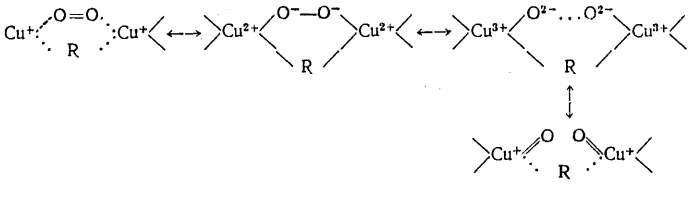
The copper ion in the superoxidised state functions as the oxidant species.

Reactions of this type have been modelled for the oxidation of ascorbic and dihydroxyfumaric acids and methanol using aquocopper ions and copper complexes of 2,2′-bipyridyl.[9]

In the case of the enzyme uricase, O_2 is activated as a result of the formation of a metal–oxygen complex of the superoxide type:

$$Cu\,(I) + O_2 \rightarrow CuO_2^{\cdot}(II),$$

$$CuO_2\,(II) + \text{substrate} \rightarrow Cu\,(I) + H_2O + \text{product}.$$



Here the oxidant species is a metal–oxygen complex of the "superoxide" type.[59]

Xanthine oxidase is the enzyme which catalyses the oxidation of hypoxanthine to xanthine and of xanthine to uric acid.[60] Xanthine oxidase is frequently used to generate O_2 radicals. The active centre incorporates a molybdenum ion, iron sulphur clusters (eight paired Fe atoms), and two FAD molecules. When FAD is removed, the enzyme loses its ability to reduce O_2 but retains its ability to oxidise xanthine. The function of molybdenum thus reduces to oxidising the substrate and the function of the iron–sulphur clusters is to transfer an electron from the reduced molybdenum to FAD, which in fact participates in the reduction of O_2. As for other FAD-dependent oxidases, O_2 is reduced without the formation of a metal–oxygen complex.

Oxygenases can be divided into copper- and iron-containing enzymes. The most typical representatives of the copper-containing oxygenases are tyrosinases, characterised by a multiplicity of forms. The coordination environment of the copper ions in the active centre is similar for enzymes of different origin and is made up of four histidine residues. The inhibition of the enzyme activity of tyrosinases by carbon monoxide indicates the involvement of the reduced form of copper in the process mechanism.[61] The mechanism of the activation of O_2 by tyrosinases has not been established.

Tyrosinase exhibits both hydroxylating and oxidase activities.[62] In the reduced state, the enzyme is capable of reversible binding of O_2, the spectrum of oxytyrosinase resembling that of oxyhaemocyanine. Like the latter, oxytyrosinase decomposes reversibly to a Cu^{2+}-enzyme and H_2O_2.[63] It has been suggested[64,65] that the structure of oxytyrosinase resembles that of oxyhaemocyanine, i.e. the active centre of this enzyme contains two copper ions. This makes it necessary to postulate distinct oxidative properties in the dinuclear copper–oxygen complex. The detection of electrophilic intermediates in the mechanism of the action of tyrosinase[66–68] indicates the possible dissociation of the O–O bond in this complex with formation of species of the type $ECuO^+$.

Within the framework of the concept of PCTC, one can postulate the coexistence of the following states of oxytyrosinase:

R = bridging ligand.

In the presence of the corresponding substrates (mono- and di-phenols), oxytyrosinase exhibits either the properties of Cu^{3+} as an electron acceptor, similarly to the dinuclear centre of the "blue" oxidases, or the properties of an O donor as a hydroxylating species.

Another representative of copper-containing monoxygenases is dopamine β-hydroxylase containing one or two Cu^{2+} ions in the active centre.[64] The activation of the apoenzyme requires two copper ions.[65] Whereas tyrosinase does not require an extraneous electron donor, dopamine β-hydroxylase functions only in the presence of a donor (ascorbate),[42] which reduces the Cu^{2+}-enzyme to the Cu^+-form.

Among iron-containing oxygenases, one may distinguish aromatic aminoacid monoxygenases (phenylalanine 4-monoxygenase, tyrosinase monoxygenase, tryptophan 5-monoxygenase) and hydroxylating enzymes containing cytochrome P-450.

Pterin-dependent aromatic acid monoxygenases contain one non-haem iron ion (Fe^{2+}) in the active centre.

As for the copper-containing oxygenases, the mechanism of the activation of O_2 has not been established. There is only evidence for the formation of a multicomponent charge transfer complex[70] (enzyme, substrate, and a coenzyme as the electron donor), which can decompose in different ways on interaction with O_2. In particular, the oxidation of the coenzyme can lead to the formation of hydrogen peroxide. The influence of the addition of peroxidase and catalase on the process stoichiometry[70] shows that the mechanism of the action of the iron-containing monoxygenases O_2 may be activated both as a result of the formation of the peroxy-type oxygen complex FeO_2 and as a result of the interaction of the reduced enzyme–substrate complex with H_2O_2.

During the last twenty years, the attention of investigators was concentrated on the study of non-specific hydroxylating enzyme systems containing cytochrome P-450.[69,71–77] These enzymes are widely distributed in nature and participate not only in processes involving the hydroxylation of endogenic substrates but also in detoxication reactions of various xenobiotics.[78,79] O_2 and two reduced equivalents, usually NADPH, participate in the substrate hydroxylation processes:

$$SH + NADP\cdot H + H^+ \rightarrow SOH + H_2O + NADP^+.$$

The haem of cytochrome P-450 participates in the activation of O_2, its reduction occurring with the aid of the electron-transport (reductase) enzyme system.[42]

Bacterial cytochrome P-450 has been isolated in a crystalline form and characterised by X-ray diffraction with a resolution of 5.5 Å.[75] The haem iron ion in the active centres of cytochrome P-450 is coordinated to cysteine residues in the 5-position and histidine residues or water in the 6-positions, undergoing comparatively readily a change in the valence spin states. In the reduced form, the enzyme forms a complex with CO, which has an intense absorption band at 447 nm and this has in fact given rise to the name of this group of haemoproteins. Oxidised cytochrome P-450 exists in a low-spin state and, on binding the substrate, it is fully or partly (depending on the temperature, pH, the polarity of the medium, and the nature of the substrate) converted into a high-spin (pentacoordinate) form. The structural aspects of cytochrome P-450 have been examined in reviews[80–83] and also in other communications.[84–90] In the reduced form, cytochrome P-450 exists predominantly in a high-spin state and readily interacts with O_2.[91]

The microsomal hydroxylating system in the liver contains, apart from cytochrome P-450, also NADPH-cytochrome P-450 reductase and phospholipids. The role of NADPH-cytochrome P-450 reductase consists in electron transport from NADPH to cytochrome P-450. The role of phospholipids in the hydroxylation process has not been ultimately elucidated. The phase transition in microsomal phospholipids at 16–25 °C alters sharply the activation characteristics of the oxidation substrates and in many instances leads to a change in the rate-limiting stage of the hydroxylation process. One cannot rule out the possibility that the effect of phospholipids on microsomal oxidation processes is associated with the manifestation of the influence of the local changes in the polarity of the medium, noted above, and the probability of electron transfer. The influence of certain lipids on the conformational states and the equilibrium involving the spin forms of cytochrome P-450 has been recorded.[92–97]

The mechanism of the enzyme reaction involves the formation of an enzyme-substrate complex with the oxidised form of cytochrome P-450 as a result of the binding of the substrate to a site adjoining haem. As a result of local structural changes, the cysteine ligand – iron ion distance changes and there is a corresponding alteration in the symmetry of the ligand environment, the spin state, and the redox characteristics of the iron ion.[98–100] After the one-electron reduction of the enzyme – substrate complex, Fe^{2+} – haem interacts with O_2 to form an oxygenated complex, which in many instances may be isolated and characterised spectroscopically.[101] The substrate is hydroxylated in the subsequent one-electron reduction of the oxygenated complex, which apparently takes place as a result of the formation of a peroxy-type iron – oxygen complex (with strong charge transfer) as the hydroxylating species.

In contrast to copper ions, whose oxidation state changes only within the limits $Cu^{+}-Cu^{3+}$, in the case of haem the range of the possible formal valence state extends from Fe^{+} to Fe^{6+}. Admittedly, the Fe^{3+} state is hardly realisable and in the $Fe^{5+,6+}$ state there is charge transfer from the porphyrin ligand to the central ion. The structural characteristics of iron-porphyrins (PFe) suggest the formation of a peroxy-type oxygen complex in the interaction of PFe^{2+} with O_2:[6]

$$(PFeO_2)^{2+}=P\left(Fe^{2+}\begin{matrix}O\\ \|\\ O\end{matrix}\longleftrightarrow Fe^{4+}\begin{matrix}O^{-}\\ |\\ O^{-}\end{matrix}\right)$$

The transfer of an additional charge to this complex leads formally either to the formation of the oxygen complex PFe^{+} or to the dissociation of the O – O bond in the limiting peroxy-structure:

$$P(FeO_2)^{+}=P\left(Fe^{+}\begin{matrix}O\\ \|\\ O\end{matrix}\longleftrightarrow Fe^{3+}\begin{matrix}O^{-}\\ |\\ O^{-}\end{matrix}\longleftrightarrow Fe^{3+}\begin{matrix}O^{2-}\\ \vdots\\ O\end{matrix}\longleftrightarrow Fe^{4+}\begin{matrix}O^{2-}\\ \vdots\\ O^{-}\end{matrix}\right)$$

On protonation of O^{2-}, the last two states are found to be stoichiometrically equivalent to the structure of compound (I) of peroxidase.[102]

The proportions of the "limiting" structures are determined by the structural-energetic characteristics of the enzyme – substrate complex and the polarity of the medium. The $PFe^{3+}O$ and $PFe^{4+}O^{-}$ states, which may be formed on protonation of a coordinated oxygen dianion, for example, via the transfer of H^{+} from an aminoacid in close proximity, are characterised by a high hydroxylating capacity. An oxenoid mechanism of the insertion of the O atom in a C – H bond is to be expected for the $PFe^{3+}O^{-}$ species and intramolecular oxidation of substrates by a radical mechanism is to be expected for species of the type $PFe^{4+}O^{-}$.[103] The ambiguity of the evidence concerning the radical or oxenoid mechanism of the hydroxylation of various substrates is apparently also associated with the "dual" reactivity of species of the type $PFeO^{3+}$.[42,104,105]

It is of interest to note that the oxidation of many substrates in the microsomal hydroxylating system takes place in the same way also in the presence of hydroperoxides instead of O_2. This indicates the presence of the same type of intermediate species in both systems. Thus the question of the activation of O_2 is indissolubly linked with the question of the activation of hydrogen peroxide in the case of cytochrome P-450 as well as other oxygenases.

Synthesis and properties of α-aminonitriles

Yu M Shafran, V A Bakulev, V S Mokrushin
Kirov Ural Polytechnical Institute, Sverdlovsk

ABSTRACT. The information about the synthesis, chemical, physicochemical, and biological properties, and also the stereochemistry of α-aminonitriles has been classified. The bibliography includes 283 references.

I. Introduction

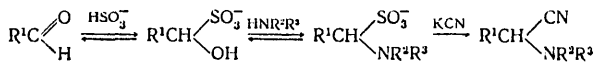
Throughout the period of over 130 years since their discovery, α-aminonitriles have been the subject of study for research scientists in different countries. There is continuous interest in this class of compounds mainly because they are intermediates in convenient preparative methods for obtaining α-amino acids [1] and nitrogen-containing heterocycles,[2] which are biologically important compounds. There has recently been a report about the possibility of the prebiological synthesis of the simplest example of an α-amino-nitrile—aminoacetonitrile—in an interstellar medium[3] as well as under conditions simulating the original atmosphere of the Earth.[4] There is theoretical interest in the mechanisms of the reactions used in the synthesis of α-aminonitriles and also the characteristics of the reactivity of the amino and cyano groups related to their close proximity in α-aminonitriles.

A brief review of methods for synthesising α-aminonitriles is given in one book.[5] The use of the Strecker reaction for obtaining α-aminonitriles has been examined.[6] A further review on α-amino-nitriles has been published in Danish[7] and is difficult to access as a literature source. Classification of the reactions involving α-amino-nitriles and examples of them have been reported in one study,[8] which, however, falls far short of including all known types of reactions of α-aminonitriles. The use of α-aminonitriles in organic synthesis is the topic of another review,[9] which appeared in Japanese in a journal that is difficult to obtain in the USSR.

II. Synthetic methods

1. The Strecker reaction

In 1850 Strecker[10] carried out the synthesis of glycine and alanine by treatment of formaldehyde and acetaldehyde with aqueous solutions of ammonia and hydrocyanic acid followed by hydrolysis of the α-aminoacetonitrile and α-aminopropionitrile formed. This reaction was subsequently extended to ketones and amines and became known as the Strecker reaction.[11]



The replacement of volatile hydrocyanic acid and ammonia by a mixture of potassium or sodium cyanide and ammonium salts was proposed by Zelinskii and Stadnikov.[11] In this case ammonium chlorides or sulphates are reacted directly or are prepared *in situ*.

A modification of the Strecker reaction proposed by Tiemann[11] involves changing the order of mixing the reagents. It is suggested that the increase in yield of α-aminonitriles that often occurs in this case is due to participation of α-hydroxynitriles (cyanohydrins) (I) in the reaction.

(I)

When the aldehydes have low reactivity, their bisulphite adducts (II) are subjected to the Strecker reaction. When primary and secondary α-aminonitriles are prepared, the reaction is carried out in water with ammonium or alkylammonium salts in the presence of an excess of free base. This form of the Strecker reaction has become known as the Knoevenagel–Bucherer method.[6] The closest parallel with it in the Soviet literature[11] is given by the first two stages of the Bucherer–Bergs reaction,[12] in which adducts (II) are also frequently used.

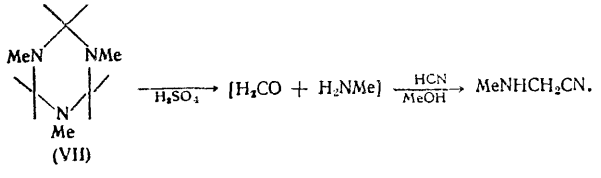
(II)

In recent years the Strecker reaction itself[13–29] as well as the Zelinskii–Stadnikov,[6,16,30–48] Tiemann,[12,52–55] and Knoevenagel–Bucherer[6,55–58] modifications have been repeated many times on other substrates. Furthermore, the Strecker reaction in a broad sense has been considerably extended by the use of other solvents and sources of amino and cyano groups.

A number of syntheses of α-aminonitriles have been carried out under non-aqueous conditions—in alcohols,[29,59–64] tetrahydrofuran,[65] benzene,[66] in excess amine,[67] and also without any solvent.[68] When

the synthesis is carried out in liquid ammonia, it is necessary to use a low temperature and high pressure,[12,52,69] which makes it difficult to obtain primary α-aminonitriles by this method.[68] By using DMSO–H_2O (9 : 1, 19 : 1, and 20 : 1) systems as the solvent together with water and a water–methanol (1 : 1) mixture, it was possible to increase the yield of a number of α-aminonitriles by improving the solubility of the initial aldehydes.[70]

The role of water in the Strecker reaction is not simply that of a solvent. It was shown[67] that water, including that formed during the reaction, accelerates the epimerisation of a kinetically controlled α-aminonitrile and is therefore a catalyst for the process.



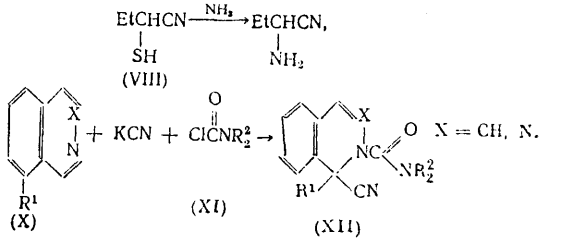
The nature of the products in the Strecker reaction is considerably affected by the pH of the medium, the ratio of reagents, and the reaction temperature. The primary or secondary α-aminonitriles formed initially are capable of undergoing a further *N*-α-cyanoalkylation reaction.[22–25,33–48,71,72] Thus in diamine (III) the hydrogen atoms of the primary amino groups are replaced first of all and then those of the secondary groups are replaced.[71] A high pH value of the medium helps to remove the primary α-aminonitrile (IV) from the reaction as an azomethine (V).[25,73] It is also possible to stop the process at the first or second stages by selecting the ratio of reagents[23,36,39,41,72] or the reaction temperature.[34,41] The exhaustive cyanomethylation of ammonia to give nitrilotriacetonitrile (VI) has been reported in a large number of patents.[22,23,33–48]

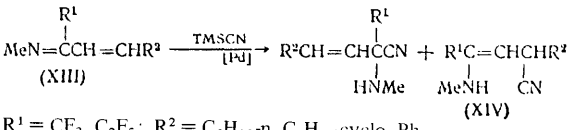
$$H_2NC_2H_4NH_2 \xrightarrow{H_2CO,HCN} NCCH_2NHC_2H_4CH_2CN \xrightarrow{H_2CO,HCN}$$
(III)
$$\rightarrow (NCCH_2)_2NC_2H_4N(CH_2CN)_2,$$

$$NH_3 + H_2CO + HCN \rightarrow H_2NCH_2CN \underset{H^+}{\overset{H_2CO}{\rightleftharpoons}} H_2C{=}NCH_2CN$$
(IV) (V)
$$\downarrow H_2CO, HCN$$
$$N(CH_2CN)_3 \xrightarrow{H_2CO,HCN} HN(CH_2CN)_2 \xrightarrow{H_2CO} H_4C(N(CH_2CN)_2)_2.$$
(VI)

N-α-polycyanoalkylation reactions are catalysed by alkali metal cyanides.[71]

It is possible to use paraformaldehyde instead of formaldehyde in the synthesis of α-aminonitriles (VI). Urotropine [37,41–43,45,74] and 1,3,5-trimethylhexahydro-*sym*-triazine (VII) [49] can serve at the same time as sources of both formaldehyde and ammonia or methylamine. The thermolysis of formamide is a convenient method in the preparative sense for generating a mixture of hydrogen cyanide and ammonia.[75]

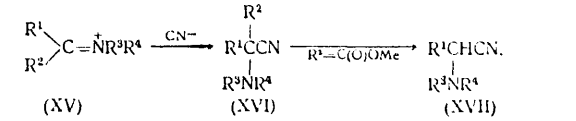




The most significant development of the Strecker reaction has been the introduction of new sources of cyano groups into synthetic use. Acetone cyanohydrin,[67,76,77] isobutyral cyanohydrin,[78] benzoyl cyanide,[79] diethylphosphonocyanide,[65] and trimethylsilyl cyanide (TMSCN) [59,60,68,80] have been used for this. The addition of TMSCN to aldehydes is catalysed by Lewis acids, in particular by zinc iodide,[59] and previously unobtainable α-aminonitriles can be prepared. However, this reagent is susceptible to hydrolysis, and therefore it is necessary to work under absolutely anhydrous conditions. The most acceptable methods for synthesising TMSCN are reported in two studies.[83,84]

A scheme for the extended Strecker reaction has been drawn up to take account of these changes (see Scheme 1 below).

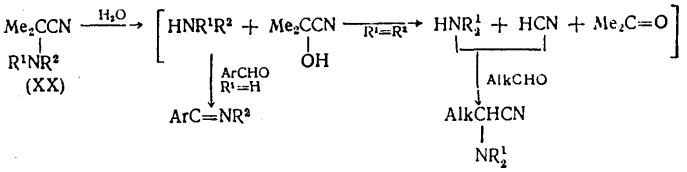
All the reactions positioned on the scheme above the continuous line are reversible. Moreover, the synthesis of α-aminonitriles is also carried out from individual compounds shown on the scheme between the horizontal dotted line and the continuous line. Thus, for example, the amination of cyanohydrins (I) with ammonia or amines[12,25,30,52,53,60,62,64,69,85–96] and even the reaction of α-mercaptobutyronitrile (VIII) with ammonia[30] can be regarded as specific examples of the Tiemann reaction.



The use of Schiff bases such as (IX) [3,19,21,77,79,80,97–100] and hydrazones[101–103] as substrates of CN^- ions has been reported. Aromatic nitrogen-containing heterocycles (X) can be regarded as Schiff bases with an endocyclic C=N bond; when they are treated with potassium cyanide and *N*,*N*-disubstituted carbamoyl chlorides (XI), analogues of Reissert compounds (XII) are obtained.[104] When they are reacted with TMSCN in the presence of palladium compounds, azomethines (XIII) also exhibit properties of 1-aza-1,3-dienes, leading to the formation of by-products (XIV) from 1,4-addition.[100]

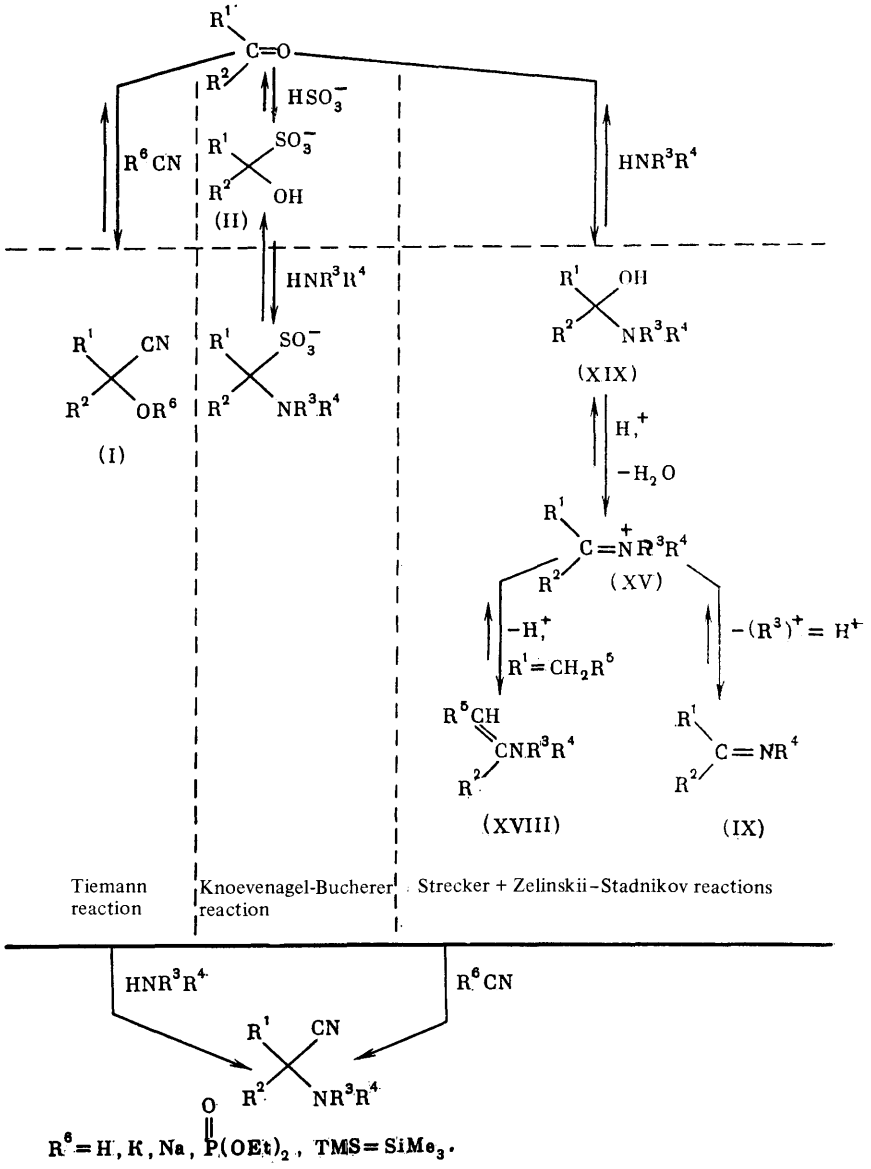
$R^1 = CF_3, C_2F_5$; $R^2 = C_6H_{13}$-n, C_6H_{11}-cyclo, Ph,
HC = CHMe-*trans*.

According to the modified method of Polonovskii–Potier[105] iminium salts of the type (XV) obtained *in situ* are treated with KCN. When a methoxycarbonyl group is present on the reaction centre it can be eliminated, and as a result demethoxycarbonylation products (XVII) are formed together with α-aminonitriles.[106,107]



The addition of hydrocyanic acid to enamines such as (XVIII) in a basic medium also gives α-aminonitriles.[108] All this naturally raises the question about the mechanism of the expanded Strecker reaction.

This problem was examined in the greatest detail in two studies.[67,96] However, the results obtained in them are ambiguous. Thus, for example, in one article,[96] α-aminonitriles obtained by the Strecker and Tiemann reactions have the same optical purity. On the basis of this experiment the authors rejected a mechanism involving stereochemical control of the reaction due to steric hindrance in attack on cyanohydrins (I) and considered the stereoselective addition of HCN to geometric isomers of Schiff bases of the type (IX) more likely. In the other study[67] it was concluded that cyanide ions most probably add on to ketiminium cations of



the type (XV), the presence of which in the reaction mixture was reliably detected. Moreover, the authors did not rule out the possibility of α-aminonitriles being formed by S_N2 attack of CN^- on aminoalcohols such as (XIX).

Valuable information about the mechanism of this reaction was obtained when the "retro-Strecker" decomposition of α-aminonitriles was analysed. This process occurred in water at different pH values,[109,110] during mass spectrometry,[111] during vacuum flash thermolysis, gas-phase pyrolysis, and thermolysis.[112] It was shown that the decomposition of *N*, *N*-dialkyl-α-aminonitriles occurs via ketiminium ions such as (XV).[109] In the case of primary and secondary α-aminonitriles, intermediates of the type (XV) are also formed, but they are much more difficult to identify because of their rapid conversion to Schiff bases.

The molecular ions generated from primary and secondary α-aminonitriles eliminate HCN to give Schiff bases, and only in the case of tertiary α-aminonitriles does the elimination of an amino group predominate, corresponding to a "retro-Tiemann" reaction.[111] The latter type of decomposition was also demonstrated for aqueous solutions of isobutyronitriles (XX) from the chemical reaction of its products.[113]

Scheme 1

A reliable determination of the mechanism of the Tiemann reaction is made possible by comparing the yield of α-aminonitriles obtained by this and other methods. In one study[63] it was shown that the yield of a number of α-aminonitriles from cyanohydrins such as (I) is invariably higher than from azomethines such as (XVIII). The difference between the Tiemann reaction and the "classical" Strecker reaction is also exhibited when TMSCN is used as the cyano group donor. In this case, however, the Strecker variant is more favourable because of the low thermal stability of cyanohydrins of the type (I) (where R^6 = TMS).[68]

The data given indicate that in some cases cyanohydrins of the type (I) lie within the sphere of the Tiemann reaction. By and large the mechanism of the Strecker reaction is not universal and depends on the nature of the solvent and the reagents and also on the order in which they are mixed.

The various forms of the Strecker reaction differ slightly with respect to their synthetic possibilities. Thus, out of the very large number of α-aminonitriles obtained by the Strecker reaction only compound (XXI) contains a substituent with distinct electron-withdrawing properties on the α-carbon atom.[17] When TMSCN was it was possible to add to this a number of compounds such as 2-amino-(4-cyano- and 4-carboxymethyl-phenyl)acetonitriles (XXII).[59] It should be noted that the yield of α-aminonitriles (XXII) is considerably lower than for the analogous compounds not containing strong electron-withdrawing groups at the α-position (15%, 17%, and 90–99% respectively).[59] α-Aminonitriles with strong electron-withdrawing groups at the 2-position, synthesised from cyanohydrins, also constitute a small proportion of the total number of compounds obtained by such methods, but nevertheless ten 2-amino-2-fluorocarbonitriles (XXIII) [86] and six 2-carbonyl-amino-2-(2-, 3-, and 4-nitrophenyl)acetonitriles (XXIV) [66] are among them.

$R^1C_6H_4CHO + H_2NR^2 \xrightarrow[AcOH+H_2O]{KCN} R^1C_6H_4CHCN,$ with HNR^2

(XXI)

$R^1 = NO_2\text{-}2;\ R^2 = Ph,\ C_6H_4Me\text{-}4.$

$4\text{-}R^1C_6H_4CHO + TMSCN + NH_3 \xrightarrow{MeOH} 4\text{-}R^1C_6H_4CHCN,$ with NH_2

$R^1 = CN,\ COMe.$ (XXII)

$R^1R^2CFCHCN \xrightarrow{H_2NR^3} R^1R^2CFCHCN,$ with OH and HNR^3

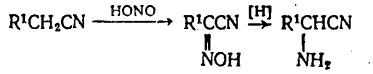
(XXIII)

$R^1 = Alk^1,\ R^2 = Alk^2,\ R^1 + R^2 = (CH_2)_n,\ n = 4.5.$

$R^1C_6H_4CHCN + HNCR^3 \rightarrow R^1C_6H_4CHCN,$ with OH, O, R^2, NCR^3, O

(XXIV)

$R^1 = NO_2\text{-}4,\ NO_2\text{-}3,\ NO_2\text{-}2;\ R^2 = H,\ Et;\ R^3 = OEt,\ NH_2.$



It should be noted that in the latter reaction weakly basic compounds such as urethane and urea are used as the amino components. Apart from urea and urethanes,[62,65] benzamide[54] and formamide[91,92] also react with cyanohydrins.

A comparison of two other modifications of the Strecker reaction (the Zelinskii–Stadnikov and Knoevenagel–Bucherer methods) on eight substrates has been carried out.[6] It showed that the first method is suitable for preparing *N*-adamantyl and *N*-benzyl derivatives of α-aminonitriles, while catalysis with sodium metabisulphite is advisable for the synthesis of primary α-aminonitriles. In this case it was only possible to obtain 2-methylamino-2-(4-benzyloxyphenyl)acetonitrile using the Knoevenagel–Bucherer method. These results indicate that the choice of a specific modification of the Strecker reaction can also be determined by the nature of the substituent in the amino group of the target compounds.

Thus, by using the Strecker reaction and its modifications with various sources of the cyano group, catalysts, and solvents it is possible to obtain a variety of α-aminonitriles in a relatively simple manner, but α-aminonitriles with strong electron-withdrawing groups at the 2-position are not very amenable to synthesis.

2. Other methods

A further limitation of the Strecker reaction is the difficulty in obtaining α-oxo- and α-cyano-aldehydes, so that 2-amino-3-oxopropionitrile and 2-aminomalonitrile cannot be prepared by it. In this case the synthesis of primary α-aminonitriles is carried out by reduction of accessible 2-hydroxyiminoacetonitriles (XXV) with sodium dithionite,[114,115] aluminium amalgam,[116–120] and bis(2-methoxyethoxy)aluminium hydride.[121] Reduction of *N*-benzyl-2-cyano-2-hydroxyimino acetamide is complicated by rearrangement of the intermediate α-aminonitriles to ethylenediamines (XXVII) and (XXVIII).[121]

$R^1CH_2CN \xrightarrow{HONO} R^1CCN \xrightarrow{[H]} R^1CHCN$, with NOH and NH_2

(XXV) (XXVI)

$B_2NHCOCCN \xrightarrow{[H]} B_2NHC_2H_4NH_2 + B_2NHC_2H_4NHMe$, with NOH

(XXVII) (XXVIII)

$R^1 = CN,\ CR^2.$

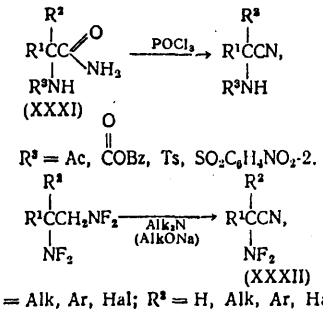
The reduction of derivatives of 2-hydroxyimino-2-cyanoacetic acid with alkali metal dithionites,[122] hydrogen on platinum,[123] and zinc dust[124,125] in simple organic acids or their anhydrides results in the formation of *N*-acylated α-aminonitriles. When these reactions are carried out it is necessary to bear in mind that the cyano group in the α-aminonitrile formed is also susceptible to reduction.

Direct introduction of an amino group into the 2-position of malonodinitrile is achieved by treating it with *O*-(2,4,6-trimethoxyphenylsulphonyl)hydroxylamine.[126]

It is possible to increase the number of α-aminonitriles by transaminating them; the yield of the secondary compounds (XXIX) in this case amounts to 13–82%.[127] Introduction of an amino group also takes place by treatment of 2-haloacetonitriles with a twofold excess of ammonia or primary amine.[128]

$R^1CCN + HNR^5R^6 \rightleftarrows R^1CCN + HNR^3R^4,$ with R^3NR^4 and R^5NR^6

(XXIX)



$R^1CCN + H_2NR^3 \rightarrow R^1CCN,$ with Hal and HNR^3

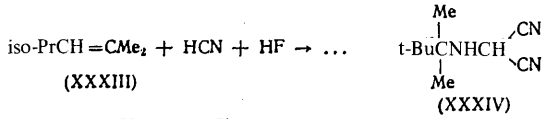
(XXX)

$R^1 = C_nH_{2n+1},\ n = 1 - 11,\ Ph;\ R^2 = H,\ Me;\ R^3 = H,\ C_6H_4Cl\text{-}4,$ CH (Me) Ph; Hal = Cl, Br.

The other group of methods for synthesising α-aminonitriles is made up by reactions that form a cyano group in amines. One of these, for example, is the dehydration of *N*-substituted α-amino-amides (XXXI) with phosphorus oxychloride.[129] However, this method has no synthetic value since the initial amides (XXXI) are, in turn, usually obtained from α-aminonitriles. A process which is

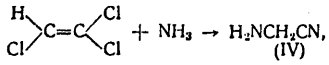
formally the reverse of reduction of α-aminonitriles forms the basis for obtaining *N*,*N*-difluoro-α-aminonitriles (XXXII).[130]

(XXXI)



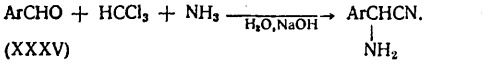
R^3 = Ac, COBz, Ts, $SO_2C_6H_4NO_2$-2.

(XXXII)



R^1 = Alk, Ar, Hal; R^2 = H, Alk, Ar, Hal.

The simultaneous introduction of amino and cyano groups is achieved when the olefin (XXXIII) is reacted with hydrocyanic and hydrofluoric acids. 2-*N*-Alkylaminomalononitrile (XXXIV) has been identified among the products of this reaction.[131] Treatment of 1,2,2-trichloroethylene with ammonia at high pressure is the most effective method for synthesising aminoacetonitrile.[132,133]



The synthesis of primary α-aminonitriles from aromatic aldehydes (XXXV), chloroform, ammonia, and water in the presence of alkali at a raised temperature and pressure[134] should be noted in particular. A study of the mechanism of this reaction could show whether its resemblance to the Strecker reaction is purely superficial. The scope for applying this method,[134] however, is limited to aldehydes (XXXV) that are readily soluble in chloroform.

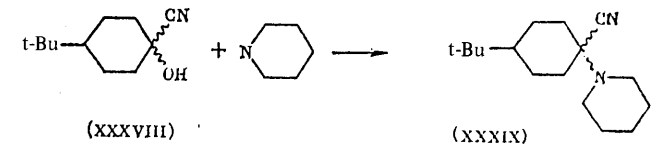
(XXXV)

III. Stereochemistry

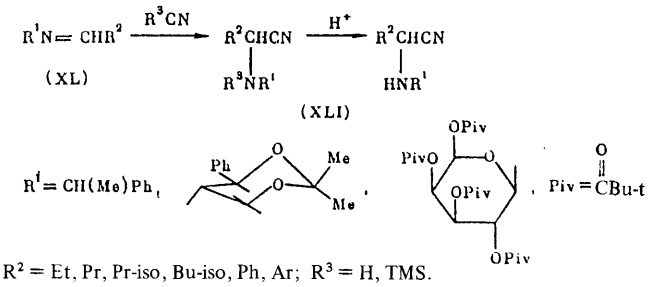
α-Aminonitriles are widely used for the synthesis of α-amino acids, whose biological activity depends fundamentally on their configuration.[1] Therefore, a considerable amount of attention has been given by synthetic chemists to stereoselective methods for obtaining α-aminonitriles.



It was possible to obtain optically active products from the Tiemann reaction by introducing just one optically pure reagent into it. Thus, for example, the reaction of optically active cyanohydrins with ammonia or amines occurs with a considerable degree of inversion of the chiral centre.[86] From a racemic mixture of cyanohydrins (XXXVII), the (*R*)-form predominantly reacts with (*S*)-amines (XXXVI).[96] When the latter reaction was carried out according to the Strecker method this also gave an optically active product, which had an optical purity that differed slightly from that achieved in the first method (36–51% and 44–48% respectively).[96]

(XXXVI) (XXXVII)

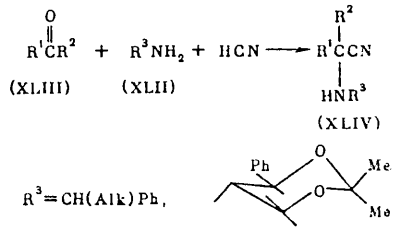
R^1 = Me, COOH; R^2 = Ph; $C_{10}H_7$; R^3 = Me, Et, Pr-iso, CH_2Pr-iso.



Under quasi-kinetic conditions, piperidine mainly attacks axially the conformer of 4-t-butylcyclohexanone cyanohydrin (XXXVIII) with an equatorial configuration of the cyano group.[67] In the presence of water the kinetically controlled α-aminonitrile (XXXIX) rapidly epimerises.

(XXXVIII) (XXXIX)

The correspondence between the thermodynamic properties of the racemisation of optically active secondary α-aminonitriles and those for their decomposition to Schiff bases and hydrocyanic acid indicates that there is a common mechanism for these two processes.[135]



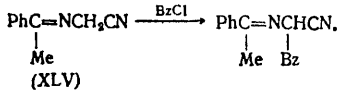
The addition of HCN and TMSCN to the C=N bond of Schiff bases (XL) also takes place stereoselectively; the optical purity of α-aminonitriles (XLI) is improved when a bulky R^1 substituent is introduced into compounds (XL) and when the addition of TMSCN is carried out in the presence of Lewis acids.[4,20,61,97,98,136–139]

(XL) (XLI)

R^2 = Et, Pr, Pr-iso, Bu-iso, Ph, Ar; R^3 = H, TMS.

An asymmetric Strecker synthesis has also been used widely to obtain optically active α-amino acids.[20,61,96,136–140] The amino components used in it are amines that are readily separated into enantiomers and containing those substituents which are readily eliminated from the required α-amino acids. Among such substituents are *N*-phenylalkyl, removed by hydrogenation of palladium, and *N*-(2,2-dimethyl-4-phenyl-1,3-dioxan-5-yl), which is eliminated on oxidation. The presence of the latter substituent in amine (XLII) gives better results.[20,61,136–140] Thus, the (*S*)-(−)-α-amino acid is obtained from amine (XLII) with a (4*S*,5*S*)-(+)-configuration, while the (*R*)-(+)-α-amino acid is obtained from the (4*R*,5*R*)-(−)-amine. It should be noted that only ketones (XLIII) (R^1 and $R^2 \neq$ H) are suitable for conducting the asymmetric synthesis; otherwise asymmetric transformation of the chiral centre formed in α-aminonitriles (XLIV) will occur during the reaction.[136]

(XLIII) (XLII) (XLIV)



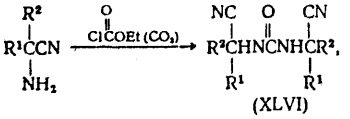
R^3 = CH(Alk)Ph,

In contrast to the Tiemann reaction, dehydration of α-aminoamides occurs with retention of configuration.[128]

In the remaining cases a racemic mixture of enantiomeric α-aminonitriles is formed. In order to resolve this, either fractional crystallisation[135] or salt formation with optically pure organic acids such as tartaric acid[57,141-143] and its derivatives[143] and brucine[89] are used. In one study[141] it was possible to obtain pure isomers only when this reaction was carried out in the presence of ketones.

IV. Chemical properties

α-Aminonitriles can contain a different number of reaction centres. Thus, for example, *C*-benzylation of compound (XLV) occurs on its methylene group.[144]

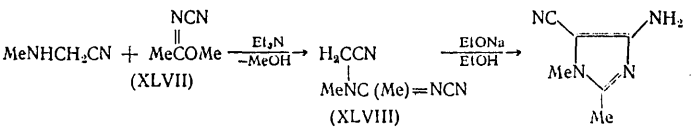


C-Alkylation,[145] *C*-bromination,[146] and intramolecular interaction between the cyano and methylene groups[147] have also been reported. Ammonia[148] and hydrazine[149] replace the ethoxyl group in ethyl 2-amino-2-cyanoacetate.

However, the overwhelming majority of reactions of α-aminonitriles involve their amino and cyano groups. In making a convenient presentation of the material, these two classes of reactions are described in the respective sections. The syntheses that involve both amino and cyano groups also shed light on the reactivity of these functional groups in α-aminonitriles. Moreover, intermediates have been isolated in some of them. However, in view of the importance of α-aminonitriles for heterocyclic chemistry, reactions of the latter type have been grouped in a separate section of this review.

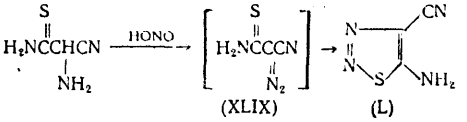
1. Reactions of the amino group

The amino group in α-aminonitriles is quite basic and therefore readily undergoes characteristic reactions. Primary and secondary α-aminonitriles undergo *N*-acylation,[26,58,77,84,90,120,123,124,135,142,150-155] which is a reason for their use in peptide synthesis.[156,157] Removal of the protecting group causes certain difficulties since the cyano group in α-aminonitriles is sensitive to both acids and bases. In this respect it is convenient to use a 2-nitrophenylsulphenyl protecting group, which is readily removed on treatment with hydrochloric acid.[128]



When primary α-aminonitriles are treated with half the quantity of ethyl chloroformate or an equimolar quantity of carbon dioxide[12,159] it is possible to obtain symmetrical ureas (XLVI).

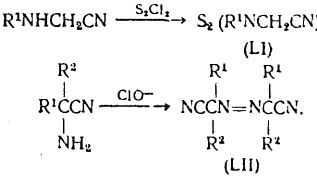
(XLVI)



$R^1 = H$, Me; $R^2 = H$, Me, Et.

The synthesis of asymmetric ureas and thioureas starting from α-aminonitriles can be achieved with the use of isocyanates[160] and isothiocyanates[149,161] respectively. The reaction of primary α-aminonitriles with aldehydes[70,73,162] and ketones[163-165] gives azomethines. When primary α-aminonitriles were treated with ortho esters and imidates under mild conditions, the corresponding *N*-substituted imidates were obtained.[166-172] On the other hand, the base-catalysed addition of *N*-cyanoimidate (XLVII) to *N*-methylaminoacetonitrile results in elimination of the methoxyl group and formation of amidine (XLVIII), which cyclises under these conditions without participation of the cyano group from the initial α-aminonitrile.[173]

(XLVII) (XLVIII)

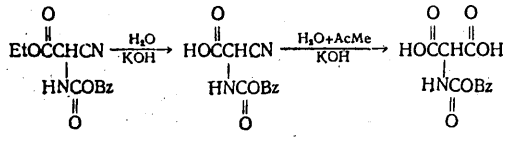


N-Alkylation of primary and secondary α-aminonitriles was carried out using derivatives of acrylic acid;[174-176] tertiary α-aminonitriles were quaternised with alkyl halides in propanol and acetone.[177] 9-Chloroacridine derivatives arylate the amino group of primary α-aminonitriles.[178,179] Diazotisation of primary α-aminonitriles gives 2-diazonitriles;[117,150,180-183] the diazothioamide (XLIX) generated in this way cyclises to 5-amino-1,2,3-thiadiazole (L) during the reaction.[184,185]

(XLIX) (L)

Primary α-aminonitriles undergo an azo–amino interaction with diazonium salts to form triazenes, which then cyclise to heterocycles containing three nitrogen atoms.[186,187]

N-Chlorination of primary and secondary α-aminonitriles is carried out with chlorine[188] and isopropyloxonium chloride.[189] Replacement of the hydrogen atoms of the amino group in α-aminonitriles by a cyano group is carried out using cyanogen chloride.[190] The reaction of secondary α-aminonitriles with 98% nitric acid results in the formation of *N*-nitro derivatives.[191] The synthesis of diaminodisulphides (LI) from secondary α-aminonitriles and sulphur monochloride has been reported in a patent.[192] Oxidation of primary α-aminonitriles with alkali metal hypochlorites in an organic solvent gives azobisnitriles (LII).[193]



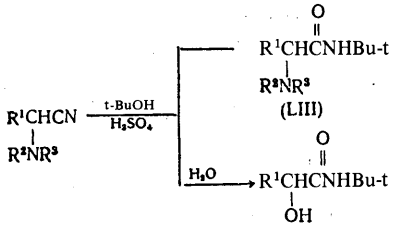
(LI)

(LII)

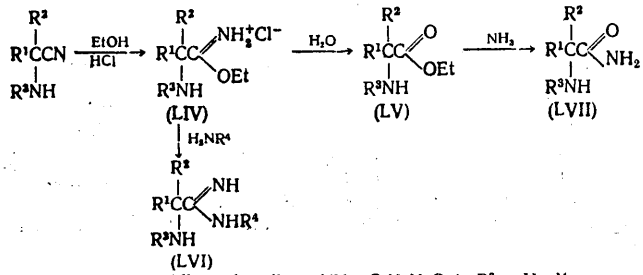
2. Reactions of the cyano group

Historically the first and most important use of α-aminonitriles has been their hydrolysis to the corresponding α-amino acids,[1] which are widely used in organic synthesis, medicine, agriculture, and other areas of the economy. The hydrolysis is carried out in aqueous and water–ethanol solutions[99] of mineral acids (hydrogen halide[50,51,71,80,86,88,96-99,141] or sulphuric acids[71] and also bases.[10,47,71,72,133,142,194-199] In one patent[200] the hydration of α-aminonitriles on polymer-bonded *N*-acyl-4-piperidones is reported.

When there are other groups that are susceptible to hydrolysis in the α-aminonitrile molecule, the reaction can be caried out selectively by choosing a suitable solvent.[201]



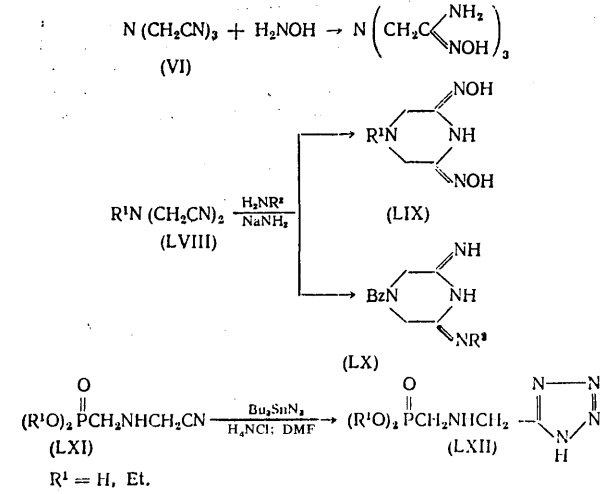
The reaction of α-aminonitriles with water is catalysed by compounds and alloys of zinc, cadmium, and boron,[64,87] and also by iron(III) chloride.[90]



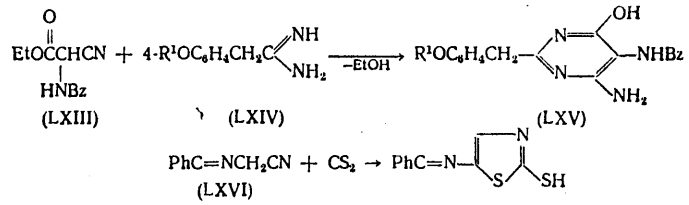
When suitable conditions (concentrated sulphuric acid at room temperature[202] or aqueous alkali in the presence of ketones[197,203]) are chosen, it is possible to discontinue the hydrolysis of α-aminonitriles at the stage when α-aminoamides are formed. On the other hand, dilution of the sulphuric acid and raising the reaction temperature[202] or increasing the time of contact with alkali[197] results in the conversion of aminoamides to amino acids.

The directed synthesis of α-aminoamides is carried out by treating α-aminonitriles with aqueous hydrogen peroxide.[204] It is possible to hydrate selectively one cyano group in polycyanomethylamines using this method.[204]

N-t-Butyl α-aminoamides (LIII) were obtained by the Ritter reaction, which was complicated in a number of cases by hydrolysis of the tertiary amino group.[205]

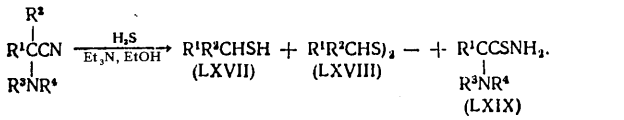


The reaction of α-aminonitriles with alcohols in the presence of hydrogen halides under anhydrous conditions gives the corresponding imidates (LIV),[86,206,207] which can then be converted to esters (LV) [128] or amidines (LVI).[206] In aqueous ethanol in the presence of hydrogen chloride the initially formed imidates (LIV) are spontaneously hydrolysed to esters (LV),[27] which can be converted to the corresponding amides (LVII).[207]



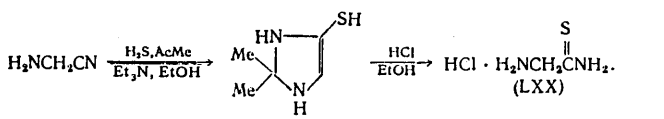
R^1 = H, Alk, Alk-cyclo, alkenyl,Ph, C_6H_4MeO-4; R^2 = H, Me; R^3 = H, Me, Ph, Ar, C(O)C_5H_{11}; R^4 = H, Bz.

Nitrilotriacetonitrile (VI) can add on 3 moles of hydroxylamine directly.[208] In the presence of sodamide, dicyanomethylamines (LVIII) add on primary amines to give 2,5-diiminopiperazines (LIX) and (LX).[208] The α-aminonitriles (LXI) add on azide ions to give tetrazoles (LXII).[209]

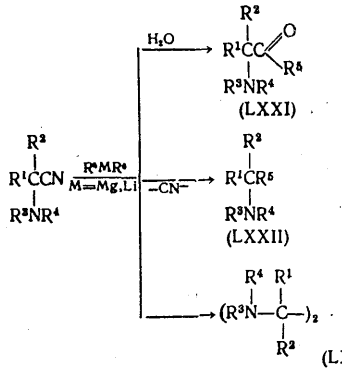


R^1 = H, Et.

The *N*-benzyl protecting group excludes the amino group of compound (LXIII) from the reaction with amidines (LXIV), which results in the formation of pyrimidines (LXV).[210] In a similar manner carbon disulphide does not affect the benzylidenamino group in the aminoacetonitrile derivative (LXVI).[164]



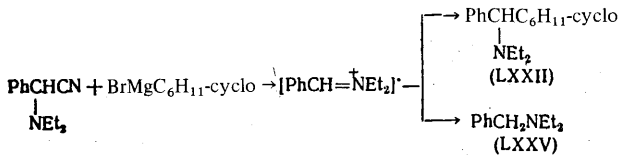
In the examples given α-aminonitriles undergo reactions that are typical for nitriles in general.[211,212] On the other hand, addition of carbon disulphide to α-aminonitriles usually gives a mixture of thiols (LXVII), disulphides (LXVIII), and α-aminothioamides (LXIX).[26,56,120] In this case the latter component is only stabilised when R^1 = H; R^2, R^3, R^4 = Ph, H, iso-Pr; $C_6H_3(MeO)_2$-3, 4, H, Me; $C_6H_3(MeO)_2$-3, 4, Me, Me; Ph, Me, Me; $C_6H_3(MeO)_2$-3, 4, H, Ph; Ph, H, H; t-Bu(O)C, R^3 + R^4 = Phth



The reaction of α-aminonitriles with hydrogen sulphide followed by oxidation of the initially formed thiols so that disulphides (LXVIII) can be obtained deliberately is reported in a patent.[213]

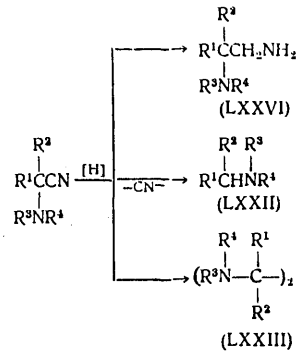
The synthesis of 2-aminothioacetamide hydrochloride (LXX) was successfully carried out in two stages.[214]

The reactions of α-aminonitriles with organometallic compounds also occur in a unique manner. Thus, for example, in the reaction of α-aminonitriles with Grignard reagents and lithium alkyls, products



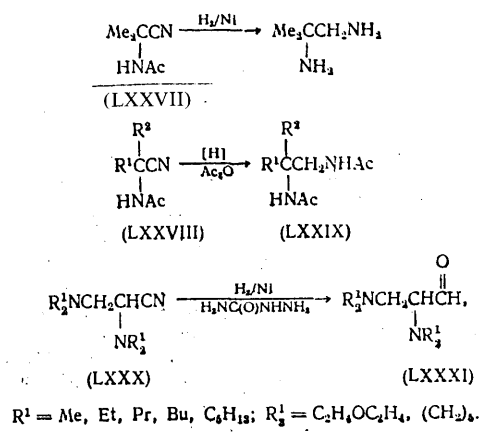
with a "normal" structure—α-aminoketones (LXXI)—have been detected.[77,215] However, a more typical course for the reaction of α-aminonitriles with organometallic compounds is replacement of the cyano group by the radical R^5, resulting in the formation of amines (LXXII).[77,216,217] In two studies[218,219] the formation of diamines (LXXIII) has been recorded in the reaction between α-aminonitriles and Grignard reagents.

(LXXIII)



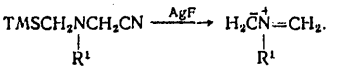
The general mechanisms of the reaction between α-aminonitriles and organometallic compounds has been discussed in a review.[220] They are determined by the nature of the α-aminonitriles themselves and the reagents. Thus, for example, it was observed that an increase in the degree of substitution of α-aminonitriles and the size of the substituents R^3 and R^4 leads to a change in the ratio of aminoketones (LXXI) to amines (LXXII) in favour of the former;[219] the sole products of the reaction between *N*-acetyl-α-aminonitriles and Grignard reagents and alkyllithium are compounds (LXXI).[77] Derivatives of aminoacetonitrile that are not substituted on the carbon atom react with alkylmagnesium halides to give mainly substitution products (LXXII).[77] In general, replacement of the Grignard reagent by alkyllithium [77] and dialkylmagnesium[215] assists in the formation of products (LXXI) derived from addition on the cyano group.

In one study[218] using a deuterium label it was possible to determine the mechanism of the reaction of α-aminonitriles (LXXIV) with cyclohexylmagnesium bromide, which gave a compound of the type (LXXII) and a reduction product (LXXV)



The other group of reactions of the cyano group that is closely related to that just considered is made up by the reactions of α-aminonitriles with reducing agents. Thus, for example, when α-aminonitriles are reduced with sodium in a water–ether emulsion[221,222] and boiling toluene,[223] with hydrogen on Raney nickel, platinum, and palladium,[224] and also with lithium aluminium hydride,[225] the same by-products (LXXII) and (LXXIII) are formed as in the reaction with organometallic compounds. In general, these reducing agents can in principle be regarded as a special case of "organometallic" compounds in which hydrogen or aluminium plays the role of the metal and H· represents the "organic" radical.

At the same time there have been reports about the reduction of α-aminonitriles with hydrogen on Raney nickel,[58,224] platinum, and palladium,[224] lithium aluminium hydride,[70,142] and also diborane and diisopropylbutylaluminium [70] giving exclusively "normal" products—ethylenediamines (LXXVI). As hydrogen is evolved it reduces α-aminonitriles to compounds of the type (LXXVI) only when R^1 and R^2 = Ar.[221] Otherwise the formation of products (LXXII) from the reductive elimination of the cyano group (LXXII) [221–223] and their dimers (LXXIII) occurs. Hydrogenation of α-aminonitriles on Raney nickel, platinum, and palladium [224] also generally gives a mixture of compounds such as (LXXVI) and (LXXIII). When the reaction is carried out in an alcoholic solution of ammonia, the formation of dimers of the type (LXXIII) is inhibited.[226] When treated with sodium borohydride [227,228] and hydrogen on palladium oxide in 0.5 *N* hydrochloric acid,[54] α-aminonitriles are selectively converted to products of the type (LXXII) derived from the reductive elimination of the cyano group.

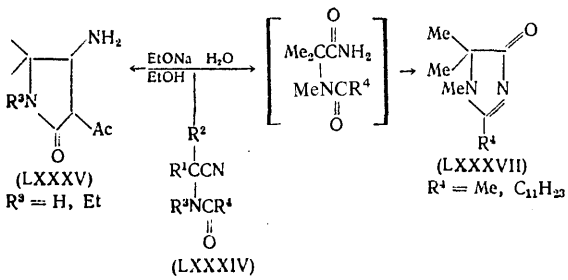


In the reaction of α-aminonitriles with lithium aluminium hydride, an excess of reducing agent[218] assists the formation of diamines of the type (LXXVI), the presence of aluminium chloride [229] favours the formation of amines (LXXII), and the formation of dimers such as (LXXIII) is assisted by an excess of initial α-aminonitrile [225] and a high reaction temperature.[230] The course of the reaction is also related to steric factors.[231]

Reduction of the cyano group in α-aminonitriles may be accompanied by side reactions. Thus, for example, the hydrogenation of *N*-acetyl-α-aminonitriles (LXXVII) on Raney nickel takes place concurrently with removal of the protecting group.[232] Reduction of the acetyl derivative (LXXVIII) in acetic anhydride, on the other hand, gives the diacylated product (LXXIX).[233] An exception to the general pattern of reactions of α-aminonitriles with reducing agents is the hydrogenation of compounds (LXXX) on Raney nickel in the presence of semicarbazide to give α-aminoaldehydes (LXXXI).[234]

R^1 = Me, Et, Pr, Bu, C_6H_{13}; R^1_2 = $C_2H_4OC_2H_4$, $(CH_2)_5$.

Treatment of *N*-trimethylsilyl-α-aminonitriles with silver fluoride results in elimination of the trimethylsilyl and cyano groups with formation of azomethine ylides (LXXXIII).[235,236]

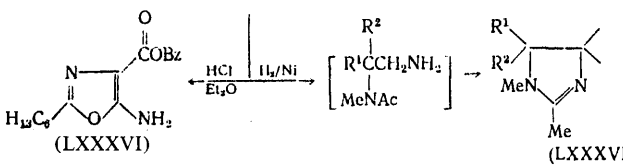


(LXXXII) (LXXXIII)

3. Reactions of the amino and cyano groups

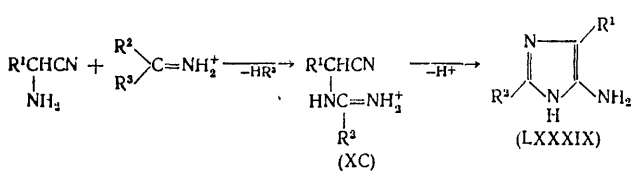
(a) α-Aminonitriles in the synthesis of heterocycles

Usually both nitrogen atoms of the initial molecule are retained when α-aminonitriles undergo heterocyclisation, while one of them can be converted to an exocyclic amino functional group. This nitrogen atom always originates from the cyano group in α-aminonitriles.



α-Aminonitriles that contain not less than one double bond in the amino functional group will undergo heterocyclisation. Thus, for example, *N*-acylated α-aminonitriles (LXXXIV) can, depending on the conditions, cyclise to pyrrolidones (LXXXV),[237] the oxazole (LXXXVI),[238] imidazolinones (LXXXVII),[38,238] or imidazolines (LXXXVIII).[58]

(LXXXV) R^3 = H, Et

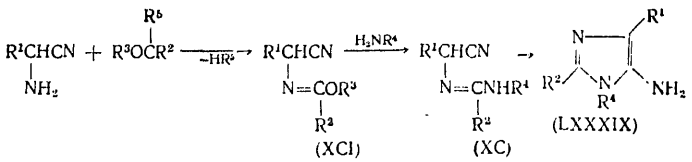


(LXXXIV)

(LXXXVII) R^4 = Me, $C_{11}H_{23}$

(LXXXVI) (LXXXVIII)

The reactions of primary α-aminonitriles with immonium salts are widely used for the synthesis of 5(4)-aminoimidazoles (LXXXIX). The reaction of α-aminonitriles with amidines,[90,149,239] imidates,[240–244] and thioimidates [242,245,246] is accompanied by elimination of ammonia, alcohols, and mercaptans respectively. In one study[242] an intermediate of the type (XC) was isolated in a pure state



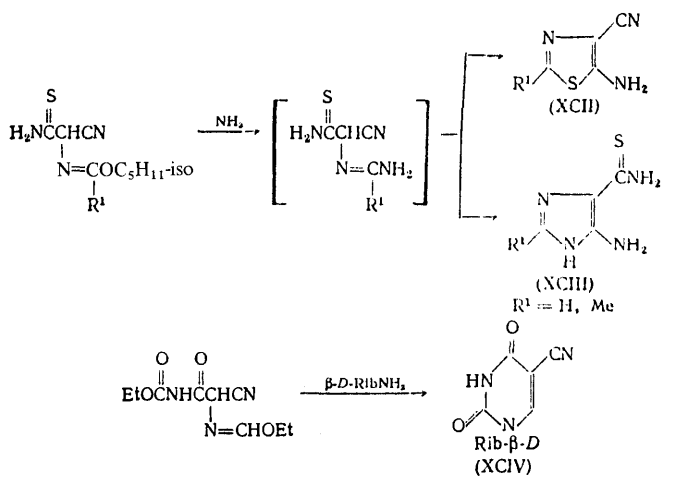
(XC) (LXXXIX)

R^1 = H, Ph, C_6H_3OMe-4, COEt, COPr-iso, COBz, COPh, COC_6H_4Cl-4, CNH_2, CONHMe, CNHEt, CNHPh, CN; R^2 = H, Alk, C(=O)C_6H_{11}-cyclo, Bz, glycosyl, CH_2OPh, C_2H_4Ph, COEt, Ar, Het, OMe, SH, SMe, SBz, SPh; R^3 = NH_2, OAlk, SMe, SBz.

However, it should be noted that only condensation of α-aminonitriles with thioimidates achieved a satisfactory yield of imidazoles (LXXXIX).

"Linear imidates" (XCI), obtained from primary α-aminonitriles and imidates under mild conditions or from α-aminonitriles and ortho esters, when treated with primary amines are also converted to amidines of the type (XC) and then cyclise to aminoimidazoles such as (LXXXIX).[93,168,169,247,248]

(XCI) (XC) (LXXXIX)



R^1 = CPh, COEt, CNH_2, CNHMe, C(=NH)NH_2, CN; R^2 = H, Me, $CH_2CH(OH)CH_2OH$, Bz; R^3 = Me, Et, Bu-iso C_5H_{11}; R^4 = H, Alk, C(=O)C_6H_{11}-cyclo, CHCOEt, *D*-ribofuranosyl, galactosyl, xylopyranosyl, phosphoribosyl

CN

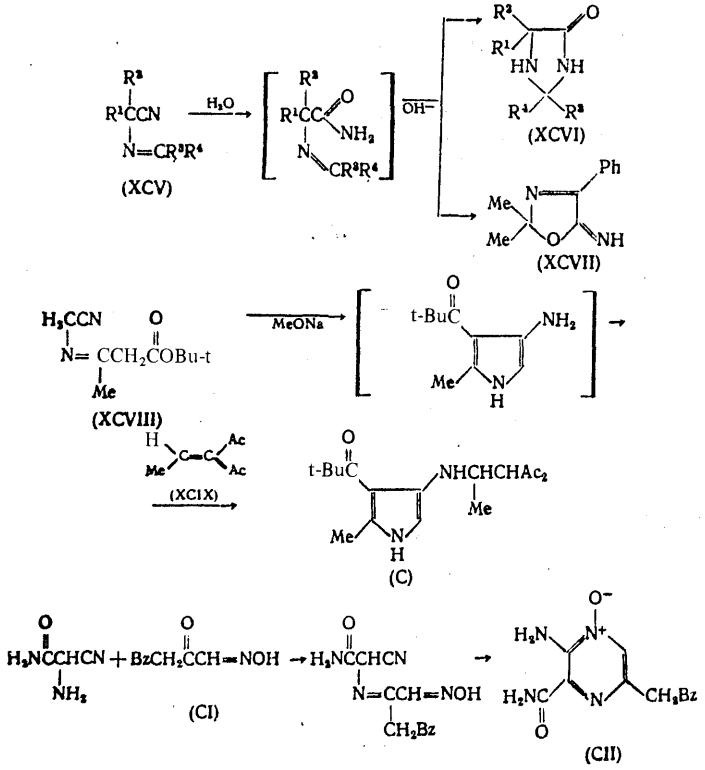
NH_2, NHMe, NMe_2;

R^5 = NH_2; OR^3.

When there are other reactive groups in addition to the cyano group in the "linear imidate" molecule, alternative pathways of cyclisation are possible, leading, for example, to thiazoles (XCII) or imidazoles (XCIII) [249] and pyrimidinediones (XCIV).[250]

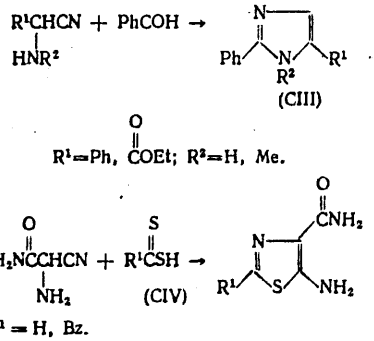
(XCII)

(XCIII)



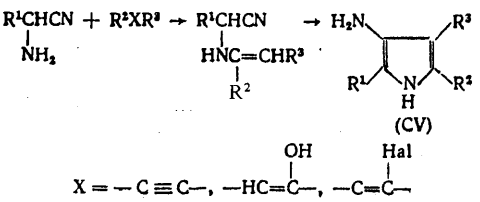
R^1 = H, Me

Rib-β-*D*

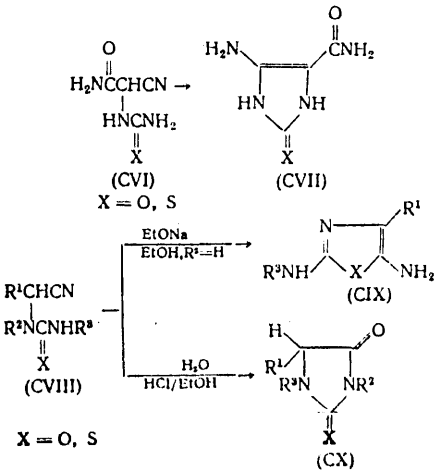


(XCIV)

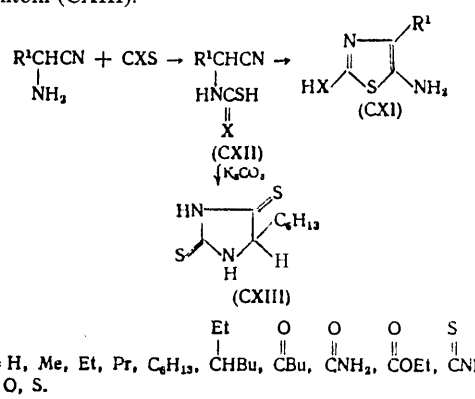
In aqueous alkali solutions azomethines (XCV) are cyclised either to imidazolones (XCVI) or to oxazolimine (XCVII).[164] The first stage in the reaction of azomethine (XCVIII) with the olefin (XCIX) in the presence of sodium methoxide, which gives pyrrole (C) in the end, is apparently intramolecular attack by the methylene group on to the carbon atom of the cyano group in compound (XCVIII).[163] The α-hydroxyiminoketone (CI) can undergo cyclisation with a primary α-aminonitrile in the absence of water to give the



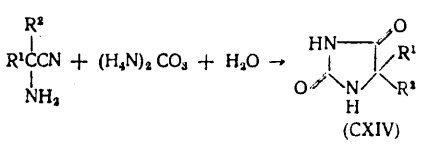
2-aminopyrazine-1-oxide (CII).[251]



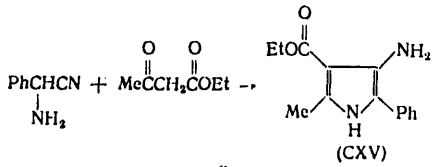
The synthesis of imidazoles (CIII) from secondary α-aminonitriles and benzaldehyde occurs in a different manner.[164] Dithiocarboxylic acids (CIV) constitute another group of condensation agents for α-aminonitriles.[149]



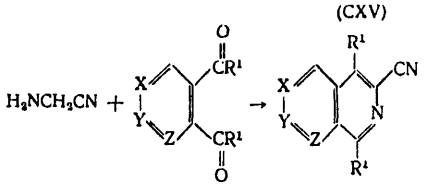
When α-aminonitriles are reacted with acetylenes or olefins that can undergo *cis*-elimination of water or hydrogen halides, 3-aminopyrroles (CV) are formed as final products.[252]



Heterocumulenes constitute a large group of reagents that react with both the amino group and cyano group of α-aminonitriles. A feature of these reagents is that they convert α-aminonitriles directly to aromatic five-membered heterocycles. Thus, for example, the monosubstituted urea and thiourea (CVI), which are obtained from 2-amino-2-cyanoacetamide and potassium cyanate and thiocyanate respectively, are cyclised to 2-oxo- [253] and 2-thio-5-aminoimidazole-4-carboxamides [254] (CVII) respectively. In turn, *N,N*-disubstituted ureas and thioureas (CVIII) in an ethanol solution of sodium ethoxide are cyclised to 5-aminooxazoles [160] and 5-aminothiazoles [148] (CIX). On the other hand, in the presence of hydrogen chloride compounds (CVIII) are converted to the hydantoin[160] and thiohydantoin [161] (CX).

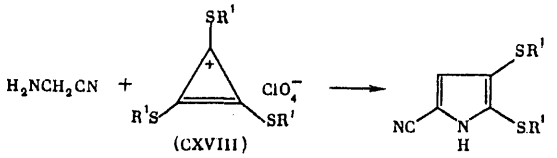


When treated with carbon disulphide[149,159,197,242] and carbon oxysulphide,[255] primary α-aminonitriles are converted to 2-mercapto- and 2-hydroxy-5-aminothiazoles (CXI). In the presence of potassium carbonate a dithiocarbamate of the type (CXII) is cyclised to the dithiohydantoin (CXIII).[256]

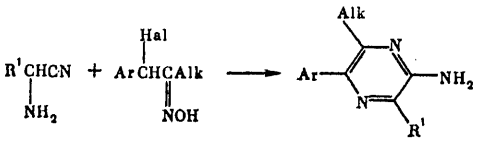


Hydantoins (CXIV) are the final products in the Bucherer–Bergs reaction.[103,157]

Condensation of 2-phenyl-2-aminoacetonitrile with ethyl acetoacetate gives the aminopyrrole (CXV).[257] The reaction of aminoacetonitrile with *o*-dicarbonyl compounds (CXVI), giving condensed pyridines (CXVII), occurs in a different manner.[258–261]



(CXV)



(CXVI) (CXVII)

X, Y, Z = CH, N.

Other bifunctional reagents such as cyclopropenyl cations (CXVIII) [262] and oximes (CXIX) [263] have also been used for the heterocyclisation of α-aminonitriles.

(CXVIII)

(CXIX)

V. Physicochemical properties of α-aminonitriles

Stretching vibrations from the cyano group of α-aminonitriles appear in the region 2210–2250 cm^{-1} in their IR spectra.[98,101,117,128,150,153] When hydroxyl or acetyl groups are present in the α-aminonitrile molecule, the intensity of this band is considerably reduced.[211] Thus, IR spectroscopy is not always a reliable method for confirming the structure of α-aminonitriles; in this respect a more promising method could be mass spectroscopy.[111]

The ^1H and ^{13}C NMR spectra,[20,136,138,140] microwave[3] and EPR [264] spectra of α-aminonitriles have been reported. In one study[265] information about the acid-base properties of aminoacetonitrile is given. It was shown that the experimental pK_a value (5.17) was in good agreement with the results of quantum-chemical calculations of the atomic charges.

VI. Biological activity of α-aminonitriles

At the present time the biological and biochemical properties of α-aminonitriles have been studied quite widely. It has been found, for example, that aminoacetonitrile inhibits different enzymes, including monoamino oxidase,[266–268] dimethylase,[269–271] glycine decarboxylase[272,273] and nitrilase.[258,274] Aminoacetonitrile also has an effect on the contraction of muscles[275–277] and the mechanical properties of bones[278–280] and it inhibits the introduction of gallium into tissues.[281]

In 1983 the first report was published on the antitumour activity of 2-amino-2-phenylacetonitrile derivatives.[66] Three compounds of this series proved to be highly effective towards carcinoma and seminoma in a clinical experiment.

A number of α-aminonitriles exhibit fungicidal[282] and herbicidal[144,154,283] activity.

Synthesis of pyrroles from aliphatic compounds

L N Sobenina, A I Mikhaleva, B A Trofimov
Irkutsk Institute of Organic Chemistry, Siberian Branch, USSR Academy of Sciences

ABSTRACT. The most recent information about the methods for constructing a pyrrole ring from functional aliphatic compounds has been classified and correlated.
The bibliography includes 196 references.

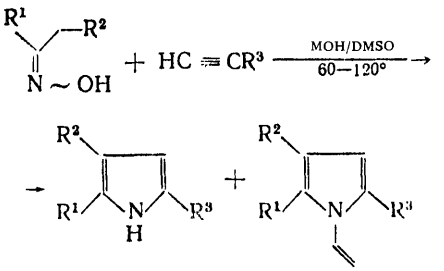
I. Introduction

The pyrrole ring forms part of the molecular structure of many natural and biologically active compounds. Hence the constant interest in the chemistry of pyrroles is understandable. Since the last monographs[1–3] and reviews[4–7] appeared, covering different questions concerning the structure, reactivity, and synthesis of pyrroles, a large number of new studies in this field which require classification and correlation have been published in the literature.

The many methods for synthesising pyrroles can be divided into three main groups: cyclisation of functional aliphatic compounds, conversion of five-membered heterocyclic compounds containing one nitrogen atom in the ring, and conversions of other heterocycles.



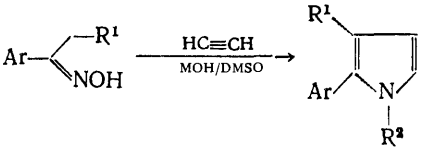
The methods for synthesising pyrroles by cyclisation of aliphatic compounds are usually classified[1,2] according to the number of carbon atoms provided to the pyrrole ring by the initial reagents: $C_2 + C_2$, $C_3 + C_1$, and $C_4 + N$ (C_4-N).

The methods for synthesising pyrroles from aliphatic compounds have undergone considerable development in recent years. They are the subject of the present review, which covers publications from 1980 to 1987 that have, as a rule, not yet appeared in monographs or reviews.

II. $C_2 + C_2$ reactions

1. Pyrroles from ketoximes and acetylene

In recent years there has been the most rapid development of a new general method for constructing a pyrrole ring which is based on the reaction, which was discovered at the beginning of the 1970s, between ketoximes and acetylenes in the system alkali metal hydroxide–DMSO [3,6] (it was suggested[8,9] that this synthesis should be called the Trofimov reaction)

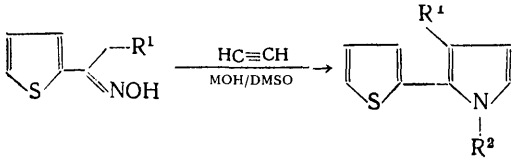


R^1, R^2 = Alk, Ar, etc.; R^3 = H, Ph; M = K, Na, Li.

The yields of pyrroles and *N*-vinylpyrroles (the latter are readily formed with excess acetylene) depend on the structure of the initial compounds and, as a rule, amount to 50–70%, while in favourable cases they reach 90%. A necessary condition for this reaction to take place is the presence of an α-CH_2 group in the ketoxime. Aldoximes do not form pyrroles but are converted to nitriles, amides, or salts of carboxylic acids.[3,6,10]

This simple and effective synthesis has made it possible to convert ketones in two stages to pyrroles with the widest range of substituents—alkyl,[3] alkenyl,[11] aryl,[3,12,13] hetaryl [3,14]—as well as to annelated pyrrole systems.[3,6] For the first time the simplest alkyl- and aryl-substituted pyrroles not containing functional groups became accessible, the majority of known methods for obtaining them being not very suitable. It is not surprising that the discovery of this reaction acted as a powerful stimulus for the development of pyrrole chemistry. Within a short time more than 120 studies were published in this field. The majority of them have already been covered in a review[6] and monograph.[3] We have therefore restricted ourselves here to examining the most recent information that has not appeared in these review publications.

In one study[15] the synthesis of the previously unknown 2-arylpyrroles and their 1-vinyl derivatives is reported.

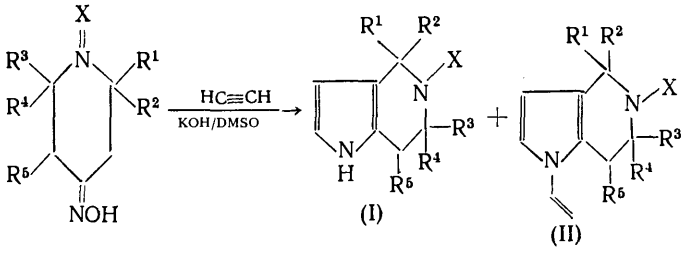


Ar = Ph, 4-RC_6H_4 (R = Me, Et, MeO, Cl, Br, iso-Pr, t-Bu), Bz;

R^1 = H, Me, C_6H_{13}, C_7H_{15}, C_8H_{17}, Ph; R^2 = H, CH = CH_2;

MOH = LiOH, KOH.

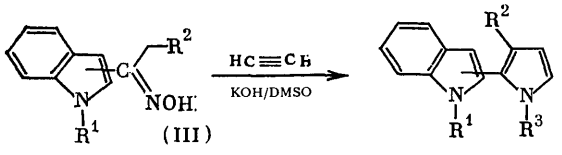
Pyrroles that are not substituted on the nitrogen atom are obtained in LiOH–DMSO (100 °C, 3 h) and their 1-vinyl derivatives are obtained in KOH–DMSO. By using an equimolar quantity of KOH relative to ketoxime and a tenfold excess of DMSO (from the total weight of the reagents) it is possible to reduce the reaction temperature considerably (to 50–60 °C) and obtain 3-alkyl-2-arylpyrroles and their 1-vinyl derivatives with total yields of up to 90%.[16]



Oximes of a thiophene series and acetylene underwent the Trofimov reaction to give thienylpyrroles and the previously unknown 1-vinylthienylpyrroles in 50–70% yield.[17]

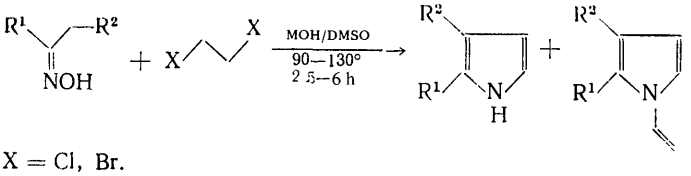
R^1 = H, Me, Et, Pr, Bu, C_6H_{13}; R^2 = H, CH = CH_2.

The reaction takes place smoothly at 100–130 °C and can be effected both at elevated pressure (1.0–1.6 MPa) and atmospheric pressure of acetylene. The ratio of pyrroles to their 1-vinyl derivatives formed in this synthesis is governed by the reaction conditions—its duration, the temperature system, concentration of acetylene, addition of water, and change in cation from the hydroxide.



The heterocyclisation (50–100 °C, 4–5 h) of acetylene with piperidine oximes,[18–21] their *N*-hydroxy derivatives, and nitroxyl radicals[18,19] has been carried out.

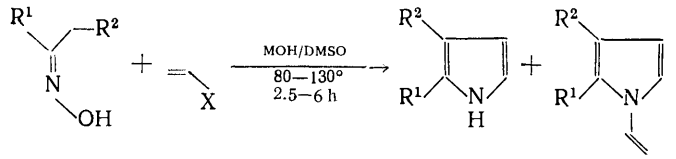
X = H, Me, OH, O·; $R^1 = R^3$ = H, Me, Ph; $R^2 = R^4 = R^5$ = H, Me.



Tetrahydro-5-azaindoles (I) and (II), including those with a free valency (X = O) have been obtained in this way. A special feature of the reaction when X = OH is that it mainly gives tetrahydroazaindoles with a nitroxyl free-radical centre (compounds with a vinyloxy group at the 5-position are formed in very small quantities in the process).[18,19]

Reaction between acetylene and oximes of 2- and 3-acylindoles (III) gives 2- and 3-(pyrrolyl)indoles with yields of 30–45%.[22,23] The optimum conditions for synthesis are: temperature 100–105 °C (30 min to 2 h), ratio of ketoxime to KOH = 1:1.2.

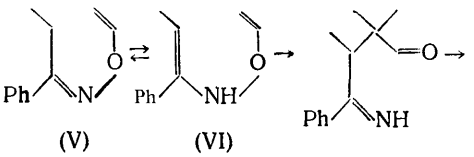
R^1=H, Me; R^2=H, Me, Pr, Ph; R^3=H, CH=CH_2.



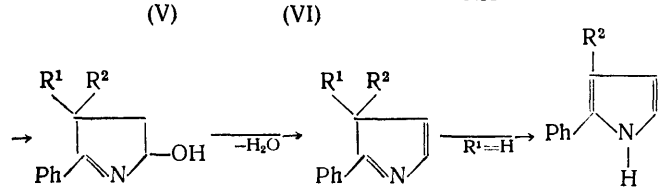
A variant of the reaction under discussion is the interaction between ketoximes and haloethanes, which gives pyrroles and their 1-vinyl derivatives with a total yield of 50–60%.[3,24,25]

X = Cl, Br.

Trofimov and Mikhaleva[3] achieved 94–95% selectivity with respect to the main product—a pyrrole—at the cost of a reduction in yield to 30%. As in the reaction with acetylene,[3,6] this was mainly achieved by adding small quantities of water (10–20%) to the reaction mixture.



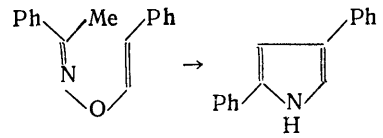
The reaction between ketoximes and vinyl halides occurs in a similar manner.[26,27]

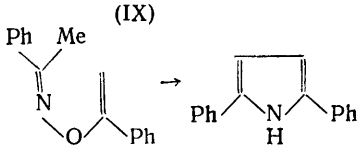


By varying the ratio of reagents and the conditions it is possible to carry out the reaction with a sufficient degree of selectivity to obtain either mainly pyrroles in about 40% yield or their 1-vinyl derivatives (yields up to 35%).

These variants of the Trofimov reaction, despite the lower yields of pyrroles, can in some cases prove to be more suitable for laboratory experiments, since they exclude the use of free acetylene.

One of the possible methods for forming pyrroles from ketoximes and acetylene in the superbasic catalytic system KOH–DMSO is a heteroatomic variant of the Claisen rearrangement of the intermediate *O*-vinyloxime (V), which undergoes isomerisation by proton transfer to give the *O*,*N*-divinylhydroxylamine (VI).[3]

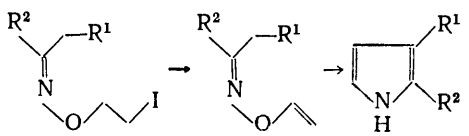




R^1 = Me; R^2 = Me; R^1 = H, R^1 = H, R^2 = iso-Pr.

It was shown[28] that *O*-vinylarylketoximes (V), which can be obtained in 50% yield from ketoximes and acetylene, on heating (100 °C) in KOH–DMSO are completely converted to the corresponding pyrroles even after 1.5 h. When isopropyl- and isobutyl-phenylketoximes were reacted with acetylene in the same system the reaction was stopped at the stage where 4*H*-2-hydroxy-2,3-dihydropyrroles (VII) were formed,[29] and on heating (70 °C, 5 h) compound (VII) (R^1 = R^2 = Me) with acetylene, the 3*H*-pyrrole (VIII) was isolated.[30]

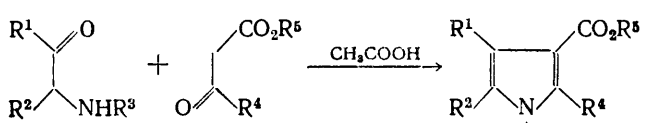
Confirmation of this mechanism was also obtained[31] by rearrangement of the isomeric *O*-(phenylvinyl) acetophenone oximes (IX) and (X) in KOH–DMSO to give the corresponding pyrroles.



(IX)

(X)

O-(2-Iodoethyl)ketoximes (XI), obtained in two stages from ketones, on heating in the presence of t-BuOK and t-BuOH are converted to pyrroles (yields 65–74%).[32]

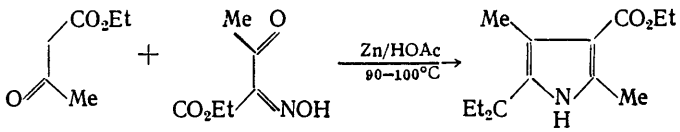


(XI) (XII)

It was possible to stop the reaction at the stage where the *O*-vinyloxime (XII) was formed, R^1 = H, R^2 = Ph (yield 41%), by lowering the concentration of t-BuOK and reducing the time of reaction. The pyrrole was obtained in 89% yield by thermolysis of oxime (XII).

2. Condensation of aminoketones with ketones

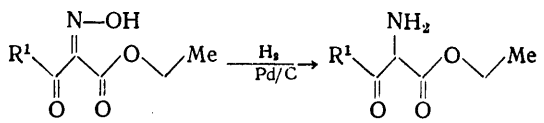
In recent years there has been further development of one of the most widely used methods for synthesising pyrroles—the Knorr synthesis, which in its original form is regarded as the condensation of α-aminoketones with carbonyl compounds that have active methylene groups adjacent to the carbonyl group such as in β-ketoesters and β-diketones.



(XIII)

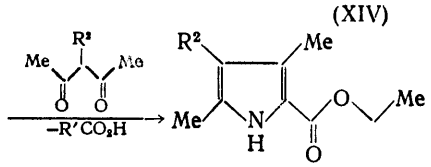
When phenylacylamines are reacted with methyl and ethyl acetoacetates, pyrroles (XIII) are obtained: (R^1 = Ar; R^2 = H; R^3 = H, Ar; R^4 = Me; R^5 = H, Me, Et),[33] (R^1 and R^3 = Me; R^2 = 4-ClC_6H_4O; R^4 = CH_2CO_2Et; R^5 = Et).[34]

The reaction of amino derivatives of sugars with dimethyl diacetylenedicarboxylate (DMADC) may be regarded as a unique version of the Knorr synthesis; this gives pyrroles with carbalkoxy substituents (XIII) (R^1 = H; R^2 = $(CHOH)_nCH_2OH$, *n* = 2, 3; R^3 = Alk, Ar; R^4 = Co_2Me; R^5 = Me).[35,36]



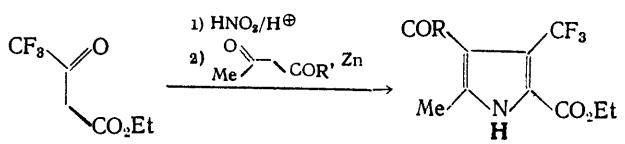
The aminoketone component of the reaction is most frequently obtained by reduction *in situ* of the corresponding monooxime, which in turn is formed by nitrosation of a ketone or β-dicarbonyl compound.[37–43]

The reducing agent most frequently used is zinc in acetic acid.



Although quite versatile, the Knorr synthesis does have some disadvantages. These are mainly the moderate yields of pyrroles (40–60%). The reaction efficiency is substantially reduced in the case of asymmetric β-dicarbonyl compounds, which usually form mixtures of different pyrroles.

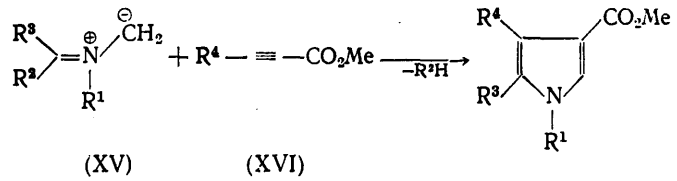
The higher yields of pyrrole-2-carboxylates (60–70% for the main product synthesised from an asymmetric ketone and 75–90% from a symmetric ketone) in comparison with the method described by Kleinspen[5] (reduction *in situ* of diethyl oximinomalonate with zinc) were achieved by reaction of 1,3-diketones with diethyl aminomalonate (XIV), which was prepared in advance in boiling glacial acetic acid.[44] Reduction of oximinomalonate is carried out in ethanol solution in the presence of Pd/C.[44]



(XIV)

R′ = Me, EtO; R^2 = H, Me, Et, Pr.

The usual conditions for the Knorr synthesis are not very suitable for the synthesis of β-trifluoromethylpyrroles (yield 5%). The yield of these compounds can be increased by using a strong acid medium during nitrosation. In neutral solution ethyl trifluoroacetoacetate is enolised to a considerable extent. A strong acid medium shifts the tautomeric equilibrium towards the keto tautomer, which results in a greater yield of pyrroles (41–47%). A mixture of acetic and trifluoroacetic acids saturated with HCl is used as the solvent.[38]

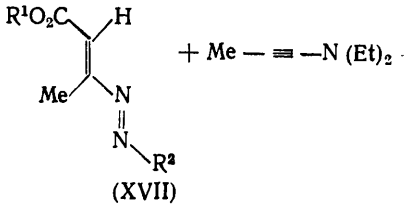


R = Alk, AlkO.

3. 1,3-Dipolar cycloaddition

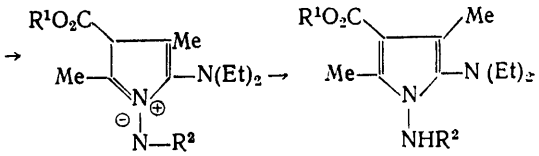
Dipolar cycloaddition[45] has formed the basis for the development of many methods for synthesising pyrroles in recent years. 1,3-Dipolar cycloaddition of nitrile or azomethine ylides to dipolarophiles gives pyrroles either directly or via pyrroline derivatives. For this purpose it is possible to use mesoionic compounds which formally contain a system of azomethine ylide bonds. Thus, the azomethine ylide (XV), which is generated by reaction of α-cyanoaminosilanes [46] or α-(phenylthio)aminosilanes [47] with silver fluoride and also by alkylation of imidates with trimethylsilylmethyltriflate (DMF, 25 °C,

3 h) followed by desilylation of the resulting salts with caesium fluoride,[48] reacts with methyl propiolate or DMADC to form pyrroles.[46-48]



(XV) (XVI)

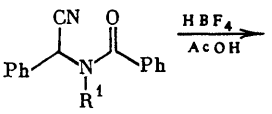
R^1 = Me, $PhCH_2$; R^2 = H, EtO, Me; R^3 = H, Me, Ph; R^4 = H, CO_2Me.



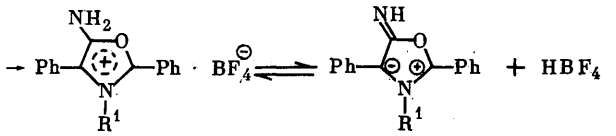
The reaction between compounds (XV) and (XVI) in the presence of silver fluoride takes place when there is a small excess of the latter in acetonitrile at 25 °C over a period of 10 h in the dark. The residue (pyrroline) formed after removal of solvent is oxidised by 2,3-dichloro-5,6-dicyano-*p*-benzoquinone to give the corresponding pyrroles in 62–65% yield.[46,47] The reaction takes place under similar conditions in the presence of anhydrous CsF, with a yield of pyrroles of up to 75%.[48]

N-Protonated azomethine ylides (XV) (R^1 = H, R^3 = Et, Bu, Ph; R^2 = NPh, $NC_6H_{11}S$) readily add on to electron-deficient acetylene compounds (dry acetonitrile, 20–25 °C, 16 h) forming the corresponding pyrroles (yield 44–96%).[49,50]

One of the most unusual examples of 1,3-cycloaddition of hetero-1,3-dienes to alkynes has been reported in one study;[51] 1,2-diaminopyrroles (XVIII) are obtained in 46–59% yield by reaction of diazabutadienes (XVII) with 1-propynyldiethylamine.

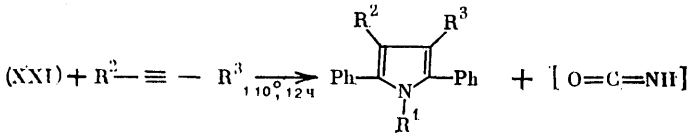


(XVII)



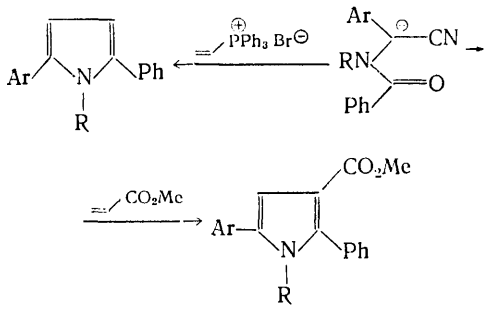
(XVIII)

R^1 = Me, Et; R^2 = Ts, $CO_2CMe_2CCl_3$.

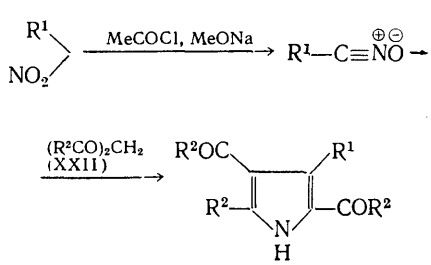


Acyclic analogues (XIX) of Reissert compounds have been used for the synthesis of pyrroles under both acidic and alkaline conditions.[52] Thus, the mesoionic compounds (XXI), which are formed by dissociation of hydrophobic salts of Reissert compounds (XX), undergo 1,3-dipolar cycloaddition to alkynes to give the corresponding pyrroles.

(XIX)



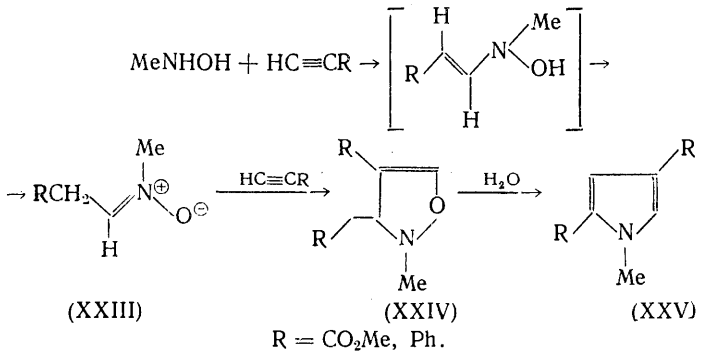
(XX) (XXI)



R^1 = Ph, Bz; R^2 = R^3 = H, CO_2Me.

Similar pyrroles are formed by reaction between methyl acrylate [52] or vinyltriphenylphosphonium cation[53,54] and anions which are products of the reactions of superbases (BuLi/THF, NaH/DMSO or DMF/NaH) with Reissert compounds. In the first case the reaction occurs at room temperature, in the second case heating is required (110 °C) for 24 h.

R = Ph, 3-$MeOC_6H_4$, 4-ClC_6H_4, C_6H_{13}, cyclo-C_6H_{11}; Ar = Ph, 4-ClC_6H_4, 3, 4-$Me_2C_6H_3$.

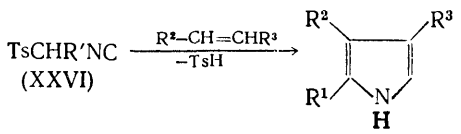


A 1,3-dipolar cycloaddition route is followed in the reaction of aliphatic nitro compounds, 1,3-diketones, and acetyl chloride (MeONa/MeOH, *N*,*N*-dimethylacetamide, 0–20 °C, 12 h), which gives diacylpyrrole derivatives in 35–85% yield.[55]

R^1, R^2 = Ph, 4-MeC_6H_4, 4-ClC_6H_4.

It is suggested[55] that the first stage of the reaction is formation of nitrile oxide, which as a result of 1,3-dipolar cycloaddition to 1,3-diketone (XXII) forms a pyrrole.

1,3-Dipolar cycloaddition of nitrones (XXIII), which are formed from methylhydroxylamine and methyl propiolate or phenylacetylene (80 °C, 12 h) gives the pyrrole (XXV).[56] When the reaction is carried out at 25 °C (24 h) it is possible to stop it at the stage involving formation of the intermediate isoxazoline (XXIV), which at 80 °C over a period of 12 h rearranges to pyrrole (XXV).



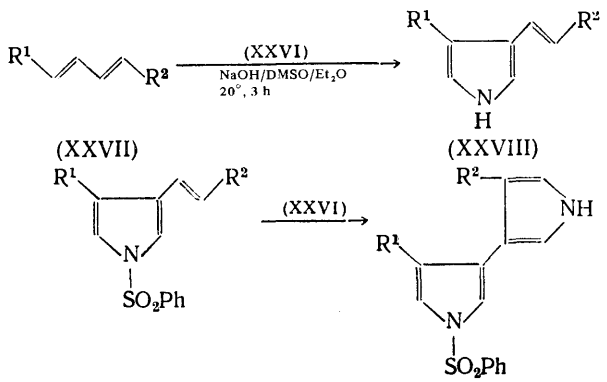
(XXIII) (XXIV) (XXV)

R = CO_2Me, Ph.

With alkyl-substituted acetylenes this reaction does not occur even with prolonged heating.[56]

4. Pyrroles from isonitriles

An effective method of obtaining pyrrole derivatives which are unsubstituted at the 1- and 5-positions is the base-catalysed addition of tosylmethylisocyanide (XXVI) to activated alkenes.[57,58]



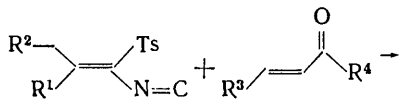
(XXVI)

R^1 = Me, CH_2=CH—CH_2, Bz; R^2 = Me, Ph;

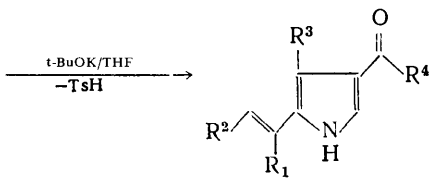
R^3 = CO_2Me, Bz, C≡N.

The reaction can be carried out in superbasic systems—NaH in a DMSO—Et_2O mixture or in dimethoxyethane. The yields of pyrroles are 70–90%.

When 1,3-diene esters (XXVII) are used as the Michael acceptor, the addition to them of two molecules of isonitrile (XXVI) to give a bipyrrolyl is to be expected. However, under the given conditions only the 3,4-substituted pyrrole (XXVIII) is obtained in 80% yield.[59–61] The addition of the second isonitrile molecule does not occur apparently because of the reduction in electrophilicity of the α,β-unsaturated ester (XXVIII). A 3,3′-bipyrrolyl can only be obtained after addition of a $PhSO_2$ group to the nitrogen atom.



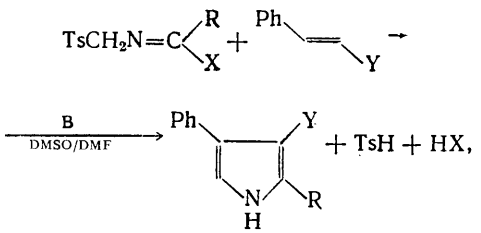
(XXVII) (XXVIII)



R^1 = Me, Et; R^2 = CO_2Me, CO_2Et.

If the reaction of isonitrile (XXVI) and the 1,3-diene ester is carried out in the presence of BuLi in THF (−70° to 0 °C, 2 h), the other isomer of pyrrole (XXVIII) (R^1 = CO_2Me, R^2 = Me) is obtained in 34% yield.[61]

Pyrroles (XXX), which have an alkenyl group at the α-position, are synthesised in high yield (83–96%) by the base-catalysed addition of 1-tosylalk-1-enylisocyanides (XXIX), readily formed by reaction of tosylmethylisocyanide with carbonyl compounds, to Michael acceptors.[62]

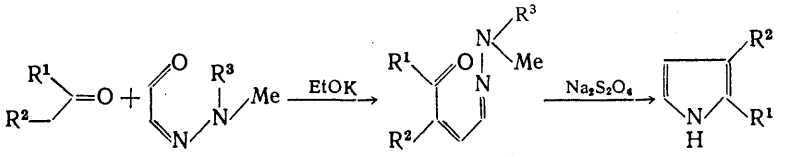


(XXIX)

(XXX)

R^1 = Me, Ph; R^2 = H; R^1R^2 = $(CH_2)_3$, $(CH_2)_4$, $(CH_2)_5$;
R^3 = H, Me, Ph; 2-furyl, 2-thienyl, MeCH = CH, PhCH = CH;
R^4 = Me, MeO, EtO, Ph, 2-furyl, 2-thienyl

Methyl isocyanoacetates (RO_2CCH_2NC) are quite frequently used for the synthesis of pyrrole-2-carboxylates.[63–65] The reaction takes place under the same conditions as for isonitriles (XXVI). *N*-(Tosylmethyl)imino derivatives[66] react in a similar manner with Michael acceptors.



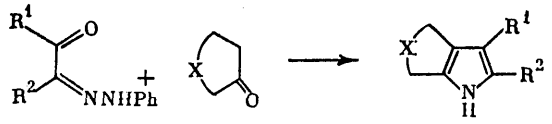
B = NaH, t-BuOK

R = Me, Ph, SMe, OMe; X = SMe, OMe; Y = COPh, CO_2Me, CN.

It appears that in this case the first stage involves removal of a proton from the activated methylene group, generating a 2-azaallyl anion $Ts\overline{C}-N=CRX$, which subsequently reacts with the unsaturated substrate either according to a 1,3-dipolar addition mechanism (after elimination of Ts^- or X^-) or according to a 1,3-anionic cycloaddition mechanism.

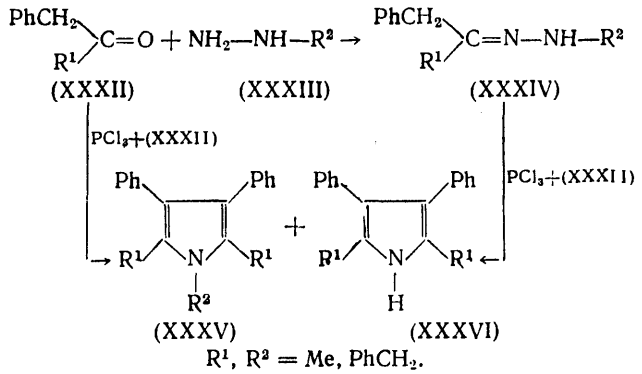
5. Reactions involving hydrazones and azoalkenes

Carbonyl compounds containing an active methylene group when reacted with glyoxal monohydrazones form hydrazones (XXXI),[67,68] which on treatment with sodium dithionite give pyrroles in 21–48% yield.[68]



(XXXI)

R^1 = H, Alk, AlkO, Ar; R^2 = H; Alk, AlkO, CN, CO_2Alk; R^3 = Alk, Ar.



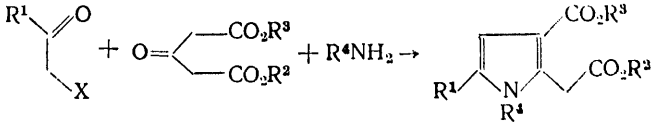
Compounds (XXXI) when treated with sodium borohydride are converted to alcohols, which on heating or in the presence of acids eliminate water to form *N*-aminopyrroles, and subsequently on hydrogenation give pyrroles unsubstituted on the nitrogen atom.[67]

Reductive condensation of phenylhydrazones with cyclic ketones in the presence of zinc and sodium acetate in acetic acid gives pyrrolocycloalkanes in 19–25% yield.[69]

R^1=Me, Et; R^2=CO_2Me, CO_2Et; X=$(CH_2)_3$, $(CH_2)_4$.

The reaction of enolisable ketones (XXXII) with their hydrazones (XXXIV) in the presence of two equivalents of PCl_3 (CH_2Cl_2, 20 °C or C_6H_6, 80 °C) results in the formation of a mixture of symmetrically substituted pyrroles (XXXV) and (XXXVI).[70] The yield (28–46%) and ratio of products depend on the structure of the reagents and the reaction conditions.

R^1, R^2 = Me, $PhCH_2$.

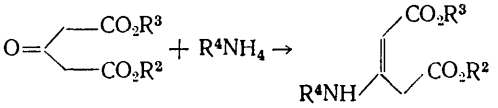


A mixture of pyrroles (XXXV) and (XXXVI) (1 : 1) is also obtained by direct reaction of the initial ketones (2 equivalents), hydrazine (XXXIII) (1 equivalent) and PCl_3 (3 equivalents).

Azoalkenes react with 1,3-dicarbonyl compounds.[71–88]

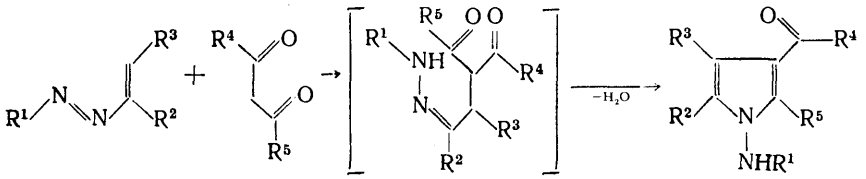
The reaction occurs via intermediate 1,4-adducts (XXXVII), which subsequently cyclise to a pyrrole by elimination of water. In a number of cases these intermediates have been isolated. The synthesis proceeds smoothly at room temperature and is complete after several hours. The process can be speeded up by heating the reaction mixture or by using a catalyst ($CuCl_2$,[71–80] Na_2CO_3 [81]). Aminocarbonyl-,[73,74] aryl-,[75–77] aroyl-,[72] arylsulphonyl-,[78,79] alkoxycarbonyl-,[71,80] and β-chloro-azoalkenes [81] have been used as the first reaction component. 1,3-Diketones,[71,73,75,77,79,81] β-ketoesters,[71,73,75,77,79,81] and 3-oxoalkanamides [72,74,76,78,80] have been used as the second components.

6. Reactions involving haloketones



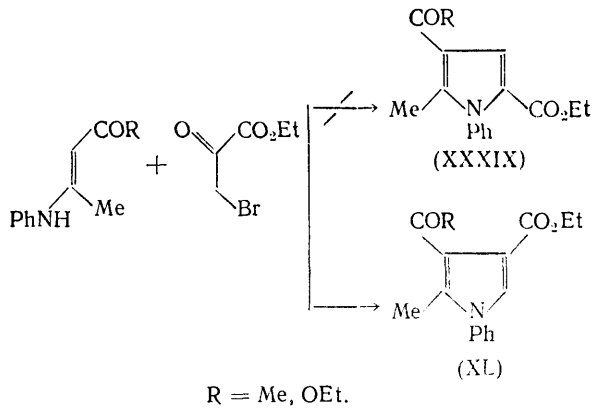
A series of studies have recently appeared which are devoted to extending the Hantzsch method,[82–95] which is based on the reaction of α-haloketones or α-haloaldehydes with β-ketoesters and amines.

R^1, R^4 = H, Alk; R^2, R^3 = Alk, Ar; X = Cl, Br.



The reaction is carried out in the same water–dioxan or water–alcohol solution, in a two-phase system, or without any solvent at room temperature (prolonged standing of the mixture) as well as with heating for several hours. In some cases[95] the reaction is catalysed by carboxylic acids.

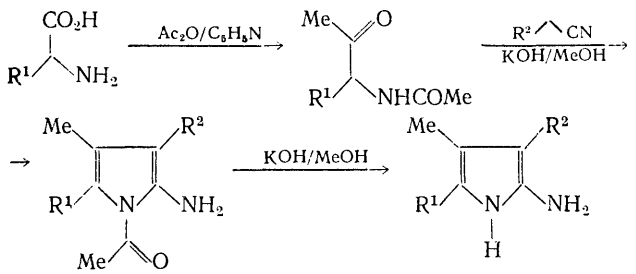
The probable reaction route[5] assumes the formation of aminocrotonate (XXXVIII) at the first stage.



(XXXVIII)

In fact, such aminocrotonates have successfully been used as initial compounds for the synthesis of pyrroles.[96]

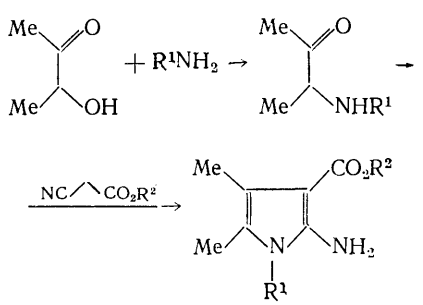
(XXXVII)



R = Me, OEt.

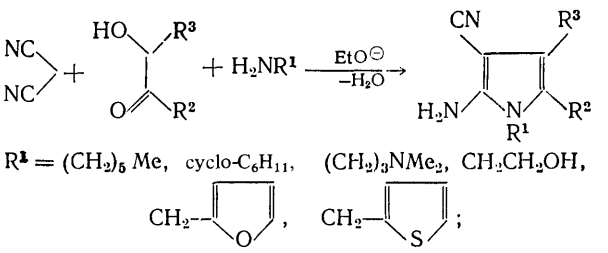
An unexpected result of this study was that instead of pyrrole (**XXXIX**) its isomer (**XL**) was formed in 72% yield. The reaction took place when the reagents were refluxed in ethanol for 30 min.

7. Reactions involving amino and nitrile groups



N-Acetyl-α-aminoketones, obtained from *L*- or *DL*-amino acids, when condensed with nitriles form substituted 2-amino-3-cyano-4-methylpyrroles (120 °C, 3–4 h).[97]

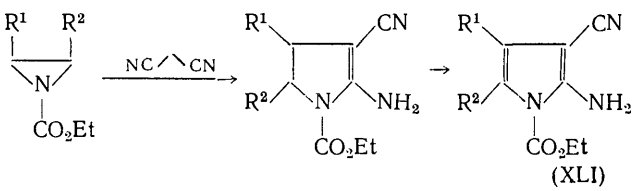
R^1 = Me, Pr, iso-Pr, Ph, Bz; R^2 = CN, SO_2R.



The pH of the medium must be kept within the range 9–10 and the temperature at 55–60 °C when decarbonylation takes place.

Condensation of 3-hydroxy-2-butanone with primary aryl- and alkyl-amines in boiling cyclohexane gives aminoketones, which react with cyanoacetates to give various 2-amino-3-carbalkoxy-4,5-dimethylpyrroles in 36–87% yield.[98]

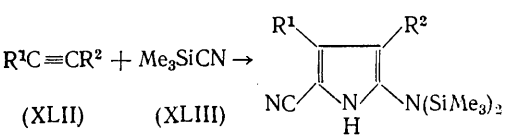
R^1 = Alk, Ar; R^2 = Me, t-Bu.



The reaction of hydroxyketones with amines and malononitrile, giving 2-amino-3-cyanopyrroles in yields up to 96%, also takes place via the intermediate formation of an aminoketone. The reaction is carried out in ethanol in the presence of sodium ethoxide.[99]

R^3 = $(CH_2)_5$Me, cyclo-C_6H_{11}, $(CH_2)_3NMe_2$, CH_2CH_2OH,

$R^1 = R^3$ = Me, Ph; $R^2R^3 = (CH_2)_4$, $(NH_2)_5$.

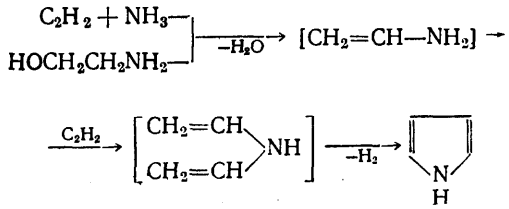


The reaction of malononitrile with 1-carbethoxyaziridines in the presence of sodium hydride (THF, 100 °C, 4 h) gives 2-amino-3-cyano-1-carbethoxy-4,5-dihydropyrroles (yield 45–50%), which are aromatised (chloranil, benzene, 80 °C, 3 h) to the corresponding pyrroles (XLI) in 30–90% yield.[100]

R^1 = H, Ph; R^2 = H, Me.

Pyrroles (XLI) (R^1 = Me, Ph; R^2 = H) were also obtained by counter-synthesis from malononitrile and *N*-phenacyl- or *N*-acetonyl-carbamates $R^1COCH_2NHCO_2Et$ on boiling the reagents in benzene in the presence of acetic acid and ammonium acetate or piperidine.

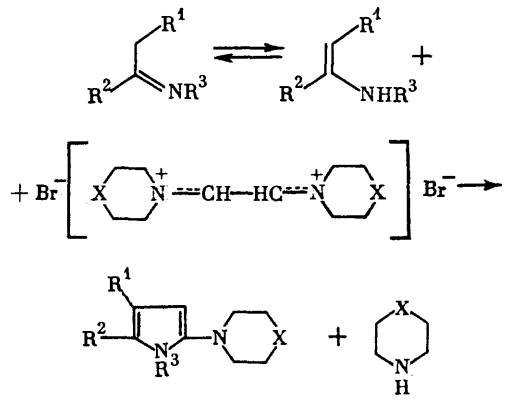
When trimethylsilylcyanide (XLIII) is reacted with alkynes (XLII) (N_2, 20 h) in the presence of palladium or nickel catalysts, 5-aminopyrrole-2-carbonitriles are obtained in high yield.[101]



R^1 = H, Ph, 4-$MeOC_6H_4$, 4-ClC_6H_4, 2-thienyl, 2-$MeOC_6H_4$;
R^2 = Ph, 4-$MeOC_6H_4$, 4-ClC_6H_4, 2-thienyl.

There has been a study of the reaction of nitrile (XLIII) with silylacetylenes (XLII) (R^1 = $Me_3SiC{\equiv}C$, $CH_3(CH_2)_5$, Ph, Me_3Si; R^2 = $SiMe_3$),[102] (120–160 °C, 9–12 h) in the presence of palladium catalysts to give 2-amino-5-cyanosilylpyrroles (yield 49–84%).

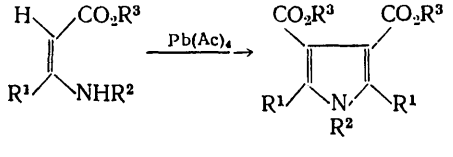
8. Reactions involving enamines and imines



The Chichibabin reaction—the catalytic interaction of acetylene with ammonia—remains one of the most promising methods for obtaining unsubstituted pyrrole.[2] In recent years definite progress has been made in this direction. By varying the catalysts and reaction conditions it has been possible to increase the yield of pyrrole to 10.4% (cadmium calcium phosphate catalyst).[103] The same catalyst has been used for the condensation of acetylene with aniline (410–430 °C),[104] with a 15–17% yield of 2-phenylpyrrole.

It has been proposed[103] that at the first stage of the reaction between acetylene and ammonia, vinylamine is generated, which then reacts with acetylene to give divinylamine, which cyclises to pyrrole.

Such a scheme is consistent with the synthesis of pyrrole from mono- and di-ethanolamines, which presumably involves the intermediate formation of mono- and di-vinylamines.[105,106] The reaction takes place at a high temperature on a complex catalyst: Al_2O_3 (95%), ZnO (2%), Cr_2O_3 (3%). The yield of pyrrole is 10% from monoethanolamine and 18.5% from diethanolamine.



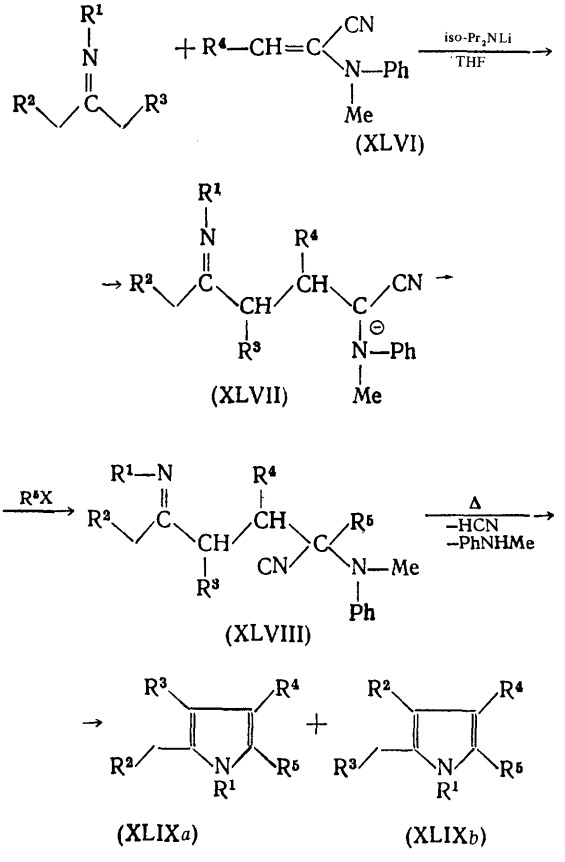
Enamines react under mild conditions (CH_2Cl_2, 20 °C, 2 h) with certain *bis*-iminium salts, forming aminopyrroles in good yield.[107]

R^1=CO_2Et, CO_2CMe_3, Ph; R^2= Me, Ph; R^3=H, Alk; X=O, NMe.

The formation of pyrroles in this reaction is due to double electrophilic attack by the dication on the nitrogen atom and β-carbon atom of the enamine. The 2,3-dihydropyrroles thus obtained eliminate an amine during the synthesis and are converted to α-aminopyrroles. When R^1 = H, pyrroles are not formed. This supports the conclusion[107] that α-aminopyrroles containing a hydrogen at C(4) are unstable compounds.

Oxidation of enaminoesters (XLIV) with an equivalent quantity of lead tetra-acetate (CH_2Cl_2, 20 °C, 3–7 h) results in the formation of symmetrically substituted pyrroles (XLV).[108–110]

(XLIV) (XLV)



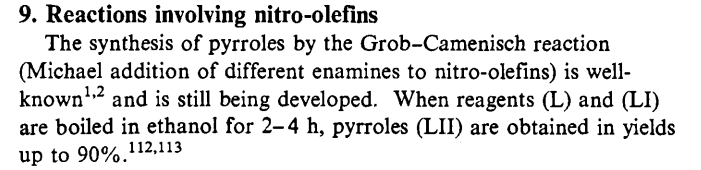
R^1 = CO_2Me, Me, Ph; R^2 = Me, Pr, Bu, $PhCH_2$, 4-ClC_6H_4, R^3 = Me, Et.

In the opinion of Vernon and co-workers,[108] the new C–C bond is formed by two-electron oxidation of enamine (XLIV).

The yields of the pyrroles synthesised from β-aminocrotonates amount to 20–40%. The oxidation of β-aminocinnamates is less effective (yields of pyrroles 10–20%) and only takes place in an atmosphere of nitrogen.

The reaction of 2-(*N*-methylanilino)-2-alkenonitriles (XLVI) with ketimine anions followed by alkylation or protonation of the intermediate carbanion (XLVII) and culminating in the pyrolysis of adduct (XLVIII) gives pyrroles.[111]

Asymmetrically substituted ketimines (R^2 = n-Pr, R^3 = H) form a mixture of pyrroles (XLIXa, b) in the ratio 85 : 15. It is possible to obtain pyrroles (XLIXa) selectively by deprotonation at –78 °C.

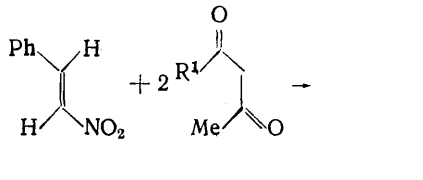


(XLVI) (XLVII) (XLVIII)

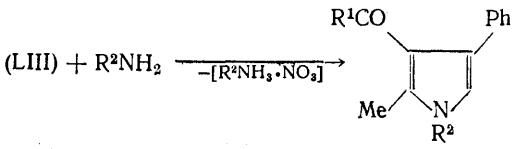
(XLIXa) (XLIXb)

R^1 = Me, cyclo-C_6H_{11}, iso-Pr, $PhCH_2$;
R^2 = H, Me, Pr; R^3 = H, Me, Pr; R^2R^3 = $(CH_2)_3$, $(CH_2)_4$;
R^4 = H, Et; R^5 = H, Me, Et, Pr; X = OH, I, Br.

9. Reactions involving nitro-olefins



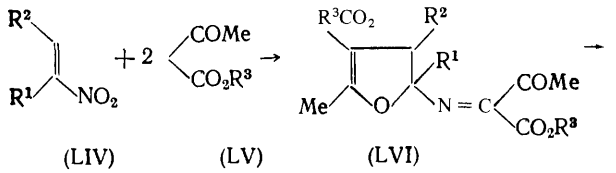
The synthesis of pyrroles by the Grob–Camenisch reaction (Michael addition of different enamines to nitro-olefins) is well-known[1,2] and is still being developed. When reagents (L) and (LI) are boiled in ethanol for 2–4 h, pyrroles (LII) are obtained in yields up to 90%.[112,113]



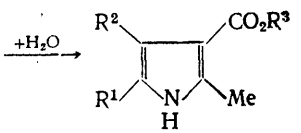
(L) (LI) (LII)

X-acceptor: COMe, CO_2Me, CO_2Et; R^1 = Me, Ph; R^2 = H, Me; R^3 = H, Me, Ph; R^4 = Me, Bu, Ph, $PhCH_2$, 4-$AlkOC_6H_4$.

1,3-Dicarbonyl compounds are being used for the reaction with nitro-olefins with increasing frequency.[114,115] Thus, the reaction of ethyl acetoacetate and pentane-2,4-dione with β-nitrostyrene in a solution of MeONa/MeOH gives the *bis*-dihydrofuran intermediate (LIII). Treatment of the latter with ammonia or amines in methanol gives 3-acylpyrroles in high yield.

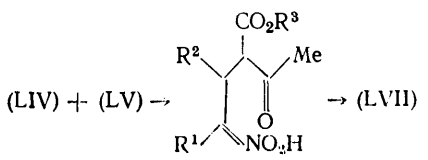


(LIII)



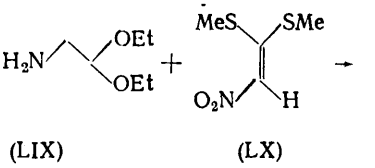
R^1 = Me, OEt; R^2 = H, Alk, Ar.

Acylpyrroles (LVII) are obtained by two methods—by hydrolysis of polyfunctional dihydrofurans (LVI) formed by reaction of nitro-olefins (LIV) with twice the amount of acetoacetates (LV) [116]

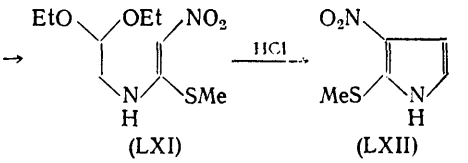


(LIV) (LV) (LVI)

(LVII)



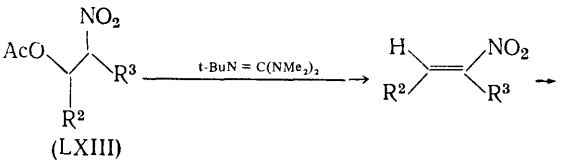
and by reduction of the nitronic acid (LVIII), which is an adduct of compounds (LIV) and (LV), with different reducing agents (Zn/HCl, $Zn/ZnCl_2$/HCl, 2-phenylethanethiol/benzene).[116]



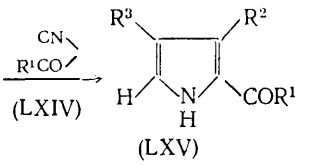
(LVIII)

R^1, R^3 = Alk; R^2 = Ar

The 3-nitropyrrole (LXII) was obtained in 58% yield by reaction of aminoacetaldehyde acetal (LIX) with 1,1-di(methylthio)-2-nitroethene (LX).[117] In this case the acyclic intermediate (LXI) is first formed and in the presence of HCl it cyclises to the pyrrole.



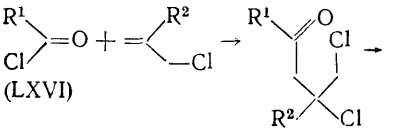
(LIX) (LX)



(LXI) (LXII)

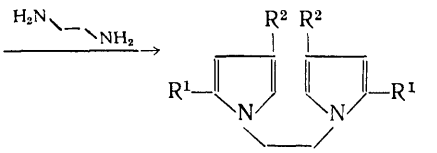
The base-catalysed reaction between α-isocyanoacetates (LXIV) and nitroalkenes or their precursors—β-acetoxynitro compounds (LXIII)—gives pyrroles (LXV) in 55–95% yield.[118]

(LXIII)



(LXIV) (LXV)

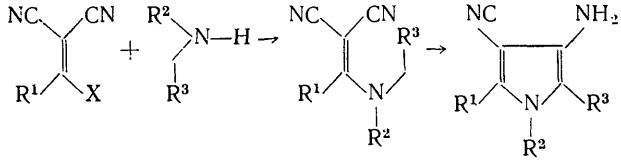
R^1 = EtO, t-BuO, Me_2N; R^2 = H, Me, Et, 4-$MeOC_6H_4$, 4-$PhCH_2OC_6H_4$; R^3 = Me, $CH_2CH_2CO_2Me$



III. C_3 + C_1 reactions

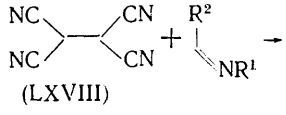
1. Pyrroles from β,γ-dihaloethanes and amines

In a refinement of the Kost–Ibragimov–Mamedov method,[119–122] the intermediate products (LXVII) from the electrophilic addition of carboxylic acid chlorides (LXVI) to allyl and methallyl chlorides ($AlCl_3$, dichloroethane, −20° to 25 °C) when treated with diamines (aqueous NaOH, 70–80 °C, 6 h) form *bis*-pyrrole compounds.[123]



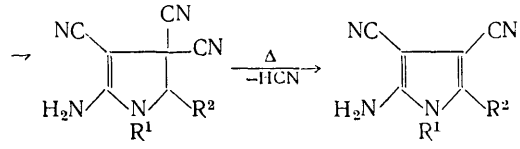
(LXVI) (LXVII)

R^1 = cyclo-C_6H_{11}, cyclo-$C_6H_{10}NH_2$; R^2 = H, Me

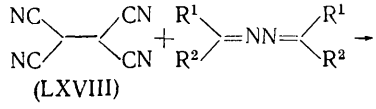


2. Reactions involving a cyano group

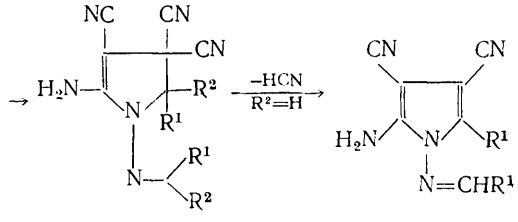
β-Aminopyrroles that have a CN group at the β'-position are obtained by reaction of α,β-unsaturated dinitriles with secondary amines containing functional groups; the intermediates are either isolated or not isolated.[124]



X = Cl, AlkO; R^1 = H, Alk, Ar; R^2=H, Alk, Ar; R^3 = CN, CO_2H, CO_2Alk.

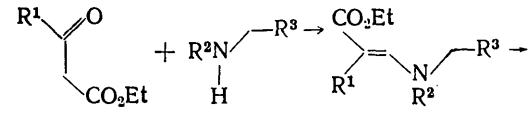


A convenient and simple method for the synthesis of pyrroles that contain amino and cyano groups is based on the reaction between tetracyanoethane (LXVIII) and azomethines or azines.[125-127] The reaction occurs in water–alcohol and alcohol media or in DMSO, giving 3-cyanodihydropyrroles, which on gentle heating in DMF eliminate a molecule of hydrocyanic acid and are converted to the corresponding pyrroles in high yield.

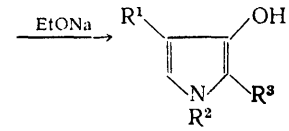


(LXVIII)

R^1 = Ph, 4-HOC_6H_4; R^2 = Ph, 2-furyl, 2-HOC_6H_4.



(LXVIII)

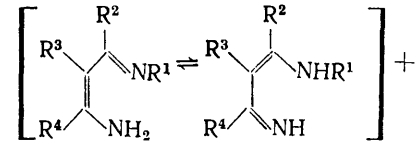


R^1 = Pr, iso-Pr, Ph, 2-furyl, 3-pyridyl, R^2 = H

3. Reactions of amino acids and their derivatives with 1,3-dicarbonyl compounds

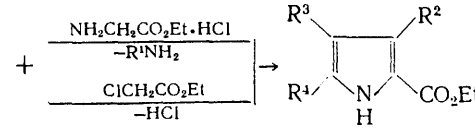
Hydroxypyrroles (LXX) [128-130] are synthesised by Dieckmann cyclisation (NaOEt/EtOH, boiling for 3 h) of enaminodicarboxylates (LXIX), which are formed by reaction of amino acid amides and esters with β-ketoesters [128] or with diethyl ethoxymethylenemalonate.[129,130]

(LXIX)



(LXX)

R^1=H, Ph, CO_2Et; R^2=H,Me,Ph,Bz; R^3=$CONH_2$, CONHMe, CO_2Et, CO_2CMe_3, CH_2CO_2Et

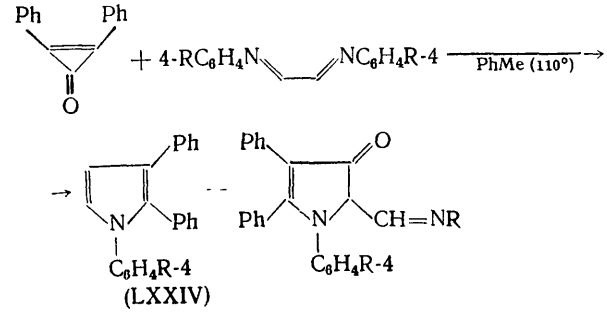


A number of pyrroles have been obtained from amino acids and 1,3-diketones [131-132] and also from α-(aminomethylene)cyclohexanone.[133] Cyclisation of the intermediates often occurs simply by heating.[133]

4. Reactions of azabutadienes

Azabutadienes (LXXI) react with glycine ethyl ester hydrochloride (80 °C, 4 h) or ethyl chloroacetate (100 °C, 6 h) in pyridine, giving in both cases pyrrole-2-carboxylates (LXXIII).[134] The regiospecificity of the reaction suggests that only one of the tautomeric diimine forms, namely (LXXII), participates in it.

(LXXI) (LXXII)

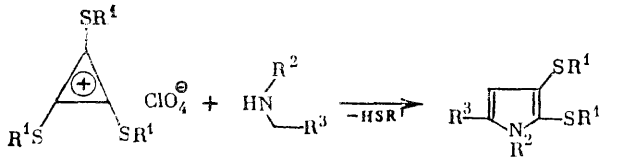


(LXXIII)

R^2 = Ph, 4-ClC_6H_4; R^3 = H, Me;

R^4 = Pr, Ph, 4-MeC_6H_4, cyclo-C_6H_{11}.

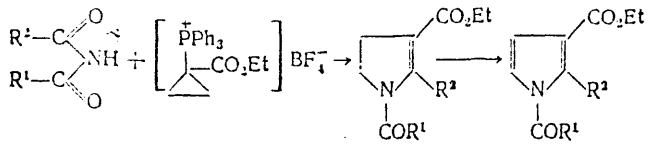
In the first case heterocyclisation probably takes place by transamination of diimine (LXXII) with the amino group of glycine.



1,4-Diazabutadienes form the pyrrole (LXXIV) as a by-product (5–17%) by reaction with 2,3-diphenylcyclopropen-1-one. The main route in this case is formation of pyrroline-4-ones.[135]

(LXXIV)

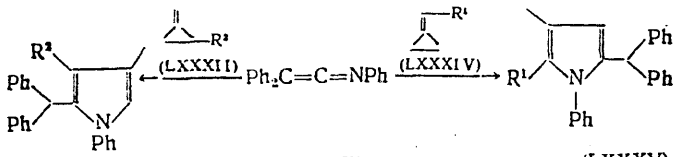
5. Reactions involving cyclopropanes



Condensation of *tris*-(t-butylthio)cyclopropenyl salts (LXXV) with secondary amines in the presence of the superbasic system t-BuOK – DMSO at 20–25 °C gives pyrroles (LXXVI) in 40–80% yield.[136–138]

(LXXV) (LXXVI)

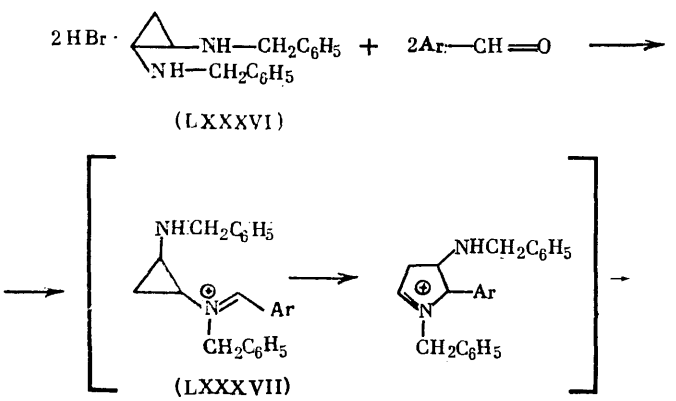
R^1 = t-Bu; R^2 = Me, Et; R^3 = Me, CN, Ph, CO_2Me; R^2R^3 = $(CH_2)_3$, $(CH_2)_4$.



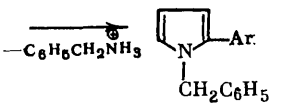
Anions of acyclic imides (LXXVII) (NaH, xylene, 20 °C) and cyclopropylphosphonium salts (LXXVIII) give Δ^2-pyrrolines, which are dehydrogenated with 2,3-dichloro-5,6-*p*-benzoquinone to the corresponding pyrroles (LXXX).[139]

(LXXVII) (LXXVIII) (LXXIX) (LXXX)

R^1 = H, Me, Ph; R^2 = H, Me, Ph



The [3 + 2]-cycloaddition of methylenecyclopropanes (LXXXII) and (LXXXIV) to the ketenimine (LXXXIII) (125 °C, 22–30 h), catalysed by $(PhP)_4Pd$, gives pyrroles (LXXXI) and (LXXXV) in 77–96% yield.[140]



(LXXXI) (LXXXIII) (LXXXV)

R^1 = H, Me; R^2 = Me

Reaction of hydrobromide salts of 1,2-cyclopropanediamine (LXXXVI) with a twofold excess of aromatic aldehydes (MeOH or EtOH, NaOAc, 20–25 °C, 15 h) goes to completion with the formation of 2-arylpyrroles (LXXXVIII).[141]

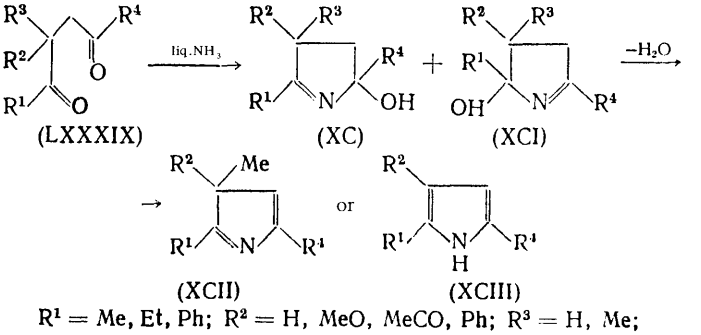
(LXXXVI) (LXXXVII)

(LXXXVIII)

Ar = Ph; 4-$NO_2C_6H_4$; 4-$(Me)_2NC_6H_4$; 2,4,6-$(Me)_3C_6H_2$; 2-pyridyl.

The benzylidenammonium ions (LXXXVII) formed at the first stage of the reaction are converted to pyrrolinium ions, which are aromatised with elimination of benzylamine.

IV. C_4 + N(C_4–N) reactions

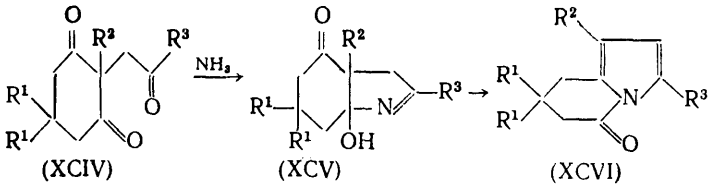


1. Reactions of 1,4-dicarbonyl compounds

The formation of pyrroles from 1,4-dicarbonyl compounds by treatment with ammonia or amines (the Paal–Knorr synthesis) is one of the most common methods for obtaining substituted pyrroles. Interest in it continues unabated. In recent years it has been developed further in several studies.[142–161] In particular, a large number of pyrroles have been obtained from hexane-2,5-dione.[143,144,148,149,156,161] Apart from simple alkyl- and aryl-amines, aminoalcohols,[144,146,147] aminoacetals,[144] amino acids and their derivatives,[146,147,156,157] sulphamoylbenzoic acid derivatives,[143] and amides[150–152] have been used in the condensation.

Reaction of 1,4-diketones with hydroxylamine and hydrazines gives 1-hydroxy- and 1-amino-pyrroles respectively.[5]

As a rule, cyclisation is carried out by boiling the reagents in an acidic medium. Acetic acid is used the most frequently for this purpose.[141,142,145,149,150–152] The method has virtually no limitations. In a number of cases it is possible to obtain (dioxan, 100 °C, 3 h) pyrroles with bulky substituents[145,149] which are difficult to prepare by another method because of steric hindrance.

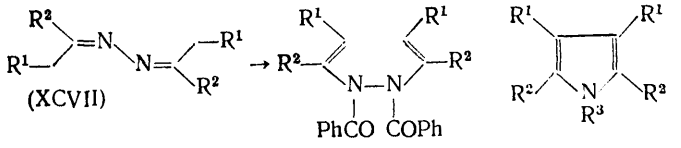


In some cases the Paal–Knorr reaction can be stopped at intermediate stages. Thus, the reaction of diketone (LXXXIX) (R^2 = R^3 = Me) with liquid ammonia results in the formation of a mixture of 2-hydroxy-3,4-dihydro-2*H*-pyrroles (XC) and (XCI), which are readily dehydrated (boiling in methylene chloride, basic Al_2O_3, 8 h) to the 3*H*-pyrrole (XCII). Less substituted diketones (LXXXIX) (R^2 = Me, R^3 = H) give the analogous hydroxypyrrolines (XC) and (XCI) (R^2 = Me, R^3 = H), which are dehydrated to the 1*H*-pyrrole (XCIII) on standing for several days.[162]

(LXXXIX) (XC) (XCI) (XCII) (XCIII)

R^1 = Me, Et, Ph; R^2 = H, MeO, MeCO, Ph; R^3 = H, Me; R^4 = Me, Ph.

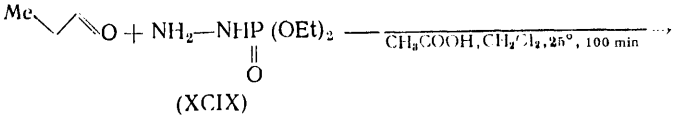
The hydroxypyrroline intermediates (XCV) have also been isolated in the reaction of cyclic 2-(acylmethyl)1,3-diketones (XCIV) with liquid ammonia.[163]



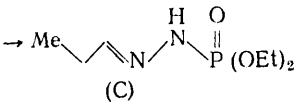
(XCIV) (XCV) (XCVI)

On heating in acetic acid in the presence of ammonium acetate or without a solvent up to the melting point, hydroxypyrrolines (XCV) rearrange to pyrroles (XCVI) in high yield. This rearrangement may occur either by dehydration to a 3*H*-pyrrole with two successive 1,5-acyl shifts or by transannular interaction between the amide nitrogen atom and the carbonyl group.

2. Pyrroles from azines



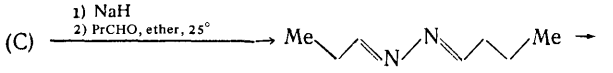
There is a continuous development of methods for the synthesis of pyrroles based on the Piloty reaction. When this reaction is used in its original form, the yields of pyrroles are usually low since strong acid media are used, and it is not possible to convert aldazines to pyrroles. Therefore, in one study[164] azines (XCVII) of enolisable aldehydes and ketones were first converted to *N,N'*-dibenzoyl-*N,N'-bis*(enyl)hydrazines (XCVIII) (by reaction with benzoyl chloride and pyridine in benzene), which on boiling in xylene gave *N*-benzoylpyrroles. Hydrazinolysis of the latter in isopropyl alcohol (80 °C, 1–3 days) yielded *N*-unsubstituted pyrroles.[164]



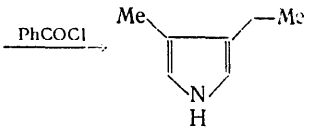
(XCVII) (XCVIII)

$R^1 = H$, Me, Et; R^2 = Me, Et; $R^1R^2 = (CH_2)_5$; R^3 = COPh, H

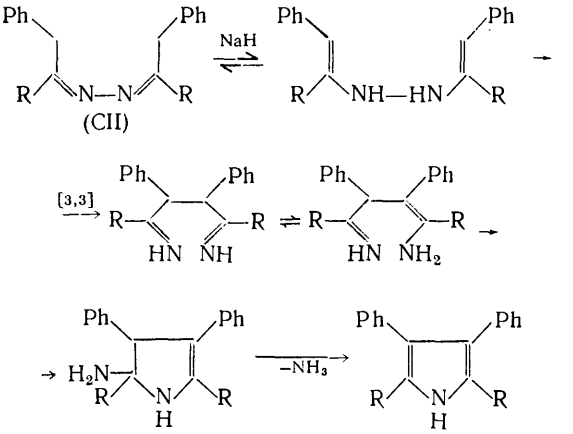
Reaction of propanal with diethyl phosphorohydrizidate (XCIX) gives the hydrazone (C).



(XCIX)



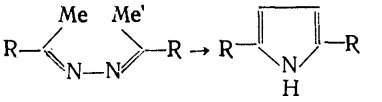
(C)



The sodium salt of (C) reacts with butanal to form the asymmetric azine (CI), which after reaction with benzoyl chloride cyclises to a pyrrole.[164]

(CI)

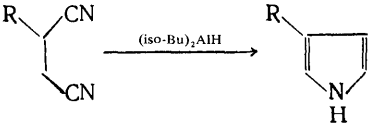
Azines (CII) of carbonyl compounds that contain a readily enolisable benzyl group can undergo thermolysis by catalysis with sodium hydride to give pyrroles.[165,166]



(CII)

R = Me, Et, Pr, iso-Pr, Ph

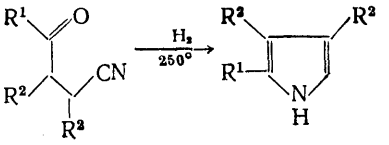
At the first stage of the cyclisation azine (CII) is converted to a dienehydrazine. An alkaline catalyst, not displacing the equilibrium itself, considerably increases the rate of the tautomeric conversion. At the next stage a [3,3]-sigmatropic shift occurs and after that (via several stages accompanied by elimination of ammonia) the pyrrole is formed. The probability that the stage involving C–C bond formation occurs as a [3,3]-sigmatropic shift is borne out by the fact that pyrrole formation takes place by thermolysis without a catalyst.



The thermal (150–170 °C) uncatalysed rearrangement of methylarylketazines to 2,5-diarylpyrroles [167] has also been reported.[167]

R = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, α-naphthyl

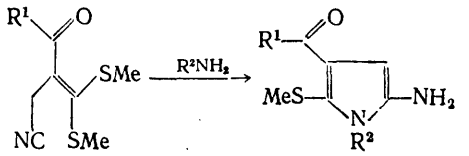
3. Reactions involving a nitrile group



Succinonitriles (CIII) when treated with diisobutylaluminium hydride followed by hydrolysis (NaH_2PO_4, 100 °C, 0.5 h) are converted to pyrroles (CIV) in 34–57% yield.[168]

(CIII) (CIV)

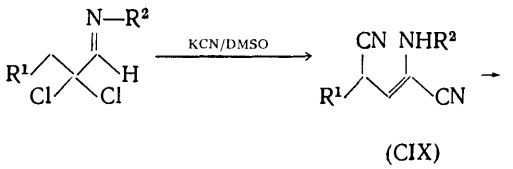
R = iso-Pr, Bu, Ph, 2-ClC_6H_4



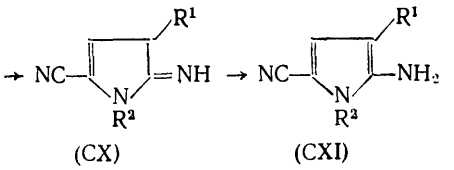
Alkylpyrroles (CVI) are obtained by gas-phase reductive cyclisation of ketonitriles (CV) in the presence of Group VIII metals (Rh, Pd, Pt, Ni).[169]

(CV) (CVI)

R^1 = Alk; R^2 = H, Alk



Cyclisation of α-acylketene *S*,*S*-acetals (CVII) with amines (EtOH, 75 °C, 1–1.5 h) gives pyrroles (CVIII) in 41–61% yield.[170]

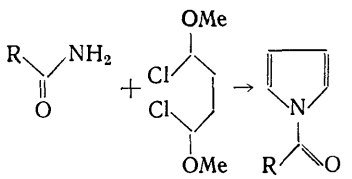


(CVII) (CVIII)

R^1 = Ph, 4-ClC_6H_4, 4-$HO_2CC_6H_4$; R^2 = Me, Et, Bz

Cyclisation of 1,3-dicyanoenamines (CIX), obtained from α,α-dichloroaldimines by treatment with KCN–DMSO (120 °C, 2 h) gives 2-amino-5-cyanopyrroles (CXI) (43–71% yield).[171] Pyrrole formation occurs as a result of intramolecular attack by the amine nitrogen on the CN group and prototropic rearrangement of the intermediate 2-iminopyrroline (CX).

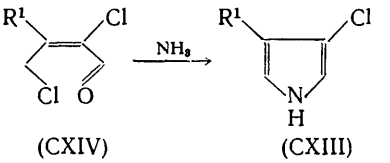
(CIX)



(CX) (CXI)

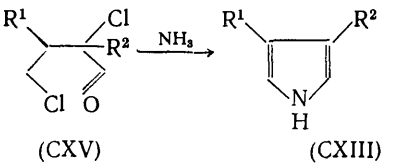
R^1 = Me, Et; R^2 = iso-Pr, t-Bu

4. Reactions of halogen-containing compounds



Some primary amides are converted to *N*-acylpyrroles (yield 55–85%) by reaction with 1,4-dichloro-1,4-dimethoxybutane (CXII) in the presence of an ion-exchange resin (MeCN, 45–60 °C, 12 h).[172]

(CXII)

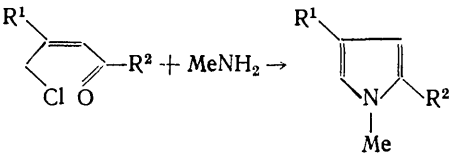


R = Me, Pr, $C_{17}H_{35}$, Ph.

The condensation of chloroaldehydes (CXIV) and (CXV) with ammonia in diglyme gives pyrroles (CXIII).[173–175]

(CXIV) (CXIII)

R^1 = H, Cl

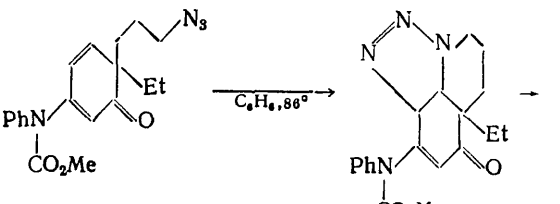


(CXV) (CXIII)

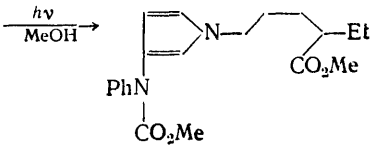
R^1 = HCl; R^2 = Ar

If 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) is used as the catalyst it is possible to carry out the reaction at room temperature.[176]

2,4-Substituted pyrroles (CXVII) are obtained by reaction of chloropropenyl ketones (CXVI) with primary amines.[177]



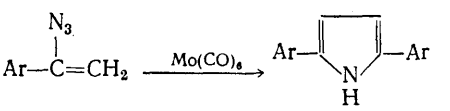
(CXVI) (CXVII)



When secondary amines are used, only replacement of the chlorine atom by an amino group occurs.[177]

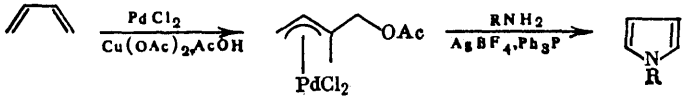
5. Pyrroles from azides

Irradiation of the triazoline (CXIX), which was derived by intramolecular conversion of azide (CXVIII), in methanol solution gave the pyrrole (CXX) in 75% yield.[178]



(CXVIII) (CXIX)

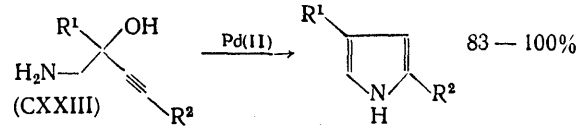
(CXX)



Reaction of the vinylazide (CXXI) with molybdenum hexacarbonyl in protic and aprotic solvents occurs with the formation of 2,5-diarylpyrrole.[179]

(CXXI)

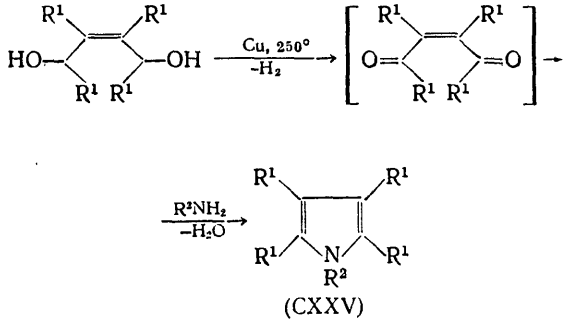
6. Other reactions



The reaction of dienes with $PdCl_2$ and $Cu(OAc)_2$ in acetic acid gives stable palladium π-allyl complexes (CXXII), which on treatment with primary amines in the presence of 1 equivalent of $AgBF_4$ and 0.1 equivalent of triphenylphosphine form pyrroles in 13–54% yield.[180]

(CXXII)

R= Et, Bz.

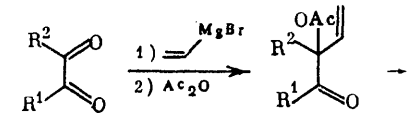


Cyclisation of the acetylenic aminoalcohols (CXXIII) to pyrroles (CXXIV) has been successfully carried out in the presence of palladium [$PdCl_2$ or $Pd(OAc)_2$].[181] A $Pd(Ph_3P)_4$ complex is less effective.

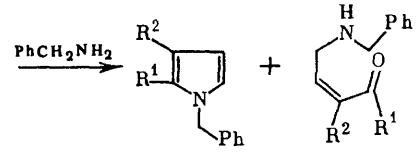
(CXXIII) (CXXIV)

$R^1 = C_6H_{13}$, Ph; R^2 = H, Et, iso-Pr

N-Substituted pyrroles (CXXV) are obtained in good yield by gas-phase cyclocondensation (250 °C) of 2-butene-1,4-diols with primary amines, catalysed by transition metals, in particular, by Cu.[182] At the first stage of the reaction the butenediol is probably dehydrated to a dialdehyde or diketone, which then reacts with the amine.



(CXXV)

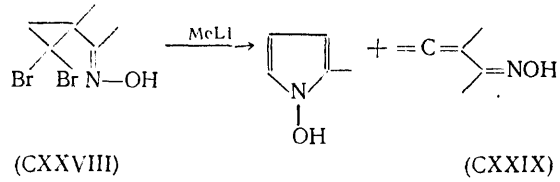


R^1, R^2 = H, Alk, Ar

The possibility of using a reduced fused iron catalyst for the gas-phase synthesis of pyrrole and its derivatives from butanediol, ammonia, and hydrogen has been investigated.[183] At 250–310 °C a mixture consisting of pyrrolidine, *N*-butylpyrrolidine, n-butylamine, n-butanol, 4-(1-pyrrolidyl)-butanol, 1,4-dipyrrolidinebutane, di-n-butylamine, pyrrole, and *N*-butylpyrrole was formed with a total yield of 10–15%. It has been suggested[183] that at lower values of the partial pressure of hydrogen, pyrrole and its derivatives could become the main reaction products.

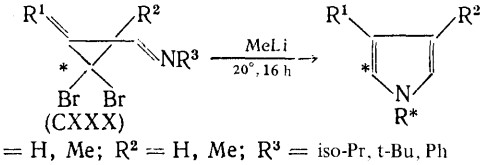
α-Acetoxy-α-vinylalkanones (CXXVI) (products derived from the reaction of α-dicarbonyl compounds with vinylmagnesium bromide and acetic anhydride) react with benzylamine in the presence of $Pd(PPh_3)_4$

(CXXVI)



(CXXVII)

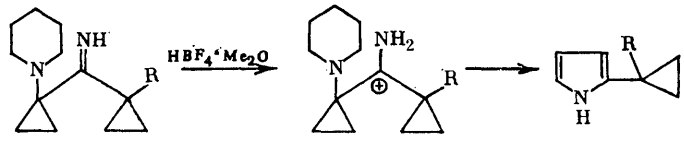
R^1 = H, Me, Ph; R^2 = H, Me, Ph; R^1R^2 = $(CH_2)_4$.



(xylene, THF) to give *N*-benzylpyrroles in 43–65% yield.[184] In addition to pyrroles, aminoketones (CXXVII) are also formed; however, they are not a source of pyrrole.

From oximes of alkyl dibromocyclopropyl ketones (CXXIII) and MeLi were isolated *N*-hydroxypyrroles and allenes (CXXIX),[185] which Santelli considered to be intermediates.

(CXXVIII) (CXXIX)

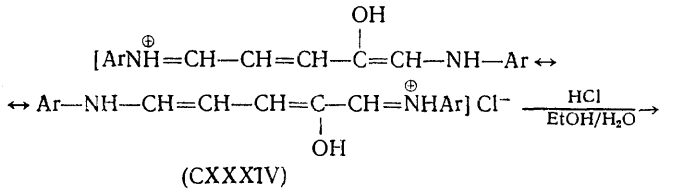


It was shown subsequently[186,187] using dibromocyclopropanimines (CXXX) that pyrroles are formed in similar reactions as a result of a carbene-carbene rearrangement. Imines with a labelled carbon atom were used to demonstrate the mechanism.

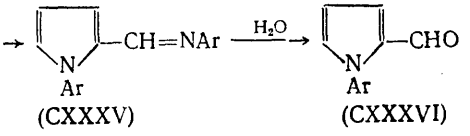
(CXXX)

R^1 = H, Me; R^2 = H, Me; R^3 = iso-Pr, t-Bu, Ph

On heating dicyclopropylketimines (CXXXI) in xylene in the presence of a dimethyl ether—fluoroboric acid complex, pyrroles (CXXXIII) are formed with yields of 32 and 42%.[188]



(CXXXI) (CXXXII) (CXXXIII)

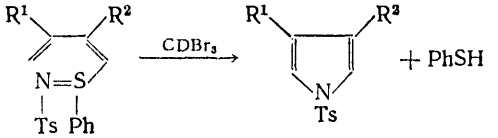


R= H, SPh.

The reaction starts with formation of the carbocation (CXXXII).

N-Arylpyrrole-2-carbaldehydes (CXXXVI) were obtained by acid hydrolysis of salts (CXXXIV).[189]

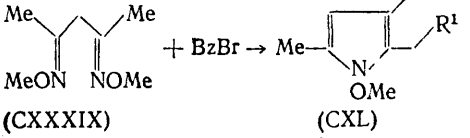
(CXXXIV)



(CXXXV) (CXXXVI)

Ar = Ph, 3-$O_2NC_6H_4$; 4-$O_2NC_6H_4$;

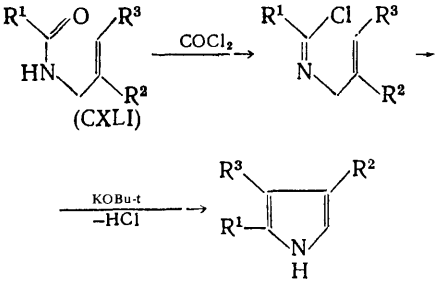
4-Me-3-$O_2NC_6H_3$, 4-MeC_6H_4, 4-BrC_6H_4, 4-ClC_6H_4



When an ethanol solution of the salts was heated without acid, the intermediate anils (CXXXV) were isolated, readily hydrolysing to aldehydes (CXXXVI) in the presence of acids.

A 1 : 1 mixture of the *N*-tosylpyrrole (CXXXVIII) and thiophenol is obtained from *S*-butadienylsulphimines (CXXXVII) (130 °C, 0.5 h, $CDCl_3$).[190] The reaction takes place with preparative yields in different solvents, but the best results are obtained in phenylisocyanate, which combines with thiophenol.

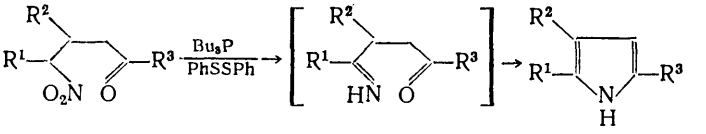
(CXXXVII) (CXXXVIII)



Condensation of benzyl bromide with the diketoxime dimethyl ether (CXXXIX) (HCl, H_2O, CH_2Cl_2, 30 °C, 12 h) gives pyrroles (CXL).[191]

(CXXXIX) (CXL)

$R^1 = H$, $R^2 = Bz$, $R^1 = Bz$, $R^2 = H$



Pyrroles with various substituents are obtained by reaction of *N*-allylamides (CXLI) with $COCl_2$ and then with t-BuOK.[192,193]

(CXLI)

R^1 = Ph, 2-furyl, 2-thienyl, 2-HOC_6H_4, t-Bu; R^2 = H, Me; R^3 = H, Me.

The intramolecular cyclisation of iminoketones (CXLIII), which are formed by reduction of nitroalkanones (CXLII) with tributylphosphine and diphenyl sulphide (THF, 20 °C) gives pyrroles (CXLIV) in high yield.[194,195]

(CXLII) (CXLIII) (CXLIV)

R^1 = Me, CO_2Et; R^2 = Me, Ph; R^3 = Ph, Me

Thus, the methods for constructing a pyrrole ring from aliphatic compounds continue to undergo rapid development. Along with an improvement of the known synthetic methods based on the classical reactions of Knorr, Paal–Knorr, Hantzsch, Chichibabin, and Piloty, there is a constant search for new preparative reactions which can form a pyrrole ring from the most accessible starting materials and under the mildest possible conditions. A particularly rapid development is taking place at present for the recently discovered formation of pyrroles from ketoximes when treated with acetylene or its equivalents (vinyl halides, dihaloethanes) in the presence of superbasic systems of the type KOH–DMSO. This reaction has opened up a simple route to groups of pyrroles that were previously difficult to obtain, including *N*-vinylpyrroles, which are now being synthesised rapidly and studied in detail.

In the present-day synthesis of pyrroles from aliphatic compounds the following trends prevail: 1) there is a wider use of acetylenic compounds or their equivalents (especially acetylenes with strong acceptor substituents and conjugated diacetylenes) as starting materials; 2) different ketone derivatives (oximes, imines, hydrazones, β-nitro derivatives, etc.) are involved in synthesis; 3) there is a change to reagents and catalysts having superbasicity,[196] such as KOH–DMSO, t-BuOK–DMSO, dimsyl sodium, NaH–THF, $NaNH_2$–NH_3, lithium diisopropylamide, etc.; this achieves a substantial increase in the yield of pyrroles, an acceleration of different base-catalysed processes, and in a number of cases gives rise to new reactions.

Heterometallic sulphide-bridged transition metal clusters

A A Pasynskii, I L Eremenko
Kurnakov Institute of General and Inorganic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The literature data on heterometallic clusters with sulphide bridges are described systematically and discussed. The methods for the specific synthesis of clusters and the dependence of their geometry on the electronic structure of their metallic core are examined. The possibilities for the modelling of catalytic systems and materials of the type of magnetic semiconductors and superconductors are discussed.

The bibliography includes 140 references.

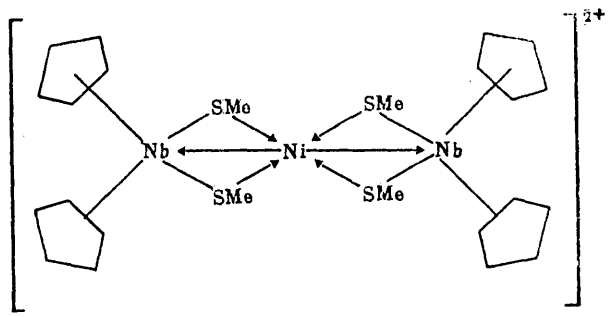
I. Introduction

In recent years, there has been an appreciable growth of interest, both here and abroad, in the study of clusters—polynuclear compounds in which three and more atoms of transition or non-transition elements are linked to one another via metal–metal bonds, bridging ligands, or both.[1] These systems are remarkable because they are shielded by the ligands, throughout the lattice, from cooperative interactions typical of solid state chemistry; clusters are therefore fairly soluble and can be investigated by the usual methods of coordination chemistry. On the other hand, when the number of metal atoms within the cluster is sufficiently large, fragments corresponding to the packing of metallic lattices (triangles, tetrahedra, squares, trigonal bipyramids, octahedra, etc.) arise. All parts of the metallic surface with chemisorbed organic ligands are thus modelled.[2] As a result of the latter factor, clusters became promising starting materials for practical application in the preparation of polymetallic coatings as well as homogeneous and immobilised catalysts.

Among compounds of this kind, heterometallic clusters (HMC) containing several atoms of different metals are especially interesting.[3,4] Sulphide-bridged heterometallic clusters (SHMC) occupy an important place among the HMC. In particular, the active component of the cofactor of the enzyme nitrogenase consists of sulphide-bridged tetrahedra containing iron and molybdenum atoms. Molybdenum atoms fix nitrogen molecules preferentially, while the cluster as a whole, together with the $Fe_4S_4(SR)_4^{4-}$ clusters, ensures electron transfer in the process involving the reduction of nitrogen to ammonia.[5]

Furthermore, the presence in one HMC molecule of atoms of different metals in precisely known (and frequently specified) proportions makes it possible to obtain materials of the type of mixed sulphides with a high degree of homogeneity and the required ratio of the elements. Examples of such practically important systems are provided by the chalcochromites $M^{II}Cr_2X_4$ with a spinel structure, which have the properties of magnetic semiconductors.[6] Superconducting systems, the socalled "Chevrel phases", containing the Mo_6S_8 clusters (an octahedron of molybdenum atoms incorporated in a cubane structure made up of sulphur atoms), which are linked to one another by heterometallic M atoms (Pb, Sn, Cu, Ag, and the lanthanides), also incorporated in cubane structures made up of sulphur atoms have attracted much attention recently.[7]

One of the main problems in the study and application of sulphide-bridged heterometallic clusters is their synthesis, whose principles will be examined in the present review. We may note that the methods for the specific synthesis of various types of HMC,[8–10] including optically active HMC,[10,11] have become available only in the most recent years and so far do not constitute a well constructed system.



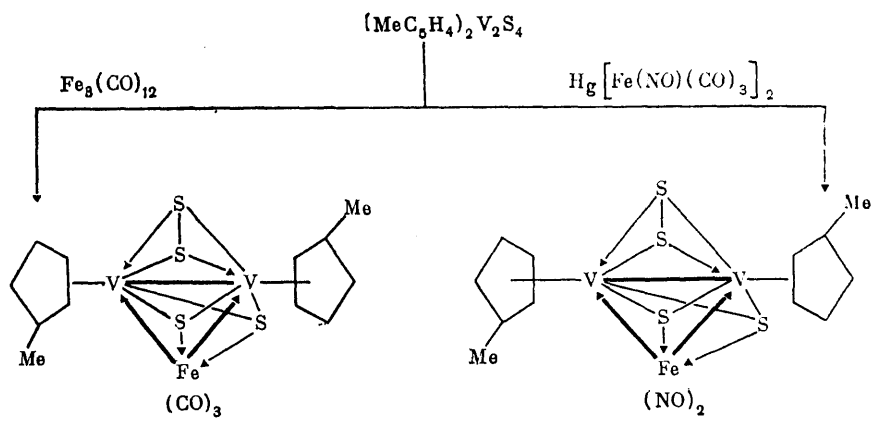
An important aspect of the specific synthesis of SHMC is the "cluster design" principle—the stepwise growth of the cluster core as a result of the employment of mono- and di-nuclear sulphur-containing metal complexes as ligands in relation to other metals (M′). Here one must take into account the electronic characteristics of the "building blocks" such as the presence of unshared electron pairs in the sulphur atoms or the metal atoms participating in the formation of new bonds with M′, the presence of S–S and M–M bonds in which an M′ atom can be inserted, and the presence of unoccupied or semioccupied orbitals of the metal atoms for which new dative bonds with M′ may be formed. Together with steric factors, these factors will be examined in the discussion of the synthesis and structure of clusters, the data being grouped in accordance with the nature of the principal "building blocks" within each Section in order of the arrangement of the heterometals in the Periodic System.

Since the complexity of the composition and geometry of the SHMC imposes special requirements as regards unambiguity in the determination of the structure of the complexes, this review discusses mainly clusters which have been obtained in the form of analytically pure single crystals and have been identified by full X-ray diffraction analysis. Literature data up to 1985 inclusive are incorporated.

II. Sulphide-bridged heterometallic clusters based on sulphur-containing complexes of group VA metals

The mononuclear trianion VS_4^{3-} functions as the central complex-forming agent in reactions with $(Me_4N)_2FeX_4^{2-}$ (X = Cl or SPh) in acetonitrile. This has resulted in the formation[12,13] of the trianions $X_2Fe(S)_2V(S)_2FeX_2^{3-}$ containing the Fe–V–Fe metal chain (for X = Cl, the length of the V–Fe bond is 2.727 Å) with two pairs of sulphide bridges and terminal X groups at the iron atoms. The clusters are paramagnetic (μ_{eff} = 4.96 B.M. for X = Cl and 4.80 B.M. for X = SPh).

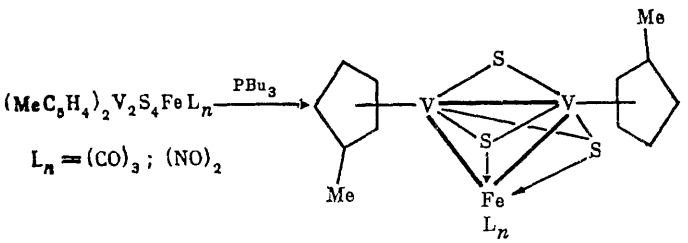
The mononuclear sandwich fragments Cp_2M (Cp = C_5H_5), containing the SR groups which are forced to assume a position in the bisector plane between two cyclopenta-dienyl rings using the frontier orbitals with the $1a_1$, b_2, and $2a_1$ symmetries (their energies increase in this sequence) can serve as terminal complex-forming agents.[14] Thus the coordination of the two chelating ligands $Cp_2Nb(SMe)_2$ is observed when the readily displaced water molecules at the Ni(II) ion are substituted. The nickel atoms in the complex $[Cp_2Nb.(SMe)_2Ni(SMe)_2NbCp_2](BF_4)_2$ are linked to the four sulphur atoms of the SMe groups (the Ni–S bond lengths are 2.186–2.206 Å) and form direct Nb–Ni bonds (2.78 Å) via orbitals located in the bisector plane of the angle between the rings:[15,16]



The complexes $(RC_5H_4)_2V_2S_4$,[18] obtained by treating $(RC_5H_4)_2.V_2S_5$ [19] with tributylphosphine, have been used recently as the starting materials for the synthesis of SHMC.[17] According to X-ray diffraction data, the complex $(RC_5H_4)_2V_2S_4$ (where R = iso-Pr) contains two sulphide bridges and the V–S–S–V fragment having a short V–V bond (2.610 Å). As a consequence of the electron deficiency, significant additional $\overline{S-V}$ π-bonding is observed, which shortens the V–S bonds (2.217–2.280 Å). The presence of unoccupied orbitals in $(MeC_5H_4)_2V_2S_4$ in combination with the presence of sulphide groups involved in different types of bonding, ensures a rich chemistry of this complex.

Thus the initial tetrasulphide complex $(MeC_5H_4)_2V_2S_4$ reacts with $IrCl(N_2)(PPh_3)_3$, affording the trinuclear cluster $(MeC_5H_4)_2V_2.(\mu,\eta^2\text{-}S_2)(\mu_3\text{-}S)_2IrCl(PPh_3)$, in which the iridium atom is located in a square planar environment (according to NMR data).[17]

Table 1. The principal geometrical characteristics of the vanadium-containing SHMC.[17,21]



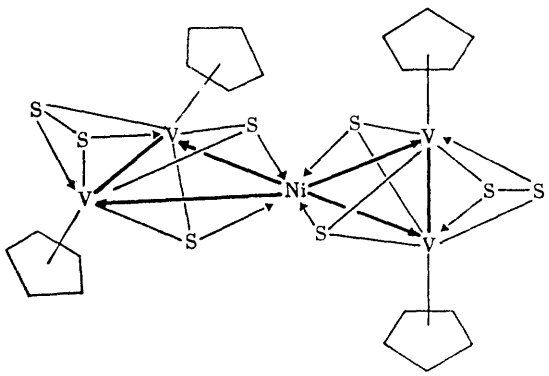
Compound	Bond length, Å (average values)					
	V–V	V–M	V–(μ_3-S)	M–(μ_3-S)	V–(μ,η^2-S)	V–(μ-S)
$(MeC_5H_4)_2V_2S_4Fe(CO)_3$	2.510	2.896	2.318	2.256	2.406	—
$(MeC_5H_4)_2V_2S_4Fe(NO)_2$	2.482	2.849	2.347	2.230	2.398	—
$(MeC_5H_4)_2V_2S_3Fe(CO)_3$	2.506	2.843	2.315	2.266	—	2.235
$(MeC_5H_4)_2V_2S_3Fe_2(NO)_2$	2.957	2.750	2.280	2.241	—	—
$[(MeC_5H_4)_2V_2S_4]_2Ni$	2.484	2.817	2.334	2.193	2.403	—

The addition of the CpCo fragment with formation of the triangular diamagnetic cluster $(MeC_5H_4)_2V_2S_4CoCp$ takes place in the reactions of $(MeC_5H_4)_2V_2S_4$ with $CpCo(C_8H_{12})$, $CpCo(CO)_2$, $[CpCo(CO)]_2$, or with the $CpCo(CO)I_2/Zn$ system (the yield reaches 25% in the last case). The trinuclear cluster $(MeC_5H_4)_2V_2(\mu,\eta^2\text{-}S_2).(\mu_3\text{-}S)_2Fe(CO)_3$ has been obtained by the reaction of $(MeC_5H_4)_2V_2S_4$ with $Fe_3(CO)_{12}$ [17] [or with $Fe(CO)_5$ in the presence of Me_3NO [20]] [$Fe_3S_2(CO)_9$ and $Fe_2S_2(CO)_6$ are formed as side products]:

The nitrosyl cluster $(MeC_5H_4)V_2(\mu,\eta^2\text{-}S_2)(\mu^3\text{-}S)_2Fe(NO)_2$, isoelectronic with the carbonyl-containing cluster, has been obtained by the reaction of $(MeC_5H_4)_2V_2S_4$ and $Hg[Fe(CO)_3(NO)]_2$ in tetrahydrofuran (THF) at 20 °C. The yield rises to 60% when $Fe(CO)_2.(NO)_2$, generated from $(PPh_3)_2N^+.Fe(CO)_3NO^-$ and $NOBF_4$ in the presence of Et_3N,[17,21] is used. When both diamagnetic clusters with the V_2Fe core are formed, the S_2 fragment changes the type of its coordination, being converted from the μ,η^1-bridging fragment (a two-electron donor) to the μ,η^2-bridging fragment (a six-electron donor). This is accompanied by an appreciable lengthening of the V–(μ-S) bond (to 2.318–2.347 Å) and the V–(μ,η^2-S) bond (to 2.406–2.398 Å) (Table 1). Apparently both facts (the rotation of the S_2 group and the lengthening of the V–S bonds) are determined by the decrease in the additional $\overline{V\text{–}S}_{bridge}$ π-bonding, since the unshared electron pairs of the sulphur atoms are used for the formation of the bond with the iron atom. Furthermore, the rotation of the disulphide bridge from the position along the V–V bond to the position at right angles appreciably diminishes (for steric reasons) the length of the V–V bond (2.510 and 2.482 Å respectively) compared with the length of the V–V bond in the initial dimer (V–V = 2.610 Å). The formation of new V–Fe bonds (2.8956 and 2.849 Å) does not interfere with the strengthening of the V–V bond, probably as a consequence of the interaction of the unoccupied orbitals of the vanadium atoms with the occupied orbitals of the iron atom.

When both clusters with the V_2Fe core are treated with tributylphosphine, the S_2 group loses one sulphur atom, affording the trisulphide clusters $(MeC_5H_4)_2V_2(\mu\text{-}S)(\mu_3\text{-}S)_2FeL_n$:[17,20]

In the tricarbonyl cluster, the overall geometry of the $V_2Fe(\mu_3\text{-}S)_2$ fragment [V–V = 2.505 Å, V–Fe = 2.8132 Å, and V–(μ_3-S) = 2.308–2.312 Å] remains the same as in the initial tetrasulphide cluster. However, the V–S bond (2.242 Å) of the V(μ-S)V group is strengthened as a result of the $\overline{V\text{–}S}$ π-bonding, since an electron deficiency arises on the vanadium atom as a consequence of the replacement of the six-electron donating $\mu,\eta^2\text{-}S_2$ group by the formally two-electron-donating bridge μ-S.



On the other hand, the active disulphide groups are capable of undergoing reactions involving the insertion of new metal atoms. Thus treatment of $(MeC_5H_4)_2V_2S_4Fe(CO)_3$ with $Pt(C_2H_4)L_2$ (L = PPh_3) at 25 °C leads to the insertion of the platinum atom in the S–S bond and the formation of the cluster $(MeC_5H_4)_2V_2.(\mu_3\text{-}S)_4Fe(CO)_3Pt(PPh_3)_2$.[17]

The nitrosyl cluster $(MeC_5H_4)_2V_2S_4Fe(NO)_2$ also contains the active $V_2(\mu,\eta^2\text{-}S_2)$ group, and its reaction with $Hg[Fe(CO)_3(NO)]_2$ or the direct interaction of $(MeC_5H_4)_2V_2S_4$ with $Hg[Fe(CO)_3(NO)]_2$ under severe conditions (in boiling toluene) leads to the addition of two Fe(NO) groups and the formation of the tetranuclear cluster $(MeC_5H_4)_2V_2S_4Fe_2(NO)_2$.[17,21]

The core of the molecule consists of the distorted V_2Fe_2 tetrahedron (V–V = 2.957 Å, V–Fe = 2.750 Å, and Fe–Fe = 2.590 Å), having μ_3-sulphide bridges over each face [$(Fe\text{–}S)_{av}$ = 2.241 Å; $(V\text{–}S)_{av}$ = 2.280 Å] and involving the additional coordination of the π-MeC_5H_4 ring at each vanadium atom and of one nitrosyl group at each iron atom. The cluster contains 58 electrons and its magnetic moment (μ_{eff} = 1.98 B.M. at 27 °C) is reduced compared with the spin-only value of 2.84 B.M. for two unpaired electrons, probably owing to antiferromagnetic exchange interactions. The paramagnetic (2.8 B.M.) 60-electron tetrahedral cluster $(MeC_5H_4)_2V_2S_4Co_2(NO)_2$ is in its turn formed readily (yield up to 95%) in the direct reaction of $(MeC_5H_4)_2V_2S_4$ with $Co(CO)_3(NO)$ in boiling toluene.[21]

The mixed paramagnetic 59-electron cluster $(MeC_5H_4)_2V_2S_4CoFe.(NO)_2$ has been obtained by the transmetallation of the cluster with the V_2Fe_2 core in the reaction with $Co(CO)_3(NO)$ in the presence of Me_3NO.[21] On treatment with metallic zinc and $[CoI(NO)_2]_x$,[17] the trisulphide cluster $(MeC_5H_4)_2V_2S_3Fe(NO)_2$ affords the diamagnetic cluster $(MeC_5H_4)V(\mu_3\text{-}S)_3FeCo_2(NO)_6$, which has 66 electrons and, according to the authors,[17] is constructed similarly to [the anion of] the block Roussin salt $Fe_4S_3(NO)_7^-$.[22]

The attempts to obtain the trinuclear cluster containing the V_2Ni core were unsuccessful and the reactions of $(MeC_5H_4)_2V_2S_4$ with nickel-containing reagents—$Ni(CO)_4$, $(COD)_2Ni$, $[CpNi(CO)]_2$, $Ni(CO)_2(PPh_3)_2$, or $Ni(CO)_2(Ph_2PC_2H_4PPh_2)$—resulted in the formation of the pentanuclear cluster $(MeC_5H_4)_4V_4S_8Ni$ with the V_4Ni metallospiran core:[17]

The peripheral S_2 bridging groups can split off one sulphur atom on treatment with a small excess of PPh_3, giving rise to the cluster $[(MeC_5H_4)_2V_2S_3]_2Ni$ with the V_4NiS_6 core.[17] Finally, insertion in the S–S bond is observed in reactions with one or two moles of $Pt(C_2H_4)(PPh_3)_2$ and leads to the growth of the core as a result of the addition of one or two $Pt(PPh_3)_2$ fragments. The clusters $[(MeC_5H_4)_2V_2S_4]_2Ni[Pt(PPh_3)_2]$ and $[(MeC_5H_4)_2V_2S_4]_2Ni[Pt(PPh_3)_2]_2$ have been identified by chemical analysis and IR and ^1H NMR spectroscopy and probably do not contain Pt–V bonds.[17]

$(MeC_5H_4)_2V_2S_5$, in which the short V–V bond (2.658 Å) is supplemented by the μ-S, $\mu,\eta^1\text{-}S_2$, and $\mu,\eta^2\text{-}S_2$ bridges (i.e. one S_2 fragment is coordinated along the V–V bond and the other is coordinated at right angles to it), can be used directly for the preparation of $(MeC_5H_4)_2V_2S_4$ derivatives.[19] However, the yields of the heterometallic clusters are in this case very low.

III. The synthesis and geometry of sulphide-bridged heterometallic clusters obtained using sulphur-containing group VIA metal complexes as ligands

The dinuclear chromium complexes $(C_5Me_5)_2Cr_2S_5$ [23] and (to an especially large extent) the antiferromagnetic complexes $Cp_2Cr_2.(SCMe_3)_2S$ and $(MeC_5H_4)_2Cr_2(SCMe_3)_2S$ described below are used

for the synthesis of chromium-containing SHMC. The complex $(C_5Me_5)_2Cr_2S_5$ [23] differs from the vanadium complex of analogous composition by the fact that it contains, apart from the μ-S and μ,η^2-S_2 bridges, the unusual S_2 bridge which is linked to two chromium atoms only via one sulphur atom [the second sulphur atom is linked to it by a weakened single bond (2.101 Å) which is probably of the donor–acceptor type]. As a result, this bridge is a two-electron ligand and the chromium atoms have the d^2 electronic configuration. The complex is diamagnetic probably as a result of the strong antiferromagnetic exchange reactions via the direct Cr–Cr bond (2.489 Å). The peripheral sulphur atom is then readily split off on treatment with PPh_3, affording the tetrasulphide complex $(C_5Me_5)_2Cr_2S_4$.[24] The sulphur atom is readily abstracted also in the reaction with $Co_2(CO)_8$, which leads to the formation of the diamagnetic cubane-like cluster $(C_5Me_5)_2Cr_2(\mu_3\text{-}S)_4Co_2(CO)_2$ (I).[25] The cluster is stable in air and contains 60 electrons. When it was treated with PR_3 (R = Ph or OMe), the products of the substitution of one and two CO groups were isolated:[26]

$$\underset{\text{(I)}}{(Me_5C_5)_2Cr_2S_4Co_2(CO)_2} \xrightarrow{PR_3} (Me_5C_5)_2Cr_2S_4Co_2(CO)(PR_3) + \underset{\text{(II)}}{(Me_5C_5)_2Cr_2S_4Co_2(PR_3)_2}$$

$PR_3 = PPh_3,\ P(OMe)_3.$

According to X-ray diffraction data, in the bisphosphine derivative (II) [$PR_3 = P(OMe)_3$] the core of the molecule consists of a distorted Cr_2Co_2 metallotetrahedron (Co–Co = 2.511 Å, Co–Cr = 2.638 to 2.660 Å, and Cr–Cr = 2.872 Å) with tridentate-bridging sulphide ligands over each face (Co–S = 2.155–2.179 Å and Cr–S = 2.256 to 2.278 Å).[26] The 60-electron clusters $Cp_2Cr_2(\mu_3\text{-}S)_4Mo_2(C_5Me_5)_2$ and $(C_5Me_5)_2Cr_2(\mu_3\text{-}S)_4Mo_2Cp_2$ with a pseudocubane core, containing chromium and molybdenum atoms, are formed in the photochemical reaction of $(C_5Me_5)_2M_2S_n$ (M = Cr, n = 5; M = Mo, n = 4) with the dinuclear complexes $Cp_2M'_2(CO)_4$ (M′ = Cr or Mo) containing M′≡M′ triple bonds.[27] On the other hand, if the rings in the dimeric carbonyls also contain methyl groups, then stable paramagnetic trinuclear clusters $(C_5Me_5)_3CrMo_2(\mu_3\text{-}S)(\mu\text{-}S)_3$ are formed.[27]

$Cp_2Cr_2(\mu\text{-}SCMe_3)_2(\mu\text{-}S)$ (III), in which chromium(III) atoms are separated by a short distance (Cr–Cr = 2.689 Å), have been used for the synthesis of a large series of magnetically active SHMC. It is formed in the reaction of chromocene with t-butanethiol and its antiferromagnetic properties are described (μ_{eff} falls from 0.96 B.M. to zero in the temperature range 295–79 K) by the exchange parameter $-2J$ = 430 cm^{-1} for the spins of the Cr(III) ions equal to 3/2.[28,29] The methylated analogue $(MeC_5H_4)_2Cr_2$.·$(\mu\text{-}SCMe_3)_2(\mu\text{-}S)$ (IIIa), which is also antiferromagnetic ($-2J$ = 478 cm^{-1}), was obtained in accordance with the same scheme from $(MeC_5H_4)_2Cr$.[30] From the formal point of view, it means that, after the formation of the Cr–Cr single σ-bond, two half-occupied orbitals, on which the magnetic properties depend, are present at each chromium atom. On the other hand, together with the presence of the unshared electron pairs in the sulphide and thiolate bridges, the presence of the above half-occupied orbitals determines the chemical behaviour of the complexes (III) and (IIIa).

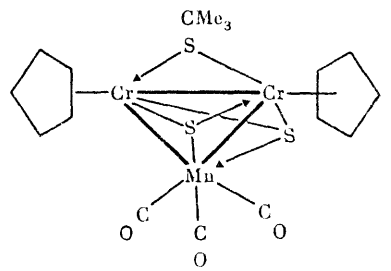
1. Ferromagnetic clusters with the Cr_2Pd core

The complexes (III) and (IIIa) readily react under mild conditions (benzene, 20 °C) with $(PPh_3)_2PdCl_2$, affording the dark-green crystalline complexes $(RC_5H_4)_2Cr_2(SCMe_3)_2(S)(Cl)_2Pd(PPh_3)$ (R = H or Me). The composition of the clusters formally corresponds to 1 : 1 adducts, but, in contrast to the initial dinuclear complexes, the new clusters manifest ferromagnetic exchange interactions [μ_{eff} = 4.11 (296 K)–4.57 (79 K) B.M. and $+2J$ = 28 cm^{-1} for R = H; μ_{eff} = 3.87 (296 K)–4.20 (95 K) B.M. and $+2J$ = 11 cm^{-1} for R = Me).[13] According to X-ray diffraction data for the cluster with R = Me, the preferred rearrangement takes place in the resulting clusters in conformity with Pearson's principle:[32] the Cl atoms (hard Lewis bases) pass from the palladium atom (a soft Lewis base) to the chromium(III) atoms (hard Lewis bases). The $SCMe_3$ groups (soft Lewis bases), which previously served as bridges between the chromium atoms, then becomes bridges between the chromium and palladium atoms. The chelate ligand $(PPh_3)Pd(SCMe)_2$ (Pd–S = 2.350 and 2.381 Å), coordinated to to chromium atoms via thiolate bridges (Cr–S = 2.396 and 2.403 Å; Cr...Pd = 3.230 and 3.380 Å), is ultimately formed. The chromium atoms in this situation are coordinated to the π-MeC_5H_4 rings and the chlorine atoms (Cr–Cl = 2.308 Å) located in the *trans*-positions relative to the Cr_2Pd plane. As a result of such ligand environment of each chromium atom [the MeC_5H_4(centre)–Cr–Cr angle is 124.5° instead of 180° in compound (III)], the effective overlap of the d_{z^2} orbitals, which mainly determines the bonding of the chromium atoms in the dinuclear complexes (III) and (IIIa), becomes impossible. The Cr...Pd distances in the clusters are also large for bonding and, in the absence of M–M bonds, the antiferromagnetic contribution to the exchange interactions diminishes sharply and it is found possible to observe the ferromagnetic exchange via the sulphide bridge (the Cr–S–Cr angle is 121.77°).

2. The $(CpCrSCMe_3)_2S.ML$ adducts

The course of the interaction of the complex (III) with metal carbonyls is determined by the coordination number of the corresponding metal [CN(M)]. For CN(M) = 6, any adducts in which the $M(CO)_5$ is linked to the virtually unaltered complex (III) (Cr–Cr = 2.73 Å) via a sulphide bridge (M–S = 2.58 Å for M = Mo or W) are formed for $M(CO)_6$ (M = Cr, Mo, or W) with CN(M) = 6 on UV irradiation. Ultimately the magnetic properties remain unaltered ($-2J$ = 440 cm^{-1}).[33,34] The reaction of compound (III) with $Mn_2(CO)_{10}$ takes place analogously in THF at 10 °C, where the $Mn_2(CO)_9$ fragment is generated under the influence of UV irradiation.[35] It adds to the sulphide bridge in the initial chromium complex (III) in the *cis*-position relative to the Mn–Mn bond. Here CN(M) is also six and the dichromium fragment remains almost unchanged (Cr–Cr = 2.739 Å, Cr–$SCMe_3$ = 2.35 Å, Cr–S = 2.31 Å) like the magnetic properties ($-2J$ = 440 cm^{-1}), although the Mn–S distance is smaller (2.448 Å) than the Mo–S distance in the adducts described above.

Finally, as a result of the photochemical reaction of compound (III) under mild conditions ($h\nu$, 7°C), cyclopentadienylmanganese tricarbonyl $CpMn(CO)_3$ with CN(M) = 6 (the Cp ring occupies three coordination sites) also gives rise to a simple adduct of the initial complex, with $CpMn(CO)_2$ "suspended" under it and linked via a sulphide bridge only, the Mn–S bond being shortened to 2.334 Å. The geometry of the dichromium fragment is virtually unchanged on coordination of the manganese atom (Cr–Cr = 2.704 Å, Cr–$SCMe_3$ = 2.350–2.364 Å, and Cr–S = 2.295 Å).[36] All these adducts have a common geometrical feature involving the coordination of the "suspended group" to an M atom having an octahedral environment (i.e. for a coordination number of 6), the possibility of further interaction of the M atom (Mo, W, or Mn) with the thiolate sulphur atom being sterically blocked by two carbonyl groups.



3. Triangular clusters with the Cr_2M core

The reactions involving complexes in which CN(M) is less than 6, i.e. when there is a possibility of the interaction of the orbitals of the M atom with the thiolate sulphur atom in the intermediates, proceed differently.

Thus the photochemical reaction of compound (III) with $Fe(CO)_5$ in THF takes place with the loss of two CO groups and one t-butyl group, the $Cp_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2Fe(CO)_3$ cluster (IV) being formed.[37] Replacement of the S–CMe_3 σ-bond in it by the Fe–S bond alters little the geometry of the $Cp_2Cr_2S_2(SCMe_3)$ fragment compared with compound (III) (Cr–Cr = 2.707 Å). However, the appearance of the paramagnetic Fe(I) ion with the d^7 electronic configuration leads to the non-equivalence of the Cr–Fe bonds (2.726 and 3.110 Å) and to the magnetic properties being described by three parameters of the antiferromagnetic exchange interactions ($-2J_{Cr-Cr}$ = 380 cm^{-1}, $-2J_{Cr-Fe}$ = 2600 cm^{-1}, and $-2J_{Cr\ldots Fe}$ = 170 cm^{-1}). Apparently the half-occupied and occupied $Fe(CO)_3$ orbitals participate in the interaction with the two half-occupied orbitals in the dichromium fragment, forming a two-electron (single) Fe–Cr bond (2.726 Å) with one of the chromium atoms and a one-electron (bond order 1/2) Fe–Cr bond (3.110 Å) with the other atom.

Although the Mn atom in the above adduct of compound (III) with the $Mn_2(CO)_9$ fragment has CN(M) = 6, on UV irradiation under more severe conditions (boiling benzene or THF) there is a possibility of the dissociation of the Mn–Mn bond with decrease of CN(M) to five:[38]

$$(C_5H_5)_2Cr_2(SCMe_3)_2S\cdot Mn_2(CO)_9 \xrightarrow[C_6H_6,\ 80^\circ]{(III)}$$

(V)

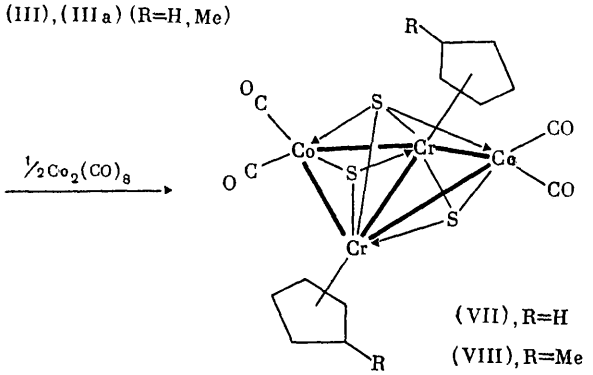
This results in the formation of the antiferromagnetic metallocyclic cluster $Cp_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2Mn(CO)_3$, whose composition is analogous to the iron-containing cluster (IV) but which differs in geometry and magnetic properties. Thus both Cr–Mn distances correspond to the presence of M–M′ bonds, although some non-equivalence, induced by the symmetry of the $Mn(CO)_3$ fragment relative to Cr_2S_2, is in fact observed in them (2.716 and 2.828 Å). On passing from the iron- to the manganese-containing cluster, in which the Mu(I) ion has the d^6 electronic configuration, the electron is apparently removed from the antibonding orbital, which leads to a marked stabilisation of the metallic core in compound (V). The Mn(I) ion is diamagnetic and the magnetic properties of the cluster (V) correspond to antiferromagnetic exchange interactions with the parameter $-2J_{Cr-Cr}$ = 670 cm^{-1}, which is much greater than for the $Cp_2Cr_2(SCMe_3)_2SML$ adducts (~440 cm^{-1}). Since the Cr–Cr bond in compound (V) (2.646 Å) has hardly changed compared with compound (III) (2.689 Å), the intensification of the exchange interactions can be evidently explained by the involvement of the bridging manganese atom.

The antiferromagnetic cluster $Cp_2Cr_2(SCMe_3)(\mu_3\text{-}S)_2FeCp$ (the iron atom in the cluster has the d^6 electronic configuration), which is formed in the form of dark-brown crystals on prolonged irradiation (17 h) of a boiling solution of compound (III) and $[CpFe(CO)_2]_2$ in THF (reactant ratio 2 : 1), is an isoelectronic analogue of the cluster (V).[39]

In contrast to the Cr, Mo, W, Mn, and Fe carbonyls or the cyclopentadienyl-manganese and -iron carbonyls, whose reactions with $Cp_2Cr_2(SCMe_3)_2S$ require UV irradiation and elevated temperatures, the dinuclear cobalt carbonyl $Co_2(CO)_8$ reacts with the dichromium complexes (III) and (IIIa) even at room temperature. The complex $Co_2(CO)_8$ exists in solutions in the non-bridged form [CN(Co) = 5] with a readily dissociating Co–Co bond (E = 9 kcal mol^{-1} [40] and the coordination with the sulphur atoms and the replacement of the S–CMe_3 bond in compound (III) or (IIIa) by the S–Co bond therefore proceed especially readily. The cluster $Cp_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2Co(CO)_3$ (A), having a composition analogous to that of the iron-containing cluster (IV) and the manganese-containing cluster (V), should then be formed. However, owing to the d^8 electronic configuration of Co(I), the intermediate (A) must contain two electrons in the antibonding orbital of the metallic core. As a result, both Cr–Co bonds must have a bond order of 0.5 (or one bond is single and the other does not exist). Stabilisation of the intermediate (A) is readily achieved by splitting off of one carbonyl group on evacuation or heating of the reaction mixture, which results in the formation of the cluster $Cp_2Cr_2(SCMe_3)(\mu_3\text{-}S)_2Co(CO)_2$ (VI).[35] According to X-ray diffraction data, compound (VI) has a stable metallic core with short Cr–Co bonds, which are almost equivalent (2.579 and 2.592 Å), since the two CO groups are distributed symmetrically relative to the pairs of chromium and sulphur atoms. The length of the Cr–Cr bond (2.617 Å) is changed relatively little (by 0.07 Å) compared with the initial complex (III). Therefore the increase in the parameter $-2J$ to 530 cm^{-1} is determined by the presence of the diamagnetic bridging cobalt atom.

The cluster $(MeC_5H_4)_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2Co(CO)_2$, whose structure differs from that of the non-methylated analogue by the appearance of the crossed conformation of the rings instead of the eclipsed conformation, has been obtained analogously. Furthermore, on methylation of the ring, a slight but distinct strengthening of the metallic core compared with compound (VI) is observed (Cr–Cr = 2.590 and 2.617 Å, Cr–Co = 2.530, 2.569, 2.579, and 2.592 Å respectively). The antiferromagnetic exchange interactions are also found to have become more intense ($-2J$ = 578 cm^{-1}).[38]

Thus the introduction of the methyl substituent into the cyclopentadienyl ring strengthens the core and intensifies the exchange interactions, which is apparently associated with the increase in the electron density at the chromium atoms. This agrees with data for the electrochemical oxidation of $(RC_5H_4)_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)Co.(CO)_2$. According to voltametric and microcoulometric data, both clusters give rise to two reversible one-electron oxidation waves in dimethylformamide (DMF) at potentials of 0.63 and 1.47 V (for R = H) and 0.44 and 1.10 V (for R = Me).



4. "Metallobutterfly" clusters with a Cr_2M_2 core

After the formation of compound (VI) and its methylated analogue, the remaining half-occupied orbitals of the chromium atoms can participate in further Cr–M bonding during the growth of the cluster core as a result of the reaction with an additional amount of $Co_2(CO)_8$, which leads to the formation of diamagnetic clusters having the general composition $(RC_5H_4)_2Cr_2(S)_3Co_2(CO)_4$, where R = H [compound (VII)] or Me [Compound (VIII)] with a metallic

core made up of two chromium atoms and two cobalt atoms.[39] We may note that, together with the replacement of the S–CMe_3 σ-bond in compound (VI) by a new S–Co bond, a μ_4-S bridge is produced by using yet another electron pair at the μ_3-sulphide bridge:

$$(C_5H_4R)_2Cr_2(\mu\text{-}SCMe_3)_2S \xrightarrow{1/2\,Co_2(CO)_8} (RC_5H_4)_2Cr_2(SCMe_3)(\mu\text{-}S)_2Co(CO)_2 \longrightarrow$$

(III), (IIIa) (R=H, Me)

(VII), R=H

(VIII), R=Me

There are no electrons in the antibonding orbitals of the Cr–Co bonds in the 62 electron clusters (VII) and (VIII) with the "metallobutterfly" core and all the Cr–Co bonds are therefore short and virtually equalised [2.617 and 2.622 Å in compound (VII) and 2.614–2.636 Å in compound (VIII)] by virtue of the symmetrical disposition of both $Co(CO)_2$ groups relative to the Cr_2S_2 fragment. The electrons participating in the formation of the Cr–Cr σ-bond are not then involved and the removal of the bulky CMe_3 groups, which hinder the mutual approach of the chromium atoms, shortens the Cr–Cr bonds to 2.544 Å (in both clusters).

The products of the formal replacement of the 13-electron $Co(CO)_2$ fragments in the cluster (VII) are the 15-electron CpNi fragments formed by the reaction of $Cp_2Cr_2(\mu\text{-}SCMe_3)_2(\mu\text{-}S)$ (III) with the dinuclear cyclopentadienylnickel carbonyl $[CpNi(CO)]_2$, which, like the isolobal $Co_2(CO)_8$ complex, exists in solution in a non-bridged form [CN(Ni) = 5] and probably readily dissociates at the Ni–Ni bond. Therefore, as for $Co_2(CO)_8$, the reactants interact in equimolar amounts even at room temperature with formation of the 66-electron cluster $Cp_2Cr_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Ni_2Cp_2$ (IX).[41] The cluster has an asymmetric "metallobutterfly" core with Cr–Ni distances non-equivalent in pairs (cf. 2.620 and 2.844 Å) and contains four superfluous electrons compared with $Cp_2Cr_2(S)_3Co_2(CO)_4$ (VII). These electrons are apparently located in the antibonding orbitals of the metallic core and not only the Cr–Ni bonds are lengthened, despite the smaller covalent radius of nickel compared with cobalt, but also the Cr–Cr bond [2.620 instead of 2.544 Å in compound (XVII)]. In addition, this leads to the appearance of antiferromagnetic properties ($-2J$ = 418 cm^{-1}).

5. Heterometallic tetrahedral clusters

The clusters $(\pi\text{-}C_5Me_5)_2Cr_2(S)_4Co_2(PR_3)_2$, containing the tetrahedral Cr_2Co_2 core, were described above.[25] An analogous cluster can be obtained by introducing a fourth sulphur atom instead of two carbonyl groups into the "metallobutterfly" $Cp_2Cr_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Co_2.(CO)_4$ (VII) in the reaction with t-butanethiol:[39]

$$(C_5H_5)_2Cr_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Co_2(CO)_4 + Me_3CSH \rightarrow (C_5H_5)_2Cr_2(\mu_3\text{-}S)_4Co_2(CO)_2.$$

A 60-electron diamagnetic cluster with an analogous structure has been obtained by the formal replacement of one Co(CO) fragment by the isoelectronic CpCr fragment. The cluster $Cp_3Cr_3(\mu_3\text{-}S)_4Co.(CO)$ (X) and its methylcyclopentadienyl analogue have been synthesised by treating the metallotriangular clusters $(RC_5H_4)_2Cr_2.(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2Co(CO)_2$ of type (VI) (R = H or Me) with diphenylacetylene which leads to the binding of some of the cobalt atoms (probably in the form of stable acetylene complexes).[42] The pseudocubane core is readily loosened on methylation of the Cp rings (the bond lengths in the Cr_3CoS_4 cores with R = H or Me are respectively Cr–Co = 2.650 and 2.692 Å and Cr–Cr = 2.810 and 2.816 Å). The M–S bonds are then found to be extremely short (Co–S = 2.163 and 2.171 Å and Cr–S = 2.244 and 2.263 Å), which indicates the undoubted occurrence of the additional $\overleftarrow{M\text{–}S}$ π-interaction.

The M–M′ bonds are loosened even more after the introduction of additional electrons into the metallic core of new electron-donating ligands, for example, on formation of the cluster $Cp_3Cr_3.(\mu_3\text{-}O)(\mu_3\text{-}S)_3Co(CO)_3HOOCCMe_3$ (XI).[43] It is produced as a result of the treatment with trimethylacetic acid of the reaction mixture of compound (III) and $Co_2(CO)_8$ in benzene [the mixture is obtained without concentration *in vacuo* and without heating, i.e. under conditions where the intermediate containing the $Co(CO)_3$ fragments may be obtained—see above]. As a result of the addition of two carbonyl groups, the metallotetrahedron (XI) is found to have four electrons more than in compound (X). They occupy antibonding orbitals of the metallic core but influence mainly bonds involving the cobalt atom. Not only the Cr–Co bonds (2.875, 3.219, and 3.230 Å), but also the Co–S (2.47 Å) and Co–O (2.16 Å) bonds are found to be greatly lengthened. On the other hand, in the metallotriangle Cp_3Cr_3 the Cr–Cr bond lengths (2.692–2.884 Å) are found to be within the limits characteristic of the trichromium fragment in the metallotetrahedral cluster (X). Trimethylacetic acid is a convenient reagent, binding some of the heterometal atoms occurring in the triangular clusters without the cleavage of the CpCr bond and with retention of the sulphide bridges. Thus treatment of the metallotriangular cluster $Cp_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)Fe(CO)_3$ (IV) with Me_3CCOOH yielded the heterometallotetrahedral cluster $Cp_3Cr_3.(\mu_3\text{-}S)_4Fe(OOCCMe_3)$ (XII), which contains a carboxylate group at the Fe atom linked only via one oxygen atom (Fe–O = 1.896 Å, C–O = 1.32 Å, and C–O = 1.25 Å) and is a structural analogue of the cluster $Cp_3Cr_3(\mu_3\text{-}S)_4Co(CO)$ (X) with a similar geometry (Fe–Cr = 2.758 Å, Cr–Cr = 2.830 Å, Fe–S = 2.218 Å, and Cr–S = 2.270 Å).[44] However, the replacement of the 11-electron Co(CO) fragment by the 9-electron $Fe(OCOCMe_3)$ fragment renders the cluster (XII) electron-deficient [58 electrons instead of the 60 electrons in compound (X)]. The two upper degenerate orbitals, which are occupied in compound (X), are found to be half-occupied in compound (XII), which is consistent with the observed paramagnetism of the cluster (μ_{eff} = 2.81 B.M.) and is close to the spin-only value for two unpaired electrons and is independent of temperature.

We may note that the reaction of compound (IV) with benzoic acid under the same conditions leads to the loss of the cyclopentadienyl ligands and of the thiolate bridge. All the metal atoms and one μ_3-sulphide bridge are then retained and the complex $Cr_2Fe.(\mu_3\text{-}S)(OOCPh)_6$ is formed.[44] The reactions of benzoic acid with the adducts $Cp_2Cr_2(SCME_2)_2S.ML_n$ [ML_n = $Cr(CO)_5$ or $Mn_2(CO)_9$] led to the analogous complexes in which the iron atom was replaced by the Cr(II) and Mn(II) atoms. The complexes are antiferromagnetic and the exchange parameters $-2J_{Cr...Cr}$ (54, 84, and 60 cm^{-1}

respectively) and $-2J_{Cr...M}$ (6, 36, and 28 cm^{-1})[44] exceed approximately by a factor of 2 the corresponding values for the known μ_3-oxo-bridged analogues.[45] This indicates an appreciable contribution of the exchange via the central bridging atom compared with the exchange via the carboxylate bridges and the small exchange parameters clearly indicate the absence of direct M–M bonds.

6. Pentanuclear heterometallospiran clusters

The cluster $[(MeC_5H_4)_2V_2S_4)_2Ni$ having the structure of a heterometallospiran with the $V_4(\mu_3\text{-}S)_4Ni$ core was described above.[17] It is the first representative of chromium-containing metallospiran clusters having the cobalt central atom. It arose very unexpectedly in the reaction of the metallotriangle $Cp_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2Co(CO)_2$ (VII) with Me_3CCOOH under severe conditions (xylene, 100 °C). This results in the binding of some of the cobalt atoms in the form $[Co(OOCCMe_3)_2]_n$ and the formation of the brown crystals of the antiferromagnetic cluster $[Cp_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2]_2Co$ (XIII) [μ_{eff} falls from 3.26 (292 K) to 2.19 (81 K) B.M.].[43] According to the results of full X-ray diffraction analysis, the two metallotriangular Cr_2Co fragments in the spiran core are arranged at an angle of 94.6° and are joined by the common cobalt atom. On the one hand, the geometry of each triangular fragment is similar to that observed in the initial triangle (VI). The dichromium fragments $Cp_2Cr_2(\mu\text{-}SCMe_3)(S)_2$ (designated henceforth by Q) remain almost unchanged under these conditions (Cr–Cr = 2.679 and 2.665 Å) (Table 2). On the other hand, pronounced loosening and asymmetry of the lengths of the Cr–Co heterometallic bonds are observed (2.766 and 2.744 Å in one triangle and 2.809 and 2.959 Å in the other).

If the dinuclear five-electron fragment Q is regarded as an unusual antiferromagnetic chelate ligand, then the cluster (XIII) is a formal product of the substitution of two CO groups in the initial compound (VI) by the fragment Q, the sulphur atoms occupying the places of the CO groups. As a result of such bonding, a 19 electron environment arises at the cobalt atom, the one superfluous electron loosening the Co–Cr and Co–S bonds [the Co–S bonds in compound (XIII) are lengthened on average by 0.075 Å compared with the initial compound (VI)]. We may note that, as in the metallotriangular cluster (IV) with the Cr_2Fe core, this occurs despite the general electron deficiency of the cluster (one half-occupied orbital remains in each chromium atom as before, which ensures the antiferromagnetic properties of the cluster).

The removal of an electron from the antibonding orbitals takes place on formal replacement of the central Co(II) ion by the Fe(II) ion. Such a cluster, $[Cp_2Cr_2(SCMe_3)(\mu_3\text{-}S)_2]_2Fe$ (XIV), has been obtained by the reaction of two moles of compound (III) with one mole of $Fe(CO)_5$ on prolonged UV irradiation in boiling THF, the reaction proceeding (according to IR spectroscopic data) via the intermediate formation of the triangular cluster $Cp_2Cr_2(SCMe_3).(\mu_3\text{-}S)_2Fe(CO)_3$ (IV) described above.[39] The cluster (XVI) was isolated in the form of fine black-green prisms, stable in air, by recrystallisation from a THF–heptane mixture; the composition of the cluster was established by elemental analysis, its IR spectrum being virtually identical with that of the cluster (XIII). The cluster (XIV) is antiferromagnetic and its μ_{eff} diminishes from 3.32 to 2.37 B.M. in the temperature range 290–80 K. Unfortunately, the crystals of the cluster (XIV) proved to be unsuitable for X-ray diffraction study.

The methylcyclopentadienyl analogue $[(MeC_5H_4)_2Cr_2(\mu\text{-}SCMe_3).(\mu_3\text{-}S)_2]_2Fe$ (XV) was obtained by the prolonged reaction of compound (IIIa) with $[CpFe(CO)_2]_2$ for a 4 : 1 reactant ratio in boiling toluene.[46] In this case the geometry of the metallic core of the cluster is determined to an appreciable extent by the steric effects

Table 2. Comparison of the principal geometrical parameters of the metallospiran clusters $[(RC_5H_4)_2Cr(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2]_2M$.

Parameter	Central metal atom M in metallospiran

of the MeC_5H_4...S repulsion (2.9–3.1 Å), leading to a marked change of the angle between the Cr_2Fe triangles (to 113.8°). This effect probably determines the non-equivalence of the Fe–Cr and Fe–S distances in the spiran core: Fe–Cr = 2.749 and 2.827 Å and Fe–S = 2.166 and 2.242 Å in one triangle and Fe–Cr = 2.910 and 2.969 Å and Fe–S = 2.293 and 2.368 Å in the other. Bearing in mind the difference between the covalent radii of iron and cobalt (1.34 and 1.29 Å), the Fe–Cr distances in compound (XV) indicate some stabilisation of the heterometallic bonds in the core compared with compound (XIII), i.e. on removal of an electron from the antibonding orbitals of the metallic core. The geometry of the $(MeC_5H_4)_2Cr_2(\mu\text{-}SCMe_3)(S)_2$ = Q′ fragments (especially the middle distance Cr–Cr = 2.675 Å) then remains very close to that found in compound (III). The cluster (XV) exhibits antiferromagnetic properties.

The same steric effects of the methyl groups in the rings are observed in the analogous cluster $[(MeC_5H_4)_2Cr_2(SCMe_3)(\mu_3\text{-}S)_2]_2Mn$ (XVI) containing the central Mn(II) ion. The cluster (XVI) was obtained by the reaction of compound (IIIa) in boiling toluene with manganocene Cp_2Mn, which readily loses the Cp ligands.[46] Owing to the short MeC_5H_4...S contacts (2.95–3.12 Å), the planes of the Cr_2Mn triangle are rotated by an angle of 109.6°. Not only do the Mn–Cr bonds differ under these conditions but also the lengths of the Cr–Cr bonds are not the same, a shorter Cr–Cr bond (2.657 Å) corresponding to the greatly lengthened Mn–Cr bonds (3.104 and 3.019 Å). The opposite picture is observed for the other triangle: a lengthened Cr–Cr bond (2.726 Å) corresponds to the shortened Mn–Cr bonds (2.839 and 2.967 Å). It is notable that all the Mn–Cr and Mn–S bonds (2.318–2.502 Å) are significantly lengthened compared with the corresponding bonds in the trinuclear cluster $QMn(CO)_3$. This is apparently due to the greater amount of ionic character in the bonds with a high-spin Mn(II) ion (d^5 electronic configuration). This idea agrees with the magnetic properties: μ_{eff} diminishes from 2.51 to 1.26 B.M. in the temperature range 295–80 K, which is described by the antiferromagnetic exchange parameters $-2J_{Cr-Cr}$ = 668 cm^{-1} and $-2J_{Cr-Mn}$ = 418 cm^{-1} for the spins of the Cr(III) and Mn(II) ions of 3/2 and 5/2 respectively.

The steric nature of the distortions in the geometries of the clusters (XV) and (XVI) is demonstrated by the removal of these distortions on passing to the non-methylated cluster $[Cp_2Cr_2.$ $.(SCMe_3).(S)_2]_2Mn$ (XVIII), which has been obtained by the reaction of two moles of compound (III) with one mole of $CpMn(CO)_3$ under severe conditions (on UV irradiation in boiling toluene).[47] The adduct $Cp_2Cr_2(SCMe_3)_2S.MnCp(CO)_2$ is formed as an intermediate and reacts with a second molecule of compound (III), affording the cluster (XVII) in the form of dark-green prisms. In compound (XVII), the angle between the Cr_2Mn planes is 90° and the geometry of the fragments Q remains unchanged (Cr–Cr = 2.690 Å and Cr–S = 2.307–2.324 Å), but, owing to the increased amount of ionic character, the Cr–Mn (2.947 and 2.936 Å) and Mn–S (2.393 and 2.324 Å) bonds are found to be lengthened compared with the triangular cluster $QMn(CO)_3$ (V).

The homonuclear cluster $[Cp_2Cr_2(SCMe_3)(S)_2]_2Cr$, containing the central Cr(II) ion (d^4 electronic configuration), which has been obtained by the reaction of compound (III) with C_6H_6 $Cr(CO)_3$ in THF on UV irradiation (not only the carbonyl groups but also the photolabile arene ligand are then substituted), has virtually the same geometry.[48] The peripheral Cr–Cr bonds are extremely short (2.665 Å) compared with the Cr_{periph}–Cr_{centr} bonds (2.933 and 2.889 Å). However, when account is taken of the difference between the covalent radii of Cr and Mn (1.46 and 1.34 Å respectively), the latter bonds are strengthened compared with Cr–Mn in compound (XVII). This can apparently be explained by the decrease in the amount of ionic character in the bonds on passing from d^5 to d^4.

We may note that the metallospiran clusters Q_2M (M = Cr, Mn, Fe, or Co) represent a new class of complex with chelate antiferromagnetic ligands Q, the character of the bonding of which to the central metal depends on the electronic configuration of M and the steric effect of the methyl substituents in the cyclopentadienyl ligands at the chromium atom.

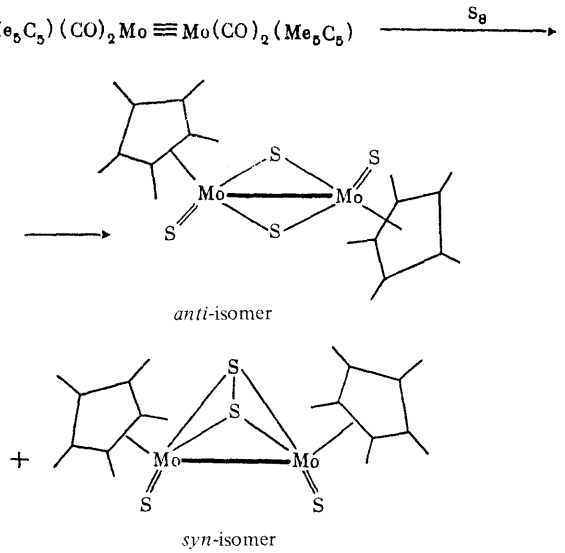
The series of the structurally characterised clusters with the Cr_4Co, Cr_4Fe, Cr_4Mn, and Cr_4Cr cores presented here is supplemented by the clusters with the Cr_4V and Cr_4Ni cores. The vanadium-containing cluster has been obtained by the reaction of $V(BH_4)_2$ with compound (III) in the presence of Et_3N:[39]

$$2\,(C_5H_5)_2Cr_2(SCMe_3)_2S \xrightarrow[Et_3N]{V(BH_4)_2} [(C_5H_5)_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2]_2V.$$
(III)

The brown antiferromagnetic crystals have been characterised by elemental analysis and by IR spectra, which are identical with the spectra of the clusters Q_2M with M = Co, Fe, Mn, or Cr.

Finally, the reactions of compounds (III) and (IIIa) with the nickel complexes [Ni], which readily lose their ligands [$Ni(CO)_4$, $Ni(COD)_2$, and $(MeC_5H_4)_2Ni$] have been used to synthesise the clusters $[(RC_5H_4)_2Cr(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2]_2Ni$ (R = H or Me):[39]

$$2\,(RC_5H_4)_2Cr_2(SCMe_3)_2S \xrightarrow{[Ni]} [(RC_5H_4)_2Cr_2(\mu\text{-}SCMe_3)(\mu_3\text{-}S)_2]_2Ni.$$



Both antiferromagnetic clusters have been isolated in the form of dark-green crystals and have been characterised by elemental analysis and IR spectra.

7. Sulphide-bridged heterometallic clusters based on $(C_5R_5)_2Mo_2S_4$ and $(C_5R_5)_2Mo_2(SH)_2(S)_2$

Dinuclear molybdenum tetrasulphide complexes exist in the form of three isomers, whose formation depends on the duration of the reaction of $(C_5Me_5)_2Mo_2(CO)_4$ with elemental sulphur. Thus the isomer $(C_5Me_5)_2Mo_2(\mu\text{-}S)_2(\mu,\eta^2\text{-}S_2)$ arises in hot toluene in the course of 17 h. It contains, apart from two sulphide bridges, the S_2 fragment coordinated at right angles to the short Mo–Mo bond (2.599 Å).[49] The analogous complex $(MeC_5H_4)_2Mo_2$ $(\mu\text{-}S)_2(\mu\text{-}S_2)$ has been described.[50] The diamagnetism of both molybdenum complexes probably indicates the presence of the Mo=Mo double bond and some shortening of the Mo–S bonds is evidence for an appreciable contribution by the additional Mo–S π-interaction.

If the reaction of $(C_5Me_5)_2Mo_2(CO)_4$ with S_8 is carried out over a period of three days, then the tetrasulphide complex described above is converted into two isomers with terminal sulphur atoms, which involves the dissociation of either the S–S bond or of the Mo–S bridge bonds. In the former case, the isomer contains Mo(V) atoms and, according to X-ray diffraction data,[51] only two sulphide bridges are present in the complex (Mo–S = 2.297 Å), while the other two sulphur atoms are terminal (Mo=S = 2.144 Å). The Mo(V) atoms then form a single Mo–Mo bond (2.905 Å). The complex has the *anti*-configuration as regards the Mo=S bonds and the C_5Me_5 rings.

The reaction via the second pathway affords a low yield of the *syn*-isomer, containing the disulphide group:

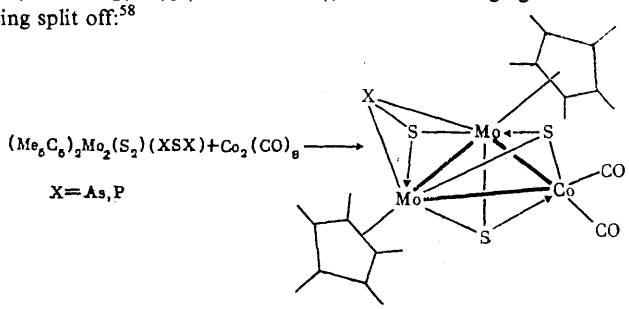
The *anti*-isomers of $(Me_nC_5H_{5-n})_2Mo_2(\mu\text{-}S)_2(S)_2$ are formed in a low yield even in the reactions of $(Me_nC_5H_{5-n})_2Mo_2(CO)_6$, where n = 0, 1, or 5, with S_8, but the main products are found to be the insoluble polymeric complexes $(Me_nC_5H_{5-n})_2Mo_2(\mu\text{-}S)_4$.[51]

The geometry of the Mo_2S_2 cores of the cyclopentadienyl[52] and methylcyclopentadienyl[51] complexes hardly differs form the geometry of the core in the pentamethylcyclodienyl analogue. The molybdenum atoms in these systems have a 16-electron environment (when account is taken of the Mo–Mo bond), which lead to a sharp shortening of the bonds with bridging sulphur atoms (to 2.297 Å) in conformity with the significant contribution of the additional Mo–S π-bonding.

The tetrahedral clusters $(C_5R_5)Mo_2(\mu_3\text{-}S)_4(Cr_2(C_5R'_5)_2$ (R = H, R′ = Me or R = Me, R′ = H), obtained by the reactions of the *anti*-isomers of $(C_5R_5)_2Mo_2S_4$ with $(C_5R'_5)_2Cr_2(CO)_4$, were described above.[27] If all the rings are methylated, then the interaction of $(C_5Me_5)_2Mo_2S_4$ with $(C_5Me_5)_2M'_2(CO)_4$ (M′ = Cr or W) gives rise to the stable paramagnetic trinuclear clusters $(C_5Me_5)_3Mo_2M'(\mu_3\text{-}S).(\mu\text{-}S)_3$.[27]

A 60-electron tetrahedral cluster, in which the $(C_5R_5)Cr$ groups have been replaced by the isoelectronic Fe(NO) groups, is formed in the reaction of $(C_5Me_5)_2Mo_2(\mu\text{-}S)_2(\mu,\eta^2\text{-}S_2)$ with $(Ph_3PNPPh_3)^+Fe.(CO)_3(NO)^-$.[53] On the other hand, the reaction of $(C_5Me_5)_2Mo_2.(\mu\text{-}S)_2(\mu,\eta^2\text{-}S_2)$ with $Fe_2(CO)_9$ at 25 °C in THF or with $Fe(CO)_5$ on UV irradiation gives rise to the tetranuclear cluster $(C_5Me_5)_2Mo_2.(\mu_3\text{-}S)_4Fe_2(CO)_4$ containing two $Fe(CO)_2$ fragments.[54] The cluster therefore has 62 electrons and the metal atoms form a "butterfly" structure with the Mo–Mo "abdomen" (2.761 Å) and the Mo_2Fe "wings" (Mo–Fe = 2.792–2.832 Å) and a non-bonded Fe...Fe distance of 3.334 Å. In addition, the trinuclear clusters $(C_5Me_5)_2.Mo_2(\mu,\eta^2\text{-}S_2)(\mu_3\text{-}S)_2Fe(CO)_2$ and $(C_5Me_5)_2Mo_2\{\mu\text{-}SC(O)S\}(\mu_3\text{-}S)_2Fe.(CO)_5$, containing the metallotriangular Mo_2Fe fragment (Mo–Mo = 2.592 and 2.574 Å and Mo–Fe = 2.777 and 2.826 Å respectively in the first and second triangular clusters) are formed. A distinctive feature of the second cluster is the insertion of the CO molecule in the disulphide bridge present in the initial dimer and in the first triangle (S–S = 2.071 Å).

The formation of the trinuclear cluster $(C_5Me_5)_2Mo_2S_4Mn(CO)_2Cp$ in the reaction of $(C_5Me_5)_2Mo_2S_4$ and $CpMn(CO)_2.THF$ has been briefly reported. It probably has the structure of an adduct with the coordination of the $CpMn(CO)_2$ fragment via one sulphide bridge, although the authors do not rule out a structure with the insertion of the Mn atom in the S–S bond.[24]



All the isomers of $(Me_nC_5H_{5-n})_2Mo_2S_4$ (n = 0, 1, or 5), including also the insoluble polymers, are converted on treatment with H_2 into the dinuclear tetrabridged complexes $(Me_nC_5H_{5-n})_2Mo_2(\mu\text{-}S)_2.(\mu\text{-}SH)_2$. These complexes are of interest because they contain two types of functional groups: MoSMo with unshared pairs in the sulphur atoms and Mo(SH)Mo with the thiol group SH.[55] The thiol groups in these complexes are readily substituted on treatment with HSR, affording $(Me_nC_5H_{5-n})_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SR)_2$ (R = Me, Et, Pr^i, or Ph). Accorinng to X-ray diffraction data, the sulphide bridges in the methyl analogue (Mo–S = 2.352 Å) alternate with the mercaptide bridges (Mo–SMe = 2.479 Å), while the Mo(IV) atoms (d^2 electronic configuration) with a 16-electron environment form the Mo=Mo double bond (2.582 Å).

The complex $(MeC_5H_4)_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2$ reacts with $Fe(CO)_5$ in the presence of Me_3NO, combining with two $Fe(CO)_3$ fragments. The cluster $(MeC_5H_4)_2\ Mo_2(\mu_3\text{-}S)_4Fe_2(CO)_6$, which has 66 electrons and the corresponding planar metallic core with a diagonal Mo–Mo bond (2.853 Å) and only two Mo–Fe bonds (2.826 Å) (the sulphide bridges are located over each Mo_2Fe fragment), is obtained. As a result, the metallic core acquires the "metallozigzag" Fe–Mo–Mo–Fe configuration[56] in contrast to the "metallobutterfly" obtained for the C_5Me_5 derivative.

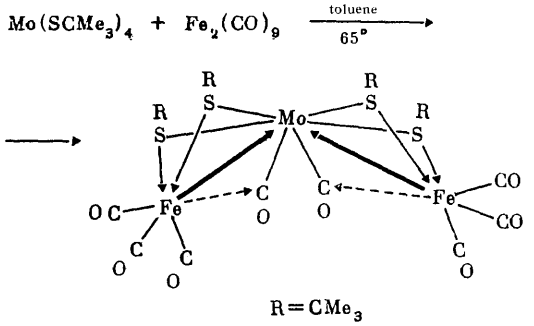
The influence of the nature of the cyclopentadienyl ligands at the Mo atom is also manifested in reactions with $Co_2(CO)_8$. In the case of the $(C_5Me_5)_2Mo_2(\mu\text{-}S)_2(\mu,\eta^2\text{-}S_2)$ isomer, a 60-electron tetrahedral cluster $(C_5Me_5)_2Mo_2(\mu_3\text{-}S)_4Co_2(CO)_2$ is formed.[25] On the other hand, if one begins with $Cp_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2$, then the 62-electron cluster $Cp_2Mo_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Co_2(CO)_4$, with a "metallobutterfly" core and containing only three sulphur atoms, is formed. As in the $Cp_2Cr_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Co_2(CO)_4$ cluster described above, one of the sulphur atoms is tetradentate and is located between the Mo_2Co_2 wings (Mo–Mo = 2.646 Å and Mo–Co = 2.640 Å). The other two sulphur atoms are tridentate and are located under the Mo_2Co wings. Each cobalt atom is linked to two CO groups and each Mo atom is linked to the Cp ring.[57]

The $Cp_2Mo_2(\mu_3\text{-}S)_4Ni_2(CO)_2$ cluster, containing four tridentate sulphide bridges and two Ni(CO) fragments, is also of the 62-electron type. It is formed in the reaction of $Cp_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2$ with $Ni(CO)_2$ and has the "metallobutterfly" Mo_2Ni_2 core (Mo–Mo = 2.829 Å and Mo–Ni = 2.772 Å) with a non-bonded Ni...Ni distance of 2.962 Å.[57]

The insertion of the $Co(CO)_2$ fragment in the S–S bond is observed in the reaction of $(C_5Me_5)_2Mo_2(\mu,\eta^2\text{-}S_2)(\mu\text{-}XSX)$ (X = As or P) with $Co_2(CO)_8$ (toluene 25 °C), one of the bridging X atoms being split off:[58]

According to X-ray diffraction data for the As-containing derivative, the cluster has the Mo_2Co metallotriangular core (Mo–Mo = 2.610 Å and Mo–Co = 2.722–2.725 Å) with tridentate sulphide bridges located above and under the metallotriangle. The AsS μ,η^2-bridging group (As–S = 2.237 Å), which is a 5-electron donor, is located along the periphery of the cluster between the molybdenum atoms. In this situation, the cluster with the Mo_2Co core is an isoelectronic analogue of the $(C_5Me_5)_2Mo_2S_4Fe(CO)_2$ complex described above,[54] containing the 6-electron group μ,η^2-S_2 in combination with the $Fe(CO)_2$ groups having one electron less than the $Co(CO)_2$ fragment.

Among other cyclopentadienyl-containing SHMC with Group VIA metals, we may mention $\{[Cp_2Mo(SMe)_2]_2Ni\}^{2+}(BF_4^-)_2$, obtained from $Cp_2Mo(SMe)_2$ and $Ni(BF_4)_2$.[17] In contrast to the analogous niobium(IV) complex described above (d^1 electronic configuration), in the given molybdenum(IV) complex (d^2 electronic configuration) there are two electrons more. They are apparently found in the antibonding orbitals, which leads to a marked lengthening of the Mo–Ni bonds to 3.39 Å (bond order 0.5).



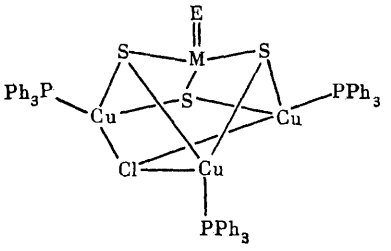
Finally, the cubane-like clusters with the $M_2Co_2(\mu_3\text{-}S)_4$ core (M = Mo or W) (Mo–Mo = 2.788 Å, Co–Co = 2.533 Å, and Mo–Co = 2.680 and 2.672 Å) have been obtained in reactions of the dinuclear molybdenum or tungsten diethyldithiocarbamate sulphides with cobalt carbonyl:[59]

$$(Et_2NCS_2)_2M_2S_4 + Co_2(CO)_8 \xrightarrow{MeCN} [(Et_2NCS_2)(MeCN)M]_2[Co(CO)]_2(\mu_3\text{-}S)_4$$
$$M = Mo, W.$$

In such a 60-electron cluster, the chelating Et_2NCS_2 group and the MeCN molecule occupy three orbitals at the M atom, donating five electrons, i.e. the entire system is similar to the $(CpMo)_2Co_2(CO)_2.(\mu_3\text{-}S)_4$ clusters described above. It has been noted that the MeCN molecule is not coordinated to the initial Mo or W dimers owing to the additional π-bonding to the sulphur atoms (the Mo–S bond length increases from 2.09 to 2.312 Å).

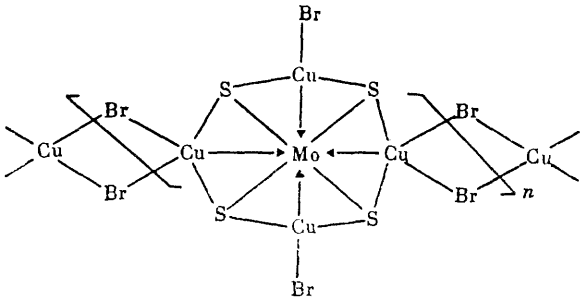
8. Sulphide-bridged heterometallic clusters based on $Mo(SCMe_3)_4$

The trimetallic complex $Mo(\mu\text{-}SCMe_3)_4(\mu\text{-}CO)_2Fe_2(CO)_6$ is formed in the reaction of $Mo(SCMe_3)_4$ with an excess of $Fe_2(CO)_9$. The reaction can be regarded as the addition of two $Fe(CO)_3$ fragments to pairs of SR groups at the Mo(IV) atom with an additional dative Fe–Mo interaction and the incomplete transfer of two CO groups to the molybdenum atom.[60] The molecular core is the almost linear Fe–Mo–Fe metal chain (Mo–Fe = 2.757 Å with an FeMoFe angle of 160.43°) having two bridging $SCMe_3$ groups above each Mo–Fe bond, the FeS_2Mo fragments having the "butterfly" configuration:



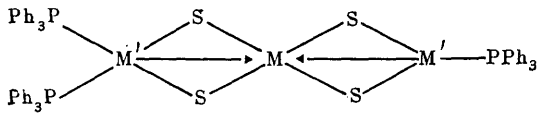
Treatment of $Fe_4S_4(SPh)_4^{2-}$ with $Mo(SCMe_3)_4$ results in transmetallation probably as a consequence of the greater strength of the Mo–Fe bonds compared with Fe–Fe. The $(Me_3CS)MoFe_3S_4.(SPh_2)^{2-}$ dianion was isolated under these conditions. It is reduced by sodium acenaphthenide in the presence of $(NBu_4)Br$ to the salt $(NBu_4)_3[(Me_3CS)MoFe_3S_4(SPh)_3]$ containing a trianion.[61] These cubane-like clusters model the active MoFeS centre of the cofactor of nitrogenase.

9. Sulphide-bridged heterometallic clusters based on the thiometallates MS_4^{2-} (M = Mo or W)



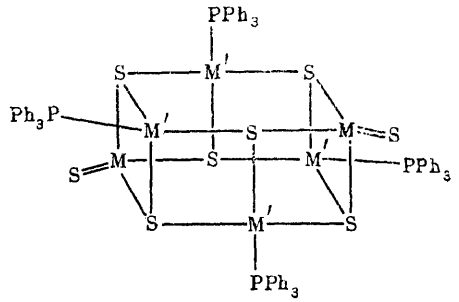
The readily available thiometallate complexes comprising Group VI transition metals, namely MS_4^{2-} (in the main, M = Mo or W), which are isolated as a rule in the form of ammonium or phosphonium salts, are extremely common starting materials for the synthesis of SHMC. Such monomeric anions contain the tetrhedral MS_4 fragment (Mo=S = 2.175 Å [62]). The highly electron-deficient character of M(VI) (d^0 electronic configuration) promotes the formation of dative M ← M′ bonds with the salts of other metals (in their absence, MS_3 and the sulphide of the heterometal are formed readily). Several reviews[63–65] have been devoted to their reactions and here we shall consider only examples of Cu- and Fe-containing complexes whose structure has been confirmed by X-ray diffraction data.

The former are of interest from the standpoint of the antagonism between copper and molybdenum in biological systems, throwing light on the nature of the Cu–Mo–S interaction.[66] The dianions MS_4^{2-} (M = Mo or W) reduce copper to Cu^+ on interaction with Cu^{2+}, forming polymers having the composition $\{[NH_4][Cu(MoS_4]\}_n$ [67] or $\{[NH_4][Cu(WS_4)]\}_n$.[68] Discrete molecules with Cu and M (Mo or W) atoms can be obtained by treating $(CN)_nCu_n(MS_4)^{m-}$ with KSPh in acetonitrile. $[PhSCu(S)_2Mo(S)_2]^{2-}$ and $[PhSCu(S)_2Mo(S)_2CuSPh]^{2-}$ were isolated under these conditions. In both cases the molybdenum atoms have a tetrahedral environment and the copper atoms have a planar trigonal environment. Furthermore, Mo ← Cu dative bonds (2.636 Å) are formed.[69] The metal chain in $Et_3PAu(S)_2.Mo(S)_2AuPEt_3$ is constructed analogously (the Mo ← Au bond length is 2.815 Å).[70] The interaction of MS_4^{2-} (or MoS_3^{2-}) with $CuCl_3$ in the presence of PPh_3 in CH_2Cl_2 results in the formation of clusters with a distorted pseudocubane core $(PPh_3)_3Cu_3S_3ClM(E)$ (M = Mo or W; E = S or O):[71]



A cluster with the ratio Cu : Mo = 3 : 1 is also formed in the reaction of stoichiometric amounts of CuCl and $(Ph_4P)_2(MoS_4)$. In $(ClCu)_3.MoS_4^{2-}$, two sulphur atoms are bidentate and two are tridentate.[72,73] There is a possibility of the situation where all four sulphur atoms become tridentate. This happens in the cluster $(CuBr)_4MoS_4^{2-}$, which is a one-dimensional polymer.[74] In this polymeric cluster, two *trans*-Cu atoms have a planar-trigonal environment and two

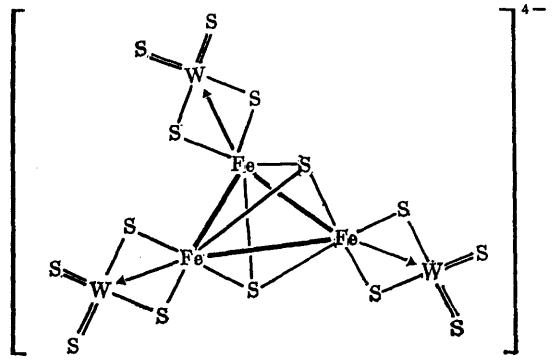
others have a tetrahedral environment (all the metal atoms are then located in a single plane):



Partial cleavage of the Cu-S-M bridges has been observed[75] when the $[Cu(MS_4)]_n$ and $[Cu_2(MS_4)]_n$ polymers are treated with PPh_3. Complexes with a non-equivalent environment of the copper atoms are then formed. A cluster containing silver atoms of an analogous type has been isolated after the reaction of MS_4^{2-} with $AgNO_3$ in the presence of PPh_3 in CH_2Cl_2:[71]

M=Mo, W M′=Cu(I), Ag(I)

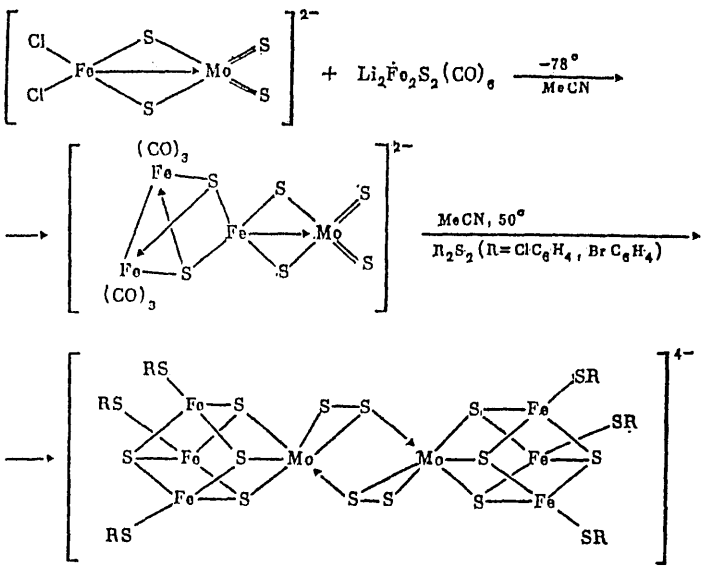
Finally, the bonding of each MS_4 group to other metals occurs in the complexes $(Ph_3P)_4M'_4(MS_4)_2$ (M = Mo or W; M′ = Cu or Ag):[76]



The core of this cluster is a complex polyhedron produced by the binding of two $MS_2M'_2S$ fragments.

The composition of the iron-containing complexes depends on the reactant ratio. For the $MS_4^{2-}:[M']^{2+}$ = 1:1 or 1:2 reactant ratio, the complexes $MoS_4FeCl_2^{2-}$ or $Cl_2FeS_2MoS_2FeCl_2^{2-}$, for example, were isolated,[64] in which the MoS_2 fragment chelates are the iron atom. Reactions of MS_4^{2-} (M = Mo or W) with iron carboxylates[77] and thiolates[78] take place analogously:

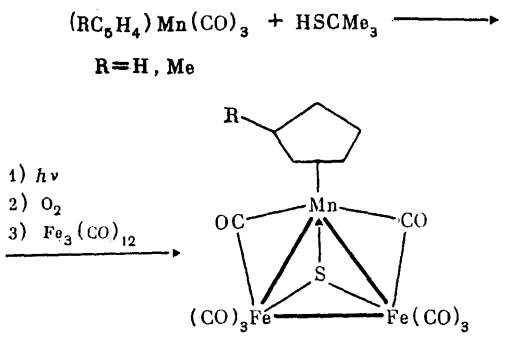
$$Fe(OOCMe)_2 + (Et_4N)_2(MS_4) \xrightarrow{MeCN} (MeCOO)_2FeS_2MS_2^{2-},$$
$$Fe(SPh)_4^{2-} + MS_4^{2-} \rightarrow (PhS)_2FeS_2MS_2^{2-}.$$



On the other hand, an excess of MS_4^{2-} reacts with various transition metal $[M']^{2+}$ salts, affording the anionic complexes $M'(MS_4)_2^{2-}$ [in particular, $TcO(MoS_4)_2^{2-}$, $(Ph_3P)_2Tc(MoS_4)_2$,[79] $Fe(MoS_4)_2^{2-}$,[80] $(FeMoS_4)_2^{3-}$,[81] $Co(MoS_4)_2^{3-}$,[82] $Co(WS_4)_2^{2-}$, $Fe(WS_4)_2^{2-}$, $Fe(WS_4)_2^{3-}$,[83] and $Fe(WS_4)_2^{4-}$], in which all the metal atoms have a tetrahedral environment made up of sulphur atoms. In the presence of an excess of PPh_4^+ and Et_4N^+ cations, the complex $Fe(WS_4)_2^{2-}$ is converted into the more stable cluster anion $Fe_3W_3S_{14}^{4-}$ with loss of some of the tungsten sulphide fragments.[84,85]

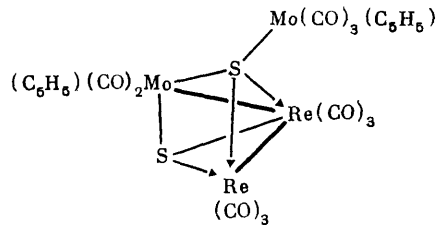
The cluster contains the triangular $Fe_3(\mu_3\text{-}S)_2$ core in which the iron atoms are linked by chelate bonds to three WS_4 fragments via sulphide bridges and have direct dative Fe → W bonds (2.774 Å).[84]

10. MoFe-containing sulphide-bridged heterometallic clusters modelling the active centre of the cofactor of nitrogenase



Thiometallate anions are good starting materials for the synthesis of the main types of the Mo–Fe–S clusters modelling the iron-molybdenum centre of the nitrogenase cofactor.[86-88] Such systems are obtained as a rule by the single-stage interaction of simple reactants ($FeCl_3$, NaSR, and MoS_4^{2-}) in methanol. Depending on the reaction conditions and the reactant ratio, three main types of complexes are formed: $Mo_2Fe_6S_8(\mu\text{-}S)(\mu\text{-}SR)_2(SR)_6^{3-}$, $Mo_2Fe_6S_8.(\mu\text{-}SR)_3(SR)_6^{3-}$, and $Mo_2Fe_7S_8(\mu\text{-}SR)_6(SR)_6^{n-}$ (n = 3, 4).[89-96] All these clusters have the structure of two Fe_3MoS_4 cubane-like moieties connected by bridging ligands. The mechanism of the formation of Mo–Fe–S clusters of this type is so far obscure, but it has been possible to achieve a multistage synthesis of compounds of this type from $Cl_2FeMoS_2^{2-}$ and iron carbonyl complexes:[97]

In the intermediate cluster $MoFe_3S_6(CO)_6^{3-}$, the diiron disulphide fragment (Fe–Fe = 2.491 Å) adds to the Fe atom of the initial complex via μ_3-S bridges [Fe–(μ-S) = 2.288 Å, Mo–Fe = 2.762 Å, Mo=S = 2.156 Å, and Mo–(μ-S) = 2.263 Å]. Further treatment of this cluster with the disulphide $(XC_6H_4S)_2$ (X = Cl or Br) affords a cluster with a double cubane-like core in which the molybdenum atoms are linked by two S_2 bridging groups (Mo...Mo = 3.97 Å). This cluster has also been obtained by specific synthesis in accordance with the traditional mechanism from MoS_4^{2-}, $FeCl_2$, Na_2S_2, $(XC_6H_4S)_2$, and NaOMe in methanol.

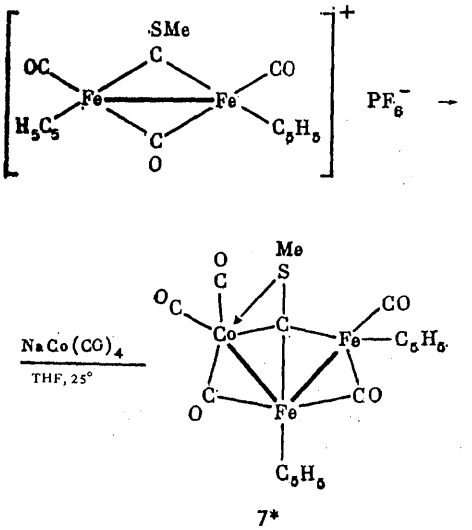


IV. Sulphur-containing group VIIA metal complexes as ligands and the clusters based on them

There are very few sulphur-containing complexes of Group VIIA metals used as cluster-forming agents. One of them is the paramagnetic complex $(C_5R_5)Mn(CO)_2SCMe_3$ (R = H or Me), which has been characterised by X-ray diffraction (for R = Me, the Mn–SR bond length is 2.187 Å).[98] It is probably in fact the cluster-forming agent in the photochemical reaction of $(RC_5H_4)Mn(CO)_3$ with $HSCMe_3$ and subsequent treatment with O_2 and $Fe_3(CO)_{12}$, which resulted in the formation of the cluster $(RC_5H_4)Mn(\mu_3\text{-S}).(\mu\text{-CO})_2Fe_2(CO)_6$ (R = H or Me):[99]

In this metallotriangular cluster (Mn–Fe = 2.660 and 2.689 Å and Fe–Fe = 2.609 Å), the sulphur atom is located above the plane of the Fe_2Mn triangle (Fe–S = 2.176 Å and Mn–S = 2.206 Å) and the sides of the triangle are linked additionally by bridging CO groups.

Another starting material for the formation of SHMC is the complex $[(CO)_4Re(\mu\text{-SSnMe}_3)]_2$.[100] Its reaction with $CpMo(CO)_3Cl$ in benzene results in the elimination of two moles of $ClSnMe_3$ and three moles of CO and the formation of a tetranuclear cluster in which the initially planar Re_2S_2 fragment is converted into a "butterfly", the electron deficiency in the partially decarbonylated rhenium atoms being compensated by the Mo–Re and Re–Re bonding:



This results in the formation of the Mo–Re–Re "metal chain" (Mo–Re = 2.909 Å and Re–Re = 2.985 Å), above and under the plane of which are located tri- and tetra-dentate bridging sulphur atoms [the latter forms a σ-bond with the $Mo(CO)_3Cp$ group[101]].

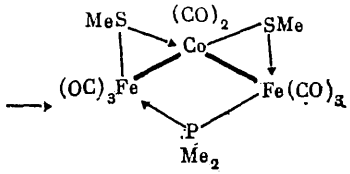
A cluster containing three different metal atoms can be obtained by using $M(SAsMe_3)(CO)_3(PMe_3)_2$ (M = Mn or Re) as ligands in relation to $FeCo(\mu\text{-AsMe}_2)(CO)_7$.[102] This leads to the formation of the trinuclear cluster $(PMe_3)_2(CO)_3M(\mu\text{-SAsMe}_2)Co(CO)_3(\mu\text{-AsMe}_2).Fe(CO)_4$ containing the M–Co–Fe (M = Mn or Re) metal chain.[103]

V. Clusters based on sulphur-containing group VIII metal complexes

Among these compounds, the greatest number of SHMC have been obtained from sulphur-containing iron complexes. For example, it has been shown[104] that treatment of 1/2 of a mole of $Rh_2(CO)_4Cl_2$ with $CpFe(CO)_2SR$ leads to the formation of the trinuclear linear cluster $[Cp(CO)_2Fe]_2(\mu\text{-SR})_2Rh^+$.

A cluster with two iron atoms and a cobalt atom is formed in the reaction of the ionic complex $Cp(CO)Fe(\mu\text{-CO})(\mu\text{-CSMe})Fe(CO)Cp^+$ with $NaCo(CO)_4$ in THF at 25 °C:[105]

7*



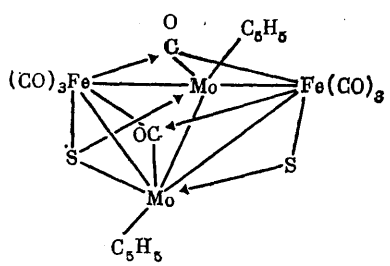
The cluster has a core consisting of a non-linear metal chain with short Fe–Co (2.500 Å) and Fe–Fe (2.537 Å) distances. The sulphur atom in this compound plays the role of a stabilising agent, building up the coordination sphere of the cobalt atom (Co–S = 2.313 Å) to an 18-electron shell.

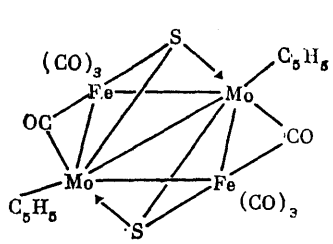
The dinuclear thiolatoiron carbonyl complexes $Fe_2(\mu\text{-SR})_2(CO)_6$, which have already been known for about 30 years, have themselves proved to be inert in relation to other metal carbonyls [for example, $Fe_2(\mu\text{-SMe})_2(CO)_6$ does not react with $Co_2(CO)_8$ even under severe conditions].[106] However, after preliminary treatment with $HPMe_2$,

the subsequent reaction with $Co_2(CO)_8$ proceeds in accordance with the scheme[107]

$$Fe_2(SMe)_2(CO)_6 \xrightarrow{PMe_2H} Fe_2(SMe)_2(CO)_5(PMe_2H) \xrightarrow{Co_2(CO)_8}$$

$$\longrightarrow (CO)_3Fe(\mu\text{-}SMe)_2Fe(CO)_2(\mu\text{-}PMe_2)Co(CO)_3 \longrightarrow$$

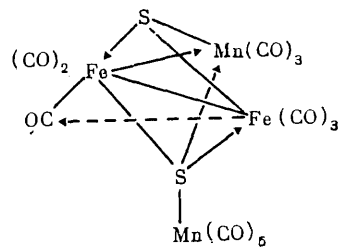




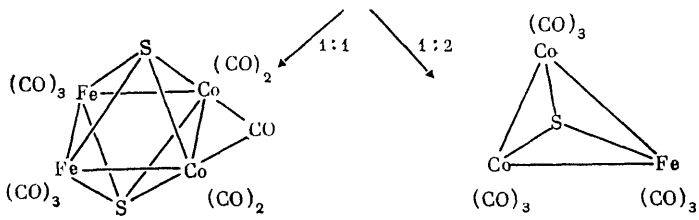
The same product has been obtained in the reaction of $Fe_2(SMe)_2(CO)_6$ with $(C_3H_5)Co(CO)_3$ in the presence of PMe_2H.[108]

The commonest starting material for the synthesis of iron-containing SHMC is the complex $S_2Fe_2(CO)_6$, first synthesised by Hieber and Gruber.[109] According to X-ray diffraction data,[110] the two iron atoms in this complex are separated by a short distance of 2.552 Å and form together with the disulphide fragment (S–S = 2.007 Å) a distorted Fe_2S_2 tetrahedron in which the angle between the planes of the Fe_2S triangles is 54°, the three Co groups at each iron atom being directed away from the S_2 group. The latter group is the site of attack by the metal-containing $M'L_n$ reagent, which donates electrons to the LUMO antibonding in relation to the S–S bond.[111,112]

On interaction of $S_2Fe_2(CO)_6$ with $[CpCr(CO)_3]_2$, the cluster $Cp_2Cr_2Fe_2(\mu_3\text{-}S)_2(\mu_3\text{-}CO)_2(CO)_6$ with the "metallobutterfly" Cr_2Fe_2 core was isolated. When the cluster is produced, the Fe–Fe bond is ruptured and the CO group at each Cr atom acquires tridentate-bridging character and is bound to two iron atoms.[113]



A "butterfly" cluster of analogous composition, containing molybdenum atoms, has been obtained by the reaction of $S_2Fe_2(CO)_6$ with $Cp_2Mo_2(CO)_4$.[114] Later it proved possible to isolate this isomer with a planar disposition of the four metal atoms and the bridging CO groups between the iron and molybdenum atoms:[115]

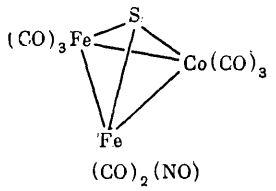


The tetranuclear clusters $Mn_2Fe_2S_2(CO)_{14}$, having a complex structure, is formed in the reaction of $S_2Fe_2(CO)_6$ with $Mn_2(CO)_{10}$. It is possible to identify in it the MnFeFe metal chain with a semibridging CO group between the iron atoms. The tetradentate bridging sulphur atom, located above the $MnFe_2$ plane, is σ-bonded to the manganese atom of the $Mn(CO)_5$ group:[116]

$$S_2Fe_2(CO)_6 + Mn_2(CO)_{10} \xrightarrow[h\nu]{THF}$$

The reaction of $S_2Fe_2(CO)_6$ with $Co_2(CO)_8$ is equimolar amounts at 20 °C gives rise to the cluster $Fe_2Co_2(\mu_4\text{-}S)_2(\mu\text{-}CO)(CO)_{10}$ with a square planar metallic core. The "capping" sulphur atoms in the cluster are involved in a tetradentate coordination and the cobalt atoms are linked in addition to the CO group.[117] The reaction of $S_2Fe_2(CO)_6$ with an excess of $Co_2(CO)_8$ at room temperature takes place with the dissociation of the S–S and Fe–Fe bonds, giving rise to the trinuclear cluster $FeCo_2(\mu_3\text{-}S)(CO)_9$.[118] The yield of the cluster increases on UV irradiation.[106] According to X-ray diffraction data, this diamagnetic 48-electron cluster has the Co_2Fe triangular metallic core with equalised M–M distances (2.550 to 2.556 Å) over which is located the tridentate sulphur atom (M–S = 2.152–2.164 Å):[118]

$$S_2Fe_2(CO)_6 + Co_2(CO)_8$$



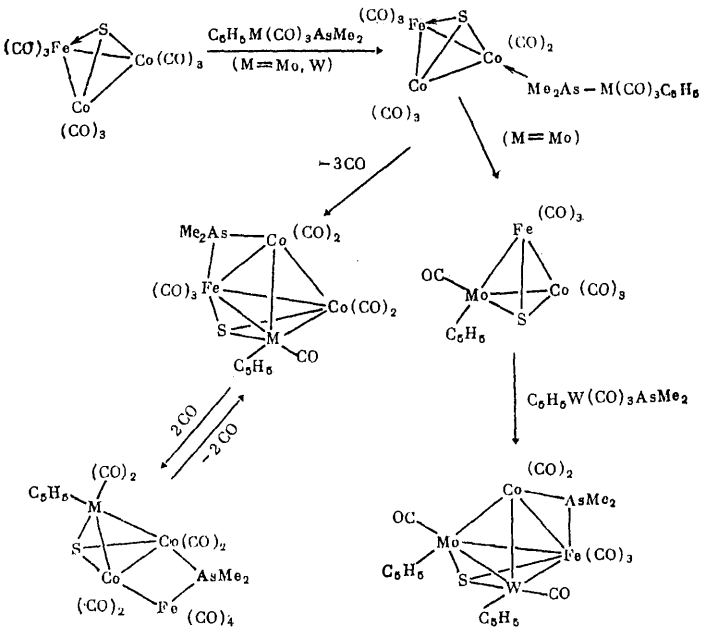
The dissociation of $S_2Fe_2(CO)_6$ into two fragments is also observed in the reaction with $[CpNi(CO)]_2$, which is isolobal in relation to $Co_2(CO)_8$. This entails the formation of the metallotriangular cluster $Cp_2Ni_2Fe(CO)_3(\mu_3\text{-}S)$.[119] According to Bogan et al.,[120] the formation of clusters with the Fe_2M_2 core is a common stage in the reactions of the dinuclear metal complexes with $S_2Fe_2(CO)_6$, which is followed by processes involving the elimination and addition of the ML or S fragments, ensuring the isolation of a wide variety of structures.

The $CpRh(\mu_3\text{-}S)_2Fe_2(CO)_6$ cluster has been obtained in the form of two isomers (a metal chain with a central or terminal rhodium atom) by treating $S_2Fe_2(CO)_6$ with $CpRh(CO)_2$ in boiling hexane.[121] Finally, trinuclear clusters without Fe–M bonds have been obtained by the reaction of $S_2Fe_2(CO)_6$ with $L_2M(C_2H_4)$ (L = PPh_3; M = Pt

or Pd).[122] The structure of the sulphide-bridged clusters $(PPh_3)_2$.$M(\mu_3\text{-}S)_2Fe_2(CO)_6$ (M = Pt or Pd) has been proposed on the basis of X-ray diffraction data for the selenium-containing analogue $(PPh_3)_2Pt(\mu_3Se)_2Fe_2(CO)_6$ (Fe–Fe = 2.533 Å and Pt–Fe = 3.45 Å).[122] A palladium-containing complex is also obtained in the reaction of $S_2Fe_2(CO)_6$ with $Pd(PPh_3)_4$ via a transmethylation reaction–the substitution of the $Fe(CO)_3$ fragment in $Fe_3(CO)_9(S)_2$ on treatment with $(PPh_3)_2PdCl_2$ and elimination of $PdCl_2$. The cluster contains no Fe...Pd bonds and the Pd atom has a square planar environment made up of phosphorus atoms (Pd–PO = 2.313 and 2.348 Å) and sulphur atoms (Pd–S = 2.305 and 2.326 Å). The PdS_2 plane is perpendicular to the Fe–Fe bond (2.504 Å).[123]

1. Reactions of iron-containing sulphide-bridged heterometallic clusters

In the reaction with THF.$Cr(CO)_5$, the $FeCo_2S(CO)_9$ cluster is capable of coordinating an additional $Cr(CO)_5$ fragment via a μ_4-sulphide bridge.[124] The mixed-ligand clusters $Fe_3(\mu_3\text{-}S)(\mu_3\text{-}ER)$.$(CO)_9$ (R = alkyl or aryl and E = P or As) react analogously with $(THF)M(CO)_5$ at 0 °C.[125] It has been shown by X-ray diffraction that the $Fe_3S(ER)$ core with ER = $PCMe_3$ remains unchanged compared with the initial cluster and the $Cr(CO)_5$ or $W(CO)_5$ fragment remains on the periphery of the molecule, adding on via a fairly long S → M bond (Cr–S = 2.428 Å and W–S = 2.547 Å).[126] The syntheses of chiral iron-containing SHMC are of special interest. Thus $Fe_2Co(CO)_9(\mu\text{-}S)^-$ has been isolated in the form of the salt with the NEt_4^+ anion on reaction of $Co_2(CO)_8$ and $Fe_3(CO)_9S^{2-}$ in CH_2Cl_2. The anion has a triangular metallic core with a "capping" sulphur atom and is converted into a neutral form on nitrosylation as a result of acidification in the presence of the nitrite ion:[127]

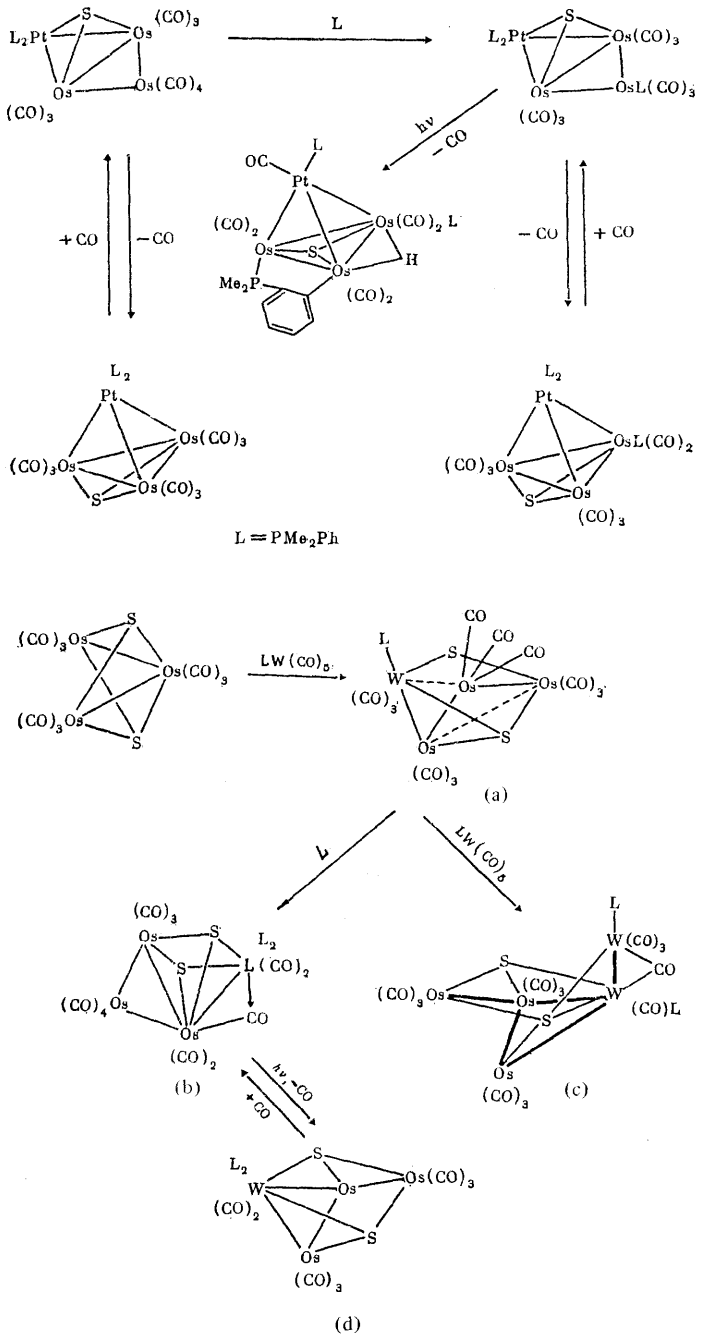


A second pathway leading to the synthesis of chiral clusters involves the formation of tetrahedra with sulphide groups at the vertices, at the base of which there is a triangle with three different metal atoms. Such clusters were first obtained[128] in 1978 by the specially developed "transmethylation" reaction of cobalt-containing clusters on treatment with dimethyl arsenide complexes of molybdenum, tungsten, and iron.[128] The cluster $CpMo(CO)_2(\mu_3\text{-}S)FeCo$.$(CO)_6$ was synthesised in this way. The substitution of one CO group at the Co atom in this cluster by the chiral ligand (*R*)-PMePrPh affords the diastereoisomers of the cluster $CpMo(CO)_2Co(CO)_2$(PMePrPh)$(\mu_3\text{-}S)Fe(CO)_3$, which were separated by crystallisation [the (–)-(*R*)-isomer with m.p. 119 °C is less soluble, while the (+)-(*S*)-isomer with m.p. 133 °C is readily soluble]. The corresponding enantiomers were then obtained by treatment with CO under conditions where phosphine was bound by methyl iodide.[129]

After transmethylation, intermediates were also isolated in which the $AsMe_2$ fragment is present as a bridging group, for example, $FeCo_2S(CO)_8$–$AsMe_2$–$MCp(CO)_3$ (M = Mo or W). The subsequent elimination of CO leads to the metallotetrahedral clusters $FeCo_2M(\mu_3\text{-}S)(\mu\text{-}AsMe_2)Cp(CO)_8$, which can in their turn combine irreversibly with two molecules of CO, the process being accompanied by the dissociation of two bonds, Fe–M and Fe–Co, whereupon the new system $CpMFeCo_2(\mu\text{-}AsMe_2)(\mu_3\text{-}S)(CO)_{10}$ (M = Mo or W) is generated.[130]

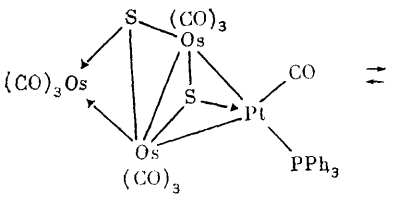
On the other hand, a cluster with four atoms of different metals was obtained for the first time with the aid of analogous reaction from the $FeCoMo(\mu_3\text{-}S)Cp(CO)_8$ cluster described above[131] (see below).

Clusters in which the iron atom has been replaced by a ruthenium atom, for example, $RuCo_2(CO)_9(\mu_3\text{-}S)$ obtained by the reaction of $Co_2(CO)_8$ with $Ru_3(CO)_{12}$ in the presence of EtSH with the reactant ratios 3 : 1 : 3.5 in an autoclave under a pressure of H_2 and CO (60 and 140 atm respectively), react similarly.[132] Treatment with the organometallic arsines $Me_3AsM(CO)_3Cp(L)$ leads to the formation of the clusters $RuCo_2(\mu_3\text{-}S)(CO)_{9-n}AsMe_2M(CO)_3Cp_n$ (M = Cr, Mo, or W; n = 1, 2), which in the case where n = 1 exists in the form of two isomers in which the ligand L is linked either to the cobalt atom or to the ruthenium atom. On heating the first isomer in cyclohexane in a CO atmosphere (T = 75–85 °C), the $Co(CO)_3$.$AsMe_2$ fragment is split off and the chiral clusters $(\mu_3\text{-}S)RuCoMCp$.$(CO)_8$ are formed. They have also been obtained by direct transmethylation in the reaction of $SRuCo_2(CO)_9$ with $[CpM(CO)_3]_2$ (M = Cr, Mo, or W).[132] The replacement of one CO group by optically active phosphines (L′) yielded the corresponding diastereoisomers $CpMoRuCo(\mu_3\text{-}S)(CO)_7L'$, in which L′ is linked to the cobalt atom:[132]

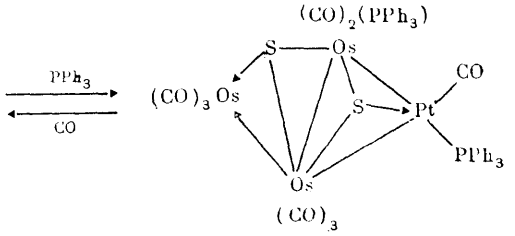


2. Sulphide-bridged heterometallic clusters based on trinuclear osmium clusters

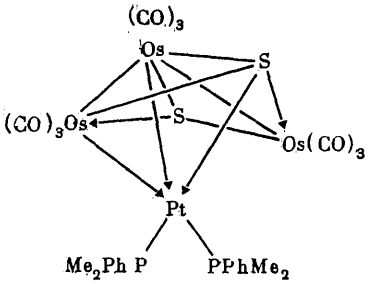
The use of the trinuclear osmium cluster $Os_3(\mu_3\text{-}S)(CO)_{10}$ as a metal-containing ligand in the photochemical reaction with $W(CO)_6$ in hexane, affording the cluster $(CO)_9Os_3(\mu_4\text{-}S)W(CO)_5$, has been described.[133] The $W(CO)_5$ group is then located on the periphery of the molecule (W–S = 2.550 Å) and the structure of the Os_3S core hardly changes compared with the initial cluster (Os–Os = 2.804



and 2.895 Å respectively). The cluster $Os_3(CO)_{10}(\mu_3\text{-}S)$ reacts readily with $Pt(C_2H_4)(PMe_2Ph)_2$ at 20 °C, forming four clusters: $PtOs_3(CO)_{10}(PMe_2Ph)_2(\mu_3\text{-}S)$, $PtOs_3(CO)_9(PMe_2Ph)_3(\mu_3\text{-}S)$, $PtOs_3(CO)_9(PMe_2Ph)_2(\mu_3\text{-}S)$, and $PtOs_3(CO)_8(PMe_2Ph)_3(\mu_3\text{-}S)$.[134] The first and second clusters with a planar metallic $PtOs_3$ core (Pt–Os = 2.768 and 2.838 Å and Os–Os = 2.869 and 2.833–2.907 Å respectively) are isoelectronic and have similar geometries, the first cluster being converted into the second on treatment with phosphine. They are readily decarbonylated, affording the third and fourth isoelectronic clusters, which contain the metallotetrahedral $PtOs_3$ core (Pt–Os = 2.740, 2.766, and 2.853 Å and Os–Os = 2.770, 2.896, and 3.064 Å) with a tridentate sulphur atom under the Os_3 triangle.



Prolonged photolysis of the second cluster leads to the formation of a cluster having a bridging hydride atom over the Os_3 triangular base of the cluster (Pt–Os = 2.684, 2.806, and 2.816 Å and Os–Os = 2.837, 2.930, and 2.972 Å). One of the phosphine ligands then becomes a bridge between two osmium atoms as a result of the formation of the Os-P and Os–C_6H_4 bonds.[134] The cluster $Os_3(CO)_9(\mu_3\text{-}S)_2$, containing two sulphide bridges, gives rise to four clusters in the formally analogous reaction with the phosphine-tungsten carbonyl complex $W(CO)_5L$ (L = PMe_2Ph); $LWOs_3(\mu_3\text{-}S)_2(CO)_{12}$ (a), $L_2WOs_3(\mu_3\text{-}S)_2(CO)_{12}$ (b), $L_2WOs_3(\mu_3\text{-}S)_2(CO)_{11}$ (c), and $(LW)_2Os_3(\mu_3\text{-}S)(\mu_4\text{-}S)(\mu\text{-}CO)(CO)_{13}$ (d):[135]



In three of them, namely (a), (c), and (d), Os_3W "metallobutterfly" core is produced to some extent with the axial Os–Os distances of 2.963, 2.923, and 2.924 Å respectively for (a), (c), and (d) and with tridentate bridging sulphur atoms located between the Os_3 and Os_2W "wings". In the 64 electron cluster (a), the two opposite M–M bonds in the "wings" are loosened under these conditions (M–Os = 3.050 and 3.054 Å). In the isoelectronic cluster (c), one WOs_2 wing contains non-equivalent W–Os bonds (2.814 and 3.016 Å), while in the second wing one Os–Os bond is missing (2.829 and 3.813 Å). Finally, in the cluster (d) the overall geometry of the "butterfly" core is close to that in (c), but the W atom is the bound to the second tungsten atom via a short bond (2.711 Å) supported by the bridging CO group, while one of the bridging sulphur atoms becomes tetradentate. In this situation, the Os–W distance (in the Os_2W wing) is shortened to 2.703 Å (the second distnce is 2.991 Å). On the basis of the analysis of the geometry of NMR data, the authors postulate the existence of the cluster (d) in two isomeric forms with short W=W and Os=W bonds. The fourth cluster (b) has a planar geometry of the rhombic Os_3W metallic core with short Os–Os (2.895 and 2.887 Å) and Os–W (3.044 Å) bonds and a long W...Os distance (3.612 Å). In this case, the sulphur atoms, remaining tridentate, bind two osmium atoms and a tungsten atom.[135]

The disulphide cluster $Os_3(CO)_9(\mu_3\text{-}S)_2$ also reacts with $Pt(PPh_3)_4$ or $Pt(C_2H_4)(PPh_3)_2$, forming the isoelectronic clusters $PtOs_3(CO)_{11-n}\cdot(PPh_3)_nX_2$ (n = 1,2), which are interconverted on treatment with phosphine or Co respectively:[136]

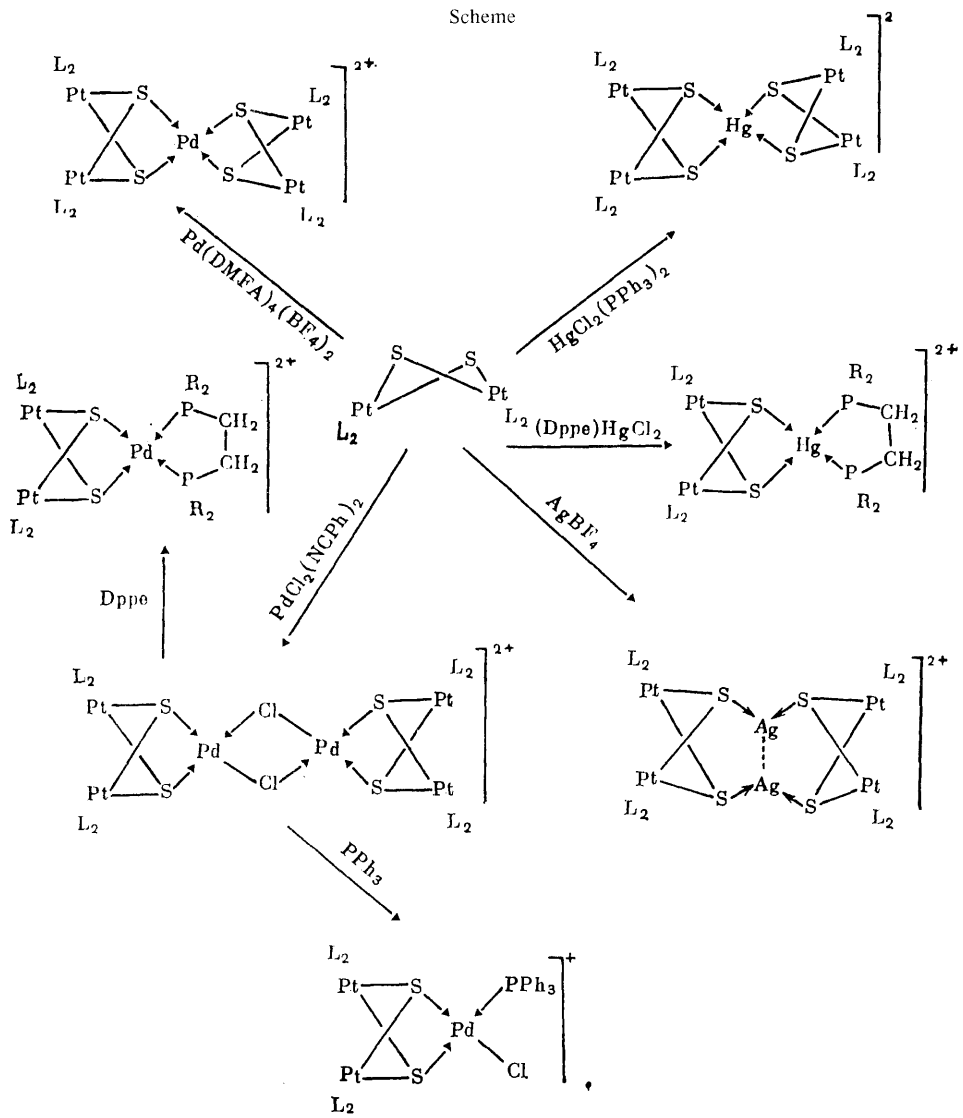
Both clusters contains the planar Os_3Pt metallic core with a metallotriangular Os_2Pt fragment (Os–Pt = 2.858–2.905 and 2.868–2.904 Å and Os–Os = 2.990 and 2.998 Å respectively) and one Os atom bound to Os_2Pt via a single direct Os–Os bond and one Os–S bond (Os–Os = 2.826 and 2.819 Å and Os–S = 2.399 and 2.403 Å respectively).[136] If PPh_3 in the platinum complex is replaced by PMe_2Ph, then both phosphine ligands in the Os–Pt-containing cluster $(PMe_2Ph)_2PtOs_3(\mu_3\text{-}S)(\mu_4\text{-}S)(CO)_9$ are bound to the Pt atom, and are non-equivalent:[137]

Although the platinum atom forms strong bonds only with the two neighbouring Os atoms (Os–Pt = 2.789 and 2.936 Å), the migration of Pt over all Os atoms is observed (according to NMR data) and the Pt–(μ_4-S) bond is always retained.[137]

3. Sulphide-bridged heterometallic clusters based on platinum-containing complexes

The "butterfly" Pt_2S_2 core is produced in the complex $(S)_2Pt_2L_4$ (L = PPh_3),[138] but here there are neither S–S (S...S = 3.1 Å) nor Pt–Pt bonds.[139] The platinum(II) atoms then have the traditional square planar environment made up of two sulphur atoms and two phosphorus atoms. As a result, the phosphine ligands are directed away from the sulphide bridges and do not prevent the coordination of the metal atoms to the latter.

Chelate coordination solely via the sulphide bridges without the formation of new M–M bonds has been observed when $L_4Pt_2(\mu\text{-}S)_2$ was used as the metal-containing ligand. The complex reacts with various mononuclear palladium compounds and affords, depending on the reaction conditions, SHMC containing between 3 and 6 nuclei.[139] The Scheme overleaf also indicates the products of the reactions of $L_4Pt_2(\mu\text{-}S)_2$ with mecury[139] and silver[140] compounds. According to X-ray diffraction data, the pentanuclear cluster $L_8Pt_4(\mu_3S)_4Pd^{2+}$ (L = PPh_3) contains no M–M bonds (M...M is greater than 3.15 Å). The palladium atom then has a square planar environment made up of four sulphur atoms (Pd–S = 2.348 Å and Pt–S = 2.344–2.351 Å, as a result of which all five metal atoms are located in the same plane (the average deviation is ±0.088 Å):[139]



In the hexanuclear $Ag_2Pt_4(\mu_3\text{-}S)_4L_8^{2+}$, the two $L_4Pt_2S_2$ fragments (Pt...Pt = 3.278 and 3.350 Å) fragments are linked by two silver atoms (in a quare-trigonal environment made up of sulphur atoms) (Ag–S = 2.381–2.399 Å and Pt–S = 2.350–2.374 Å), which are separated by a fairly short distance (2.815 Å). The Ag...Pt distances of 3.450–3.905 Å imply the absence of bonds between these atoms.[140]

Application of thermoscanning methods using gas detectors in the quantitative assessment of the results of separation in thin layer chromatography

V G Berezkin, V S Gavrichev
Topchiev Institute of Petrochemical Synthesis, USSR Academy of Sciences, Moscow

ABSTRACT. The review deals with the application of gas detectors in combination with the thermoscanning of adsorption layers in thin layer chromatography for the recording of the results of the separation. Attention is concentrated on a combined method, based on the use of cylindrical thin layer chromatography and a flame-ionisation detector; which fulfills two functions simultaneously: thermoscanning of the adsorption layer with separated organic compounds and detection of the thermoscanning products. The prospects for the development of the method are discussed. The biology includes 179 references.

I. Introduction

Thin layer chromatography (TLC) is one of the most effective and economical methods in liquid chromatography. At the present time optical scanning methods are most widely used in TLC practice for the quantitative and qualitative assessment of the results of the separation.[1,2] However, the application of these methods is limited, firstly, by the possibility of analysing only the compounds which absorb radiation or fluoresce in parts of the spectrum which are not too inconvenient for measurement and, secondly, by the need for laborious calibration which is usually associated with the high individual selectivity of the method. Therefore, for a series of compounds (lipids, carbohydrates, many polymers of practical importance, etc.), it is necessary to employ in many instances detectors of other types.

Gas detectors, for example the flame-ionisation detector (FID), the katharometer, etc., are used widely and successfully in gas chromatography; they are universal and highly sensitive, especially the FID. Their use for the scanning of TLC plates is therefore undoubtedly a promising application in the development of quantitative TLC methods. However, for analysis with the aid of gas detectors, it is first necessary to achieve transfer of the organic substances in the chromatographic bands from the adsorbed state to the gas phase. This stage is usually based on evaporation, oxidation, or thermal degradation of the substances and can be combined with the detection proper. For example, if the FID is used, then the high temperature of the flame usually ensures the quantitative conversion of the compound analysed into volatile chemical forms.

The characteristic features (and certain fundamental limitations) of this method consist in the fact that the process described above must be performed within a very narrow range to increase the resolving power, especially in the assessment of high performance chromatograms. The evaporation (degradation) band width must apparently be not more than 0.1–0.3 of the width of the chromatographic band. However, firstly, the practical application of the TLC–gas detectors (TLC–GD) method has shown that there exist many problems of practical importance for which a high resolving capacity is not required and, secondly, the possibilities of modern experimental techniques as regards a significant improvement of sensitivity are far from being exhausted.

The problem of detection is one of the central problems in TLC on the successful solution of which many investigators are working. As mentioned in a review devoted to the prospects of TLC,[3] the development of effective and universal detection methods is very important.

II. General characteristics of the thermoscanning method

Fig. 1 presents two main schemes used at present for the quantitative assessment of thin layer chromatograms by the thermoscanning method with subsequent (*a*) and simultaneous (*b*) detection.

In scheme (*a*), a furnace heated to 600–700 °C is moved over the reaction *3* containing the absorption layer with the separated components. In order to increase the temperature gradient, a cooling unit is placed in front of the furnace. As the chromatographic band is heated, the volatile evaporation-degradation products are transferred continuously with the stream of carrier gas (inert or oxidising) to the detector *5* (FID, katharometer, or a detector of another type). According to some investigators, the quantitative characteristics of the detection can be improved if the volatile products are oxidised on copper oxides to CO_2 with subsequent hydrogenation on a nickel catalyst.

A version of the method in which the TLC plate is placed within a rectangular reactor *3* was first proposed by Cotgreave and Lynes,[4] while the method using an adsorption layer deposited on the

inner walls of the reactor tube was developed by a number of investigators.[5-7]

An FID, the size of the flame of which is significantly greater than that normally used in gas chromatography, is employed in scheme (*b*) for the scanning of a cylindrical adsorption layer deposited on the lateral surface of a rod. The FID then fulfills simultaneously the function of a furnace (thermodegrader) and a detector. The method involving the thermoscanning of a cylindrical adsorption layer using an FID was first proposed by Padley.[8,9] A version of this procedure is used most widely nowadays in chromatographic practice.[10]

We shall consider these two groups of methods in greater detail.

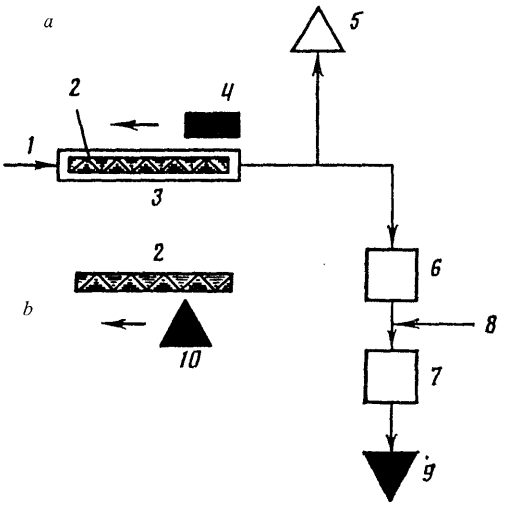

Figure 1. Generalised thermoscanning schemes in TLC: *a*, scheme with separated thermoscanning and detection devices; *b*, scheme for scanning with a thermodetector; *1*, stream of inert gas or oxidant (air); *2*, thin layer chromatogram; *3*, reactor; *4*, scanning furnace; *5*, universal detector (for example, a katharometer or an FID); *6*, reactor with oxidant; *7*, catalytic reactor; *8*, stream of hydrogen; *9*, highly sensitive universal detector; *10*, thermodetector (FID).

III. The thermoscanning method with subsequent detection of the thermoscanning products

The existing versions of this method (Fig. 1*a*) differ in a series of principal characteristics: (1) the position of the adsorption layer relative to the reactor walls; (2) the type of carrier gas used; (3) the function of the gas stream in the reactor; (4) the type of detector used (Table 1). It is noteworthy that Table 1 does not include TLC methods involving the thermoscanning and detection of radioactive compounds,[6,11] in particular, those containing isotopes with soft radiation whose detection in the gas phase is preferable.

The TLC-GD method was first described by Cotgreave and Lynes.[4] The TLC plate (150 × 12 mm, silica gel as the adsorbent on a quartz support) was placed in a heated tube with a rectangular cross-section. The authors[4] justifiably narrowed the limits of applicability of the method developed, indicating only the possibility of analysing compounds evaporated from the adsorption layer and disregarding the possibility of their thermal degradation. However, overall, this study demonstrated the possibility, in principal, of a new aspect of quantitative TLC—thermoscanning of the adsorption layer.

Table 1. Characteristics of the method for the thermoscanning of the adsorption layer with subsequent detection.

Characteristic of method	Characteristics of the application of method	
Form of adsorption component of thin layer	traditional (layer on a rectangular plate) (Ref.4)	tubular (Refs.5-7)
Linkage between adsorption layer and reactor	support not linked to the reactor; quartz support (plate) (Ref.4)	adsorption layer deposited on the inner walls of tubular reactor; reactor plays the role of support (Refs.5-7)
Function of gas stream through reactor	carrier gas transports volatile products to detector (Refs.4-7); the carrier gas is also a reactant, for example, an oxidant, which helps to convert the adsorbed compounds into volatile products	
Type of detector used	gas detector employed, for example, in gas chromatography (thermal conductivity detector, FID) (Refs.4-7)	

It is notable that the development of this method for liquid chromatography with a capillary column has been proposed.[12,13] The mobile phase was used in an amount sufficient for the separation of dyes without their elution from the sorbent (Al_2O_3) layer. The free part of the column, without the sorbent, was filled with an inert friable material and CuO to ensure the completion of the combustion of the dyes. The carrier gas (air) passed through the column to the katharometer. The electric furnace, heated to 650–700 °C at a rate of 1 cm min^{-1}, was moved onto the column in opposition to the stream of air; the CO_2 formed on combustion of the components was recorded by the detector (Fig. 2). This method can be used not only for liquid chromatography, but also, for example, for tubular TLC.

An interesting version of the TLC-GD procedure is the method of tubular TLC in which the inner walls of the tubes serve as the support for the fixed layer of the active sorbent.[5-7] After the separation (and the volatilisation of the mobile phase), the tube is thermoscanned and the products pass through the detector in the stream of carrier gas. Thus the tube fulfills the function of a solid carrier for the sorption layer and of a device for the formation of the gas stream.

In the apparatus for tubular TLC (Fig. 1*a*), one can use a katharometer. For this purpose, the substances separated are oxidised (by the oxygen present in the carrier gas and by the CuO in the adsorbent layer), the resulting water is collected in a trap, and CO_2 is detected.[7] The detector signal is proportional to the carbon content in the chromatographic band. When an FID is used in the TLC-GD method, the sensitivity of the detection of, for example, lipids, is close to the sensitivity of the analysis by column chromatography. It is notable that the separation of, in particular, shark liver oil is the same in both of the above versions, but polar lipids have been detected solely by the TLC-GD method.[7]

A detection system for the thermoscanning of the adsorption layer deposited on the inner walls of the tube has also been described by Mukherjee et al.[14] A quartz or Pyrex tube with a silica gel layer passes through three zones after the separation of, for example,

neutral lipids and bile acids and the removal of the organic eluent—a cooling unit, the pyrolytic furnace, and a thermostat, which prevents the condensation and adsorption of the pyrolysis products.

We may note that, in the method considered, the inner diameter of the reactor tube must be sufficiently large to ensure the rise of the mobile phase solely via the adsorption layer and not via the tube. This creates certain difficulties when an attempt is made to increase the temperature gradient and hence the resolving capacity of the method, which is nowadays used extremely rarely.

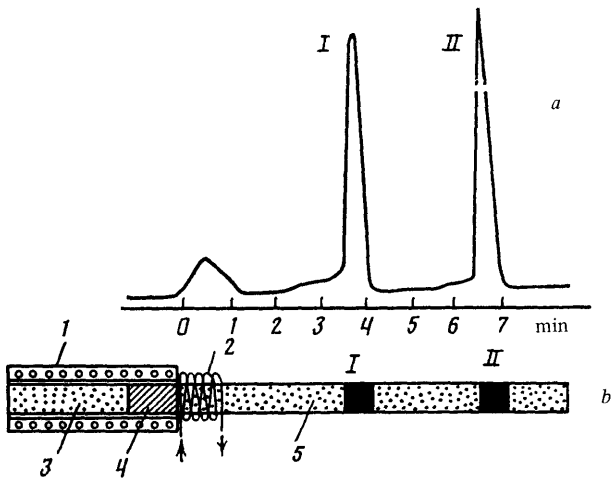

Figure 2. Schematic illustration of the thermoscanning of a capillary column for liquid chromatography (*b*) in the chromatogram (*a*) for azobenzene (I) and sudan red (II) separated on a column with Al_2O_3;[13] *1*, electric furnace; *2*, water-cooled quartz coil; *3*, part of the column filled with solid carrier (Spherochrom); *4*, part of the column filled with CuO; *5*, separating section of the column filled with Al_2O_3.

Fig. 3 illustrates schematically the scanning device of the "Iatroscan" apparatus.[18] The FID signal is known[19,20] to be directly proportional to the rate at which the organic substance enters the flame and, in the case under consideration (for a constant rate of movement of the rod), also to the concentration of the substance in the chromatographic band. In the "Iatroscan" apparatus, ten rods are fixed in a frame which moves in accordance with a definite programme, rod after rod being scanned automatically. The scanning time of a single rod is 30 s and the hydrogen flow rate is 160 ml min^{-1}. The results of the separation on a cylindrical thin layer are recorded by a pen recorder in the form of the usual chromatogram and in the integral form.

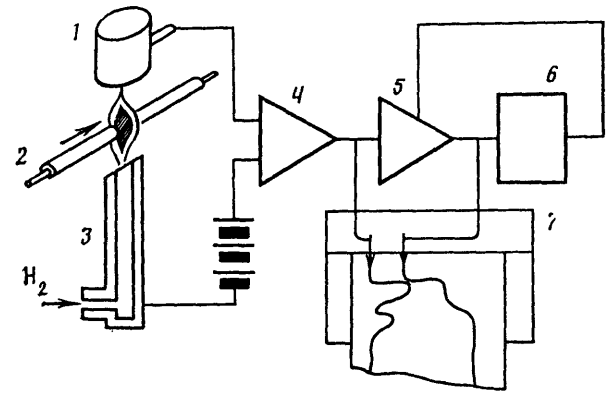

Figure 3. Schematic illustration of a device with an FID for the scanning of a rod with an adsorption layer containing the separated bands:[18] *1*, collector electrode; *2*, chromarod; *3*, burner; *4*, current amplifier; *5*, and *6*, signal integration units; *7*, two-channel pen recorder.

IV. A method for the thermoscanning of a cylindrical adsorption layer with simultaneous detection

The method for scanning a thin adsorption layer with the aid of an FID, described in 1967 [8] (Fig. 1*b*), is simpler than the methods described above in which the thermoscanning and detection stages are separated. An entirely satisfactory separation of glycerides has been achieved using a quartz rod 0.5 mm in diameter and 200 mm long with deposited silica gel. It was shown that the disposition of the rod in the flame and the rate of its movement relative to the flame influence the sensitivity of detection.

A scanning method using an FID was described in 1970.[15] The chromium–nickel alloy strip (215 mm long, 3 mm wide, and 0.1 mm thick) on which a silica gel layer 0.3–0.4 mm thick had been deposited, was used as the chromatographic system. Despite the entirely satisfactory analytical results, this system has not come to be widely used in chromatographic practice.

The development and investigation of repeatedly used rods with an adsorption layer, carried out by Okumura and Kadono[16,17] were very important for the application of Padley's method. This system, which was subsequently modified somewhat, is widely used in practice.

Since a cylindrical adsorption layer is used in this method as the chromatographic system, which is of fundamental importance for this variety of TLC, it is useful to call this version cylindrical TLC (CTLC) and to designate the above combined method as a whole by CTLC-FID.

The first three stages in this method are usual for transitional TLC: the deposition of the sample on the adsorption layer, its separation in a stream of an ascending mobile phase, and the removal of the mobile phase (at an elevated temperature). The preliminary rod activation stage with the aid of FID and the last stage involving the scanning of the rod with the separated bands by the same detector have no analogues in traditional TLC.

At the present time the CTLC-FID method has come to be most widely used in analytical practice compared with other thermoscanning methods. In our view, this can be explained by the following causes: (1) the scanning apparatus and the analytical method are distinguished by simplicity (the FID fulfills simultaneously the thermoscanning and detection functions); (2) the FID is characterised by a wide linear dynamic range, a high sensitivity, and universality also as regards organic compounds (hydrocarbons, lipids, etc.), to which the widely used optical detection methods are almost applicable; (3) the availability of commercial rods of the "Chromarod"

brand and equipment manufactured by the Japanese Company Iatron Laboratories;[18] (4) the high productivity of the method (about 10 analyses in 10 min) by virtue of the high scanning rate.

Since the CTLC-FID method differs from traditional TLC as regards the form of the adsorption layer and the type of scanning and detection, it is necessary to examine the features of this method both in chromatographic separation and in quantitative analysis.

1. Characteristic features of the chromatographic separation by the CTLC method

The widely used cylindrical open chromatographic system (chromarod) consists of a quartz rod on the surface of which a porous layer of silica gel or Al_2O_3 is deposited (Fig. 4). The geometrical parameters of the chromarod are as follows: length 152 mm, diameter 0.9 mm, length of an adsorption layer 120 mm, thickness of adsorption layer 75 μm. After thermoscanning, the rod is automatically activated by the FID, is cleaned, and becomes suitable for re-use. One rod can be used for 100 analyses.

Three types of rods are being manufactured at the present time: chromarod SI, chromarod SII, and chromarod A (since 1987 also chromarod SIII). The first two types of rods are based on silica gel, the particle diameters of which are 10 and 5 μm respectively, chromarod SII being characterised by a higher resolving power. The adsorption layer on chromarod A is obtained from Al_2O_3 particles 10 μm in diameter and is normally employed for the separation of compounds which are unstable on silica gel and also of certain stereoisomers. The adsorption layers on the rods are obtained by sintering the adsorbent particles in the presence of a small amount of readily fusible glass particles added as a binder. The cylindrical shape of the adsorption layer has definite advantages. In this system there are no edge effects disturbing the movement of the eluent front and observed in many cases on the usual rectangular TLC plates. The width of the adsorption layer is small amounting to πd = 2.8 mm (d = 0.9 mm is the diameter of the adsorption layer) and the possible disturbances of the eluent front show a tendency towards "self-healing". For separation the small size of the adsorption system needs only small amounts of the mobile phase, which is frequently extremely expensive.

Further reduction of the rod diameter is justified, which would apparently make it possible (1) to increase the resolving power in the detection of the separated bands by virtue of the increase in the temperature gradient on the rod during scanning, (2) to reduce the uncontrollable losses of the substances analysed during detection, (3) to increase the rate of detection, and (4) to reduce the amount of eluent consumed.

The sample is deposited and separated by the procedure of traditional TLC,[21,22] although, in our view, it would be more justifiable to use special apparatus taking into account the geometry of the rods. The samples (with a volume not exceeding 1 μl) are deposited on the adsorption layer of the rod at a distance of 1–2 cm from its end and the syringe or an applicator of another type must not touch the adsorption layer. The deposited samples on rods fixed in cassettes, which can contain up to 10 rods, are separated in small rectangular chambers for 15–40 min. After the separation, the rods are dried to remove the mobile phase: at a temperature above 100 °C, this takes several minutes. For example, 3 min is sufficient to evaporate a mixture of chloroform, benzene, and formic acid at 130 °C.[23] For labile compounds, the drying can be carried out at low temperatures in a stream of an inert gas or *in vacuo*.

The removal of the mobile phase before scanning is an important stage, since even its traces create an appreciable background and reduce the sensitivity of the detection. Therefore, in our view, it is useful to use as mobile phases substances to which the FID is almost insensitive: water,[19,24] carbon disulphide,[25] ammonia,[26,27] formamide,[25] formic acid,[24] and certain other substances. It is possible and desirable to employ also combinations of these compounds.

It is likewise useful to point out the possibilities of the use of chemically selective inorganic phases in CTLC. Thus organic acids and their methyl esters or triglycerides have been separated on chromarods impregnated with a silver nitrate solution as a function of the degree of unsaturation and isomerisation of the molecules.[28–30] It has been noted[30] that the rods employed are not washed entirely free of silver nitrate even after they have been kept for a long time in aqua regia. The possibility of reusing the rods with silver nitrate has been investigated also in another study.[31]

Another example of the employment of a chemically selective phase is provided by the separation of the glycerides on rods impregnated with a 3% solution of boric acid.[32]

Single separation in CTLC is the simplest but not the only method of chromatographic analysis. The application of repeated elution using several mobile phase systems to improve the separation of samples with a complex composition has been described. For example, a clear separation of the main groups of hydrocarbons present in the residue from the vacuum distillation of petroleum using three consecutive elutions over definite distances has been achieved on a chromarod.[33]

The repeated elution procedure with intermediate scanning of part of the rod is important and methodologically elegant. Thus, in the analysis of blood serum lipids,[34,35] neutral lipids were initially

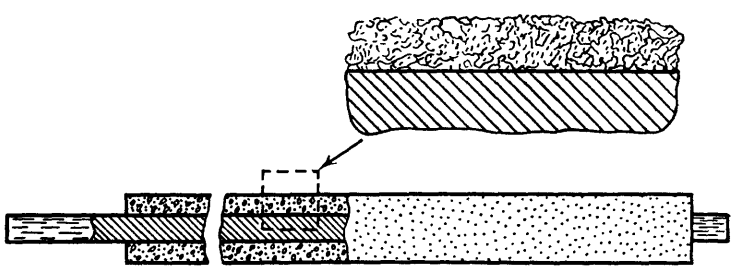

Figure 4. Schematic illustration of the chromarod.[18]

separated and scanned with the aid of an FID and the phospholipids remaining at the start were then separated using a more polar eluent and were also thermoscanned. This version has no direct analogue in traditional TLC and can apparently be regarded as a version of the two-dimensional separation.

It is necessary to differentiate an important application of the CTLC-FID method for the quantitative analysis of components, including impurity components, which cannot be determined by the traditional TLC. The lipid components of the crab have been determined[36] using for the analysis the extract from the part of the TLC plate, which, according to optical scanning data (after the corresponding derivatives have been obtained), did not contain even traces of any compounds. The CTLC-FID method can be used successfully for the analysis of fractions separated by column chromatography and of extracts obtained from sorbent specimens from definite sections of the TLC plate.[10,37]

The combination of the separation on a traditional TLC plate with subsequent separation of individual bands by the CTLC-FID method can also be regarded as one version of the two-dimensional separation.

The moving transporter system proposed earlier[38] is of interest for the analysis of components which cannot be determined by an optical detector especially when packed capillary columns are used in liquid chromatography. A chromarod can apparently be used as such a transporter.

In our view, the CTLC-FID method is promising, since it makes it possible to analyse complex objects rapidly and with a resolving capacity which is sufficient for many practical purposes. It is therefore useful to compare both the versions of chromatography realised in this method as well as those which have not yet been used.

Table 2. Classification of the chromatographic systems used in TLC on the basis of the state of aggregation of the mobile and stationary phases.

Chromatographic system	TLC	
(Mobile phase) [stationary phase]	traditional, on plates	cylindrical, on rods
(Liquid) [solid]		
Traditional, direct phase (non-polar or polar liquid) [polar solid]	is used	is used
Reversed phase (polar liquid) [non-polar solid]	is used	is possible
(Liquid) [liquid–solid]		
Traditional, direct phase (non-polar liquid) [polar liquid–solid]	is used	is possible and desirable
Reversed phase (polar liquid) [non-polar liquid–solid]	is used	is possible

Table 2 presents a classification of various chromatographic systems in traditional and cylindrical TLC. In fact, only one chromatographic system is used in CTLC: (liquid) [polar solid]. The application of other types of chromatography, especially the reversed phase chromatography, is likely to be extremely promising in the future. Here there is apparently a possibility of two approaches: firstly, to obtain the grafted phase each time on the adsorption layer (by standard grafting methods in the gas or liquid phases) and, secondly, to obtain rods with a coating of a carbon adsorbent which will probably also have to be renewed after each use of the rod.

Comparison of the traditional TLC and CTLC in terms of the types of chromatographic processes suggests that at the present time only adsorption is used in CTLC. The employment of partition chromatography will permit, in our view, a significant expansion of the number of parameters for the selection of the optimum solution. The only additional requirement is the use of a volatile compound or substance to which the FID is almost insensitive to the stationary phase.

By using an adsorbent with a known and controllable porosity, it is undoubtedly possible to achieve exclusion CTLC.

Fundamentally new possibilities arise when electromigration methods on cylindrical rods are resorted to. The application of ion exchange to the separation of inorganic and organic ions is also extremely promising. In this version of CTLC, it is desirable to employ optical detectors, for example, the flame-photometric detector, together with the FID.

Table 3 compares the known and possible methods of elution in traditional and cylindrical TLC. In our view, among the elution methods which have not been used in CTLC hitherto, descending and centrifugal elution, whose application would permit an acceleration of the separation process, is of interest.

Table 3. Elution methods in traditional and cylindrical TLC.

Elution method	TLC	
	traditional, on a plate	cylindrical, on a rod
Ascending	is used	is used
Descending	is used	is desirable
Horizontal	is used	is possible
Continuous	is used	is possible
Radial and circular	is used	–
Repeated	is used	is used
Stepwise	is used	is used
Stepwise with intermediate detection of some of the separated compounds and their removal from adsorption layer	is desirable	is used
Two-dimensional	is used	–
Centrifugal	is used	is desirable
Gradient	is used	is desirable

Table 4. Combination of CTLC with other analytical physicochemical methods.

Analytical method	Combination with CTLC
Thin layer chromatography	is used (Refs.10, 36)
Column liquid chromatography	has been proposed (Ref.10)
Gas chromatography	is possible
Mass spectrometry	is used (Ref.10)
Spectroscopic methods	is desirable
Electrochemical methods	is possible

Hybrid methods (see, for example, Zolotov[39]) based on the joint employment of two and more methods, have been increasingly introduced into analytical chemistry and chromatography in recent years. It is therefore of interest to analyse the possibility of combining different methods with CTLC (Table 4).

Thus, it follows from the analysis of Tables 2–4, that the CTLC method has wide prospects for development and the majority of the known separation principles in liquid chromatography can apparently be used successfully in this procedure also.

An important aspect of any analytical method is the estimation of the reliability and reproducibility of the results obtained. We shall now consider the quantitative aspects of the CTLC-FID method.

2. Quantitative aspects of the CTLC-FID method

In the FID method considered, the FID is not used under the normal conditions for which it has been designed.[40,41] Thus the coefficients of sensitivity of this type of detector with respect to lipids differ for the CTLC-FID method from the coefficients for gas chromatography.[42] The main characteristics of the quantitative analysis by the CTLC-FID method are influenced not only by the FID operating conditions (the rod passes through the flame whose dimensions are comparable to those of the rod), but also by the unusual conditions in the detection of organic compounds adsorbed on the porous layer of the rod. The transport of these compounds (or their degradation products) to the hydrogen flame is hindered by the limited mass exchange and also by the high scanning rate (about 4 mm s^{-1}). The adsorbed involatile compounds must be initially subjected to thermal degradation which complicates detection and undoubtedly influences the accuracy of the quantitative determination. It has been noted[43] that, in order to obtain the full signal due to the chromatographic bands of certain substances, repeated scanning of the rod with the summation of the results of all the scans is essential. With increase in the size of the molecule of the substance analysed, the number of scans increases.

In order to avoid repeated scanning, it has been suggested[44] that the rod be rotated through 180°, which improves the contact between the flame and the adsorbed substance.

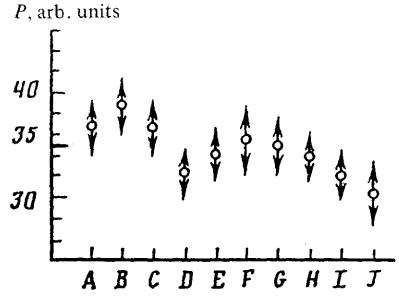

Figure 5. The areas of the peak (P, arbitrary units) of octadecanoic acid for 10 chromarods S (from A to J);[45] sample size 10 μg; the sample deposited on the rod was not eluted and the measurements on each rod were performed ten times.

The reproducibility of the analytical properties of the adsorbent and hence of the results of the quantitative analysis constitutes an extremely important problem in the adsorption chromatogaphy in general and in CTLC in particular. It has been shown[45] that the quantitative results of repeated analysis for chromarods S are different and that this applies both to the average peak area (the points on Fig. 5) and to its standard deviation (arrows). Mares et al.[46] suggest that the reproducibility of the method can be increased in the future by a preliminary selection of the rods (see, for example, Hirayama and Morita[47]).

The large standard deviation is explained by some investigators in terms of the differences in the properties of the rods,[48] while according to others it is due to the inadequate reproducibility of the detection process.[49] Some workers[48,50–53] have concluded that the results of the quantitative determinations by the CTLC-FID method are unfortunately characterised by a low accuracy, although it is sufficient for the solution of many practical problems.

The study[54] in which it has been suggested that the rods with a silica gel layer be impregnated beforehand with a 5% $CuSO_4$ solution appears important in connection with the foregoing. It has been shown that, in the determination of lipids, the base line of the detector is improved and the scatter of the results from rod to rod is diminished. However, it has to be said that the impregnation with copper sulphate shortens the useful life of the rods.[55]

The reproducibility of the results improves with increase in the scanning rates from 3.2 to 4.2 mm s^{-1}.[56] It is of interest that impregnation with copper sulphate alters the relative sensitivities for different substances. For example, the sensitivity with respect to methyl haptanoate increases relative to triglycerides.

The choice of the quantitative determination method is important. Many investigations have been devoted to the analysis of lipids—one of the most important practical applications of the CTLC-FID method.[10,57–61]

It has been shown,[18] in relation to the analysis of glycerides and free acids, that, when the relative and not the absolute peak area is used for the calculations, the "individuality" of the rod is not manifested quite so sharply.

It has been confirmed experimentally that the application of the internal standard method permits, in contrast to the absolute calibration, a significant improvement of the reproducibility of the results of the method. Despite the fact that the use of an internal standard reduces the scatter of the results when one rod is replaced by another,[51,52,62] it is difficult to obtain accurate quantitative analytical results because the relative sensitivity depends on the sample size,[62–64] the ratio of the concentrations of the substance analysed and the internal standard,[65] the scanning rate,[61,66] and whether a biological object or an artificial mixture is analysed.[46]

It has been stated[63] that the CTLC-FID method using an internal standard can yield an approximate result in the study of the lipid composition of marine organisms and deposits as well as sea water, whose determination had been attempted earlier:[67,68] for a <2–3 μg sample, the relative sensitivity coefficients change appreciably and to different extents for lipids of different classes.

The calibration plots for lipids are not linear and cannot always be extrapolated to the zero point.[62,64,69–72] For lipids, aliphatic hydrocarbons, esters, ketones, free aliphatic acids, triglycerides, free alcohols, and free sterols, present in sea water, the calibration plots are described by different equations:[73] for example, $y = 0.07 + 4.19x$ for polar lipids, while $y = -0.72 + 1.39x + 0.09x^2$ for free sterols and, in order to attain an accuracy of the quantitative analysis better than to within 10 rel.%, it is essential to carry out many measurements (see also Tanaka et al.[74]).

The multifactorial experiment on the analysis of triglyceride mixtures of different composition, differing in the acidities of the components, on 10 chromarods S showed[56] that the previous history of the rod, the mixture composition, and the acid composition of the triglyceride are very important for quantitative analysis, the relative sensitivity (with an ester as the standard) gradually diminishing as a function of time. It has also been established that the sensitivity

coefficients for single and mixed triglyceride specimens are not the same[56] and yet the majority of investigators use coefficients obtained by calibration with respect to individual compounds for the analysis of biological objects.[46,52,61,72,74-76]

It is noteworthy that, in the analysis of hydrocarbons, the results obtained by the CTLC-FID method are stable as a function of time. Thus, in the determination of the composition of petroleum on chromarod SII, random oscillations in the absolute values of the signal were observed in the course of 5 days, although they were different for different groups of hydrocarbons.[77]

Thus the nature of the substance influences the error of the measurement. It may be that the scanning of each band or separate groups of bands can be usefully carried out separately under optimum conditions for each band.

Studies designed to improve not only the accuracy of the quantitative analysis but also the sensitivity of the method are of great interest. The size of the sample analysed influences significantly the standard deviation of the signal and it must be greater than 1 μg in order to obtain reproducible results.[46]

It has been shown that the sensitivity of the Iatroscan apparatus in the determination of lipids (combined with a satisfactory accuracy and reproducibility) is a maximum for a hydrogen flow rate >200 ml min^{-1}, a distance between the rod and the detector burner nozzle not greater than 0.8 mm, when the vibration air pump is replaced by a compressor, and when new rods are washed with concentrated nitric acid.[78] The above measures led to an increase in sensitivity by a factor of ~ 2 and to a decrease in background by a factor of ~ 5; the standard deviations of the signal were then 5–15 rel.%. It was possible to determine 0.05 μg of each lipid in a small sample volume (0.2 μl). According to the data in Ref. 18, the sensitivity of the CTLC-FID method is fairly high: the detection limit is about 0.07 μg m^{-1}. Different procedures are used to increase the sensitivity: mounting of the ion collector at a distance of ~ 1.7 mm about the rod,[79] the focussing of the band of the test substance on the rod,[69] and chemical treatment of the rods, for example with iodine vapour, to intensity the FID signal in the analysis of unsaturated lipids.[80]

Comparison with the traditional methods for the solution of the same problem is important for the estimation of the quantitative aspect of the new method. Mares et al.[46] compared the accuracies of the analysis of human blood plasma lipids by the CTLC-FID and gas chromatographic methods. The reproducibility of the former method proved significantly lower, but one must agree with the above authors,[46] who assume that further development of the CTLC-FID method will permit an improvement in this important parameter.

We may note the following important advantages of the CTLC method compared with gas chromatography: (1) the possibility of using involatile and thermally labile compounds for analysis; (2) an unusual selectivity which is frequently difficult to achieve in gas chromatography—for example, group separation of hydrocarbons, phospholipids, etc. is possible; (3) high rate of detection (1 scan in ~ 30 s).

The results of the determination of malthenes and asphaltenes in heavy petroleums by the CTLC-FID method agree well with data obtained by the traditional IP 143 method of the Institute of Petroleum (London).[81] Both methods are characterised by virtually the same reproducibility, but the CTLC-FID method is less laborious: the time required for the analysis of 9 specimens is about 30 min (excluding the time consumed in the weighing and dissolution of the specimens).

In the determination of the group compositions of heavy hydrocarbons, the data obtained by the CTLC-FID method and the standard ASTM D2007 method differ significantly, which is associated with the sharp difference between the fractions actually isolated by the ASTM method and the declared fractions.[33]

When the CTLC-FID method is used to analyse heavy petroleum and coal processing products, a disadvantage of high performance column chromatography, namely the loss of appreciable proportions (from 5 to 15%) of the specimen analysed, is eliminated.[44]

It has been shown[82] that the CTLC-FID method yields reliable quantitative results in the determination of polycyclic aromatic hydrocarbons, in contrast to methods such as liquid–liquid extraction, liquid column chromatography, and gas chromatography.

In conclusion, it must be emphasised that, despite many critical comments concerning the quantitative characteristics of the CTLC-FID method, numerous studies indicate a positive aspect of its practical application for the quantitative analysis of a wide variety of objects—ranging from petroleum to biologically active compounds.

There is no doubt that the further perfection of the apparatus will permit a significant improvement in the quantitative characteristics of this promising method.

3. Practical applications of the CTLC-FID method

The CTLC-FID method is widely used in various branches of science, industry, medicine, protection of the environment, etc. It is of special interest for the study of objects in which the optical detection methods, widely used in liquid chromatography (column chromatography and TLC), are almost inapplicable and the preparation of the corresponding derivatives is complicated or undesirable. We shall quote certain examples of the practical employment of the CTLC-FID method.

(a) Lipids. Tanaka et al.[74] investigated the separation of complex lipid mixtures. The products of the methanolysis of sphingoglycolipid were fully separated on chromarod SII using two consecutive elutions.

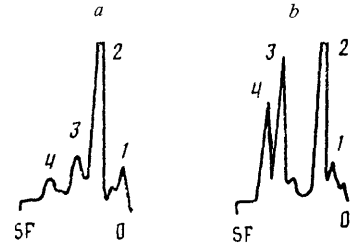

Figure 6. Chromatography of rat brain phospholipids;[83] chromarod S with copper sulphate; eluent: chloroform–methanol–water (68.5:29:2.5) without (*a*) and with (*b*) addition of 0.5% of formic acid; *1*, sphingomyelin; *2*, phosphatidylcholine; *3*, phosphatidylethanolamine; *4*, diphosphatidylglycerol; 0, start; SF, solvent front.

The separation of rat brain phospholipids has been demonstrated[83] on rods impregnated with copper sulphate (Fig. 6*a*). As in the author's previous studies using non-impregnated rods,[75,84] the eluent was a mixture of chloroform with methanol and water. The addition

of formic acid decreased the spreading of the bands of certain compounds (peaks *3* and *4* on Fig.6 *b*) and reduced the peak at the start.

Analysis of lipids is of definite interest also in connection with the diagnosis of certain diseases. For example, a sharp qualitative change in the lipid content of the amniotic fluid of pregnant women occurs in the case of illness.[51,85,86] The determination of lipids by the CTLC-FID method is used in pharamaceutical and clinical studies, in toxicological analysis, and in the analysis of food.[87-89] Data on the quantitative determination of lipids and their derivatives by the CTLC-FID method have been surveyed.[90] Apart from the investigations mentioned here and in the preceding Sections, other studies of lipid objects must be indicated: blood plasma,[91-94] blood serum,[91,92,95] human gums,[96] yeast,[97] micro-organisms,[98] vegetable oils,[99,100,133] as well as glycerides and fatty acids,[95,99,101-117] phospholipids,[118-120] and lipids of other classes.[121-129]

It is notable that the use of computers has expanded in chromatographic practice. Thus the application of computers in the Iatroscan apparatus for the analysis of lipids of biological origin has been described.[130]

In conclusion we may mention that the determination of lipids in various specimens is at present the most thoroughly developed field of the practical application of the CTLC-FID method and its use in this field alone undoubtedly justifies the development of this method.

(b) Petroleum and hydrocarbon fuel. The application of the CTLC-FID method in the determination of the group composition of heavy fuel was first described by Suzuki and Takeuchi.[131,132] The study of Yamamoto and Kawanobe[134] was devoted to a method for the rapid determination of asphaltenes in heavy oils and of the composition of these oils. The method for the determination of malthenes and asphaltenes on rods with a silica gel layer has been successfully tested on 16 specimens of bitumen, heavy petroleums, and synthetic fuels.[81] Components insoluble in benzene were removed before the analysis.

The liquid products of the hydrogenation of coal from Japanese deposits were resolved into the following fractions: saturated, polycyclic aromatic, and heteroaromatic compounds, tars, and asphaltenes.[135]

Other examples of the use of the CTLC-FID method in the analysis of hydrocarbon raw materials and products should also be mentioned.[136-143] It has been concluded[33] that the CTLC-FID method ensures the rapid determination of the group composition of high-boiling fractions of petroleum, heavy oils, and liquid coal processing products and preliminary deasphaltisation is not required.

Thus the determination of hydrocarbons of different classes is an important practical application of the method considered.

(c) The monitoring of the environment and analysis of physicologically active objects. The possibilities and advantages of the CTLC-FID method in the determination of polycyclic aromatic hydrocarbons extracted from filters for the selection of contaminated air samples have been demonstrated.[82] The determination of the composition of the particles present in the exhaust from diesel engines has been described.[144] The method made it possible to analyse involatile organic compounds with $T_b \geqslant 300$ °C (the limit of the determination is ~ 0.03 μg).

Numerous studies have been devoted to the analysis of biological objects and medicinal drugs: psychotropic preparations,[145,146] alkaloids,[17,124] aminoacids, vitamins, pesticides, corticosteroids, cardiac glucosides and genins,[17] oestrogens, progestins and androgens,[17,124] saccharides,[147] antibiotics,[148] bile acids,[149-151] aglucones,[152] and glycyrrhizin.[153]

Here one may also indicate the following objects analysed: surfactants (quaternary ammonium chlorides, oleates, and sulphonates,[45] olefin sulphates,[149] and other surfactants[154-156]), sulphanilic acid and sulphonamides,[17] phthalates,[157] ginseng saponins,[158] perfumes,[159] peony extracts,[160] food products,[161-163] leather articles,[164] and cosmetics.[165]

The examples quoted in this section indicate the possibility of the effective application of the CTLC-FID method also in those fields which are important for human health.

(d) Applications in other fields. The distribution of liquid rubbers in terms of "functionality" has been investigated.[166] αω-Polybutadienols have been separated by the CTLC method into three fractions: a fraction without functional groups and fractions with one and two functional groups. Comparison of two scanning methods—the optical and FID methods—showed that the results of the optical method are too high by 30–50%.

The CTLC-FID method has been used successfully to investigate the radiation-induced graft copolymerisation of styrene on cellulose.[167] Homopolystyrene and homopolyacrylonitrile have been determined.[168] The analysis of polymers has also been described in another communication.[169] The composition of industrial emulsions and its variation during use have been studied.[170]

One of the examples of the employment of the CTLC-FID method in the study of the kinetics of the formation of an ester has been described.[171] Ethyl benzoate and benzoic acid have been determined on chromarod SII. Chemical reactions have also been investigated in other studies.[70,172-174]

---o0o---

Analysis of the data described in this review permits the conclusion that a new promising aspect of TLC and of the scanning field has been established, namely CTLC-FID. The practical application of this combined method is particularly useful primarily for compounds whose detection by optical methods is unsatisfactory. Numerous communications, and reviews published in recent years[175-178] as well as the monograph by the Czechoslovak scientist Ranny[179] are an indication of the great and continuing interest in the CTLC-FID method.

The method has good prospects, some of which have been noted in the present review. In the course of the further development of the method, it will be desirable to concentrate attention to the following promising aspects: (1) the development of new methods of improving the resolving power of thermoscanning detection; (2) the application of new detection methods, for example flame-photometric methods; (3) use of other versions of chromatography apart from the familiar liquid–solid version.

Organic compounds of silicon with non-standard types of coordination

V E Shklover, Yu T Struchkov, M G Voronkov
Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow
Irkutsk Institute of Organic Chemistry, Siberian Division of the USSR Academy of Sciences

ABSTRACT. The structures of organosilicon compounds in which the coordination number of silicon is other than 4 are examined. Derivatives of pentacoordinate silicon, in which silicon has a trigonal-bipyramidal geometry, have been most thoroughly investigated among them. Appreciably much less information is available about the unstable derivatives of tricoordinate silicon, whose structure is close to being planar. Examples of compounds in which the coordination number of silicon is greater than five are also examined. Attention is concentrated on the geometry of compounds with an increased coordination number of silicon atoms as intermediates in chemical reactions.
The bibliography includes 111 references.

I. Introduction

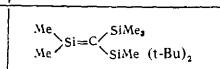
The main advances in the chemistry of organosilicon compounds (OSC) are associated with studies on derivatives of traditional tetrahedral silicon. This is why the commonest valence and coordination state of silicon is in fact mainly considered in the structural chemistry of OSC.[1,2] However, compounds in which the coordination number of silicon is higher (in the first place silatranes[3,4]) have been synthesised comparatively recently and have now ceased to be unique, while in the last 5–7 years it has been possible to obtain compounds with multiple bonds at the silicon atom.[5–10] The structures of these new OSC have been investigated in fair detail (see, for example, the relevant reviews[1–6]), but so far there has been no general survey of these investigations. The aim of the present review is the examination of the structural features of all the known OSC with a non-tetrahedral coordination of the silicon atom or a coordination which differs appreciably from the tetrahedral. Attention is concentrated on compounds with a silicon–carbon bond, but certain new interesting compounds without such bonds are also considered.

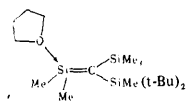
The review does not claim to cover all the structural data on OSC with a non-tetrahedral silicon atom. Preference is given to X-ray diffraction studies (the most reliable method for the investigation of new structures), new results, and the authors' own data.

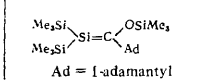
II. Tricoordinate silicon compounds

1. Silaethylenes

The available data on the structures of compounds with Si=C double bonds (silaethylenes) are summarised in Table 1. Their Si=C bond lengths are in the range close to the length (1.69–1.73 Å) predicted by MO calculations for sterically unhindered silaethylenes.[11] The molecule of compound (I) with the shortest Si=C bond [1.702(5) Å] has a virtually planar core $C_2Si=CSi_2$ (Fig. 1), the sum of the valence angles at each of the atoms Si(1) and C(1) being 360°. The torsional distortion (twisting) relative to the Si=C bond is only 1.6°. The deviations of the valence angles at the unsaturated Si(1) and C(1) centres from the standard values for the sp^2 hybridisation can be fairly well accounted for by the steric strain introduced by the $SiMe_3$ and especially $SiMe(Bu_t)_2$ groups at the C(1) atom.[8]







The differences between the Si=C bond lengths and the torsional distortions in the silaethylenes (I)–(III) are probably caused by the greater size of the substituents and also by their electronegativity [the $OSiMe_3$ group in compound (III)]. Since the silaethylene (I) contains less bulky and not unduly electronegative substituents, its Si=C bond length [1.702(5) Å] can be regarded as characteristic of the silaethylene $R_2Si=CR_2$ with moderately large substituents.

The most interesting feature of the silaethylene tetrahydrofuranate (II) molecule is the presence in it of a significantly planar bond system at the sp^2-hybridised C(1) atom, which forms a double bond with the tetracoordinate Si(1) atom which is involved in an unusual coordination (Fig. 2). The sum of the valence angles of the C(1) atom is 358.8° and the atom is displaced from the Si(1)Si(2)Si(3) plane by only 0.11 Å. Large valence angles at the C(1) atom are probably caused by the steric interaction between the substituents. The largest Si(1)C(1)Si(3) angle, which is 126.7(3)°, is due to the extremely bulky $Si(3)MeBu_2$ group whose Si(3)–C(8) and Si(3)–C(12) bonds are in the *gauche*-conformation relative to the Si(1)–C(1) bond.

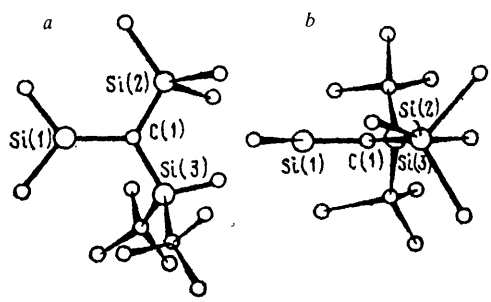
The coordination involving the Si(1) atom does not correspond to the ideal tetrahedral geometry, which can be difficult to explain by steric hindrance. The C(1)Si(1)C(2) and C(1)Si(1)C(3) angles, which are respectively 119.7° and 124.1(3)°, unexpectedly differ little from 120°, the usual value of the angle in the sp^2-hybridisation. The C(2)Si(1)C(3) = 104.9(3)° angle is appreciably smaller than the tetrahedral value. The angles at the oxygen atom in the THF

molecule can be divided into two groups: the OSi(1)C(1) = 107.9(2)° angle is much greater than the OSi(1)C(2) = 97.9° and OSi(1)C(3) = 96.5(2)° angles. The Si(1)–O = 1.878(4) Å distance is much greater than the Si–O bond lengths characteristic of the dicoordinate O atom in siloxanes (1.68 Å) [12–15] and the bonds involving a tricoordinate O atom aluminosiloxanes (1.66–1.76 Å),[16] although in the latter the O atom is incorporated in some cases in a strained four-membered Al_2O_2 ring.

Table 1. The principal geometrical parameters of molecules with Si=C double bonds.

No. of compound	Compound	Molecular symmetry	r(Si=C), Å	τ*, deg	Refs.
(I)		C_1	1.702 (5)	1.6	[8]
(II)		C_1	1.747 (5)	22.4	[9]
(III)	 Ad = 1-adamantyl	C_1	1.764 (3)	14.6	[10]

*τ = angle of twist about the Si=C double bond.



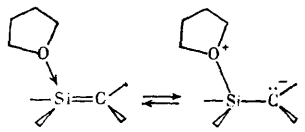


Figure 1. The structure of the molecule of compound (I): projection onto the Si_3C plane (*a*) and onto a surface perpendicular to the plane of the π-system of the C(1)=Si(1) double bond (*b*).[8]

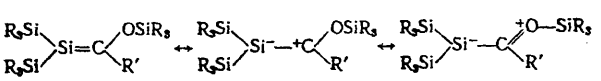


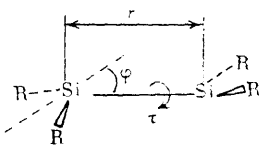
The Si(1)–C(2) and Si(1)–C(3) bond lengths [1.850 and 1.858(5) Å respectively] are somewhat greater than the C(1)–Si(2) and C(1)–Si(3) bond lengths [1.853 and 1.836(5) Å] and are much smaller than the Si–Me bond lengths in silyl groups [1.879 Å to 1.907(6) Å]. The Si(3)–C(Bu_t) [Si(3)–C(8) and Si(3)–C(12)] bonds are even longer [1.939 and 1.927(6) Å], which may be caused by steric strain.[9] The usual geometry of compound (II) can be explained by equilibrium between the forms (A) and (B):[9]

The canonical form (A) corresponds to the formation of an adduct with THF, as a consequence of which the Si atom acquires ten electrons, which requires the participation of *d* orbitals in the bonding. It is important to emphasise that the presence of an excess Si–O bond in compound (II) does not induce a sharp increase in the length of the Si=C bond, which remains shorter than, for example, in the silaethylene (III), with bulky substituents (Table 1). The second canonical form (B) presupposes charge separation between the atoms in the 1- and 3-positions as a consequence of the formation of the covalent Si–O bond, as happens in the phosphorus ylides $R_3P^+-\dot{C}R_2^-$. The increased Si–O bond length in the molecule of compound (II) agrees with a relatively low stability of the adduct (A), in which suitable *d* orbitals of the Si atom can overlap with the donor orbitals of the O atom and the approximately tetrahedral form (albeit distorted) coordination of the Si(1) atom agrees with the zwitter-ionic form (B).

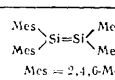
The conformation of the molecule of compound (II) is apparently determined by the steric interactions of the substituents at the Si(1) and C(1) atoms. In particular, the twisting around the double bond [the C(3)Si(1)C(1)Si(3) angle is 22.4°] is probably caused by the minimisation of the steric interactions between the methyl groups at Si(1) and the t-butyl groups at the Si(3) atom. According to ^{1}H NMR data, both Me groups at the Si(1) atom in the molecule of compound (II) in solution in THF at 30 °C are equivalent.[9] This is a powerful argument in support of form (B), the ylide type of bonding in which presupposes free rotation about the Si(1)–C(1) bond.

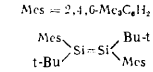
The high stability of the silaethylene (III) can be explained partly by steric causes (bulky substituents, especially the adamantyl substituent, prevent dimerisation and other reactions) and partly by the electronic influence of the substituents Me_3SiO and Me_3Si at the double bonded C and Si atoms respectively. As a consequence of the inductive effect of the substituents and the existence of resonance forms, the polarisation of the double bond is found to be much smaller than would have been expected from the difference between the electronegativities of the Si and C atoms:

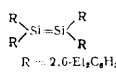
Quantum-chemical calculations confirm the stabilising influence of the silyl group at the Si atom and of the siloxy-group at the C atom on the Si=C double bond (as a consequence of electronic effects).[9]



2. Disilenes







The first stable disilene, investigated by X-ray diffraction, proved to be tetramesityldisilene (IV),[17] synthesised by the photolysis of the polysilane precursor.[17] The Si–Si = 2.160(1) Å distance in the molecule of compound (IV) is shorter by 0.19–0.20 Å than in tetramesityldisilane,[19] which is consistent with the presence of a double bond in compound (IV).

It follows from the X-ray diffraction data for the heteroethylenes M_2R_4 that, with increase in the atomic number of the M atom, there arises a tendency towards an increase in the pyramidal form of

its coordination {the sum of the valence angles of the M atom is 360° in C_2Ph_4, 355.3° in compound (IV), 348.5° in $Ge_2[CH(SiMe_3)_2]_4$, and 342° in $Sn_2[CH(SiMe_3)_2]_4$} and towards the shortening of the M–M bond compared with the standard $M(sp^3)-M(sp^3)$ bond lengths adopted in the diamond-like modification of M [C(12%) > Si(8%) > Ge(4%) > Sn(2%)].[20]

Table 2. The principal geometrical parameters of molecules with Si=Si double bonds

No. of compound	Compound	Molecular symmetry	r, Å	τ, deg	φ^*, deg	Refs.
(IV)	 Mes = 2,4,6-$Me_3C_6H_2$	C_2	2.160 (1)	6.5	15	[17]
(V)		C_i	2.143 (1)	0	0	[21]
(VI)	 R = 2,6-$Et_2C_6H_3$	C_i	2.15	0	10	[5]

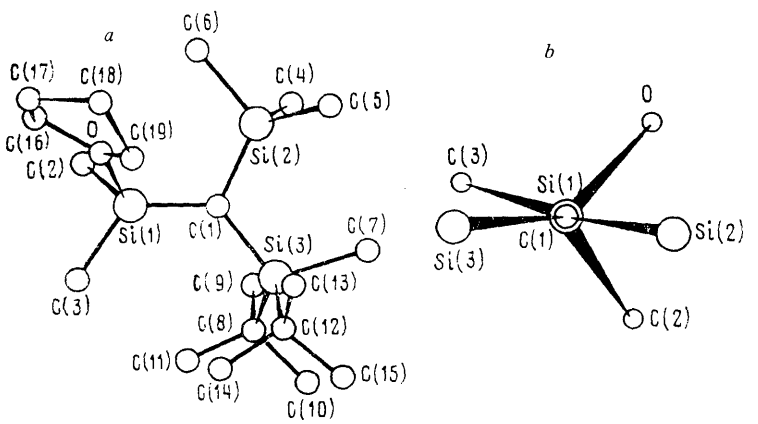
*φ = angle between the plane and the Si=Si bond.

Both these features indicate the presence of a large, albeit smaller than in alkenes, π-contribution to the Si–Si bond in disilenes.[21] These conclusions agree with the results of a large number of theoretical studies in which the energy of the π-bond in the Si_2H_4 model disilene was estimated as approximately 30 kcal mol^{-1},[22,23] which is smaller by a factor of approximately two than the π-bond energy in ethylene.

The weaker π-interaction in disilenes compared with alkenes is usually attributed to the less effective overlap of the 3*p* orbitals of the Si atoms.[21] The overlap of 4*p* or 5*p* orbitals of Ge or Sn analogues of olefins should be even weaker. The distinctly antipyramidal structure of distannenes probably arises as a consequence of the ineffectiveness of the $p_\pi-p_\pi$ bonding: the Sn–Sn distance in tetrakis(trimethylsilyl)distannene agrees with the length of a single Sn–Sn bond in hexaphenyldistannane.[21]

As can be seen from Table 2, the molecules of the three disilenes listed in it are characterised by very similar Si=Si bond lengths, but differ significantly in the deformability of the central fragment. According to the results of *ab initio* calculations, disilenes are appreciably more susceptible to deformations than alkenes and the differences between the molecular geometries of the environments of the Si=Si double bonds in compounds (IV)–(VI) can be explained by packing effects.[21] It is therefore entirely possible that other conformations of compounds (IV)–(VI) predominate in solution rather than in the solid phase. According to calculations of the structure of the Si_2H_4 molecule in the ground state, its potential energy level is described by a low-slope surface with two minima corresponding to antipyramidal and planar geometries, the first form being more stable than the second by ~0.5 kcal mol^{-1}.[21]

Quantum-chemical calculation[24] of the energies of the M_2H_4 molecules (M = C, Si, or Ge) as a function of the pyramidalisation angle φ showed that "for ethylene this function is a parabola with a minimum at φ = 0°, for disilene it is a U-shaped curve with low-slope bottom, indicating a contribution by a structure with a large angle φ, while for digermene the curve has a maximum at φ = 0° and a minimum at φ = ±40°. The latter can be regarded as an indication of the possibility of an intermediate structure with a single Ge–Ge bond and the resonance of the unshared electron pair, which corresponds to the angle φ ≃ 55°".[25]



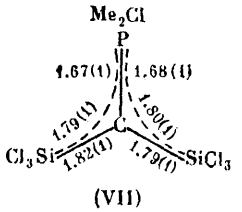


Figure 2. The structure of the molecule of compound (II): projection onto the Si_3C plane (*a*) and view along the C(1)=Si(1) bond (*b*).[10]

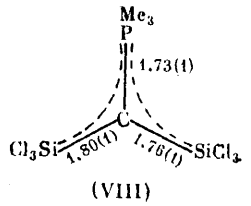
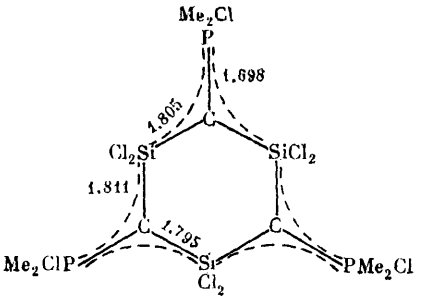


III. Compounds of tetracoordinate silicon with an appreciably distorted structure

1. Disilaphosphorane ylides



An unexpected feature of the disilaphosphorane ylides (VII)–(IX) [26]

(VII)

(VIII)

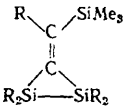
(IX)

proved to be appreciably smaller lengths of the Si–C (1.76–1.82 Å) and P–C (1.67–1.73 Å) bonds involving central planar-trigonal C atoms compared with the standard Si–C (1.84–1.87 Å) [12–15] and P–C (1.78–1.82 Å) distance.[27] This indicates an increased order of the ylide bonds for what is actually an undistorted tetrahedral coordination of the Si and P atoms. Using the equations $n_i = (d_1/d_i)^5$ (d_1 is the length of the bond whose order is $n = 1$, assumed to be equal to the sum of the covalent radii with a Shomaker–Stevenson correction for the difference between the electronegativities),[28,29] the authors[26] calculated the approximate orders n_i of the shortened bonds Si–C and P–C. For all three structures (VII)–(IX), the average sum of the bond orders involving the ylide carbon atoms is ~4 and that for the Si and P atoms is ~4.33. Thus the orders of the shortened Si–C and P–C bonds are close to one another and amount to $n \simeq 1.33$. Consequently, the intensification of the interaction of the ylide C atoms with the surrounding Si and P atoms is caused not by the weakening of the interaction of the latter with the peripheral substituents [for example the Si–Cl distances in the molecules of compounds (VII)–(IX) have the usual values of 2.024–2.098 Å] but are caused by additional $p_\pi - d_\pi$ bonding.[26]

The concept of the $p_\pi - d_\pi$ interaction has also been used to explain the shortening of the Si–C bonds with participation of the carbanionic C atom [to 1.799(2) and 1.816(4) Å] in the dimeric organolithium-silicon compound $[Li^+C^-(SiMe_2OMe)_3]_2$.[30]

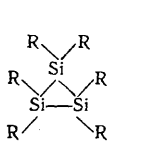
2. Small rings

Many organosilicon compounds containing small three-, four-, and five-membered Si-heterocycles are known in which the valence angles at the Si atoms are much smaller than the standard values. In these systems, the Si atom retains a distorted tetrahedral coordination and the lengths of the bonds involving it usually have the normal values characteristic of unstrained rings. However, in certain cases, for example in cyclodisiloxanes $(R_2SiO)_2$ and cyclodisilathiiranes $R_2Si-SiR_2-S$, the molecular geometry is less trivial and the presence in these compounds of some kind of coordination of the Si atom other than the distorted tetrahedral coordination may be postulated.

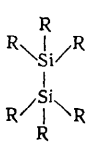


The small length of the Si–Si bond proved to be an unexpected structural feature of the 1,1,2,2-tetramesityl-1,2-disilathiiran (X) molecule.[31] It is 2.289(2) Å, which is smaller by 0.05 Å than the typical Si–Si bond length in disilane derivatives (2.34 Å).[1]

(X): R = mesityl

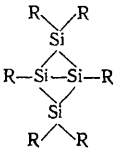


(XI): R = 2,6-dimethylphenyl



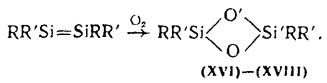
(XII): R = mesityl

The Si–Si distance in disilacyclopropane (XI) is even smaller (2.272 Å),[32] while the corresponding bond in the molecule of compound (XII) (2.327 Å) [33] has almost the normal length. In all three compounds (X)–(XII), the disposition of the second Si atom and of the exocyclic C atoms around the first Si atom of the three-membered ring is almost planar.[31] For example, in compound (X) the sum of the two CSiSi valence angles and of the CSiC angle around both Si atoms is 357.4(4)°. The corresponding values in compound (XI) are 357.4(2)° and 357.7(1)°, while in compound (XII) it is 356.6°. These structural features show that in all three molecules the hybridisation of the Si atom is of the sp^2-p-type rather than the sp^3-type. The interaction of the Si atom with the S and C atoms of the three-membered rings then takes place mainly via the 3p orbital of silicon. Furthermore, the small length of the Si–Si bond in compounds (X)–(XII) suggests that there is some overlap of the 3p orbitals of the neighbouring Si atoms leading to the π interaction between them and hence to an increase in the Si–Si bond order ($n > 1$).[31]



A small length of the Si–Si bond is not characteristic of all compounds containing a three-membered ring: thus in hexakis(2,6-dimethylphenyl)cyclotrisilane (C_1 symmetry) [34] and especially in hexa(t-butyl)cyclotrisilane [35] (XIII) (D_3 symmetry), the Si–Si bond lengths are greater than the normal values [2.407(4) and 2.511(3) Å respectively]. The greater length of the Si–Si bond [2.511(3) Å] in the cyclotrisilane (XIII) molecule containing more bulky substituents is striking.

(XIII): R = Bu-t

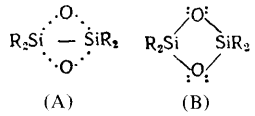


(XIV): R = Bu-t

(XV): R = 2,6-$Et_2C_6H_3$

An appreciable increase in the length of the Si–Si bond to 2.697 Å has been observed in the sterically greatly hindered acyclic molecule of compound (XIV); the Pauling order of this bond is $n = 0.45$.[36] The variability of the Si–Si bond length is as a rule explained by the characteristic features of the steric structure of the molecules. Thus in the bicyclosilane (XV) [37] the central Si–Si bridge bond is somewhat lengthened (it is readily ruptured by oxygen and chlorine; furthermore, the bicyclic system undergoes rapid inversion), while the peripheral bonds are on the whole somewhat shortened.

1,3-Cyclodisiloxanes (Table 3) are formed when the corresponding disilenes are oxidised in air:[38,39]



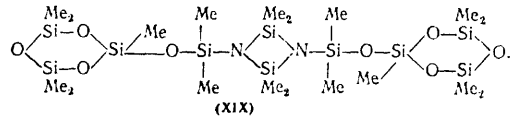
(XVI)–(XVIII)

A characteristic feature of these structures is the small transannular Si...Si distance: it amounts to 2.349(1) Å in compound (XVIII), i. e. it is the same as the length of a single Si–Si bond (2.34 to 2.35 Å),[38] it is somewhat shorter in compound (XVI) 2.306(3) Å, while in compound (XVII) it is somewhat longer (2.396 Å) than the normal Si–Si bond. The transannular O...O distances in compounds (XVI)–(XVIII) are also smaller than twice the van der Waals radius of the oxygen atom (3.40 Å).[40] The Si–O bond lengths in cyclodisiloxanes are somewhat greater than in cyclosiloxanes with a larger ring (1.61–1.65 Å).[1,2] Their SiOSi angles are forced to assume values reduced to 86.2(3)° in compound (XVI), 91.13(7)° in compound (XVII), and 89.7° and 89.4° in compound (XVIII) (in cyclosiloxane the SiOSi valence angles are usually 130–150° [1,2]).

Table 3. The principal geometrical parameters of 1,3-cyclodisiloxanes $(RMeSiO)_2$.[38,39]

Compound	R	Molecular symmetry	Interatomic distances, Å				OSiO' angle, deg	SiOSi angle, deg
			Si...Si	O...O	Si–O	Si–O'		
(XVI)	Me	C_2	2.306 (3)	2.480 (8)	1.721 (4)	1.658 (4)	95.5 (1)	86.2 (2)
(XVII)	t-Bu	C_i	2.396 (1)	2.349 (3)	1.676 (2)	1.679 (2)	88.87 (7)	91.13 (7)
(XVIII)	$(Me_3Si)_2N$	C_1	2.349 (1)	2.358 (4)	1.663	1.668	90.2	89.7
					1.667 (3)	1.672 (3)	89.8 (1)	89.4 (1)

There exist two alternative points of view on the structure of cyclodisiloxanes.[38,39] According to the first, there is a σ-bond between the Si atoms and the Si–O bonds are therefore electron-deficient [structure (A)]; according to the second, there is strong repulsion between the O atoms, which forces the Si atoms to approach one another, but there is no bond between them [structure (B)].



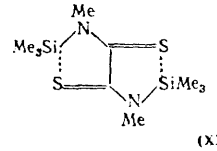
(A) (B)

If the first point of view is adopted, then the addition of oxygen to disilenes during the oxidation reaction induces the dissociation not only of the π-component of the Si=Si double bonds but also of the σ-component.[38] The first calculation by the MNDO method for the model H_4SiO_2 molecule failed to confirm the presence of a bond between the Si atoms but, as pointed out by Fink and co-workers,[38,39] this question has not yet been finally resolved.

In order to explain the structure of cyclodisiloxanes, the model of the bonding in cyclobutadiene is also used.[39] There is a 3*p* orbital (of the π-type) on the silicon atom, which is characterised by a smaller electron density than the 2*p* orbital of the O atom and the diagonal antibonding interactions of the O atoms are therefore stronger than those of the Si atoms, which leads to the rhombic distortion observed in the cyclodisiloxane molecules, for example, in compound (XVI). The differences between the SiOSi angles and the Si...Si distances in the molecules of compounds (XVI)–(XVIII) are a result of the operation of packing forces or steric factors.

The distortions observed in cyclodisiloxanes are characteristic also of cyclodisilthianes, for example of $(Me_2SiS)_2$,[41] in which the SiSSi angle, amounting to 82.41(6)°, is even smaller than in $(Me_2SiO)_2$ [86.2(2)°], because the van der Waals angle of the sulphur is even greater than that of the oxygen atom.

On the other hand, in the cyclodisilazanes $(R_2SiNR)_2$ the SiNSi angles are always greater than 90°—for example, in compound (XIX) this angle is 91.3(1)°:[42]



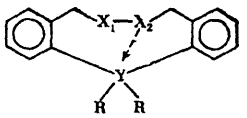
(XIX)

The stretching of the cyclodisilazanes rings in the opposite direction (along the Si...Si diagonal) may be caused by the tendency towards an increase in the valence angles at the N atoms as a result of the movement of the unshared electron pairs of the N atoms away from one another. This is associated with the fact that the Si–N bond lengths in cyclodisilazanes (1.71–1.75 Å) are somewhat greater than the Si–O bond lengths in cyclodisiloxanes [1.663(3)–1.721(4) Å—see Table 3].[39]

IV. Compounds of pentacoordinate silicon

1. Dibenzochalcogensilonins

The additional intramolecular Si ← Si interaction was first observed in the molecule of compound (XX), where the Si...S distances are 3.718 and 3.719 Å (for two symmetrically independent molecules).[43]



(XX)

A stronger intramolecular transannular Si ← S interaction has been observed in dibenzochalcogensilonins (Table 4). The Si...S and Si...Se distances in compounds (XXI)–(XXIII) are smaller than the sums of the corresponding van der Waals radii by 0.4–0.5 Å. The intermolecular secondary (donor–acceptor) bonds in the $H_3SiSSiH_3$ and $H_3SiSeSiH_3$ crystals are characterised by approximately the same Si...S and Si...Se distances (3.55 and 3.60 Å respectively).[48] The energy of this interaction is low.

Analysis of the conformations of the heterocycles considered using the foldability parameters[47] showed that they all have a form intermediate between the twisted double boat and double boat conformations. However, the disposition of the heteroatoms along the perimeter of the rings of this form common to them depends on the transannular donor–acceptor interaction between the silicon and chalcogen atoms: the ring in which such interaction takes place

differs from that where it does not by the shift of the X_1, X_2, and Y atoms by two positions:

It is of interest that the dihedral angle between the phenylene rings is actually the same in all the compounds (XXI)–(XXIII) of this series (97–99°). Despite this, the overall form of the molecule depends greatly on the presence of the donor–acceptor bond (between the silicon and chalcogen): if this bond is absent, the molecule has the approximate C_2 symmetry; if it is present, the molecule becomes asymmetric (Fig. 3).

Table 4. The transannular Si ← S interactions in the molecules of dibenzochalcogensilonins

Compound	$X_1 = X_2$	Y	R	Interatomic distances, Å		Σ*	$X_2 \rightarrow Y$ interaction	Refs.
				$X_1 \ldots Y$	$X_2 \ldots Y$			
(XXI)	S	Si	Ph	4.193	3.372	3.90	present	[44]
(XXII)	S	Si	Me	4.190	3.438	3.90	»	[45]
(XXIII)	Se	Si	Ph	4.382	3.608	4.00	»	[46]
(XXIV)	Se	Si	Me	4.322	4.228	4.00	absent	[47]
(XXV)	Se	Ge	Me	4.327	4.216	4.10	»	[46]

*Σ = sum of van der Waals radii.

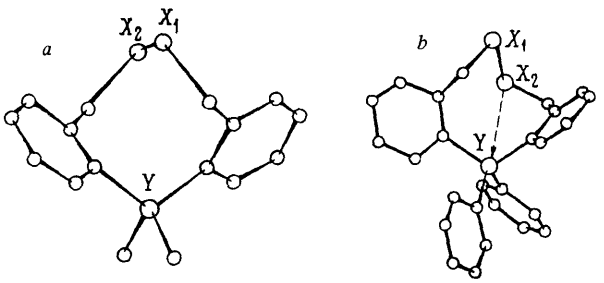


Figure 3. General view of the molecules of the (XXI)–(XXV) series in the presence (*b*) and absence (*a*) of the $X_2 \rightarrow$ Si donor–acceptor bond.[44–47]

Comparison of the lengths of the donor–acceptor bonds in compounds (XXI)–(XXIII) leads to the following conclusions: (1) the X → Si interaction is greatly intensified on passing from X = Se to X = S; (2) the replacement of the methyl groups at the Si and Ge atoms by phenyl groups also strengthens the donor–acceptor bonds; (3) the Ge atom has the same electron-accepting properties (as regards strength) as the Si atom. The replacement of the methyl groups by phenyl groups has different effects in the (XXI)–(XXII) and (XXIV)–(XXIII) pairs: in the latter case, such replacement leads to the appearance of a donor–acceptor bond, while in the former the corresponding $X_2 \ldots$ Si distance is shortened by only 0.06 Å.

Furthermore, in the structure of compound (XXII), where the S...S intermolecular distance is only 3.456 Å (twice the van der Waals radius of the S atom is 3.60 Å [40]), there is a possibility of a more complex Si ← S...S → Si intermolecular interaction.[44]

2. The (dimethylamino)silane pentamer and the chloro(dimethylamino)silane dimer

One of the first pieces of evidence for the quinary coordination of the Si atom was provided by an X-ray diffraction study of (dimethylamino)silane (XXVI), whose structure in the crystalline state proved to be pentameric (Fig. 4), while in the gas phase its molecules are monomeric.[49] This made it possible to explain the anomalously high melting point of compound (XXVI) (again 276 K) compared with other compounds $Me_{3-n}N(SiH_3)_n$ (n = 0–3),[50] which are monomeric in the solid state.[51] The crystal structure of compound (XXVI) is discussed here on the basis of a more accurate reinvestigation by X-ray diffraction.[51]

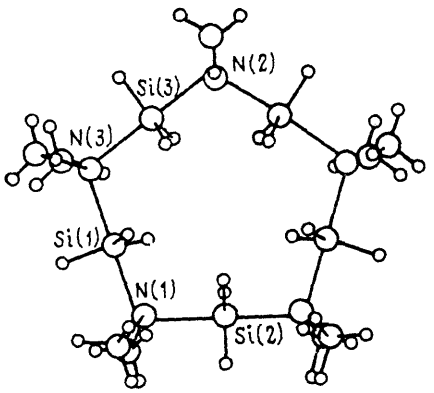

Figure 4. The structure of the (dimethylamino)silane pentamer (XXVI).[51] The molecule has the C_s symmetry.

In the crystal, the molecule of compound (XXVI) occupies a special position on the symmetry plane and has an extremely unusual structure: the N atoms are located at the vertices of a regular pentagon, while the Si atoms are in the centres of its sides, being slightly displaced from the centre of the ring. The average planes of the two crystallographically independent halves of the pentamer molecule intersect the Si(2)...N(2) line, forming a dihedral angle of 170.5°.

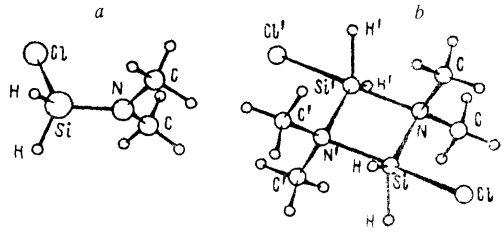
Whereas in the gas phase the "isolated" Me_2NSiH_3 molecule is characterised by a pyramidal geometry of the N atom and a tetrahedral geometry of the Si atom or Si–N and N–C bond lengths of 1.712(3) and 1.459(3) Å respectively,[21] in the crystalline state, the Si atoms are involved in a trigonal-bipyramidal coordination, while the N atoms are involved in a tetrahedral coordination; the average interatomic Si–N and N–C distances then increase to 1.976(4) and 1.476(4) Å respectively. Thus the Si–N distances in the pentamer, corresponding to a pentacoordinate Si atom, are

greater by 0.26 Å than the corresponding distance in the monomeric molecule in the gas phase with a tetrahedral coordination of Si. On the other hand, the N–C distances increase by only 0.02 Å when the coordination of N changes from pyramidal to tetrahedral.

We may note yet again that the silicon atom in the structure of this pentacoordinate derivative has a rigorously trigonal-bipyramidal geometry and is located precisely in the plane of the three equatorial H atoms, while both axial Si–N bonds have the same lengths. Thus the Si atom in this compound has the [3 + 2] coordination.

The distortions of the geometry of the tetrahedral molecules as a consequence of the interaction of their central atoms with a relatively close nucleophile can be described as the initial stages of S_N2 nucleophilic substitution reactions whose transition states or intermediates have a trigonal-bipyramidal geometry.[51–53] In this context, the dimethylsilylamine pentamer can be regarded as a "frozen" ensemble of five molecules of a fully symmetrical intermediate.

The vibrational spectra of chloro(dimethylamino)silane (XXVII) in the gaseous and solid states differ sharply, especially in the region of stretching vibrations of the Si–N bond (600–900 cm^{-1}).[54] According to electron diffraction data, compound (XXVII) is monomeric in the gas phase and contains a tetrahedral Si atom (Fig. 5*a*). The Si–N and Si–Cl bond lengths, which are 1.689(4) and 2.070(2) Å respectively, are close to those found in related compounds. The coordination of the N atom is slightly pyramidal and the ClSiN and CNC planes are almost perpendicular to one another.



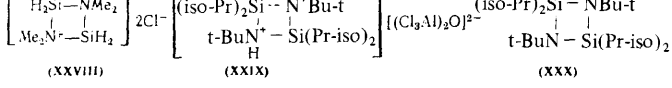


Figure 5. The structure of chloro(dimethylamino)silane (XXVII) in the gas (*a*) and solid (*b*) phases.[54]

The crystal structure of compound (XXVII) includes discrete dimers (Fig. 5*b*) [54] having the C_{2h} crystallographic symmetry: the symmetry plane coincides with the plane of the Si_2N_2 ring. In this ring, the two opposite Si–N distances are 1.81(1) Å, while the other two Si–N distances are much greater [2.05(1) Å]. Consequently the dimer can be described as a species produced by the association of two strongly interacting monomeric molecules. This interaction is manifested by a strong distortion of the tetrahedral coordination of the Si atom in the dimer. The N–Si–Cl angle in the dimer [96.1(5)°] is much smaller than the angle of 113.0(6)° in the monomer, which entails the possibility of the formation of a coordinate bond between the Si and N atoms. The N...Si–C angle is 179.0(4)°, i.e. it is in fact linear and the Si atom acquires a trigonal-bipyramidal coordination, although the N...Si–Cl line, passing through the axial N and Cl atoms, is not rigorously perpendicular to the equatorial plane in which the N atom and the two H atoms linked to the Si atom are located. The axial (and not equatorial) position of the Cl atom creates conditions for the formation of a hypervalent bond, listed by Tandura et al.,[3] and, in particular, it corresponds to the tendency by the most electro-negative substituents to occupy axial positions in a trigonal-bipyramidal molecule. The Si...N coordination interaction leads to an appreciable lengthening of the Si–Cl and Si–N bonds in the crystal (by 0.16 and 0.12 Å respectively) compared with the gas phase, the S–Cl bond being in the *trans*-position relative to the Si–N coordinate bond, while the Si–N′ bond is almost perpendicular to it. The Si–Cl bond length approaches the Si–Cl bond lengths in other derivatives of pentacoordinate (2.148–2.307 Å) or hexacoordinate Si (2.199–2.392 Å).[55] The Si–N...Si = 97.0(6)° angle proved to be intermediate between linear and tetrahedral angles.

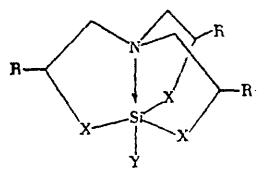
It has been suggested[54] that the dimer (XXVII) be regarded as a "frozen" intermediate in an S_N2 reaction, which reduces to attack by the Si atom on the N atom. The Cl atom behaves as the leaving group and the tentative reaction "product" [compound (XXVIII)] represents the ionic form of the dimer with Si–N bonds of equal length:

The equalisation of the Si–N distances in the $(SiN)_2^{2+}$ ring has demonstrated by an X-ray diffraction study of the salt (XXIX).[56] It is of interest that these distances in compound (XXIX) (the average value is 1.792 Å) are appreciably greater than in the usual silazanes, for example, in compound (XXX) (1.747 Å).[56]

3. Silatranes

Silatranes constitute the most thoroughly investigated class of pentacoordinate silicon derivatives, including also the structural aspect (see, for example, the relevant reviews[1–4]). The transannular Si ← N interaction in silatranes with participation of the Si atom involved in a trigonal-bipyramidal coordination has been explained by the participation of the *d* orbitals of the silicon atom in bonding (see, for example, Tandura et al.[3]) and the hypervalent interaction in the N → Si–R fragment.[3,57] It has also been considered from the standpoint of the interaction of Lewis acids and bases.[4]

The strength of the transannular Si ← N bond depends on the structure of the silatranes, in the first place on the electron-accepting properties of the axial substituents at the Si atom. The enhancement of the electron-accepting properties (for any of the three explanations mentioned above) should strengthen the Si ← N bond.



Since there are many reviews on the structure of silatranes (see, for example, Refs. 1–4), we concentrated attention here on the very latest (predominantly our own) results.

The structures of two silatranes in which the Si atom is linked to four O atoms have been determined: 1-(*m*-chlorophenoxy)silatrane (XXXI) [58] and 1-(t-butoxy)silatrane (XXXII).[59] By virtue of the greater electron-accepting capacity of the *m*-chlorophenoxy-group, the Si ← N distance in the silatrane (XXXI) [2.079(2) Å] is appreciably smaller than in compound (XXXII) [2.189(4) Å], where it is actually identical with the Si ← N distance in the α-modification of 1-phenylsilatrane (XXXIII).[60] On the other hand, the axial Si–O distance in compound (XXXI) is greater than in compound (XXXII) [1.690(2) and 1.659(4) Å respectively]. Since, judging from

the interatomic distances, the axial bond orders in compound (XXXI) are closer to one another than in compound (XXXII), the shift of the Si atom (Δ_{Si}) from the plane of the three equatorial O atoms in the silatrane (XXXI) is smaller than in compound (XXXII) [0.136(1) and 0.201(2) Å respectively]. The shift of the N atom from the plane of the three C atoms linked to it (Δ_N) is, on the other hand, smaller in compound (XXXII) than in compound (XXXI) [0.371(4) and 0.407(2) Å respectively], although the decrease in Δ_N is less distinct than the increase in Δ_{Si}. The values of Δ_{Si} and Δ_N observed in compound (XXXII) agree well with those calculated from the empirical equations[59]

$$\Delta_{Si} = 0.479 d_{Si-N} - 0.840 = 0.206 Å,$$
$$\Delta_N = -0.385 d_{Si-N} + 1.200 = 0.357 Å.$$

The replacement of the equatorial O atoms in 1-phenylsilatrane by NH groups [transition to 1-phenyltriazasilatrane (XXXIV)] does not actually affect the transannular interaction: the Si—N = 2.132(4) Å bond length in the silatrane (XXXIV) [60] is the same as the corresponding bond length in the γ-modification of compound (XXXIII) [61] and is somewhat smaller than in two other (α and β) modifications of this compound [2.193(5) Å [62] and 2.156(4) Å [63] respectively]:

(XXXIII): X = O, Y = Ph, R = H;
(XXXIV): X = NH, Y = Ph, R = H;
(XXXV): X = O, Y = C_6H_4Me-*p*, R = H;
(XXXVI): X = O, Y = C_6H_4Me-*p*, R = Me.

(XXXIII) – (XXXVI)

On the other hand, the Si—C(Ph) bond length in compound (XXXIV), which is 1.922(5) Å, is greater than in the α-, β-, and γ-modifications of compound (XXXIII) [1.882(6), 1.908(4), and 1.894(5) Å respectively]. The displacement of the Si atom from the plane of the three equatorial atoms towards the phenyl group in compound (XXXIV) is greater (0.24 Å) than in the α-, β-, and γ-forms of compound (XXXIII) (0.20, 0.20, and 0.18 Å respectively), which leads, for approximately the same Si ← N distances, to an appreciable shift of the axial N atoms from the plane of the three C atoms linked to it towards the Si atom (0.42 Å against 0.34, 0.38, and 0.39 Å).

The somewhat different parameters characterising the transannular interaction in the α, β-, and γ-modifications of compound (XXXIII) indicate their lability, a possible dependence on the packing effects, and the necessity of using in the interpretation the data for a large number of compounds.

The lengths of the equatorial Si—N bonds in compound (XXXIV) [1.731–1.756(4) Å] are close to the upper limit of the range of the Si—N distances in silazanes[64] and agree with the length of the equatorial bond [1.746(2) Å] in 1-(trichlorosilyl)-1,2,3,4-tetrahydro-1,10-phenanthroline (see subsection 5), which contains a pentacoordinate Si atom. Such increase in the lengths of the equatorial bonds in compounds (XXXIV) is analogous to a slight increase in the lengths of the equatorial Si—O bonds characteristic of "oxygen" silatranes [thus they amount to 1.656, 1.657, and 1.656 Å in the α-, β-, and γ-modifications of compound (XXXIII) respectively], whereas the range 1.61–1.65 Å is typical for the tetrahedral silicon derivatives $(RO)_nSiR_{4-n}$ with $n > 1$.[2]

The Si ← N transannular interaction is weakened when methyl groups are introduced in the 3-, 7-, and 10-positions of the silatrane nucleus: the Si—N distances in two symmetrically independent molecules of 1-(*p*-tolyl)silatrane (XXXV) are 2.171 and 2.167(1) Å, while the corresponding distance in 3,7,10-trimethyl-1-(*p*-tolyl)-silatrane (XXXVI) is 2.236(3) Å.[65] This effect is explained both by the electron-donating influence of the CH_3 group (which reduces the electron-accepting effect of the equatorial O atoms) and by the conformational difference between the five-membered chelate rings in the silatranes (XXXIV) and (XXXV) caused by them.

The breakdown of the C_3 symmetry of the silatrane ring, induced by the different directions of the deviation of the C_β atoms (and hence of the methyl groups attached to them) from the planes of the remaining atoms of the five-membered rings, observed for the first time in compound (XXXVI), is also remarkable.[65,66]

Naturally the introduction of C atoms in the equatorial positions relative to the Si atom (transition to tricarbasilatranes) weakens the transannular Si ← N interactions. Thus the Si...N distance in the $[Si(CH_2CH_2CH_2)_3N]_2O$ molecule[67] is 2.477(5) Å, which indicates a weak Si ← N coordination (a formal bond order of 0.35). The coordination of the Si atom in this compound is intermediate between tetrahedral and trigonal-bipyramidal (the difference between the sums of the equatorial and apical valence angles is 40.2°). The NSiO and SiOSi valence angles are 180° (C_{3i} intrinsic symmetry of the molecule).

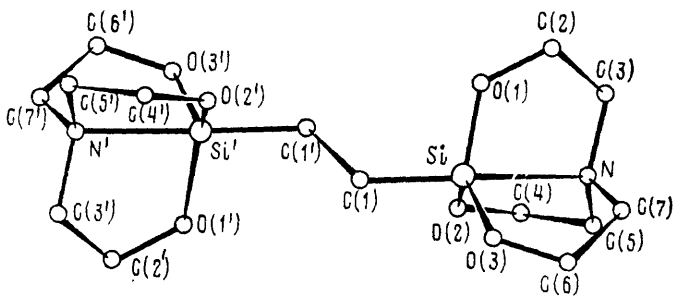


Figure 6. The structure of the centrosymmetrical molecule of compound (XXXVII).[64]

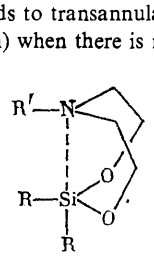
The linking of the two silatranyl groups in 1,2-bis(1-silatranyl)-ethane (XXXVII) by the CH_2CH_2 bridge is hardly reflected in their geometry. The length of the Si ← N transannular bond [2.230(5) Å] and the shift of the Si atom from the plane of the equatorial O atoms (Δ_{Si} = 0.24 Å) of the centrosymmetric molecule of compound (XXXVII) (Fig. 6) [64] are close to those observed in 1-ethylsilatrane, which are respectively 2.21(1) and 0.23 Å.[68] Thus there is virtually no mutual influence of the silatranyl groups in compound (XXXVII). On the other hand, the presence of the methylene bridge ensures this influence to some extent. The Ge ← N bond length and Δ_{Ge} in bis(1-germatranyl)methane [69] are greater than in 1-ethylgermatrane by 0.05 and 0.08 Å respectively.

In the series of onium derivatives of the type $[RCH_2Si(OCH_2CH_2)_3N]^+I^-$ [R = Me_2S^+ (XXXVIII),[70] Me_3N^+ (XXXIX),[71] and Ph_3P^+ (XL) [72]], the lengths of the transannular

Si ← N bonds, correlated with electron-accepting properties of the substituent R, are respectively 2.046(2) Å in compound (XXXVIII), 2.08(1) Å in compound (XXXIX), and 2.07 and 2.12(1) Å in compound (XL) (in the last case there are two independent molecules). In fact, the l_{Si-N} distance in compound (XXXIX) for example, should be 2.08(2) Å according to the equation $l_{Si-N} = 2.20(1) - 0.063(6)\sigma_X^*$ [71] (σ_X^* is the Taft inductive constant) for $\sigma^*_{Me_3NCH_2} = 1.90$, which agrees with X-ray diffraction data.[71] Among all the onium compounds considered, intramolecular steric hindrance has been observed only in the molecule of compound (XXXIX). Thus the SiCR angles in these compounds have the following values: 114.4(1)° in compound (XXXVIII), 121.2(9)° in compound (XXXIX), and 113.6° and 115.3(6)° in compound (XL).



Among the silatranes whose structures have been investigated, the shortest Si ← N distance (l = 2.023 Å) has been noted in 1-chlorosilatrane, although, according to the correlation equations used to predict the values of l from the Taft inductive constant σ^* [73] and the average electronegativity of the substituent in the 1-position,[4] this distance in 1-fluorosilatrane (XLI) should be even smaller (2.007 and 1.927 Å respectively).[74] However, according to X-ray diffraction data, the Si ← N distance in compound (XLI) proved to be 2.042(1) Å, which is somewhat greater than in 1-chlorosilatrane.

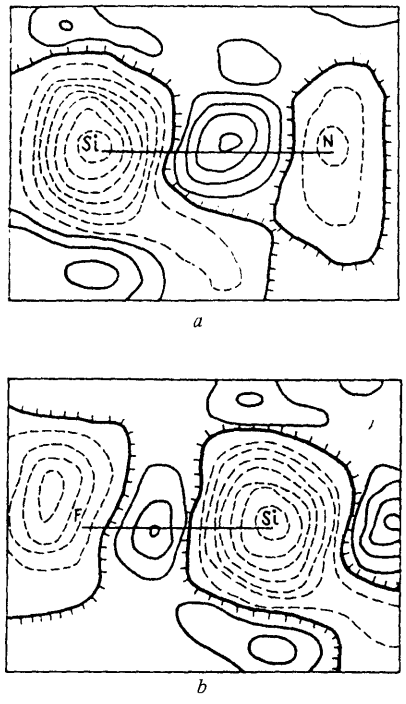
Since the mechanism of the interaction of the N and Si atoms in silatranes still remains controversial, the experimental (X-ray diffraction) study of the distribution of electron density in the region of the Si ← N bond assumes special importance.[74] Two maps of the deformation electron density in the planes passing through the Si ← N and Si–F bonds are presented in Fig. 7. In the region between N and Si atoms, there is a distinct maximum with a height of 0.4 eÅ^{-3} actually on the lines connecting them, its distances from the Si and N atoms corresponding approximately to the ratio of the covalent radii. The reliability of this experimental manifestation of the hypervalent Si ← N interaction is confirmed by the presence of a comparable maximum on the line corresponding to the Si–F covalent bond.

A precision X-ray diffraction study made it possible to investigate also the distribution of deformation electron density in the chloromethylsilatrane crystal.[75] The peak corresponding to the unshared electron pair of the N atom is separated from it in the direction towards the Si atom by 0.7 Å, which is greater than the distances usually observed between the N atom and the peaks due to its unshared electron pairs (0.40–0.42 Å). This finding can be interpreted as confirmation of the transannular Si ← N interaction.

4. 1,3-Dioxa-6-aza-2-silacyclo-octanes

Depending on the electronic and steric properties of the substituents at the Si and N atoms in 1,3-dioxa-6-aza-2-silacyclo-octanes, the Si...N distance varies from 2.30 Å (for R = Ph and R′ = H), which corresponds to transannular interaction, to 3.19 Å (for R = Me and R′ = Ph) when there is no such interaction.[76]

As the Si...N interaction intensifies, the coordination of the Si atom deviates increasingly from the tetrahedral and there is an increase in the contribution of the "crown" conformation to the shape of the eight-membered ring.[76] The replacement of the N atom in the molecules considered, where R = Ph and R′ = H, by the O atom (transition to 1,3,6-trioxa-2-silacyclo-octane) weakens appreciably the transannular interaction. The corresponding Si...O distance is 2.976(5) Å, which is smaller by only 0.5 Å than the sum of the van der Waals radii of Si and O.[40,44–47] As a result of the Si ← O interaction, the eight-membered ring in 1,3,6-trioxa-2-silacyclo-octane assumes the unfavourable crown conformation.[77]



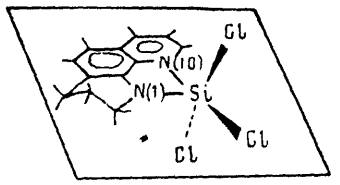


Figure 7. The distribution of deformation electron density in the Si(1)O(2)N(5) (*a*) and Si(1)O(2)F (*b*) planes in the molecule of compound (XLI) in the crystalline state. The isolines are drawn at 0.1 e Å^{-3} intervals, the dashed lines correspond to negative values of the density, and the "spiked" line corresponds to zero density.[74]

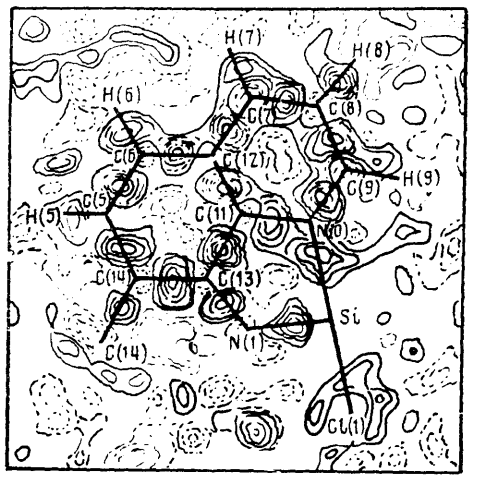
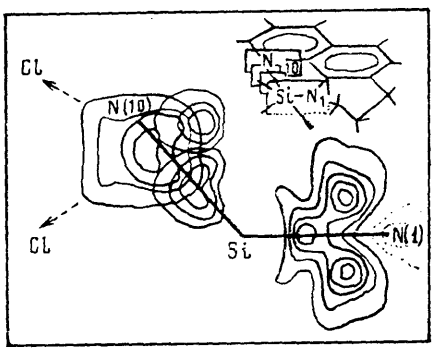


5. 1-(Trichlorosilyl)-1,2,3,4-tetrahydro-1,10-phenanthroline

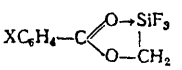
In order to elucidate the electronic nature of the sharp difference between the lengths of the axial (donor–acceptor) and equatorial (covalent) Si–N bonds involving the pentacoordinate Si atom in the 1-(trichlorosilyl)-1,2,3,4-tetrahydro-1,10-phenanthroline (XLII) molecule (Fig. 8) [1.979(2) and 1.746(2) Å respectively], a precise X-ray diffraction study has been made of the distribution of electron density in a crystal of compound (XLII).[78]



The molecule of compound (XLII) is located in a crystallographic plane with symmetry *m*, while the Si atom is involved in a trigonal-bipyramidal coordination with the N(10) and Cl(1) atoms in the axial positions. Fig. 8*a* shows that the unshared electron pair of the pyridine N(10) atom is highly polarised by the neighbouring Si atom. The maximum deformation electron density between these atoms is separated from the N(10) atom by a distance of ~0.7 Å, is

highly distorted, and decreases more gently in the direction of the Si atom than in the direction of the N(10) atom. On the other hand, the electron density maximum on the Si–N(1) bond decreases much faster in the direction of the Si atom than the N(1) atom and is located at a distance of ~1 Å from the latter. A similarity is observed in the character of the distribution of electron density of the unshared electron pair of the N(10) atom and of the pyridine nitrogen atom in the structure of 2-amino-5-chloropyridine involved in the formation of the intermolecular N–H...N bond.[79]

a



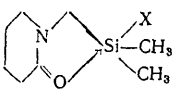
b

Figure 8. Distribution of deformation electron density in the molecule of compound (XLII) in the crystalline state: *a*, section by the crystallographic plane *m* through the molecule as shown at the top of the figure (two C atoms of the tetrahydropyridine ring are arranged above and below this plane); *b*, sections perpendicular to the Si–N(10) bond (on the left) and the section along the Si–N(1) bond (on the right). The isolines are drawn at 0.1 e Å^{-3} intervals.[78]

It is believed[78] that the donor–acceptor N(10) → Si bond in compound (XLII) is formed by the unshared electron pair of the pyridine N(10) atom and is highly polarised by the Si atom. This interaction can increase the barrier to the rotation of the $SiCl_3$ group about the Si–N(1) bond. Furthermore, the unshared electron pair of the amine N(1) atom of the saturated heterocycle is displaced towards the Si atom and towards the Si–N(1) bond (Fig. 8*b*). Such anisotropic distribution of electron density between the Si and N(1) atoms can also increase the barrier to rotation about the Si–N(1) bond, which has been confirmed by NMR data for solutions.[78]

6. (Aroyloxymethyl)trifluorosilanes

The length of the Si ← O bond in (aroyloxymethyl)trifluorosilanes (XLIII)–(XLVII) varies in the range from 1.95(2) to 2.08(2) Å:[72,80,81]

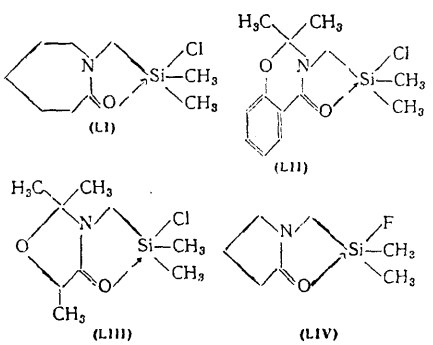


(XLIII)–(XLVII)

(XLIII): X = 4-H,
(XLIV): 4-F,
(XLV): 4-Cl,
(XLVI): 4-Br,
(XLVII): 2-Cl.

It amounts to 2.029(2) Å in the structure of compound (XLV), which has been established most precisely. The length of the Si–F axial bond in compounds (XLIII)–(XLVII) is greater than that of the equatorial bonds by ~0.03 Å and reaches 1.59(2)–1.61(1) Å, which agrees with the concept of the three-centre hypervalent F–Si ← O bond. The introduction of the Cl atom in the *ortho*-position of the benzene ring [compound (XLVII)] increases the angle between the plane of the ring and the average plane of the five-membered ring, resulting from the cyclisation via the Si ← O bond, from 5–7° to 17.5°.[81]

7. *N*-(Halogenodimethylsilylmethyl)lactams

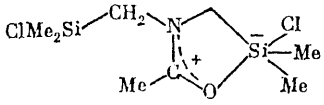


Compounds (XLVIII)–(L) constitute a new class of derivatives of pentacoordinate silicon. Measurements of the electrical conductivities of solutions and analysis of IR spectra showed that the Si ← O interaction weakens with decrease in the atomic number of the halogen X in the sequence I → Br → Cl:[57,82]

(XLVIII)–(L)

(XLVIII): X = I,
(XLIX): X = Br,
(L): X = Cl.

The authors of the present review carried out an X-ray diffraction study of compounds (XLVIII)–(L) and the related compounds (LI)–(LIV), differing in the structure of the lactam fragment:[82]



The Si atom has in fact an undistorted trigonal-bipyramidal [3 + 2]-coordination in the chloro-derivatives (L)–(LII) and an appreciably distorted, almost tetrahedral [4 + 1]-coordination in the iodo-derivative (XLVIII), the bromo-derivative (XLIX), the fluoro-derivative (LIV), and the chloro-derivative (LIII) with a modified bicyclic lactam system (Table 5).

The axial positions at the Si atoms are occupied in all the structures investigated by the O and X atoms and the equatorial positions are occupied by three C atoms. The Si–O distance in the axial O–Si–X fragments varies within very wide limits [from 1.749(2) Å in the iodo-derivative (XLVIII), which is close to the Si–O distances in compounds of tetrahedral silicon, for example, 1.690(5) Å in the 2,2′-dimethyl-5,10-dioxoanthra-[1,2-*e*]-1′,4′,2′-dioxasilin,[83] to 2.316–2.461(8) Å in the fluoro-derivative (LIV)]. The character of the lactam ring and the nature of the substituent also have a strong influence on the Si ← O interaction: the Si ← O distance in the chloro-derivatives varies from 1.954(2) Å in compound (L) to 2.425(4) Å in compound (LIII).[82,84]

It has been found that the stronger the Si ← O interaction, the weaker the Si–X interaction. Thus the Si–I distance in compound (XLVIII) is smaller by only 0.3 Å than the sum of the van der Waals radii of the Si and I atoms (4.08 Å [85]); on the other hand, in compound (LIV) the Si–F = 1.652 Å distance is close to the length of the Si–F covalent bond (1.55 Å) in derivatives of tetrahedral silicon.[37]

An increase in the size of the lactam ring [to the seven-membered ring in compound (LIII)] and the fusion with the latter of the benzene ring [as in compound (LII)] hardly influence the structure of the axial fragment. Thus the Si–O distances, amounting to 1.950(2) Å in compound (LII) and 1.989(4) Å in compound (LIII), differ little from the distance of 1.954(2) Å in compound (L). On the other hand, according to Onan et al,[86] the length of the Si–O bond in the related structure (LV), where there is no lactam ring, is appreciably smaller [1.918(3) Å] than in the lactam chloro-analogue (L) with a six-membered lactam ring [1.954(2) Å].

The replacement of the I atom by Br, Cl, and F in the series of compounds (XLVIII)–(L) and (LIV) entails, as it were, a "migration" of the Si atom along the O...X line from the O atom to the X atom relative to the plane of the three equatorial C atoms (Fig. 9). It is remarkable that in this migration the distance from the carbonyl O atom to the equatorial plane remains almost unaltered [2.097 Å in compound (XLVIII) and 2.109 Å in compound (LIII)].

The crystal of compound (LIV) (with a weak Si ← O interaction) is made up of four symmetrically independent molecules whose different environments lead to a difference between the geometrical parameters of the axial O–Si–F fragment. In particular, the Si ← O bond length changes appreciably, from 2.316 to 2.461(8) Å, although the Si–F bond length remains actually unaltered.

We may note yet again the unusual nature of the structure of compound (LIII). In contrast to the structures of compounds (L)–(LII), the Si–Cl distance in compound (LIII) is close to values typical for derivatives of tetrahedral silicon, while the Si ← O distance approaches the values observed in the fluoro-derivative

Table 5. The principal geometrical parameters of the molecules of *N*-(halogenodimethylsilylmethyl)lactams.

Compound	*l*, Å	*r*, Å	Δ*l*, %	Δ*r*, %	ω, deg	Δ, Å	n_0	n_X

	2.461 (8)	1.630 (7)				−0.297 (3)		

Note. Notation adopted: *l* is the Si–O bond length, *r* the Si–X bond length, Δ*l* and Δ*r* are the increments in *l* and *r* relative to the lengths of the covalent bonds of tetrahedral Si,[13,83] ω is the axial OSiX angle, Δ the shift of the Si atom from the equatorial plane in the direction towards the O atom, and n_0 and n_X are the Si–O and Si–X bond orders calculated as described by Allmann.[28]

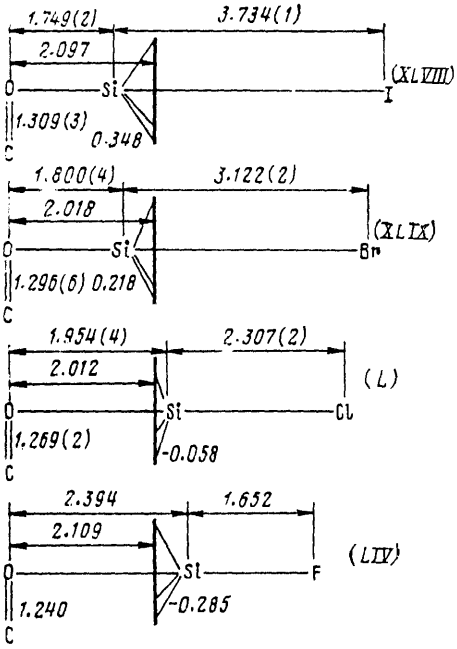
* Data for two independent molecules are quoted.

** Data for four independent molecules are quoted.

*** The average value for independent molecules is quoted.

(LIV). It may be that this is caused by the conjugation of the unshared electron pair of the ether oxygen atom with the π-electron density of the carbonyl bond. A decrease in the size of the lactam ring [or its absence as in the structure (LIV)] is less significant.

A very large and concerted change in the lengths and orders of the O–Si and Si–X bonds is observed in compounds (XLVIII)–(LIV). It is also accompanied by the "inversion" of the coordination polyhedron of the Si atom, which makes it possible to regard the geometry of these compounds as a component part of the model of the hypothetical S_N2 reaction at the Si atom.



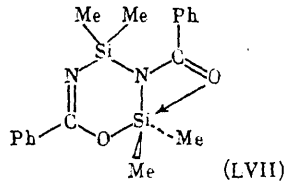


Figure 9. Variation of the coordination of the silicon atom as a function of the nature of the axial halogen atom in *N*-(halogenodimethylsilylmethyl)lactams. The plane of three equatorial C atoms is indicated by a bold line. The deviations of the Si atom from this plane and the lengths of the C=O carbonyl bond, diminishing in succession with intensification of the Si–O interaction, are indicated.[57,82]

strength.[88] The weak additional Si...O interaction in compound (LVII) is accompanied by an appreciable deviation of the O_a–Si...O_a angle from 180°, which amounts to 161°.

(LVII)

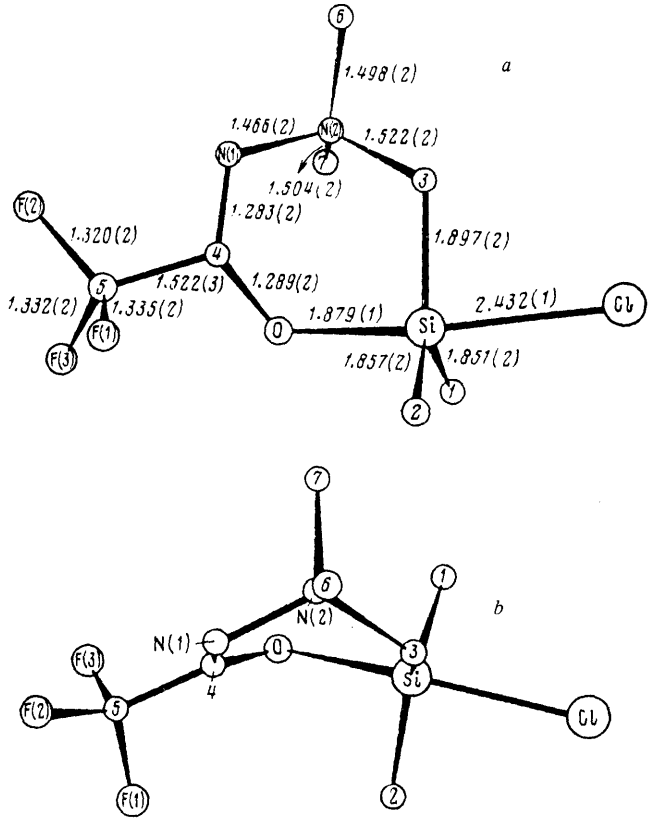

Figure 10. The structure of the molecule of compound (LVI): *a*, projection onto the average plane; *b*, projection onto the plane perpendicular to the average plane and passing through the N(1) and C(3) atoms.[87]

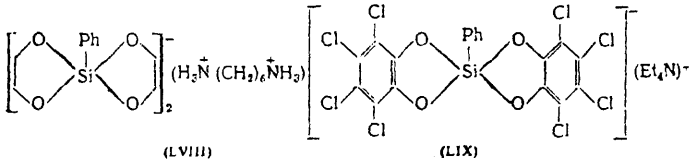
8. (O–Si)-Chloro-[1-(1,1-dimethyl-2-trifluoroacetylhydrazonium)methyl]dimethylsilane



(O–Si)-Chloro-[1-(1,1-dimethyl-2-trifluoroacetylhydrazonium)-methyl]dimethylsilane (LVI) (Fig. 10) is the first example of a pentacoordinate silicon derivative in which the "additional" (coordinate) Si ← O bond is part of a six-membered, and not a five-membered, chelate ring.[87] Admittedly, in the molecule of compound (LVII) the pentacoordinate Si atom is also incorporated in a six-membered heterocycle, but in this case the additional O → Si interaction with the carbonyl group is very weak [the Si...O distance is 2.613(2) Å] and the endocyclic (second axial) Si–O bond is close to the usual covalent bond as regards length [1.670(2) Å] and

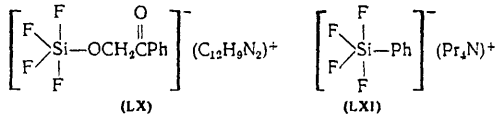
The coordination of the Si atom in compound (LVI), namely the [3 + 2]-coordination, is close to its coordination in the pentacoordinate silicon derivatives, examined above, with an axial O–Si–X fragment, where the O–Si bond is incorporated in a five-membered ring. The shift of the Si atom from the equatorial plane (in the direction towards the Cl atom) is very small [Δ_{Si} = 0.078(1) Å]. The lengthening of the Si–Cl axial bond [2.432(1) Å] relative to the "normal" Si–Cl = 2.048(1) Å bond in the H_3SiCl molecule[89] is somewhat greater than the increase in the

length of the Si–O = 1.879(1) Å axial bond relative to the Si–O = 1.68 Å "normal" bond in the molecule of 2′,2′-dimethyl-5,10-dioxoanthra[1,2-*e*]-1′,4′,2′-dioxasilin.[83] The O–Si–Cl angle is 172.20(5)°. However, despite the similarity of the coordination of the Si atom in compound (LVI) and in the lactam derivatives (L) and (LV), the Si ← O interaction in compound (LVI) is somewhat stronger, which may be caused by the greater electron density in the conjugated N⋯C⋯O fragment in compound (LVI).

9. Phenyl spirosilicates

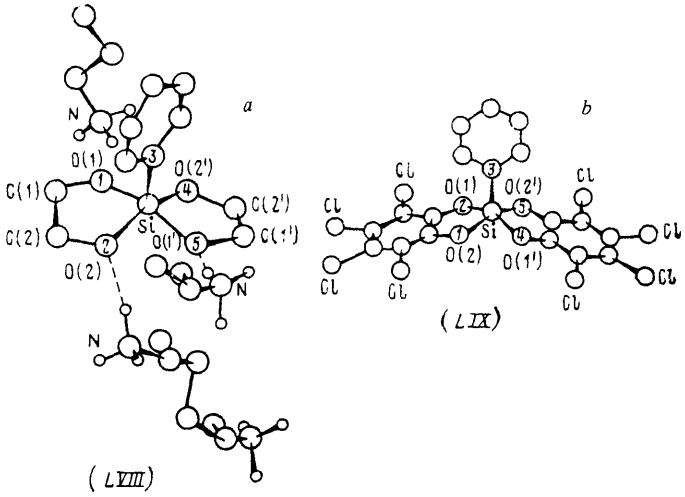
The change in the coordination geometry of the Si atom in the cyclic anionic phenyl spirosilicates of type (LVIII) and (LIX) from that of a square pyramid (SP) to that of a trigonal bipyramid (TBP) makes it possible to trace the hypothetical path followed in the ligand rearrangement of the Berry pseudorotation type:[90]

(LVIII) (LIX)



The coordination polyhedron of the Si atom in both phenyl spirosilicates, (LVIII) and (LIX), represents a distorted SP, although the structure of the latter is much closer to the ideal geometry.[91] This is indicated best by the *trans*-basal 1-Si-5 (θ_{15}) and 2-Si-4 (θ_{24}) angles which are closer to one another in compound (LIX) [152.9° and 147.3(2)°] than in compound (LVIII) [159.2° and 143.6(1)°] (Fig. 11). The Si–O bond lengths in these compounds also indicate that the coordination polyhedron of the Si atom in compound (LIX) is closer to the ideal SP. If the structure of compound (LVIII) is described as a TBP, then the average lengths of the axial and equatorial Si–O bonds should be 1.748(3) and 1.701(3) Å respectively. The corresponding values for the spirosilicate (LIX) are 1.756(6) and 1.752(6) Å, i.e. they are identical within the limits of the error of the determination. In compound (LIX), the four atoms forming the basal plane of the SP are coplanar to within 0.05 Å with the Si atom displaced from this plane in the direction of the apical C atom. The Si–C distances in compounds (LVIII) and (LIX), amounting to 1.854(4) and 1.883(3) Å, are close to the values typical for tetrahedral silicon derivatives.[84]

For a more rigorous quantitative description of the structural distortions in related compounds, the dependence of the *trans*-basal angles θ_{15} and θ_{24} in the SP (which become the axial and equatorial angles respectively in the TBP) on the angle δ_{24} between the normals to the (124) and (245) faces of the TBP with a common equatorial edge (24) was examined.[85] The above dihedral angle, which can be regarded as a coordinate of the Berry pseudorotation, is 53.1° in the ideal TBP and becomes zero when the (24) edge in the SP vanishes.



The results of the application of the method of the sums of the dihedral angles[92] to the estimation of the geometrical distortion of the molecules of pentacoordinate silicates have been published.[91] This method makes it possible to estimate (in percentages) the degree of transition of the real structure from the TBP to the SP. For example, the degrees of the TBP → SP transition are 72.1 and 89.8% respectively for compounds (LVIII) and (LIX).

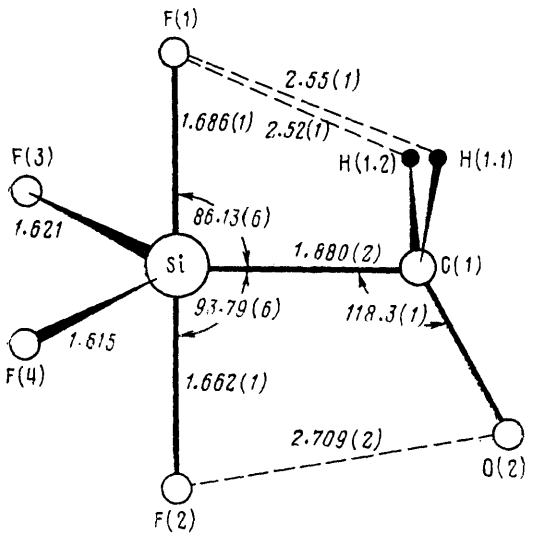
10. Organyl tetrafluorosilicates

The Si atoms in both compounds of this class whose structures have been investigated, 1,10-phenanthrolinium benzoyloxymethyltetrafluorosilicate (LX) [93] and tetrapropyl-ammonium phenyltetrafluorosilicate (LXI),[94] form similar trigonal-pyramidal systems with the organic ligands in the equatorial positions:

(LX) (LXI)

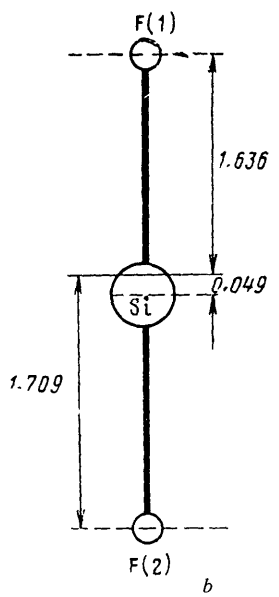
(LVIII) (LIX)

Figure 11. The structure of the anions (LVIII) (*a*) and (LIX) (*b*).[91]



The Si–F axial bonds [1.686 and 1.662(1) Å] in compound (LX) are longer by 0.05–0.06 Å than the equatorial bonds [1.615 and 1.621(1) Å]. Approximately the same picture is observed also in the anion of compound (LXI), where the difference is 0.067 Å. The axial Si–F distances in the anions of compounds (LX) and (LXI) are also greater than in the derivatives of hexacoordinate silicon (see below). For example, the Si–F_a bond length in dipyridinesilicon tetrafluoride is 1.656(3) Å, while the Si–F_e bond length is 1.630(2) Å.[95]

The Si–F = 1.602(2) Å axial bond in compound (XLIV) is also longer than the equatorial bonds [1.582 and 1.585(2) Å], but the difference is smaller than in the anions of compound (LX) and (LXI). Overall, the Si–F distances in compound (LXIV) are appreciably shorter than in the anions of compounds (LX) and (LXI), although they do in fact exceed the Si–F distances in derivatives of tetrahedral silicon [for example, 1.56 Å in SiF_4 or 1.55(1) Å in $F_3SiOSiF_3$ [93]].



The F(1)–Si–F(2) group in the anion of compound (LX) is actually linear [the F(1)SiF(2) angle is 179.74(5)°]. On the other hand, owing to the presence of non-valence contacts of the type $F_a \ldots$ H-*o*(Ph) as in the anion of compound (LXI) (2.48 and 2.55 Å, while the sum of the van der Waals radii of F and H is 2.67 Å [40]), the F_aSiF angle in this species is 174.6(2)°, as in the molecule of the compound $PhPF_4$ isoelectronic with compound (LXI) (174.0°).[96]

The non-valence contacts F(1)...H in the anion of compound (LX) (Fig. 12*a*) lead to the appearance of the eclipsed orientation of the Si–F(2) and C(1)–O(2) bonds [the torsional angle

F(2)SiC(1)O(2) is 3.29(9)°]. However, such coordination of the anion of compound (LX) promotes in its turn the appearance of a short F(2)...O(2) contact [2.709(2) Å], while the sum of the van der Waals radii of O and F is 2.99 Å,[40] which induces an increase in the F(2)SiC(1) and SiC(1)O(2) valence angles. The latter can be interpreted as a shift of the Si atom from the equatorial plane (Fig. 12*b*). On the other hand, the shift of the Si atom in the direction of the F(2) atom intensifies the non-valence interactions with participation of the F(1) atom, which increases the Si–F(1) distance.

a

b

Figure 12. The coordination environment of the Si atom in the anion (LX) (*a*) and the shifts of the F(1), Si, and F(2) atoms from the equatorial plane passing through the F(3), F(4), and C(1) atoms (continuous horizontal line) (*b*).[93]

11. Complexes of the three-centre Mn–H–Si bond

The oxidative addition of the silanes $HSiR_3$ to the 16-electron coordinatively unsaturated manganese complex $C_5R_5(CO)(L)Mn$ [R = H, or Me; L = CO, PR_3, $P(OR)_3$, or CNR] leads to the formation of the compounds $C_5R_5(CO)(L)Mn(H)SiR_3$ with the two-electron three-centre bond Mn–H–Si. They can be regarded as "frozen" intermediates in this reaction.[97]

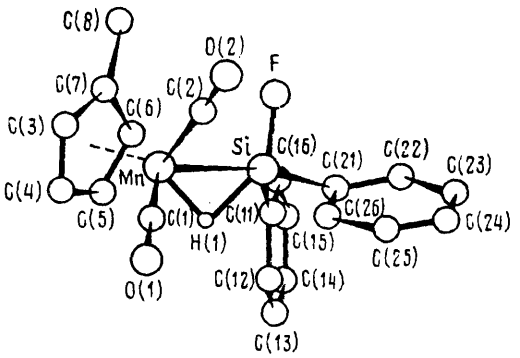


Figure 13. The structure of the molecule of compound (LXII).[99]

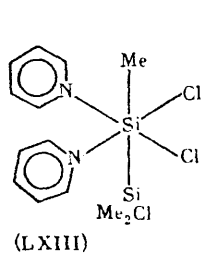
In complexes of this type, the "agostic" H atom[98] occupies a bridging position between the Mn and Si atoms. In the structure of the compound $C_5H_4Me(CO)_2Mn(H)SiFPh_2$ (LXII), the Mn–H(1) and Si–H(1) distances are 1.569(4) and 1.802(5) Å respectively according to neutron diffraction data (Fig. 13).[99] The observed Si–H(1) distance is appreciably smaller than the sum of the van der Waals radii of the Si and H atoms (about 3.20 Å [40,85]) and exceeds by only ~0.40 Å the length of the covalent Si–H bond, which is 1.40 ± 0.02 Å according to electron diffraction and microwave spectroscopic data for tetrahedral silane derivatives. The Mn–H(1) distance in compound (LXII) was actually found to be somewhat smaller than the Mn–H = 1.601(16) Å distance in $(CO)_5Mn–H$, where H is the terminal ligand.[100] The Mn–Si = 2.352(4) Å distance in compound (LXII) corresponds to approximately the middle of the range of variation of the Mn–Si distances [2.254(1)–2.461(7) Å] in complexes of the type $MeC_5H_4(CO)_2Mn(H)SiR_3$ with the three-centre Mn–H–Si system.[99]

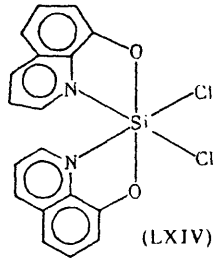
Owing to the Mn–H–Si interaction indicated above, the Si atom in the complex (LXII) requires quinary coordination. The coordination polyhedron of the Si atom can be described as a strongly distorted trigonal bipyramid with the H(1) and F atoms in the axial positions [the H(1)SiF valence angle is 148.8(2)°] and the Mn, C(11), and C(21) atoms (see Fig. 13) in the equatorial positions [MnSiC(11) = 115.8(1)°, MnSiC(21) = 117.3(1)°, and C(11)SiC(21) = 109.0(1)°]. The absence of an appreciable lengthening of the axial Si–F bond in compound (LXII) [1.634(3) Å compared with 1.624(2) Å in $C_5H_5(CO)_2FeSiFPh_2$ [99]] does not conflict with such a description in view of the large difference between the electronegativities of the apical H and F atoms.

Comparison of the adduct (LXII) with the related complexes $C_5Me_5(CO)_2Mn(H).SiR_3$ shows that, if the substituents R shorten the Mn—Si distance, then the Mn—H distance also diminishes, while the Si—H distance increases slightly. The oxidative addition of the silane $HSiR_3$ to the $C_5Me_5(CO)_2Mn$ fragment proceeds tentatively in accordance with the scheme



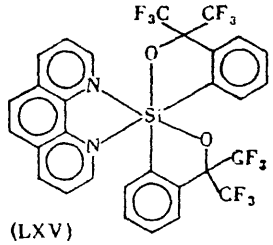
$$L_nMn + \overset{H}{\underset{SiR_3}{\diagdown\!\diagup}} \rightleftarrows L_nMn\cdots H\cdots SiR_3 \rightleftarrows L_nMn\cdots H\cdots SiR_3 \rightleftarrows L_nMn\overset{H}{\underset{SiR_3}{\diagdown\!\diagup}}.$$

It agrees with the observed changes in the distances between the Mn, H, and Si atoms in the series of complexes of type (LXII).



V. Compounds of silicon with coordination numbers of six and above

1. Derivatives of hexacoordinate silicon



Only three examples of organosilicon compounds with a hexacoordinate silicon atom whose structures have been confirmed are known [compounds (LXIII)—(LXV)].[102-104] Their structure provides important information for the understanding of the structures of the intermediates formed as a result of the wide variety of reactions of organosilicon compounds.

(LXIII)

(LXIV)

(LXV)

According to the hypervalent bonding model, the silicon atom in a hexacoordinate state forms two covalent and two three-centre four-electron bonds.[3] Its coordination polyhedron is therefore an octahedron with four equatorial bonds longer than the axial bonds.

Table 6 shows that the equatorial bonds in compounds (LXIII) and (LXIV) are indeed lengthened compared with the corresponding bonds of tetrahedral silicon, relative to the axial bonds. However, in compound (LXV) the situation is more complicated: the increase in the length of the equatorial and axial bonds is almost the same in this instance. This structure can be described as a trigonal bipyramid with the phenanthroline ligand occupying one coordination site. This treatment agrees with the ability of the complex (LXV) (according to ^1H NMR data) to undergo enantiomeric and diastereoisomeric transformations in solution as a result of the dissociation of the Si—N bond with the phenanthroline ligand.[104]

In contrast to compounds of pentacoordinate silicon, whose coordination can be in most cases described approximately as of the [4 + 1] type with only one lengthened axial bond (for example the Si ← N bond in silatranes), an increase in the length of four [compound (LXIII)], three [compound (LXIV)], or two [compound (LXV)] equatorial bonds has been observed in compounds of hexacoordinate silicon.

Table 6. The lengths of the bonds involving the Si atom in its hexacoordinate derivatives (LXIII)—(LXV) [102-104] and the difference between them and the lengths of the bonds involving tetrahedral silicon.

Compound	Axial bond	*l*, Å	Δ, Å	Equatorial bond	*l*, Å	Δ, Å
(LXIII)	Si—Si	2.367	0.03	Si—Cl	2.274	0.24
	Si—C	1.888	0.02		2.392	0.36
				Si—N	2.007	0.28
					2.029	0.30
(LXIV)	Si—O	1.763	0.08	Si—Cl	2.199	0.17
		1.766	0.09	Si—N	2.016	0.29
					2.014	0.28
				Si—C	1.940	0.07
(LXV)	Si—O	1.772 (7)	0.09	Si—O	1.772 (7)	0.09
	Si—C	1.93 (1)	0.06	Si—N	2.051 (9)	0.33
					2.089 (9)	0.36
				Si—C	1.91 (1)	0.04

Note. Typical lengths of the bonds involving tetrahedral silicon: Si—Si = 2.34 Å,[1] Si—Cl = 2.03 Å,[89] Si—N = 1.73 Å,[66] Si—O = 1.68 Å,[81] and Si—C = 1.87 Å.[1] The subdivision into axial and equatorial bonds is based on the literature data.[102-104]

2. The cluster $[Co_9Si(CO)_{21}]^{2-}$

The great possibilities inherent in the silicon atom as regards coordination can be illustrated in relation to the cobalt carbonyl cluster $[Co_9Si(CO)_{21}]^{2-}$ with an encapsulated silicon atom (Fig. 14).[105] Nine cobalt atoms form a one-cap tetragonal antiprism with the Si atom occupying a cavity within the latter. Eight Si—Co distances are in the range usual for Si—Co bond lengths [cf. 2.299(2) Å]. The Si—Co(1) distance to the atom of the cap is much greater [2.527(4) Å] and can correspond only to a weak interaction. The distances between the cobalt atoms, Co(1)—C(2) = 2.613 Å, Co(2)—Co(2′) = 2.940 Å, Co(2)—Co(3) = 2.688 Å, Co(2)—Co(3′) = 2.593 Å, and Co(3)—Co(3′) = 2.808(1) Å, indicate an appreciable expansion of the core made up of the Co atoms when the Si atom is incorporated in it. The cavity within the regular square antiprism made up of Co atoms (the covalent radius of cobalt is 1.35 Å) has a radius of ~0.85 Å, which is much less than the covalent radius of the Si atom (1.12 Å) [sic]. It is not surprising that the attempt to obtain an analogous cluster with encapsulation of the larger Ge atom (r_{Ge} = 1.22 Å) was unsuccessful.[106] On the other hand, the C atom, whose size is smaller (r_C = 0.77 Å) forms a stable encapsulated square-antiprismatic cluster $(Co_8C(CO)_{18}]^{2-}$, in which the Co—Co distances are 2.47—2.59 Å.[107]

3. Sandwich complexes of silicon

Unexpected results have been obtained in an X-ray diffraction study of the recently synthesised decamethylsilicocene $(C_5Me_5)_2Si$ (LXVI).[108] This is the first silanediyl which is stable under the usual conditions and the first π-complex with a central silicon atom. In the crystal of compound (LXVI), there are two crystallographically independent molecules of A and B (A : B = 1 : 2, Fig. 15). One of them is at the centre of symmetry and the other is in a common position (space group $C2/c$, $Z = 12$). In the A molecule, the pentamethylcyclopentadienyl rings are antiparallel, i.e. are in the crossed conformation. On the other hand, in the B molecule the rings form a dihedral angle of 25.3° whilst retaining the crossed conformation. Whereas the Si–C distances in the A ring are equalised [cf. 2.42(1) Å], in the B molecule they are unequal and amount to 2.324(8) Å [Si(2)–C(22) and Si(2)–C(28)], 2.526(7) Å [Si(2)–C(25)], and 2.541(7) Å [Si(2)–C(26)]. The approximate intrinsic symmetry of this molecule is C_{2h}. On the other hand, the distances from the Si atoms to the centres of the C_5Me_5 rings in the A and B molecules are very close (2.11 and 2.12 Å). The character of the disposition of the molecules in the crystal of compound (LXVI) shows that the non-parallel arrangement of the C_5Me_5 rings in the B molecule is caused by intermolecular interactions.[108]

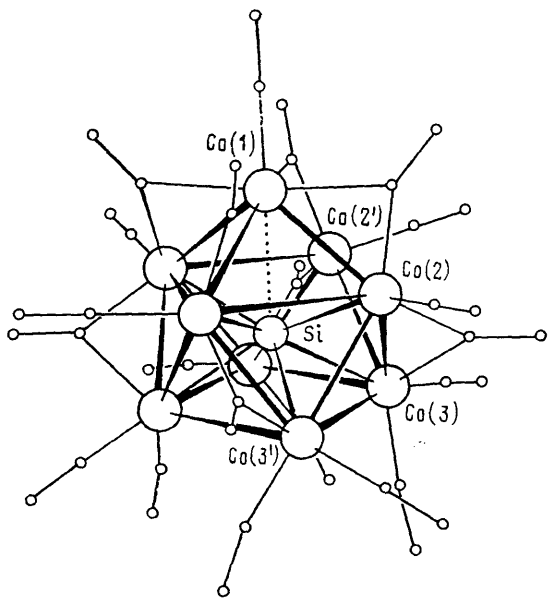


Figure 14. The structure of the anion $[Co_9Si(CO)_{21}]^{2-}$.[105] The Si–Co(1) vector coincides with the fourfold crystallographic axis.

It is of interest that bis[(1,2,4-trimethylsilyl)cyclopentadienyl]-germanium (LXVII) also exists in the crystal as two conformers[109] in which the Cp–Ge–Cp angles of similar size differ little from the linear angle of 180° (by 10.5 and 8.2° respectively). The Ge–Cp distances (Cp corresponds to the centre of the ring) are also almost identical (2.250–2.256 Å) and the Ge–C distances differ very little for all four unsubstituted Cp rings (2.556–2.574 Å).

Using the EENY2 program, the conformational energy of the molecule of compound (LXVII) was calculated by varying the Cp–Ge–Cp angle, the Ge–Cp–C angles of inclination, and the orientations of the rings and $SiMe_3$ groups.[109] It was found that the conformation arising in the crystal does indeed have a low energy, which, however, does not have a distinct minimum. Thus one cannot rule out the possibility of certain changes in the molecular geometry of compound (LXVII) under the influence of the crystal field.

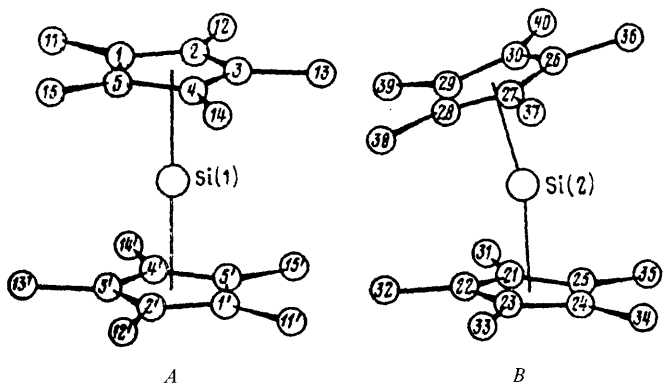

Figure 15. The structure of the crystallographically independent molecules of compound (LXVI) in the crystal:[108] *A*, at the centre of symmetry; *B*, in the common position.

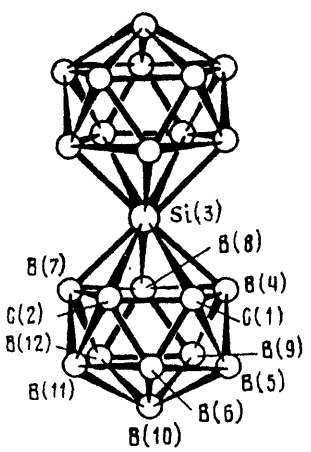

Figure 16. The structure of the centrosymmetrical molecule of compound (LXVIII).[110]

A second confirmation of the possibility of the existence of stable silicon π-complexes has been provided by an X-ray diffraction study of a sandwich derivative of *o*-carbaborane—*commo*-3,3-Si-(1,2-$C_2B_9H_{11}$) (LXVIII) (Fig. 16).[110] The molecule of compound (LXVIII) is centrosymmetrical and the Si(3) atom is

therefore separated by equal distances from the planes of both antiparallel five-membered C_2B_3 rings to which it is coordinated but is displaced relative to their centres towards the B(8) and B(8′) atoms: Si–B(8) = 2.05(1) Å, Si–B(4) and Si–B(7) = 2.14(1) Å, and Si–C(1) and Si–C(2) = 2.22(1) Å. Thus the Si–C distances in compound (LXVIII) are appreciably smaller than in compound (LXVI).

A model has been proposed for the bonding of the Si atom to the dicarbaboryl ligands in compound (LXVIII).[111] At the instant of bonding, these ligands are characterised by the presence of a combination of occupied ligand orbitals (LO): a_g, a_u, e_{1g}, and e_{1u}. The ligand orbitals e_{1u} are suitable as regards symmetry for the π-type bonding interaction with the silicon atomic orbitals (AO) p_x and p_y, while the a_u LO undergoes a σ-type interaction with the p_z AO of the Si atom. If the participation of the silicon *d* AO in bonding is postulated, then the silicon d_{xz} and d_{yz} AO have a symmetry suitable for a π-type overlap with the e_{1g} LO. On the other hand, if the difference between the energies of these AO and LO is large, the two electron pairs of the Si atom remain non-bonding and the ligand electrons remain in the e_{1g} LO. Finally, either the combination of the silicon *s* and d_{z^2} AO or only the *s* AO can interact with the a_g LO, which leads to σ-bonding.

VI. Conclusion

During recent years, extensive information has been obtained about the structure of a wide variety of organosilicon compounds in which a coordination of silicon other than the tetrahedral is realised. Silatranes have been undoubtedly most thoroughly investigated among these compounds. We have obtained recently data on the structure of *N*-(halogenodimethylsilylmethyl)lactams. On the other hand, other classes of compounds of non-tetrahedral silicon have been studied inadequately and are represented by one–two structures.

It is remarkable that the interpretation of the structures of organic silicon compounds with a non-trivial geometry of the Si atom (disilaphosphorane ylides, the complex of silaethylene with THF, and others) is difficult without resorting to the idea of $p_\pi - d_\pi$ bonding with participation of the *d* orbitals of the Si atom. On the other hand, if one uses the results of a precise study of the distribution of electron density, as was done for 1-(trichlorosilyl)-1,2,3,4-tetrahydro-1,10-phenanthroline and 1-fluorosilatrane, then there is no need to consider the *d* orbitals of the pentacoordinate Si atom in order to explain the mechanism of the formation of bonds with its participation.

Analysis of the geometry of compounds with an expanded coordination of the Si atom as intermediates in chemical reactions provides information of greatest chemical interest. The structural correlations of a series of compounds examined have been investigated to different extents. They have been studied in greatest detail for *N*-(halogenodimethylsilylmethyl)lactams (S_N2 reactions) and phenyl spirosilicates (Berry pseudorotation).

Thus structural studies on derivatives of non-tetrahedral silicon not only deepen our ideas about the coordination and valence possibilities of this element but are also of definite general importance for the modelling and mapping of reaction pathways.

Factors that determine the reactivity of reactants in normal and catalysed Diels–Alder reactions

V D Kiselev, A I Konovalov
Ul'yanov-Lenin Kazan' State University

ABSTRACT. The effects of intermolecular stabilisation, the energies of the reacting bonds, and the geometry of the reactants on their reactivity in normal Diels–Alder reactions and those catalysed by Lewis acids have been analysed. The main causes of the small ($1–10^2$ times) or large ($10^4–10^9$ times) increase in the rate of the process in the presence of catalysts and the conditions for synthesising products which often cannot be obtained when the reaction is carried out in the absence of a catalyst are examined.
The bibliography includes 190 references.

I. Introduction

The increased interest in the Diels–Alder reaction is due both to the considerable synthetic possibilities of using it to obtain various carbocyclic and heterocyclic compounds[1–22] and the high reliability of the quantitative data obtained, which are used as a basis for establishing and verifying many theoretical concepts in organic chemistry.[14–18]

A large amount of information on the kinetics and thermochemistry of the Diels–Alder reaction and the effect of the medium on the enthalpy levels of the reactants, molecular complexes, transition states, and reaction products has been collected. At the present time it is clear that the activity of the addends in the Diels–Alder reaction cannot be accounted for by relying solely on information about the energy of frontier orbitals, namely, using a simple model of molecular orbital perturbation. A large amount of experimental material on the enthalpy of reaction has been collected. With this it is possible to determine the relationship between the activity of the addends and the stability of the adducts and to select the optimum conditions for concurrent displacement of one of the reactants from the reaction adducts. Furthermore, the difference in enthalpies of molecular Diels–Alder reactions primarily reflects the difference in energies of the reacting π-bonds. From this it is possible to understand many "anomalous" kinetic features of the behaviour of a number of reactants. Only when the energy of the donor-acceptor interaction, the energy of the reacting bonds, and the interatomic distance in the diene ($R_{1,4}$) are taken into joint consideration can there be a quantitative representation of the kinetics for conversion of various reactants, the activity of which may differ by a factor of 10^{20}.

With the use of Lewis acids that form highly reactive *n,v*-complexes with one of the reactants, usually the dienophile, it is possible to increase the rate of reaction by a factor of 10^9 and readily obtain products which are often impossible to synthesise by other methods.[23–25]

At the present time a sufficiently large amount of data has been collected to make it possible to correlate the main mechanisms of the course of these reactions, including those carried out in the presence of catalysts.

---o0o---

In this review the following notation for the physicochemical characteristics and their dimensions has been adopted:

k_2 is the rate constant of a second-order reaction in l mol^{-1} s^{-1};

K_e is the equilibrium constant of reaction or formation of a 1:1 complex in l mol^{-1} s^{-1};

$\Delta G^{\neq}$ is the free energy of activation, $\Delta H^{\neq}$ is the enthalpy of activation, ΔH_{reac} is the enthalpy of reaction, ΔH_{solut} is the enthalpy of solution, ΔH_{solv} is the enthalpy of solvation, ΔH^0_{IC} is the enthalpy of formation of an intermolecular complex, all in kJ mol^{-1};

$\Delta S^{\neq}$ is the entropy of activation of reaction in J mol^{-1} K^{-1};

I_D is the ionisation potential, E_A is the electron affinity, E_{CT} is the energy of the charge-transfer band maximum in the molecular complexes, all in eV;

[*c*] is the concentration of reactants in mol l^{-1}.

II. Position and role of intermolecular complexes in the reaction

Three main types of reaction have been established: 1) "diene donor, dienophile acceptor", 2) "diene acceptor, dienophile donor", and 3) a neutral type corresponding to the case where introduction of donor and acceptor substituents increase the rate of the process.[5–13,26] The most common is the first type of reaction, in which the activity increases as the donor properties of the diene and the acceptor properties of the dienophile increase.[5–18,26] The intermolecular stabilisation energy of the donor-acceptor pairs assists the formation of charge-transfer complexes.[27–29] As the strength of the complexes between the reactants increases, their reactivity also

usually increases.[30-32] According to the theory of frontier orbital interaction,[18,33-36] the stabilisation energy is given by relationship (1), which includes the contributions of charge and orbital interactions to the stabilisation of the system:

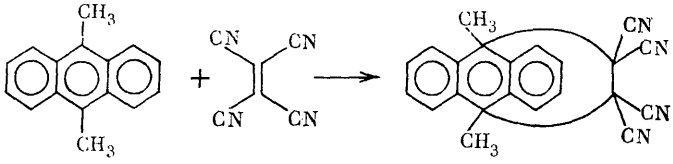
$$E_{ST} = -q_D q_A \gamma/\epsilon + 2(c_D c_A \beta)^2/(I_D - E_A) \quad (1)$$

where q_D and q_A are the charges on the reacting atoms of diene (D) and dienophile (A), γ is the Coulomb integral, ε is the dielectric constant of the medium, c_D and c_A are the coefficients of the frontier orbitals on the reacting atoms of diene and dienophile, β is the interaction integral (the values of the interaction and overlap integrals are assumed to be equal), I_D is the ionisation potential of the diene, and E_A is the electron affinity of the dienophile. For neutral molecules the contribution of the charge interaction is usually ignored,[11,37] so the stabilisation energy is determined by the orbital term, the main contribution being made by interaction of the highest occupied molecular orbital (HOMO) of diene and lowest unoccupied molecular orbital (LUMO) of dienophile.[38,39] The variation in reactivity in a series of dienes or dienophiles is quite frequently determined by the variation in ionisation potential of diene or electron affinity of dienophile. This type of dependence in the reaction of cyanoethylenes with cyclopentadiene and 9,10-dimethylanthracene (Fig. 1) has become a select example of the successful application of frontier orbital theory to represent the activity of reactants in the Diels–Alder reaction.[11,37] Similar linear relationships have also been found for many other series of reactants[6,7] (Fig. 2). They are usually parallel lines on the coordinates $\lg k_2$ and $(I_D - E_A)^{-1}$, displaced relative to each other. The question naturally arises as to the reason why there is no single dependence for different classes of reactants. It is clear that for a general representation of the reactivity of addends in the Diels–Alder reaction it is not sufficient to take into account only donor-acceptor interactions. It is therefore advisable to examine the question concerning the position and role of the intermolecular complexes, whose presence in the reaction mixture has been established many times by various methods.[27-29,40-43] This question has been the subject of active discussion for a number of years.[30-32,44,45]

The representation of the stabilisation energy of intermolecular complexes that is given in one monograph[40] is to a considerable degree similar to the representation of the stabilisation energy of the transition state in the Diels–Alder reaction as reported in several studies.[18,33-36] Two reaction schemes involving an intermolecular complex are possible.

1. The intermolecular complex (IC) lies on the reaction pathway:[30-32]

$$A + B \overset{K_e}{\rightleftarrows} IC \overset{k_1}{\rightarrow} \text{Product}. \quad (2)$$



In this case the inherent properties (donor capacity of the diene and acceptor capacity of the dienophile) and the external conditions (solvent and pressure) can equally affect the strength of the complex and the rate of reaction.

2. The intermolecular complex that is formed does not lie on the reaction pathway:

$$IC \overset{K_e}{\rightleftarrows} A + B \overset{k_2}{\rightarrow} \text{Product}. \quad (3)$$

There is thus no similar effect.

It has been found that the donor properties of substituted anthracenes affect in the same way the strength of their molecular complexes with *p*-chloroanils and the rate of reaction with maleic anhydride.[30] Moreover, a similar agreement was noted in a study of the effect of the acceptor properties of a number of *N*-arylmaleimides on the rate of reaction and the stability of their complexes.[31] Thus, by comparing the effect of donor-acceptor properties of the reactants,[30-32] the solvent,[44,46,47] and also the pressure[48,49] on the molecular complex and transition state of the reaction it was possible to conclude that the complexes lay on the reaction pathway.[32] Direct experimental confirmation of this was obtained after determination of the activation parameters of the reaction between the clearly defined donor-acceptor pair—9,10-dimethylanthracene (I_D = 7.04 eV [30]) and tetracyanoethylene (E_A = 2.88 eV [37]):

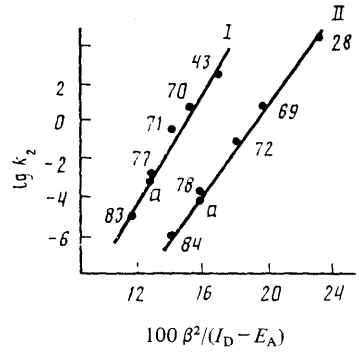


Figure 1. Relationship between the reactivity of cyanoethylenes in the Diels–Alder reaction with cyclopentadiene (*I*) and 9,10-dimethylanthracene (*II*) and the interaction energy of the frontier orbitals of diene and dienophile.[11,37] Point *a* corresponds to the reaction with dinitrilomaleate. Here and in Fig. 2 the value of β is assumed to be equal to 1 eV.

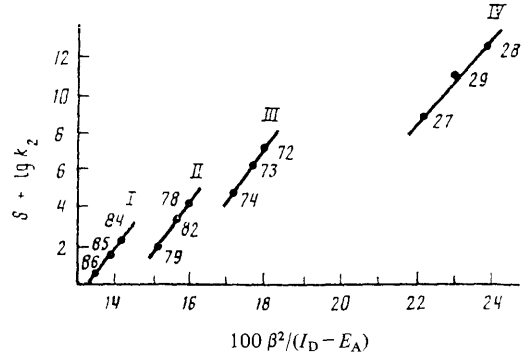

Figure 2. The effect of interaction energies of the frontier orbitals on the reactivity of acrylonitrile (*I*), dinitrilofumarate (*II*), *gem*-dicyanoethylene (*III*), and tetracyanoethylene (*IV*) in reactions with substituted anthracenes.[6,7]

If the reaction occurs in accordance with scheme (2), its rate (v) is given by Eqn. (4)

$$v = k_{exp}[A][B] = k_1[IC] = k_1K_e[A][B]/(1 + K_e[B]), \quad (4)$$

and if it occurs in accordance with scheme (3), v is given by Eqn. (5):

$$v = k_{exp}[A][B] = k_2[A][B]/(1 + K_e[B]), \quad (5)$$

where k_{exp} is the experimentally determined rate constant for reaction, k_1 and k_2 are the rate constants of reaction for formation of product from the molecular complex or from free reactants A and B, K_e is the equilibrium constant of the complex. If $[A] \ll [B]$ and $K_e[B] \ll 1$, the experimentally determined activation parameters include the following parameters for formation of complex:

a) when scheme (2) occurs:

$$\Delta G^{\neq}_{exp} = \Delta G^{\neq}_{real} + \Delta G^{0}_{IC};\ \Delta H^{\neq}_{exp} = \Delta H^{\neq}_{real} + \Delta H^{0}_{IC};\ \Delta S^{\neq}_{exp} = \Delta S^{\neq}_{real} + \Delta S^{0}_{IC}; \quad (6)$$

b) if scheme (3) is true, then:

$$\Delta G^{\neq}_{exp} = \Delta G^{\neq}_{real};\ \Delta H^{\neq}_{exp} = \Delta H^{\neq}_{real};\ \Delta S^{\neq}_{exp} = \Delta S^{\neq}_{real}. \quad (7)$$

Although kinetic schemes (4) and (5) are indistinguishable, their activation parameters differ according to the magnitude of the parameters for complex formation. If the molecular complexes lie on the reaction pathway, for reactants with well-defined donor-acceptor properties a low, zero, or even negative enthalpy of activation can be expected. The results of kinetic measurements (Table 1) are convincing evidence that the geometry of the complex between the reactants corresponds to the structural demands made on the transition state. This assists its formation. The experimentally determined enthalpy of activation contains two components (Fig. 3). If the addends are not capable of intermolecular stabilisation, the energy of activation ($\Delta H_1^{\neq}$) is determined by the distribution of energies of bond cleavage and bond formation. If such a stabilisation takes place (ΔH^{II}_{ST}), formation of the transition state is considerably assisted by using the intermolecular stabilisation energy for expenditure of energy in breaking up the old π-bonds and the apparent energy of activation ($\Delta H^{\neq}_{2,exp}$) is small. When there are considerable intermolecular interactions (ΔH^{III}_{ST}), as a result of such a superposition the energy of activation may be equal to zero and can even acquire a negative value.[50]

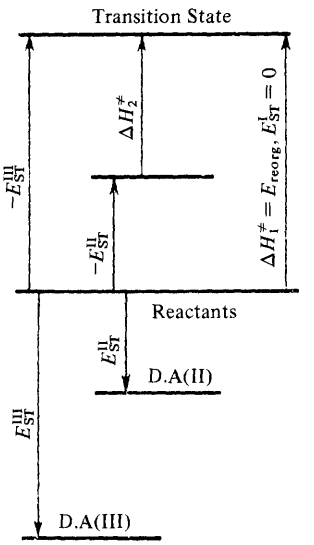

Figure 3. Relationship between the experimental enthalpy of activation ($\Delta H^{\neq}$) and the sum of the contributions from the energy of bond reorganisation (E_{reorg}) and the intermolecular stabilisation energy (E_{ST}).[70]

Since the molecular complex that is formed between the reactants to a considerable extent determines the pathway of the subsequent chemical reaction, the interest shown in studying such complexes

Table 1. Rate constants and activation parameters of the reaction between tetracyanoethylene [TCNE] and 9,10-dimethylanthracene (DMA) in certain solvents when $[TCNE]_0 \gg [DMA]$.[50]

Solvent	$10^4 \times [TCNE]_0$	k_2/T (°C)				$\Delta H^{\neq}$	$-\Delta S^{\neq}$

Tetrachloromethane	3.34	40 160/25.0	—	—	—	—	—

becomes understandable. There are sufficiently argued proposals for the existence of molecular complexes on the reaction pathway in the acylation of amines,[51,52] electrophilic addition to double bonds,[53,54] and a number of other processes.[27,28,51]

It is important to note that the activity of reactants with different structures cannot be explained solely from the energy of the donor-acceptor interaction, although the difference in reactivity of addends of a single structural type is satisfactorily represented by the change in interaction energy.

III. Kinetic and thermodynamic study of the uncatalysed reaction

Thermochemical enthalpy data assist in establishing the relationship between the activity of the reactants and the stability of the adducts. As will be demonstrated below, when the factors determining reactivity are analysed these data serve as a basis for analysing the change in energy of the reacting bonds in the reactants.

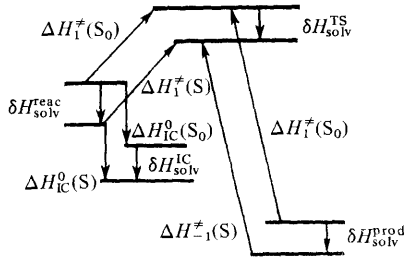

Figure 4. Enthalpies of reactant transfer (δH_{solv}^{reac}), the molecular complex (δH_{solv}^{IC}), the transition state (δH_{solv}^{ST}), and products (δH_{solv}^{prod}) in the Diels–Alder reaction on changing the solvent.[163,164]

1. Effect of solvent

There is a considerable amount of information about the effect of the solvent on the reactivity of the reactants and the stability of the molecular complexes formed by them.[44,46,47,55] However, this does not elucidate the cause of the variation in width of energy gap between the initial and final states of the system. An additional treatment of thermochemical data can be used for such an analysis.[56–58] Examination of the thermodynamic cycle (Fig. 4) shows that the change in enthalpy level of the solvated reactants (δH_{solv}^{reac}) is determined by the difference in enthalpies of solution (ΔH_{solut}^{reac}) in different solvents (S) relative to a given reference solvent (S_0):

$$\delta H_{solv}^{reac} = \Delta H_{solut}^{reac}(S) - \Delta H_{solut}^{reac}(S_0).$$

In order to calculate the change in enthalpy level of the solvated complex (δH_{solv}^{IC}) it is necessary to have data on the enthalpy of formation of the complexes (ΔH_{IC}^0) in different solvents:

$$\delta H_{solv}^{IC} = \Delta H_{IC}^0(S) - \Delta H_{IC}^0(S_0) + \delta H_{solv}^{reac}.$$

Such an analysis was carried out for the first time on complexes formed by the π-donors, mesitylene and benzene, with tetracyanoethylene.[46] The change in transfer enthalpies for mesitylene and benzene was similar to that found for anthracene.[57] A change of medium has a more pronounced effect on tetracyanoethylene than on the π-donors. By using enthalpy of activation data for the reaction of tetracyanoethylene with anthracene in different solvents[55,57] it is possible to calculate the change in enthalpy level of the transition state (ΔH_{solv}^{TS}) relative to cyclohexane chosen as a reference solvent:

$$\delta H_{solv}^{TS} = \delta H_{solv}^{reac} + \Delta H^{\neq}(S) - \Delta H^{\neq}(S_0).$$

The change in enthalpy level of the transition state when the solvent is altered is proportional to the change in enthalpy level of the molecular complex.[46] The type of effect of the medium on the enthalpy levels of solvated reactants and reaction adducts is considerably different from the type of effect of the solvent on the transition state of reaction.[23,46,57] Since a change of solvent leads to a change in enthalpy levels of all states—donor, acceptor, and complex—it becomes obvious that an analysis of the effect of the medium on the enthalpy of formation of the complex based on the change in activity of only one component (usually the acceptor) is not reliable in every case.[59–61]

Table 2. Enthalpy contributions of specific (ΔH_{sol}^{spec}) and nonspecific ($\Delta H_{solv}^{nonspec}$) solvation to the total enthalpy of solvation (ΔH_{solv}) of tetracyanoethylene in given solvents at 22 °C.[23,46]

Solvent No.	Solvent	$[IC]/[TCNE]_0$	K_p	$-\Delta H_{solv}$	$-\Delta H_{solv}^{spec}$	$-\Delta H_{solv}^{nonspec}$	$-\Delta H_{IC}^0$
1	Cyclohexane	0.40	0.072	49.8	1.3	48.5	3.2
2	Tetrachloromethane	0.69	0.217	53.1	4.4	48.7	6.4
3	Chloroform	0.85	0.48	56.9	7.4	49.5	8.7
4	Dichloromethane	0.94	0.98	57.7	10.0	47.7	10.7
5	Benzene	0.96	2.27	66.1	17.3	48.8	18.1

By using information about the equilibrium constants of complexes of tetracyanoethylene with a number of solvents, it is possible to calculate the proportion of specifically solvated acceptor:

$$[IC]/[TCNE]_0 = K_e[S]/(1 + K_e[S]),$$

where [S] is the number of moles of solvent in a litre of solution. By multiplying the proportion of bonded tetracyanoethylene ($[IC]/[TCNE]_0$) by the enthalpy of formation of complex with solvent, it is possible to determine the enthalpy of specific interaction of acceptor with solvent (Table 2). For cyclohexane this interaction proves to be negligible, which is consistent with the results of two studies,[62,63] while on changing to benzene it increases substantially.[46] The contribution of the nonspecific solvation ($\Delta H_{solv} - \Delta H_{solv}^{spec}$) remains constant in this series of solvents.[46] The variation in the enthalpies of solution of tetracyanoethylene (TCNE) in different solvents is virtually the same as the variation in the enthalpies of formation of its complexes with these solvents (Fig. 5).

A similar analysis of the effect of the medium was carried out on n,σ- and π,σ-complexes of iodine with a number of donors using thermochemical solution data[47] and data on the enthalpy of formation of complexes in solution.[59] In these cases also the change

in enthalpy of formation of the complex is determined to a greater degree by the change in solvation of the acceptor—iodine—but the effect of the medium on the enthalpy of formation of the complexes is completely dependent on the change in enthalpy levels of both reactants and the complex. The total enthalpy of solvation of iodine varies mainly as a result of the difference in energy of the specific interaction; consequently, the enthalpy of nonspecific solvation of iodine, as for tetracyanoethylene (see Table 2), does not vary very much in different solvents.[47]

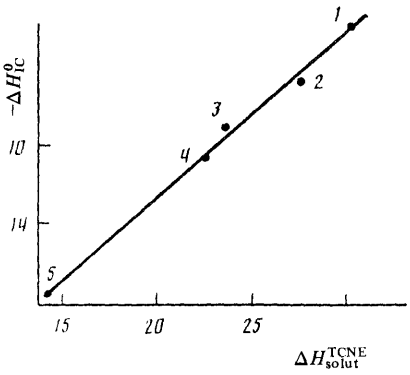

Figure 5. Relationship between the enthalpies of solution of tetracyanoethylene (ΔH^{TCNE}_{solut}) and the enthalpies of complex formation between TCNE and different solvents (ΔH^0_{IC}). The solvents are numbered as in Table 2.

Table 3. Enthalpies of activation for the Diels–Alder reaction between tetracyanoethylene and anthracene ($\Delta H^{\neq}$), enthalpies of solution of tetracyanoethylene (ΔH^{TCNE}_{solut}) and anthracene (ΔH^{An}_{solut}), and the change in enthalpies of solvation of the reactants (δH^{reac}_{solv}) and transition state (δH^{TS}_{solv}) of the reaction at 25 °C.[55,57]

Solvent No.	Solvent	ΔH^{TCNE}_{solut}	ΔH^{An}_{solut}	$\Delta H^{\neq}$	δH^{reac}_{solv}	δH^{TS}_{solv}
1	*o*-Xylene	1.4±0.1	24.0±0.3	51.5	(0)	(0)
2	Toluene	9.4±0.5	24.8±0.8	46.0	9.2	3.6
3	Cyclohexanone	7.6±0.3	20.6±0.6	40.2	2.9	−8.5
4	Benzene	14.9±0.4	24.7±0.4	38.5	14.3	1.2
5	Ethyl acetate	9.2±0.5	25.1±0.2	37.7	8.9	−4.9
6	Chlorobenzene	23.1±0.3	24.6±0.4	31.4	22.3	2.2
7	Methyl acetate	10.5±0.9	25.1±0.2	31.8	10.2	−9.5
8	Acetonitrile	15.2±0.2	28.0±0.3	30.5	17.8	−3.2
9	1,2-Dichloroethane	21.3±0.3	24.9±0.4	26.8	20.9	−3.9
10	Chloroform	24.5±0.3	20.8±0.3	17.6	19.9	−14.0
11	Mesitylene	−2.7±0.4	—	—	—	—

A more extensive analysis of the solvation of the transition state in the Diels–Alder reaction between tetracyanoethylene and anthracene[57] showed that when the solvent was varied there was a change in the enthalpy levels of the reactants and the transition state (Table 3). The considerable increase in the enthalpy of activation on changing to aromatic solvents is due to the sharp decrease in enthalpy level of the reactants with a small change in the level of the transition state. The increased stabilisation of the transition state in chloroform, as noted in a number of studies[44,46,57,58] is due to strengthening of the hydrogen bonds in the activated complex. The kinetics of the reaction between anthracene and tetracyanoethylene in both directions were studied in different solvents.[23] When the large difference in the capacity of tetracyanoethylene and its adduct with anthracene to undergo specific solvation is taken into account, the equal enthalpies of the reactions, calculated from data obtained by direct thermochemical measurement and from the difference in enthalpies of activation for formation and decomposition of the adduct in different solvents, can be taken as proof of the equilibrium solvation of the transition state.[23]

There is a compensating effect between the enthalpies and entropies of activation of this reaction in the given series of solvents (Fig. 6). Consequently, a combined thermochemical and kinetic analysis of the effect of the medium on the enthalpy levels of the reactants and the transition state of the Diels–Alder reaction can explain the change in enthalpy of activation and reactivity as a whole.

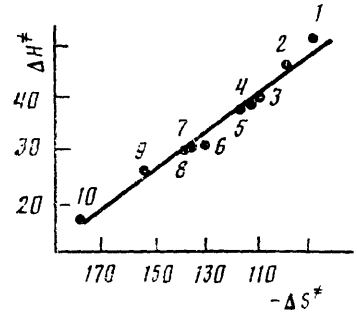

Figure 6. Relationship between the enthalpies and entropies of activation for the reaction of anthracene with tetracyanoethylene in different solvents from published data.[55,57] The solvents are numbered as in Table 3.

Similar studies on solvation effects in the reactions of 9,10-dimethylanthracene with maleic anhydride[64,65] and *trans,trans*-1,4-diphenyl-1,3-butadiene and anthracene with 4-phenyltriazolinedione[58] indicate that in the absence of strong specific interactions between the reactants and the solvent, the effect of the medium on the ground state and transition state is small. Since there is a marked solvent effect on the solvation of the transition state when reactions with effective charge separation are carried out,[66,67] the results of the solvation analysis indicate that the transition state has low polarity.[46,57,58]

2. Main factors determining the reactivity of the reactants

According to the approach of Evans and Polanyi[68] and Semenov,[69] the height of the activation barrier is determined by the distribution of bond cleavage and bond formation energies in the absence of other factors that affect reactivity (Fig. 7). With this approach the enthalpy coordinate of the transition state of reaction is determined

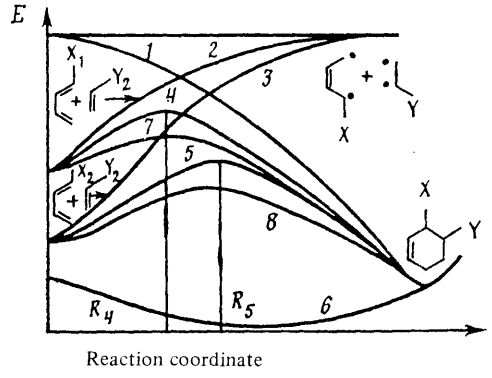
by the relationships:

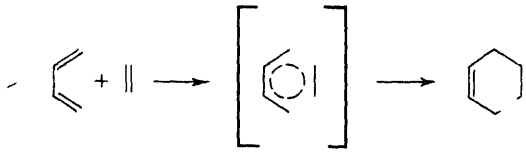
$$\partial(E_1 + E_2)/\partial R = 0 \quad \text{or} \quad \partial(E_1 + E_3)/\partial R = 0,$$

and the energy of activation is given by the equations:

$$E_{a,4} = (E_1 + E_2)_{R_4} - (E_1 + E_2)_{R_0} \text{ or}$$
$$E_{a,5} = (E_1 + E_3)_{R_5} - (E_1 + E_3)_{R_0},$$

where E_1 is the energy of formation of σ-bonds, and E_2 and E_3 are the energies of cleavage of π-bonds in reactants with a different system of conjugation, R is the reaction coordinate.





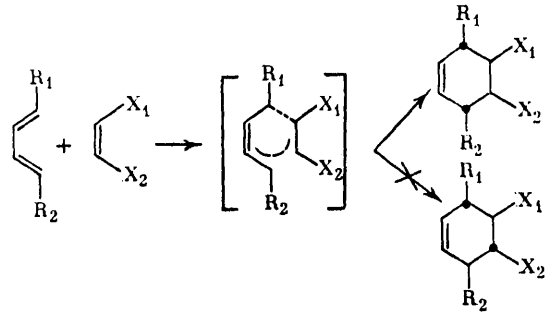


Figure 7. Diagram of energy changes on formation of σ-bonds (*1*) and cleavage of π-bonds in the reactants (*2* for X_1 and Y_1 and *3* for X_2 and Y_2); energies of bond cleavage and bond formation are superimposed (*4* and *5* for a combination of curves *1* + *2* and *1* + *3* respectively), excluding the intermolecular stabilisation energy (*6*) and including it (*7* and *8*).[70]

Since the initial change in energy of cleavage of π-bonds ($\partial E_2/\partial R$ and $\partial E_3/\partial R$) is greater than the change in energy of formation of σ-bonds ($\partial E_1/\partial R$), an activation barrier must occur for exothermic reactions, with a height that increases as the strength of the reacting bonds increases namely with an increase in their conjugation energy [E_3 (Fig. 7, curve *3*)]. If the reactants can undergo intermolecular stabilisation [E_6 (curve *6*)], the compensation of energies of bond cleavage and bond formation must appear at a lower value of the reaction coordinate and hence with lower perturbation energies of the system [E_7 and E_8 (curves *7* and *8*)]. For the Diels–Alder reaction this indicates[70] that both the donor-acceptor stabilisation (E_6) and the energy parameters of the reacting bonds (E_1, E_3, and E_2) affect the height of the activation barrier and the reactivity as a whole. Although the necessity for calculating the energies of cleavage of the reacting bonds in studying the kinetic charactersitics is not in doubt, difficulty arises because there is either no data or insufficient data on these energies and also because there is a wide variety of possible methods of bond cleavage (homolytic, heterolytic with formation of a carbanion, carbocation, etc.).

As regards the Diels–Alder reaction, the wide variety of experimental data on the structural characteristics of the reaction taking place and adherence to the principle of *cis*-addition,[1,26,71] the data on the kinetic isotope effect,[72–76] and on the effect of the solvent[2,77] and pressure,[48,49] and the results of a number of nonempirical calculations[78,79] are consistent with the proposal of a synchronous mechanism for cleavage and formation of bonds in the transition state:

It is suggested that with an increase in asymmetry of the reacting bonds, the asymmetry of the transition state increases,[14,80,81] but for *cis*-addition to be achieved for donor-acceptor systems, the second bond needs to be "fastened" after a shorter time than the period necessary for a change in geometry of the substituents:

For this reason calculation of the energy of the reacting bonds in the molecular Diels–Alder reaction can be carried out more rigorously using the experimental data.

On the basis of the ideas of Evans and Polanyi[68] and Semenov,[69] Hammond[82] predicted an increase in kinetic activity of the reactants as the exothermicity of the process increases. It was suggested[83] that the bislocalisation energy of the electrons on the reacting atoms should be regarded as an index of the reactivity of addends in the Diels–Alder reaction:

For a number of aromatic dienes the calculated 1,4-bislocalisation energies correlate with the reactivity.[83,84] Since the 1,4-bislocalisation energy of π-bonds in a diene by its very nature corresponds to the energy of cleavage of the reacting bonds, it is obvious that in the given series of dienes—polynuclear hyrocarbons—the variation in bond energy is similar to the variation in their activity. The donor properties of dienes also vary in a similar manner to their activity.[83,84] This led to the mistaken assumption that there was a connection between the bislocalisation energy and the donor-acceptor interaction energy.[22,39] For many dienes and the majority of dienophiles such a relationship does not occur. Thus in a number of cyanoethylenes the activity varies inversely to the change in 1,2-bislocalisation energy.[85] In this case the reactivity is related to the acceptor properties of the cyanoethylenes.[85,86] Thus, in far from every case does an increased stability of adducts correspond to more active reactants in the Diels–Alder reaction. The fact that activity series more often reflect the nature of change of donor-acceptor properties of the reactants and also the difficulties in calculating the

bislocalisation energy for substituted dienes and particularly for dienophiles have meant that less attention has been given to the problem of the effect of the conjugation energy on reactivity.

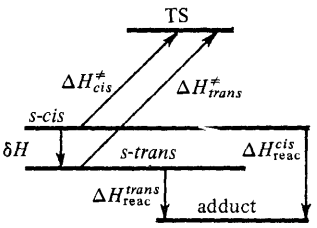

Figure 8. Effect of *trans-cis* conformational change on the enthalpies of activation and reactions of 1,3-butadienes.

Since the cleavage and formation of bonds in the transition state of the Diels–Alder reaction take place according to a concerted mechanism and substituents have a greater effect on the strength of π-bonds than on σ-bonds, the proposal was made[86] that the difference in the enthalpies of reaction reflects the difference in conjugation energies. This proposal is supported by the occurrence of a linear relationship between the change in enthalpy of the reactions of a series of substituted anthracenes with tetracyanoethylene[86] and a series of substituted dienophiles (cyanoethylenes) with 2,5-diphenylisobenzofuran[87] on the one hand and the calculated 1,4- and 1,2-bislocalisation energy on the other hand. These results indicate that the differences in the enthalpies of reaction are due not to steric strain in the adducts formed but to the change in strength of the reacting bonds. The proportional relationship between the enthalpy of reaction and the energy of the reacting π-bonds suggests that there is a small or proportionate change in energy of the σ-bonds formed. To a certain extent data on the change in enthalpy of reaction can provide more information on the reactivity of the reactants in a molecular Diels–Alder reaction than data on the bislocalisation energy. Although the substituents have a greater effect on the strength of the π-bonds than on the strength of the σ-bonds,[88,89] the height of the activation barrier is determined by superimposing the changes in energy of both types of bonds (π and σ) during reaction (see Fig. 7). This effect is reflected in the enthalpy of reaction, whereas the bislocalisation energy in a diene or dienophile only reflects the change in energy of the reacting bonds. Apart from this, the forms of solvation and possible conformational conversions have an effect on the enthalpy of reaction. For example, substituted butadienes mainly have a *trans*-conformation.[84,90] The height of the activation barrier for the reaction of s-*cis*-butadiene is determined by the sum of these factors—the distribution of energies for bond cleavage and bond formation and the donor-acceptor interaction energy (Fig. 8). The experimentally found height of the activation barrier, in addition to the value of $\Delta H^{\neq}_{cis}$ also includes the product of the enthalpy of *trans-cis* conformational change and the proportion of the *trans* form under the experimental conditions (δH). But it is the enthalpies of s-*trans*- and s-*cis*-butadienes and the enthalpies of the reactions involving them which differ by this magnitude of σH. In other words, the enthalpy of the conformational change included in the enthalpy of activation is also included in the enthalpy of reaction.

What results are obtained from a combined calculation of the donor-acceptor interaction energy and the enthalpy of reaction, which reflects mainly the distribution of energies of the reacting bonds, in representing the reactivity of hydrocarbon addends?

By using the enthalpy of reaction as an indicator of reactivity it was possible to account for what appeared at first to be an unusual change in activity of the reactants, occurring sometimes even in the same structural series (Table 4). Thus 9-methoxy- and particularly 9,10-dimethoxy-anthracenes, which exhibit high donating capacity, are appreciably less active when reacting with dienophiles that cannot undergo strong donor-acceptor interaction. The "anomalous" behaviour of these dienes is understandable if the increased conjugation energy (reduced exothermicity of the reaction) is taken into account (Table 4). By calculating at the same time the donor-acceptor interaction energy and the enthalpy of reaction it is possible to determine the overall relationship representing the reactivity of all the reacting pairs of addends. In a number of substituted butadienes the change in donor properties and conjugation energy, which has an opposite effect on the rate of reaction, also results in an "anomalous reactivity" in relation to frontier orbital theory (see Table 4 and Fig. 9).[70] Here also when a combined calculation of both factors is made it is possible to account for the observed activity of the reactants.[70]

Table 4. The reactivity ($8 + \lg k_2$), ionisation potentials (I_D) of dienes, electron affinities (E_A) of dienophiles, characteristics of the donor-acceptor interaction energy [$100\beta^2/(I_D - E_A)$], and enthalpies of Diels–Alder reactions (ΔH_{reac}) at 25 °C.

* Enthalpy of reaction calculated by Konovalov and Kiselev.[70]

** Calculated from published data[88,89] on the enthalpy of formation.

In the majority of cases the parallel displacement of straight lines relative to each other on the coordinates $\lg k_2$ and $(I_D - E_A)^{-1}$ (see Figs. 1 and 2) is consistent with the variation in the experimentally determined enthalpy of reaction. In this connection attempts were made to represent the activity of different reacting pairs on the basis of the two given factors affecting reactivity.[64,70] The range of reactions to be analysed was restricted to compounds with reacting C=C bonds since for heteroatomic reactants considerable differences in the atomic orbital coefficients and a substantial increase in the contribution of charge interaction to the total stabilisation energy are to be expected[80,81,91] [cf. Eqn.(1)]. A study was made of all reactants for which there existed data on reactivity, ionisation potentials of the diene donors, electron affinities of the dienophile acceptors, and the enthalpy of the Diels–Alder reaction. Known kinetic,[5,11,31,55,87,92–97] thermochemical,[70,86,87,98–102] and orbital data[11,30,31,37,41,70,103–106] are presented in Table 4. It transpired that for all the diene-dienophile hydrocarbon systems there was only a slight tendency towards an increase in reactivity with a rise in donor-acceptor interaction energy (the correlation coefficient r equals 0.635).[70] Analysis shows[70] that calculation of only the stabilisation energy cannot represent the reactivity of all the reactants.

Additional treatment of the data on the enthalpy of reaction does not improve the overall correlation.[70] But a plot of the dependence $\lg k_2 = A/(I_D - E_A) + B\Delta H_{reac}$ shows that the points are grouped

in three distinct regions corresponding to the reactions involving 2,5-diphenylisobenzofuran (Fig. 10, line *I*), cyclopentadiene (Fig. 10, line *II*) and substituted anthracenes and butadienes (Fig. 10, line *III*).

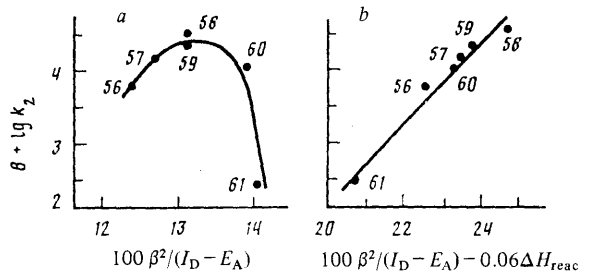

Figure 9. Dependence of the activity of substituted butadienes reacting with maleic anhydride on the intermolecular stabilisation energy excluding (*a*) and with an additional calculation of the change in enthalpy of reaction (*b*). Here and in Figs. 10 and 11 the value of β is assumed to be equal to 1 eV. The reactions are numbered as in Table 4.

It was recently shown[107,108] that the activity of the addends strongly depends on the distance between the reacting diene atoms ($R_{1,4}$). As this distance decreases there is a sharp increase in activity of the dienes. This type of behaviour of dienes in the Diels–Alder reaction can be accounted for[108] by the large variation in overlap of orbitals on the reacting atoms, since there is a proportional dependence $r = 0.999$ [108] between the calculated value of the square of the overlap integral (S^2) and the interatomic distance ($R_{1,4}$) in cyclic 1,2-*bis*-methylenes. In dienophiles the distance $R_{1,2}$ varies insignificantly, although the difference in bond lengths of ethylenic and acetylenic reactants can affect their activity, imparting a higher activity to ethylenic dienophiles when the other conditions are equal.[70]

By arranging the data on the interatomic distance ($R_{1,4}$) in furan (2.19 Å), cyclopentadiene (2.36 Å), anthracene (2.81 Å) and *cis*-1,3-butadiene (2.90 Å) [109] and assuming the corresponding distances in substituted reactants to be unchanged, it was possible to determine the activity of 102 diene-dienophile pairs in relation to the donor-acceptor interaction energy [$\beta^2/(I_D - E_A)$], the enthalpy of reaction (ΔH_{reac}) and the geometrical characteristics of the diene ($R_{1,4}$) [70] (Fig. 11). The significant improvement of the correlation factors ($r = 0.946$, root-mean-square deviation 1.13) achieved by this is shown by the possibility of representing the reactivity of all the pairs of reactants shown in Fig. 11 by a single relationship.

When the proportional relationship identified between the change in the interatomic distance in dienes ($R_{1,4}$) and the square of the overlap integral (S^2) [108] is taken into account, the latter value can be replaced by an experimental factor: $S^2 = A—BR_{1,4}$, where A and B are proportionality coefficients. Then the expression for the stabilisation energy when the resonance integral and overlap integral are equal can be given by the following relationship:

$$E_{ST} = \beta^2/(I_D - E_A) = (A - BR_{1,4})/(I_D - E_A) = A/(I_D - E_A) - BR_{1,4}/(I_D - E_A).$$

The calculated[70] linear regression coefficients lead to the relationship:

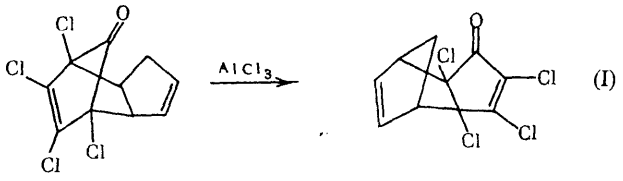
$$\lg k_2 = (290 \pm 10)/(I_D - E_A) - (60.8 \pm 2.8)R_{1,4}/(I_D - E_A) - (5.05 \pm 0.39)\Delta H_{reac} - 28.2.$$

The correlation factors in this equation, which has a sounder physical basis, ($r = 0.950$, root-mean-square deviation 1.04) are on the same level as those obtained by Konovalov and Kiselev[70] (see Fig. 11).

It follows from this that calculation of the three main factors that determine reactivity achieves a satisfactory representation of the activity of the compounds, which varies over a wide range (by 10^{20}). Thus, the possibility arises for predicting the reactivity of addends which have not been studied by using the data on donor-acceptor properties of the reactants and the geometric structural features of the diene. In many cases the enthalpy of reaction can be determined from data on the heat effects of other reactions involving the reactants studied.[70] It follows from Table 4 that the low exothermicity of the reaction between hexachlorocyclopentadiene and tetracyanoethylene (–42 kJ mol^{-1}) corresponds to a large displacement of the reaction equilibrium towards the reactants. A similar situation occurs in the reaction of 9,10-dimethoxyanthracene with tetracyanoethylene, the enthalpy of which is equal to –53 kJ mol^{-1}, the equilibrium constant is 6 l mol^{-1}, and the degree of conversion of reactants to adducts under normal conditions does not exceed 2–5%.[86] It is understandable that attempts to obtain an adduct in the reaction between hexachlorocyclopentadiene and tetracyanoethylene at elevated temperatures[110] were not successful.

By using kinetic and thermochemical data it is possible to select reactants for the purpose of liberating concurrently from adducts addends that are difficult to obtain by direct synthesis or from an equilibrium mixture of reactants and also to select addends of equilibrium processes used for the storage of solar energy.[111]

Kinetic and thermochemical studies of the solvation effect in the Diels–Alder reaction[44,57,58] indicate that there is a marked acceleration of the reaction in solvents that form hydrogen bonds with the dienophile. The formation of H-complexes increases the acceptor capacity of the dienophile and consequently its reactivity.[44] Lewis acids form even stronger complexes, which results in a sharp increase in activity of these complexes in the Diels–Alder reaction.



IV. Stoichiometric coordination catalysis

Determination of the factors governing the reactivity of addends does not eliminate the problem concerning the development of methods for involving inactive reactants in the Diels–Alder reaction. The usual methods for accelerating the rate of reaction by increasing the temperature and pressure are not always acceptable because of contamination of the required products with by-products or a displacement of the reaction equilibrium towards the reactants.

1. Catalysts of the Diels–Alder reaction

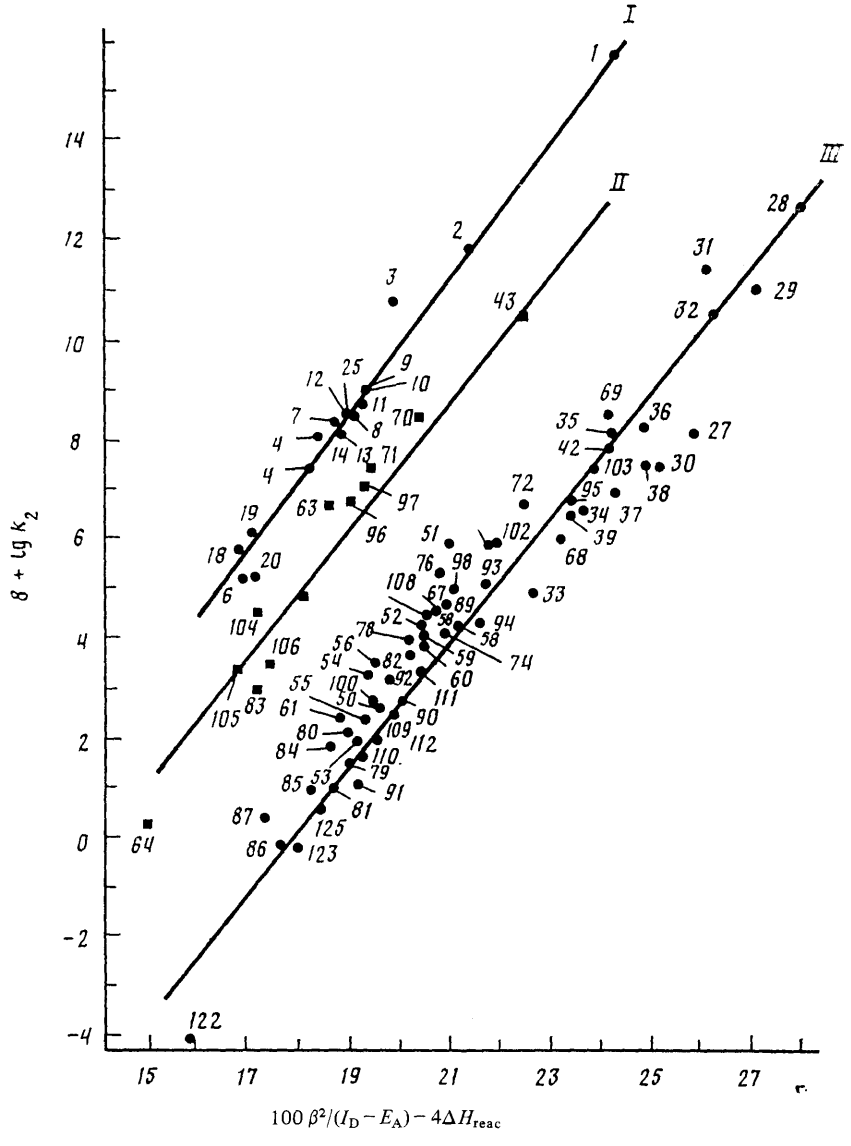
Data exists on the acceleration of the Diels–Alder reaction by a hydrophobic or cellular effect of the medium.[112–116] However, these only relate to a limited number of compounds, and the rate is not usually increased by more than a factor of 10–10^3.[112–116] A much more marked acceleration effect occurs in the presence of Lewis

acids. The increase in the rate of rearrangement of tetrachlorobicyclopentadien-8-one to tetrachlorobicyclopentadiene-1-one

(I)

in the presence of aluminium chloride[117] served as an impetus for using Lewis acids in the Diels–Alder reaction,[118–129] the ene synthesis,[130–132] [2 + 2]-cycloaddition[130,133] and [2 + 3]-cycloaddition reactions.[134–136] The qualitative prediction of acceleration of the Diels–Alder reaction between anthracene and maleic anhydride in the presence of $AlCl_3$ by a factor of 2×10^5 [118] was recently confirmed by the results of kinetic measurement (acceleration by a factor of 2.60×10^5 found).[137] Such a rapid acceleration of the reaction can be used to obtain adducts at room temperature in a number of minutes. For example, the reaction of anthracene with *p*-benzoquinone to give the bis-adduct in the presence of gallium chloride is complete after 3–5 min.[138] Possibilities arise for the synthesis of carbocyclic and heteroatomic compounds as Diels–Alder adducts which under normal conditions either have a low yield or are not formed at all.[139–141]

Considerable acceleration of the Diels–Alder reaction occurs in the presence of halides of Group II, III, and IV elements of the Periodic Table. The effect of aluminium chloride has been studied



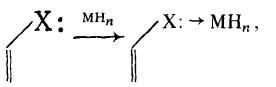


Figure 10. Dependence of the reactivity of reactants in the Diels–Alder reaction on the donor-acceptor interaction energy allowing for the enthalpy of reaction (in eV).

in the greatest detail, but not all reactants are stable in its presence because of the occurrence of polymerisation, isomerisation, or various rearrangements.[118,138,142] The occurrence of these side reactions makes it necessary to find milder Lewis acids and to make a careful selection of solvent and optimum experimental temperature. Traces of moisture in the solvent cause a partial deactivation of the catalyst and the formation of hydrogen halides with side effects that can be avoided in a number of cases by carrying out the reaction in the presence of alkyl halides of metals:[130]

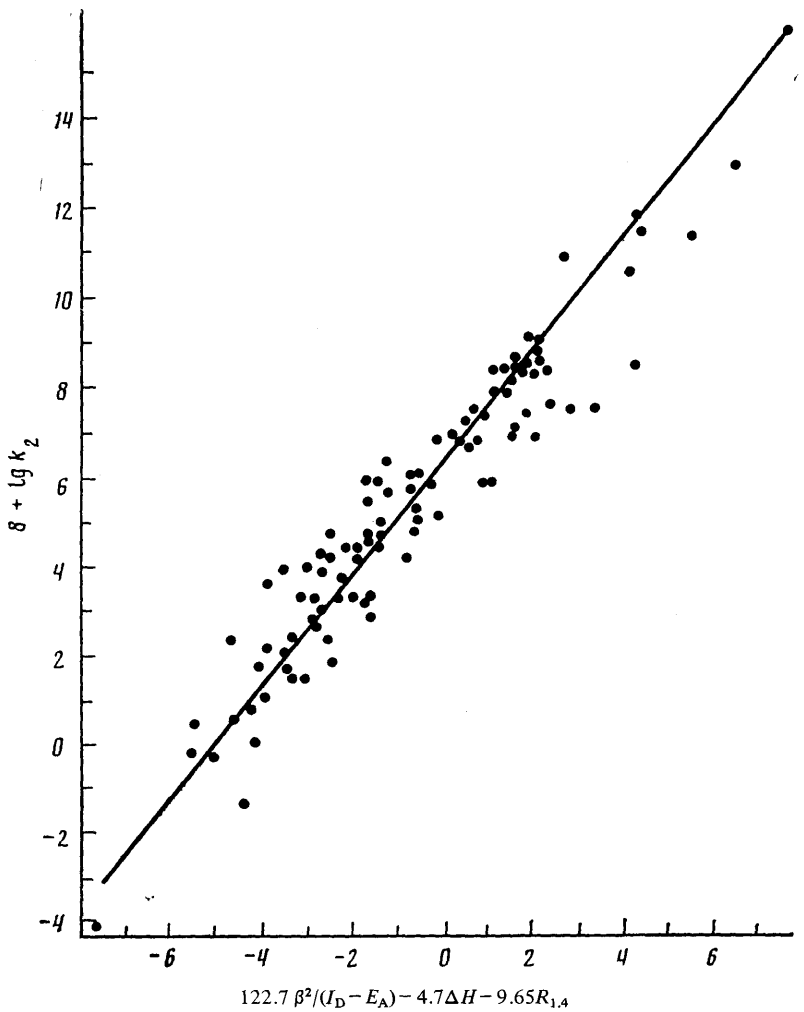
$$RAlCl_2 + HCl \rightleftarrows RH + AlCl_3.$$

Acceleration of the reaction occurs when there are *n*-donor groups in the reactant (usually in the dienophile).[118] It was shown by means of IR, UV, and NMR spectroscopy[43,143–153] that the catalyst interacts with the *n*-donor to form an *n,v*-type molecular complex, which is stabilised by interaction of the unshared electron pair in the functional group of the dienophile with a low vacant orbital of the acceptor:

where X is the dienophile substituent containing a heteroatom with an unshared pair of electrons, M is a Group II, III, or IV element, H is a halogen, alkyl, or aryl.

Organometallic compounds of the type MR_n or MR_mH_{n-m} also form quite strong *n,v*-complexes.

The physicochemical properties of various *n,v*-complexes have been discussed in a review.[43] Analysis of ^{13}C and ^{1}H NMR spectra indicates that there is a considerable reduction in electron density in complexes of unsaturated esters and primarily on the carbonyl and β-carbon atoms of the *n*-donor.[144–146,154,155]



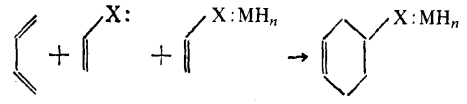


Figure 11. Determination of the reactivity of different compounds in the Diels–Alder reaction by a combined calculation of the donor-acceptor interaction energy, energy of the reacting bonds (from the change in enthalpy of the reactions, in eV) and the distances (in Å) between the reacting atoms in the diene.

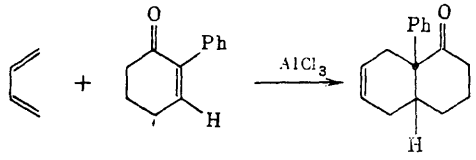
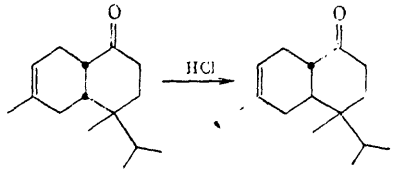


Since *n,v*-complexes of dienophiles with B, Al, and Ga halides are formed almost quantitatively and the acceleration effect on the reaction is quite large (10^4–10^6 times), the rate of reaction between the diene and free dienophile is usually ignored,[23,25] and the diene and *n,v*-complex are regarded as the true reactants.

It was demonstrated by means of thermochemistry[24,138,156] that complexes between the adduct and a Lewis acid does not have inferior stability compared to complexes involving dienophiles:



Only when there is a large excess of dienophile relative to the diene and catalyst is there a redistribution of the Lewis acid and its recovery by the dienophile. Only in this case can the reaction strictly be regarded as catalytic, although such a definition has held true for all reactions that occur in the presence of Lewis acids.

A large number of studies have been concerned with the preparation of the necessary adducts in the presence of catalysts and a determination of the structure of the reaction products.[118–130] The main mechanisms of the Diels–Alder reaction—the *cis*-addition principle, steroselectivity, and regioselectivity—are retained in a catalysed reaction. A lack of adherence to the *cis*-addition principle suggests an asynchronous, two-stage formation of bonds in the transition state of the reaction. At the same time, adherence to this principle is not a guarantee of a synchronous mechanism since even in a photochemical [2+2]-cycloaddition the *cis* principle is often fulfilled.[157] Disruption of the orientation of substituents in the adduct of the reaction between 2-phenyl-2-cyclohexen-1-one with butadiene in the presence of aluminium chloride[141] led to the proposal that this reaction had an ionic mechanism:

It was recently shown by ^{13}C NMR that in the presence of trace amounts of hydrogen chloride that develop in the reaction because of the presence of moisture in the solvent, the initially formed adduct with a *syn* configuration of hydrogen atoms rapidly rearranges to a product with an *anti* configuration:[158]

It follows from this that rearrangement occurs after initial formation of an adduct in which the orientation of the substituents is retained.

The conclusion about the asynchronous formation of bonds in the transition state of the reaction between fumaric acid esters and 9,10-dimethylanthracene, catalysed by aluminium chloride, was attributed not to violation of the *cis*-addition principle but to the lack of cooperativity of the asymmetric induction effect.[159] While the existence of the cooperativity of substituents in an uncatalysed reaction can be justified because of the equal effect from the same substituents,[75] in a catalysed reaction the free ester group and the other ester group included in the complex with aluminium chloride can in no way be considered equivalent. The enthalpy of formation of a complex with a 1:1 composition is much higher than half the enthalpy of formation of a complex with a 2:1 composition.[137] Thus the initial condition of cooperativity of the effect is not fulfilled and consequently the proposal about asymmetric formation of bonds in the transition state, despite its attraction, does not have any experimental basis at present.

Since the difference in energies of activation for regioisomers is usually small, formation of an *n,v*-complex between the dienophile and a Lewis acid can lead to both an increase in the difference of the orbital coefficients of the reacting atoms and hence to a predominance of one regioisomer and also to the opposite effect.[160,161] Activation of the dienophile in an *n,v*-complex considerably increases the proportion of *endo* adduct.[121,147]

A study of the kinetics of the Diels–Alder reaction in the presence of catalysts is of particular interest. It should be noted that use of UV spectroscopy, the most common spectrophotometric method for following the course of the reaction, is complicated because during the reaction there is a redistribution of the catalyst between the adduct and the free dienophile, and the *n,v*-complexes between dienophile and Lewis acid are usually brightly coloured.[156,162] Therefore, in the reaction of substituted butadienes with methyl acrylate the relative reactivity was determined from the ratio of adducts of the reaction between two different dienes and the same activated dienophile using GLC.[120–127] However, a more widely used method that has been developed recently is the analysis of kinetic data[156] obtained by following the absorption of *n,v*-complexes and taking into account the redistribution of catalyst.

It is understandable that a marked acceleration of reaction occurs in those solvents which do not form complexes with the catalyst or form complexes that are much less stable than the complexes between catalyst and reactant.[163,164]

In order to determine the true concentration of activated dienophiles it is necessary to know the concentration of catalyst that has lost activity because of the presence of traces of moisture in the solvent. This type of analysis is usually carried out using the data of kinetic or spectrophotometric titration.[156,162,165,166] In Table 5 data on the kientic parameters and the acceleration effect on the Diels–Alder reaction in the presence of a number of Lewis acids have been collected. In all reactions of the type "diene donor, dienophile acceptor" a considerable acceleration effect occurs (10^3–10^9 times) due to a sharp reduction in the enthalpy of activation ($\delta H^{\neq}$ = 30–50 kJ mol^{-1}) with a considerably smaller change in the entropy component of the free energy of activation ($T\delta S^{\neq}$ = 0–10 kJ mol^{-1}).

Although aluminium chloride produces a large acceleration effect on the reaction, a number of dienophiles are oxidised and form tar in its presence. Aluminium bromide accelerates the reaction even more, but kinetic measurements are often complicated by the formation of highly coloured complexes involving hydrogen bromide.[43,156] Boron chloride gives quite strong and active complexes with *n*-donors, and in this case there are only certain disadvantages due to its low boiling point. Boron trifluoride etherate and tin chloride have a weak activating effect because of the low strength of their *n,v*-complexes with dienophiles. Gallium chloride is the most convenient catalyst, and it forms a nondissociated complex which is readily soluble in many inert solvents; its accelerating effect is only slightly less than that of aluminium halides.

Table 5. Enthalpies of formation of *n,v*-complexes (ΔH^0_{IC}), rate constants (k_2), enthalpies ($\Delta H^{\neq}$) and entropies ($\Delta S^{\neq}$) of activation and the apparent acceleration effect in catalysed Diels–Alder reactions (benzene as solvent, 25 °C).

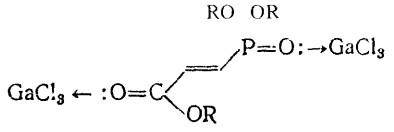
* A 1:1 complex with cyclone.

** A 1:1 complex with imide is formed first, then also a 1:1 complex with cyclone.



R = *O,O*-diethyl-β-carbomethoxyvinylphosphonate.

In virtually all cases kinetic measurements have been carried out for activated dienophiles in a Lewis acid complex of 1:1 composition. The formation of 2:1 complexes between α,β-dicarbonyl, ester, and

nitrile dienophiles and gallium chloride is usually not quantitative and the free Lewis acid readily gives π- and then σ-complexes with many dienes.[43,153]

In the case of β-carbomethoxyvinylphosphonate a stronger complex involving gallium chloride and the P=O group is mainly formed, and only when the ratio of catalyst to dienophile is higher than 1:1 does the catalyst coordinate also with the β-carbonyl group:[142]

Formation of the first bond P=O·$GaCl_3$ has virtually no effect on the strength of the subsequent complex C=O·$GaCl_3$. Despite the considerably greater strength of the bond between gallium chloride and the phosphoryl group compared to that with the carbonyl group (see Table 5), the acceleration effect on the reaction is greater in the latter case than in the former. By determining the acceleration effect on the reaction from the enthalpy of the *n,v*-complexes formed it was concluded[142] that the action of the catalyst on the system via the phosphorus atom constitutes 30–40% of the effect via the carbonyl carbon atom.

An increased acceleration effect occurs in catalysed reactions involving conjugated acceptor dienophiles such as quinones (see Table 5). It is suggested[169] that on formation of the *n,v*-complex a carbonyl group is excluded from the conjugation system of the quinone.

We shall now examine the factors which determine the acceleration effect in reactions involving a dienophile ligand bonded to a Lewis acid.

2. Solvation effects in a catalysed Diels–Alder reaction

Thermochemical and kinetics methods of approach are the most fruitful in studying the effect of the medium on the enthalpy of solvation of the reactants, *n,v*-complexes, and transition state of a catalysed reaction.[163,164] It follows from the kinetic data that the rate of reaction of tetracyanoethylene, which is an active acceptor dienophile, is substantially reduced in π-donor solvents,[55,57] while the effect of the medium on the rate of reaction of the no less active *n,v*-complexes is small.[163,164] A complete thermochemical analysis of solvation effects in a catalysed reaction requires available data on the change in enthalpy of solvation for each reactant. It follows from Fig. 4 that the change in enthalpy of solvation of an *n,v*-complex is determined by the relationship:

$$\delta H^{IC}_{solv} = \delta H^{A}_{solv} + \delta H^{GaCl_3}_{solv} + \Delta H^{0}_{IC}(S) - \Delta H^{0}_{IC}(S_0).$$

The results of thermochemical measurements made in a series of solvents for the complex of *N*-phenylmaleimide (PMA) with gallium chloride[164] show that the enthalpy of solvation of gallium chloride increases substantially on changing not only to *n*-donor solvents but also to π-donor solvents (Fig. 12). As the enthalpy of solvation of the Lewis acid increases, there is a proportional decrease in the enthalpy of formation of the *n,v*-complex in solution (Fig. 12). The constant enthalpy level of the *n,v*-complex in the series of solvents studied is achieved because the gain in enthalpy of solvation of the reactants in donor solvents is completely balanced by the loss in enthalpy of formation of the complex. This means that on formation of a complex between gallium chloride and imide, which is stronger than a complex with solvent, there is a complete break-up of the weaker complexes. The change in enthalpy of solvation of the reactants (PMA + $GaCl_3$) is mainly determined by the change in enthalpy of solvation of gallium chloride. The constant enthalpy level of the *n,v*-complex of MPA·$GaCl_3$ in the series of solvents indicates that there is approximately the same activation of the dienophile moeity in the complex. This conclusion is consistent with the results of two studies,[43,169] in which cases are noted where the same charge transfer in complexes occurs when there is a different enthalpy of formation of the complexes.

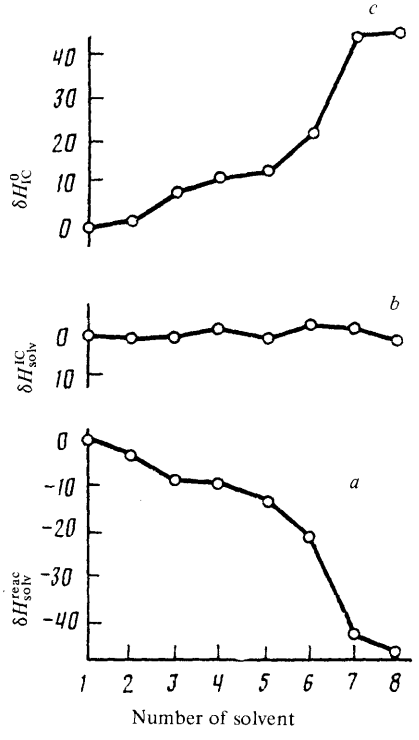


Figure 12. Enthalpies of transfer of the reactants (*a*) and the *n,v*-complex of *N*-phenylmaleimide with gallium chloride (*b*) and also the change in enthalpy of formation of this complex (*c*) in different solvents: *1*, chlorobenzene; *2*, benzene; *3*, toluene; *4*, dichloromethane; *5*, *p*-xylene; *6*, mesitylene; *7*, nitromethane; *8*, nitrobenzene.[163,164]

The insignificant change in enthalpy of solvation of the complex PMA·$GaCl_3$ on changing from nonpolar to polar media is unexpected in view of the high polarity of this complex.[43] A more detailed investigation involving other complexes[170,171] showed that this kind of solvation effect is the rule rather than the exception. More accurate findings on the change in enthalpy of solvation of boron trifluoride etherate[163] are in agreement with this conclusion. The change in enthalpy of solvation of the transition state of a

catalysed reaction[160,163] to a considerable degree corresponds to the nature of the effect of medium on the enthalpy level of a normal reaction involving tetracyanoethylene. The difference in the rate of reactions involving dienophiles that have comparable activity—tetracyanoethylene and imide complexes with gallium chloride—thus becomes clear. The formation of a strong complex between the dienophile and the Lewis acid results in an increase in the rate of reaction by a factor of 10^4, the enthalpy level of this new reactant being insensitive to a change of medium. The complex between tetracyanoethylene and the solvent is less strong, and the specific solvation of this dienophile makes it less active compared to free tetracyanoethylene. In this case the observed rate of reaction is determined mainly by the concentration of free tetracyanoethylene, which varies considerable over a range of π-donor solvents. It is interesting to note that the enthalpy level of a π,π-complex between tetracyanoethylene and a π-donor does not vary very much over this range of solvents.[46]

3. Factors that determine the activity of reactants in a catalysed Diels–Alder reaction

The factors governing the activity of reactants in an uncatalysed Diels–Alder reaction were examined above. In a catalysed process the conversion of the dienophile to an *n,v*-complex only slightly changes the lengths of the C=C bond and hence the magnitude of the overlap integral of the reacting atoms. Thus, the change from ethylene ($R_{1,2}$ = 1.332 Å [172]) to a strong acceptor such as tetracyanoethylene ($R_{1,2}$ = 1.317 Å [173]) is accompanied by only a slight variation in C=C bond length.

Since it is the dienophile and not the diene that forms an *n,v*-complex with the Lewis acid, the value of the ionisation potential of the diene (I_D) and the interatomic distance ($R_{1,4}$) remain constant and do not control the observed acceleration of reaction.[25]

The next factor to affect the reactivity concerns the energies of the reacting bonds, with differences that are reflected in the enthalpy of reaction. This also bears no relation to the observed vigorous acceleration of reaction since the thermochemically determined enthalpies of the reactions with and without involvement of a catalyst differ by not more than 3–5 kJ mol^{-1}.[162]

According to perturbational molecular orbital theory the increase in reactivity of activated dienophiles is due, by analogy with a normal Diels–Alder reaction, to the decrease in energy gap between the HOMO of diene and the LUMO of dienophile.[174,175] In view of the qualitative nature of the calculations carried out, the data obtained by spectrophotometric analysis of *n,v*-complexes containing activated dienophiles[156,176,177] should be considered more reliable. By using the thermodynamic cycle depicted in Fig. 13, it is possible to calculate the change in energy of the LUMO of dienophile on formation of an *n,v*-complex:

$$\Delta E_{LUMO} = E^{II}_{CT}(HMB.(AMA.GaCl_3)) - E^{I}_{CT}(HMB.AMA),$$

where E^{II}_{CT} is the charge-transfer energy in π,π-complexes of hexamethylbenzene (HMB) with *N*-arylmaleimides which are activated due to the formation of an *n,v*-complex with gallium chloride (AMA·$GaCl_3$); E^{I}_{CT} is the charge-transfer energy with unactivated *N*-arylmaleimides.

The formation of π,π-complexes between a π-donor and a π-acceptor which is activated by a Lewis acid is reported in several studies.[144,178,179] A complex between cyclopentadiene and a methyl acrylate–titanium chloride *n,v*-complex has been identified at low temperatures.[179] A large number of ternary complexes of the type B·A·MX_n, where B are π-donors (alkylbenzenes), A are σ-acceptors (acid chlorides) and MX_n are Lewis acids, have been obtained and characterised by IR and NMR spectroscopy.[179] The equlibrium constants and enthalpies of formation of π,π-complexes of styrene and toluene with methyl methacrylate and its *n,v*-complex with tin chloride have been determined.[144]

Hexamethylbenzene is stable in the presence of Lewis acids and has a high π-donor capacity (I_D = 7.85 eV [105]). As the bond energy in the π,π-complex is low, a small perturbation of the HOMO level in the π-donor and the LUMO level in the π-acceptor is to be expected when a complex is formed.[40]

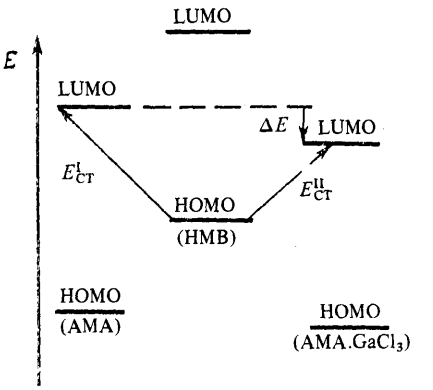

Figure 13. Diagram for determination of the change in energy of the LUMO of *N*-arylmaleimides (AMA) on conversion to an *n,v*-complex with gallium chloride according to the data on the π → π* transfer energy in π,π-complexes with hexamethylbenzene (HMB).[156]

The data from two studies[156,176] (Table 6) indicate an increase in electron affinity of ligands in a complex with gallium chloride (reduction in the LUMO level) by 0.7–1.15 eV. An even larger increase in electron affinity occurs in 1:1 aluminium chloride complexes and 2:1 gallium chloride complexes. The fact that for each group of complexes the difference in energy (ΔE_1 and ΔE_2) is fairly constant is worthy of note. Such a correspondence can occur when the HOMO levels of normal and activated dienophiles vary insignificantly.

The correlation of the acceleration effect on the Diels–Alder reaction with the charge-transfer energy, which is proportional to the electron affinity, is most interesting.[156] The linear nature of such a dependence for the reaction of cyanoethylenes with anthracene has been well established.[11,37] The retention of this type of dependence in the reaction of maleimides activated with Lewis acids (Fig. 14) can serve as experimental evidence that the catalytic effect in a Diels–Alder reaction of the "diene donor, dienophile acceptor" type is due to an increase in orbital interaction because of a significant rise in electron affinity of the dienophile in an *n,v*-complex.[156,165] Moreover, this dependence is regarded as a considerable argument in favour of the invariability of the reaction mechanism.[25] The line for cyanoethylenes is situated below, which is completely consistent with a higher conjugation energy (smaller enthalpy of reaction,

see Table 4) in these compounds compared to maleimides. The values representing the reactivity of all the maleimides activated by gallium or aluminium chlorides lie on a common line which represents the dependence of the reactivity on the three main controlling factors (see Fig. 11).

unsubstituted, 9-methyl-, and 9,10-dimethyl-anthracenes (3.0, 2200, and 93 000 l mol^{-1} s^{-1} respectively) with only a small change in ionisation potential (ΔI_D = 0.29 eV).[30,50,86] It should be noted that with such changes in electron affinity the reactivity in a series of *N*-arylmaleimides only varies by a factor of 10 (see Table 4).

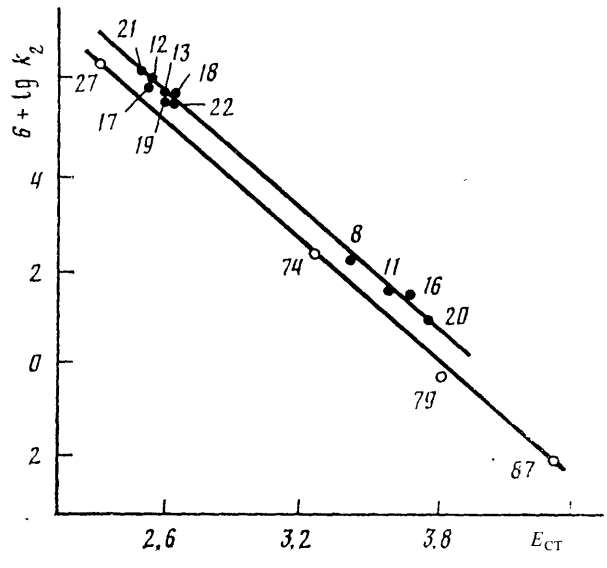

Figure 14. Dependence of the reactivity of anthracene in the Diels–Alder reaction with normal and activated *N*-arylmaleimides on the charge-transfer energy in π,π-complexes with hexamethylbenzene.[25,156] For the numbering of the reactions on the lower line, see Table 4; for those on the upper line, see Table 5.

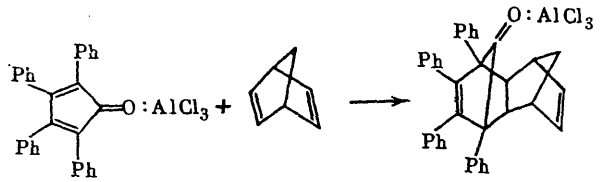
What is the reason for the differing acceleration of reactions in which the same activated dienophile participates with different dienes?

The Diels–Alder reaction is assumed to be orbital controlled, so that a first-order interaction is usually ignored[11,37] [charge interaction, see, Eqn.(1)]. In a structural series of diene donors and dienophile acceptors the strengthening of donor-acceptor properties of the reactants leads to an increase in nucleophilicity of the reaction centre in the diene and electrophilicity in the dienophile.[180,181] The effective representation of the reactivity of these reactants in terms of frontier orbital interaction energies is possibly due to both types of interaction (charge and orbital) varying in a similar manner.

A combined calculation of the charge and orbital contributions is necessary to elucidate the kinetic mechanisms of reactions involving heteroatomic reactants.[4,80,81,91]

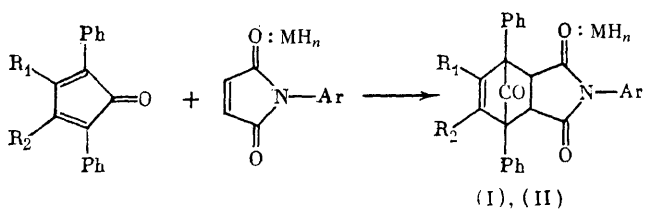
Even in a series of hydrocarbon addends the change in reactivity cannot always be accounted for from a study of the frontier orbital interaction energies. The rate constants of the reaction between 2.5-diphenylisobenzofuran and unsubstituted, methyl-, and dimethylmaleic anhydrides differ considerably (3.36, 9.0 × 10^{-3}, and 1.1 × 10^{-5} l mol^{-1} s^{-1} respectively), whereas the electron affinity remains approximately the same (ΔE_A = 0.30 eV).[137] A substituent effect which is just as marked but works in an opposite direction occurs in the reaction between tetracyanoethylene and



An increase in the charges on the reaction centre in the activated reactants must promote their affect on the reactivity. This effect will be exhibited in those cases where the orbital and charge contributions are not expected to have similar effects.

While in a Diels–Alder reaction of the type "diene donor, dienophile acceptor" the formation of an n,ν-complex with the dienophile leads to a large acceleration due to the increase in electron affinity and electrophilicity of the reacting atoms of dienophile, in reactions of a neutral type and of the type "diene acceptor, dienophile donor" acceleration would be expected when an n,ν-complex was formed with the diene.

Substituted cyclopentadienones—cyclones—can undergo a neutral type of reaction because of the convergence of their HOMO and LUMO levels.[182] An acceleration of the reaction between tetracyclone and alkenes in the presence of aluminium chloride has been recorded.[183] Spectrophotometric measurement showed[166] that tetracyclone forms a strong n,ν-complex with aluminium chloride, which is stable over a period of time and has an intense absorption in the region 800–1000 nm. When stronger Lewis bases are added, the absorption that characterises the free diene is rapidly restored. The enthalpy of formation of the n,ν-complex of tetracyclone with gallium chloride as determined by a thermochemical method



(-39 kJ mol^{-1} [166]) suggests the high strength of the bond in the complex. Phencyclone and indanocyclone decompose even in the presence of gallium chloride.[166]

Dienophiles such as *trans*-stilbene and norbornadiene do not have *n*-donor groups and therefore do not compete with the diene in the formation of a complex:

It is evident from the data given in Table 5 that quite a large acceleration effect occurs in the reaction of alkenes with an activated diene ($\sim 10^3$), but it is noticeably less than the acceleration effect in normal reactions with dienophile activation ($\sim 10^5$).

N-Arylmaleimides form more stable complexes with gallium chloride than does tetracyclone. The results of spectrophotometric titration show that when gallium chloride is added to a solution of tetracyclone and imide, there is no change in the absorption of the diene up to a 1:1 ratio of imide to catalyst. With a further increase in the proportion of Lewis acid an absorption appears in the region 800–1000 nm, which is typical for a complex between the diene and gallium chloride. The Lewis acid bonded to imide in the complex no longer has a destructive effect on cyclones, so it is possible to carry out a kinetic study of the reaction between tetracyclone (I) and phencyclone (II) on the one hand, and a number of dienophiles on the other hand[167] (Table 5):

(I), (II)

I: $R_1 = R_2 =$ Ph; II: $R_1 - R_2 =$ *cis*-*o*,*o*'-biphenylene

The acceleration effect on the reaction of imides in a complex of 1:1 composition with gallium chloride or aluminium chloride is surprisingly small. When aluminium chloride is coordinated with the carbonyl groups of the imide (1:1) and tetracyclone (1:1), the reaction is not accelerated at all (see reactions 49 and 53 in Table 5). Such unusual behaviour of the imides reacting with cyclones cannot be due to the properties of the activated dienophiles. An insignificant acceleration effect also occurs in the reaction of phencyclone with activated esters of unsaturated acids.

V. Conclusion

The considerable progress made in studying the factors that determine the reactivity of compounds in the Diels–Alder reaction has been achieved as a result of involving thermochemical methods. The comprehensive investigation of this reaction using chemical kinetics, spectroscopy, thermochemistry, and structural analysis has led to the identification of three main factors affecting the reactivity: 1) the interaction energy of the frontier orbitals, 2) the energy of the reacting π-bonds, and 3) the interatomic distance in the diene.

The existing data indicate (see Table 4) that the difference in bond energies for dienes (δH_{reac} = 150 kJ mol^{-1}) is greater than for dienophiles (δH_{reac} = 40–50 kJ mol^{-1}). The maximum value of the exothermic reaction between dienophiles and alkylbutadienes corresponds to an increased thermal stability of the addition products. It should be noted that butadiene has the highest interatomic distance $R_{1,4}$ compared to other dienophiles and has a low donor capacity. Since ethylene has the lowest electron affinity, its reaction with butadiene cannot be regarded as a typical example of the Diels–Alder reaction, although it is the simplest for quantum-chemical calculations and therefore a convenient model.

In the series of dienes—isobenzofuran, cyclopentadiene, anthracene, butadiene—the $R_{1,4}$ value increases from 2.19 to 2.90 Å.[109] Taking into account the increasing structural changes which occur when a cyclic adduct is formed with these dienes, a decrease in exothermicity of reaction would be expected if both factors affecting the reactivity ($R_{1,4}$ and E_{C-C}) were interrelated. However, the experimentally found values of the enthalpy of reaction increase in this series of dienes (see Table 4) and hence these factors act independently.

By using reactants that are activated by Lewis acids it is possible to obtain adducts which are difficult to synthesise by other methods.[141,184–187]

The acceleration effect can vary over a very wide range. Thus, in the presence of tin chloride or boron trifluoride etherate the rate of reaction remains virtually unchanged, while in the presence of boron, gallium, or aluminium halides it increases by a factor of 10^4–10^6, and when complexes of composition 2:1 are formed it even increases by a factor of 10^7–10^8 (see Table 5). While, for example, the half-life for formation of an adduct between *O*,*O*-diethyl β-carbomethoxyvinylphosphonate and 9,10-dimethylanthracene at 25 °C and with a concentration of reactants equal to 0.1 mol^{-1} l^{-1} is 350 years, in the presence of two equivalents of gallium chloride only 10 min is needed for this.[142] It is clear that this type of activation, especially in the case of unreactive reagents, is always desirable for the preparation of various cyclic products.

This type of acceleration effect is also possible in other cycloaddition reactions. For example, the rate of addition of a nitrone to an activated dipolarophile approximately increases by a factor of 10^5 (see Table 5).

It follows from an analysis of the spectra of π,π-complexes (see Table 6) that the electron affinity of the dienophile increases in the series of *n*,*v*-complexes with $GaCl_3$, $AlCl_3$, and $2GaCl_3$. In this case the effect of two moles of gallium chloride on the change in electron affinity is considerably less than doubling the effect in a 1:1 complex. These data are consistent with the observed acceleration effect in catalysed reactions (see Table 5).

In reactions of the type "diene donor, dienophile acceptor", activation of the dienophile leads to an increase in stabilisation energy for frontier orbital interaction and a decrease in repulsion energy of the reacting nucleophilic and electrophilic centres in the diene and dienophile. This effect also occurs in a reaction of the type "diene acceptor, deinophile donor" when the diene is activated. In reactions involving dienes that have an acceptor nature (cyclones;[182] 2-cyano- or 2-trifluoromethyl-butadienes[160,161]), the acceleration effect is substantially reduced, possibly because of the increase in repulsion energy between the converging electrophilic atoms in both reactants. The formation of *n*,*v*-complexes by both

partners is clearly unfavourable for reaction (see Table 5). Similar behaviour is noted in the uncatalysed Diels–Alder reaction involving tetracyclone. Here the rate of reaction with tetracyanoethylene is considerably less than with tricyano- and *gem*-dicyano-ethylenes.[182] In a similar manner the rate constant of the reaction between tetracyanoethylene and phencyclone (0.13 l mol^{-1} s^{-1}) is less than the rate constant of the reaction involving *N*-phenylmaleimide (0.76 l mol^{-1} s^{-1}).[182] Since *N*-phenylmaleimide complexed with aluminium chloride has acceptor properties (E_A = 1.99 eV [156]) approaching those of tetracyanoethylene (E_A = 2.88 eV [37]) the small acceleration effect is understandable. The development of various types of acceleration effect has been confirmed experimentally.[117,120–129,142,162,166,167] The kinetic behaviour of normal and activated reactants is consistent with the assumption that there is not always a similar effect from charge and orbital interactions on the stabilisation energy of the transition state of the Diels–Alder reaction.[168,180,181,188–190]

Reactions of *N*-chloramines and *N*-haloamides with unsaturated compounds

A N Mirskova, T I Drozdova, G G Levkovskaya, M G Voronkov
Irkutsk Institute of Organic Chemistry, Siberian Branch, USSR Academy of Sciences

ABSTRACT. The results obtained from studying the reactions of *N*-chloramines, *N*-halocarbamates, and *N*-haloamides of carboxylic, sulphonic, and phosphoric acids with unsaturated compounds have been correlated and classified. It is shown that the direction of addition of *N*-haloamines and *N*-haloamides to alkenes, dienes, alkenynes, and acetylenes, giving saturated adducts, is determined by the conditions of homolytic or heterolytic initiation. The reactions of *N*-chlorodialkylamines with olefins in the presence of sulphur trioxide are discussed. A new method of activating electrophilic reagents by introducing sulphur trioxide on to the N–Cl bond is identified.

An essentially new trend is reported for the reactions of *N,N*-dihaloamides of sulphonic and carboxylic acids and also *N,N*-dihalocarbamates with polyhaloethylenes, giving acylimines of polyhaloaldehydes, which are highly reactive syntones for the synthesis of fine organic chemicals.

The bibliography includes 216 references.

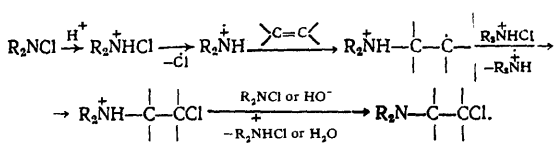
I. Introduction

The chemistry of *N*-haloamines, *N*-halourethanes, and *N*-haloamides of sulphonic and carboxylic acids has undergone considerable development in the last ten years. The interest shown in compounds containing an N–Hal bond is due to their high and varied reactivity, so they have been able to remain for a long time as fertile subjects in theoretical and synthetic organic chemistry. Up to the present time a large amount of experimental material on the study of homolytic and heterolytic addition reactions of *N*-chloramines, *N*-halourethanes, and *N*-halo- and *N,N*-dihaloamides of carboxylic, phosphoric, and sulphonic acids to alkenes, dienes, alkenynes, and acetylenes has been collected.



Information on the tendency of compounds with an N–Hal bond to add on to alkenes first appeared in 1930;[1] it was reported that *N*-bromo-*N*-methylbenzenesulphonamide and *N*-monobromoacetamide react with 1-phenylpropylene to give saturated adducts. However, systematic studies of the reactivity of *N*-haloamides in addition reactions to multiple bonds only started 30 years later. The period of rapid development of this branch of chemistry was in the 1960s and 1970s. Progress made up to 1970–1973 in this branch of chemistry was described in reviews.[2–4] Despite the merits of these reviews none of them can be regarded as sufficiently comprehensive. Moreover, in the last 10–12 years the flow of studies devoted to examining the reaction of *N*-haloamides of sulphonic, carboxylic, and carbamic acids with unsaturated compounds has increased steadily. Hence, it is advisable to correlate the literature material on this subject in order to establish the general mechanisms and also the prospects for further development of this branch of chemistry.

We have not examined the problems concerning the methods of forming aminyl and amidyl intermediates since they have been covered in sufficient detail in two reviews[2,5] and three studies.[6–8]

II. Reactions of *N*-chloramines with unsaturated compounds

An extensive series of studies devoted to examining the reactions of *N*-chloramines with unsaturated compounds was carried out in the 1960s by two groups of research workers[3,9–16,17–23] and covered in reviews.[2–4,24] These studies made a decisive contribution to the chemical potentialities of compounds containing an N–Hal bond. In this section the general mechanisms for reactions of this type are summarised.

The reactions of *N*-chloramines with unsaturated compounds mainly take place with homolytic cleavage of the N–Cl bond. Two methods are principally used to initiate them. Thus, the reaction of *N*-chloroalkyl- and *N*-chlorodialkyl-amines with alkenes, dienes, and acetylenes, initiated by UV irradiation or by bivalent iron salts in a mixture of H_2SO_4 and glacial acetic acid, is known to occur.[9–16] The reactions occur rapidly, giving β-chloroalkylamines $(Alk)_2NCH_2CR^1R^2Cl$, β-chloroalkenylamines $(Alk)_2NCH_2CH=CHCH_2Cl$, and α-chloroaldehydes AlkCHClCHO or α-chloroketones AlkCHClCOR. These reactions take place by a free-radical mechanism via the formation of a protonated aminyl radical cation according to the scheme:

The generation of aminyl radicals by redox systems (salts of iron, titanium, and copper) in alcohol solution is also known to occur.[17-24] The addition of these radicals to the multiple carbon–carbon bond of alkenes, dienes, and acetylenes occurs readily:

$$R_2NCl \xrightarrow[-[MCl]^+]{M^+} R_2\dot{N} \xrightarrow{>C=C<} R_2N-\overset{|}{C}-\dot{C}< \xrightarrow[-M^+ \text{ (or } R_2\dot{N})]{[MCl]^+ \text{ (or } R_2NCl)} -R_2NC(Cl)C(Cl)-,\quad M^+ = Cu^+,\ Fe^{2+},\ Ti^{3+}.$$

The most active redox initiators are bivalent iron salts and methanol is the solvent of choice.[3-4] When other solvents—ethanol [23] or an ethanol–acetone mixture[17]—are used, there is no increase in the yield of adducts.

The yield and structure of the adducts depend on the structure of the unsaturated compound and *N*-chloramine and also on the reaction conditions. Thus, the reactions of *N*-chlorodialkyl-, *N*-chlorocycloalkyl-, and *N*-chloro(hexa- or penta-methylene)-amines with aliphatic,[10,13,16] halogenated [$CH_2=C(Hal)R$ (Hal = Cl, Br, F) and $CH_2=C(X)CH_2Cl$ (X = H, Cl)],[13,16] and functionally substituted alkenes [$CH_2=CHCH_2X$ (X = OH, OC_2H_5, OAc, OPh, CN)] [13,15] in 4 M H_2SO_4 in glacial acetic acid or in methanol in the presence of redox systems give β-chloroalkylamines $R(R^1)NCH_2C(Cl)R^2R^3$. *N*-Chloramines add on to 1,2- and 1,3-dienes at the 1,2- and 1,4-position respectively[10,14] to give β-chloro- and γ-chloro-alkenylamines of the type

$$R(R^1)NCH_2CCl=C(R^2)R^3 \text{ and } R(R^1)NCH_2CH=CHCH_2Cl.$$

The reactions of *N*-chloramines with acetylenes occur in an unique manner; α-chloroaldehydes or, in the case of disubstituted acetylenes, α-chloroketones, have been isolated:[10,14]

$$(Alk)_2NCl + RC\equiv CR^1 \xrightarrow{H_2SO_4-AcOH} (Alk)_2NC(R)=C(R^1)Cl \xrightarrow{H_2O} RCOCHClR^1,$$

$$Alk = C_2H_5,\ n\text{-}C_4H_9,\ n\text{-}C_5H_{11}.$$

Finally, reactions involving chloramination of alkenynes such as vinylacetylene, 1-penten-3-yne, and 2-methyl-1-buten-3-yne,[25] are known; these take place in an acid medium to give mainly 1,4-addition products in 60–85% yield.

In the free radical addition of a protonated *N*-chloramine to alkenes that have allyl hydrogen atoms, a competing reaction occurs—electrophilic chlorination leading to chloroalkenes and β-chloroalkyl acetates by stabilisation of carbocation (A):[13]

$$R_2\overset{+}{N}HCl \rightarrow [R_2NH + Cl^+],$$

$$[Cl^+] + >C=C-CH< \rightarrow ClC-\overset{+}{C}-CH< \begin{cases} \longrightarrow ClC-C=C< + H^+ \\ \xrightarrow[-H^+]{AcOH} ClC-C(OAc)-CH< \end{cases}$$

(A)

In a number of cases, namely, in reactions with alkenes that have electron-donating substituents on the double bond (isobutylene, *cis*-2-butene), the yield of products from electrophilic chlorination is considerable (up to 60%). At the same time, electrophilic chlorination occurs to a lesser degree when electron-withdrawing substituents that reduce the stability of the intermediate ion (A) are present in the alkenes, thus assisting the free-radical addition of chloramines to the double bond of unsaturated compounds to give adducts. Thus, in the series $CH_2=CHR$, where R = Cl, F, CH_2Cl, CH_2CF_3, CH_2CN, $CH_2OC_6H_5$, the yield of adducts in the reaction with *N*-chlorodialkylamine increases and it reaches 85%.

It should be noted that chloramination of unsaturated compounds is often accompanied by other side reactions. Thus, *N*-chlorodialkylamines $RCH_2(CH_2)_3N(Cl)R^1$ with long-chain alkyl substituents undergo a Hofmann–Löffler rearrangement to give chlorine-substituted amines, which entails a reduction in yield of 1 : 1 adducts:[3,11,26]

$$RCH_2(CH_2)_3N(Cl)R^1 \xrightarrow[-Cl^\cdot]{H^+} RCH_2(CH_2)_3\overset{\cdot}{\overset{+}{N}}HR^1 \longrightarrow$$

$$\rightarrow R\dot{C}H(CH_2)_3\overset{+}{N}H_2R^1 \xrightarrow{RCH_2(CH_2)_3N(Cl)R^1} RCHCl(CH_2)_3\overset{+}{N}H_2R^1 \rightarrow$$

$$\xrightarrow{OH^-} RCHCl(CH_2)_3NHR^1.$$

Finally, the reaction conditions have a considerable effect on the yield of adducts. Thus, chloramination of aliphatic alkenes takes place with a higher yield of adducts (47–68%) when redox systems are used as initiators and the addition is carried out in methanol[17-24] than when UV irradiation in an acid medium is used for initiation (yield of adducts 16–42%).[10,13-14] At the same time, the use of an acid mixture as solvent and initiation with UV irradiation have proved favourable for the reactions of *N*-chlorodialkylamines with halogenated olefins such as $CH_2=C(Hal)R$ [Hal = Cl, F; R = H, CH_3, $C(CH_3)_3$] and $CH_2=CXCH_2Cl$ (X = H, Cl) (yield of adducts 61–92%) [13,15,16] and also functionally substituted alkenes $CH_2=CHCH_2X$ (X = OC_2H_5, $COCH_3$, CN) (yield of adducts up to 88%).[15] With 1,3-dienes, addition of *N*-chlorodialkylamines takes place both in the presence of redox systems in methanol and with UV irradiation in an acid medium with yields of 44–68%.[10,14]

It should be particularly stressed that the nature of the substituents on the nitrogen atom in *N*-chloramines substantially affects the addition to multiple bonds. In the reactions of substituted *N*-chloroalkylamines of the type $RN(Cl)CH_2Y$ (Y = CH_2OH, CN, $CH(OCH_3)_2$, $CH_2=CH$, $C\equiv CH$, *p*-ClC_6H_4) with 2-chloropropene in a mixture of 4 M H_2SO_4–AcOH at 30 °C in daylight, adducts are not formed,[15] which is probably due to a reduction in the degree of protonation of *N*-chlorodialkylamines by the action of electronegative substituents and also to a decrease in polarity of the N–Cl bond. The only exception to this is *N*-chloromethylbenzylamine (Y = C_6H_5), which gives an adduct in 27% yield.

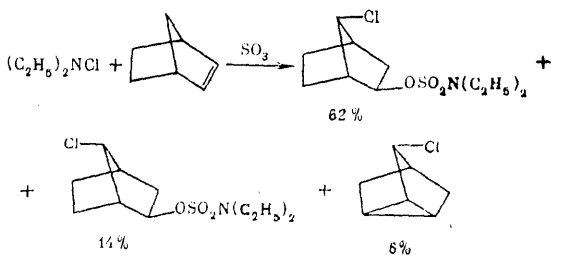
Introduction of electron-donating substituents into *N*-chloramines, on the other hand, has a favourable effect on their addition to a double bond. An example of this is the reaction of chloramines $CH_3NCl(CH_2)_nN(Cl)CH_3$ with 2-chloropropene, which under similar conditions results in the formation of the bis-adducts $[CH_3CCl_2CH_2N(CH_3)]_2(CH_2)_n$.[15] We should note that their yield depends on the degree of diprotonation of chloraminoalkanes. Thus, as the length of the chain increases to $n = 6$ (a hexamethylenediamine derivative), there is the highest yield of bis-adduct (72%), when $n = 4$ it amounts to 49%, and when $n = 2$ or 3 bis-adducts are not formed. At the same time, steric hindrance, which occurs when a protonated aminyl radical attacks the double bond of the olefin, has a lesser effect, in our opinion. Conformation of this could be the

observation that the reaction of *N*-ethyl-*N*-isopropylchloramine with 2-chloropropene in a mixture of 4 M H_2SO_4–AcOH at 30 °C in daylight does take place (yield of adduct 78%).[15]

Although the method for obtaining *N*,*N*-dichloroamines has been known for a long time,[27] there has been no information in the literature about their addition to a double bond; this is apparently due to the instability and danger of explosion from these compounds. Only after the development of methods for obtaining relatively stable *N*,*N*-dichloroalkylamines that contained functional groups on the α-carbon atom[28–30] was it possible to study their addition to alkenes. Thus, *N*,*N*-dichloro-α-aminonitriles $Alk_2C(CN)NCl_2$ add on to styrene; 1:1 adducts are thereby obtained, but they have low stability and have been isolated as the hydrochloride salts of reduction products:[28]

$$Alk_2C(CN)NCl_2 + C_6H_5CH{=}CH_2 \rightarrow Alk_2C(CN)N(Cl)CH_2CHClC_6H_5 \xrightarrow{HCl} Alk_2C(CN)NHCH_2CHClC_6H_5 \cdot HCl.$$

It transpired in this case that *N*,*N*-dichloramines containing substituents [$OCOCH_3$, $CONH_2$, $P(O)(C_2H_5)_2$] on the α-carbon atom that are less electronegative than a nitrile group do not add on to styrene.[28] *N*,*N*-Dichloro-β-aminopropylnitrile also does not react with styrene (in contrast to *N*,*N*-dichloro-α-aminoalkylnitriles), which suggests that the nitrile group on the β-carbon atom has an insignificant effect on the reactivity of the *N*,*N*-dichloramino group.[28] A similar substituent effect in *N*,*N*-dichloramines occurs in the reaction between *N*,*N*-dichloraminoethyl hypochlorite with hexene, where the *N*,*N*-dichloramino group remains inert and an addition product—$ClCH_2CH(C_4H_9)OCH_2CH_2NCl_2$—is formed with involvement of the O–Cl bond.[28]

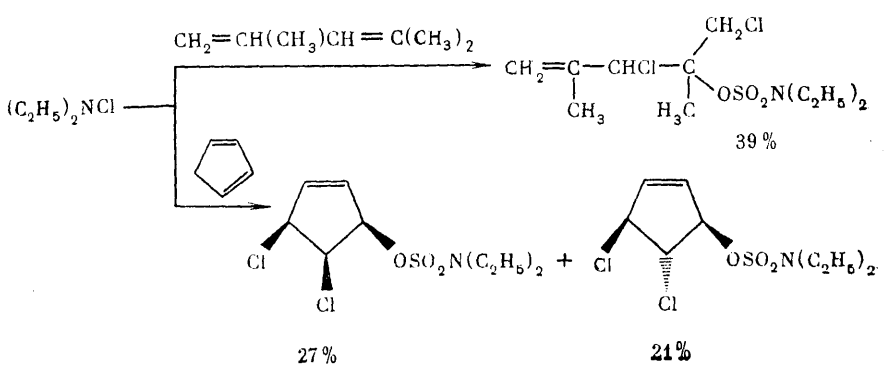


Recently (1984–86), a number of studies have been published,[31–38] in which a new approach to the activation of weak electrophilic reagents in electrophilic addition reactions to olefins is proposed. The authors show that reactions of *N*-chloramines with olefins in the presence of sulphur trioxide initially lead to the formation of highly reactive *O*-chlorosulphamates (R_2NSO_2OCl), which are products derived from introduction of sulphur trioxide into the N–Cl bond of *N*-chloramines, which subsequently add on to the double bond in accordance with Markownikoff's rule to form saturated adducts:

$$R_2NCl + SO_3 \xrightarrow{CH_2Cl_2} R_2NSO_2OCl \xrightarrow{>C=C<} R_2NSO_2OC-CCl$$

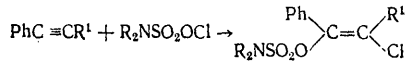
The reactions of *O*-chlorosulphamates with ethylene, hexene, styrene, and cyclopentene take place with quite a high yield of adducts (88%).[33,34]

The high regioselectivity of the addition of *N*-chloramines to olefins in the presence of SO_3 was demonstrated in the case of the reaction with 1-hexene [70–88% yield of adducts $C_4H_9CH(CH_2Cl)OSO_2NR_2$, where R_2 = $(C_2H_5)_2$, $(CH_2)_5$, $O(CH_2CH_2)_2$], and there was high stereospecificity—in the reaction with cyclohexene the *trans*-adduct was formed in 85–93% yield.[4] The stereoselectivity and regioselectivity of the addition of *N*-chloramines to olefins are in good agreement with a scheme involving electrophilic addition.

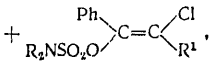


There is an interesting reaction between *O*-chlorosulphamates with norbornene, which results in rearrangement of the adducts, with the adduct in the *syn-exo* configuration for a normal Wagner–Meerwein rearrangement predominating. Formation of the adduct with an *anti-exo* configuration is due to a Wagner–Meerwein rearrangement followed by a 2,6-hydride shift:[33,35]

The skeletal rearrangements that occur in this reaction suggest that *O*-chlorosulphamates have a clearly defined electrophilic nature.



The reactions of *N*-chloramines with dienes (*cis*,*cis*-cyclooctadiene, norbornadiene) in the presence of sulphur trioxide give adducts from 1,2-addition and also isomeric adducts obtained by participation of the second double bond of the diene as well as by-product dichlorides (with a yield of about 34%).[34]



The reactions of *N*-chloramines with cyclopentadiene and 2,4-dimethyl-1,3-pentadiene (with an equimolar ratio of reactants) in the presence of SO_3 take place with the involvement of only one C=C bond of the diene. However, this reaction is complicated by the simultaneous occurrence of electrophilic substitutive chlorination processes:[35]

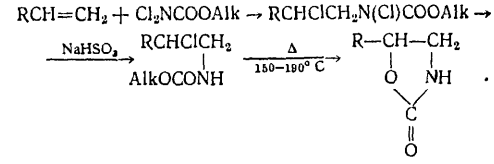
The reactions of *O*-chlorosulphamates with the dimethyl esters of norbornene and tricyclodecadiene dicarboxylic acids are unusual. Under conditions where the nucleophiles, in particular the ester group and the sulphamate anion, are competing, intramolecular attack by the carbomethoxy group on the double bond of the alkenes is more favourable, giving chlorolactones in 90–95% yield.[34,35]

The possibility of chlorosulphamation of phenyl- and diphenylacetylene has been demonstrated. The reactions take place (at −80 to −60 °C in CH_2Cl_2) in accordance with Markownikoff's law and give the *Z*- (13–36%) and *E*- (5–21%) products:[35,38]

$R_2 = (CH_2)_5$; R = C_2H_5, R^1 = H, Ph.

We should mention in passing the possibility of using *O*-chlorosulphamates as mild chlorinating agents—for ketones or aromatic compounds, for example.[35]

Thus, the reactions of *N*-chloramines with unsaturated compounds are new methods of obtaining β-chloroalkylamines, β-chloroalkenyl- and γ-chloroalkenyl-amines (intermediates in the synthesis of aziridines[3]), and also highly reactive β-chloroaldehydes and β-chloroketones. When these reactions are carried out in the presence of sulphur trioxide there are extensive prospects for the synthesis of β-chloroalkyl- and β-chloroalkenyl-sulphamates, which are biologically active compounds with future potential.



III. The reactions of *N*-haloamides with unsaturated compounds

1. *N*-Halocarbamates

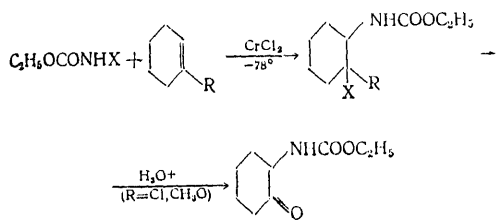
The first successful attempt to obtain *N*-(β-chloro-α-phenylethyl)-*N*-ethoxycarbamate by reactions of *N*, *N*-dichlorourethane with styrene was carried out in 1942.[39] More than 20 years later (in the 1960s) studies by other authors[40–44] on the addition reaction of *N*-halocarbamates to unsaturated compounds started to appear. Three reviews[2–4] cover the reactions of *N*-chloro- and *N*, *N*-dichlorourethanes with styrene, *trans*-stilbene,[43] 2-butene, isobutene,[42] 2-methyl-1-pentene, 1-dodecene, 1-octadecene,[43] cyclic alkenes,[41–43] and alkenes having electron-withdrawing substituents on the double bond (vinyl acetate, methyl vinyl ketone, acrylates).[43,45]

In recent years the number of studies in this area of chemistry has grown considerably, which is due to the perfection of methods for obtaining dihalocarbamates[46] and also because the reactions of *N*, *N*-dihalocarbamates with unsaturated compounds can be used to synthesise highly reactive compounds that are intermediates in the preparation of isocyanates,[47–49] oxazolidinones,[50–51] aziridines,[52] etc.

Investigation of the reactions of *N*, *N*-dichlorourethanes with terminal alkenes was continued in further studies.[47–49] It was established that whatever the method of initiation [UV irradiation (75–80 °C), heating (80–85 °C) in a current of nitrogen or in air] the addition took place with the amidyl fragment being attached to the terminal carbon atom and the formation of saturated adducts—*N*-β-chloroalkyl-*N*-chlorourethanes—with a yield of up to 83%. The N−Cl bond in these products is readily converted to an N−H bond on treatment with sodium bisulphite, and the position of the carbamate group in the adducts obtained has been demonstrated by chemical conversions such as pyrolysis, which gives 5-alkyl-2-oxazolidones:[49]

Products derived from electrophilic chlorination $R^1CHClCH=CH_2$ are formed in side reactions as also are monochlorourethanes, the yield of which increases (from 14 to 42%) in the series of R: $C_4H_9 < C_5H_{11} < C_6H_{13} < C_8H_{17} < C_{10}H_{21} < C_{13}H_{27}$. It should be noted that the occurrence of electrophilic halogenation as a competing reaction is only typical for alkenes that have allylic hydrogen atoms.

The reactions of *N*, *N*-dihalocarbamates with cyclic alkenes in an inert medium with heating (35–40 °C) are interesting; they take place stereospecifically, mainly as a *trans*-addition process, with the formation of adducts and a series of halogenated products, the ratio of which is determined by the nature of the substituents on the nitrogen atom. Thus, methyl *N*, *N*-dibromocarbamate reacts with cyclohexene fairly readily without initiation, giving the *trans*-adduct in high yield (67%).[46] This direction of addition is confirmed by conversion of this adduct to *cis*-perhydrobenzoxazol-2-one, since it is known[53] that only the appropriate compounds having a *trans*-configuration can undergo such a cyclisation .



N, *N*-Dichlorocarbamates react with cyclohexene in a more complex manner; in addition to adducts of a similar stereochemistry (44%), a number of chlorinated by-products and monochlorocarbamates are formed.[51]

While heating is required for the reaction of *N*, *N*-dihalocarbamates with aliphatic and cyclic alkenes, the reaction of *N*-monohalocarbamates with cyclic alkenes takes place both with heating (40° to 60 °C) and at low temperatures (0° to −78 °C) in methanol or in a mixture of methanol and chloroform in the presence of Cr(II) halides.[53,54] It was shown[51] that on heating (45 °C) a mixture of *N*-monobromocarbamate and cyclohexene in benzene, the *trans*-adduct was formed in 72% yield. In the presence of Cr(II) at low temperatures (0° to −78 °C), a mixture of *cis*- and *trans*-1,2-adducts was obtained, with their ratio dependent on the reaction conditions (temperature, amount of catalyst, medium) as well as the effect of substituents in the carbamate group and also the nature of the halogen on the nitrogen atom.[53,54] The optimum conditions, ensuring a high yield of adducts, are attained when the reaction is carried out in a mixture of methanol and chloroform cooled to −78 °C in the presence of an equimolar quantity (relative to monochlorocarbamate) of chromium(II) chloride.[53,54] Under these conditions addition of monochlorocarbamate ROCONHCl to cyclohexene takes place with the *cis*-adduct mainly formed in the mixture (by a factor of 4–6). The total yield of isomeric adducts

increases from 65 to 87% in the series of R: $C_2H_5 \leqslant CH_2C_6H_5 < CH_2Cl \leqslant CH_2CCl_3$. A similar dependence of the yield of 1 : 1 adduct (from 61 to 85%) occurs in the analogous series for the reaction with *N*-monobromocarbamates, but the ratio of *cis*- to *trans*-adducts is about 1 : 1. At higher temperatures (0 to −40 °C), carbamates (up to 64%) and halogenated cyclohexene products are mainly formed.[53] When chromium bromide is used as the catalyst, there is a reduction in the yield of adducts and at the same time the yield of carbamates increases up to 53% and that of 1,2-dibromoalkanes rises to 20%.

Similar behaviour occurs in the reaction of *N*-monohalourethanes $C_2H_5OCONHX$ with norbornene (in a mixture of methanol and chloroform at −78 °C in the presence of $CrCl_2$); when X = Cl, the *cis*-adduct is mainly formed, and when X = Br, the *cis*- and *trans*-adducts are formed in equimolar quantites.[53]

The regiospecific and stereospecific nature of the addition of amidyl residues to alkene systems was confirmed when the reactions of *N*-monohalourethanes with 1-chloro-, 1-methyl-, 1-methoxy-, 1-acetyl-, and 1-*N*-(piperidino)-cyclohexene in the presence of Cr(II) in a methanol–chloroform solution at −78 °C were studied. In this case ethyl *N*-(1-halo-1-R-cyclohexyl)carbamates were formed:[5,53,55,56]

X = Cl, Br; R = Cl, CH_3, CH_3O, CH_3CO, $(CH_2)_6N$.

Hydrolysis of the adducts obtained to the corresponding ketones also suggests that these reactions are regiospecific. The addition of benzyl *N*-monochlorocarbamates to trimethylsilyloxynorbornene [56] takes place in a similar manner.

An analysis of the literature data showed that not all *N*-halocarbamates are active in reactions with aliphatic and cyclic alkenes. Thus, *N*-alkyl-substituted *N*-halocarbamates $HalN(R)COOCH_3$ (R = CH_3, $C_6H_5CH_2$) do not add to the double bond of alkenes that contain allylic hydrogen atoms but only form allylic halogenation products in high yield (70–80%).[57-58] Because of this, *N*-alkyl-substituted *N*-bromocarbamates could be recommended as allylic brominating agents.[57] The inertness of *N*-alkyl-*N*-halocarbamates in 1,2-addition reactions to alkenes is apparently due to both steric hindrance and a reduction in electrophilicity of the amidyl radical by the introduction of electron-donating substituents on to the nitrogen atom. On the other hand, for *N*-chlorocarbamates $C_2H_5OCON(R)Cl$ with electronegative substituents on the nitrogen atom (R = CH_3OCO, CH_3CO), an increase in electrophilicity of the amidyl radical is typical. For this reason the reactions of *N*-acyl- and *N*-ethoxycarbonyl-*N*-chloro-urethanes with cyclohexene and 1-octene take place quite readily with UV irradiation (15–20 °C, 3–5 h), and the chlorine atom adds on to the more substituted carbon atom of the C=C bond of 1-octene (yield of adducts 53–67%). Chlorinated alkenes and *N*-substituted urethanes are formed as by-products (39–42%).[58]

The reactions of *N*,*N*-dichlorourethanes with styrene and its derivatives occur readily, with an induction period, most frequently being accompanied by heat liberation, and take place with practically no side reactions to give adducts with an N–Cl bond that readily undergoes reduction with sodium thiosulphate to compounds with an N–H bond. Thus, in the reactions of *N*,*N*-dichloro-substituted methyl, ethyl, and butyl carbamates with styrene, α-chloro-, and α-bromo-styrene, adducts are formed in high yield (59–99%):[51,52,59]

$$AlkOCONCl_2 + C_6H_5CR{=}CH_2 \rightarrow C_6H_5C(R)ClCH_2NClCOOAlk.$$

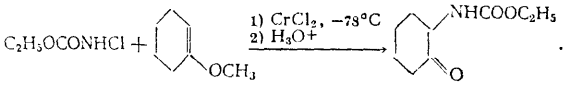
It is interesting that the nature of the α-substituents has a very marked effect in the reduction of the alkenes. Thus, when ethyl *N*-chloro-*N*-(2-chloro-2-bromo-2-phenylethyl)carbamate, which is obtained by reaction of *N*,*N*-dichlorourethane with α-bromostyrene, is reduced with sodium thiosulphate, hydrogen bromide is eliminated and ethyl *N*-(2-chlorostyryl)carbamate is formed,[59] which is due, in our opinion, to the low strength of the C–Br bond (C–Br bond energy is 68 kcal mol^{-1}, C–Cl bond energy is 81 kcal mol^{-1} [60]):

$$C_6H_5CBr{=}CH_2 + Cl_2NCOOC_2H_5 \rightarrow C_6H_5CClBrCH_2NClCOOC_2H_5 \xrightarrow[-HBr]{Na_2S_2O_3} C_6H_5CCl{=}CHNHCOOC_2H_5.$$

Having analysed the effect of the conditions for initiation, Bal'on and Moskaleva[51,52,59] established that the use of radical initiators—UV irradiation, peroxides, copper powder—accelerated the reaction between *N*,*N*-dichlorocarbamates and substituted styrenes. Thus, the addition of *N*,*N*-dichlorourethane to α-bromostyrene in the absence of radical initiators is complete after 3–5 h and the yield of adduct only reaches 30%, while in the presence of copper powder an almost quantitative yield of adduct is obtained after 40 min. The initiator participates in the reaction both at the initiation and chain transfer stages.[59]

The radical nature of the reaction of *N*,*N*-dichlorourethanes with alkenes is also confirmed by the reaction between *N*,*N*-dichloro-urethane and *trans*-stilbene, which has an induction period, and occurs without stereoselectivity to give a mixture of *erythro* and *threo* isomeric adducts $C_6H_5CHClCH(C_6H_5)NClCOOAlk$.[61] *N*,*N*-Dibromocarbamates and even *N*-alkyl-*N*-bromocarbamates, which are known[57] to be inert to the double bond of aliphatic alkenes, add on to styrene and α-methylstyrene in a similar manner to the corresponding chloro derivatives. However, the yields of the adducts obtained are considerably lower (49–71%) than for the reaction of these alkenes with dichlorocarbamates. A feature of the reaction of *N*-bromo- and *N*,*N*-dibromocarbamates with styrene and its derivatives is that the adducts cannot always be isolated since even on gentle heating they readily cyclise to phenyloxazolidinones with elimination of alkyl bromide.[46,57,62]

In contrast to *N*,*N*-dichlorourethane, *N*-bromo-*N*-alkylcarbamates react with *trans*-β-methylstyene stereoselectively, and in these reactions the stereoselectivity is reduced as the effective size of the substituent on the nitrogen atom decreases. Thus, in the case of *N*-bromo-*N*-benzylcarbamate mainly *trans*-addition products are formed, while *N*-bromo-*N*-methylcarbamate gives an equimolar mixture of *cis*- and *trans*-adducts.[57]

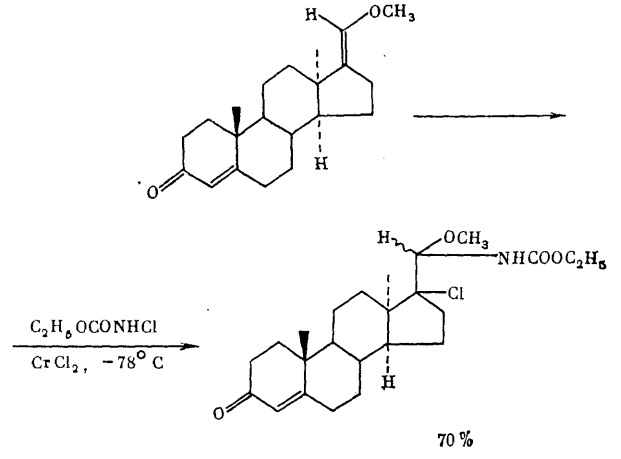


The direction of addition of *N*,*N*-dichlorocarbmates to substituted alkenes containing functional groups—vinyl acetate, methyl vinyl ketone,[45,63] and acrylates[64]—is similar to that for the addition of

amidyl radicals to styrene and its derivatives and is not dependent on the initiation conditions:

$$RCH{=}CH_2 + Cl_2NCOOAlk \rightarrow RCHClCH_2NClCOOAlk \rightarrow \xrightarrow{NaHSO_3} RCHClCH_2NHCOOAlk,$$
$$Alk = CH_3, C_2H_5;\ R = CH_3COO, CN, CONH_2, COOCH_3, COCH_3.$$

An induction period and acceleration by radical initiators are typical for these reactions. Thus, when *N*,*N*-dichlorocarbamates are reacted with acrylonitrile without an initiator the yield of adducts is 25–60% after 4–5 h,[43,51] while in the presence of univalent copper salts the yield is 78–90% after 30–40 min.[64]



The reactions of *N*-chlorocarbamates with vinyl ethers are interesting; they occur in different directions depending on the initiation conditions. Thus, reaction of ethyl or butyl vinyl ether with *N*,*N*-dichlorocarbamates takes place with the formation of alkyl *N*-chloro-*N*-(2-chloro-1-alkoxyethyl)carbamates if there is no radical initiator present.[65] The direction of addition changes if the same reactions are carried out in the presence of chromium chloride; in this case the amidyl radical becomes attached to the less substituted carbon atom to give adducts $C_2H_5OCHCl-CH_2NHCOOR$, where R = $ClCH_2$, $ClCH_2CH_2$, $C_6H_5CH_2$.[56] The direction of addition of the amidyl radical to the double bond of cyclic vinyl ethers is similar, as is indicated by the structure of the products isolated as a result of hydrolysis or methanolysis of the 1 : 1 adducts:[56]

The products of the 1,2-addition of *N*-monochlorocarbamates to dihydrofuran, triacetyl-*D*-glyoxal, and acetylbenzylidene-*D*-glyoxal have not been isolated, since under the reaction conditions (in the presence of water, methanol) they readily undergo chemical reactions to give acetal derivatives.[56]

The direction of addition of amidyl radicals to the double bond in these reactions, namely, to the 2-position, is determined by electronic effects.

As regards the effect of different factors (electronic and steric) on the direction of addition of the amidyl fragment to the multiple bond of alkenes, the reaction of *N*-monochlorocarbamates with the steroid derivative—17-methoxymethyleneandrost-4-en-3-one—is of interest,[56] attack of the amidyl radical in it being determined to a greater extent by steric rather than electronic effects:

Let us turn to the reaction of *N*,*N*-dichlorourethanes with vinylidene chloride, which enters into the overall scheme of addition of amidyl radicals to unsaturated compounds and takes place independently of the initiation conditions (heating in an atmosphere of argon, in the presence of benzoyl peroxide, or in air) to give alkyl *N*-2,2,2-trichloroethyl-*N*-chlorocarbamates in yields that are almost quantitative:[66]

$$AlkOCONCl_2 + CCl_2{=}CH_2 \rightarrow AlkOCONClCH_2CCl_3.$$

N-Bromo-*N*-alkylcarbamates, in contrast to their dichloro-substituted analogues, undergo reaction with vinylidene chloride with greater difficulty and the yield of adducts amounts to 40–73%,[57] which is due to steric hindrance that occurs during attack by the *N*-alkyl-substituted amidyl radical, which is more bulky than AlkOCONCl.

The reactions of *N*-bromocarbamates with 1,3-alkadienes have been studied in the case of 1,3-butadiene, 2,3-dimethyl-1,3-butadiene, 2-methyl-1,3-butadiene, and 1,3-pentadiene.[67] They take place at −5° to −10 °C in chloroform and regardless of the structure of the diene mainly give the thermodynamically more stable *trans*-1,4-adducts in high yield (66–70%).[67] 1,2-Adducts are found only in the reactions with butadiene (20%) and piperylene (8%). Diene dibromides are formed as by-products:[67]

$$CH_2{=}CR^1{-}CR^2{=}CHR^3 \xrightarrow{BrNHCOOCH_3} \begin{cases} \xrightarrow{1,4-} CH_3OCONHCH_2CR^1{=}CR^2CHBrR^3 \\ \xrightarrow{1,2-} CH_2{=}CR^1{-}CBr(R^2)CH_2(R^3)NHCOOCH_3 \\ \longrightarrow C_4H_3R^1R^2R^3Br_2 \end{cases}$$

$R^1{=}R^2{=}R^3{=}H$; $R^1{=}R^2{=}CH_3$, $R^3{=}H$; $R^1{=}CH_3$, $R^2{=}R^3{=}H$; $R^1{=}R^2{=}H$, $R^3{=}CH_3$.

Addition of *N*-bromocarbamate to piperylene gives a mixture of 1,4- and 4,1-adducts in the ratio 1 : 1, which remains unchanged when the initial quantities of the reactants are varied. In the case of isoprene, a compound (about 10%) that corresponds to an adduct of *N*, *N*-dibromocarbamate and isoprene in the ratio 1 : 2—$[BrCH_2CH=C(CH_3)CH_2]_2NCOOCH_3$—is formed together with the main 1,4-isomer (71%).[67]

The regioselectivity and stereoselectivity of the addition of *N*, *N*-dichlorocarbamates to dienes is virtually no different from that in the analogous reactions of *N*-bromocarbamates. Thus, methyl and isopropyl *N*, *N*-dichlorocarbamates with the same 1,3-alkadienes mainly form *trans*-1,4-adducts with a yield of up to 94%.[44] 1,2-Addition products were only isolated in the case of the reaction with butadiene (14% [44] or 37% [53]), 1,3-cyclohexadiene (78%) [53] and piperylene (26%). With piperylene, 4,1-addition products (30%) are also formed.[67]

The reactions of the *N*, *N*-dichlorocarbamate $[NCl_2COOCH_2]_2$ with chloroprene take place with the exclusive formation of 1,4-adducts (96–98%).[44]

The reaction of 1,5-hexadiene with *N*, *N*-dichlorourethane, in which 1,2-addition products of composition 1 : 1 (27.5%) and 1 : 2 (18%) are formed, has been studied.[68] A distinctive feature of the reactions of *N*, *N*-dichlorocarbamates with dienes is the absence of diene dihalides, which are formed in appreciable yield (10–32%) in the reactions of *N*-bromocarbamates.

Alkenynes, which have two reaction centres, have been of definite interest in recent years. The reactions of *N*, *N*-dichloro- and *N*-bromo-carbamates with conjugated alkenynes such as vinylacetylene,[69] 1-hexen-3-yne, 2-methyl-1-buten-3-yne, and 2-penten-4-yne [67] have been studied. The reactions take place at −10 to −5 °C in an inert atmosphere and proceed exothermically by 1,2- and 1,4-addition pathways to give isomers with acetylene and allene structures

$$R^1C{\equiv}C{-}CR^2{=}CHR^3 + CH_3OCONX^1X^2 \xrightarrow{\text{then } NaHSO_3}$$
$$\xrightarrow{1,2} R^1C{\equiv}CC(R^2)CHNHCOOCH_3 \quad (X^1,\ R^3)$$
$$\xrightarrow{1,4} R^1C{=}C{=}C(R^2)CH(R^3)NHCOOCH_3 \quad (X^1)$$

$R^1{=}R^2{=}H$, $R^3{=}H$, CH_3; $R^1{=}C_2H_5$, $R^3{=}R^3{=}H$;
$R^1{=}R^3{=}H$, $R^2{=}CH_3$; $X^1{=}X^2{=}Cl$; $X^1{=}Br$, $X^2{=}H$.

The ratio of isomers depends on the nature of the enyne system and the nature and number of halogen atoms in the *N*-halocarbamate.[69] Thus, *N*, *N*-dichlorocarbamates react with vinylacetylene to give mainly allene derivatives (70%, only 30% acetylene isomer is formed), while in the reaction with *N*-bromocarbamates the ratio of isomers is the reverse, which is due to steric factors.

Introduction of an alkyl substituent into the 1- or 4-positions of a vinylacetylene molecule mainly assists the formation of an acetylene derivative, while its introduction into the 2-position mainly gives an allene isomer. In fact, the acetylene isomer is the predominant product (95–100%) of the reaction between *N*-halocarbamate and 1-hexen-3-yne,[67] while in the reaction with 2-methyl-1-buten-3-yne (isopropenylacetylene) [67] the allene derivative is formed in 85–100% yield.

It has been suggested by Labeish and co-workers[67] that the addition of *N*, *N*-dichloro- and *N*-bromo-carbamates to conjugated alkenynes is a radical process which starts with attack by an amidyl radical on the terminal ethylene atom of the vinylacetylene molecule rather than attack by chlorine on the terminal carbon atom of the triple bond followed by an allene-acetylene rearrangement.

Reactions between *N*-monochlorocarbamates and acetylenic compounds are known. Reaction with 1-octyne gives the adduct $C_6H_{13}CCl=CHNHCOOC_2H_5$ (28%); $C_6H_{13}\underset{\underset{O}{\|}}{C}CH(NHCOOC_2H_5)_2$ is formed as a by-product (13%).[53]

It was recently established that phenylacetylene reacts exothermically under mild conditions with *N*, *N*-dichlorocarbamates, giving alkyl *N*-(2-chlorostyryl)-*N*-chlorocarbamates in 57–59% yield, which rearrange on standing to alkyl *N*-(1,2-dichlorostyryl)-carbamates [70,71]

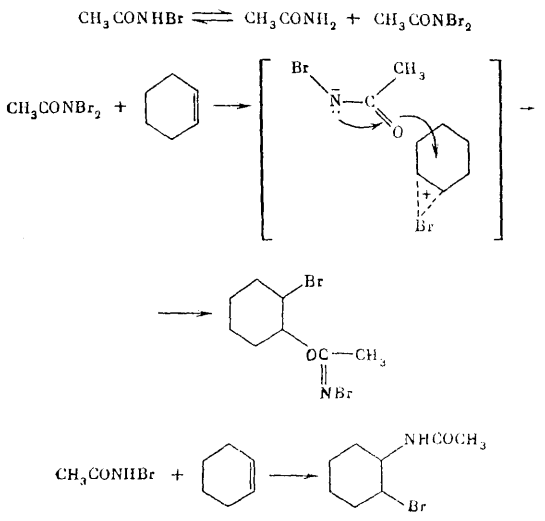
$$C_6H_5C{\equiv}CH + Cl_2NCOOAlk \rightarrow C_6H_5CCl{=}$$
$$- CHN(Cl)COOAlk \rightarrow C_6H_5CCl{=}CClNHCOOAlk,$$
$$Alk = CH_3,\ C_2H_5.$$

Phenylchloroacetylene (7–9%), *N*-monochlorocarbamate (6–8%), and a compound with a structure that the authors did not establish (24–30%) were isolated as by-products. Unfortunately, Bal'on and Moskaleva[70,71] did not specify any physicochemical constants for this compound in their study. When recent data[72–77] are taken into account, the product of unknown structure is probably a compound with an azomethine bond or a product derived from its subsequent conversion.

Thus, for the reactions of *N*-halo- and *N*, *N*-dihalo-carbamates with unsaturated compounds an induction period is typical; their acceleration in the presence of radical initiators (UV irradiation, peroxides, transition metal salts) and retardation by radical inhibitors as well as the lack of stereospecificity for addition indicate the radical nature of the reaction, which takes place according to the general scheme:

$$AlkOCONX^1X^2 \xrightarrow[-\dot{X}^2]{} AlkOCO\dot{N}X^1 \xrightarrow{>C=C<}$$
$$\rightarrow AlkOCONX^1{-}\overset{|}{\underset{|}{C}}{-}\dot{C}< \xrightarrow[-AlkOCO\dot{N}X^1]{AlkOCONX^1X^2} AlkOCONX^1{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}X^2,$$

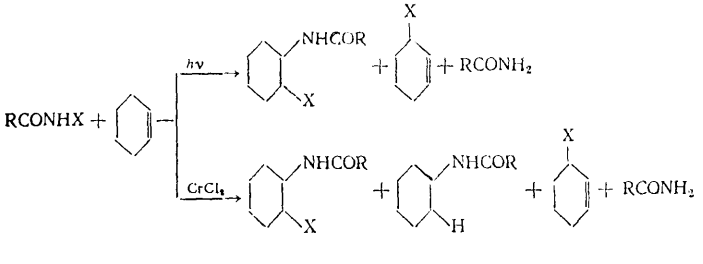
$X^1 = H,\ Cl,\ Br,\ Alk;\ X^2 = Cl,\ Br.$



Three studies[53,64,78] describe the mechanism of the reaction between *N*-halocarbamates and olefins in the presence of transition metal salts [CuCl, Cu, Cr(II)] in greater detail.

2. *N*-Halocarboxamides

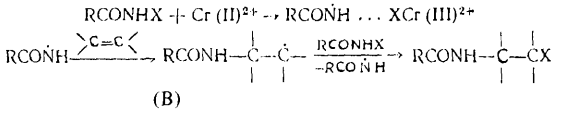
The addition of *N*-halocarboxamides to unsaturated compounds has been studied in the reactions of quite a large number of *N*-haloamides with cyclohexene and its derivatives,[24,53,55,56,79–83] 1-hexene, 3,3-dimethyl-1-butene,[82] 1-octene, 1-dodecene,[53,81] and also with cyclohexadiene and norbornadiene.[53,55,78]



The first known example of a photochemical reaction was the addition of *N*-bromoacetamide to cyclohexene, taking place on refluxing in CCl_4 and giving a low yield of adduct (1%).[79,83] Wolfe and Awang[79,83] maintained that in the main reaction *N*-monobromoacetamide was initially converted to *N*, *N*-dibromo-acetamide, which added on to the double bond of alkene according to

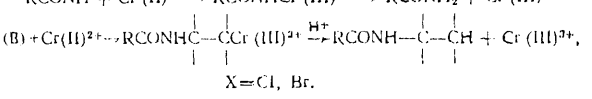
an ionic mechanism, giving *trans*-β-bromoalkyl-*N*-bromoacetimidate in 36% yield:

However, such results were isolated and were not confirmed by subsequent studies.



It was possible to carry out the addition of *N*-haloamides to unsaturated compounds both with UV irradiation[55,80,81] and in the presence of $CrCl_2$,[5,53,56,84] substituted adducts being formed in yields of up to 92%. In the case of the reaction of *N*-monohaloamides with cyclohexene a study was made of the dependence of the yield of reaction products on the conditions for carrying out the reaction and on the nature of the halogen atom and substituent R in monohaloamides:

With photochemical initiation the reaction took place in methylene chloride or a chloroform–methanol solution at 20° to −70 °C with a yield of *cis*- and *trans*-adducts of 25 to 99%,[5,55,80,81] in nitromethane the yield was 53%,[55] in benzene it was 42%,[55] while with catalytic initiation the reaction took place in a chloroform–methanol solution at −20 to −78 °C with a yield of isomeric adducts of 34 to 88%.[5,53,56,78]



The main competing reaction in the photochemical and catalytic interaction of amidyl radicals with cyclohexene is allylic halogenation, which gives 3-chlorocyclohexene, and *N*-monohaloamide is reduced to amide. One of the main factors that influences the occurrence of electrophilic halogenation is the reaction temperature. At 10–20 °C allylic halogenation is as high as 59%.[81] At lower temperatures (−70° to −78 °C) the formation of adducts is more favourable (64–97%).[55,81]

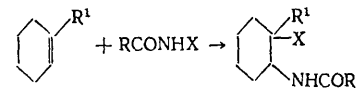
Driguez and co-workers[53,78] proposed that in allylic halogenation the hydrogen in cyclohexene is removed not by an amidyl radical, as was maintained previously,[85] but by a chlorine free radical. In order to confirm this hypothesis, a study was made of the reactions of *N*-monohaloamides with cyclohexene in the presence of chromium chloride in $CH_3OH-CHCl_3$, in which amidyl radicals were formed but there were no halogen free radicals:[5,24,53,56,78]

(B)

side reaction:

A competing process in these reactions, in addition to halogenation of the olefins, is the formation of 1-*H*-adducts by reduction of the adduct radical (B) with chromium(II) chloride.

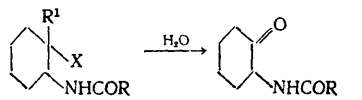
The nature of the halogen atom and substituents in *N*-haloamides RCONHX has a considerable effect on the yield of the reaction products. Thus, in photolysis there is an increase in yield of 1,2-adducts in the series of R: $(CH_3)_3C < n\text{-}C_3H_7 < C_2H_5 < CH_3 < CH_2CH_2Cl < CH_2Br < CH_2Cl < CH_2F < CHCl_2 < CCl_3 < CF_3$ ranging from 37 to 99% with the *cis*-adduct predominating (when X = Cl). Although the reaction of *N*-monobromamides occurs more rapidly (4–5.5 h) than with *N*-monochloramides (21–53 h), the yield of 1,2-adducts in the analogous series is considerably lower (from 25 to 84%).[55,80] The increase in the yield of adducts is due to a rise in electrophilicity of the amidyl radical RCONH when electronegative substituents R are introduced.



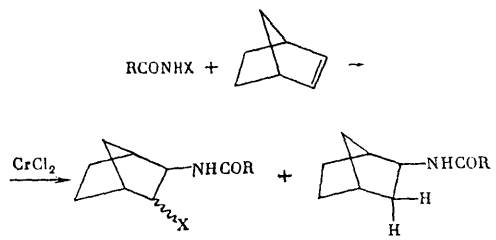
In the presence of chromium chloride when X = Cl, the yield of *cis*- and *trans*-1,2-adducts increases from 34 to 78% in the series of R: $CH_3 \leqslant NH_2 < CCl_3 < CH_2Cl < CF_3$ (there is 1.5–2 times as much *cis*-adduct present compared to *trans*-adduct), while the yield of 1-*H*-adducts, on the other hand, falls (from 36 to 2%).[53]

The effect of the structure of R on the yield of addition products when the reaction is catalysed by $CrCl_2$ is not significant in the case of *N*-monobromamides. Thus, in the reaction of cyclohexene with *N*-bromamides RCONHBr, the yield of 1,2-adducts varies from 66% to 74% with a change of substituents in the series: $CH_3(CH_2)_3 \leqslant CH_3 \leqslant CCl_3 < CH_2Cl$, and the ratio of *cis*- to *trans*-adducts is almost equimolar; the yield of 1-*H*-adducts is insignificant (~2%). In the reaction of bromamides RCONHBr (R = Alk), in contrast to chloramides, there is a side-reaction—electrophilic bromination.[53]

The effect of the length of the alkyl chain in *N*-monohaloamides RCONHX is shown principally with alkyl substituents containing more than four carbon atoms, since in this case addition of amidyl radicals to the double bond of alkene competes with intramolecular detachment of hydrogen in monohaloamides by a 1,5-shift, which gives γ-chloroalkylamides as chlorotropic rearrangement products:[85]



Photochemical and catalytic ($CrCl_2$) addition of amidyl radicals to the double bond occurs regiospecifically, as is suggested by the results of the reactions of 1-chloro-, 1-methyl-, 1-methoxy-, and 1-acetyl-cyclohexene with *N*-monohaloamides, which give a mixture of the *cis*- and *trans*-adducts with yields of 35 to 85%:[5,53,56,80]



$R=CH_3$, CH_2Cl, CF_3; $R^1=CH_3$, OCH_3, Cl, $COCH_3$.

Confirmation of this orientation of substituents in the adducts is also provided by the conversion of the latter on treatment with water to the corresponding ketones:[55]

$R=CH_2Cl$, CH_3; $R^1=Cl$, OCH_3; X=Cl, Br.

There is high regiospecificity in the reaction of *N*-monohaloamides RCONHX with 1-octene [53,81] and 1,1-diethoxyethylene [55] to form adducts $RCONHCR^1(R^2)CH_2X$ ($R^1 = C_6H_{13}$, $R^2 = H$, $R^1 = R^2 = OC_2H_5$) in 80–92% yield. An adduct with norbornene is also formed in high yield (88–91%), but in a number of cases, namely, in the reaction of the *N*-monochloramide of acetic and monochloroacetic acids with this alkene the yield of 1-*H*-adducts (55 and 93%) is greater than the yield of 1,2-adducts (2 and 33%):[53]

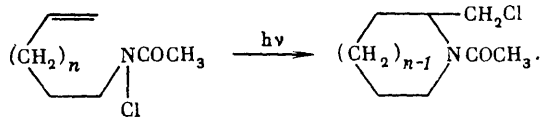
cis, trans

R = CH_3, CH_2Cl; X=Cl, Br.

By studying the reaction of *N*-halocarboxamides with alkenes, the effect of the alkyl substituents on the nitrogen atom has been established. Like *N*-alkyl-*N*-halocarbamates, *N*-alkyl-*N*-halocarboxamides are inert towards reaction with olefins. Thus, attempts to add on the *N*-methyl-*N*-chloramides of acetic and monochloroacetic acids to cyclohexene have proved unsuccessful even with UV irradiation and at a temperature of 20 to −70 °C; in this case only chlorination of cyclohexene and conversion of the *N*-methyl-*N*-chloramides $RCON(CH_3)Cl$ to the corresponding amides occurred (yield 96–98%).[58,81] Exceptions to this were the reactions of *N*-methyl-, *N*-ethyl-, and *N*-chloroacetyl-*N*-chloroacetamides with 1-octene, norbornene, and 1-dodecene, which were initiated by UV irradiation at 20 to −70 °C. Although the main products were the corresponding amides (up to 87%), the 1,2-adducts were however formed in low yield.[55,81] It was only possible to achieve a higher yield of adducts (70–71%) in the reaction of *N*-methyl-*N*-chlorotrifluoroacetylamide with 1-dodecene.[55] It transpired that introduction of electronegative substituents on to the nitrogen atom helped to increase the reactivity of the amidyl radicals. Thus, it was possible to carry out the addition of *N*-acyl-*N*-chloroacetamide to cyclohexene with UV irradiation in CH_2Cl_2 (15–20 °C), although with an insufficiently high yield of adduct (24%).[58]

Cyclic *N*-haloamides are characterised by a fairly high reactivity. In the photochemical initiation of the reaction between *N*-halosuccinimides and ethylene, 3,3-dimethyl-1-butene,[86,87] styrene,[86] 1-octene,[58] and cyclohexene and 1-methylcyclohexene [58] in CH_2Cl_2 or CCl_4 (15–20 °C), adducts are formed with yields ranging from low (16–22%) to high (80%), and the yield for *N*-bromo derivatives is 1.5–2 times lower than with the corresponding chloro derivatives. High yields of adducts (60–85%) were obtained in the photochemical reaction of *N*-bromosuccinimide with 3,3-dimethyl-1-butene and 1-hexene in a mixture of acetonitrile and ethylene oxide at −10 °C.

Finally, there are some individual examples in the study of the reactivity of *N*,*N*-dihalocarboxamides in reactions with unsaturated compounds.



In contrast to monohaloamides, *N*,*N*-dichlorobenzamides are known to react with styrene without secondary processes, forming *N*-(2-chloro-2-phenylethyl)arenamides in high yield (75–92%).[88]

It was possible to react *N*,*N*-dichlorobenzamide with phenylacetylene, resulting in the formation of a mixture of products: *N*-(1,2-dichlorostyryl)benzamide (I) (68.5%) and 1,1-dichloro-1-phenyl-2,2-di(benzoylamino)ethane (II) (12.7%):[89]

$$C_6H_5C{\equiv}CH + Cl_2NCOC_6H_5 \rightarrow$$
$$\rightarrow \underset{\text{(I)}}{C_6H_5CCl{=}CClNHCOC_6H_5} + \underset{\text{(II)}}{C_6H_5CCl_2CH(NHCOC_6H_5)_2}.$$

Unfortunately, the authors did not suggest possible routes for the formation of these compounds.

It is also interesting to note reactions involving intramolecular addition to the double bond in olefinic *N*-haloamides of the type:

These reactions take place with UV irradiation and give various cyclic compounds.[5] A number of studies[90–93] have been devoted to reactions of this type and so they are not examined in detail in the present review. We should also note the tendency of *N*-haloamides RCONHHal with three or more methylene groups to undergo a Hofmann–Löffler rearrangement,[85,94] while *N*-alkyl-*N*-chloramides $RCONR^1Cl$ with alkyl substituents on the nitrogen atom (t-butyl, 1,1-dimethyl-2-phenylethyl, 1,1-dimethylpentyl) tend to undergo intramolecular rearrangements with UV irradiation (20 °C) with migration of the chlorine atom to the alkyl substituent R^1 and formation of *N*-(chloroalkyl)amides, which are readily cyclised on heating to oxazoline and pyrrolidine derivatives.[95,96]

3. *N*-Halosulphonamides

In *N*-halosulphonamides the nitrogen-halogen bond is susceptible to both homolytic and heterolytic cleavage, so that it is possible under different reaction conditions to obtain from *N*,*N*-dihalosulphonamides and alkenes various structural forms of β-haloalkylsulphonamides, which are intermediates in the synthesis of aziridines.[97-99]

The first study in which it was found to be possible to add on *N*-halosulphonamides to the double bond of unsaturated compounds was published in 1930.[1] Several years later, in 1937–38, a series of studies appeared,[100-103] in which in the course of seeking new methods for the chloroalkoxylation of olefins in order to obtain β-chloroethers it was found that when *N*,*N*-dichlorosulphonamides react with alkenes in the presence of phenols,[100] alcohols,[101,102] or carboxylic acids,[103] *N*-(β-chloroalkyl)arenesulphonamides are formed together with β-chloroethers.

At the present time it is established that addition of *N*,*N*-dichloro- and *N*-chloro-*N*-methyl-ethanesulphonamide to terminal alkenes such as 1-hexene, 1-butene, 1-octene, and 1-dodecene takes place with the formation of saturated adducts, the structure of which depends on the initiation conditions.[104,105]

Under conditions where radicals are formed (UV irradiation) the sulphonamide residue adds on to the terminal carbon atom according to the scheme:

$$C_2H_5SO_2NClR \xrightarrow[-Cl^{\cdot}]{} C_2H_5SO_2\dot{N}R \xrightarrow{R^1CH=CH_2}$$

$$\rightarrow C_2H_5SO_2N(R)CH_2\dot{C}HR^1 \xrightarrow[-C_2H_5SO_2\dot{N}R]{C_2H_5SO_2NClR} C_2H_5SO_2N(R)CH_2CH(Cl)R^1,$$

$R=Cl,\ CH_3;\ R^1=C_2H_5,\ C_4H_9,\ CH_3(CH_2)_3,\ CH_3(CH_2)_5,\ CH_3(CH_2)_{10}.$

These reactions are inhibited by oxygen, which also confirms their radical character.

It is interesting to note that with more prolonged UV irradiation the adduct of *N*,*N*-dichloroethanesulphonamide with 1-hexene undergoes a free-radical rearrangement with 1,5-migration of hydrogen to give *N*-(2,4-dichlorohexyl)ethanesulphonamide.[104,105]

Under ionic conditions for initiating the reactions of *N*,*N*-dichloro-substituted arene- and ethane-sulphonamides with 1-hexene, the direction of addition changes, and the reactions lead to the adducts $RCH(NHSO_2C_2H_5)CH_2Cl$.[104,106] A similar direction of addition occurs in the reactions of *N*,*N*-dibromoarenesulphonamides with acyclic alkenes of known stereochemistry—*cis*- and *trans*-3-hexene, *cis*-2-heptene, *cis*-5-decene, and *cis*- and *trans*-9-octadecene; in this case *N*-bromo-*N*-(2-bromo-1,2-dialkylethyl)arenesulphonamides are formed as adducts in 42–70% yield.[107]

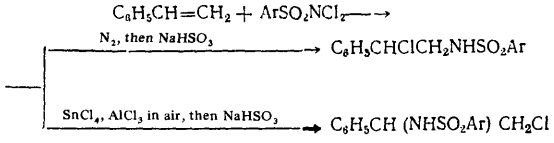
The mechanism of this reaction involves the formation of a bromonium ion:

$$ArSO_2NBr_2 + \rangle C{=}C\langle \rightarrow \rangle \overset{Br^+}{C{-}C}\langle + ArSO_2\bar{N}Br \rightarrow$$

$$\rightarrow ArSO_2NBrC{-}CBr$$

This type of mechanism dictates the high stereoselectivity of the process. In fact, as a result of the addition of *N*,*N*-dibromoarenesulphonamides to a *cis*-alkene, an adduct with a *threo*-configuration is obtained, while for reaction with a *trans*-alkene, the adduct has an *erythro*-configuration.[107] It was shown that the yield of adducts in heterolytic reactions of *N*,*N*-dibromoarenesulphonamides with aliphatic alkenes depends on the structure of alkene. Thus, with long-chain alkenes (*cis*- and *trans*-octadecene) the yield of adducts is considerably lower (38–42%) than with C_6 and C_7 alkenes (75 to 80%).[107] With a tertiary alkene (2,3-dimethyl-1-butene) the yield of adduct is only 16%, with a secondary alkene (isobutene) it is 22%,[108] and with 2-butene it increases to 61%,[109] which is due to the effect of steric factors on attack by the amidyl anion on the bromonium ion.

The effect of the substituents on the nitrogen atom in sulphonamides on the yield of adducts during heterolytic reaction should also be noted. The reactions of *N*,*N*-dibromo- and *N*-bromo-*N*-alkyl-substituted arenesulphonamides with alkenes (2-butene and isobutene) take place with a higher yield of adducts.[109,110] In the reactions of the *N*-chloro derivatives, chlorination of the alkenes is preferred, and adducts are only isolated in low yield (10%).[111]



A number of studies by Japanese research workers are devoted to the reactions of *N*,*N*-dihaloarenesulphonamides with cyclohexene [112-116] and cyclopentene.[117] These reactions, as for the addition of *N*,*N*-dihalocarbamates to cyclic alkenes, are stereoselective and take place mainly as a *trans*-addition with the formation of 1 : 1 adducts (yield 50–96%). *cis*-Adducts are also formed, but in low yield. Moreover, reactions with cyclic alkenes are accompanied by side-reactions—halogenation of the double bond of alkene, allylic halogenation, oxidation of cyclohexene to 1-cyclohexen-3-one, and also dehydrogenation of the cycloalkene to a 1,3-cycloalkadiene (with a substantial yield—49%).[112-117]

It is interesting that *N*-bromo-*N*-alkylsulphonamides, by analogy with *N*-bromo-*N*-alkylcarbamates, do not add on to the double bond of cyclohexene but behave as brominating agents.[114] The inertness of *N*-bromo-*N*-alkyl-substituted amides in addition reactions to the double bond of alkenes is probably due to a decrease in electrophilicity of *N*-alkyl-substituted amidyl radicals.

The possibility of heterolytic bromosulphonamidation of cyclic alkenes has been shown for the reactions of *N*-bromosulphonamides with bicyclic alkenes such as bicyclo[2.2.1]heptene, bicyclo[2.2.2]-octene, and *endo*-bicyclo[2.2.1]-5-hepten-2,3-dicarboxyanhydride. The reactions are exothermic and stereoselective and involve the formation of a bromonium ion or a bridgehead carbocation.[118] The yields of 1 : 1 adducts in these reactions, however, are low, the main products being brominated bicycloalkenes.

In contrast to the reactions of aliphatic alkenes, reactions of styrene and its derivatives with *N*,*N*-dichloroalkane-, *N*,*N*-dichloroarene-, and *N*,*N*-dichloro-*N*^{1}-dimethyl-sulphonamides take place with virtually no side reactions and they give the saturated adducts $4\text{-X-}C_6H_4CCl(R^1)CH(R^2)NClSO_2R$ [R = Ar, Alk, $R^1 = R^2 = H$, X = H; R = $(CH_3)_2N$, R^1 = H, C_6H_5, R^2 = H, X = H, *p*-CH_3O] in high yield.[99,106,111,119] The reactions occur readily under mild conditions in chloroform or methyl chloride on cooling[111,119] or in benzene at 20–22 °C in an atmosphere of nitrogen,[106] most frequently exothermically. It was shown that these reactions are considerably accelerated by UV irradiation, with the yields of adducts being almost quantitative. Subsituents at the α- and β-positions of styrene do not have any substantial effect on the yield of adducts. The reactions with both styrene (yield 85–96%) [106] and α-phenylstyrene (85%) or 1-*p*-methoxyphenyl-propene [119] occur with equal ease. Meanwhile, the direction of addition of *N*,*N*-chloroarenesulphonamides to styrene changes

if the reaction is carried out in air in the presence of Lewis acids:[106,111,120,121]

It is interesting that not only the initiation conditions but also the nature of the halogen atom in the sulphonamide affect the direction of addition of *N,N*-dihalosulphonamides to styrene and its analogues. Thus, in contrast to *N,N*-dichlorosulphonamides, *N,N*-dibromosulphonamides add on to styrene,[107,110,116] α-methylstyrene,[98] and propenylbenzenes 3-R-4-$R^1C_6H_3CH=CHCH_3$ (R = H, OMe; R^1 = H, OMe, OBz; RR^1 = OCH_2O [122-123]) with attachment of the amidyl fragment to the more substituted carbon atom of the double bond in these alkenes. *N*-Bromo-*N*-alkyl-substituted sulphonamides add on to styrene in the same direction.

Chlorosulphonamidation of alkanes which contain electron-withdrawing groups on the double bond has been studied in the case of reactions with allyl chloride,[99,120,124] 1,1,1-trichloropropene,[125] and acrylates;[98,108,124,126] they take place with the formation of adducts $ArSO_2NClCH_2CHClR$ (R = CH_2Cl, CCl_3, CN, $CONH_2$, $COOCH_3$).

It has been established that the use of radical initiators considerably accelerates these reactions. Thus, the reaction of allyl chloride with *N,N*-dichloro-*p*-chlorobenzenesulphonamide takes place on heating in CCl_4 (75–80 °C) for 5 h, while in the presence of $(C_6H_{11}OCO_2)_2$ or $(C_6H_5OCO)_2$ only 1.5 h is needed and the yield of the adduct p-$ClC_6H_4SO_2NHCH_2CHClCH_2Cl$ increases from 75% to 93%.[120,124] Another example is the addition of *N,N*-dichloroarenesulphonamides to acrylonitrile, which is complete after 30 h without a catalyst to give a 51% yield of the adduct $C_6H_5SO_2NHCH_2CHClCN$,[98] while with initiation by $(C_6H_{11}OCO)_2$ only 1.5 h is needed and the yield is 84%.[124]

An initiation system such as a mixture of a univalent copper salt and tetraethylammonium bromide has proved effective.[126] When using it, the time of reaction of *N,N*-dichloroarenesulphonamides with acrylates $XCH=CH_2$ could be reduced to 40 min and the yield of adducts $ArSO_2NHCH_2CHClX$ could be increased to 95% (X = CN), 86% (X = $COOCH_3$), or 88% (X = $CONH_2$). The low redox potential of the system $Cu^0 \rightleftarrows Cu^+ \rightleftarrows Cu^{2+}$ favours these reactions involving copper or its univalent salt both at the initiation stage and in chain propagation, thereby increasing the yield of adducts.

N,N-Dibromoarenesulphonamides add on to acrylates in a similar manner to give 1:1 or 1:2 adducts, depending on the ratio of reactants.[108]

An alkene with a trichloromethyl group on the double bond (1,1,1-trichloropropene) during homolytic initiation forms adducts $ArSO_2NHCH_2CHClCCl_3$ in 60–63% yield.[125] Under initiation conditions for formation of ions (in the presence of $SnCl_4$, in air), adducts of the same structure are formed (yield 18–70%), which is in line with the usual principles for electrophilic addition to unsaturated compounds that contain electron-withdrawing substituents on the double bond.[125]

Finally, the reactions of *N,N*-dichloroarenesulphonamides with polyhaloethylenes (vinylidene chloride[120] and 1,1,3-chloropropene[97]) deserve special consideration. A characteristic feature of these reactions is that the direction of addition does not depend on the initiation conditions as was the case for other alkenes.[104,106] The reaction takes place with the same ease both in an inert medium in the presence of peroxides and in air in the presence of $AlCl_3$, with adducts formed in high yield (up to 97%):

$$ArSO_2NCl_2 + CCl_2=CHR \rightarrow ArSO_2NClCHRCCl_3,$$
$$R=H,\ CH_2Cl;\ Ar=C_6H_5,\ p\text{-}ClC_6H_4.$$

In continuing our investigation of the free-radical reactions of halogenated derivatives of ethylene, we have studied for the first time the reactions of 2,2-dichlorovinyl acylates, 2,2-dichlorovinylketones, *N*-(2,2-dichlorovinyl)carboxamides, and 2,2-dichlorovinyl ethers with *N,N*-dichlorosulphonamides.[127-132] Free-radical additions to the double bond were not known for these compounds. Moreover, the reactions of *N,N*-dichloroarenesulphonamides with functional derivatives of 2,2-dichloroethylene attracted our interest as a method for obtaining the previously unknown trichloroethyl derivatives of arenesulphonamides of the type $ArSO_2NHCH(R)CCl_3$, which are biologically active compounds with future potential:

$$ArSO_2NCl_2 + CCl_2=CHR \rightarrow ArSO_2NClCH(R)CCl_3 \rightarrow ArSO_2NHCH(R)CCl_3,$$
$$Ar = C_6H_5,\ p\text{-}CH_3C_6H_4,\ p\text{-}ClC_6H_4;\ R = OCOCH_3,\ NHCOAr^1,\ COR^1,\ OAlk.$$

The reaction of *N,N*-dichloroarenesulphonamides with 2,2-dichlorovinyl acetate is the first example of a free-radical addition to the double bond of this compound. The reaction occurs readily when there is a twofold excess of dichlorovinyl acetate, which also serves as the solvent, and leads to adducts in 90–97% yield.[127,128]

A high regiospecificity for addition was recorded in the reaction of 2,2-dichlorovinylamides with *N,N*-dichloroarenesulphonamides; the adducts were isolated with yields up to 95%.[128,129] It was of particular significance that this reaction showed for the first time the possibility of the enamide tautomeric form of 2,2-dichlorovinylamides participating in free-radical addition reactions to the double bond.

The reaction of 2,2-dichlorovinyl ketones and 2,2-dichlorovinyl ethers with *N,N*-dichlorobenzenesulphonamide is complicated by a side-reaction—reduction of the dichlorosulphonamide to a benzenesulphonamide in about 30–40% yield.[130,131] The high activity of the N–Cl bond in the adducts should be noted; it is very readily converted to an N–H bond even in air and *N*-(2,2,2-trichloro-1-R-ethyl)benzenesulphonamides are formed in about 75% yield.[130,131]

The reactions of functional derivatives of vinylidene chloride with *N,N*-dichloroarenesulphonamides have an induction period, and they are inhibited in the presence of hydroquinone, which is confirmation of their free-radical nature:

$$ArSO_2NCl_2 \xrightarrow[-Cl]{} ArSO_2\dot{N}Cl \xrightarrow{CCl_2=CHR} \rightarrow \dot{C}Cl_2CH(R)NClSO_2Ar \xrightarrow{ArSO_2NCl_2} \rightarrow$$
$$(C)$$
$$\rightarrow CCl_3CH(R)NClSO_2Ar \rightarrow CCl_3CH(R)NHSO_2Ar,$$
$$R=OCOCH_3,\ NHCOAr,\ COR^1,\ OAlk.$$

A characteristic feature of these reactions is that the addition is highly regiospecific. This is due to polar effects of the substituents in the amidyl radical $ArSO_2\dot{N}Cl$ and the vinylidene chloride

derivative and to steric hindrance which would occur if the amidyl radical attacked the β-carbon atom in molecules of the substituted vinylidene chloride derivatives $CCl_2=CHR$ to form the radical $ArSO_2NClCCl_2\dot{C}HR$ (D). The driving force of the reaction would appear to be the formation of the more stable radical (C).

A study has been made of the addition of *N,N*-dichloroarenesulphonamides to dienes that takes place exothermically under mild conditions (−10 °C) at the 1,4-position with a high yield of adducts (77–88%):[111]

$$CH_2=C(R)CH=CH_2 + R^1SO_2NCl_2 \xrightarrow{NaHSO_3} R^1SO_2NHCH_2C(R)=CHCH_2Cl,$$
$$R=H,\ Cl;\ R^1=C_6H_5,\ p\text{-}ClC_6H_4,\ CH_3,\ (CH_3)_2N.$$

Yamasaki and co-workers[68] have shown that the reactions of *N,N*-dihalosulphonamides with 1,5-hexadiene, 1,4-pentadiene, 1,4-diphenyl-1,3-butadiene, and 1,4-cyclohexadiene are not regiospecific and 1 : 1 and 1 : 2 adducts of 1,2- and 1,4-addition are formed. The yields of these compounds, however, are low—only 2–21.3%.

The reactivity of *N,N*-dihaloarenesulphonamides in reactions with alkenynes, resulting in the formation of allene and acetylene isomers, was studied in the case of reactions with vinylacetylene, isopropenylacetylene, and vinylethylacetylene:[133]

$$R^1C\equiv C-CR^2=CH_2 + n\text{-}ClC_6H_4SO_2NCl_2 \xrightarrow{\text{then } NaHSO_3}$$
$$\xrightarrow{1,2-} R^1C\equiv C-C(R^2)ClCH_2NHSO_2C_6H_4Cl\text{-}p$$
$$\xrightarrow{1,4-} R^1CCl=C=CR^2CH_2NHSO_2C_6H_4Cl\text{-}p$$
$$R^1=R^2=H;\ R^1=C_2H_5,\ R^2=H;\ R^1=H,\ R^2=CH_3.$$

It has been established that the direction of addition of *N,N*-dichloro-*p*-chlorobenzenesulphonamide to conjugated vinylacetylenes is similar to that which occurs in the reactions of *N,N*-dihalocarbamates with alkenynes [67] and is determined by the structure of the alkenyne, in other words, when an alkyl substituent is introduced into the 2-position of a vinylacetylene molecule (isopropenylacetylene) the 1,4-adduct is mainly formed (allene isomer), while introduction into the 4-position gives an acetylene isomer. A distinctive feature of the reaction of *N,N*-dichloro-*p*-chlorobenzenesulphonamide with 5,5-dimethyl-1-hexen-3-yne is the absence of a 1,4-adduct—only the acetylene derivative $CH_3C(CH_3)_2C\equiv CCHClCH_2NClSO_2C_6H_4Cl\text{-}p$ is isolated—while in the reaction with an unsubstituted alkenyne (vinylacetylene) the allene isomer predominates (ratio of 1,4- to 1,2-adducts is 2 : 1).[133] In the case of *N,N*-dibromo-*p*-chlorobenzenesulphonamide only the reaction with hexen-3-yne was studied and, in contrast to the analogous reaction of *N,N*-dichloroarenesulphonamides and *N,N*-dihalocarbamates, the main product in this reaction is the dibromide of the 1,2-adduct; the 1,2-adduct is also formed, but in low yield:[133]

$$C_2H_5C\equiv C-CH=CH_2 + p\text{-}ClC_6H_4SO_2NBr_2 \xrightarrow{\text{then } NaHSO_3}$$
$$\longrightarrow C_2H_5CBr=CBr-CHBrCH_2NHSO_2C_6H_4Cl\text{-}p$$
$$\longrightarrow C_2H_5C\equiv C-CHBrCH_2NHSO_2C_6H_4Cl\text{-}p$$

N,N-Dichloroarenesulphonamides also add on to organosilicon derivatives of vinylacetylene such as 1-trimethylsilyl-3-buten-1-yne, 1-trimethylsilyl-3-penten-1-yne, 1-trimethylsilyl-3-methyl-3-buten-1-yne [134–138] both at the 1,2- and 1,4-positions to give allene and acetylene isomers, the ratio of which is determined by the structure of the alkenyne. Thus, in the reaction with 1-trimethylsilyl-3-buten-1-yne the 1,2-adduct is mainly formed, while with an alkenyne containing alkyl substituents on the double bond (1-trimethylsilyl-3-penten-1-yne) the 1,4 adduct is mainly formed:

$$(CH_3)_3SiC\equiv CCR^1=CHR^2 + ArSO_2NCl_2 \rightarrow$$
$$\xrightarrow{1,2-} (CH_3)_3SiC\equiv CCClR^1CHR^2NClSO_2Ar$$
$$\xrightarrow{1,4-} (CH_3)_3SiCCl=C=CR^1CHR^2NClSO_2Ar$$
$$R^1=R^2=H;\ R^1=H,\ R^2=CH_3;\ R^1=CH_3,\ R^2=H.$$

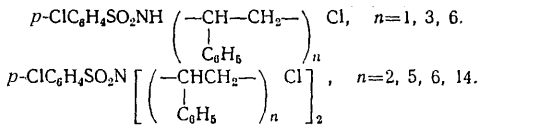
1,2-Adducts and 1,4-adducts tend to undergo allene-acetylene isomerisation. Their reduction with $NaHSO_3$ is also accompanied by allene-acetylene isomerisation. The triple bond of organosilicon vinylacetylene remains inert towards the addition of *N,N*-dichlorosulphonamides.

A characteristic feature of the reactions of *N,N*-dihalosulphonamides with carbon and organosilicon alkenynes is the induction period, which is an indication of the free-radical nature of the course of these reactions. In all cases attack by the amidyl radical is directed at a carbon atom on the double bond with formation of the most stable adduct radicals.[133,134]

In a single study,[139] where the reaction of *N,N*-dichloro-*p*-chlorobenzenesulphonamide with phenylacetylene was investigated, the formation of an azomethine in 66.7% yield was recorded; in this case a saturated adduct was isolated in low yield (5%):

$$C_6H_5C\equiv CH + Cl_2NSO_2C_6H_4Cl\text{-}p \rightarrow C_6H_5CCl=CHNClSO_2C_6H_4Cl\text{-}p \rightarrow$$
(E)
$$\xrightarrow{NaHSO_3} C_6H_5CCl=CHNHSO_2C_6H_4Cl\text{-}p$$
$$\longrightarrow C_6H_5CCl_2CH=NSO_2C_6H_4Cl\text{-}p$$

The authors attribute the formation of an azomethine to an intramolecular 1,3-migration of chlorine in the initial adduct (E).



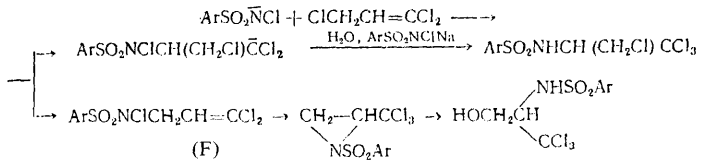
(a) Dichloroarenesulphonamides in telomerisation reactions

Finally, it was established that *N,N*-dichloroarenesulphonamides are initiators for the telomerisation of alkenes. Thus, Freidlina and co-workers[124] carried out the radical telomerisation of allyl chloride and acrylonitrile with *N,N*-dichloroarenesulphonamide to form the telomers $p\text{-}ClC_6H_4SO_2N(X)(-CH_2-\underset{\displaystyle R}{\underset{|}{CH}}-)_nCl$ (X = H, Cl; R = CN, CH_2Cl; *n* = 1, 2).

The radical nature of these reactions is borne out by their significant acceleration on exposure to UV radiation and in the presence of peroxides. It was shown that with an increase in the ratio of acrylonitrile to *N,N*-dichloro-*p*-chlorobenzenesulphonamide the yield of lower telomers decreases and the yield of higher telomers (*n* > 3) increases.[140]

The ionic telomerisation of styrene with *N,N*-dichloro-*p*-chlorobenzenesulphonamide occurs in the presence of $SnCl_4$ in methylene

chloride in air,[141] telomers with the following composition being formed:



p-$ClC_6H_4SO_2NH$ $\left(-CH(C_6H_5)-CH_2-\right)_n$ Cl, n=1, 3, 6.

p-$ClC_6H_4SO_2N\left[\left(-CHCH_2(C_6H_5)-\right)_n Cl\right]_2$, n=2, 5, 6, 14.

(b) Nucleophilic addition of *N*-chloro-*N*-sodium arenesulphonamides to alkenes

There are several known examples of the nucleophilic addition of *N*-chloro-*N*-sodium arenesulphonamides to alkenes such as 1,1,3-trichloropropene,[142] 3,3,3-trichloropropene,[143], allyl chloride,[144] and acrylonitrile.[144]

Thus, the reaction with 1,1,3-trichloropropene in an aqueous medium mainly gave 1,3,3,3-tetrachloro-2-(arenesulphonamido)-propane (28–49%); this indicates the greater readiness of *N*-chloro-*N*-sodium arenesulphonamides to add on to the dichlorovinyl group of 1,1,3-trichloropropene than to replace the allylic chlorine in this compound:

$ArSO_2\bar{N}Cl + ClCH_2CH{=}CCl_2 \longrightarrow$

$\rightarrow ArSO_2NClCH(CH_2Cl)\bar{C}Cl_2 \xrightarrow{H_2O,\ ArSO_2NClNa} ArSO_2NHCH(CH_2Cl)CCl_3$

$\rightarrow ArSO_2NClCH_2CH{=}CCl_2 \rightarrow CH_2(NSO_2Ar)CHCl_2 \rightarrow HOCH_2CH(NHSO_2Ar)CCl_3$

(F)

Ar=C_6H_5, p-ClC_6H_4.

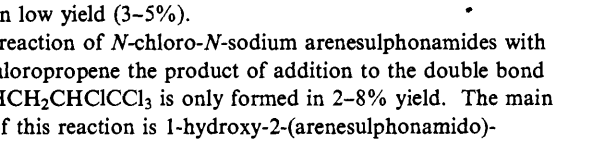
The dichlorovinyl derivative (F) was not isolated pure, since its intramolecular cyclisation to an aziridine took place. Hydrolysis of the latter gave 1-hydroxo-2-(arenesulphonamido)-3,3,3-trichloropropane in low yield (3–5%).

In the reaction of *N*-chloro-*N*-sodium arenesulphonamides with 3,3,3-trichloropropene the product of addition to the double bond $ArSO_2NHCH_2CHClCCl_3$ is only formed in 2–8% yield. The main product of this reaction is 1-hydroxy-2-(arenesulphonamido)-3,3,3-trichloropropane (37–51%), which, as Rybakova and co-workers[143,144] suggest, is formed by migration of the reaction centre when the amidyl anion attacks the terminal carbon atom of the alkene to form the unstable compound (F) and its subsequent conversion during reaction in a similar manner to the scheme suggested above.

In contrast to the reactions mentioned above, chlorosulphonamidation of allyl chloride mainly occurs via substitution of the allylic chlorine to form *N*-chloro-*N*-allyl-*p*-chlorobenzenesulphonamide (about 50%). The competing nucleophilic addition to the double bond does not occur to any significant extent.[144]

The reaction of *N*-chloro-*N*-sodium-*p*-chlorobenzenesulphonamide with a two- or three-fold excess of acrylonitrile in an aqueous medium takes place as a cyanoethylation reaction and *N*,*N*-di(2-cyanoethyl)-*p*-chlorobenzenesulphonamide is formed with a yield of about 61%.[144]

The reaction studied in the greatest detail has been that between the sodium salt of *N*-chloro-*p*-toluenesulphonamide and alkenes (cyclohexene, methylcyclohexene, cyclooctene, norbornene, 1-dodecene, 5-dodecene, 2-methyl-2-hexene, styrene and its derivatives, acrylates, cyclohexadiene, etc.),[145–148] which occurs in an alcoholic medium (60 °C) in the presence of OsO_4 and results in the formation of hydroxyalkyl derivatives of sulphonamides with fairly high yields:



p-$CH_3C_6H_4SO_2NClNa \cdot 3H_2O + RCH{=}CHR^1 \xrightarrow[t\text{-}C_4H_9OH,\ 60\,^\circ C]{1\%\ OsO_4} p$-$CH_3C_6H_4SO_2NHCH(R)—CH(OH)R^1 + NaCl.$

Unfortunately, the number of studies on the reaction of *N*-halo-*N*-sodium arenesulphonamides are not sufficient to make any conclusions about the general mechanisms for these reactions.

Thus, analysis of the literature data on the reactions of *N*-halo- and *N*,*N*-dihalosulphonamides with unsaturated compounds has shown that these reactions take place, depending on the initiation conditions, by homolytic and heterolytic cleavage of the N—Hal bond to form *N*-haloalkyl-substituted sulphonamides, which are important intermediates for the synthesis of aziridines.[97–99,149] *N*-Halosulphonamides add on to functional derivatives of vinylidene chloride $CCl_2{=}CHR$ (R = H, $COOCH_3$, NHCOAr, COAlk, COAr, OR^1), dienes, and vinylacetylenes only according to a radical mechanism, as is suggested by the acceleration of these reactions in the presence of radical initiators and their inhibition in the presence of hydroquinone or atmospheric oxygen.

4. *N*,*N*-Dihalophosphoramidates

The addition of *N*,*N*-dihalophosphoramidates to alkenes has been studied in the case of reactions with ethylene,[150] hexene,[150] 2-ethyl-1-hexene,[150,151] 2-ethyl-1-butene, isobutene, 1-octene,[150,152,153] and styrene.[154–158] In the majority of cases the reactions have an induction period when exposed to UV radiation and on heating in benzene or carbon tetrachloride, and they are regiospecific, with the adducts formed in high yield (70–97%):

$(RO)_2P(O)NX_2 + CH_2{=}CHR^1 \rightarrow (RO)_2P(O)NXCH_2CHR^1X \xrightarrow{NaHSO_3}$

$\rightarrow (RO)_2P(O)NHCH_2CHR^1X \xrightarrow[0\text{–}10\,^\circ C]{HHal} NH_2CH_2CHR^1X,$

X=Cl, Ar; R=C_2H_5, C_3H_7, iso-C_3H_7, C_4H_9, C_6H_5, R^1=C_6H_5;

R=C_2H_5, R^1=H, C_3H_7, C_4H_9, C_5H_{11}, n-C_6H_{13}, t-C_4H_9.

Confirmation of the orientation of the substituents in the adducts, namely, attachment of the amidyl fragment to the less substituted carbon atom of the alkene double bond is the conversion of dialkyl *N*-[2-halo-2-alkyl(phenyl)ethyl]phosphoramidate to the hydrochloride or hydrobromide salts of 2-halo-2-alkyl(phenyl)ethylamine by treatment with hydrogen chloride or bromide.

Addition of *N*,*N*-dibromophosphoramidates to long-chain terminal alkenes $RCH{=}CH_2$ (R = t-C_3H_7, t-C_4H_9, C_4H_9, C_6H_{13}), in contrast to the reactions of the chloro analogues, is complicated by side-reactions involving bromination of alkenes, which reduces the yield of the adducts.[159]

Formation of adducts $PhCCl(R)CH(R^1)NHP(O)(OC_2H_5)_2$ occurs in the reaction of diethyl *N*,*N*-dichlorophosphoramidate with phenylethylenes $Ph(R)C{=}CHR^1$, where R and R^1 = CH_3, Ph.[160]

In order to carry out the reactions of diethyl dihalophosphoramidates with alkyl esters of α,β-unsaturated carboxylic acids,[150,157,158] more prolonged UV irradiation (3–4 h) is required. The addition is

regiospecific, and adducts are formed in high yield:

$$R^1CH{=}C(R^2)COOR^3 + (C_2H_5O)_2P(O)NX_2 \xrightarrow{h\nu} \rightarrow (C_2H_5O)_2P(O)NXCH(R^1)CX(R^2)COOR^3 \xrightarrow{NaHSO_3,\ 0-5^\circ C} (C_2H_5O)_2P(O)NHCH(R^1)CX(R^2)COOR^3,$$

$X{=}Cl,\ Br;\ R^1{=}R^2{=}H,\ R^3{=}C_2H_5;\ R^1{=}H,\ R^2{=}R^3{=}CH_3;$
$R^1{=}R^3{=}CH_3,\ R^2{=}H.$

In contrast to the chloro analogues, diethyl *N,N*-dibromophosphoramidate [157] adds on to these olefins more readily (at 20–45 °C) and with a quantitative yield of adducts.

The occurrence of an induction period, acceleration of the reactions by UV irradiation, and also the regiospecificity in addition of *N,N*-dihalophosphoramidates to terminal $RCH{=}CH_2$ and α,β-substituted alkenes $R^1CH{=}C(R^2)COOR^3$ are indications of the radical nature of the addition taking place according to the scheme:

$$(RO)_2P(O)NX_2 \xrightarrow[-\dot{X}]{h\nu,\Delta} (RO)_2P(O)\dot{N}X \xrightarrow{-\dot{C}{=}\dot{C}-Y} \rightarrow (RO)_2P(O)N(X)\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{\dot{C}}}-Y \xrightarrow[(RO)_2P(O)\dot{N}X]{(RO)_2P(O)NX_2}$$

(G)

$$\longrightarrow (RO)_2P(O)NX\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}-Y,$$

$X{=}Cl,\ Br;\ Y{=}Alk,\ COOR,\ CONH_2.$

The regiospecificity of addition is determined by the formation of the adduct radical (G), which is more stable than the adduct radical $>\dot{C}-\underset{|}{C}(Y)NXP(O)(RO)_2$.

N,N-Dihalophosphoramidates are most active in reactions with terminal 1,3-alkadienes. These reactions occur under mild conditions (at 0–15 °C in CH_2Cl_2 for 30 min) and give (*E*)-1,4-adducts in 87–93% yield:[161]

$$(C_2H_5O)_2P(O)NCl_2 + CH_2{=}CR^1{-}CR^2{=}CH_2 \xrightarrow[0-15^\circ C]{CH_2Cl_2} \rightarrow (C_2H_5O)_2P(O)NClCH_2CR^1{=}CR^2CH_2Cl \xrightarrow[0-10^\circ C]{\text{then } 10\%\ Na_2SO_3} \rightarrow (C_2H_5O)_2P(O)NHCH_2CR^1{=}CR^2CH_2Cl,$$

$R^1{=}R^2{=}H;\ R^1{=}CH_3,\ R^2{=}H,\ CH_3.$

The reactions have high regiospecificity. They are inhibited in the presence of hydroquinone. The mechanism proposed by Gajda and Zwierzak[162] involves formation of an allylic type of adduct radical (H):

$$(RO)_2P(O)NCl_2 + >C{=}\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}{=}C< \xrightarrow{-\dot{C}l} (RO)_2P(O)NCl-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}-$$

(H)

$$\xrightarrow[-(RO)_2P(O)N\dot{C}l]{(RO)_2P(O)NCl_2} (RO)_2P(O)NCl-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}{=}\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}Cl$$

$$(RO)_2P(O)N\dot{C}l + >C{=}\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}{=}C< \longrightarrow (H)$$

Radical (H) is stabilised by removal of a chlorine atom from the *N,N*-dichlorophosphoramidate, and so the thermodynamically more favourable 1,4-addition product is formed, which dictates the high regiospecificity of the reaction.

N,N-Dichlorophosphoramidates add on to 1,3-alkadienes such as *trans*-piperylene, 2,5-dimethyl-2,4-hexadiene, and 4-methyl-1,3-pentadiene only when initiated with UV irradiation.[162] These reactions are not regiospecific—1,2- and 4,1-addition products are formed together with 1,4-adducts.

It is interesting to note that the reaction of 1,4-diphenyl-1,3-butadiene with diethyl *N,N*-dichlorophosphoramidate has high regiospecificity—only the 1,2-addition product is formed:

$$(C_2H_5O)_2P(O)NCl_2 + PhCH{=}CH{-}CH{=}CHPh \xrightarrow{\text{then } 10\%\ Na_2SO_3} \rightarrow (C_2H_5O)_2P(O)NHCH(Ph)CHClCH{=}CHPh.$$

81%

This orientation of substituents in the adduct is consistent with the proposal[162] about stabilisation of the radical

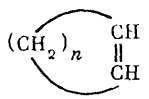
$$(C_2H_5O)_2P(O)NClCH(Ph)\overset{\dot{}}{\underset{\dot{}}{CH}}{-}CH{-}CHPh \qquad (I)$$

by addition of a chlorine atom to the 2-position with formation of the more stable compound.

There is an interesting study[163] in which the spontaneous addition of *N,N*-dichlorophosphoramidates to α-pinene is investigated; the products isolated are not those from addition of amidyl radicals to the double bond but products in the *trans* configuration formed from them by an intramolecular Wagner–Meerwein rearrangement (33%).

One study[164] was recently published, in which the addition of diethyl *N,N*-dibromophosphoramidate to olefins was examined using conditions for a heterolytic reaction—in the presence of boron trifluoride ethereate. It was shown that the reaction is regiospecific and gives saturated adducts:

$$PhCR{=}CHR^1 + Br_2NP(O)(C_2H_5O)_2 \xrightarrow[-20^\circ C]{BF_3\cdot(C_2H_5)_2O} \rightarrow PhC(R)CH(Br)R^1 \xrightarrow{NaHSO_3} PhC(R)CH(Br)R^1,$$



$\quad\quad\quad

The addition of *N,N*-dibromophosphoramidates to 1,2-dialkyl-substituted ethylenes is not regiospecific:

$$R^1CH{=}CHR^2 + Br_2NP(O)(OC_2H_5)_2 \xrightarrow[2)\ NaHSO_3]{1)\ BF_3\cdot(C_2H_5)_2O} \rightarrow \underset{(C_2H_5O)_2P(O)NH\ \ Br}{R^1CH{-}CHR^2} + \underset{Br\ \ NHP(O)(OC_2H_5)_2}{R^1CH{-}CHR^2}$$

(I) (II)

With terminal alkenes ($R^1 = C_4H_9$, $R^2 = H$ and $R^1 = C_3H_7$, $R^2 = H$), mainly products (I) are formed, while the 2-pentene and 2-hexene products (I) and (II) are formed in equimolar quantities. The reactions with 3-hexene and 2-butene are highly stereoselective (only products with the *erythro*-configuration are formed, in 84–92% yield).[164] The addition of diethyl *N,N*-dibromophosphoramidates to cyclic

alkenes is highly stereospecific, only the *trans*-isomers are formed (79–80%). A similar reaction with indene has high regiospecificity and stereospecificity and gives *trans*-2-bromo-3-(diethoxyphosphoramido)indane (yield 96%).[164]

It is interesting that, in contrast to *N*-alkyl-*N*-halocarbamates, N–R-substituted *N*-halophosphoramidates $(C_2H_5O)_2P(O)N(R)Br$ undergo a reaction with styrene on heating to form saturated adducts in appreciable yield: 40% (R = C_2H_5); 76% (R = CH_3).[165] The introduction of stronger electron-donating substituents on to the nitrogen atom (R = OAlk, OCH_2Ph) hinders the addition to styrene, since stabilisation of the amidyl radicals $(C_2H_5O)_2P(O)\dot{N}OR^1$ occurs with elimination of nitrogen and formation of alkyl diethyl phosphates.[166] In this case chlorination of styrene is the preferred process (about 66%). It was also possible to identify products from the non-regiospecific addition of amidyl radicals to styrene, with the adduct $(C_2H_5O)_2P(O)N(OR)CH_2CHClPh$ present in threefold excess. It was not possible to isolate adducts in the reaction between *N*-methyl- or *N*-ethyl-*N*-bromophosphoramidate with 2-methyl-1-butene. However, when the reaction mixtures were treated with hydrogen chloride in tetrahydrofuran, the formation of *N*-alkyl-*N*-(2-bromoalkyl)amine hydrochlorides occurred in 10–28% yield.[165]

The introduction of bulkier alkyl substituents on to the nitrogen atom in the phosphoramidates $(AlkO)_2P(O)N(R)Br$ (R = n-C_4H_9, t-C_4H_9) hinders the addition of amidyl radicals to the double bond of an alkene or prevents it completely.[165]

In the presence of boron trifluoride etherate the addition of similar *N*-alkyl-*N*-halophosphoramidates to styrene or cyclohexene gives saturated adducts or products derived from their subsequent conversion.[165,167,168]

Thus, the direction of addition of dialkyl *N*-halophosphoramidates to the C=C bond is mainly determined by the conditions of homolytic and heterolytic initiation.

IV. Reactions of *N,N*-dihaloamides with polyhaloethylenes—a new method for the synthesis of compounds with an azomethine bond

In the large number of studies discussed in the preceding sections of this review it was shown that the *N,N*-dihaloamides of different acids add on to unsaturated compounds, including halogenated products (vinylidene chloride,[120] 1,1,3-trichloropropene,[97] chloroprene [44]), to form saturated adducts.

It was of interest to study the reaction of polyhaloethylenes with amidyl radicals in order to extend the range of homolytic reactions of haloolefins as well as amidyl radicals centred on nitrogen.

The results obtained from studying the reactions of homolytic thiylation of trichloroethylene and 1,2-dichloroethylene[169–173] and chlorovinylation of triethylsilane with trichloroethylene[174] suggest that the adduct radical $RCHCl\dot{C}Cl_2$ formed is stabilised not by formation of a saturated adduct but by elimination of a halogen atom from the α-position relative to the radical site, and an unsaturated compound $RCH{=}CCl_2$ is isolated. In the reaction of amidyl radicals with trichloroethylene, formation of an unsaturated compound could also be expected.

In fact, when *N,N*-dichloroarenesulphonamides react with trichloroethylene, chloral *N*-arylsulphonylimines are formed in quantitative yield. The saturated adducts $CCl_3CHClNClSO_2Ar$ were not detected in this reaction even though the ratio of reactants, the reaction conditions, and the structure of the aromatic group were varied:[72,74]

$$ArSO_2NCl_2 + CHCl{=}CCl_2 \rightarrow CCl_3CH{=}NSO_2Ar + Cl_2 + CHCl_2CCl_3,$$
$$Ar = C_6H_5,\ p\text{-}ClC_6H_4,\ p\text{-}CH_3C_6H_4.$$

The reactions were carried out in a stream of inert gas (nitrogen or argon) with UV irradiation (30 °C) in the presence of azobisisobutyronitrile or benzoyl peroxide (50–60 °C) and also without an initiator (85 °C). The maximum yield of imines (98–99%) was achieved when a four- to six-fold excess of trichloroethylene was used and the reactants were heated at 85 °C for 12–14 h. The chlorination of trichloroethylene to pentachloroethane by the chlorine generated occurred as a parallel process.

The acceleration of the reaction by radical initiators and its retardation in the presence of radical inhibitors (hydroquinone, atmospheric oxygen, etc.) suggests that the reaction of *N,N*-dichloroarenesulphonamides with trichloroethylene has a radical nature. The following reaction scheme has been proposed:[74]

N-Arylsulphonylimines are obtained via the formation of adduct radical (J). It can be stabilised in several ways: by 1,2- or 1,3-migration of a chlorine atom followed by elimination of a chlorine atom from the α-position of the isomerised radicals or by formation of an enamide derivative (K) followed by its chlorotropic rearrangement (the possibility of stabilising the adduct radicals by elimination of a chlorine atom from the α-position relative to the radical site to give enamides has been reported[169–174]).

The possibility that *N*-arylsulphonylimines are synthesised by dehalogenation of the saturated adducts (L) cannot be ruled out, but this reaction route is not the main one, as is indicated by the ^1H NMR spectroscopic data.[74]

The routes involving 1,2-migration of a chlorine atom in radical adduct (J) and also formation of enamide (K) from it seem less probable because of the greater tendency of the N–Cl bond towards homolytic cleavage (37 kcal mol^{-1}) than the C–Cl bond (81 kcal mol^{-1}).[60] When the reaction mixtures were studied by IR and ^1H NMR spectroscopy there was no indication that compounds with the $CCl_2=CH-NCl$ group were present in them. 1,1,1,2-Tetrachloroethylsulphonamides $ArSO_2NHCHClCCl_3$ were also not detected.

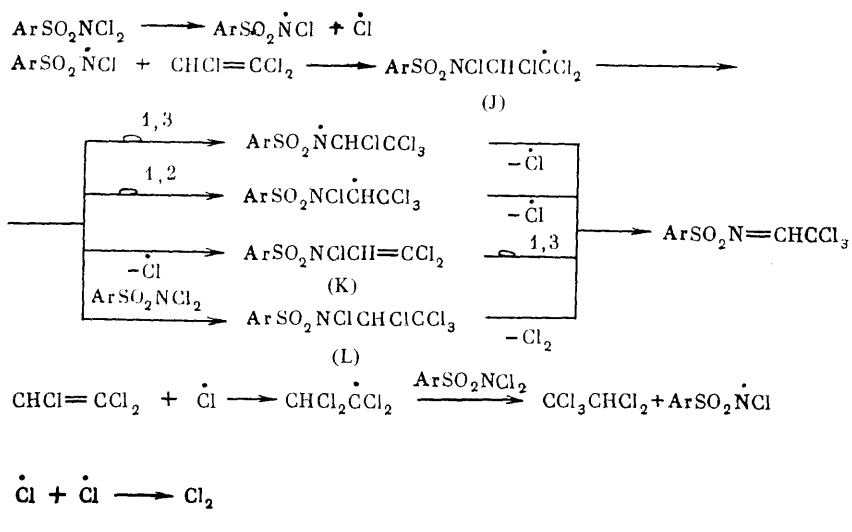
The previously known methods for obtaining chloral sulphonylimines [175–179] are characterised by multiple-stage reactions, the use of catalysts, and the toxicity and instability of the reactants. The new method for obtaining chloral sulphonylimines that has been developed is based on a large-tonnage organochlorine feedstock. As a result of the high yield of the products, the single-stage reaction, and technological effectiveness of the method it can be recommended as a new convenient method for the synthesis of highly reactive azomethines.

In order to extend the limits of the reaction that had been found for the synthesis of compounds with an azomethine bond and also to verify its mechanism, a study was made of the reaction between *N*,*N*-dichlorobenzenesulphonamide and tribromoethylene.[75] The reaction took place in an inert solvent by heating (85–90 °C) the dichloramide with a four- to six-fold excess of tribromoethylene for 9–14 h. The previously unknown dibromochloroacetaldehyde *N*-benzenesulphonylimine was formed (yield 80%) as a mixture of *syn*- and *anti*-isomers.[75] The reaction was accompanied by the evolution of chlorine and bromine and the formation of 1,2-dichloro-1,2,2-tribromoethane. Dibromochloroacetaldehyde *N*-benzenesulphonylimine is formed in a similar manner to that given in Scheme 1.

The structure of this imine can be used to verify the reaction mechanism, namely to exclude the reaction pathway via a 1,2-halotropic rearrangement in the adduct radical $C_6H_5SO_2NClCHBr\dot{C}Br_2$ since this would lead to the formation of the corresponding bromal derivative $C_6H_5SO_2N=CHCBr_3$. Exclusion of the reaction pathway via a 1,2-halotropic rearrangement in the adduct radical (see Scheme 1) is also confirmed by the reaction between *N*,*N*-dibromobenzenesulphonamide and trichloroethylene, which gives dichlorobromoacetaldehyde *N*-benzenesulphonylimine:[180]

$$C_6H_5SO_2NBr_2 + CHCl=CCl_2 \rightarrow C_6H_5SO_2N=CHCCl_2Br.$$

In order to obtain highly reactive sulphonylimines of polyhaloaldehydes, the reaction of *N*,*N*-dichloroarenesulphonamides with 1,2-dichloroethylene [73,181,182] has been studied.



It should be noted that an attempt to react 1,2-dichloroethylene with compounds containing an N–Cl bond was made in an earlier study,[3] where the inertness of this olefin towards amidyl radicals was noted. However, it was later established that the reaction of 1,2-dichloroethylene with *N*,*N*-dichloroarenesulphonamides, occurring on exposure to UV radiation (47–55 °C) for 4 h and a ratio of reactants of 10:1, takes place in a similar manner to the reactions of *N*,*N*-dichloroarenesulphonamides with trichloro- and tribromo-ethylene and gives the corresponding azomethines in 50–60% yield. When the reaction time is increased to 9–26 h and the initiation conditions are also changed, the result is that the reaction is complicated by a number of subsidiary processes, which give 2,2-dichloro-1,1-di(*N*-arenesulphonamido)ethanes, chloral *N*-arylsulphonylimines, sulphonamides, and also products derived from chlorination of 1,2-dichloroethylene:[73]

$ArSO_2NCl_2 + CHCl=CHCl$ →
- $ArSO_2N=CHCHCl_2$
- $(ArSO_2NH)_2CHCHCl_2$
- $ArSO_2N=CHCCl_3$
- $ArSO_2NH_2$
- $CHCl_2CHCl_2 + CHCl=CCl_2 + CCl_2=CCl_2$

Ar = C_6H_5, *p*-ClC_6H_4, *p*-$CH_3C_6H_4$.

The yield of the reaction products depends on the conditions. When mixtures of 1,2-dichloroethylene and *N*,*N*-dichloroarenesulphonamides (in the ratio 1:8–10) are exposed to UV radiation at

Scheme 1

47–55 °C for 8–9 h the main reaction products are dichloroacetaldehyde sulphonylimines and 2,2-dichloro-1,1-di(*N*-arenesulphonamido)-ethanes. On heating without UV irradiation there is a considerable increase in the proportion of 1,2-dichloroethylene chlorination products and chloral sulphonylimines formed as a result of a side reaction between trichloroethylene and *N*,*N*-dichloroarene-sulphonamides.[74]

The reaction of *N*,*N*-dichlorourethane with trichloroethylene occurred under conditions similar to those for the reaction between *N*,*N*-dichloroarenesulphonamides and trichloroethylene[74] and led to the formation of chloral *N*-ethoxycarbonylimine in 75% yield.[76–77] When the reactants were heated for a longer period and water was introduced into the reaction mixture, the main reaction products isolated were 2,2,2-trichloro-1,1-di(*N*-ethoxycarbonylamino)ethane (50%) and 2,2,2-trichloro-1-hydroxy(1-*N*-ethoxycarbonylamino)ethane (20%) as a result of the reaction between chloral *N*-ethoxycarbonyl-imine and urethane which is formed in a side reaction and by reaction with water:[76]

$$C_2H_5OCONCl_2 + CHCl{=}CCl_2 \rightarrow C_2H_5OCON{=}CHCCl_3 \rightarrow$$
$$\rightarrow \begin{cases} \xrightarrow{C_2H_5OCONH_2} (C_2H_5OCONH)_2CHCCl_3 \\ \xrightarrow{H_2O} C_2H_5OCONHCH(OH)CCl_3 \end{cases}$$

The reaction of *N*,*N*-dibromourethane with trichloroethylene takes place in a similar manner, the main product being dichloro-bromoacetaldehyde *N*-ethoxycarbonylimine $C_2H_5OCON{=}CHCCl_2Br$, which is isolated in 67% yield. 2-Bromo-2,2-dichloro-1,1-di(*N*-ethoxy-carbonylamino)ethane—derived from the addition of a urethane molecule to the double bond of the dichlorobromoacetaldehyde imine—is formed as a by-product (10%):[183]

$$C_2H_5OCON{=}CHCBrCl_2 \xrightarrow{C_2H_5OCONH_2} \rightarrow (C_2H_5OCONH)_2CHCBrCl_2$$

The reaction occurs in a similar manner to that given in Scheme 1. Since the dichlorobromacetaldehyde acylimine is formed, the possible route involving a 1,2-chlorotropic rearrangement of the adduct radical (M) followed by elimination of bromine can be excluded, as in this case the reaction product would be chloral acylimine:

$$C_2H_5OCONBrCHCl\dot{C}Cl_2 \xrightarrow{1,2}$$
(M)
$$\rightarrow C_2H_5OCONBr\dot{C}HCCl_3 \xrightarrow[-Br^{\cdot}]{} C_2H_5OCON{=}CHCl_3$$

It was possible to carry out the reaction of *N*,*N*-dichlorobenzamide and *N*,*N*-dichloroacetamide with trichloroethylene under similar conditions, with products from further reaction of azomethines $RCON{=}CHCCl_3$ being formed, namely, *N*-(2,2,2-trichloro-1-hydroxy-ethyl)-substituted benzamide or acetamide and 1,1-di(*N*-benzamido)- or 1,1,-di(*N*-acetamido)-2,2,2-trichloroethanes.[184]

In the presence of atmospheric oxygen these reactions are complicated by the concurrent oxidation of trichloroethylene to dichloroacetyl chloride and the reaction of by-products to give the mixed amide $C_6H_5CONHCOCHCl_2$.

The reaction of diethyl *N*,*N*-dichlorophosphoramidate with trichloroethylene also takes place in accordance with Scheme 1 as proposed and gives 1,1,1-trichloro-2,2-bis(diethylphosphamido)-ethane.[185]

A study of the reactions of *N*,*N*-dihaloamides of sulphonic and carboxylic acids as well as *N*,*N*-dihalourethanes and dialkyl *N*,*N*-dichlorophosphoramidates with trichloro-, tribromo-, and 1,2-dichloro-ethylene showed that the reactions were accelerated by photochemical and thermal initiation as well as in the presence of peroxides and were inhibited in the presence of air or hydroquinone, which was an indication of their free-radical nature. The free-radical nature of the process was confirmed by chemically induced polarisation of ^1H nuclei and EPR spectroscopy.[186]

A study of the photochemically induced reaction of *N*,*N*-dichlorobenzenesulphonamide with trichloroethylene and 1,2-dichloroethylene by EPR in the presence of a 2-methyl-2-nitroso-propane trap (in benzene) demonstrated the formation during reaction of adduct radicals $C_6H_5SO_2NClCHClCXCl$ (J) (see Scheme 1), for which the EPR spectrum showed a characteristic splitting on the nitrogen atom with hyperfine coupling constant = 12.2 G, on the two non-equivalent chlorine nuclei $a_{Cl(1)}$ = 4.1 G, $a_{Cl(2)}$ = 1.0 G (X = Cl) and the chlorine atoms: $a_{^{35}Cl}$ = 6.2 G, $a_{^{37}Cl}$ = 4.7 G (X = H). Thus, the reactions of amidyl radicals $R\dot{N}Hal$ (R = SO_2Ar, COOAlk, COAlk, COAr) with polyhaloethylenes are of a common type and constitute an essentially new method for the synthesis of compounds with an azomethine bond. By selecting suitable partners the synthesis of azomethines $CHal_3CH{=}NR$ can likewise be carried out with different combinations of halogen atoms.

At the same time mention should be made of the high reactivity of synthesised polyhaloaldehyde acylimines in nucleophilic addition reactions of alcohols,[74–76] phenols, carboxylic acids,[127,184] sulphonamides and carboxamides,[129,176,184,187] thiols,[176] oximes, hydrazines,[187,188] bifunctional compounds,[176,187] chloroalkanols, α-halocarboxylic acids,[189] and benzalazine.[190]

Diene condensation reactions of chloral sulphonylimines with butadiene, isoprene, piperylene, and cyclopentadiene [178,191] have been carried out. For the first time the possibility of using chloral sulphonylimines as *C*-amidoalkylation agents of aromatic compounds (anisole, thioanisole, *N*,*N*-dimethylaniline),[192] heterocycles (thiophene, furan and its derivatives),[193] etc. has been demonstrated.

V. Conclusion

Thus, a common property of the reactions of *N*-haloamines, *N*-halocarbamates, and *N*-haloamides of carboxylic, sulphonic, and phosphoric acids with unsaturated compounds is the formation of saturated adducts. An analysis of the literature data showed that the majority of these reactions have a radical nature. The abundance of experimental and theoretical material which has been collected makes it possible to propose a general scheme for these reactions, involving the formation of a radical adduct $RN(X)\underset{|}{\overset{|}{C}}-\dot{C}\diagdown$ [R = Alk, R^1COO, R^1CO, $ArSO_2$, $AlkSO_2$, $(AlkO)_2P(O)$; X = H, Alk, Cl, Br] obtained by attack of an amidyl radical on the less substituted carbon atom at the double bond of alkene derivatives. Thus, the driving force of the process is formation of the most stable radical.

It follows from the material presented in this review that in recent years a new trend has developed in the sphere of radical reactions between *N*-haloamides and olefins—the reaction of acid

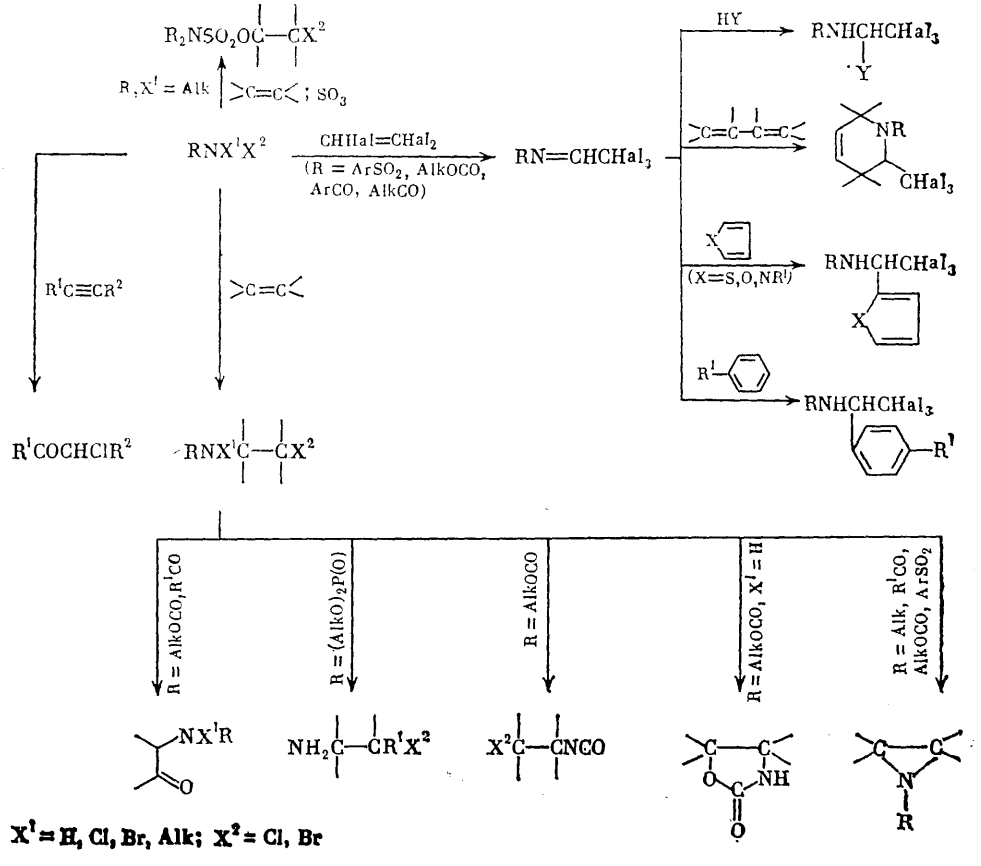
N,N-dihaloamides with polyhaloethylenes to form polyhaloaldehyde acylimines, which are highly reactive syntones in organic synthesis.

From among the known ionic reactions of *N*-haloamides and *N*-haloamines with unsaturated compounds, in recent years there has been active study of the reaction of *N*-chloramines with olefins in the presence of SO_3, which can give a new type of highly reactive electrophilic reagent at the first stage—*O*-chlorosulphamates—which then readily add on to the double bond of different alkenes.

Nevertheless, there are still a number of unresolved problems relating to the study of the mechanism of reactions between acid *N*-haloamides with alkenes under ionic initiation conditions. The reactions of acid *N*-haloamides with acetylene and polyhaloethylenes have not been studied in sufficient detail. There are no quantitative data on these reactions.

The various reactions described in this review illustrate the extensive reaction possibilities which are opened up by the chemistry of aminyl and amidyl intermediates.

Various types of compounds which have extensive application both in fine organic synthesis and in practical work can be obtained from these reactions (Scheme 2).



Among these products there are biologically active compounds with neurotropic and antibactericidal activity,[188] and insecticides,[194-198] herbicides,[199,200] and plant growth regulators[201] have been identified.

Aziridine derivatives—compounds with anticancer activity—have attracted considerable attention in recent years.[149] Various derivatives of isocyanates and oxazolidines have been widely used in the production of foamed plastics,[202] lacquers,[203] electrical insulating materials,[203] components of rubber mixtures,[204,205] etc.

The recent results should act as a stimulus for carrying out new studies aimed at investigating the reactions of *N*-haloamines and *N*-haloamides with different unsaturated compounds.

We can draw the attention of research workers to this field of chemistry by indicating the studies in which are reported the methods for synthesising *N*-chloramines,[23,27-30,206-208] *N*-monohalo- and *N,N*-dihalo-carbamates,[43,46,50,209] *N*-alkyl-*N*-halo- and *N,N*-dihalo-carboxamides,[95,210,211] *N,N*-dihaloarenesulphonamides,[112,212] and dialkyl *N,N*-dihalo- and *N*-alkyl-*N*-halophosphoramidates.[152,153,165,166,213-216]

Catalytic conversion of paraffinic hydrocarbons into isoparaffins and olefins

N R Bursian, S B Kogan
All-Union Institute of Petrochemistry, Leningrad Petrochemical Scientific-Industrial Association

ABSTRACT. The catalytic isomerisation, disproportionation, and dehydrogenation reactions of the C_4–C_{12}, C_4–C_8, and C_3–C_{18} hydrocarbons respectively are examined. The chemical composition, the methods of preparation of the catalysts, the effect of promoting agents, and the kinetics and mechanisms of the reactions are discussed. The principal characteristics of the existing and likely future processes leading to the synthesis of C_4–C_{12} isoparaffins and C_3–C_{18} mono-olefins are presented.
The bibliography includes 154 references.

I. Introduction

The isomeristion, dehydrogenation, and also disproportionation reactions of paraffinic hydrocarbons are linked together by the application of catalytic systems of the same type and by the existence of common features in their chemistry and technology. These reactions are carried out on heterogeneous catalysts in the presence of hydrogen, using individual paraffinic hydrocarbons or their narrow fractions as the starting materials. The limititation of the degree of conversion by the thermodynamic equilibrium necessitates the isolation and recirculation of the hydrocarbons which have not reacted.

Isomerisation and dehydrogenation constitute traditional methods for the selective conversion of paraffinic hydrocarbons[1,2] and during the last decade these have been the object of vigorous investigation, which is to a significant extent due to the appearance of new highly efficient catalysts.[3,4] The isomerisation and dehydrogenation reactions of lower paraffins are combined in the proposed technological schemes for the processing of hydrocarbons in order to attain the optimum yield of the branched olefins [Bursian (Ref.3, page 99), Zhorov (Ref.4, page 218), Pujado and Vora,[5] and Bursian et al.[6]]. The manufacture of scarce C_4–C_5 paraffinic hydrocarbons can be expanded by employing a new process involving the disproportionation of C_6–C_8 hydrocarbons.[7-9]

The need for isoparaffinic and olefinic hydrocarbons has been increasing continuously owing to the need to solve the general world problem of the pollution of the atmosphere and water. In all countries, the use of ethylated types of automobile petrols has been decreasing, the consequent reduction in the octane number of petrols being compensated for by increasing the amount of isomerisation and alkylation mixtures and oxygen-containing compounds as additives—see Bursian (Ref.3, page 157) and other investigators.[5,6] Ecological requirements are also responsible for the growth in the manufacture of biodegradable surfactants based on higher linear olefins (Refs.10, 11, page 11).

The hydrocarbon composition of the most promising (North Siberian) petroleums of the Soviet Union is distinguished by a fairly high content of C_4–C_{20} paraffinic hydrocarbons (~20 wt.%), the ratio of the iso- and normal hydrocarbons varying within the limits 0.3–0.8 (Ref.12, p.126). Paraffinic hydrocarbons are extracted from petroleum by processes involving fractionation (C_4–C_6 paraffins) and isolation by absorption on zeolites (C_{11}–C_{18} paraffins) (Ref.3, page 7).

The economic efficiency of the processes involving the isomerisation and dehydrogenation of paraffinic hydrocarbons is determined by the low consumption of metals and energy, the high selectivity of the reactions, reaching 97–99%, the technological simplicity, and the waste-free technology.

In particular, platinised alumina containing halogen promoting agents[1-3] and metal-containing zeolites[3,4,13] are used as isomerisation catalysts. Metallozeolite catalysts are extremely effective also in the paraffin disproportionation reactions.[14] Non-acid polymetallic aluminoplatinum catalysts are used for the dehydrogenation of higher paraffins to olefins.[10,15] Catalysts based on chromium oxide have come to be widely used in the preparation of lower olefins by the dehydrogenation of paraffins.[16-18]

A series of large-scale industrial processes are based on the application of isomerisation and dehydrogenation reactions. The catalytic isomerisation of paraffinic C_4–C_{12} hydrocarbons increases the available raw material resources for the manufacture of isoprene rubber, ensures the preparation of high-octane components of AI-93 petrol and of reactive diesel C_3–C_5 paraffinic hydrocarbons—the source of mono-olefins used in the synthesis of monomers for isoprene and butadiene fuels and oils with a low setting temperature,[3] and dehydrogenation of natural rubbers.[16-18] The dehydrogenation of C_8–C_{18} hydrocarbons is used to obtain linear olefins which are necessary for the manufacture of plasticisers and components of surfactants characterised by high biodegradability.[10,15]

II. Isomerisation of paraffinic hydrocarbons

The isomerisation of paraffinic hydrocarbons in the presence of aluminium chloride was discovered in 1933 by Nenitzescu and Dragan. In 1935, Moldavskii demonstrated the possibility of

accelerating the isomerisation of paraffins in the presence of aluminium chloride by adding hydrogen chloride, which resulted in the practical application of this reaction (Ref.19, page 512).

The vapour-phase isomerisation of paraffinic hydrocarbons under hydrogen pressure was subsequently achieved at 350–500 °C in the presence of bifunctional catalysts—the oxides and sulphides of Group VI elements as well as Group VIII metals on carriers with acidic properties (alumina promoted by halogens and aluminosilicates).[1-4]

The fluorine-promoted aluminoplatinum catalyst became the first widely used catalyst of an industrial isomerisation process.[3,4,15,20]

1. Thermodynamics, kinetics, and mechanism

The isomerisation reaction of paraffinic hydrocarbons proceeds without change in volume and the thermodynamic equilibrium depends virtually only on temperature. Theoretical corrections for the non-ideality of the gas[21] under the usual isomerisation conditions do not exceed 1% (Ref.4, page 11). The data on the composition of the equilibrium mixtures of isomeric paraffins are well known.[1-4,22] A common characteristic is the increase in the content of branched isomers as the temperature is reduced.

The form of the kinetic equation and the isomerisation mechanism depend on the type of catalyst and the experimental conditions. At the same time, comparison of the various existing equations (Table 1) shows that the reaction is found in all cases to be of first order with respect to the hydrocarbon and is inhibited by hydrogen. The optimum hydrogen partial pressure is determined by the nature of the catalyst (Ref.3, pages 18–28).

The study of the kinetics of the isomerisation of paraffinic hydrocarbons as well as the mechanism of the poisoning of catalysts by poisons acting on various active centres of bifunctional isomerisation catalysts established that the rate-limiting stage of the reaction is the conversion of the intermediate unsaturated products on acid centres of the catalysts (Ref.3, page 18; Ref.31, page 347; Ref.32, page 38).

In the limiting cases of high and low partial hydrogen pressures, the rate of isomerisation can be limited by the rates of dehydrogenation of paraffins and hydrogenation of olefins on the metallic centres of catalysts respectively (Ref.3, page 28). In contrast to aluminium chloride, in the presence of bifunctional aluminoplatinum catalysts the rate of isomerisation of C_4–C_6 paraffins increases with increase in their molecular weight; the isomerisation of C_7 and higher hydrocarbons takes place non-selectively on all the catalysts investigated with the cracking reaction predominating.[1]

The relative rates of interconversions of hexanes in the presence of metal halide salts and an aluminoplatinum catalyst have been measured in a number of studies (Ref.33–35, page 171; Ref.36, page 99) and it has been established that the migration of the methyl group along the paraffinic hydrocarbon chain takes place at the highest rate.

In the isomerisation of C_5–C_6 mixtures on the platinum/mordenite catalyst, n-hexane is found to have a strong influence on the rate of isomerisation of n-pentane.[28] This effect, which can be explained by the preferential adsorption of n-hexane on the active centres of H-mordenite, is reflected in the inverse dependence of the rate of isomerisation of n-pentane on the partial pressure of n-hexane (Table 1).

The activation energies for isomerisation reactions on various catalysts diminish with increase in the activity of the latter, which is manifested by a decrease in the process temperature (Table 1).

The side reactions involving hydrogenolysis, cracking, and disproportionation accompanying the main isomerisation reaction of paraffinic hydrocarbons leads to a decrease in the selectivity and

Table 1. Kinetics of the n-pentane and n-hexane isomerisation reactions on different catalysts.

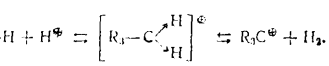
stability of the catalyst. Hydrogenolysis takes place on metallic centres and cracking and disproportionation take place on acid centres.

In order to restrict the side reactions under the conditions of isomerisation on bifunctional catalysts, the optimum ratio of the concentration of the metal and the acidity of the carrier, regulated by the chemical composition of the latter and the selection of the partial hydrogen pressure, is established. The rates of the cracking and disproportionation reactions are maximum in the absence of hydrogen and, with increase in its partial pressure, they gradually diminish to a definite limit and then increase (Ref. 3, page 35).

The principal question concerning the mechanism of the isomerisation reaction is the mechanism of the formation of the carbonium ion. Such ions can be formed as a result of intermolecular hydride transfer:[37]



There exists also another view,[35,38] according to which carbonium ions are formed as a result of the abstraction of a hydride ion from the paraffin molecule by a Lewis acid:

In this case the recombination of a proton and a hydride ion can lead to the formation of gaseous hydrogen.

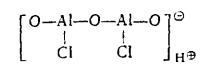
The isomerisation of paraffinic hydrocarbons in superacid media[39,40] proceeds via the protonation of paraffinic hydrocarbons at the σ-bond, whereupon a non-classical carbonium ion with a two-electron three-centre bond is formed and its subsequent cleavage leads to the formation of the usual tricoordinate carbonium ion and hydrogen:

A mechanism according to which the isomerisation proceeds via the formation of cyclic carbonium ions has been proposed.[1,40]

The isomerisation of paraffins on bifunctional catalysts of the aluminofluoroplatinum and metallozeolitic types takes place in accordance with the classical scheme[41] via stages involving the formation of unsaturated compounds on the metallic centres (M) of the catalyst, their further conversion via the carbonium ion mechanism on the acid centres (A) into the corresponding iso-olefin, and the rehydrogenation of the latter on the metallic centres:

$$\text{paraffin} \overset{M}{\rightleftarrows} \text{olefin} \overset{A}{\rightleftarrows} \text{iso-olefin} \overset{M}{\rightleftarrows} \text{isoparaffin}.$$

This scheme was confirmed by numerous experimental studies and mathematical analysis.[42] There exists also a different point of view on the mechanism of the reactions of paraffinic hydrocarbons on bifunctional catalysts, according to which a special role is attributed to the metal (Ref.31, pages 327, 347). The different ideas about the isomerisation mechanism (catalysis by metals, bifunctional catalysis, and catalysis by acids) are not mutually exclusive and their relative contributions depend on the nature of the catalyst and the reaction conditions.



2. Catalysts

As already mentioned, paraffin isomerisation catalysts can be divided into three groups:

(a) platinum on halogenated alumina; (b) Group VIII metals on zeolites; (c) "superacids" (the fluorides of Group V and VI elements).

The study of the isomerisation of paraffinic hydrocarbons on these catalysts established a series of characteristic features. The most important include the dependence of the activity of the catalyst on its acidity. In the case of aluminoplatinum catalysts promoted by halogens, the acidity and activity increase with increase in the amount of fluorine and chlorine up to a certain limit (Ref.3, pages 17, 70). The acidity and activity also increase up to a definite value with increase in the modulus and degree of removal of sodium.[13] The maximum activity and acidity are shown by the SbF_5–HF system among metal fluorides.[43]

There exist a series of hypotheses concerning the structure of the active centres of the isomerisation catalyst promoted by chlorine or fluorine. According to one of them,[1] the acidity of alumina treated with HCl increases if the chloride ion substitutes one of a pair of hydroxy-groups, whereupon the hydrogen of the other hydroxy-group becomes capable of dissociation in the form of a proton by virtue of the presence of the electronegative chlorine atom in its immediate vicinity. The structure of the active centre of chlorine-substituted alumina can be represented by a formula according to which the halogenated alumina is an acid having mobile hydrogen ions:

The enhancement of the acidity when halide ions and hydroxy-groups are accommodated on neighbouring aluminium atoms has been postulated.[44]

The mechanism of the gas-phase activation of the aluminoplatinum catalyst by halogens and organochlorine compounds (especially carbon tetrachloride) in the absence of water has been discussed.[15,45–48] It has been suggested that organochlorine compounds react with the surface hydroxy-groups and the sections of the η-alumina surface generated on dehydroxylation; the oxygen of the oxygen-containing groups is then replaced by chlorine and active centres with the properties of acid Lewis centres are formed.

The interaction of CCl_4 with pairs of dehydroxylated surface sites on the γ-Al_2O_3 surface leads to the formation of centres with an enhanced acidity.[45] The requirements which must be met by the structures of alumina and the chlorinating agent have been formulated (Ref.3, page 66). It has been suggested that the active centres of the chlorinated η-alumina represent complexes whose composition includes chloride, oxygen, and aluminium ions as well as a proton. The chemisorbed hydrogen chloride, whose presence is ensured by the small amounts of water on the catalyst surface, serves as the source of protons. Centres which are active in the isomerisation reaction of paraffinic hydrocarbons are generated when platinised alumina is treated with aluminium chloride as a result of the formation on the surface of aluminium oxide chlorides stabilised by added hydrogen chloride (Ref.3, page 73).

The formation of acid active centres as a result of the introduction of up to 2 wt.% of fluorine into the aluminoplatinum catalyst proceeds via the substitution of the hydroxy-groups on neighbouring aluminium atoms by fluorine;[49] when the content of fluorine is above 2 wt.%, it substitutes isolated hydroxy-groups, which increases

the strength of the existing acid centres without increasing their concentration. The proton centres on the surface of fluorinated alumina can be formed on chemisorption of water.

The influence of fluorine on the isomerising, hydrogenating, and cracking functions of the aluminoplatinum catalyst has been investigated (Figs. 1 and 2) (Ref.3, page 48).

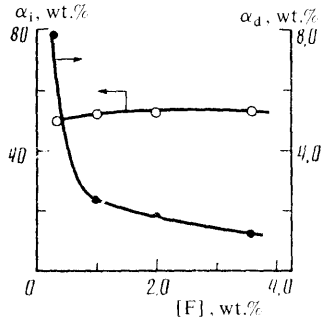


Figure 1. Dependence of the yield of the n-pentane conversion products on the fluorine content [F] in the aluminoplatinum catalyst (Ref.3, page 49); T = 380 °C; p = 3.5 MPa; α_i and α_d are the yields of isopentane and the decomposition products respectively.

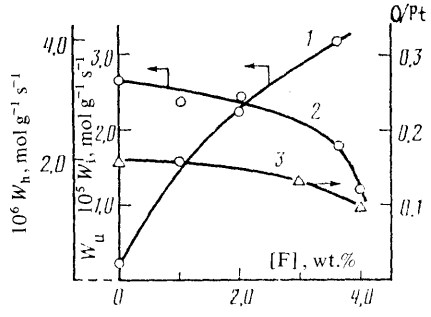

Figure 2. The influence of fluorine on the activity of the aluminoplatinum catalyst in the n-pentane isomerisation (curve *1*) and benzene hydrogenation (curve *2*) reactions and on the chemisorption capacity of platinum (curve *3*) (Ref.3, page 48); W_i and W_h are the rates of isomerisation and hydrogenation respectively.

The increase in the isomerising activity when aluminoplatinum catalysts are promoted by fluorine (Fig. 2) is associated with increase in the Lewis acidity and the appearance of Brønsted acidity. The simultaneous decrease in the activity of the catalyst in the reactions involving the hydrogenation of benzene and the hydrogenolysis of paraffins indicates a change in the state of the platinum, which has been confirmed by an IR spectroscopic study of the adsorption of carbon monoxide (Ref.3, page 49). The fluorination of the catalyst increases significantly the CO vibration frequency, which indicates an increase in the electron deficiency in the platinum. The latter can be explained by the strengthening of the electron-accepting centres of the carrier with which platinum interacts.

The introduction of sulphur into an aluminoplatinum catalyst promoted by fluorine suppresses the hydrogenolysis reaction in the course of the isomerisation of n-pentane without altering the isomerising activity of the catalyst (Ref.3, page 55).

The IR spectroscopic study of the adsorption of CO on the sulphur-treated catalyst showed that the maximum of the band corresponding to the CO adsorbed on platinum undergoes a hypsochromic shift in the presence of sulphur and that its position is independent of the degree of surface coverage of platinum by carbon monoxide (Ref.3, page 49). This finding indicates the inhomogeneity of the platinum in the non-sulphur-treated catalyst. On treatment with sulphur, the latter forms a strong bond with some of the platinum centres (the least electron-deficient centres), while the electron-deficient platinum centres remain free after heat treatment in the presence of hydrogen. The increase in the electron deficiency of platinum as a result of promotion by fluorine and sulphur weakens the Pt–C bond in the chemisorption of hydrocarbons and suppresses the hydrogenolysis reactions, whose rate is determined by the chemisorption stage.

The studies which have been carried out have served as a basis for the selection of the chemical composition of the catalysts of the high-temperature isomerisation of paraffinic hydrocarbons (IP-62, IP-62-M, and IP-82). Their platinum content is 0.45–0.55 wt.%, the fluorine content in γ-alumina is 3.5 ± 0.5 wt.%, and the sulphur content is 0.2 wt.%.[3,4,15,20]

The discovery of a new method for the introduction of chlorine into the carrier by the gas-phase chlorination of the catalyst with organic chlorides is of fundamental importance for the synthesis of bifunctional aluminoplatinum isomerisation catalysts (Ref.3, page 74; Refs.15,20,50,51). The gas-phase chlorination procedure, which consists in treating the aluminoplatinum catalyst at 250 to 300 °C with an inert gas containing carbon tetrachloride, makes it possible to obtain a catalyst whose acid strength approaches that of aluminium chloride, which creates the possibility of carrying out the isomerisation of paraffinic hydrocarbons in the absence of a metal at 50–100 °C. The introduction of platinum ensures the stability of the catalyst.

The isomerisation of paraffins on metallozeolitic catalysts was first described by Rabo et al.[52] and has been widely used by Minachev and co-workers.[13] Faujasite in the calcium- and H-forms and zeolites of the type of mordenite and ZSM in the H-forms are used for this reaction. Catalysts with a high activity, making it possible to achieve the isomerisation at 230–270 °C, can be obtained by maintaining a number of conditions; they must have a definite value of the silicate modulus (not less than 4.5 for faujasite, 12–18 for mordenite, and 40 for ZSM), adsorption capacity, and degree of crystallinity. The required acidity is obtained by removing sodium by ion exchange or de-alumination. H-Mordenite exhibits the highest activity and selectivity in the paraffin isomerisation reactions; the metal is introduced to increase the stability of the catalyst.[53]

The possibility of isomerising paraffinic hydrocarbons on Group V and VI metal fluorides in the presence of HF in hydrogen was first demonstrated by Oeldrik.[54] The reaction takes place at a higher rate and with a high selectivity at 20–50 °C and a hydrogen pressure of 0.5 MPa in the liquid phase in the presence of the MF_5–HF complex. The TaF_5–HF system is the most stable and the SbF_5–HF system is the least stable.

The nature of the active centres on "superacid" catalytic systems of the type of MF_x–HF has been examined.[43] The sharp increase in the acidity of hydrogen fluoride following the addition of SbF_5 is explained by the formation of the more acid ion H_2F^+. The low nucleophilicity of superacids, promoting the stabilisation of carbonium ions, is due to the stablisation of the F^- and FSO_3^- ions as a consequence of the formation of complex anions in which antimony has a coordination number of 6. The instability of the given catalytic system is associated with the formation of polymeric compounds and their dissolution in the catalyst.

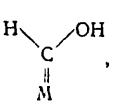
The selectivity and stability of the catalytic system depend on the ratio of the rates of formation of carbonium ions and of their alkyl rearrangement and hence are determined to a significant extent by the properties of the initial hydrocarbon. Thus the isomerisation of n-butane can be achieved at an acceptable rate and with an acceptable selectivity in the presence of aluminium chloride and chlorine-promoted aluminoplatinum catalysts. In the presence of fluorine-promoted aluminoplatinum catalysts and metallozeolitic catalysts, it proceeds with a lower selectivity, while it hardly occurs at all in the presence of metal fluorides, with the exception of the MoF_6–HF and AsF_5–HF systems, which nevertheless exhibit some activity.[43] The lack of activity of the SbF_5–HF system in the isomerisation of n-butane can be explained by the fact that the secondary butyl cation can rearrange to a tertiary butyl cation only via the formation of an intermediate carbonium ion with a very high energy (in contrast to the pentyl and hexyl cations, whose rearrangement proceeds via the formation of secondary carbonium ions). The isomerisation of n-butane on the $AlCl_3$–HCl, AsF_5–HF, and MoF_6–HF systems can be explained by the rearrangement of the butyl cation via a preliminary carbonium ion dimerisation stage, where the product rearranges and is cleaved without the formation of primary cations.[33]

High-silica zeolites (H-mordenite, ZSM-5), promoted by Group VI and VIII elements, are the most effective in the isomerisation of higher n-paraffins (Ref.3, pages 63, 118; Ref.4, page 142).

In practice, isomerisation catalysts are always used at an appreciable hydrogen pressure which promotes the desorption of the unsaturated intermediate compounds and ensures high stability.

One of the most important questions associated with the isomerisation of paraffinic hydrocarbons is that of the poisoning of the catalysts as well as the protection of the latter against the action of poisons. Sulphur and nitrogen compounds, carbon oxides, and water are some of the poisons. As a result of the reactions of sulphur and nitrogen compounds in hydrogen on platinum catalysts, hydrogen sulphide and ammonia are formed respectively.

Bearing in mind the bifunctional nature of the isomerisation catalysts, model reactions characterising the functions of the catalyst are selected to investigate the influence of the poisons on the properties of the metal and carrier.



Sulphur compounds are poisons for all the catalysts investigated in the reactions occurring preferentially on metallic centres (hydrogenation and dehydrogenation). Nitrogen compounds do not have such a pronounced effect on the dehydrogenating activity at comparable concentrations but they do poison selectively the acid centres of the carrier, which is indicated by the change in the activity of the catalysts in the isomerisation reactions.[55]

The poisoning action of hydrogen sulphide is due to its interaction with platinum involving the formation of fairly stable sulphides. The toxicity of sulphide sulphur is determined by the presence of an unshared electron pair.[56] The comparatively weak influence of nitrogen is associated with the conversion of ammonia in the presence of water into the ammonium ion, which has a "non-toxic" fully shielded structure (Ref.31, page 307, Ref.56). The influence of sulphur and nitrogen compounds on the isomerising properties of platinum and palladium catalysts depends on the nature of the carrier. Thus sulphur compounds suppress the isomerisation of n-hexane on the Pd–CaY catalyst but do not influence the isomerising properties of the fluorine-promoted aluminoplatinum catalyst.[55] The latter indicates the absence of influence by sulphur on the slow stage in the isomerisation of paraffinic hydrocarbons—the structural isomerisation of olefins.

The poisoning of the aluminofluoroplatinum catalyst by sulphur (at concentrations in excess of 0.01 wt.%) is due to its effect on the rate of the paraffin dehydrogenation stage, which determines in the given instance the rate of isomerisation. Another possible cause is the action of sulphur on the acid centres of the alumina (Ref.3, page 88). There are data indicating the influence of carriers on the sensitivity of the deposited platinum to poisoning by sulphur. In the case of a stable (irreversible) adsorption of sulphur on platinum without a carrier, the ratio of the surface S and Pt atoms is 0.5.[57–59] Such adsorption fully deactivates the metal (and leads to the absence of adsorption of CO, H_2, O_2, acetylene, ethylene, and benzene at temperatures below 400 °C).[59] For the same or even a higher degree of surface coverage by sulphur, the platinum on alumina is capable of adsorbing CO, H_2, and O_2[60–64] and retains its activity in the reactions involving the hydrogenation of aromatic hydrocarbons[60] and the isomerisation of n-pentane.[64] In the adsorption of CO on platinum converted into a sulphide, there is a possibility of the formation of groups of the type CO–Pt–S.[61] Presumably bridged sulphide Pt_2S is also formed on massive platinum, while on more isolated deposited platinum centres the linear PtS structure predominates.[65] As the degree of surface coverage of platinum by sulphur is 0.5, isolated adsorption centres should be retained in this case on the surface of the aluminoplatinum catalyst, which agrees with the absence from the IR spectra of "sulphided" catalysts of the band due to the bridge-type form of adsorption of CO[63] and with the independence of the position of the maximum due to the linear CO–Pt form of adsorption from the degree of surface coverage of the Pt–Al_2O_3–F (Ref.3, pages 49,57; Ref.64) and Pt–Al_2O_3[66] catalysts.

The mechanism of the poisoning effect of sulphur on the Pt–Al_2O_3–Cl catalyst for low-temperature isomerisation should differ fundamentally from that examined above. In this case, the toxicity of sulphur is due to the dissociative adsorption of H_2S on the donor–acceptor centres of chlorinated alumina (Ref.3, page 88; Ref.67, pages 50–55).

The effect of carbon oxides on the different functions of platinum and palladium catalysts on alumina and of zeolitic catalysts has also been studied.[68] The dehydrogenating activity of all the catalysts fell in the presence of carbon monoxide regardless of the nature of the carrier, which indicates a direct interaction of CO with the metal of the catalyst. The toxicity of carbon monoxide is due to the formation of adsorption complexes with platinum. In the presence of carbon monoxide, the degree of chemisorption of hydrogen on the metal surface increases, which can be attributed to the formation of the complexes

the toxicity of CO in relation to platinum decreasing as a consequence of its hydrogenation to methane. However, for a

constant supply of the poison, the detoxification phenomenon may not be observed. Presumably, the poisoning of the platinum catalyst by carbon oxides is associated with their simultaneous action on the metal and the carrier–alumina or zeolite. The poisoning effect of CO and CO_2 on alumina is due to the formation and adsorption of water on its acid centres. The effect of carbon monoxide on platinum or palladium has been explained by the competitive adsorption of hydrocarbons and carbon oxides on the metal surface. Since carbon monoxide is adsorbed more strongly, its presence in hydrogen even in small amounts suppresses the dehydrogenation of cyclohexane and the isomerisation of n-pentane (Ref.3, page 90).

The study of the poisoning of platinum and palladium catalysts by water has shown that in this case the properties of the carriers are of decisive importance in the isomerisation of paraffinic hydrocarbons (Ref.3, page 91). The poisoning by water is thus caused by its interaction with the acid centres of the carrier. The rehydration of the catalysts based on alumina results in the formation of new hydroxy-groups which reduce the concentration of the active centres of the Al_2O_3 surface. In zeolite-containing systems, this phenomenon is observed at much higher water concentrations and the palladium-zeolite isomerisation catalyst is therefore relatively resistant to poisoning by water.[68] The metallozeolitic isomerisation catalysts (Pt–CaY, Pd–CaY) are relatively insensitive even to poisoning by nitrogen compounds[55] and carbon dioxide.[68]

The characteristic features observed in the study of the influence of poisons on the rates and selectivities of the reactions occurring on platinum and palladium catalysts established the permissible content of the poisoning impurities in the raw material and hydrogen and have led to the recommendation of measures for the protection of catalysts against the action of these impurities.[3]

3. Industrial application

Depending on the catalyst employed, the isomerisation of paraffinic hydrocarbons takes place with high yields at temperatures in the range 20–370 °C, hydrogen pressures in the range 0.5 to 3.5 MPa, space velocities at which the raw material is supplied in the range 2.0–3.0 h^{-1}, and a hydrogen: hydrocarbon molar ratio of 2–3 (Table 2).

Isomerisation reactions of paraffinic hydrocarbons of several types are used nowadays in industry, the differences between them being determined by the properties of the catalyst employed (Table 2).

In the high-temperature isomerisation reactions of pentane–hexane fractions, metal–fluorine-promoted alumina and metal–aluminosilicate systems are used as catalysts. The attainable degree of isomerisation of n-pentane in one pass at temperatures in the range 360–400 °C amounts to 50–55% and the octane number of the isomerisation reaction mixture resulting from the pentane–hexane fraction reaches 75 measured purely by the research method (RM) (Ref.3, page 76).

The application of high-silica zeolites of the type of mordenite[3,4,13] has served as the basis of a moderate-temperature isomerisation process for the pentane–hexane fraction, which is carried out at 230–260 °C; the isomerisation reaction mixture obtained after a single pass of the raw material has an octane number of 80–82 (RM).

The isomerisation reactions of n-butane, n-pentane, and of the pentane–hexane fraction at temperatures in the range 140–180 °C on aluminoplatinum catalysts modified by organochlorine compounds or aluminium chloride have been developed to the greatest extent. The vast majority of industrial plants use the technology of the low-temperature isomerisation of the pentane–hexane fraction via the "one pass" scheme with formation of an isomerisation reaction mixture having an octane number of 83–84 (RM).

If it is necessary to obtain individual isoparaffins, the part of the paraffinic hydrocarbons which have not reacted must be returned to the process. When n-butane and n-pentane are isomerised, recirculation is economically useful and is generally used. In the isomerisation of pentane–hexane fractions, which contain a large number of hexane isomers having similar boiling points but different octane characteristics, the usefulness of the recirculation of n-hexane

Table 2. Conditions in the isomerisation of n-pentane (P) and n-hexane (H) in the presence of different catalysts.[3,69]

and of its low-octane monosubstituted isomers is determined by the required octane number of the isomerisation reaction mixture. The energy expenditure on the recirculation increases with increase in the octane number of the isomerisation reaction mixture. There is a corresponding increase in the intrinsic cost of the isomerisation reaction mixture as well, which depends also on the method of isolation of the paraffinic hydrocarbons—fractionation or extraction on molecular sieves; the latter method is much more economical.[3]

One of the ways of increasing the antiknocking capacity of the isomerisation reaction mixtures obtained from the hexane fraction involves their processing by selective hydrocracking on metallo-zeolitic catalysts. The selective hydrocracking of normal paraffinic hydrocarbons takes place in this process; the selectivity of the action of the catalyst, determined by the molecular sieve effect of zeolites of the type of erionite and ZSM, can be explained by the difference between the critical diameters of molecules of different structure (Ref.3, pages 145, 174).

The isomerisation of C_7 and higher paraffins (combined with partial hydrocracking) is used to improve the characteristics of diesel fuels and oils. A number of corresponding Soviet and foreign technological processes are known in which 98% conversion of the raw material is attained in one pass.[3,4]

More than 80 plants for the isomerisation of n-butane, n-pentane, and pentane–hexane fractions are functioning at the present time throughout the world. The tendency towards a decrease in the content of tetraethyl-lead and of aromatic hydrocarbons in automobile petrols has promoted an increase in the number of isomerisation plants being built and in the planning stage[70] and an expansion of the manufacture of the corresponding catalysts.[71]

III. Disproportionation of paraffinic hydrocarbons

The disproportionation of paraffinic hydrocarbons, which takes place in the simplest case in accordance with the equation

$$2C_nH_{2n+2} \leftrightarrows C_{n-x}H_{2n+2-2x} + C_{n+x}H_{2n+2+2x}, \quad (1)$$

was first observed[72] as a side reaction in the isomerisation of paraffinic hydrocarbons in the presence of aluminium chloride. Later this reaction was studied by Moldavskii and co-workers.[73–75]

The conversion of n-pentane at 50–90 °C resulted in the formation of 25–40% of products heavier than C_5 compounds and of up to 30–50% of light hydrocarbons (mainly butanes).[74] The products for the interaction of copper and lead sulphates with hydrogen chloride, which were regarded as HCl donors, were used as activating additives. It was shown later that the promoting effect of metal sulphates and chlorides is manifested also in the absence of HCl under anhydrous conditions and is evidently caused by the formation of molecular complexes between aluminium chloride and the promoting salts.[76,77] The study of the disproportionation of C_5–C_7 paraffins on aluminium chloride at temperatures up to 100 °C established that, together with copper salts, those of zinc, cadmium, gallium and a series of Group VI–VIII elements exhibit the properties of promoting agents.[78]

The disproportionation in the presence of aluminium chloride is accompanied by the extensive isomerisation of the products obtained and by polymerisation side reactions leading to the deactivation of the catalyst, which restricts the applicability of the catalytic system in question.

The deficit of C_4 and C_5 hydrocarbons which arose in the 1970's, combined with the availability of superfluous C_6–C_8 paraffins, stimulated the interest of investigators in this reaction. It was established that extensive (more than 50%) disproportionation of paraffinic hydrocarbons can be achieved at a pressure above 1 MPa in the presence of high-silica zeolites (mordenite and type ZSM zeolites),[7,79–81] as well as bifunctional catalysts containing Group VI and VIII metals and a non-acid carrier.[82,83] In the latter case, the process proceeds without the isomerisation of the products of the kind which occurs on aluminium chloride and zeolites.

On zeolitic catalysts, the paraffin disproportionation products are undoubtedly formed via repeated intermediate reactions, as a result of which the composition of the products does not correspond to the equivalent contents of paraffins which are lighter and heavier than the initial hydrocarbon.

This type of process makes it possible to obtain the light homologues closest to the initial paraffinic hydrocarbons virtually without the formation of low-molecular-weight C_1 and C_2 products, the appearance of such products being inevitable in the usual hydrogenolysis. Thus the conversion of n-butane into propane with a selectivity of about 90% has been achieved on H-mordenite:[80]

$$3C_4H_{10} + H_2 = 4C_3H_8.$$

Table 3. Proportions of the products of the disproportionation of C_5–C_7 paraffins on the H-mordenite catalyst[9] [T = 320–340 °C, p = 5 MPa, rate of supply of raw material (space velocity) 1 h^{-1}, molar ratio hydrogen : raw material = 0.5].

*iso : n ≃ 2 : 1.

According to the results of Bursian et al.,[9] the predominance of light paraffins in the disproportionation products on the metallo-mordenite catalyst becomes more pronounced on passing from n-pentane to n-hexane, which can be explained by the vigorous hydrocracking of heptanes (Table 3). Indeed, n-heptane undergoes hydrocracking under the conditions investigated with formation of equimolecular amounts of propane and butanes. Thus the reaction of n-hexane can be described by the overall equation

$$2C_6H_{14} + H_2 = C_3H_8 + C_4H_{10} + C_3H_{12}. \quad (2)$$

In this sense, this process can be regarded as bimolecular hydrocracking.[9] The significant role of disproportionation in the hydrocracking of paraffins on metallozeolitic catalysts had been pointed out previously.[84] Approximately 70% of paraffinic C_4 and C_5 hydrocarbons have a branched structure. Together with the main reaction, side reactions involving the unimolecular hydrocracking of the raw material and the C_4 and C_5 products take place

to a slight extent: the yield of the C_1 and C_2 products does not exceed 5 mol % relative to the hexane which has reacted, while the yield of propane is close to the stoichiometric value corresponding to Eqn. (2).

There exist different points of view concerning the mechanism of the disproportionation of paraffinic hydrocarbons. Some workers[7,77,81] believe that it takes place via a condensation fragmentation mechanism, i.e. without the formation of low-molecular-weight alkylating agents. According to other workers,[75,85] the reaction takes place via a transmethylation mechanism.

According to the results of Kogan et al.[86] and Zhdanov et al.,[87] considerable amounts of C_7–C_{10} alkylbenzenes are formed in the reaction of C_5 and C_6 paraffins on H-mordenite and H-ZSM-5 zeolite in the presence of benzene at 300–380 °C and a pressure of 3.5 MPa (the degree of alkylation of benzene exceeds 50%), which is regarded as confirmation, in principle, of the transalkylation mechanism.[75,85] However, from the same data[86,87] one can conclude that the intermolecular transfer of the C_2, C_3 fragments plays the most significant role because the main primary alkylation products are ethylbenzene (on H-mordenite) and propylbenzene (on H-ZSM-5).

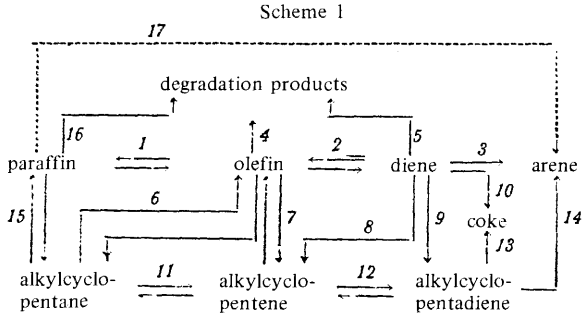
Analysis of the few data available[7,79–83] shows that metal-containing high-silica zeolites are the most promising catalysts of the disproportionation of C_6 and C_7 paraffins with formation of isoparaffinic C_4 and C_5 hydrocarbons. The reaction is carried out at a hydrogen pressure of 3–10 MPa, temperatures in the range 300–450 °C, and with the raw materials supplied at a space velocity of 0.5–2 h^{-1}. For the vigorous occurrence of the disproportionation reaction, it is essential to maintain a higher partial pressure of the hydrocarbon than in hydrocracking.

In a study of the disproportionation of mixtures of isobutane and n-hexane on a metallozeolitic catalyst with formation of isopentane [the reverse of reaction (1)], it was shown that, with increase in the isobutane : n-hexane molar ratio from 0.5 to 2.7, the yield of isopentane increases from 14.3 to 49.3 wt.%.[7] The data on the hydrocracking of n-hexane presented in the above study[7] for comparison show that the disproportionation ensures a more favourable composition of the reaction products (an increased content of isopentane and isohexanes).

The industrial application of paraffinic hydrocarbon disproportionation processes will make it possible to increase the manufacture of the acutely deficient C_4 and C_5 paraffins by processing their nearest homologues without the formation of the C_1 and C_2 light products, which are of little value, and, as can be seen from Eqn. (2), will significantly restrict the consumption of hydrogen compared with hydrocracking.

IV. Dehydrogenation of paraffinic hydrocarbons on aluminoplatinum catalysts

The dehydrogenation of C_4 and C_5 paraffinic hydrocarbons was first achieved on oxide catalysts. This led to the creation of large-scale industrial processes involving the dehydrogenation of butanes and isopentane on chromium oxide catalysts promoted by the addition of alkali metals (Ref.11, pages 147, 157; Ref.17). The dehydrogenation of higher n-paraffins to the corresponding mono-olefins was also initially investigated on aluminochromium catalysts.[18] Subsequently, in order to increase the selectivity and stability of aluminochromium catalysts, the reaction was carried out in hydrogen on catalysts promoted by lithium or potassium.[88,89]



In connection with the development of the industrial manufacture of polymetallic reforming catalysts and the growth of the requirement for higher linear mono-olefins in order to obtain surfactants and detergents, at the end of the 1960's the dehydrogenation of C_8–C_{18} n-paraffins on an industrial scale began to be carried out on platinum polymetallic catalysts.[10,90] The number of patents for the dehydrogenation of lower paraffins, starting with propane, as well as ethylbenzene on platinum increased.[15] Data concerning the development of similar processes for the dehydrogenation of C_3–C_5 paraffins to mono-olefins appeared in the 1980's.[5,6,8,90] The main advantages of the platinum catalysts, namely their ability to effect the reaction at a high rate and with a high selectivity (90–95%), make them especially valuable in the light of modern requirements for the intensification of technology and the economic use of raw materials.[91,92] Nevertheless, it follows from reviews and monographs,[17,18,93–96] that the characteristic features of the dehydrogenation of paraffinic hydrocarbons to olefins or metallic catalysts have been little described in the literature compared with the dehydrogenation on oxides.

1. Thermodynamics, kinetics, and mechanisms

According to data for equilibrium in the reaction involving the dehydrogenation of paraffins to mono-olefins, a degree of hydrogenation which is acceptable in practice (30–40% for light paraffins and 10–15% for higher paraffins) in hydrogen is attained at a pressure not exceeding 0.2–0.4 MPa (Table 4).

According to Kazanskii et al.[101] and Isagulyants et al.,[102] the set of the possible reactions of paraffinic hydrocarbons heavier than C_5 on platinum catalysts can be represented by the following Scheme:

Scheme 1

The main mono-olefin formation reaction (*1*) is catalysed by metallic centres and is the primary process relative to most of the side reactions (*2–14*), which occur both on the metal and on the carrier. This is the reason for the need to modify both components of the catalyst and for the significant restriction of the contact time.

Studies on the kinetics of the dehydrogenation of paraffins with formation of olefins on platinum were begun comparatively recently. The kinetic data for the dehydrogenation of C_{10}–C_{14} n-paraffins on catalysts promoted by the addition of lithium and tungsten,[103] tin,[104] and lead[105] agree with the consecutive parametrisation scheme (reactions *1–3* in Scheme 1).

The rate of formation of mono-olefins from higher n-paraffins (C_{10}–C_{12}) on an aluminoplatinum–tin catalyst at 430–470 °C and atmospheric pressure can be expressed by the equation[104]

$$r = (k_1 p_1 - k_2 p_2 p_{H_2})/(p_{H_2}^{1.5} + n_2 p_2 + n_3 p_3),$$

where p_1, p_2, and p_3 are the partial pressures of the paraffin, the mono-olefins, and the diolefins respectively and k_1, k_2, n_2, and n_3 are constants ($n_3 \gg n_2$).

* The reaction products are equilibrium mixtures of mono-olefins with different positions of the double bond in the molecule.
** The equilibrium degrees of dehydrogenation are quoted in the literature source only for a pressure of 0.1 MPa in the absence of hydrogen; the remaining values have been calculated.

Aromatic hydrocarbons do not influence the rate of formation of olefins under the conditions investigated.

The kinetics of the dehydrogenation of isobutane on bimetallic aluminoplatinum catalysts (promoting agents—copper, cadmium, indium, tin, and selenium; 500–600 °C; 0.1 MPa) correspond to the equation[106]

$$r = k_1 p_1 \gamma/(p_2 + k_2 p_{H_2}^{0.5}),$$

where γ is the coefficient which allows for the reversibility of the reaction; for the significance of the other notation, see above.

The mechanism of the dehydrogenation reaction includes the following stages:[104,106,107]

(1) the adsorption of the paraffinic hydrocarbons with elimination of one hydrogen atom; (2) the elimination of a second hydrogen atom with formation of an adsorbed olefin; (3) desorption of the olefin; (4) desorption of hydrogen.

In the case of consecutive dehydrogenation to the diolefin and an aromatic hydrocarbon, additional stages involving the readsorption of the mono- and di-olefin and the desorption of the diolefin and the aromatic product appear. Appreciable differences as well as common features (first order with respect to the initial hydrocarbon, inhibition by the reaction products) are characteristic of the kinetics of the dehydrogenation of paraffins with different molecular weights. Thus, according to isotopic data, the slow stage in the dehydrogenation of isobutane is dissociative adsorption of the paraffin,[106] while in the dehydrogenation of higher paraffins the slow stage is the desorption of the products.[104]

The presence of promoting agents can induce significant differences in the kinetics and chemistry of the dehydrogenation reaction on platinum. On bimetallic catalysts (in contrast to the unpromoted catalyst), the aromatisation via pathways related kinetically to olefins (reactions *2*, *6*, and *7* in the Scheme) is inhibited with a corresponding increase in the contribution of the "latent" aromatisation pathway *17* without the desorption of the intermediate products.[108]

A kinetic equation has been obtained[109] for the rate of dehydrogenation of isopentane to isopentenes in the presence of water vapour on a platinotin catalyst deposited on a zinc–aluminium oxide spinel (546–589 °C, 0.1 MPa) with allowance for the deactivation of the catalyst by coke:

$$r = \frac{k_1 p_1}{(1 + b p_1)^2}\left(1 - \frac{p_1 p_{H_2}}{p_1 K_e}\right)\exp(-\alpha c_c),$$

where K_e is the dehydrogenation equilibrium constant, k_1 and b are constants, c_c is the concentration of coke in the catalyst, and α is a parameter; for the significance of other notation, see above.

2. Catalysts

Platinum paraffin dehydrogenation catalysts are highly dispersed multi-component systems deposited on a thermostable oxide carrier with a high surface area. The concentration of platinum and the promoting agents does not usually exceed 1 wt.%. The most widely used carrier is γ-alumina.[10,15] Previously such platinum catalysts were widely used in the low-pressure reforming process.[31,32]

When the dehydrogenation process is carried out in the presence of steam at a temperature of about 600 °C, extremely stable spinels based on alumina and containing magnesium[110] or zinc[111] are used as the carrier.

In order to suppress the acidity, alkali or alkaline earth metals are introduced into the catalyst and also the halogen (chlorine) is removed. Group IB–VIB elements are added mainly with the aim of modifying the platinum.

Lithium or potassium as well as germanium subgroup elements are most often used as the promoting agents.[15] The nature of the surface of the highly dispersed deposited platinum catalyst is usually considered in terms of clusters—non-crystalline species whose size is as a rule less than 1 nm.[112]

The state of the atoms and the character of their interaction in clusters and crystals differ significantly, which is due to the coordinative unsaturation of the majority of atoms in the former case. Complex clusters, incorporating either only metal atoms (clusters of the alloy type[112]) or the atoms of an active metal together with the low-valence cations of the promoting agent stabilised by interaction with the carrier,[95,113] are formed on the surfaces of polymetallic deposited catalysts. Depending on the particle size and the nature of the interaction of the active metal with the carrier and the promoting agents, a significant change in the specific activity and selectivity of the active metal can occur[95,114,115] owing to both the geometrical effect (dilution of the active metal by the inert component, decrease in the size of the clusters) and the electronic effect (modification of the active metal as a result of the electronic interaction with the promoting agents[116,117]). The main cause of the deactivation of platinum dehydrogenation catalysts under the reaction conditions is coke deposition. Apart from the blocking of the surface of the metal and of the carrier pores by coke,[118] contact between platinum and the hydrocarbon medium diminishes the surface area of the metal as a result of its crystallisation[119] or the formation of a spinel with aluminium oxide.[120]

These effects evidently represent special forms of a general process involving the formation of the catalyst surface under the influence of the reaction mixture, which has been considered by Balandin,[121] Roginskii,[122] and Boreskov.[123]

Saturation by carbon alters the activity and selectivity of platinum in the hydrogenolysis, isomerisation, and dehydrocyclisation reactions of n-hexane[124] and in the dehydrogenation of cyclohexene (Ref.125, page 487). The degree of the poisoning of the catalyst by coke is not determined exclusively by its concentration and may differ significantly depending on the coke formation conditions and the nature of the catalytic reaction. The causes of the variation in the toxicity of coke may be (a) a difference in the structure of the coke deposits[125,126] (in particular the influence of the ordered and disordered layers of coke may be significantly different[125]), (b) a change in the quantitative distribution of coke between the metal and the carrier when the coke formation conditions are altered,[127] and (c) selective poisoning of the metallic centres catalysing the given reaction (deuterium exchange, dehydrogenation, and hydrogenolysis[128,129]).

The most important feature of modern polymetallic catalysts is their increased stability under coke formation conditions. The causes of the resistance to coke of catalysts of this kind is believed to be a decrease in the intensity of coke deposition as a result of the poisoning of the strong acid centres by the promoting agents (when tin is introduced[130,131]), saturation of the intermediates—precursors of coke (rhenium[132,133]), or hydrogenation of the carbon deposits (iridium[134]). At the same time, data have been obtained in recent years which indicate a sharp limit to the saturation of platinum by carbon in deposited dehydrogenation catalysts promoted by the zinc, gallium, and germanium subgroup elements, without the reduction in the overall coke concentration.[15,65,66,135–142] A similar effect involving protection against coke is caused, according to IR spectroscopic data for CO[135,136,138] and data for the chemisorption of benzene,[66] by the weakening of the adsorption of the reactants on platinum associated with the migration of the precoke intermediates onto the carrier, i.e. with the accumulation of coke outside the surface of the active metal.

The rhenium–sulphur system affords analogous protecting properties in relation to coke,[15,65] which has been explained by the high stability of rhenium sulphides.[65] A dependence of the promoting effect of rhenium on the presence of sulphur in platinum catalysts has been observed.[143,144]

The ideas examined here make it possible to explain the retention of the high effectiveness of bimetallic aluminoplatinum dehydrogenation catalysts even for a coke content exceeding 10% of the mass of the catalyst (Ref.31, pages 355, 358; Ref. 32, page 101; Refs.145–148).

3. Technological processes involving the dehydrogenation of paraffinic hydrocarbons

The dehydrogenation of higher n-paraffins is carried out in a stationary bed of a non-acid polymetallic aluminoplatinum catalyst with the raw material supplied at high space velocities (20–40 h^{-1}), in the presence of a small excess hydrogen pressure (0.3–0.4 MPa), and at a temperature 450–500 °C. The degree of conversion per pass is ~10 wt.%, which necessitates the repeated recirculation of the unreacted paraffins.[10,15,149,150] The low degree of dehydrogenation makes it possible to carry out the process in a single adiabatic reactor.

The "Pacol" process developed by the UOP Corporation (USA), characterised by the above features, has found application in industry.[149,150] The synthesis of mono-olefins by this method is promising because of the exclusively high (not less than 90%) selectivity and economy of the process. An additional valuable product is also the hydrogen-containing gas with a purity of 96 vol.%, whose yield relative to the initial raw material is 2–2.7 wt.%. The catalytic dehydrogenation reaction mixture can be used directly for the alkylation of benzene with isolation of the unreacted paraffins in the stage involving the fractionation of the alkylation products. When olefins are used to synthesise higher alcohols using the oxo synthesis, the catalytic reaction mixture is directed from the dehydrogenation plant to the stage in which olefins are isolated by adsorption (the "Oleflex" proces), where a concentrate containing 90–95% of the linear mono-olefins is obtained. By 1983, 22 "Pacol" plants were in operation or were being built[150] with an output of 25 000–100 000 tonnes of olefins per year. The development of a forced version of the process with a conversion of 13–14.5% per pass has been reported.[150]

It follows from Table 5 that Soviet technological processes have analogous basic parameters. An increase in the degree of conversion from 10–11% to 16–17% makes it possible to reduce the number of circulations of the unreacted raw material by a factor of 1.5 and to diminish the energy expenditure, in agreement with the conclusions reached by Vora et al.[150] In industrial practice, the catalyst is replaced by a fresh portion after a single raw material cycle, the old one being directed to the platinum extraction stage.

The possibility of the selective dehydrogenation of C_3–C_5 paraffinic hydrocarbons to mono-olefins on promoted aluminoplatinum catalysts with an up to 15 day reaction cycle was demonstrated at the beginning of the 1980's.[90,97,151] In an isothermal reactor with a fixed catalyst bed, where the raw materials were supplied at a rate of 1000 h^{-1} (with respect to the gas), a 30–40 wt.% conversion of C_4 and C_5 paraffins was achieved with a selectivity up to 91–92.5 wt.% with respect to mono-olefins. These parameters are significantly better than in the fluidised chromium

oxide catalyst bed (Table 6). The coke content in the catalyst at the end of the cycle reaches 12–15 wt.% (0.007–0.012 wt.% relative to the raw material passed through the system).

Table 5. Characteristics of the dehydrogenation reactions of C_{11}–C_{14} paraffinic hydrocarbons on a polymetallic aluminoplatinum catalyst.[15]

Parameters	Regime	
	normal	severe
Pressure, MPa abs.	0.4—0.5	0.3
Conversion, wt.%	11.2	17.8
Selectivity in formation of n-monoolefins, wt.%	90	85*
Duration of reaction cycle, days	30	20

Note. Temperature 460–500 °C, rate of supply of liquid raw material (space velocity) 20–30 h^{-1}, molar ratio hydrogen : raw material = 8 : 1.
** Without the hydrogenation of dienes.

The considerable interest in the synthesis of C_3–C_5 olefins by the paraffin dehydrogenation method is due to their wide application in petrochemistry, mainly for the preparation of synthetic rubber monomers and polyolefins[15–17] and to the considerable growth of the extraction of the raw material—liquefied petroleum gases.[152] Three new processes have been developed for this purpose during a short period.[153]

In the "Oleflex" process of the UOP Corporation (USA), a unit of three adiabatic reactors, analogous to the reactor for the "Pacol" process, is used with intermediate heating of the stream to compensate for the endothermicity of the reaction (~130 kJ mol^{-1}). The process is carried out in a fluidised bed of a polymetallic platinum catalyst (of the type of the catalyst for the "Pacol" process) with continuous regeneration. Coke formation does not exceed 0.02 wt.% relative to the raw material.[97] The working cycle of the catalyst, withstanding more than 250 regenerations,[97] is 3–14 days.[153] For a 45% conversion of isobutane, the selectivity for the formation of isobutene was 87.5% and that for the dehydrogenation of isopentane, taking into account the formation of isoprene, was 77.5 wt.%.[97]

In the "Star" process of the Philips Company, carried out in an isothermal tubular reactor with a fixed catalyst bed in the presence of steam,[153] a promoted platinum catalyst based on a thermostable spinel is also used judging from the patents of this Company.[17,111]

According to Choudhury's communication,[153] for an 8 h working catalyst cycle the selectivity in the dehydrogenation of isobutane reaches 95 mol % with ~50% conversion, which agrees with patent and research data for the dehydrogenation of paraffins on catalysts of this kind under similar conditions.[111,154] The "Oleflex" and "Star" processes are being tested on a semi-industrial scale.[153]

Thus, among the three new C_3 and C_4 paraffin dehydrogenation processes, two are based on the use of polymetallic platinum catalysts, which indicates the maintenance of the tendency towards the expansion of their applications noted previously.[15]

ABSTRACT. **The review is devoted to the reactions of unsaturated systems (alkenes, alkynes, arenes, alkadienes, and alkenynes) with carbonyl compounds (aldehydes, ketones, carboxylic acids, and α-, β-, γ-, and δ-dicarbonyl compounds) initiated by manganese(III) acetate. Attention is concentrated on the regio- and stereo-chemistry of the interaction, the pathways leading to the stabilisation of the intermediate radical-adducts, and also the assessment of the synthetic possibilities of reactions of the given type.**

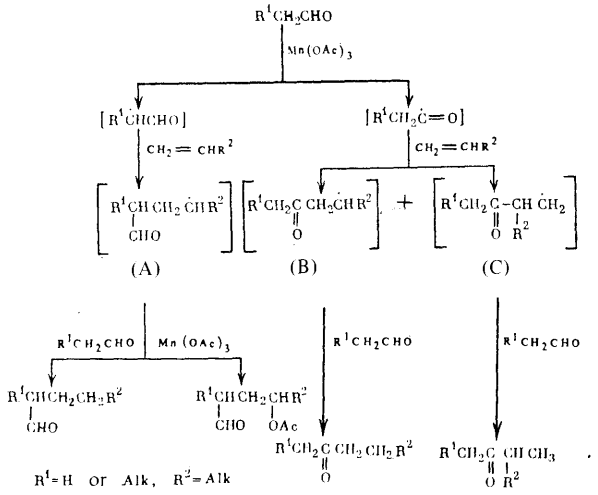
The bibliography includes 91 references.

I. Introduction

The development of methods for the generation of free radicals with the aid of oxidation-reduction systems, especially the salts and oxides of variable-valence transition metals (Mn^{3+}, Co^{3+}, Cu^{2+}, Fe^{3+}, Ag^{2+}, Pb^{4+}, Ce^{4+}, Mn^{4+}, Ag^{+}, Cu^{+}, Fe^{2+}, and Cr^{2+}), has been a powerful stimulus to the development of the chemistry of such radicals.[1–4] Compared with the traditional method of radical generation, oxidation-reduction methods have a greater selectivity, in particular in relation to polyfunctional organic compounds. Furthermore, radicals which cannot be generated by classical methods can be obtained with their aid.[3]

The oxidation radical generation methods, proceeding via outer- and inner-sphere mechanisms, have now been investigated most widely.[4] The fundamental difference between them consists in the fact that the oxidant not only generates the radical from the addend in the initiation stage but reacts effectively with the radical-adduct formed when the radical adds to the organic substrate; as a result of this, the synthetic result of the reaction is different from that of the reaction initiated by classical methods.[5]

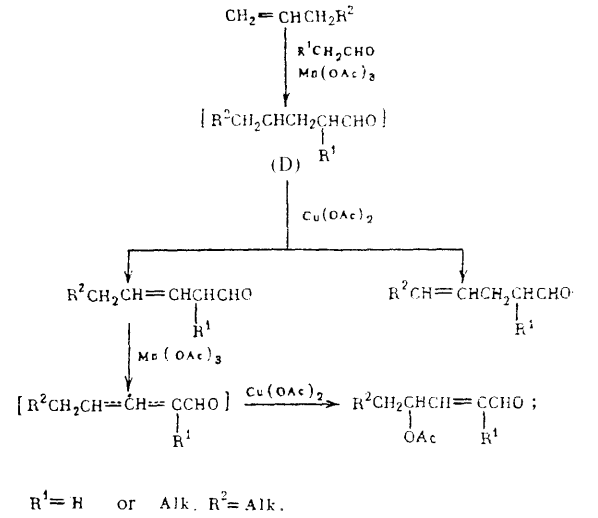
In the series of oxidants listed above, manganese(III) acetate is of special interest. The one-electron oxidation by the latter of the α-C–H bonds of carbonyl compounds generates α-oxo- and αα-dioxo-alkyl radicals, which react with unsaturated substrates when the latter are present in the reaction mixture. The subject of the present review is the consideration of reactions of precisely this type where monocarbonyl compounds—aldehydes, ketones, carboxylic acids, and α-, β-, γ-, and δ-dicarbonyl compounds—serve as the addend, the initiator is manganese(III) acetate, used separately or in combination with copper(II) acetate, and the unsaturated substrates consist of alkenes, alkynes, arenes, alkadienes, alkenynes, and alkadiynes. Attention will be concentrated on the regiochemistry of the generation of the oxoalkyl radicals, the regio- and stereochemistry of the interaction of the latter with the substrates, the pathways leading to the stabilisation of the intermediate radical-adducts, and the assessment of the synthetic possibilities of the reactions of the given type, including their use for the synthesis of natural products.



II. Reactions of alkenes with monocarbonyl compounds

1. Reactions with aldehydes

When aldehydes are oxidised by manganese(III) acetate, radicals of two types are formed—the α-formylalkyl radicals $R\dot{C}HCHO$ and the acyl radicals $RCH_2\dot{C}=O$, the type of the radical generated depending on the manganese(III) acetate concentration in the solution.[3,6] In a polar solvent (homogeneous conditions), the α-formylalkyl radicals are formed preferentially, while in the absence of solvent (heterogeneous conditions) the main product is acyl radicals, as for peroxide initiators.[7] It has been established that a primary isotope effect (k_H/k_D = 6) is observed for the reaction of CD_3CHO with $Mn(OAc)_3$, while in the reaction of CH_3CDO with $Mn(OAc)_3$ it is absent. This finding permits the conclusion that the direct interaction of the aldehyde with $Mn(OAc)_3$ yields the α-formylalkyl radicals, while the corresponding acyl radicals are apparently formed as a result of a secondary hydrogen atom transfer reaction.[3] It is also noteworthy that, in the oxidation of aldehydes without α-hydrogen atoms, for example, pivalaldehyde, acyl radicals are formed directly.[8]

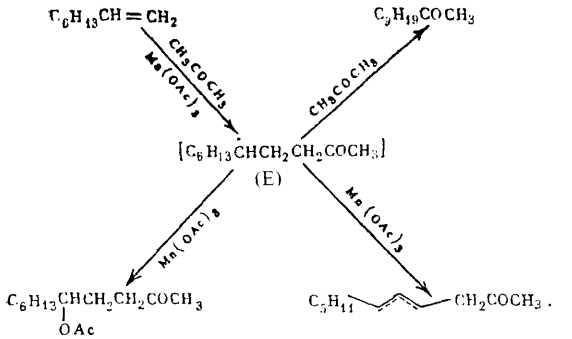


The addition of α-formylalkyl radicals to an alk-1-ene under homogeneous conditions affords radical-adducts of type (A), which are stabilised by the abstraction of a hydrogen atom or by oxidation with manganese(III) acetate via a ligand transfer mechanism.[1]

Radical-adducts of types (B) and (C) are formed under heterogeneous conditions and are stabilised by the addition of a hydrogen atom, which leads to isomeric saturated ketones:[9]

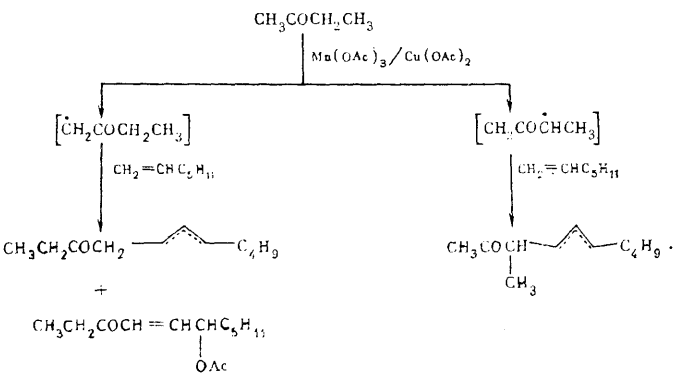
Depending on the structure of the aldehyde and the alkene, the ratio of the products listed in the above scheme is between 74:26 to 100:0 for homogeneous conditions and from 20:80 to 52:75 for heterogeneous conditions. This reaction has been proposed as a single-stage method of synthesis of higher α-alkyl-substituted aldehydes.[10]

The modification of the reaction of aldehydes with alkenes by the addition of catalytic amounts of copper(II) acetate proved to be extremely effective: the intermediate radical-adduct of type (D) was stabilised as a result of the oxidative elimination of β-protons, which led to γδ- and βγ-unsaturated aldehydes. Under the reaction conditions, the latter underwent further oxidation with formation of *trans*-4-acetoxyalk-2-enals:[11]



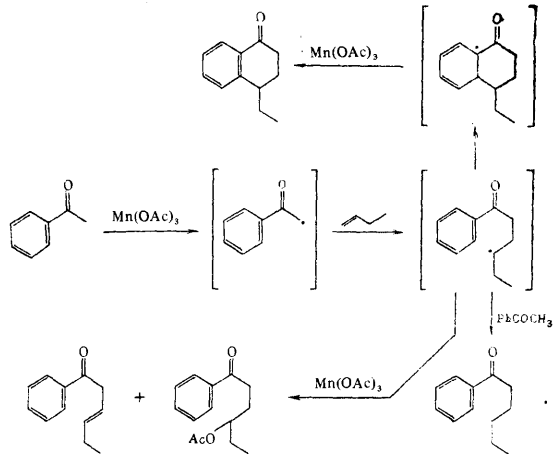
On passing from monosubstituted to 1,1-disubstituted alkenes, the chemistry of the reaction changes appreciably.[12] The main reaction products then become βγ- and γδ-unsaturated aldehydes also in the absence of copper(II) acetate. The authors explain this result by the nature of the intermediate radical-adducts, the difference between which is reflected quantitatively by the ratio of the rate constants for the oxidative elimination (k_{ox}) and abstraction of a hydrogen atom (k_{abs}). The ratio k_{ox}/k_{abs} is higher by 1–2 orders of magnitude for tertiary radical-adducts than for secondary radical-adducts. The reaction of aldehydes with β-pinene proceeds analogously, the intermediate radical-adducts undergoing skeletal isomerisation with the opening of the four-membered ring under these conditions.[13]

A mechanism, according to which the aldehyde reacts with the manganese(III) salt to form initially an oxallyl complex, has been proposed on the basis of kinetic data for the reactions of aldehydes with alkenes. The oxallyl complex decomposes reversibly with formation of α-formylalkyl free radicals, the regioselectivity of the alkylation of aldehydes by alkenes being determined by the equilibrium position.[14]



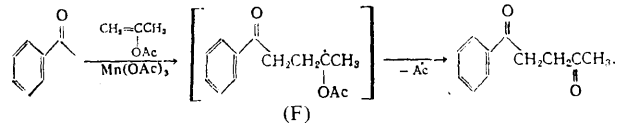
2. Reactions of ketones

The interaction of aliphatic and aromatic ketones with manganese(III) acetate leads to the formation of α-oxoalkyl radicals.[15–17] In the presence of unsaturated substrates, for example an alk-1-ene, the acetonyl radical, generated from acetone, affords the radical-adduct (E), which abstracts a hydrogen atom from the acetone or acetic acid molecule and undergoes oxidative elimination or substitution on treatment with manganese(III) acetate:[18,19]



The authors established a direct proportionality between the ratio of the reaction products and the acetone concentration, and showed that, in the hydrogen atom transfer stage, acetone is four times more active than acetic acid. In addition, it was demonstrated that the addition of copper(II) acetate to the reaction mixture greatly increases the content of unsaturated ketones and γ-acetoxyketones as a result of the ability of $Cu(OAc)_2$ to oxidise alkyl radicals more effectively compared with $Mn(OAc)_3$.[5] The $Mn^{3+}/Ce^{4+}/Cu^{2+}$ relative reactivity of the ions in the oxidation of secondary radical-adducts was determined quantitatively as 1/12/350.[19]

The methylene group participates preferentially in the oxidation of ethyl methyl ketone, but the methyl group is also involved:[20]



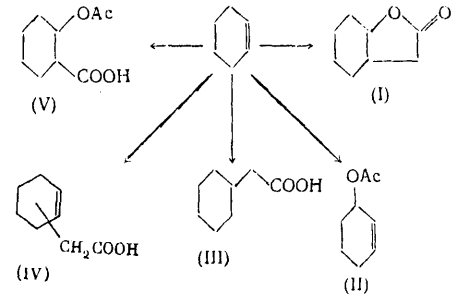
The interaction of aliphatic-aromatic ketones with alk-1-enes involves a new reaction pathway, together with those described above, namely intramolecular cyclisation leading to bicyclic compounds.[21] In particular, the reactions involving the cyclisation of acetophenone and but-1-ene yield a substituted tetralone:

The intramolecular cyclisation of δ-phenylalkyl radicals has been used to synthesise tetralin and indan derivatives.[21]

Cyclic ketones are oxidised by manganese(III) acetate, forming 2-oxocycloalkyl radicals, which interact with alkenes analogously to acyclic radicals.[20,22] It is remarkable that the ratio of the oxidative elimination products (βγ- and γδ-enones) depends on the ring size of the initial cycloalkanone.[22]

Enol ethers have also been involved in the reaction with ketones, which has made it possible to develop a single-stage method for the synthesis of 1,4-diketones—intermediates in the synthesis of jasmonoids.[23-25] For example, the addition of acetophenone to isopropenyl acetate leads initially to the radical-adduct (F), which is stabilised via the β-elimination of the acetyl radical with formation of a 1,4-diketone:[23]

(F)



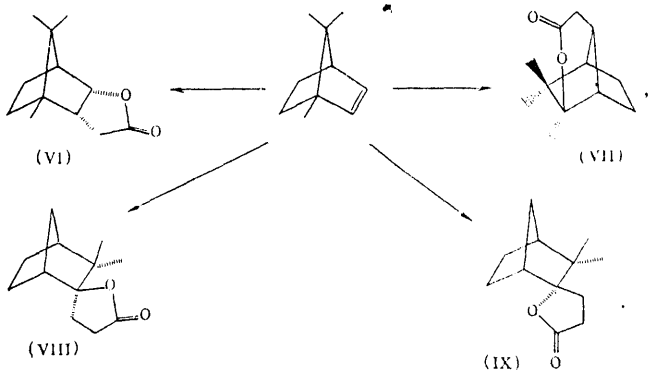
The analogous reactions of cyclohexanone, 2-octanone, and 3-methyl-2-heptanone have been investigated; the reaction involving asymmetric ketones results in the formation of a mixture of isomeric 1,4-diketones in accordance with two types of α-oxoalkyl radicals generated by the oxidation with manganese(III) acetate.[23] This reaction was subsequently extended by involving in it terpene ketones—nopinone, *cis*-verbanone, isonopinone, and isomenthone[24]—and has also been used in a key stage in the specific synthesis of 2-pentyl-2-cyclopent-1-enone—the precursor of dihydrojasmone and methyldihydrojasmonate.[25]

The telomerisation of ethylene with acetone, initiated by manganese(III) acetate, has also been investigated.[26-28] The products are 2-alkanones with a linear structure and isomeric 3-butyl-2-alkanones, formed as a result of the intermolecular rearrangement of the intermediate radical-adduct with 1,5-migration of a hydrogen atom. On catalysis by copper(II) acetate at an ethylene pressure of 100 atm, the main reaction pathway becomes the oxidative elimination of the telomeric radicals, leading to ω-unsaturated ketones.[27]

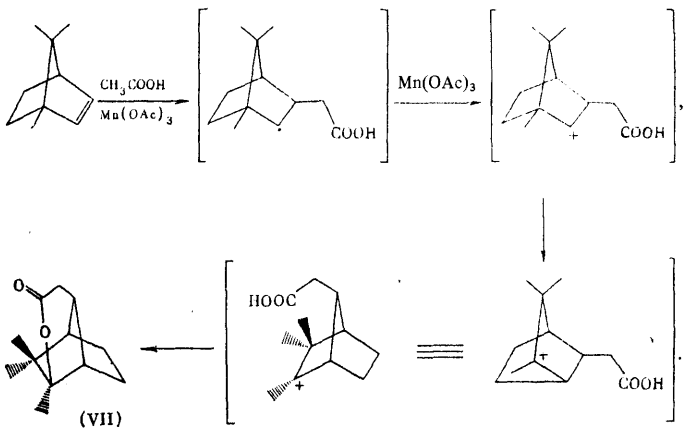
3. Reactions with carboxylic acids

The interaction of carboxylic acids with manganese(III) acetate is known to generate α-carboxyalkyl radicals.[3] The latter are capable of adding to the double bond of alkenes with formation of 3-carboxyalkyl radicals, which cyclise to alkan-4-olides in the presence of one-electron oxidants.[29-35] The formation of allyl acetates[30,32] as a result of the abstraction of the allyl hydrogen atom by the α-carboxymethyl radical and subsequent acetoxylation has been detected in a number of instances. It is notable that the selectivity of the lactonisation of the lactone:allyl acetate product ratio is 30:1 for methylstyrene and 50:1 for oct-1-ene.[32]

The lactonisation of alkenes by treatment with acetic acid and manganese(III) acetate is achieved in the presence of acetic anhydride[30] or potassium acetate.[32] The synthetic result of the application of two alternative methods is frequently the same,[30-32] but in the case of oct-1-ene the addition of potassium acetate leads to the corresponding lactone[32] whereas the main product resulting from the use of acetic anhydride is decanoic acid together with small amounts of decan-4-olide and 3- and 4-decenoic acids.[36] It is remarkable that the application of the same method involving the use of acetic anhydride by different investigators yielded different results. In the reaction involving cyclohexene, the formation of the lactone (I) and allyl acetate (II) has been detected by Bush and Finkbeiner.[30] Subsequently carboxymethylcyclohexane (III), carboxymethylcyclohexene (IV), and 1-acetoxy-2-carboxymethylcyclohexane (V) were also isolated:[37]



An analogous picture has been observed for cyclopentene, 1-methylcyclohexene, hex-1-ene, and 2-methylpent-2-ene.[37,38]

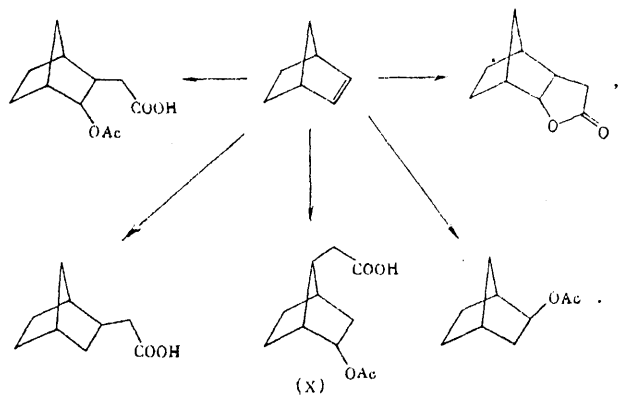


The monoterpenes *p*-menth-1-ene, 3-carene, α-pinene, bornene, and camphene have also been involved in the reaction with acetic acid initiated by manganese(III) acetate.[39-42] The products of the reactions for the first two compounds are lactones[39,40] but, on passing to α-pinene, the reaction chemistry changes appreciably.[41] The expected lactone is a minor reaction product, a mixture of the acetates of *cis*-pin-3-en-2-ol, myrtenol, and α-terpineol being mainly formed.[41] The last compound is produced as a result of the isomerisation of α-pinene via a carbonium ion mechanism under the influence of acetic acid.

The interaction of bornene with acetic acid affords a mixture of the isomeric lactones (VI)–(IX) and it has been demonstrated unambiguously that the formation of the *exo*- and *endo*-lactones (VIII) and (IX) is a result of the acid-catalysed rearrangement of

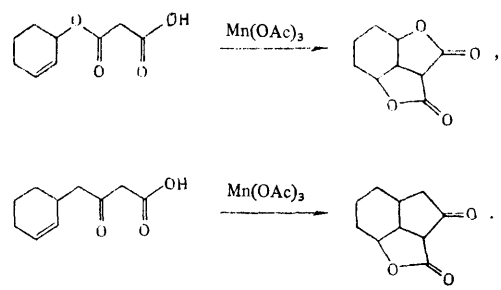
bornene to camphene and its subsequent interaction with acetic acid:[42]

The presence among the reaction products of the δ-lactone (VII), which is formed via the scheme presented below involving the Wagner–Meerwein rearrangement stage, is of separate interest:



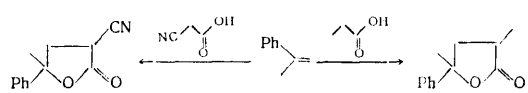
Since the Wagner–Meerwein rearrangement does not take place for radicals, the authors believe that this reaction indicates the intermediate formation of carbonium ions in the oxidation of radicals by manganese(III) acetate.[42]

Reactions of the above type have been modified by carrying them out in the presence of potassium bromide[43,44] and potassium or copper(II) acetates.[45,46] In the former case, the main reaction products are substituted allyl acetates while in the latter the main products are *trans*-alk-4-enoic acids.



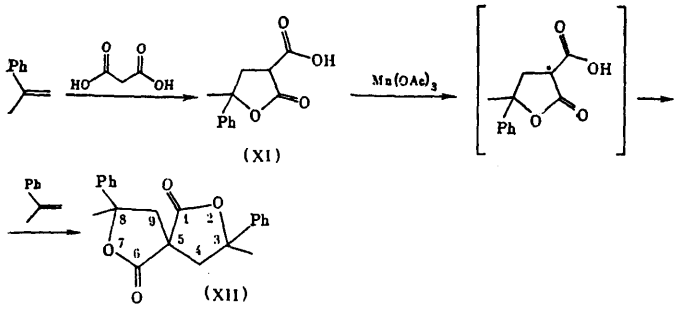
Detailed investigation of the reaction of alkenes with acetic acid has shown that (a) the use of manganese(III) acetate trihydrate is more effective in the synthesis of alkan-4-olides than the use of the anhydrous salt, that (b) acetic anhydride increases the rate of reaction as a consequence of its greater C–H acidity compared with acetic acid but the yields of alkan-4-olides are reduced as a result of the formation of unsaturated and α-acetoxy-substituted carboxylic acids, and that (c) potassium acetate increases the yield of alkan-4-olides by playing the role of a base facilitating deprotonation in the acetoxidation stage.[47] The study of the stereochemistry of the lactonisation reaction showed that the alkan-4-olides are mixtures of geometrical isomers and that their ratio varies within wide limits depending on the structure of the alkene—from 67:1 to 1:5.4.[47]

Like bornene, norbornene gives rise to a mixture of products on lactonisation, among which compound (X)—the result of the Wagner–Meerwein rearrangement of the intermediate cation—is formed in 1% yield.[47] On this basis, the authors claim that the reaction takes place almost fully via a radical mechanism and that there is no formation of intermediate carbonium ions in the oxidation of alkyl radicals by manganese(III) acetate:



It is remarkable that this conclusion conflicts with the conclusion reached by Witkiewicz and Chabudzinski[42] that a carbonium ion is formed in an analogous reaction.

The lactonisation of alkenes by acetic acid has been used to synthesise jointed ketolactones and dilactones, which are intermediates in the synthesis of polycyclic compounds of natural origin:[48]

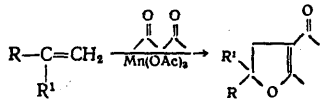


It has been reported that propionic[31,38,49] and cyanoacetic[31,50] acids also enter into the cycloalkylation reaction with alkenes and that the reaction involving α-methylstyrene results in the selective formation of 2-methyl- and 2-cyano-4-phenyl-lakan-4-olides:[31]

The interaction of camphene with cyanoaectic acid proceeds analogously.[50] On the other hand, the interaction of cyclohexene, cyclopentene, 1-methylcyclohexene, hex-1-ene, 2-methylpent-2-ene with propionic acid proceeds non-selectively.[38,49]

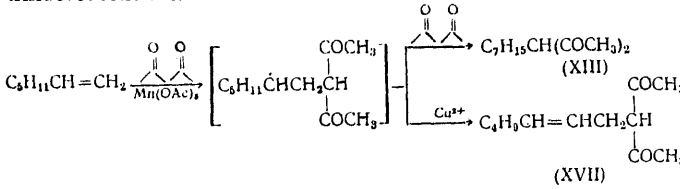
Malonic acid is the only dicarboxylic acid which has been introduced into the reaction with alkenes initiated by manganese(III) acetate;[51] the αα-dicarboxymethylradical adds in this reaction, in particular to α-methylstyrene with formation of the lactone (XI), which undergoes further oxidation and this leads to the

spirolactone (XII) in the form of a mixture of stereoisomers [3(*R*), 5(*R*), 8(*R*)-, 3(*S*), 5(*R*), 8(*S*)-, and 3(*R*), 5(*R*), 8(*S*)-]:



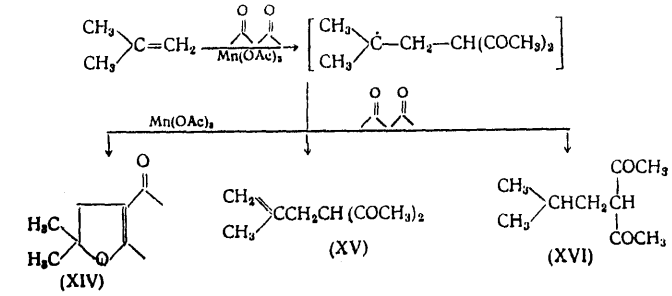
(XI)

(XII)



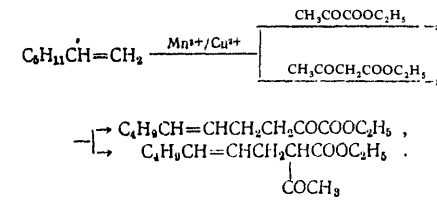
Manganese(III) acetate also initiates the interaction of carboxylic acid anhydrides with alkenes. The reaction products are saturated carboxylic acids.[52]

III. Reactions of alkenes with dicarbonyl compounds



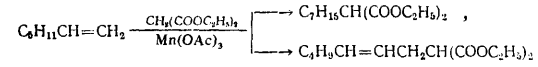
Acetylacetone is oxidised selectively by manganese(III) acetate at the methylene group of the acetylacetonyl.[53,54] When the above reaction is carried out in the presence of α-methylstyrene,[53] styrene,[53,54] 2-methylpent-2-ene,[53] and oct-1-ene,[53] it is accompanied by oxidative cyclisation to the 4,5-dihydrofuran derivatives:

The interaction of hept-1-ene with acetylacetone results in the formation of an adduct—3-acetyl-2-decanone (XIII), while the reaction of isobutene affords, together with dihydrofuran (XIV), also the diketones (XV) and (XVI) in proportions of 35:18:3.[54] In the presence of copper(II) acetate, the unsaturated diketone (XVII) is also obtained together with compound (XIII) (in proportions of 1:2). On the other hand, in the case of isobutene the effect of the introduction of $Cu(OAc)_2$ proved to be insignificant.[54] A detailed investigation of the reaction of hex-1-ene with acetylacetone showed that, depending on the reaction conditions, there is also a possibility of the formation of a 4,5-dihydrofuran derivative of type (XIV) together with an adduct of type (XIII).[55] The content of the dihydrofuran derivative increases with increasing acetic acid/acetylacetone ratio and manganese(III) acetate concentration and when water and trifluoroacetic acid are added:



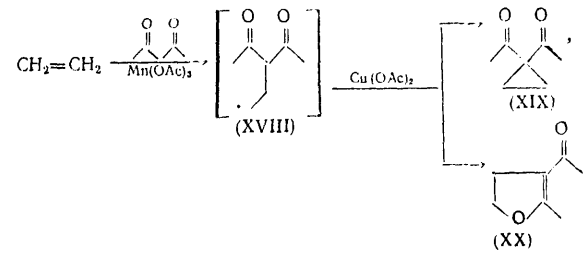
(XIII), (XVII)

(XIV), (XV), (XVI)



Cyclohexane-1,3-dione reacts with alkenes similarly to acetylacetone and the reaction products are substituted benzofurans.[53] Together with 1,3-diketones, the esters of carboxylic α-, β-, and γ-ketoacids and α-, β-, and γ-acetoxy-substituted aliphatic ketones have also been involved in the reaction with alkenes.[53,56,57] The selectivity in the formation of radicals on oxidation with manganese(III) acetate depends on the structure of the ketoesters. In the reaction of the acetoacetic ester, the radicals are generated from the methylene group, while in the reaction of the acetate of diacetonyl alcohol and ethyl pyruvate they are formed from the ethyl group. On the other hand, acetylpropyl acetate, methyl levulinate, and acetoxyacetone give rise to mixtures of isomeric radicals and, with decrease in the number of carbon atoms between the carbonyl and ester groups, the involvement of the methyl group in the oxidation increases appreciably.[57]

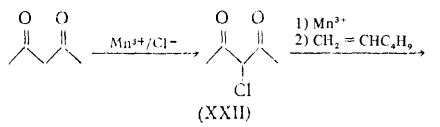
The nature of the products formed in the interaction of ketoesters with alkenes depends both on the structure of the latter and on the participation of copper(II) acetate in the reaction. In particular, styrene reacts with acetoacetic ester in the same way as with acetylacetone, forming 4,5-dihydrofuran derivatives.[53] The reaction of hept-1-ene with ethyl pyruvate and acetoacetic ester leads selectively to γδ-unsaturated ketoesters:[57]



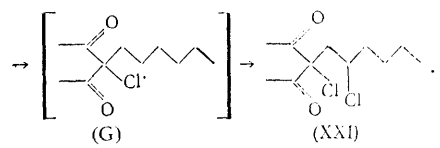
The remaining ketoesters listed above afford products with both linear and branched structures in which the double bond is in the βγ-and γδ-positions relative to the keto-group in their reactions with alkenes.[57]

Diethyl malonate has also been introduced into the reaction with alkenes initiated by manganese(III) acetate.[56,58] In the reaction with hept-1-ene, addition is observed; when the reaction is catalysed by copper(II) acetate, the main pathway becomes oxidative deprotonation:

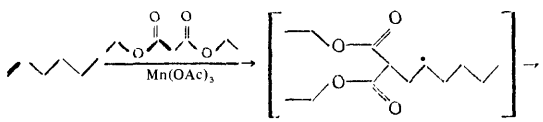
The reaction proceeds similarly also with ethyl cyanoacetate and with diethyl butylmalonate.[56]



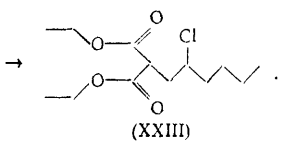
A new reaction pathway was discovered in the interaction of ethylene with β-dicarbonyl compounds.[59] The intermediate radical adduct (XVIII) undergoes oxidative 1,3-cyclisation on treatment with copper(II) acetate with formation of the *gem*-disubstituted cyclopropane (XIX) together with the dihydrofuran (XX):



(XVIII), (XIX), (XX)

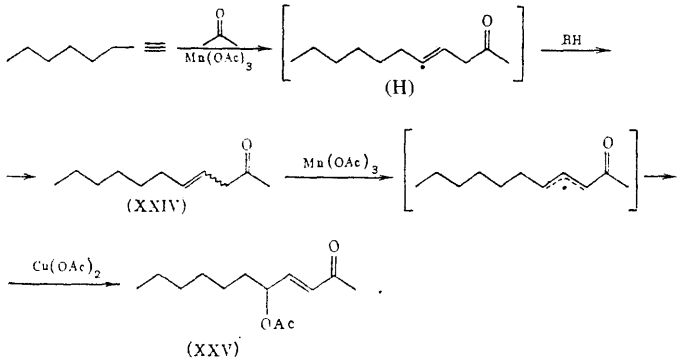


In contrast to reactions with acetylacetone and acetoacetic ester, in the interaction of ethylene with cyanoacetic and malonic esters the radical-adducts of type (XVIII) undergo oxidative elimination and prototropic isomerisation with formation of ethylidenecyanoacetic and ethylidenemalonic esters.[60]

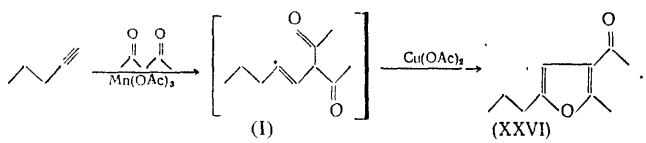


The reactions of alkenes with dicarbonyl compounds initiated by manganese(III) acetate have been modified by carrying them out in the presence of lithium chloride.[55,61] In this case, the products are either 1,3-dichloro- or monochloro-derivatives of β-dicarbonyl compounds. In particular, 3-acetyl-3,5-dichloro-2-nonanone (XXI) was isolated in the reaction of hex-1-ene with acetylacetone. The proposed reaction mechanism involved the formation of monochloroacetylacetone (XXII), the oxidative addition of the latter to the double bond of the substrate, and the subsequent chlorination of the radical-adduct (G):[55]

The mechanism of the reaction involving diethyl malonate differs from that illustrated above by the fact that lithium chloride participates in the reaction in the stage involving the oxidation of the intermediate radical-adduct and not in the radical generation stage, which leads to the monochlorosubstituted diester (XXIII):[61]

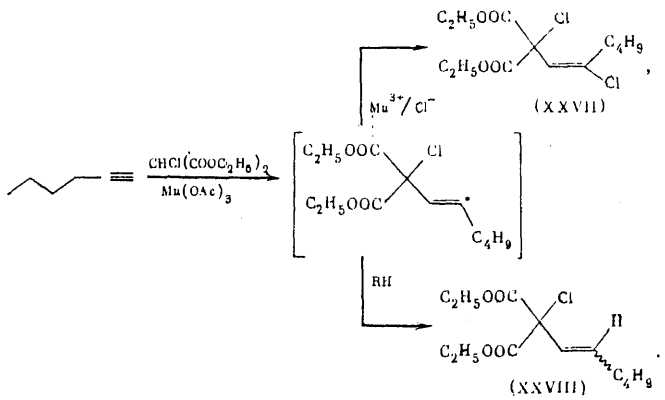


Chloromalonic ester can also be used in this reaction as the dicarbonyl compound.[62]



IV. Reactions of alkynes with carbonyl compounds

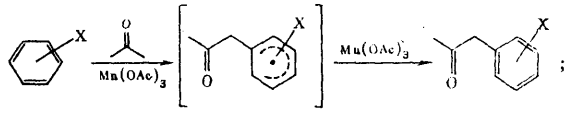
Alkynes have been investigated to an incomparably smaller extent than alkenes in reactions with carbonyl compounds initiated by manganese(III) acetate.[20,22,62,63] In particular, the interaction of oct-1-yne with acetone entails the initial formation of the vinyl radical-adduct (H), whose stabilisation as a result of the abstraction of hydrogen from the addend or the solvent leads to the βγ-unsaturated ketone (XXIV). The latter undergoes partial oxidation under the reaction conditions, being converted into *trans*-5-acetoxyundec-3-en-2-one (XXV):[20]



In the reactions with cyclic ketones, the primary products are βγ-unsaturated ketones, which are converted as a result of prototropic isomerisation into 2-substituted 2-cycloalkenones, in particular the analogues of dihydrojasmone.[22]

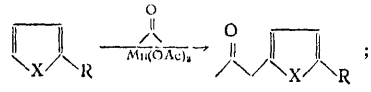
On passing from monocarbonyl to β-dicarbonyl compounds, a qualitatively new synthetic result has been achieved in reactions with alkynes. The vinyl radical-adduct (I), formed in the first stage of the reaction, undergoes oxidative cyclisation on treatment with copper(II) acetate, which leads to the furan derivative (XXVI):[63]

Acetylene, pent-1-yne, phenylacetylene, acetylacetone, and acetoacetic ester have been introduced into the above reaction.[63]



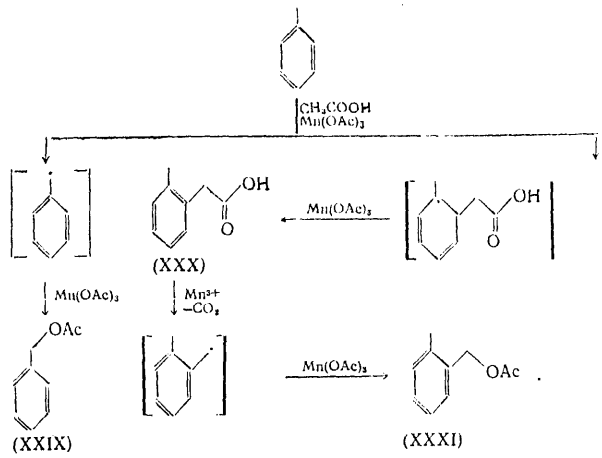
The reaction of chloromalonic ester with hex-1-yne has been investigated in the presence of the manganese(III) acetate–lithium chloride system[62] and it has been shown that the intermediate radical-adduct is stabilised by oxidative chlorination and addition of a hydrogen atom:

It has been established that the double bond in compound (XXVII) has the (*E*)-configuration, while the monochloro-derivative (XXVIII) is a mixture of geometrical isomers owing to the partial inversion of the vinyl group.[64]



V. Reactions of arenes with carbonyl compounds

The oxoalkyl radicals generated in the oxidation of carbonyl compounds by manganese(III) acetate can interact with aromatic systems: benzene, its mono- and di-substituted derivatives, and naphthalene.[20,65–67] In the reaction with acetone, the intermediate radical-adducts are converted by oxidative elimination into *p*-, *m*-, and *o*-methylbenzyl ketones with the last predominating:[66,67]

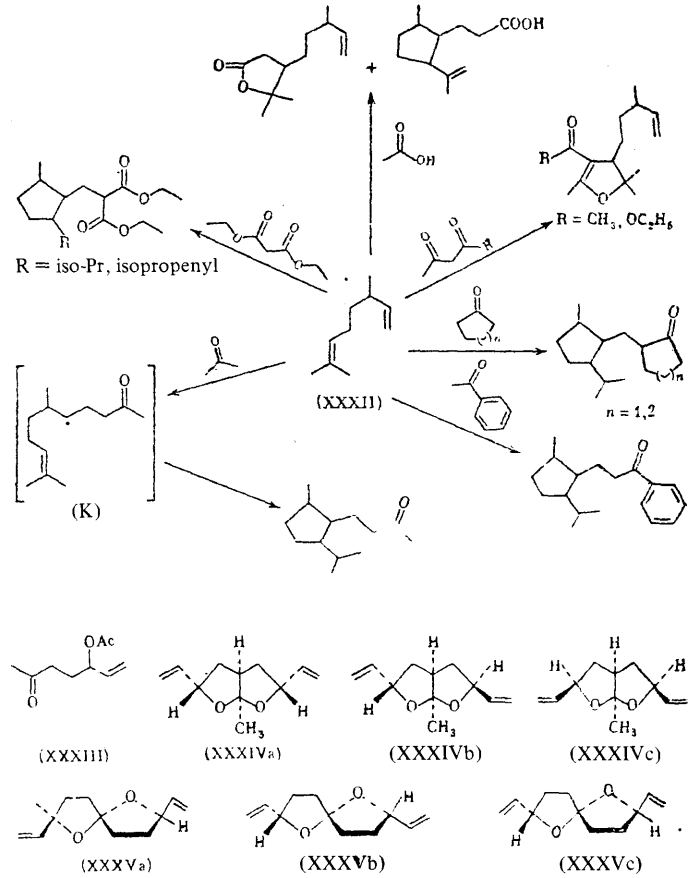


X = H, CH_3, CH_3O, Cl, CN, $COOC_2H_5$, F .

Furan, silvan, and thiophen also undergo homolytic substitution reactions with α-oxoalkyl radicals, but, in contrast to carbocyclic compounds, the reactions take place selectively via the α-carbon atom of the heteroaromatic ring:[66,68]

R = H, CH_3; X = O, S .

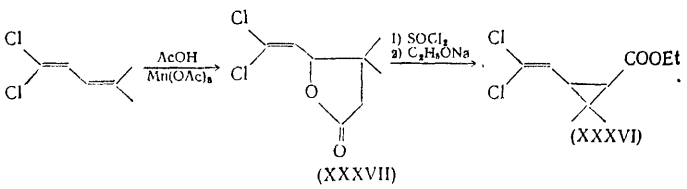
An analogous picture is observed in the interaction of the above heterocycles with acetylacetone.[68] The formation of benzyl acetate as a minor component has been detected in the reaction of toluene with acetone.[19] The same compound is one of the main products of the reaction of toluene with acetic acid.[69] Tolylacetic acid (XXX)—the result of the attack by the carboxymethyl radical on the aromatic nucleus—as well as methylbenzyl acetate (XXXI)—the product of the further oxidation of compound (XXX)—are formed under these conditions together with benzyl acetate (XXIX):



The interaction of arenes with nitromethane, leading to arylnitromethanes, is related to reactions of the type considered in this Section.[70,71]

VI. Reactions of alkadienes with carbonyl compounds

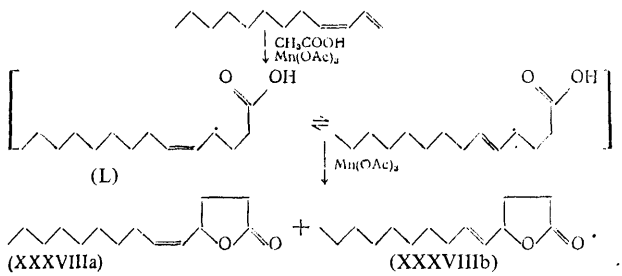
Alkadienes with isolated double bonds—octa-1,7-diene, 2,4-dimethylpenta-1,4-diene, and 2,5-dimethylhexa-1,5-diene—can interact with carbonyl compounds via both one and both double bonds,[72] which leads to 4-alkenylbutan-4-olides and bisbutan-4-olides in the reactions with acetic and cyanoacetic acids respectively. In the presence of double bonds substituted to different extents in the alkaldiene molecule, the regiochemistry depends on the nature of the carbonyl component.[73] In the reactions involving acetyl acetate and acetoacetic ester, radical attack is directed selectively to the C(6) atom of 3,7-dimethylocta-1,6-diene (XXXII), while in the reactions with cyclopentanone, cyclohexanone, acetophenone, diethyl malonate, and acetone the attack is directed to the C(1) atom. In contrast to this, the carboxymethyl radical generated from acetic acid adds to both the C(6) and the C(1) atoms.



When a trisubstituted double bond is involved in the reaction, derivatives of a γ-lactone and 4,5-dihydrofuran are formed in the reactions involving acetic acid, acetylacetone, and acetoacetic ester, as in the analogous reactions of alk-1-enes.[29,31,53] The reaction involving a monosubstituted double bond leads to cyclopentane derivatives as a result of the intramolecular cyclisation of radical-adducts of type (K). The cyclopentane derivative is also the main product of the reaction of hexa-1,6-diene with acetic acid in the presence of manganese(III) acetate.[46]

An unexpected result has been obtained in the study of the reaction of acetone with butadiene.[74] It was found that the reaction products are 5-acetoxyhept-6-en-2-one (XXXIII), three isomeric 1-methyl-3,7-divinyl-2,8-dioxa-*cis*-bicyclo[3.3.0]octanes (XXXIV a–c), and three isomeric 2,7-divinyl-1,6-dioxaspiro[4,4]nonanes (XXXV a–c):

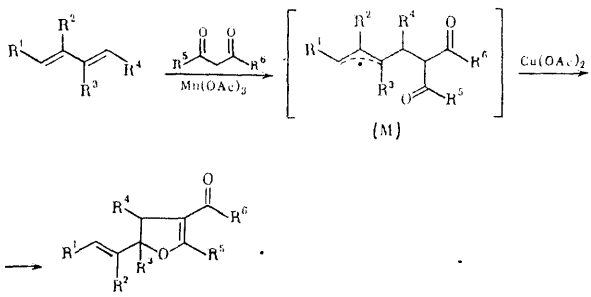
The authors proposed a mechanism involving the initial formation of compound (XXXIII), its subsequent oxidation by manganese(III) acetate, and interaction with a second butadiene molecule.[74]



The reaction of an alkadiene with acetic acid, initiated by manganese(III) acetate, has been used as the key stage in the specific synthesis of pyrethroid (XXXVI); it involves the selective lactonisation of the tetrasubstituted alkadiene, leading to the lactone (XXXVII):[75]

(XXXVII) (XXXVI)

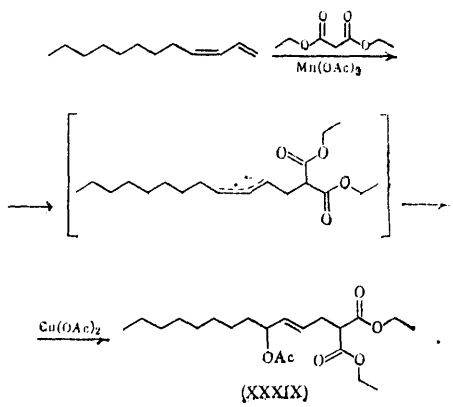
The analogous reaction of cyclopentadiene with acetic acid has also been described.[34]



The data obtained in the stereochemical tests on the lactonisation reaction of *cis*-dodeca-1,3-diene are of individual interest.[76] It has been established that the reaction involves the inversion of the *cis*-double bond, leading to the *cis*- and *trans*-isomers of 5-tetradecen-4-olide (XXXVIIIa, b):

(XXXVIIIa) (XXXVIIIb)

The change in the configuration of the double bond apparently occurs in the *cis*-allyl radical-adduct (L). We may note that the lactones (XXXVIIIa, b) have been isolated from the females of the japanese beetle, the *cis*-isomer (XXXVIIIa) being the sex pheromone of the given species.[77]



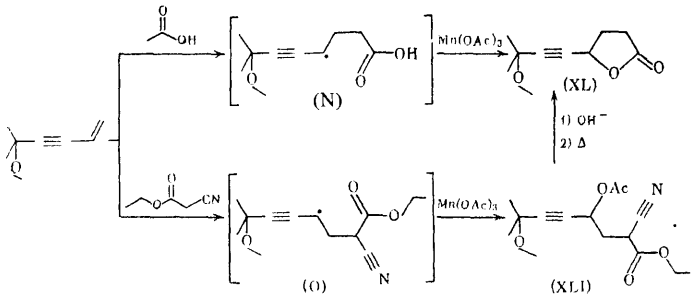
The oxidative addition of β-dicarbonyl compounds to conjugated alkadienes in the presence of manganese(III) and copper(II) acetates has also been investigated.[78–82] Butadiene, piperylene, isoprene, myrcene, methyl sorbate, crotonylideneacetone, cyclopentadiene, cyclohexadiene, bicyclopentadiene, 2,3-dimethylbutadiene, and vinylfuran were introduced as the unsaturated component, while acetylacetone, acetoacetic ester, dimedone, and diethyl acetonedicarboxylate were used as the carbonyl component. In all the cases examined, the products are derivatives of 4,5-dihydrofuran, formed as a result of the oxidative cyclisation of radical-adducts of type (M):

(M)

Reactions with isoprene and myrcene form mainly disubstituted double bonds. The activated dienes—methyl sorbate and crotonylideneacetone—react with acetylacetone preferentially via the α-carbon atom.[80]

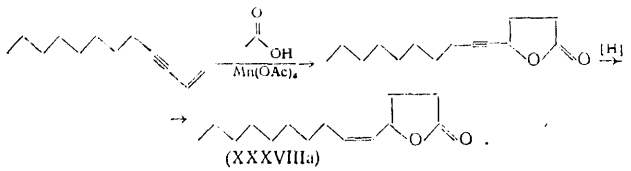
The study of the stereochemistry of the reactions of conjugated alkadienes with β-dicarbonyl compounds has shown that *cis*-5-methylhexa-1,3-dien-5-ol and *cis*-dodeca-1,3-diene interact with acetoacetic ester and acetylacetone with partial inversion of the *cis*-double bond, while in the reaction of *trans*-5-methylhexa-1,3-dien-5-ol the configuration of the double bond is retained.[82] The degree of inversion varies depending on the structures of the unsaturated and carbonyl components: the inversion apparently occurs in the intermediate *cis*-allyl radical-adducts. The inversion of the *cis*-double bonds indicates unambiguously the formation of intermediate allyl radical-adducts, but the available experimental data did not permit a decision as to whether the inversion of the double bond of the allyl radical-adduct takes place in the coordination sphere of manganese(III) or outside it, i.e. after the decomposition of the π-allylmanganese(III) complex and the liberation of the free radical-adduct into the surrounding space,[80,82]

(XXXIX)



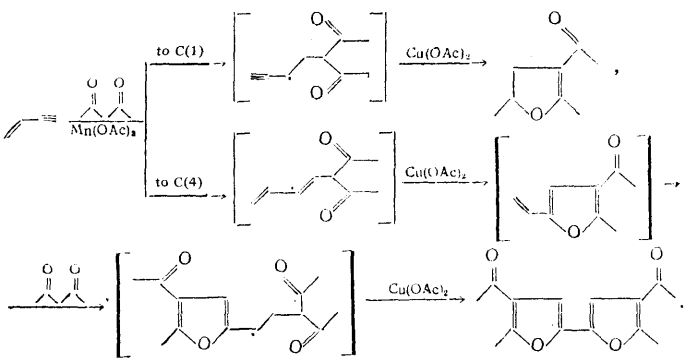
Derivatives of 4,5-dihydrofuran are obtained via the 1,2-cycloaddition of carbonyl compounds to alka-1,3-dienes. In contrast to this, the interaction of *cis*-dodeca-1,3-diene with malonic ester involves 1,4-addition with formation of the *trans*-ester (XXXIX) as a result of the stabilisation of the intermediate radical-adduct via the oxidative substitution mechanism.[82]

It has been reported that butadiene reacts with malonic ester, forming the products of both 1,2- and 1,4-addition.[81] On the other hand, in the reaction of the monoethyl ester of malonic acid cyclisation via the carboxy-group, leading to 5-vinylbutan-4-olide, takes place.[81]



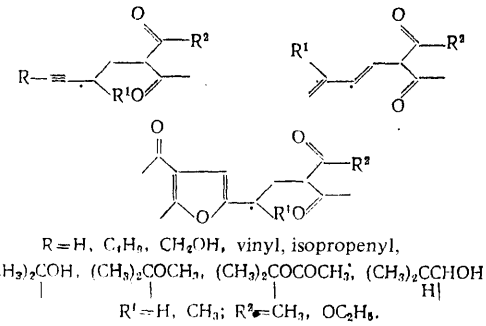
VII. Reactions of alkenynes and alkadiynes with carbonyl compounds

Conjugated alkenynes have also been involved as substrates in the interaction with carbonyl compounds initiated by manganese(III) acetate.[78,83–86] One of the motives which stimulated these investigations has been the development of the method of synthesis of 5-alkyn-4-olides—the key synthons in the synthesis of γ-butyrolactone derivatives, which are the sex pheromones of certain animals.[87–89] The lactonisation of the methyl ether of dimethylvinylethynylcarbinol was carried out by treatment with acetic acid or ethyl cyanoacetate in the presence of manganese(III) and copper(II) acetates.[85] In the former case, the reaction product was the lactone (XL), formed on cyclisation of the radical-adduct (N) via the carboxy-group. In the latter case, the radical-adduct (O) is stabilised via the 'oxidative substitution' mechanism, forming compound (XL), which is

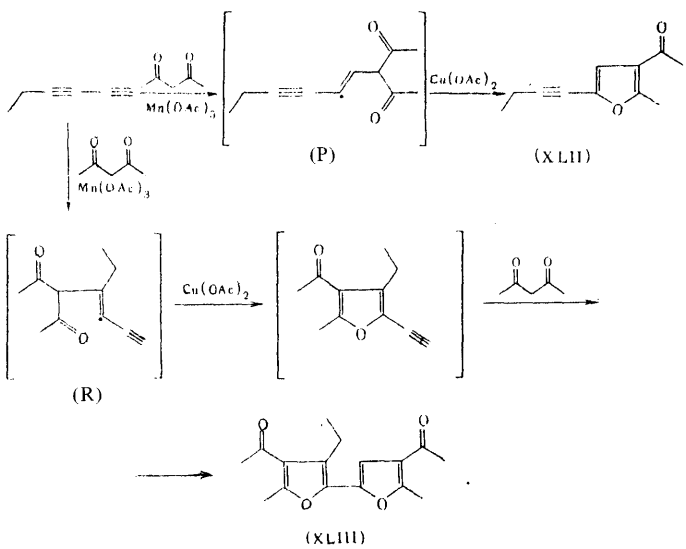


converted into the lactone (XL) as a result of alkaline hydrolysis and thermal decarboxylation-dehydration:

The method involving the direct lactonisation by treatment with acetic acid has been applied successfully in the synthesis of 5-alkyn-4-olides with different carbon skeletons, with the exception of the isoprenoid skeleton.[90] The reaction has been used as the key stage in the synthesis of (±)-*cis*-tetradec-5-en-4-olide (XXXVIIIa)—the racemate of the sex pheromone of the japanese beetle:[76]



The regiochemistry of the interaction of conjugated alkenynes with β-dicarbonyl compounds in the presence of manganese(III) acetate and catalytic amounts of copper(II) acetate has been investigated[78,83,84,86] using but-1-en-3-yne (vinylacetylene) and its 2- and 4-alkyl or 2,4-dialkyl-derivatives as the substrate. In particular, it has been shown that the reaction of but-1-en-3-yne with acetylacetone is non-regioselective and leads to addition-cyclisation products with participation of the double and triple bonds:



Vinylacetylene and isopropenylacetylene interact analogously with acetoacetic ester and, whereas in the former case the reactivities of both multiple bonds are comparable, in the reaction involving isopropenylacetylene an appreciable change in the regioselectivity of the process is observed with the preferential occurrence of the reaction via the double bond.[84] A similar picture has been observed for 4-substituted and 2,4-disubstituted derivatives of but-1-en-3-yne.[83,86]

The dihydrofuran and furan rings are formed in the reactions of conjugated alkenynes with β-dicarbonyl compounds as a result of the intramolecular cyclisation of secondary and tertiary propargyl, vinylpropargyl, dienyl, or α-furylalkyl radical-adducts on treatment with copper (II) acetate:

For comparison, one should note that the benzyl radical-adduct is also stabilised via cyclisation[53,54] whereas the alkyl radical-adducts, formed in the interaction of β-dicarbonyl compounds with alk-1-enes, undergo oxidative elimination on treatment with copper(II) acetate, affording γδ-unsaturated carbonyl compounds.[54,57] The set of these findings combined with data on the cyclisation of the allyl radical-adduct (Section VI) permitted the conclusion that alkyl radicals containing unsaturated groups in the α-position are stabilised, when the molecule contains at least one acetyl group, on treatment with copper acetate exclusively via the intramolecular cyclisation pathway.[84,90] It is to be expected that this postulate may have a predictive function in forecasting the structures of products of the type of reaction considered and also related processes.

The first study of the interaction of conjugated alkadiynes with β-dicarbonyl compounds initiated by manganese(III) acetate has been published recently.[91] It has been shown for the interaction of hexa-1,3-diyne with acetylacetone and acetoacetic ester that the reaction proceeds non-regioselectively with participation of both triple bonds. The intermediate radical-adducts (P) and (R) are stabilised by intramolecular cyclisation with formation of the furan derivatives (XLII) and the bifuryl derivatives (XLIII):

---o0o---

Analysis of the literature data indicates a high synthetic potential of the reactions involving the introduction of functional groups into unsaturated systems by carbonyl compounds, initiated by manganese(III) acetate. Novel methods have been developed for the synthesis of compounds of different classes, including products of natural origin. Further development of this field should occur, tentatively, in the direction involving the use of new classes of substrates as the unsaturated components, a detailed investigation of the process mechanisms, and also a wider employment of reactions of this type in specific syntheses of substances of practical importance.

The electrochemistry of sandwich and bent sandwich transition metal complexes

V V Strelets
Institute of Chemical Physics, USSR Academy of Sciences, Chernogolovka

ABSTRACT. The result of electrochemical studies of homo- and hetero-ligand sandwich as well as bent sandwich biscyclopentadienyl complexes of transition metals are surveyed and described systematically. The existence of a linear relation between the redox potentials of these complexes and the gas-phase ionisation potentials of the corresponding metals and their ions is demonstrated. The electrochemical reactions catalysed by sandwich and bent sandwich complexes and the possibilities of the electrochemical synthesis of the above complexes and metal complex catalysts based on them are examined.
The bibliography includes 164 references.

I. Introductions

Electrochemical studies on sandwich complexes (SC) of transition metals began to develop soon after the synthesis of ferrocene in 1951.[1] During the period which has elapsed since then, a large number of SC have been investigated by electrochemical methods. The application of polarography, cyclic voltammetry, and other methods have made it possible to obtain important information about the oxidation-reduction properties of these compounds in the condensed phase, i.e. about the reactivity of the SC in oxidation-reduction reactions. This information is extremely important for the correct understanding of the mechanisms of many reactions involving SC, the selection of optimum conditions in their synthesis and electrochemical synthesis, and the solution of important structural problems in the chemistry of the large class of complexes considered. Furthermore, the electrochemical methods provide valuable information about the distribution of electron density in the molecule and about the relative disposition of the highest occupied (HOMO) and the lowest unoccupied (LUMO) molecular orbitals.

Since the publication of the last reviews[2,3] on the electrochemistry of SC more than 10 years have elapsed and there has been so far no systematic consideration of bent sandwich complexes (BC) of the type Cp_2ML_n ($Cp = \eta^5\text{-}C_5H_5$ = cyclopentadienyl). There has been a significant increase in the number of publications in recent years on the electrochemical investigation of SC and BC. Individual studies in this field have been mentioned in reviews[4,5] and monographs.[6–8]

The author's aim has been to trace the principal characteristic features of the variation of the oxidation-reduction properties of SC and BC as a function of the nature of the metal and of its formal oxidation state and to find a parameter, common to SC and BC, which determines the reactivity of these complexes in oxidation-reduction reactions rather than the greatest possible accumulation of factual data.

The properties of the primary products of the electrochemical reactions of SC and BC are also examined in a number of instances. The review does not include studies dealt with in previous surveys[2,3] with the exception of cases which have been subjected to a repeated, more accurate analysis.

II. Electrochemical reactions of sandwich complexes

Sandwich complexes constitute a class of organometallic compounds in which the metal atom is located between two plane-parallel (or approximately parallel) aromatic π-ligands of the type $\eta^5\text{-}C_5H_5^-$, $\eta^6\text{-}C_6H_6$, $\eta^7\text{-}C_7H_7^+$, $\eta^8\text{-}C_8H_8^{2-}$, etc. The bond between the metal and the ligand is formed as a result of the overlap of the *d* orbitals of the metal and the π orbitals of the ligand. A characteristic feature of the SC is that their metal atom is surrounded by two bulky ligands and that its direct contact with solvent molecules is difficult. The latter prevents the appearance of specific solvation effects. As a result, the solvation effects in the redox reactions of SC are determined mainly by the electrostatic component, which is approximately the same for isostructural complexes bearing equal charges.[7,9,10] This makes it possible to investigate and compare electron transfer reactions in the series of SC in various solvents. The transfer reactions are usually uncomplicated by chemical reactions of the electrochemically generated species with the solvent molecules.

Quantum-chemical study of SC has shown[11-13] that the atomic orbitals (AO) of the metal make the main contribution to their HOMO and LUMO on which the changes of electron density as a result of the occurrence of oxidation-reduction reactions are localised (redox orbitals). Reactions occurring with a change in the formal oxidation state of the metal are therefore characteristic of SC.

1. Metallocenes

Reversible one-electron reactions according to the scheme

$$Cp_2M^{2+} \overset{e}{\rightleftarrows} Cp_2M^{+} \overset{e}{\rightleftarrows} Cp_2M \overset{e}{\rightleftarrows} Cp_2M^{-} \qquad (1)$$

are characteristic of the majority of compounds of this kind. The electron transfer in these systems is of the outer-sphere type[2,3] and the reversibility of the electrode reactions of the majority of metallocenes suggest that the transition from the oxidised form to the neutral form and further to the reduced form does not entail significant changes in the coordination sphere and geometry of the complexes, at least during the electrochemical measurements.

Depending on the nature of the metal and the solvent, the possibility of the electrochemical generation of members of the redox series (1) and their stability, especially the stability of Cp_2M^{2+} and Cp_2M^-, change significantly. As a result of the employment of solvents which are extremely stable in the anodic and cathodic potential regions, in which the reactive members of the redox series (1) are most stable, only in recent years has it been possible to identify the majority of the products of the redox reactions of metallocenes, which are possible in principle. We shall consider the electrochemical behaviour of metallocenes belonging to different Groups in the Periodic System.

Group IVB elements do not form stable metallocenes with a plane-parallel disposition of the rings.[14,15] Among the Group VB metallocenes, only vanadocene has been thoroughly investigated. It has been demonstrated by polarographic and cyclic voltammetric methods at Hg and Pt electrodes[16-18] that Cp_2V undergoes one-electron reversible reduction in tetrahydrofuran (THF) with the formation of the metastable anion Cp_2V^- and one-electron reversible oxidation with formation of the cation Cp_2V^+. Further oxidation of Cp_2V^+ to the dication Cp_2V^{2+} takes place irreversibly, which is believed[16,17] to be associated with the transition in the Cp_2V^{2+} generation stage from the plane-parallel to the bent sandwich structure (*EC*-process, where *E* and *C* represent respectively the electrochemical and chemical stages) as a result of the interaction with solvent molecules or other suitable ligands.

The electrochemical behaviour of the vanadocene analogues Cp_2Nb and Cp_2Ta has not been investigated because of their metastability.[19,20]

The electrochemistry of Group VIB metallocenes has been studied in detail in relation to Cp_2Cr. It has been shown by cyclic voltammetry at the Pt electrode[16,17] that chromocene is reduced reversibly in THF or acetonitrile to the Cp_2Cr^- anion with transfer of one electron. Preparative electrolysis at the limiting current Cp_2Cr reduction potentials does not, however, make it possible to obtain and characterise the Cp_2Cr^- anion in solution because of its low stability. It has also been shown that chromocene can undergo reversible one-electron oxidation to the unstable cation Cp_2Cr^+.[16,17,21]

Molybdenocene and tungstocene, whose stability is low (lifetime $\sim 10^{-2}$ s), have been generated and identified by cyclic voltammetry involving two-electron reduction of the corresponding metallocene dichlorides.[22,23] The potentials of the redox couples Cp_2Mo^0/Cp_2Mo^+ and Cp_2C^0/Cp_2M^+ are respectively −1.25 and −1.48 V.† These are the most readily oxidisable metallocenes among all those known. If E^0 = −0.68 V is adopted for the Cp_2Cr^0/Cp_2Cr^+ redox couple,[16] one may conclude that, within the framework of a single subgroup of the Periodic System, an increase in the atomic number of the metal facilitates the abstraction of an electron from the corresponding metallocene and not conversely, as had been postulated earlier in a review.[2]

†All the potentials in this review are quoted relative to the aqueous saturated calomel electrode.

Among the biscyclopentadienyl complexes of Group VIIB metals, only the manganese compound is known at present, although manganocene cannot be included among metallocenes because of its ionic character.[24] A substituted analogue of this compound [$(C_5Me_5)_2Mn$], in which the metal–ring bond is covalent and which has the metallocene structure, has been described.[25] It has been shown by cyclic voltammetry at a Pt electrode[25] that permethylmanganocene is reduced in acetonitrile to the $(C_5Me_5)_2Mn^-$ anion with transfer of one electron and is oxidised to the cation $(C_5Me_5)_2Mn^+$. Both processes are electrochemically reversible but the stability of the products has not been reported.

Like molybdenocene and tungstocene, rheniocene belongs to the class of relatively unstable metallocenes. These metallocenes are formed by the photolysis of the corresponding hydrides Cp_2MH in low-temperature matrices and their sandwich structure has been demonstrated by IR spectroscopy.[26-28] Rheniocene can be generated by cyclic voltammetry at a Hg electrode in THF by the two-electron reduction of the dimer $Cp_2Re-ReCp_2$ with the subsequent oxidation of the anion $[CpRe(\eta^3\text{-}C_5H_5)]^-$ formed under these conditions.[29] E^0 = −1.06 V for the Cp_2Re^0/Cp_2Re^+ redox couple.

Ferrocene, the first of the metallocenes synthesised, is undoubtedly the most thoroughly investigated representative of the Group VIIIB metallocenes. The Cp_2Fe^0/Cp_2Fe^+ redox couple is one of the most highly reversible systems. Numerous studies have been devoted to it.[2,3] In recent years, it has been possible to show, using solvents stable at high cathodic and anodic potentials, that ferrocene can be oxidised to the dication and can be reduced to the anion. In $AlCl_3$/1-butylpyridinium chloride melts (in 1 : 1 molar proportions), the $(C_5Me_5)_2Fe^+$ cation undergoes reversible one-electrochemical reduction at a carbon glass electrode to the stable dication $(C_5Me_5)_2Fe^{2+}$, which has been characterised by UV spectroscopy.[30] The electrochemical behaviour of the ferrocenium cation and of its permethylated analogue has also been investigated in liquid sulphur dioxide.[31] It has been shown by cyclic voltammetry at a Pt electrode that the reversible one-electron oxidation of Cp_2Fe^+ leads to the formation of the unstable dication Cp_2Fe^{2+}, the decomposition products of which partly block the electrode. The reversible one-electron oxidation of the decamethyl analogue under these conditions results in the formation of the high-spin dication $(C_5Me_5)_2Fe^{2+}$ (magnetic moment μ = 2.73 B.M.), which is stable at −30 °C.

The high purity of the solvent and electrochemical measurements at temperatures between −45° and −30 °C made it possible[32,33] to observe the reversible reduction of ferrocene to the relatively unstable anion Cp_2Fe^- at Pt and carbon glass electrodes in dimethylformamide (DMF) or dimethoxyethane. It has also been shown that an increase in temperature leads to the occurrence of the two-electron reduction of ferrocene via the *ECE*-mechanism involving the formation of an unidentified intermediate X:[32]

$$Cp_2Fe \overset{e}{\rightleftarrows} Cp_2Fe^- \rightarrow X \overset{e}{\rightarrow} 2Cp^- + Fe^0.$$

In order to elucidate the nature of X, a study has been made of the electrochemical reduction of substituted ferrocenes in DMF and THF under a CO atmosphere.[34] It is possible to identify the unstable anion $CpFe(CO)_2^-$, which interacts with MeI to form $CpFe(CO)_2Me$ or is oxidised at a Pt electrode to the radical $CpFe(CO)_2^{\cdot}$, which rapidly dimerises to the complex $[CpFe(CO)_2]_2$ with an Fe–Fe bond. These data led to the conclusion that the intermediate X is the $CpFe^{\cdot}$ + Cp^- mixture.

It has been noted[33] that the formal rate constant for the heterogeneous electron transfer to the ferrocene molecule ($k_e \cong 10^{-3}$ cm s^{-1}) is much lower than the analogous constant for the Cp_2Fe^0/Cp_2Fe^+ couple ($k_e > 10^{-1}$ cm s^{-1}). According to the authors,[33] this difference is due to the increase in the internal reorganisation energy on formation of Cp_2Fe^- as a result of the transition of one of the Cp rings from the planar η^5-conformation to the non-planar η^4-conformation, which makes it possible to retain the energetically most favourable 18-electron configuration of the metal atom in the anion. It is notable that this is not the only possible explanation of the decrease in k_e on passing from the Cp_2Fe^0/Cp_2Fe^+ redox system to Cp_2Fe^0/Cp_2Fe^-. In contrast to its oxidation, when ferrocene is reduced an electron is transferred to an antibonding MO which should undoubtedly entail an increase in the process activation energy and hence a decrease in k_e.

The kinetics of the heterogeneous electron transfer involving substituted ferrocenes and the Cp_2Co^+ ion in acetonitrile at a semiconductor (*p*-InP)/electrolyte interface have been investigated by cyclic voltammetry.[35] The above semiconductor is characterised by the presence of a forbidden gap and also a potential range at the limits of which the composition of the oxide layers changes as a result of electrode reactions involving the material of the electrode. Reversible electrode reactions are characteristic of alkylated ferrocenes, whose $Cp^*_2M^0/Cp^*_2M^+$ redox transition potential (Cp* is a substituted cyclopentadienyl) lies within this region, whereas irreversible electrode reactions are characteristic of the acylated ferrocene and Cp_2Co^+, whose potentials E^0 correspond to the limits of this region or are outside its limits. Furthermore, irreversible electrode reactions become characteristic also of complexes of the first type (with potentials E^0 lying outside the forbidden gap) when the potential at which the polarisation of the electrode changes moves outside the limits of the gap.

The electrochemical behaviour of heavier ferrocene analogues—ruthenocene and osmocene—has a number of characteristic features. Ruthenocene undergoes irreversible two-electron oxidation at a Pt electrode in acetonitrile, forming probably the dication.[2,3] Under the same conditions, the permethylated ruthenocene is oxidised reversibly to a stable cation which has been characterised by EPR spectroscopy ($e^3_{2g}a^2_{1g}$ electronic configuration), but its subsequent oxidation is irreversible.[36] The stepwise two-electron oxidation of Cp_2Ru, which is irreversible at each stage, has been observed by cyclic voltammetry in the $AlCl_3$/1-butylpyridinium chloride melt (with a molar ratio in excess of unity) at a carbon glass electrode.[37]

The oxidation of osmocene is characterised by the stepwise abstraction of two electrons, which is irreversible at each stage.[2,3] The preparative one-electron oxidation of Cp_2Os leads to the formation of a cation, which has been isolated as the salt $Cp_2Os^+BF_4^-$.[2] The difference in the electrochemical behaviour of ferrocene, ruthenocene, and osmocene is associated with the fact, according to Gale et al.,[30] that, with increase in the atomic number of the metal, the stability of the half-occupied d_5 electronic configuration of the singly charged cation diminishes and the formation of doubly charged cations becomes preferable. It is also noteworthy that the redox reactions of Cp_2Ru and Cp_2Os should be studied on solid electrodes, since on mercury these reactions are complicated by the formation of the corresponding organomercury compounds $(Cp_2M)_2Hg$.[2,3]

The cobaltocenium cation, formed as a result of the reversible one-electron oxidation of cobaltocene, is an isoelectronic analogue of ferrocene.[2,3,38,39] Cobaltocene can also undergo reversible one-electron reduction to the Cp_2Co^- anion.[38–41] In aqueous solutions, Cp_2Co^- is stable in an alkaline medium (pH > 8), while in an acid medium it is protonated at the ligand with formation of cyclopentadiene(cyclopentadienyl)cobalt, which is in its turn oxidised chemically at pH < 4 by the protons of the medium with liberation of H_2 and the formation of Cp_2Co^+.[39] It has been suggested that in acid media the $(C_5H_4COOR)_2Co^+$ (R = H or Me) ions can undergo electrochemical reduction at the substituent with formation of the corresponding aldehyde and alcohol derivatives. In non-aqueous media, the electrochemically generated Cp_2Co^- is protonated by phenols at the ligand with formation of $CpCo(\pi\text{-}C_5H_6)$ but without the formation of the hydride.[41]

The electrochemical behaviour of the heavier cobaltocene analogue—rhodiocene—has also been investigated.[42] It has been shown by polarographic and cyclic voltammetric methods at Hg and Pt electrodes that the Cp_2Rh^+ cation is reduced in acetonitrile in accordance with the scheme

$$Cp_2Rh^+ \overset{e}{\rightleftarrows} Cp_2Rh \overset{e}{\rightleftarrows} Cp_2Rh^-$$
$$\downarrow$$
$$(Cp_2Rh)_2$$

The intermediate rhodiocene is unstable under the conditions of preparative electrolysis and dimerises. Irreversible electrochemical oxidation of the dimer is accompanied by the regeneration of the Cp_2Rh^+ cation. There are no reliable data for the redox reactions of iridiocene and its ions.

Nickelocene, which is reduced most readily among all the known metallocenes, is the last as regards the position of the metal in the Periodic System among the class of metallocenes investigated.[16,17] However, the mechanism of this process is fairly complex. Under the conditions of the preparative electrochemical reduction of Cp_2Ni, a series of products are formed, one of which has been identified as $CpNi(\eta^3\text{-}C_5H_7)$.[17] At a reduced temperature (–58 °C) in DMF, nickelocene undergoes one-electron reduction to the anion Cp_2Ni^-, which is stable under these conditions, the electrode reaction being characterised by a slow charge-transfer stage. According to the author,[17] this is associated with the fact that the electron transfer is accompanied by a change in the solvation shell and/or in the structure of the complex (transition to a "slipped sandwich structure"). The electrochemically generated Cp_2Ni^- reacts with carbon monoxide[43] via the *CEC*-mechanism with decomposition of the sandwich structure:

$$Cp_2Ni^- \rightarrow Cp^- + CpNi \xrightarrow{CO,e} [CpNi(CO)]^- \xrightarrow{3CO} Cp^- + Ni(CO)_4.$$

Apart from the reduction reaction, the electrochemical oxidation reactions of nickelocene, which are electrochemically reversible, have been investigated. Thus the one-electron oxidation of Cp_2Ni in THF, DMF, and acetonitrile at a Pt electrode[16,17] and in the Al/1-butylpyridinium chloride melt at a carbon glass electrode[44] lead to the formation of the Cp_2Ni^+ cation. The subsequent oxidation of Cp_2Ni^+ in acetonitrile at a Pt electrode[45] and in the melt mentioned above[44] is also reversible and is completed by the formation of the Cp_2Ni^{2+} dication, which has been characterised by UV spectroscopy.[44] The dication interacts extremely readily with nucleophiles.

Thus extensive experimental data have accumulated on the redox reaction of metallocenes. Together with the Cp_2M^0/Cp_2M^+ redox transition known previously, the possibility of the Cp_2M^0/Cp_2M^- and Cp_2M^+/Cp_2M^{2+} redox transitions has been demonstrated for a series of metallocenes. The experimentally established forms of the metallocenes are presented in Table 1.

In earlier studies,[8,16] a similar Table resembled in its form an inverted triangle whose height was determined by the number of the known metallocenes or their ions with the d^6 electronic configuration, which is associated with the high stability of these 18-electron complexes. By virtue of the vigorous investigations the metastable metallocenes derived from the transition metal at the beginning of the series and the highly reactive Cp_2M^- and Cp_2M^{2+} ions, the form of Table 1 has changed significantly at the present time.

Table 1. Classification of the experimentally detected metallocenes and their ions in terms of the electronic configuration of the metal in Cp_2M.

d^2	d^3	d^4	d^5	d^6	d^7	d^8	d^9
V^+	V Cr^+ Mo^+ W^+	V^- Cr Mo W Mn^+ * Re^+ Fe^{3+} Ru^{3+}	Cr^- Mn * Re Fe^+ Ru^+	Mn^-,* Fe Ru Co^+ Rh^+ Ni^{2+}	Fe^- Co Rh Ni^+	Co^- Rh^- Ni	Ni^-

*Data for $(C_5Me_5)_2Mn$ are presented.

2. Homo- and hetero-ligand sandwich complexes with other π-ligands

Redox reactions involving a change in the formal oxidation state of the metal are characteristic of all the homo- and hetero-ligand SC as well as metallocenes.[2,5,8,46]

Diarenemetals. The metal in these neutral complexes is formally zerovalent and $(arene)_2M^0/(arene)_2M^+$ transitions are therefore characteristic of these compounds. Examples of such systems are provided by the $(arene)_2Cr$ complexes (where arene = C_6H_6, C_6Me_6, $C_6H_5-C_6H_5$, etc.)[2,47,48] and $(C_6H_6)_2Mo$.[2]

The electrochemical behaviour of the cationic complexes $(C_6H_6)_2Fe^{2+}$, $(C_6Me_6)_2Fe^{2+}$,[49] $(C_6Me_6)Ru^{2+}$,[50] and $(C_6Me_6)Co^{2+}$ [51] has also been investigated. It has been shown by polarographic and cyclic voltammetric methods at Hg and carbon glass electrodes in proton-donating and aprotic media that all of these complexes undergo multistage electrochemical reduction, reversible at each stage, according to the scheme

$$(arene)_2M^{2+} \overset{e}{\rightleftharpoons} (arene)_2M^{+} \overset{e}{\rightleftharpoons} (arene)_2M.$$

It has been shown for $(C_6Me_6)Ru^{2+}$ [50] that the replacement of CH_2Cl_2 by the more strongly coordinated acetonitrile leads to a greater change in the relative solvation energy (E_S) in the $(arene)_2Ru^{2+}$ transition, as a result of which the dication is electrochemically reduced to the neutral complex in a single two-electron stage. It is of interest that the reduction of $(C_6Me_6)Ru^{2+}$ is described by the *EEC*-scheme, where the chemical stage represents the transition from (η^6-arene)$_2$Ru to (η^6-arene)Ru(η^4-arene). Here it is appropriate to consider also the fundamental problem of oxidation-reduction reactions—the problem of the consecutive or multistage transfer of two electrons. If an oxidation-reduction reaction of this type is represented by the scheme

$$A \pm e \underset{}{\overset{E_1^0}{\rightleftharpoons}} A^{-(+)} \pm e \overset{E_2^0}{\rightleftharpoons} A^{2-(2+)},$$

it becomes evident that the quantity $\Delta E^0 = E_1^0 - E_2^0$ reflects the change in the gas-phase ionisation potential I_D in the transition from A to A^+ (for oxidation) or the change in the electron affinity in the transition from A to A^- (for reduction) and, furthermore, the change ΔE_S in the transition from $A^+(A^-)$ to $A^{2+}(A^{2-})$. The quantity ΔE^0, which is significantly smaller than ΔI_D, is determined by the greater solvation energies of A^{2+} and A^{2-} compared with A^+ and A^-. As a result, solvation effects can lead to a transition from the multistage ($1e^- + 1e^-$) mechanism to the apparently single-stage ($2e^-$) mechanism, as happens in the case considered above.[50] On the other hand, the true two-electron transfer, determined by the fact that the transfer of the second electron is energetically more favourable than that of the first, is observed only when the transfer of the first electron is accompanied by structural changes in the SC (*ECE*-process). The AO of the metal usually make the main contribution to the HOMO and LUMO of the sandwich complexes, as a result of which the HOMO and the LUMO have the *d* character. This leads to a relatively weak electronic influence of the substituents in the π-ligands on the quantities E_1^0 and E_2^0.[52] For example, E^0 changes only by approximately 0.2 V for the $(C_6H_{6-x}Me_2)Cr(CO)_3/C_6H_{6-x}Me_x)Cr(CO)_3^-$ redox couples in the transition from $x = 0$ to $x = 6$.[53,54] It is therefore difficult to suppose that the introduction of substituents into the π-ligand can induce the $1e^- + 1e^- \rightarrow 2e^-$ transition. Explicit reversible two-electron processes (the difference between the potentials of the cathodic and anodic peaks on cyclic voltammograms, amounting to 30 mV, can serve as an electrochemical sign of their occurrence) are observed only for certain SC and semi-sandwich complexes. As an example, one may quote the reduction of $(arene)Cr(CO)_3$,[54] where the operation of the $2e^-$ mechanism is a consequence of the $\eta^6 \rightarrow \eta^4$ haptoisomerisation of the arene ligand in the radical-anion stage. An analogous $2e^-$ process, accompanied by a change in the hapto-binding of the ligand, is also characteristic of the reduction of $Cp(\eta^6\text{-}C_6Me_6)Ir^{2+}$.[55] In all these cases, the structural changes occurring in the stage involving the formation of the one-electron reduction products lead to species which are reduced more readily than the initial complexes.

The $(arene)_2Cr^0/(arene)_2Cr^+$ redox couples together with ferrocene[56] have been recommended by IUPAC as internal standards and "pilot" ions for the comparison of the potentials $E_{1/2}$ measured in different solvents. The greater radius and spherical shape of the molecule, the solubility of both redox forms, the high reversibility of the redox reaction, the virtually complete absence of specific solvation effects as a consequence of the shielding of the metal by bulky ligands, and the insignificant change in the electrostatic components of ΔE_S in the transition from one solvent to another [as a consequence of the low surface charge of the complexes], make the $(arene)_2Cr^0/(arene)_2Cr^+$ systems, together with transition metal heteropolyanions[57] and tris(bipyridyl) complexes,[58] more promising as standard redox systems than the metallocenes.[10]

There are data indicating the possibility of the adsorption of $(arene)_2Cr^+$ on a Hg electrode in an aqueous medium.[59] It has been suggested that the adsorption is due to the positive charge of the complex, the "squeezing out" effect, the presence of an unpaired electron, the π-electronic interaction of the cation with the electrode, and the influence of the supporting electrolyte anion.

Metallocarbaboranes. As in other SC, in these complexes the transition metal is linked to dicarbaboryl ligands by π-bonds.[60,61] The study of the electrochemical behaviour (d.c. and a.c. polarography, cyclic voltammetry, and preparative electrolysis) of the dicarbaboryl complexes of iron,[60] cobalt,[38,60] rhodium,[42] nickel,[38,60] palladium,[62] copper[62] and gold[62] in aprotic media showed that, in contrast to the Cp ligands, the dicarbaboryl ligand [Cb = η^6-(3)-1,2-$C_2B_9H_{11}$] stabilises the metal in both the highest and lowest oxidation states. The overall scheme for the redox reactions of these complexes can be represented in the following form:

$$Cb_2M \overset{e}{\rightleftarrows} Cb_2M^- \overset{e}{\rightleftarrows} Cb_2M^{2-} \overset{e}{\rightleftarrows} Cb_2M^{3-}$$

The only exception in the series of dicarbaboryl complexes is platinum dicarbaboride, which has been shown [by cyclic voltammetry in dimethyl sulphoxide (DMSO) and DMF] to undergo the reversible two-electron Cb_2Pt^0/Cb_2Pt^{2-} transition with the subsequent quasi-reversible Cb_2Pt^{2-}/Cb_2Pt^{3-} transition at more cathodic potentials.[63] The two-electron character of the Cb_2Pt^0/Cb_2Pt^{2-} electrode process is probably associated with the transfer of the first electron to the antibonding LUMO and possibly with the solvation effects of the highly coordinating solvents in which the measurements were performed.

Ti, V, and Cr complexes, as well as Mn, Fe, and Co complexes, with another dicarbaboryl ligand $Cb^- = \eta^6$-(4)-1,6-$C_2B_{10}H_{12}$ have also been synthesised and characterised electrochemically.[64,65] The reversible redox transitions

$$Cb'_2M^- \overset{e}{\rightleftarrows} Cb'_2M^{2-} \overset{e}{\rightleftarrows} Cb'_2M^{3-}$$

are characteristic of these complexes too. Metallocarbaboranes can also be recommended as standard redox systems, although they are less readily available.

Other homoligand sandwich complexes. It has been shown by voltammetric and coulometric methods at Pt electrodes that bis(azaboralinyl)metal complexes [η^5-$C_3H_3B(Me)NR]_2M$ (R = H, Et, Bu, or $SiMe_3$; M = Co or Fe) in THF and CH_2Cl_2 undergo reversible one-electron oxidation to the corresponding cations, whose stability depends on the nature of R and M.[66]

Bis(cyclo-octatetraene)uranium $(COT)_2U$ is oxidised in THF, acetonitrile, benzonitrile, and CH_2Cl_2 at Hg, Pt, and carbon glass electrodes at temperatures below 10 °C in a single reversible two-electron stage to the dication via the *ECE*-mechanism, according to which the transfer of the first electron leads to the formation of the unstable cation $(COT)_2U^+$, which undergoes rapid structural and/or solvation changes with formation of a new more readily oxidisable cation.[67] With increase in temperature or with decrease in the rate of scanning of the potential, the electrochemically generated dication reacts with the initial "uranocene", forming the dimeric dication $(COT)_4U_2^{2+}$, which is capable of irreversible one-electron oxidation with elimination of cyclo-octatetraene and the formation of $(COT)_3U_2^{3+}$.

Mixed-ligand sandwich complexes. The heteroligand SC resemble in their electrochemical properties their homoligand analogues. They too are characterised by reversible one-electron reactions, which proceed with a change in the formal oxidation state of the metal. It has been established by polarographic, cyclic voltammetric, and preparative electrolysis methods in non-aqueous media that the redox transitions

$$[CpMCb]^+ \overset{e}{\rightleftarrows} CpMCb \overset{e}{\rightleftarrows} [CpMCb]^- \overset{e}{\rightleftarrows} [CpMCb]^{2-},$$
M = Fe (Ref.38), Co (Ref.45), Ni (Ref.60);

$$[CpMCb']^- \overset{e}{\rightleftarrows} [CpMCb']^{2-} \overset{e}{\rightleftarrows} [CpMCb']^{3-},$$
M = Fe (Ref.64), Co (Ref.64), Ti (Ref.65);

$$[(arene)MCp]^{2+} \overset{e}{\rightleftarrows} [(arene)MCp]^+ \overset{e}{\rightleftarrows} (arene)MCp \overset{e}{\rightleftarrows} [(arene)MCp]^-,$$
M = Fe (Refs.2, 51), Co (Ref.55), Ir (Ref.68), Rh (Ref.69);

$$(COT)\,TiCb \overset{e}{\rightleftarrows} [(COT)\,TiCb]^- \text{ (Ref.65)};$$

$$(COT)\,TiCp \overset{-e}{\rightleftarrows} [(COT)\,TiCp]^+ \text{ (Ref.70)};$$

$$(\eta^5\text{-L})\,Ti\,(COT) \overset{e}{\rightleftarrows} [(\eta^5\text{-L})\,Ti\,(COT)]^-,$$
L = indene, fluorene (Ref.70);

$$(\eta^5\text{-}C_7H_7)\,MCp \overset{-e}{\rightleftarrows} [(\eta^5\text{-}C_7H_7)\,MCp]^+,$$
M = V (Ref.71), Cr (Ref.72).

are possible. The study of the electrochemical synthesis of η^4-arenemetal complexes by the electrochemical reduction of the corresponding η^6-arene complexes as well as the electrochemical investigation of $\eta^6 \rightleftarrows \eta^4$ hapto-isomerisation—the postulated key stage in the catalytic hydrogenation of arenes,[73] ligand substitution reactions,[74] and isomerisation of complexes[75]—by polarography, cyclic voltammetry, and preparative electrolysis showed[55] that in non-aqueous media (CH_2Cl_2, acetonitrile, DMF, etc.) the complex $[(C_5Me_5)M(C_6Me_6)]^{2+}$ is reduced in two one-electron stages when M = Rh, whereas with M = Ir it is reduced in one two-electron stage, to the corresponding neutral complexes which consist, according to ^1H NMR data, of compounds having the structure $(\eta^5\text{-}C_5Me_5)M(\eta^4\text{-}C_6Me_6)$. It has been suggested that the $\eta^6 \rightarrow \eta^4$ hapto-isomerisation ($k \cong 10^3$ s^{-1}; stabilisation energy ~38 kJ mol^{-1}), leading to the thermodynamic stabilisation of these complexes, takes place in the stage involving the transfer of the second electron and is accompanied by the transition from the relatively unstable 20-electron complex to the stable 18-electron complex. The $\eta^6 \rightleftarrows \eta^4$ hapto-isomerisation is facilitated on passing from 3*d* metals to 4*d* and 5*d* metals. It has been shown for the redox transitions

$$[(C_6Me_6)\,Rh\,(C_6Me_6)]^{2+} \overset{e}{\rightleftarrows} [(C_5Me_5)\,Rh\,(C_6Me_6)]^+ \overset{e}{\rightleftarrows} (C_5Me_5)\,Rh\,(C_6Me_6)$$

that an increase in the Gutman's donor number of the solvent from 0 to 30 lowers $\Delta E^0 = E^{2+}/E^+ - E^+/E^0$ from 0.37 to 0.09 V as a result of the greater influence of the solvation effects on E^{2+}/E^+, but hardly affects the kinetics of the hapto-isomerisation. The oxidative cleavage of polyolefin cobalt SC (COT)CoCp and (COD)CoCp (whhere COD = cyclo-octadiene) in strongly (acetonitrile) and weakly (CH_2Cl_2) coordinating solvents has been investigated electrochemically.[76] In acetonitrile, these complexes undergo irreversible electrochemical oxidation accompanied by the cleavage of the polyolefin–metal bond, which can be described by the scheme

$$LCoCp \xrightarrow{-e} \underset{(A^+)}{[LCoCp]^+} \xrightarrow{+nMeCN} L + [CpCo\,(MeCN)_3]^+ \xrightarrow{-0.5e} \rightarrow 0.5Cp_2Co^+ + 0.5Co^{2+} + 3MeCN, \quad L = COT, COD. \qquad (2)$$

On the other hand, in CH_2Cl_2 the transfer of the first electron is reversible, while the A^+ cation is more stable (it has been characterised by its EPR spectrum in relation to the compound where L = COD), although it does undergo further reaction according to formula (2). The possibility of the isomerisation 1,5-COT ⇄ 1,3-COT in the cation A^+ has been discussed.

In order to investigate the possibility of carrying out electrochemically the reaction involving the abstraction of a hydride ion from $[CpM(\eta^6\text{-}C_7H_8)]^+$ (where M = Fe or Ru; $\eta^6\text{-}C_7H_8$ = η^6-cycloheptatriene) accompanied by its conversion into $[CpM(\eta^7\text{-}C_7H_7)]^{2+}$, which is possible in principle, by the cyclic voltammetric method in acetonitrile, a study has been made of the electrochemical oxidation of $[CpM(\eta^6\text{-}C_7H_8)]^+$.[77] Despite the fact that the electrochemical oxidation does indeed involve the coordinated cycloheptatriene with its conversion into $\eta^7\text{-}C_7H_7^+$, the passivation of the electrode by the products of the decomposition of the complexes prevents the preparative electrochemical synthesis of $[CpM(\eta^7\text{-}C_7H_7)]^{2+}$. It has also been noted that, for $E < -1$V, the complexes $[CpM(\eta^7\text{-}C_7H_7)]^{2+}$ undergo one-electron reduction, specific with respect to the method, which is, however, electrochemically irreversible.

The redox properties of mono- and di-phosphaferrocenes have been investigated[78] in CH_2Cl_2, $H_2\overline{COCOOCH}Me$, acetonitrile, DMF, and other non-aqueous solvents. Like ferrocene, these SC undergo reversible one-electron reduction to relatively unstable anions and one-electron oxidation to cations, whose stability depends significantly on the nature of the solvent. Analysis of the EPR spectra of the phosphaferrocenium cations permitted the conclusion that the unpaired electron is predominantly localised on the metal atom. The character of the change in the redox properties on passing from Cp_2Fe to phosphaferrocenes (the anodic shifts of E^0 on reduction and oxidation are respectively 0.39 and 0.19 V) is due to the change in the energy of the redox MO on replacement of the CH group in the Cp ligand by the phosphorus ligand.

The standard potentials of the redox reaction of the majority of homo- and hetero-ligand SC have been compiled in tables in a number of communications.[23,79,80]

Dinuclear sandwich complexes. It has been shown by cyclic voltammetry[81] that the dications $\{(\eta^{10},\mu^2\text{-}C_{10}H_8)[(\eta^6\text{-}C_6R_6)Fe]^2\}^{2+}$ (R = H or Me; $C_{10}H_8$ = fulvalene), designated henceforth by B^{2+}, are capable of the redox transitions

$$B^{2+} \overset{e}{\rightleftarrows} B^{+} \overset{e}{\rightleftarrows} B^{0} \overset{e}{\rightleftarrows} B^{-} \overset{e}{\rightleftarrows} B^{2-}$$

which are separated on the potential scale, with the intermediate formation of the mixed-valence complexes [Fe(2+) Fe(1+)](B^+) and [Fe(1+) Fe(0)](B^-). The complexes B^+ and B^0 have been characterised in terms of their magnetic susceptibility and also by EPR and NMR spectra. The electron exchange between the Fe nuclei in B^+ takes place at a rate $> 10^9$ s^{-1} at 4.2 K, the fulvalene ligand being involved in this process.

The oxidation-reduction properties of monometallic and dimetallic cyclophane complexes of ruthenium[50,82] and iron[83] in non-aqueous media (THF, CH_2Cl_2, CH_3COCH_3, DMF, etc.) have been investigated by cyclic voltammetry, chronoammetry, and preparative electrolysis. Together with the $\eta^6 \rightleftarrows \eta^4$ hapto-isomerisation of the arene ligand, accompanying the multistage two-electron reduction of the dications $[(\eta^6\text{-}C_6Me_6)Ru(\eta^6\text{-}L)]^{2+}$ (L = cyclophanes),[50,82] the complex $[(CpFe)_2(\eta^6\text{-}L)]^{2+}$ is reduced via two stages with similar potentials.[83] This process leads to the formation of the relatively unstable [Fe(2+)Fe(1+)] and [Fe(1+)Fe(1+)] complexes, which decompose with ejection of the cyclophanes and the formation of the solvated CpFe fragment, which disproportionates to ferrocene and Fe^0. It has been suggested[83] that the low stability of the neutral cyclophane complexes compared with CpM(arene) is due to the smaller degree of overlap of the orbitals of the cyclophane ligand and the AO of the metal as a result of the steric strain in the cyclophane structure.

We shall now consider metallocenophanes having the general formula $[(\eta^5\text{-}C_5H_4)CH_2]_2M^1M^2$, where M^1M^2 = FeFe, FeRu, or RuRu.[84]. In benzonitrile, the compound with $M^1 = M^2$ = Fe undergoes oxidation, specific with respect to each of the ferrocene fragments, in two reversible one-electron stages, which indicates the absence of appreciable interactions between these fragments. Such interaction is also absent from the complex with M^1 = Fe and M^2 = Ru, which undergoes a quasi-reversible one-electron oxidation specific with respect to the ferrocene fragment and irreversible two-electron oxidation specific with respect to the ruthenocene fragment. For $M^1 = M^2$ = Ru, both metallocene fragments probably interact strongly with one another, as a consequence of which the complex undergoes quasi-reversible two-electron oxidation at potentials displaced to the cathodic region by 0.54 V compared with the ruthenocene oxidation potentials. Analysis of the ^1H NMR spectra of the oxidation products has led to the conclusion that the oxidation involves a single ruthenocene fragment.[84]

The electrochemistry of bis(fulvalene)dimetal complexes $(C_{10}H_8)_2M_2$ (M = V, Cr, Fe, Co, or Ni) has been investigated in acetonitrile.[85] It has been shown by cyclic voltammetry at a Pt electrode that most of these complexes are capable of redox transitions:

$$(C_{10}H_8)_2M_2^0 \overset{e}{\rightleftarrows} [(C_{10}H_8)_2M_2]^+ \overset{e}{\rightleftarrows} [(C_{10}H_8)_2M_2]^{2+}.$$

Redox transitions with a change in the formal oxidation state of the metal are also characteristic of triple decker SC[86-88] and there is a significant increase in the number of possible redox transitions as a result of the increase in the numbers of metal atoms.

Examples of such systems are

$$[CpCo(\eta^5\text{-}C_2B_3H_5)CoCp]^{2+} \overset{e}{\rightleftarrows} [CpCo(\eta^5\text{-}C_2B_3H_5)CoCp]^{+} \overset{e}{\rightleftarrows}$$
$$\rightleftarrows [CpCo(\eta^5\text{-}C_2B_3H_5)CoCp]^{0} \rightleftarrows [CpCo(\eta^5\text{-}C_2B_3H_5)CoCp]^{-} \overset{e}{\rightleftarrows}$$
$$\rightleftarrows [CpCo(\eta^5\text{-}C_2B_3H_5)CoCp]^{2-} \quad \text{(Ref.87)}$$

and

$$[CpCo(COT)]^{2+} \overset{e}{\rightleftarrows} [CpCo(COT)]^{+} \overset{e}{\rightleftarrows} [CpCo(COT)]^{0} \overset{e}{\rightleftarrows} [CpCo(COT)]^{-} \text{ (Ref.88).}$$

The behaviour of other polynuclear SC in redox reactions has been described in a number of communications.[2-8,61,86,89-91]

In concluding the consideration of the oxidation-reduction reactions of SC, we may note that the author's aim was not the unrealistic task of providing exhaustive information about all the investigations in this large field. In particular, the question of the electronic effects of substituents on the redox properties of SC, with which one can become acquainted from other publications,[2-6,90] has been hardly dealt with. Whenever possible, later studies are quoted in which earlier publications on the same topic are mentioned. The author's aim was to demonstrate that the quantitative characteristics of the oxidation-reduction reactions of the class of complexes considered are determined primarily by the nature of the metal atom involved. The discovery of a quantitative relation between the redox properties of SC and the corresponding metals would make it possible, without resorting to additional physicochemical studies, to estimate beforehand, from tabulated data for metals, the redox properties of the corresponding complexes. This problem of

predicting the reactivities of metal complexes from the properties of the metal involved (even for individual classes of complexes and individual types of reactions) is of fundamental importance.

3. Linear relations between the redox potentials of sandwich complexes and the gas-phase ionisation potentials of metals

A model has been proposed[79] permitting the estimation of the contribution of the energies of the *d* orbitals of the metal to the redox orbitals of the complexes. This model has been used to discover the trends in the behaviour of the redox potentials of octahedral and pseudo-octahedral complexes, in particular metallocenes. However, the variation of the quantities E^0 as a function of the number of the *d* electrons of the metal, the charge of the complex, the type of the ligand environment, the character of the spreading of the redox MO, the electron pairing energy, etc. has been examined at a purely descriptive level. Attempts have been made to find a correlation between the quantities $E_{1/2}$ for metallocenes and the gas-phase ionisation potentials of metals (IP), but these were limited, since the comparison was carried out only for a single Cp_2M^0/Cp_2M^- redox transition and for a limited range of metals (V, Cr, Fe, Ni).[17] An attempt has also been made to find a correlation[16] between the potentials $E_{1/2}$ of the Cp_2M^0/Cp_2M^+ (M = V, Cr, Fe, Co, or Ni) redox transitions and the ionisation potentials of the complexes in the gas phase, but for certain metallocenes an appreciable deviation from the linear relation predicted by the equation[6,92]

$$E_{1/2} = 0.92\,I_D - 6.20.$$

was observed. Although the ionisation potentials have now been measured for a large number of SC,[13] such correlation is hardly suitable for the prediction of the redox properties, especially if one is dealing with complexes which have not yet been synthesised or which are unstable, for which the values of I_D are unknown. Furthermore there are no reliable literature data for the second, third, and subsequent ionisation potentials of the complexes, while the values of IP for the metals are readily available.[93]

A completely different approach has been proposed in studies[23,80,94] in which the existence of a linear relation between the standard potentials *of all possible redox transformations* of SC [see, for example, Eqn.(1) for metallocenes] and the IP of the corresponding metals has been established and justified. The existence of such a relation is due to the fact that the main contribution to the HOMO and LUMO of sandwich complexes comes from the AO of the metals[11-13,93] and the potentials E^0 for the electron transfer reactions in the series of SC, involving precisely the HOMO and LUMO,[2,3] should in fact reflect the change in the state of oxidation of the metal, whose measure is the IP.[23] Furthermore, the SC retain their plane-parallel structure regardless of the formal oxidation state of the metal and the solvation energy of the components of the redox couples, for example, Cp_2M^x/Cp_2M^{x-1}, depend little on the nature of the metal, since the manifestation of the effects of specific solvation is prevented by the bulky ligand environment in the SC. As a result, the solvation effects in the redox transition of SC are associated mainly with the electrostatic component E_S, which is approximately the same for equally charged isostructural complexes.[9,57,94] The change in E_S on transition from, for example, Cp_2M^x to Cp_2M^{x-1} makes approximately the same contribution to E^0 for different metals. Furthermore, the predominantly electrostatic character of the influence of E_S on the potentials E^0 for SC permits a comparison of the redox potentials of the SC measured in different solvents.[23] The set of these quantities leads to a significantly linear relation between E^0 and IP for all possible redox reactions of homo- and hetero-ligand SC.[23,80,94] However, in certain cases, for example, for individual di(arene)metal complexes,[47,48] whose redox reactions occur with electron transfer to the ligand, such a linear relation does not hold.

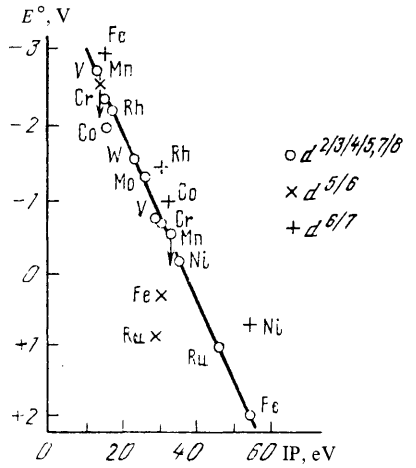

Figure 1. Dependence of E^0 for the d^x/d^{x+1} transitions in the series of metallocenes on the corresponding gas-phase ionisation potentials of the metals.[23] The values of E^0 for $(C_5Me_5)_2Mn$ are quoted in the case of manganocene; the arrows indicate the shift of E^0 taking into account the effects of the substituents.

Figs. 1 and 2 present the E^0–IP relations for metallocenes and metallocarbaboranes respectively. The parallel variation of the potentials E^0 and the corresponding IP is clearly seen (E^0 increases with IP), but certain points deviate significantly from the straight line. All these deviations refer to the redox transitions involving the most stable 18-electron configuration of the complex. The deviation of the quantities E^0 for the d^5/d^6 redox transitions in the direction of more positive potentials, which might have been expected from the IP of the metals, is not fully understood if account is taken of the order in which the redox orbitals of the metallocenes are filled with electrons. However, such deviations are characteristic only of iron subgroup metallocenes and are in all probability caused by the extraordinary stability of the metallocenes of this subgroup. As regards the d^6/d^7 redox transitions, it is clear, since in this case the electron is transferred to the antibonding e_1^* orbital of the SC,[11-13,95] that the potentials E^0 for these electronic transitions must deviate consistently in the direction of more negative potentials, because electron transfer to the given orbital requires an additional energy expenditure in order to overcome the splitting energy in the crystal field of the ligand. The splitting between non-bonding (a_{1g}) and antibonding (e_{1g}^*) orbitals can probably be estimated from the degree of deviation of the E^0 in the case of the d^6/d^7 redox transitions.

It is seen from Figs. 1 and 2 that the same slope of the E^0–IP relations, amounting to approximately 0.1 V eV^{-1}, is characteristic of SC of three different types. This makes it possible to predict the

redox properties of different SC from the IP of their metals, *provided that E^0 is known for at least one of the redox transitions of one of the complexes of the given type*. In fact, this is equivalent to the creation of a single redox scale for transition metal SC, which is especially important for SC which have been weakly characterised electrochemically, have not yet been synthesised, or are so unstable that their electrochemical investigation is impossible. This approach permits the expression of the potential of any possible redox transitions of hetero- and homo-ligand SC by the simple equation

$$E^0 = \sum_{i=1,2} a_i + 0.1 \text{ IP}.$$

The constants a_i have been calculated[23] for the principal types of π-ligands (in V): −2.08 for Cp, −0.73 for η^6-C_6H_6, +1.52 for η^7-C_7H_7, −3.61 for η^8-COT, −2.05 for Cb, and −1.70 for Cb′. Fig. 3 illustrates graphically the validity of the proposed approach (the E^0–IP relations calculated from the constants a_i found previously are shown by dashed lines).

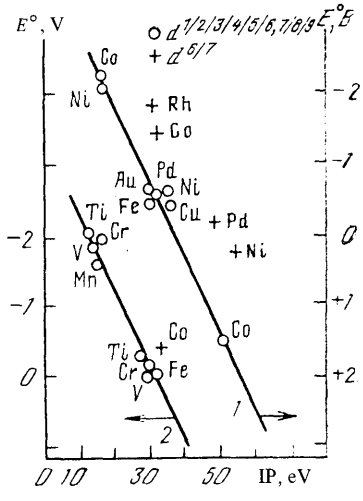

Figure 2. Dependence of E^0 for the d^x/d^{x+1} redox transitions in the series of metallocarbaboranes Cb_2M (line *1*) and Cb'_2M (line *2*) on the corresponding gas-phase ionisation potentials of the metals.[23]

The existence of a linear relation between the reactivity of SC in oxidation-reduction reactions and the ionisation potentials of the metals makes it possible to investigate systematically the regions of the thermodynamic stability of compounds of this type as a function of the nature of the metal, to understand the causes of the two-electron character of the oxidation-reduction reactions of certain complexes uncharacteristic of SC, to select the optimum conditions for the synthesis and investigation of the physicochemical characteristics of SC, to assess the possibility of the synthesis of various SC, to determine the redox properties of both relatively unstable and hitherto not synthesised SC, etc. A study has been devoted to the consideration of these questions.[23] In addition, its authors (see also Ref. 94) discuss questions associated with the application of the linear relations between E^0 and IP to the estimation of the reactivities of octahedral metal complexes in oxidation-reduction reactions and consider the factors which determine the slopes of these relations.

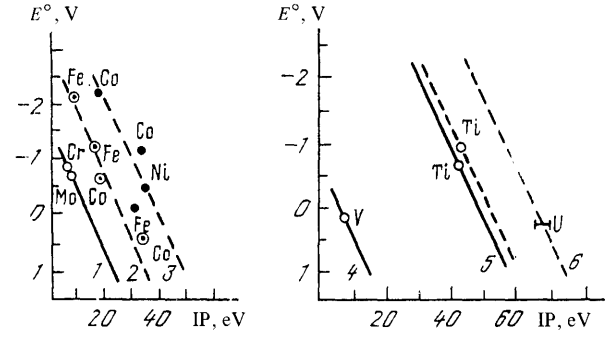

Figure 3. Dependence of E^0 on IP for the d^x/d^{x+1} redox transitions in the series of homo- and hetero-ligand sandwich complexes:[23] *1*, $(arene)_2M$; *2*, (arene)MCp; *3*, CpMCb; *4*, $CpM(C_7H_7)$; *5*, $(C_8H_8)MCb$; *6*, $(C_8H_8)_2M$. The dependences calculated from the values of a_i found previously are shown by dashed lines.

III. Electrochemical behaviour of bis(cyclopentadienyl) bent sandwich complexes

The enhanced interest in the mechanism of the electrochemical reduction of metallocene dichlorides is due to the fact that these compounds are components of catalytic systems used for the polymerisation, hydrogenation, and isomerisation of olefins,[96,97] while the products of their reduction activate small molecules such as molecular nitrogen,[98] and CO,[99–104] promote the reduction of the latter, etc. The catalytic activity of systems based on the complexes Cp_2MCl_2 is manifested as a rule for low oxidation states of the metal, so that the study of the mechanism of the reduction of these complexes is an important task.

Quantum-chemical analysis[12] shows that in both BC and SC the AO of the metal makes the main contribution to the HOMO and LUMO of the complexes, so that compounds of this type can also evidently undergo redox reactions with a change in the formal oxidation state of the metal, i.e. with a change in the electron density mainly on the metal atom.

Among the BC of Group IVB metals, titanocene dichloride has been most thoroughly investigated (as regards electrochemical properties). However, despite the fact that many studies have been carried out,[105–111] until recently there has been no unanimous view concerning the detailed mechanism of its reduction.

The reduction of Cp_2TiX_2 (X = Cl or Br) in THF has been investigated by polarography, cyclic voltammetry (Pt and carbon glass electrodes), preparative electrolysis, and EPR spectroscopy.[105] It has been suggested that the reduction takes place in three reversible one-electron stages:

$$Cp_2TiX_2 \overset{e}{\rightleftarrows} [Cp_2TiX_2]^- \overset{e}{\rightleftarrows} [Cp_2TiX_2]^{2-} \overset{e}{\rightleftarrows} [Cp_2TiX_2]^{3-}.$$

The $Cp_2TiX_2^-$ anion is stable in solution and can be obtained on a preparative scale, while the $Cp_2TiX_2^{2-}$ dianion is unstable and is converted under these conditions into Cp_2TiX^- with elimination of X^-. The paramagnetic $Cp_2TiX_2^-$ and $Cp_2TiX_2^{2-}$ complexes have been characterised by EPR spectra. The conclusion that the stage involving the transfer of the first electron is electrochemically and chemically reversible and that the $Cp_2TiX_2^-$ anion is stable in solution in the absence of moisture and oxygen has been confirmed also in subsequent studies.[106,107]

It has been found from cyclic voltammetric, preparative electrolysis, and EPR spectroscopic data[108–110] that, although Cp_2TiCl_2 does in fact undergo electrochemically reversible reduction to the $Cp_2TiCl_2^-$ anion in an aprotic medium, the anion is unstable and rapidly loses Cl^-, which is replaced by a molecule of the solvent or another suitable ligand (L) with formation of the complex $Cp_2Ti(L)Cl$. The complex $Cp_2Ti(L)Cl$ is in its turn capable of reversible one-electron oxidation to $Cp_2Ti(L)Cl^-$, which is converted into the initial Cp_2TiCl_2 in the presence of an excess of Cl^-.[109] As the electron-donating properties of L are enhanced in the sequence THF < Py < DMF, the rate of the forward reaction

$$Cp_2TiCl_2^- + L \rightleftarrows Cp_2Ti(L)Cl + Cl^- \qquad (3)$$

increases while that of the reverse reaction falls. The complex $Cp_2Ti(THF)Cl$ has been characterised by EPR spectroscopy.[108]

The electrochemical reduction of Cp_2TiCl_2 has also been investigated in the $AlCl_3$/1-butylpyridinium chloride melt.[37] It has been suggested that the product of the first reversible one-electron stage is the complex $Cp_2Ti[Al_2Cl_7]$ with two Ti–Cl–Al bridge bonds.

The replacement of Cl^- by the more electronegative ligand NCS^- greatly facilitates the reduction of Cp_2TiX_2.[111] The electro-chemically generated $Cp_2Ti(NCS)_2^-$ (characterised by EPR spectroscopy) is stable under these conditions in THF and CH_2Cl_2 at room temperature. The irreversibility of the first reduction stage in DMF has been attributed to the irreversible dimerisation of the anion, which forms a diamagnetic dimeric titanium(III) complex.

The data of Kukharenko et al.[112] in the main agree well with the results of other studies.[108–110] According to these data, the electro-chemically generated $Cp_2TiCl_2^-$ anion is unstable and is rapidly but reversibly dehalogenated in accordance with Eqn.(3) with formation of Cp_2TiCl_3.‡ The subsequent one-electron reduction of Cp_2TiCl leads to the formation of the unidentified "titanocene Cp_2Ti", which is capable according to the authors,[110–112] of undergoing one-electron reduction. However, it has been suggested[110] that the product of the reduction of Cp_2TiCl is a dimeric titanium(II) complex and not the "titanocene".

Among heavier analogues of Cp_2TiX_2, the dichlorides of zirconocene[105,112–115] and hafnocene[112,113,115] have been investigated in electrochemical reduction processes. In THF, these metallocene dichlorides undergo reversible one-electron reduction with formation especially at reduced temperatures (from –40° to –20 °C), of extremely stable $Cp_2MCl_2^-$ anions, which have been characterised by EPR spectroscopy.[113–115] The $Cp_2ZrCl_2^-$ and $Cp_2HfCl_2^-$ anions undergo further irreversible one-electron reduction in the region of extremely cathodic potentials (from –2.95 to –3.05 V) probably to the "corresponding metallocenes".[112] At room temperature the electrochemically generated $Cp_2MCl_2^-$ anions are apparently dehalogenated with formation of the more readily reduced mono-chlorides.[112] The rate of dehalogenation of $Cp_2MCl_2^-$ diminishes in the sequence Ti > Hf > Zr as a function of the nature of the metal, but the rate of the reverse reaction (3) increases in the sequence Hf $\lesssim$ Zr $\ll$ Ti.[112] Together with dehalogenation, there is also a possibility of the destruction of the zirconium- and hafnium-containing anions $Cp_2MCl_2^-$ via the reaction[113,115]

$$Cp_2MCl_2^- \rightleftarrows Cp^- + CpMCl_2.$$

The electrochemical behaviour of bridged titanocene dichlorides $(CH_2)_x(C_5H_4)_2TiCl_2$ (x = 1–3) and substituted titanocene dichlorides in THF has been investigated.[116,117] While the reduction mechanism is the same, the potentials $E_{1/2}$ for the reduction of the bridged monochloride complexes are displaced towards more cathodic values by 0.05–0.3 V compared with the non-bridged analogues. It has been suggested[116] that the influence of the bridging substituents on $E_{1/2}$ is due to their steric and not the inductive effect.

The reversible one-electron reduction of dialkyl derivatives of titanocene and zirconocene—Cp_2MR_2 (R = Me or $PhCH_2$)—in THF leads to the formation of corresponding unstable anions, which are destroyed with the elimination of R^- or Cp^-.[113,118–120] In THF, {2,3-bis(methylene)bicyclo[2.2.2]octane}zirconocene undergoes one-electron reduction to the corresponding radical-anion, which is relatively stable at 20 °C (characterised by its EPR spectrum), but decomposes with the dissociation of the zirconocene–diene bond on raising the temperature.[121] References to other studies on the electrochemical reduction of dialkylmetallocenes may be found in other reviews.[4,5]

The $Cp_2TiR_2^-$ anion, stable at –30 °C, has been obtained by the reversible one-electron reduction of Cp_2TiR_2 (R = C≡CPh) in THF. On heating to 25 °C, it slowly and reversibly splits off Cp^- with formation of $CpTiR_2$, which reacts in its turn with $Cp_2TiR_2^-$ to form $CpTiR_2^-$.[122]

Cp_2TiCl, generated electrochemically in THF, reacts with benzo[*c*]cinnoline (RN=NR) to form the dinuclear complex $Cp_2Ti(Cl)N(R)N(R)(Cl)TiCp_2$. This reaction has been considered[123] as a model for the activation of the N=N double bond.

The electrochemistry of Group VB metallocene dichlorides has been investigated in relation to vanadium and niobium compounds. However, there is no unanimous view in the literature concerning the detailed mechanism of the stability of the products of the electro-chemical reduction of these BC. Thus, the following mechanism for the reduction reaction has been proposed on the basis of data for the polarographic reduction of Cp_2VCl_2 in THF:[16]

$$Cp_2VCl_2 \overset{e}{\rightleftharpoons} [Cp_2VCl_2]^- \overset{e}{\rightleftarrows} [Cp_2VCl_2]^{2-} \xrightarrow{-2Cl^-} Cp_2V.$$

It has been claimed[16] that the $[Cp_2VCl_2]^-$ anion is stable and can be obtained by preparative electrochemical reduction. The agreement of the values of $E_{1/2}$ for the third wave on the Cp_2VCl_2 polarogram and the vanadocene reduction wave permitted the conclusion that vanadocene is the product of the two-electron reduction of Cp_2VCl_2.

In contrast to this, it has been concluded[18] that the transfer of the first electron to Cp_2VCl_2 is accompanied by the formation of the $Cp_2VCl_2^-$ anion, which, however, is extremely stable and rapidly but reversibly splits off Cl^- with formation of the monochloride Cp_2VCl, which is in fact reduced to vanadocene. Other data[124] confirm the validity of this conclusion.

‡Here and henceforth the coordinated solvent molecule is not shown for the sake of simplicity in the formulae of the monochloride complexes Cp_2MCl.

The study of the reduction of the biscyclopentadienylvanadium complexes with different types of chelating agents showed that the product of the two-electron multistage reduction of these complexes is vanadocene.[125]

A reversible one-electron wave, corresponding to the formation of the $Cp_2NbCl_2^-$ anion, has been observed in the electrochemical reduction of niobocene dichloride in THF.[126,127] On the basis of cyclic voltammetric and preparative electrochemical reduction data, it has been suggested[127] that the electrochemical reduction of Cp_2NbCl_2 proceeds via the *ECE*-mechanism and is completed by the formation of a dimeric μ-chloride complex, which is stable at −30 °C:

$$Cp_2NbCl_2 \overset{e}{\rightleftharpoons} Cp_2NbCl_2^- \xrightarrow{-Cl} Cp_2NbCl \xrightarrow{+Cp_2NbCl_2^-} [Cp_2NbClCl_2NbCp_2]^-.$$

At room temperature, the one-electron reduction of niobocene dichloride leads to the formation of $(Cp_2NbCl)_2$, while in the presence of L = Ph_3P or $(PhO)_3P$ it yields $Cp_2Nb(L)Cl$.[128] The subsequent one-electron reduction of $(Cp_2NbCl)_2$ is accompanied by the rapid dissociation of the anion generated to Cp_2NbCl and Cp_2NbCl^-; it has been suggested that the dehalogenation of Cp_2NbCl^- [128] results in the formation of metastable niobocene, which is destroyed in subsequent reactions. Previously the formation of niobocene as the primary metastable product of the amalgam reduction of Cp_2NbCl_2 was detected by EPR.[129]

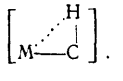
The reversible one electron oxidation of niobocene dichloride in THF leads to the preparation of the unstable $Cp_2NbCl_2^+$ cation, which is converted into Cp_2NbCl^+ as a result of the reductive elimination of the chlorine atom.[130]

It has been established by cyclic voltammetry that the dithiolene complexes $(Cp_2NbS_2C_2R_2)^+$ (R = Me or Ph) are reduced in THF in two reversible one-electron stages to a neutral compound and a monoanion respectively. The complex $Cp_2NbS_2C_2R_2$ can be obtained by preparative electrolysis.[131]

The complex $[Cp_2TaL]^+$, where L = 1,2-bis(dimethylphosphino)-ethane, is oxidised in an aprotic medium (CH_2Cl_2, acetonitrile, or acetone) in two reversible one-electron stages to $[Cp_2TaL]^{2+}$ (characterised by its EPR spectrum) and $[Cp_2TaL]^{3+}$ respectively according to data obtained by cyclic voltammetry.[132]

In contrast to Group IVB and VB metallocene dichlorides, the complexes Cp_2MCl_2 (M = Mo or W) are reduced in an aprotic medium to the corresponding unstable metallocenes in one two-electron stage, [22,23] because the first electron in the Group IVB and VB complexes is transferred to a non-bonding orbital, while in the Group VIB metallocene dichloride the analogous transfer is to an antibonding MO. On the one hand, this entails a cathodic shift of the Cp_2MCl_2 (M = Mo or W) wave relative to the first reduction waves of the Group IVB and VB complexes, since the electron is transferred to an antibonding MO whose energy is significantly higher[12] and, on the other hand, it leads to marked destabilisation of the $Cp_2MCl_2^-$ form, which is rapidly and irreversibly dehalogenated with formation of an M(III) complex more readily reducible than the initial metallocene dichloride.[22] It has been shown[124] that Cp_2M^+ is a product of this kind. Thus the reduction of Group VIB metallocene dichlorides proceeds via the *ECE*-mechanism with $E^0 < E_2^0$.

The electrochemical oxidation of the complexes Cp_2MX_2 (M = Mo or W; X = Cl, Br, I, or SR, where R = alkyl) has been investigated.[133] In acetonitrile, these complexes undergo reversible one-electron oxidation to the metastable cations $Cp_2MX_2^+$, in which the ligand is substituted by a reductive elimination reaction with ejection of X$^{\cdot}$, which results in the formation of the complexes $[Cp_2M(MeCN)X]^+$. The potentials of the $Cp_2MX_2^0/Cp_2MX_2^+$ redox couples depend only on the nature of M and not X, which has led to the hypothesis that the oxidation involves a non-bonding MO of the complexes to which the main contribution comes from the AO of the metal. The electrochemically generated cations $[Cp_2MSR]^+$ can also dimerise with formation of $[Cp_2M(\mu\text{-}SR)_2MCp_2]^{2+}$. The redox properties of the trinuclear heterometallic complex $Cp_2Ti[(C_5H_4)FeCp]_2$ have also been investigated.[133]



The electrochemical oxidation of the hydrides Cp_2WH_2 and $Cp_2W(Ph)H$ in acetonitrile has been investigated by cyclic voltammetry and preparative electrolysis.[134] The above compounds undergo reversible one-electron oxidation to the corresponding unstable radical-cations (lifetime from 10^{-3} to 20s; characterised by EPR spectroscopy), which are stabilised either via the reductive elimination reaction

$$Cp_2W(Ph)H^{+\cdot} \xrightarrow{-H^+} Cp_2WPh \rightarrow Cp_2W + Ph^{\cdot} \xrightarrow{MeCN} PhH,$$

or as a result of the additive dimerisation

$$Cp_2WH_2^{+\cdot} \xrightarrow{-H^+} Cp_2WH \xrightarrow{Cp_2WH_2} (Cp_2W)_2H_3 \xrightarrow{-e} (Cp_2W)_2H_3^+.$$

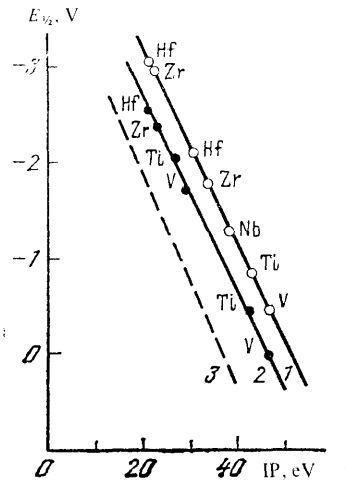
The oxidation of $Cp_2WR^1R^2$ (where R^1, R^2 = alkyl, aryl, or Cl) in acetonitrile has been studied.[134] It is suggested that the agostic interaction

takes place in the electrochemically generated cations $[Cp_2WR^1R^2]^+$.

Data on the electrochemical behaviour of lanthanide and actinide BC are extremely limited. It has been shown[136,137] that $(C_5Me_5)_2UCl_2$ undergoes reversible one-electron reduction to the anion in THF and acetonitrile, but the available data on the stability of this anion are contradictory. It has also been reported[138] that Cp_3UX (X = Cl or Me) undergo reversible one-electron reduction in THF with formation of the stable anion Cp_3UX^-. Finally it has been shown by cyclic voltammetry that the reversible one-electron reduction of $(C_5Me_5)_2NpCl_2$ to the anion takes place in acetonitrile.[139]

According to quantum-chemical calculations,[12] the structure of the frontier MO of the bent sandwich complexes Cp_2MCl_2 and Cp_2MCl is qualitatively virtually the same for different metals and the dominant contribution of the metal AO to the redox orbitals of the complexes is retained in all cases. One can therefore expect that the potentials $E_{1/2}$ for the Group IVB and VB biscyclodienylmetal chloride complexes, the characteristic reactions of which are one-electron reduction and oxidation, are also linearly related to the corresponding IP of the metals. This has been confirmed.[94,112] Thus it is seen from the relation between $E_{1/2}$ and IP presented in Fig. 4 that the values of $E_{1/2}$ for the metallocene dichloride complexes[112] fit satisfactorily on the straight line not only for the reversible $Cp_2MCl_2^0/Cp_2MCl_2^-$ redox couples but also for the irreversible $Cp_2MCl_2^-$ reduction reactions of the anions. This is due to the retention of the bent sandwich structure in the Cp_2MCl_2 and $Cp_2MCl_2^-$ complexes and the $Cp_2MCl_2^{2-}$ dianion formed as the primary reduction product of the latter. A specific linear relation exists also for the monochlorides Cp_2MCl, which differ somewhat in their structure (Fig. 4). The same figure shows by a dashed line the analogous relation for metallocenes. Evidently the slopes of all three relations are virtually the same ($\sim$0.1 V eV^{-1}), which is

probably associated with the retention of the dominant contribution of the AO of the metal to the SC and BC redox orbitals and with the similar changes in solvation energies in the redox transitions of the complexes of all three types. On the other hand, the discrepancy between the linear relations for complexes of different types is due to the energy differences between the corresponding redox orbitals of the complexes, which are associated with the differences in the angles of inclination between the cyclopentadienyl rings and with the presence of the electronegative Cl^- ligands.[94,112]



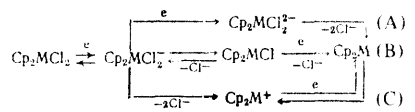


Figure 4. Linear dependences of the half-wave potentials of the complexes Cp_2MCl_2 (line *1*), Cp_2MCl (line *2*), and Cp_2M (line *4*) on the ionisation potentials of the corresponding metals in the gas phase according to Kukharenko et al.[112]

A single mechanism for the electrochemical reduction of the Group IVB–VIB metallocene dichlorides has been proposed on the basis of the linear relation between $E_{1/2}$ and IP established by Kukharenko et al.[112] and the consideration of the character of the redox MO of the complexes. It can be represented schematically as follows:

Pathway A obtains for M = Zr and Hf at a reduced temperature, pathway B for M = Ti and V and M = Zr and Hf at room temperature, and pathway C for M = Mo and W. When metallocenes whose lifetime is comparable to the time of the electrochemical measurement are formed (M = V, Mo, or W), their subsequent reduction to relatively unstable anions becomes possible.[22,24]

In conclusion of the consideration of the electrochemical reactions of the biscyclopentadienyl complexes, we shall deal briefly with the reactivities of the electrochemically generated species in relation to small molecules and certain other substrates. The products of the electrochemical reduction of metallocene dichlorides frequently activate inert molecules, especially CO,[99–103,140,141] CO_2,[140] and N_2,[98] in oxidation-reduction reactions, are inserted in the CH bond,[142] and participate in reactions involving the oxidative addition of olefins with formation of metallocycles,[143] i.e. play an important role in many synthetic reactions. So far there have been comparatively few studies of this kind, but the relative ease of the electrochemical generation of species in non-standard valence states, including unstable states, leads to considerable possibilities for the investigation of the reactivities of the low-valence products of the reduction of SC and BC in reactions with different substrates.

The products of the electrochemical reduction of titanocene dichloride react with CO to form $[Cp_2Ti(CO)Cl_2]^-$ and $Cp_2Ti(CO)_2$, the current yield of the latter amounting to approximately 100%.[107] However, it has been suggested[103] that the product of the one-electron reduction of Cp_2TiCl_2 in a CO atmosphere is the 17-electron complex $Cp_2Ti(CO)Cl$ and not the 19-electron anion $[Cp_2Ti(CO)Cl_2]^-$. This is confirmed by the fact that the significantly more stable $Cp_2MCl_2^-$ anions (M = Zr or Hf) do not react with CO.[103,112]

It is of interest to investigate the possibility of the electrochemically induced insertion of CO in the metal–carbon bond in the alkyl derivatives of metallocenes, because a reaction of this kind has been observed[144] in the electrochemical reduction of $CpFe(CO)_2Me$ in THF in the presence of Ph_3P and the acyl complex $CpFe(CO)(Ph_3P)(COMe)$ was formed as the product.

The interaction of the electrochemically generated "titanocene" with molecular nitrogen has been briefly mentioned.[110] A cathodic shift of the second reduction wave of bridged titanocene dichlorides, attributed to the electrochemical reduction of unidentified hydride and dinitrogen complexes of "titanocene", was observed in THF in the presence of N_2 and H_2. Finally, it has been claimed[145] that the products of the electrochemical reduction of Cp_2TiCl_2 in THF or methanol catalyse the electrochemical reduction of N_2 to NH_3 with a current yield of approximately 2%. However, the fixation of nitrogen was not confirmed by a blank experiment (Ar) and by experiments with $^{15}N_2$.

It has been shown by cyclic voltammetry and preparative electrolysis that the complexes Cp_2VL (L = CO or $C_6H_{11}NC$) undergo reversible one-electron reduction in THF to the corresponding anions, which rapidly decompose to the metal, L, and Cp^-, probably via the immediate formation of CpVL.[146,147]

In the presence of proton donors (phenols, diethylbarbituric acid) in non-aqueous media (THF, DMF, and DMSO, etc.), vanadocene catalyses the amalgam reduction of CO to C_1–C_4 hydrocarbons.[99–103] $Cp_2V(CO)$ behaves as a catalyst-substrate complex, which undergoes one-electron reduction during the catalytic cycle to the $Cp_2V(CO)^-$ anion, as a result of the subsequent protonation and reduction of which the methyl complex Cp_2VMe is formed. The protolysis of this intermediate leads to the formation of methane and chain growth takes place as a result of the insertion of CO in the V–Me bond. As a consequence of the rapid subsequent protonation of the $[Cp_2V(CO)]^-$ anion, the transfer of the first electron to the catalyst-substrate complex takes place against the standard potential gradient.[102] This reaction has been considered as a kind of electrochemical analogue of the Fischer–Tropsch reaction which takes place at room temperature and atmospheric CO pressure. It has been noted[103] that other metallocenes Cp_2M (M = Nb, Mo, or W) also form reducible carbonyl complexes, which can be observed polarographically, for example in the case of M = Mo and W.[22]

However, the deactivation of the unstable metallocenes during the catalytic process prevents their use as catalysts of the conversion of CO into hydrocarbons.

The electrochemical reactions of the complexes of bis(fulvalene)-divanadium with CO and acetonitrile, which take place with a change in the formal oxidation state, have been examined.[85]

IV. Electrochemical synthesis of sandwich and bent sandwich transition metal complexes and of metal complex catalysts based on them

The principal methods of synthesis of SC and BC involve the interaction of the cathodically generated carbanions with the transition metal cations formed on the dissolving anode.[8,148] Bis(cyclopentadienyl) derivatives of manganese, iron, and cobalt[148] and the dicarbaboryl complexes of iron, cobalt, and nickel[148,149] have been obtained recently by this method. The carbonyl complexes of the cyclopentadienyl derivatives of manganese, iron, cobalt, titanium and vanadium are formed when Cp^- is generated by the electrochemical reduction of cyclopentadiene in an aprotic medium and under a CO atmosphere under conditions where transition metal ions are generated anodically.[8,148]

A review[150] has been devoted to the synthesis of SC with cycloolefin ligands and to the reactions involving the introduction of functional groups into SC by the electrophilic addition of alkyl halides and CO_2 to the electrochemically generated metallocene anions with formation of monosubstituted metallocene compounds or via the anodic substitution of hydrogen atoms in ferrocene by alkyl or alkylcarboxy-groups, which are obtained by the anodic decarboxylation of the anions of monocarboxylic and dicarboxylic acids and the half esters of dicarboxylic acids. Individual examples of the introduction of functional groups into the ferrocene and other SC can be found in a number of communications.[4,5,151]

A review[152] has been devoted to the chemical synthesis from metallocenes of various complexes, including catalysts for the cyclooligomerisation and trimerisation of alkynes and nitriles and also for the hydrogenation of alkenes and arenes. The key stage in these reactions is the reduction of Cp_2M by an alkaline metal to the Cp_2M^- anion with subsequent substitution of one or both Cp ligands by an olefin, an arene, a phosphine, CO, N_2, etc. The reduction by an alkali metal can be fully replaced by electrochemical reduction, which makes it possible to expand significantly the scope of the electrochemical synthesis of metal complex catalysts.

--o0o--

In conclusion one should note that the use of solvents which are stable in the regions of extremely anodic and cathodic potentials greatly expanded our ideas about the possible oxidation-reduction reactions of sandwich and bent sandwich complexes and the establishment of a linear relation between the standard potentials of the redox reaction of complexes of this class and the gas-phase ionisation potentials of the corresponding metals made it possible to find a convenient parameter for defining the reactivity of the SC and BC in oxidation-reduction reactions. The mechanisms of the electrode reactions involving SC and BC have been studied in fair detail. On the other hand, there exist a series of promising aspects of this field in which there are still many unsolved problems. These include the electrochemistry of the BC of the actinides and lanthanides, the reactivity of intermediates in the redox reactions of SC and BC in relation to reagents of different kinds (electrophiles, nucleophiles, small molecules, etc.), and the electrochemical synthesis of SC and BC and of the metal complex catalysts based on them. The study of the electrode reactions of SC and BC in the absence of supporting electrolytes by means of the technique using ultramicroelectrodes is also of interest.[153] This will permit an even more significant expansion of the working range of potentials (from −4 to +5 V) and will make it possible to generate and identify species with an unusual formal oxidation state of the metal and also to avoid the undesirable interaction of the species generated with the components of the supporting electrolyte. Finally, low-temperature studies (cryoelectrochemistry), which will probably make it possible to identify many metastable intermediates in the electrochemical reactions of SC and BC and to investigate their properties, are promising.

--o0o--

During the preparation of the present review, there has been a sharp growth of the number of studies concerning the use of SC as promoting agents for reactions involving electron transfer from the electrode to different kinds of inorganic and organic substrates. The reduction reactions of oxygen, the nitrate ion, and carbonyl and other organic compounds catalysed by iron SC as well as ligand substitution, *cis–trans* isomerisation, chelation, and demetallation reactions and reactions involving the migration insertion of carbon monoxide in a carbon–metal bond in metal complex and organometallic compounds, induced by charge transfer in catalysis by SC, have been considered in a number of reviews.[154–156]

The oxidation-reduction reactions of the iron SC with polyaromatic hydrocarbons (L = biphenyl, naphthalene, phenanthrene, triphenylene, pyrene, perylene, and caronene), having the general formula $[(\eta^5\text{-}C_5R_5)Fe(\eta^6\text{-}L)]^+$ (R = H or Me) have been investigated.[157] It has been shown by cyclic voltammetry[158] that the reduction of the double decker dinuclear cations $\{[(\eta^5\text{-}C_5Me_5)Fe]_2(\eta^{12}, \mu^2\text{-}L\}^{2+}$ (L = biphenyl, 9,10-dihydrophenanthrene, or triphenylene) to the corresponding neutral complexes in non-aqueous solvents is a multistage process which proceeds via the intermediate formation of mixed valence [Fe(1+)Fe(2+)] complexes. The redox reactions of ferrocene-substituted phosphazenes and polyphosphazenes[159] and of the diferrocene complex containing germanium octaethylporphyrinate as the bridge linking the two ferrocene fragments have been investigated.[160] The oxidation-reduction reactions of polynuclear homo- and hetero-ligand SC of transition metals, especially bridged dimetallocenes, bis(fulvalene)-dimetal complexes, metallocenophanes, and multidecker SC have been examined in a review.[161]

On the basis of a comparative study of the electrochemical oxidation of $(C_5Me_2)_2M$ (M = Fe, Ru, or Os) to the corresponding cation in acetonitrile, it has been noted[162] that the variation of the potentials $E_{1/2}$ for the oxidation of the metallocenes investigated in the sequence Fe < Os < Ru parallels the variation of the ionisation potentials of the complexes and the atomic ionisation energies of the corresponding metals. It has been shown[163] by cyclic voltammetry in THF at temperatures in the range −90 to −70 °C that the cobaltocene and nickelocene anions are capable of subsequent one-electron reduction with formation of the unstable Cp_2M^{2-} dianions at potentials more cathodic than −3 V. Under analogous conditions, the formation of the corresponding substituted titanocene and

zirconocene derivatives has been detected in a study of the mechanism of the electrochemical reduction of pentamethyl- and t-butyl-substituted titanocene and zirconocene dichlorides.[164] Thus the cryoelectrochemical approach to the study of the oxidation-reduction reactions of SC and BC proposed by Kukharenko and co-workers[163,164] has made it possible to expand the redox series (1) for metallocenes by yet another member (Cp_2M^{2-}) and also to establish the fundamentally important fact of the existence of the previously unknown Group IVB metallocenes.

The formation, structure, and properties of network polyurethanes

V P Dorozhkin, P A Kirpichnikov
Kirov Kazan Institute of Chemical Engineering

ABSTRACT. Questions concerning the influence of the density and chemical nature of the cross-links on the properties of cross-linked polyurethanes are examined. The existing ideas about the mechanism of the formation of the network structure in polyurethanes are analysed and the causes of the inhomogeneity of the three-dimensional network in cross-linked polyurethanes are discussed. The principal advances in the study of the influence of the chemical microstructure of the macrochains of polyurethanes on the microphase separation process in thermoelastoplastics are described.
The bibliography includes 174 references.

I. Introduction

Probably none of the classes of industrial polymers existing at the present time and produced on a large scale, with the exception of polyurethanes (PU), permits the variation of their properties, from those of elastomers, thermoelastoplastics, and foams to plastics and fibres by a slight alteration of the chemical structure of the macromolecules. A combination of increased hardness, a high modulus of elasticity, and a high elasticity is characteristic of polyurethane elastomers alone, while as regards resistance to wear they have no equal. It is not fortuitous that the industrial output of PU in the countries of Western Europe, the USA, and Japan has been doubling in each decade[1] and has reached about four million tonnes in 1986. In the USSR, the output of PU is approximately 100 000 tonnes per year and a growth of the manufacture of network polyurethanes (NPU) by a factor of four relative to 1985 is planned for 1990. The aim of the present review is to consider the principal results of research into the formation, structure, and properties of network polyurethanes.

II. Network formation in polyurethanes and its influence on the properties of network polyurethane

Processes involving the branching and subsequent cross-linking of linear macromolecules of a polymer have a decisive influence on its properties.[2] At the present time, one may claim that the formation of a network suppresses the microphase separation characteristic of certain polyesterurethanes to a greater extent the denser the network formed.[3,4] On the other hand, when a more flexible polydiene block has been introduced into the PU macromolecule instead of the ester block, then the microheterogeneity is retained regardless of the density of the network.[5]

Numerous studies have been devoted to the influence of the frequency of the cross-linking on the crystallisation and glass point (T_g) of network polyurethanes (NPU). Whereas the available data on the crystallisation of NPU are unambiguous,[6,7] namely the degree of crystallisation diminishes down to zero with increasing degree of cross-linking, the results for T_g differ greatly. It has been established for the NPU based on polyoxy(ethylene glycol) and 4,4′-diphenylmethane diisocyanate (MDI) [8] that T_g increases linearly with the density of cross-linking. On the other hand, when hexamethylene diisocyanate (HMDI) is used, the above relation passes through a maximum. On these grounds, it has been concluded that the aromatic nuclei and urethane groups in the macrochains exert a decisive influence and that T_g depends only slightly on the chemical cross-linking. A similar conclusion that the interaction of the polar groups in NPU has a strong influence has been reached in another study.[9] Nevertheless, some investigators believe that the T_g for NPU tends to increase with increasing degree of cross-linking.[10] Using the principle that individual structural elements influence independently the T_g for the polymer, Becker and Neumann[11] obtained formulae for the theoretical calculation of T_g taking into account the degree of cross-linking. An experimental test was performed on 59 linear and 27 cross-linked amorphous PU and demonstrated a satisfactory agreement between the calculated and experimental data.

The influence of the chemical nature of the cross-links on T_g is characteristic of NPU. It has been observed by broad band NMR [12] that T_g for PU based on poly(ethylene glycol adipates) (PEGA) and MDI with allophanate cross-links is −20 °C, while that for the PU with biuret cross-links is −15 °C. On the other hand, when ionic cross-links are introduced into the same PU, the mobility of the segment diminishes and T_g is in the range between −13° and −8° C. With increase in the concentration of interchain carbon–carbon bonds, T_g increases from −50 °C for a weight fraction of dicumenyl peroxide of 1.4 to 0 °C for a weight fraction of 2.5 relative to the non-cross-linked PU. Cross-linking by chemical bonds by employing trifunctional polyesters (PE) with a molecular weight (MW) in excess of 5000 g mol^{-1} does not alter the degree of self-association compared with linear PU.[13]

The nature of the cross-links influences not only T_g and the degree of self-association but also many other properties of the NPU. Thus the interaction of 2,4-tolylene diisocyanate (2,4-TDI) with the ions of 3*d* elements[14,15] in certain solvents can yield in the

final stage polynuclear complex forms of the diisocyanate whose functionality with respect to the NCO group is greater than two. Subsequent reaction with polyesters results in the formation of an NPU whose specific conductance is 5–6 orders of magnitude greater[16] than that of the usual NPU.[17] The strengths and thermal parameters of such NPU are close to those of the industrially manufactured PU, while their elasticity and resistance to wear are actually greater. The thermal stability of NPU can be significantly increased by using Mannich bases as catalysts of the urethane formation reaction.[18] This entails not only an increase in the length of the macromolecules as a result of the interaction of the macrodiisocyanate with polyesters but also the formation of a network as a result of the cyclotrimerisation of the terminal NCO groups.

The degree of homogeneity of the reactions occurring in the reaction system has become one of the first controversial problems as regards the formation of NPU. Two points of view have arisen in this connection. According to the studies by Lipatova and co-workers,[19–21] the formation reaction of the three-dimensional structure consists of two stages which differ sharply in their rates. The reaction is described by a second-order kinetic equation only up to 45–50% conversion owing to a change in the physical process conditions.[19] Beyond the gel point, the formation of the polyurethane network is described satisfactorily by the Avrami-Erofeev equation. It has been suggested that, after the attainment of a certain degree of conversion, the system undergoes microphase separation and the urethane formation kinetics begin to be determined by physical and no longer by chemical processes. Indeed, studies on the formation of NPU by the turbidity spectrum methods[20] have shown that, in the two-stage method of synthesis of NPU, particles of sizes of the order of 650 Å appear by the time of attainment of 70% conversion. Measurements of the angular dependence of the scattered light intensity indicate the presence of cross-linked microparticles and not aggregates of macromolecules. A single network is produced by the chemical cross-linking of network microblocks.[21] On the other hand, it is now difficult to regard the conclusion that physical factors have a decisive influence on the urethane formation kinetics beyond the gel point as rigorously demonstrated, because the power exponent in the Avrami-Erofeev equation is almost unity.

The study of the urethane formation kinetics before the attainment of the gel point and beyond it revealed[22] that in the temperature range 20–60 °C the reaction rate constants are virtually identical and the activation energies are 40.8 and 45.6 kJ mol^{-1} respectively, from which it is concluded that the rate of reaction is not diffusion controlled after gel formation. This conflicts with the view expressed by Lipatova and Ivashchenko[23] and Rumyantsev et al.[24] Data obtained[25] by the repeatedly distorted total internal reflection method led to the analogous conclusion that the kinetics of the formation of PU both in the liquid phase and beyond the gel point are the same. These results conflict with the conclusions reached by Lipatova and co-workers. It is notable that experimental data similar to the observations by the Kiev group of investigators have been obtained in a number of foreign studies. Hager et al.[26] and Huang et al.[27] arrived at the conclusion that phase separation takes place during the urethane formation process. A dependence of the urethane formation rate constant on the degree of conversion starting from 30 – 40% conversion has also been reported.[28]

In our view, the conflict between the conclusions reached by these research groups is only apparent. As will be seen from further exposition, the chemical processes leading to gel formation are extremely sensitive to many factors: the chemical nature of the reaction system, the presence and nature of a solvent, the concentration and stoichiometry of the reactants, the temperature, etc. For this reason, in each case a specific situation can arise. Under certain conditions, microregions with an increased content of the cross-linking agent or an increased concentration of NCO groups can appear in the reaction system even at the beginning of the reaction. This can occur either as a result of self-association,[29] or as a result of the poor compatibility of the components,[30,31] or because of the physical influence of the urethane groups which have appeared in the reaction system.[32,33] Clearly cross-linking in these regions occurs already in the early stages, which results in the appearance of the microgel. Further consumption of the NCO groups can take place in regions with different ratios of the functional groups, which is the reason for the observed change in kinetics. On the other hand, when the gel formation conditions are such that the concentration of the reactants is constant throughout the reaction volume, the microgel is not formed up to the gel point. The kinetics of the consumption of the NCO group beyond the gel point remain the same as before, because their reactions occur mainly in the sol fraction. The results of the studies considered above and our own data[34,35] lead to these conclusions. Thus the study of the influence of the number of stages in the formation of NPU on their strength parameters revealed that the bimodality of the distribution on the probability curve for the appearance of a particular tensile strength is more pronounced for the single-stage NPU preparation conditions. On the other hand, when the network polyurethane was obtained via a stage involving the synthesis of the macrodiisocyanate, the bimodality was much less marked, which can be explained by the lower concentration inhomogeneity of the terminal NCO group and hence by the lower inhomogeneity of the three-dimensional network of the PU. When rolled PU was vulcanised, the distribution curve was unimodal.

The change in the urethane formation mechanism is frequently inferred from the deviation of the kinetics of the consumption of NCO group from a second-order irreversible reaction. Apparently this can be done legitimately only for non-catalytic urethane formation processes. In the case of catalysed reactions, the consumption of NCO groups is described by more complex relations. Indeed, in a study of the urethane formation reaction between the macrodiisocyanate based on PEGA and 2,4-TDI and butane-1,4-diol (BD) in the presence of iron acetylacetonate,[36] the order of the reaction varied from three at the beginning to two at the end. The analytical expression describing the rate of consumption of NCO groups assumes the following form:

$$R = (AX^3 + BX^2)/(CX + K_1^-),$$

where A, B, and C are algebraic combinations of the rate constants for the individual urethane formation stages and the catalyst concentration, X is the current concentration of NCO groups, and K_1^- the rate constant for the decomposition of the binary intermediate complex into the initial reactants. At the beginning of the reaction, $AX^2 < BX^3$ and $CX < K_1^-$, so that the order of the reaction is three. As the reaction proceeds, the term BX^3 diminishes faster than AX^2 and the order tends to two. For other reaction systems, where this mechanism operates, a situation may be encountered where $AX^2 > BX^3$ and $CX \gg K_1^-$. The order of the reaction should then be unity throughout the kinetic curve. Thus the observed change in the rate of urethane formation is presumably in many cases associated with purely kinetic factors and not with a change in mechanism.

A complex gel formation process depends on many factors. In a study of the formation of NPU from PE, 1,1,1-tri(hydroxymethyl)-propane (THMP) and 2,4-TDI, it was shown[37] that, depending on the type of medium and the degree of dilution, the relative reactivities of the reactant as well as the tendency of the system towards ineffective macrocyclisation or three-dimensional polycondensation change significantly. The changes in the relative reactivities of the hydroxylated components in the reaction with diisocyanate can be achieved also by introducing a catalyst. The addition of tin dibutyl dilaurate [bis(butyl laurate)tin?] to the reaction system described above leads to the formation of a NPU with good physicomechanical properties,[38] while in its absence gel formation does not occur at all. The presence of hydroxylated compounds with different reactivities can entail a non-equilibrium distribution of cross-links in the polymer network and can reduce the modulus of elasticity compared with the calculated value.[39] The self-association of THMP can actually result in the appearance of polyfunctional branching units.[29]

Network formation in PU is frequently complicated by cyclisation especially near the gel point.[40,41] The fraction of cyclised molecules in the synthesis of PU in bulk can attain 2–3% for a degree of conversion of 0.9 and an initial ratio of the NCO and OH groups of unity. In the 0.1% solution, the fraction of cyclised molecules for the same conversion in the synthesis of PU increases to 85%.[42] The study of the cyclisation process is also essential because the pre-gel formation of loops and not entanglement make the main contribution to the defects.[43] Furthermore, there is a close relation between the intramolecular reactions before the gel formation point and the network defects. Such reactions result in the formation of elastically ineffective rings whose influence on the physical parameters of the network is opposite to that exerted by molecular entanglement.[44] The elastically ineffective rings at a concentration of 3% diminish the concentration of elastically active chains and the equilibrium modulus by ~30%.[45] With increase in the degree of cyclisation, the molecular weight of the region between neighbouring nodes of the network increases.[46] The degree of cyclisation depends not only on the ratio of the NCO and OH groups in the system, the degree of its conversion, and its dilution, but also on the MW of the polyester[47] as well as on the presence or absence of the catalyst in the system.[48] The higher the MW of the polyester, the greater the tendency towards cyclisation.[47,49] The tendency towards cyclisation is greater in the case of a two-stage cross-linking process than for a single-stage process, which is associated, according to the authors, with the possibility of the formation of MDI–THMP clusters when the reactivities of the OH groups are not the same.

It is of interest to note that macrocyclisation is observed even in those cases where the possibility of the formation of NPU is ruled out[50,51]—for example, the degree of cyclisation increases with increasing MW of the chain.

The influence of the flexibility of the polyester chain on the effective density of the three-dimensional network of the PU and on their structure has been traced in the study of Eremeeva et al.[52] It was then found that a denser and more stable effective three-dimensional network is formed in NPU based on flexible-chain oligoesters compared with PU having rigid macromolecules.

There exist interesting data concerning the influence of the nature of the PE on the gel formation process.[53] In the synthesis of linear oligoesters based on diethylene glycol and various dicarboxylic aliphatic and aromatic acids and the study of their reactions with the adduct 2,4-TDI–THMP in cyclohexanone, it was found that the rate of formation of MPU up to a degree of conversion of 60–70% is described by a second-order equation, while for higher conversions the process is complicated by gel formation and takes place under microheterogeneous conditions. The degree of reaction at the gel point and the critical degree of branching depend on the nature of the acid residue of the PE and particularly the greater the flexibility and the smaller the steric hindrance characterising the PE chain.

Complex PE [polyethylene(diethylene glycol adipates)], characterised by different degrees of molecular and topological inhomogeneity have been synthesised.[54] The degree of inhomogeneity of the chemical three-dimensional network of the NPU obtained on their basis depended directly on the degree of inhomogeneity of the initial PE. On the other hand, the inhomogeneity of the physical three-dimensional network, observed for small degrees of monoaxial equilibrium stretching deformation (<2%), was proportional to the concentration of the urethane groups in the macrochain. A transition from linear to viscoelastic behaviour, occurring in the region of low deformations of ~0.5–3.0%, has been reported.[55] The authors believe that the phenomenon is due to the thixotropic breakdown of the aggregate formed via intramolecular interaction.

The influence of a solid surface on the characteristics of gel formation in PU has been traced.[56,57] The data obtained have been interpreted from the standpoint of the heterogeneity in the reaction mixture, which is manifested at a specific stage of the PU formation process.[56] The nature of the PE does not alter the character of the influence of the filler (aerosil) on the structure formation in the hardening system. The filler prevented the formation of a gel in the system comprising a polyether, THMP, and MTI. On the other hand, when 2,4-TDI was used instead of MDI,[57] then the aerosil actually created more favourable conditions for gel formation. The strong influence of fillers on the structure of the three-dimensional network has been indicated.[58,59] A strong chemical interaction of the PU macromolecules based on a polyester with technical carbon particles has been observed.[60] The activation energy for the formation of the chemical bond was 123 kJ mol^{-1} and the limiting surface area of the technical carbon per bond of this kind was 11 $Å^2$. Under conditions where physical as well as chemical interaction between the technical carbon and PU is possible, this area is 7 $Å^2$, which indicates an appreciable fraction of physical cross-links.

The presence of a well developed physical network, whose appearance is due to a broad spectrum of intermolecular interactions, is characteristic of PU. This is no longer disputed at the present time but quite a few studies have been devoted to the determination of the quantitative relation between the densities of the chemical and physical networks in the NPU and also to the elucidation of factors influencing this relation. Such studies have been stimulated primarily by the strong influence of the nodes of the three-dimensional physical network on a series of physicochemical and operational characteristics of the PU. Thus sorption, thermo-mechanical, and spectroscopic studies have been carried out[61,62] on the network in the PU based on tri(hydroxymethyl)propane phthalate and aliphatic polyisocyanate. It has been shown that a fairly open chemical network is formed with M_n = 2500 g mol^{-1}. The physical nodes are extremely varied with respect to density (M_n of the order of 200 and 500 g mol^{-1}) and greatly increase the effective density of the network. The appearance of three-dimensional structures with network nodes, formed as a result of specific physical interactions, has been noted[63] already in the initial stages. Deformation tests on an NPU with a controllable network topology led Allen et al.[64] to the conclusion that the influence of physical entanglements in unswollen specimens on the modulus of the network is comparable

in magnitude to the influence of chemical cross-linking. Admittedly, the nature of the physical entanglement was not specified and one cannot therefore rule out the possibility that the increase in the modulus is associated with the occurrence of intermolecular interactions. Indeed, Dusek and Ilavsky[65] found in the determination of the equilibrium moduli of urethane networks that the structural front-factor A may be greater than unity, i. e. greater than the value expected for phantom networks, for which $A \leqslant 1$. This confirms the hypothesis that the interchain contacts may contribute to the equilibrium moduli. It has been stated[66] that the networks obtained are affine rather than phantom. This shows that polyurethane networks are more perfect than fully random networks.

As a rule, the dependence of the conventional strain in the NPU (σ) on the degree of its deformation (λ) is described satisfactorily by the Mooney–Rivlin equation.[67,68] However, it has been observed[69] that the classical relation $\sigma = f(\lambda - \lambda^{-2})$ for the PU investigated is represented by straight lines as far as $\lambda - \lambda^{-2} \simeq 0.1$, which subsequently become bent as the origin of coordinates is approached. In terms of the variables of the Mooney–Rivlin equation, the experimental data did not fit on the straight line and the constant C_2 did not really remain constant. It decreased with increasing degree of deformation and became a maximum at $\lambda = 1$; analogous data have been described elsewhere.[70]

Walsh et al.[71] concluded that polyurethane networks containing short polyol chains differ significantly in their deformation behaviour from ideal networks. They explain the results in terms of phase separation occurring in such PU. In a study of the deformation of diamine-hardened PU,[72] the constant C_2 of the Mooney–Rivlin equation actually proved to be negative.

All these facts definitely indicate that, with rare exceptions, the polyurethane networks are not ideal. This is apparently associated with the occurrence of strong intermolecular interactions in the NPU. These physical interactions are responsible for the large contribution by the energy component of the highly elastic deformation of NPU.[73,74]

The great influence of the chemical and topological structures of polyurethane networks on the properties of NPU has already been noted frequently above and in certain cases the effect of the network topology is comparable or even superior to the effects of the remaining factors. It is therefore extremely important to investigate the homogeneity of the polyurethane networks. The ideas of various authors on this question agree[75–79] and reduce to the fact that the network structure of the PU formed is inhomogeneous. The studies[80,81] in which it was concluded that the networks are highly homogeneous after investigating the mechanical, dielectric, rheopectic, and optical properties of model polyurethane networks constitute an exception. Admittedly, the same workers[82] reported the observation of an inhomogeneous network, but they explained its appearance by the microsyneresis occurring when the temperature of the synthesis is altered abruptly.

Lipatova et al.[77] also explained the increase in the heterogeneity of the NPU with increasing degree of cross-linking or the MW of the oligomer by the increase in the number of associated rigid chain fragments. The possibility of regulating the microheterogeneity of NPU by varying the intermolecular interactions in this system has been discussed.[74] It has been suggested in 1973 [32] that intermolecular interactions, leading to the fluctuation of the structural network in the oligomer even before the formation of a continuous chemical network, may play a major role in gel formation in oligomeric systems. Under such conditions, a preliminary order, leading to the microheterogeneity of the system, is established beforehand. X-Ray diffraction and other studies on swollen polyurethane networks[78,83] have also led to the development of an approach to the NPU as heterogeneous systems, their microregions being characterised by different parameters of interaction with the solvent.

It has likewise been demonstrated[84] that polyurethane networks are inhomogeneous, but the kinetic aspect of urethane formation, in particular the presence of monofunctional molecules in the system, is used as the mainstay of the explanation of the causes of this phenomenon. The observation of additional maxima in the thermostimulated depolarisation current is attributed to the accumulation of charge at the boundaries of regions with different degrees of cross linking.[85] The existence of a relation between the kinetics of the main chemical reaction (the formation of the urethane linkage), the gel formation process, and the structural characteristics of the hardened NPU has been reported also in another study by the same workers.[49]

The inhomogeneity of polyurethane networks as regards the cross-linking density results in a variable rather than a constant (as in an ideal network model) MW of the regions between the cross-linking nodes. In the treatment of the experimental data obtained, this must be taken into account, since a change in the conditions governing the synthesis of the polyurethane network can entail a significant alteration of the properties of the finished material.[86] An increase in the temperature of the synthesis led to an increase in the density of the three-dimensional chemical network as a result of a change in the ratio of the rate constants for the reactions of bi- and tri-functional alcohols with diisocyanate. Since the concentration of THMP was unaltered in all the experiments, the results obtained can be accounted for by a change in the distribution of M_n with respect to length.

Theoretical analysis of the MWD of the macrochain fragments between neighbouring cross-links carried out in a number of studies[87–89] makes it possible to approach the control of the molecular structure of network polymers with the aid of purely kinetic methods. Thus it has been shown theoretically[88] that, if the MWD in the initial oligomer is narrow, then the network chain distribution curve has a polymodal character. If the MWD becomes wider, the polymodality of the network chain distribution can ultimately vanish. An interesting outcome of the application of Zabrodin's theory[88,89] is the demonstration of the theoretical possibility of obtaining a narrower network chain distribution under certain kinetic conditions than the initial distribution. This conclusion has been criticised by Irzhak as erroneous.[2]

The kinetic approach to the study of the influence of the MWD and of the distribution with respect to different types of functionality (DTF) of the initial oligomers on the MWD and the DTF of linear molecules and network fragments has been developed.[90–92] It is notable that systems of differential equations are obtained with difficulty for the most realistic conditions in the synthesis of NPU, the equations often being simply insoluble, and the statistical approach to the solution of problems of this kind therefore appears more promising.[2]

When the mathematical theory of graphs was used in the study of the topology of a network polymer, it was demonstrated from the standpoint of conformational statistics[93] that the topological factors influencing the entropy of the system are responsible for the inhomogeneity of the networks, the inhomogeneity being greater the higher the network density.

Technological factors exert an enormous influence on the properties of the NPU and in the first place comes the number of stages in the urethane formation process.[94] In the single-stage

process, all the components of the reaction mixture are charged into the reactor simultaneously. In the two-stage version, the macrodiisocyanate pre-polymer is obtained initially by the reaction of the oligomer having terminal OH groups with an excess of the diisocyanate to which a chain lengthening cross-linking agent is added in the second stage. In the single-stage method of synthesis, the melting range of the PU crystallising is wider[95] than in the case where the pre-polymer with terminal NCO groups is formed in the preliminary step. According to the results of a number of workers, the set of physicomechanical properties is found to be best with the single-stage synthesis regime,[95,96] but the results of one study[97] permit the conclusion that the method of synthesis of PU based on polyethers is not appreciably reflected in the mechanical properties. For PU based on polyesters, the two-stage method has led to more effective mechanical parameters. The content of the sol fraction is reduced,[13,98] while the modulus of elasticity increases in the two-stage method of synthesis. Admittedly, Cherkasova et al.[99] arrived at the opposite conclusion that the less regular disposition of the units in the chain, observed in the single-stage method, ensures a higher value of the modulus.

A detailed comparison of the gel formation processes established[100] that the gel formation in NPU obtained in a single stage begins earlier. The networks formed in the single-stage process exhibit broader transitions at the glass point,[98] in agreement with data[95] indicating a broadening of the melting temperature range.

The facts presented show that the topological structure of the three-dimensional PU network depends greatly on the method by which it is produced and the results of different workers concerning the dependence of the mechanical properties on the regime used in the synthesis of the NPU do not agree. This is apparently due to the dependence of these properties on many factors and not only on the synthesis regime.

It has been shown in relation to the preparation of the network structure in rolled and cast PU [101] that the macromolecules of the oligomer obtained in the first stage are highly branched even in the presence of a small excess of the diisocyanate relative to the polyester. Since the kinetic characteristics of the linear growth of the oligomer macromolecules and of their branching are various, the possibility arises of regulating the temperature of the first stage to alter specifically the degree of branching of the prepolymer and hence the topology of the network obtained in the second stage of the synthesis of the NPU. By carrying out the first stage of the synthesis in accordance with the temperature regime ensuring a low probability of the branching of the prepolymer macromolecules, a significant increase in the tensile strength and in the relative elongation of the NPU was achieved compared with specimens obtained in accordance with the traditional isothermal regime.[102] Furthermore, there was a sharp growth of the viability of the cast composition and the densities of the effective and chemical three-dimensional networks diminished somewhat. In view of the demonstration of the strong influence of the degree of branching of the macromolecules being cross-linked on the properties of the NPU, an accelerated method for its estimation, based on a combination of intrinsic and maximum Newtonian viscosity data, was developed.[103] It has already been mentioned earlier[86] that the density of the nodes of the three-dimensional network formed varies as a function of the urethane-formation temperature. Later the same workers[104] studied in detail the influence of the polycondensation temperature on the gel formation kinetics and the properties of cross-linked polyester urethanes based on the copolymer of tetrahydrofuran with epoxypropane, THMP, and 2,2-bis(4-isocyanatophenyl)hexafluoropropane. It was then found that the amount of the gel fraction and the effective concentration of the chains between the branching nodes are maximum at 27 °C, diminishing with increase in the hardening temperature. The glass point of the NPU obtained depends only slightly on the hardening temperature. The conventional tensile stress is a maximum for a hardening temperature of 50 °C and the relative tensile deformation at rupture increases with increasing gel formation temperature. Somewhat different results have been obtained for another reaction system using a copolymer of tetrahydrofuran with epoxypropane, THMP, BD, and 2,4-TDI. With increase in the synthesis temperature from 30° to 60 °C, the limiting content of the gel fraction rose and the gel point appeared for a lower degree of conversion of the isocyanate groups and tended to the theoretically calculated value. An increase in the density of cross linking, the conventional tensile stress, and the modulus of elasticity accompanied by a decrease in the tensile deformation were also observed. The authors see an explanation of these findings in a decrease in the fraction of the unreacted THMP cross-linking agent with increase in the temperature of the synthesis as a result of the equalisation of its reactivity to that of the tetrahydrofuran–epoxypropane copolymer.

At the same time, the changes in the growth of the macromolecules with increase in the reaction temperature from 70° to 125 °C have also been attributed[105] to the decrease under these conditions in the molecular interaction, which leads to a greater mobility of the macromolecules. There has been a tendency to explain the influence of the synthesis temperature on the structure and relaxation properties of elastic polyurethane networks in terms of purely physical factors.[96,106] The observed anomaly in the elastic properties and in the effective density of the network, consisting in a decrease in these characteristics with decrease in the hardening temperature when the latter is below 80 °C has been attributed to a corresponding increase in the amount of globular formations—the main type of supermolecular structures in the majority of NPU.[96] The size of the globules depends both on the MW of the PE and on the hardening temperature.

Globular formations in NPU have been observed also in other investigations.[12,107,108] The specimens synthesised by the single-stage method sometimes do not exhibit any signs of a globular structure and have better mechanical properties.

The possibility of regulating the dimensions and morphology of the supermolecular PU structures with the aid of the temperature regime has been reported.[109] A low-temperature regime ensured the formation of PU with a monodisperse granular structure.

The conditions in the synthesis of the NPU have a definite effect also on their resistance to thermal degradation.[110] Whereas the NPU synthesised at 40–90 °C decompose with an effective activation energy of 159–169 kJ mol^{-1}, the kinetic parameters of the thermal degradation of the specimens obtained at 30 °C depend on the rate of hardening of the polymer: the higher the rate of urethane formation, the lower the activation energy for thermal degradation. It has been suggested that the decrease in the activation energy for the cross-linked polyesterurethanes can be due to the formation of stressed chemical bonds.

The thermal stability of NPU is determined to a large extent by the chemical nature of the diisocyanate (DI). The NPU based on aromatic dinuclear DI exhibit the greatest thermal stability, while that of the NPU based on aliphatic DI is smallest.[111]

The hardening temperature can influence significantly the mechanical behaviour of NPU on extension. It has been observed[112] that a specimen of cast NPU, hardened at 80 °C, has a higher initial modulus and relative deformation on monoaxial extension compared with the specimen obtained at 140 °C (Fig. 1), which indicates the existence in it of a structure divided into separate regions.

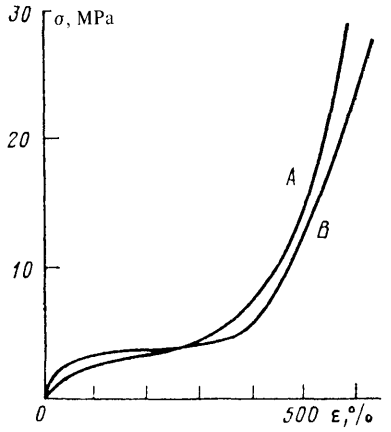

Figure 1. Dependence of the conventional stress σ on the relative elongation ε on monoaxial extension of the NPU: *A*, NPU specimen hardened at 140 °C; *B*, NPU specimen hardened at 80 °C.[112]

The influence of the ratio of the isocyanate and hydroxy-groups and also of the nature of the chain elongating agent on the chemical and physical nodes of the NPU network has been examined.[113] It was found that an increase in the NCO/OH molar ratio from 2.75 to 5.0 in the macrodiisocyanate formation stage leads to an increase in the densities of both the chemical and physical networks, the effective network density being much higher when the chain elongating agent is an aromatic diamine and not a low-molecular-weight diol. The study of the IR absorption spectra of the NPU obtained led the authors to the conclusion that hydrogen bonds exist up to 200 °C. The same view was arrived at also in other studies[114,115] where it was discovered that urethane–urethane hydrogen bonds exist even at 200 °C. On the other hand, Hagawa et al.[116] assume that hydrogen bonds begin to dissociate at ~70 °C. The differences between the results are apparently due to the presence in the NPU of hydrogen bonds of different nature and hence to their different thermal stabilities.

III. Urethane thermoelastoplastics

One of the most interesting types of network polyurethanes is that of thermoelastoplastics (UTEP), sometimes referred to as segmented PU. Their distinctive feature compared with the usual NPU consists in the fact that the three-dimensional network of the UTEP is capable of reversible decomposition on heating. Depending on the nature of the three-dimensional network of the UTEP, it is possible to classify them in the following way. The first type of UTEP is characterised by a linear structure of the macromolecules and the presence of domains, whose appearance is due to microphase separation as a result of the presence in the macrochains of sections differing sharply in flexibility and in the strength of intermolecular interaction. The domains play the role of multifunctional physical cross-links between the macromolecules, which decompose reversibly at an elevated temperature. The presence of a chemical three-dimensional network with allophanate or biuret nodes is characteristic of the second variety of UTEP. The density of the chemical three-dimensional network is such that there is no microphase separation or it is extremely weak. At temperatures of the order of 110–150 °C the allophanate (or biuret) nodes decompose reversibly and the UTEP macromolecules acquire the ability to move relative to one another when a load is applied. The third variety of UTEP is intermediate between the first and second.

The greatest number of structural studies have been devoted to the microphase UTEP. The development of the ideas of Cooper and Tobolsky[117] about the morphology of PU using wide and small angle X-ray diffraction and light scattering methods as well as differential thermal analysis (DTA) has led to the demonstration that the rigid units of the macromolecules, formed when the diisocyanate interacts with a low-molecular-weight diol (and/or diamines), aggregate into individual microphases.[118–121] A microscope study of the segmented PU established[122,123] that the domains have a lamellar structure, whose extent can reach in certain cases 3000–8000 Å but is usually in the range 30–200 Å.[124–127] The rigid units in the domain are extented into a rod-like tactoid form,[128] the length of the rigid block being identical with the width of the domain.[129]

It has been recently observed[130] that flexible polyesterurethane segments of UTEP based on polyoxy(tetramethylene glycol) (POTMG) with a MW of 2000 g mol^{-1}, MDI, and BD are also capable of becoming ordered. They form lamellae ~300 Å high and 2000 Å wide.

Treatment of UTEP with polar solvents leads to the formation of domains with a more ordered structure, which affects the physicomechanical parameters.[131]

Two types of fine structure have been discovered by IR spectroscopy in UTEP based on di(hydroxyethyl)terephthalamide, MDI, and POTMG.[132] A difference in the orientational behaviour of different sections of the rigid segment in the more ordered structure has been established and its inhomogeneity has been postulated.

The conclusion that the structure of the domains is inhomogeneous has been reached also by Vatulev et al.[133] from calculations of the orientation factor for the probable conformation of the diphenylmethaneurethane fragment. The calculated data do not make it possible to reduce the difference in the dichroism of the corresponding bands solely to a difference in the mutual orientation of the urethane and amide carbonyls.

Interpretation of literature data showed[134] that the kinetics of phase separation in segmented PU based on polyethers and polyesters can be represented as the segregation of two types of rigid segments with relaxation times τ_1 and τ_2.

Various physical and chemical processes, influencing greatly the formation of domains, may occur in the reaction system where the complex urethane formation process takes place. The chemical cross-linking of macromolecules lowers their mobility, inhibiting the ordering processes,[132] and thereby prevents microphase separation. The physical three-dimensional network restricts the process involving the segregation of the flexible and rigid blocks in the

NPU to a greater extent than does the chemical network.[135] The cross-linking resulting from the introduction of low-molecular-weight agents diminishes the degree of self-association to a greater extent than the network with the same density formed by a trifunctional polyester with MW $\geqslant$ 5000 g mol^{-1}.[136] The degree of phase separation increases with increasing MW of the PE [137] and, in the case where oligodienediols are used in the reaction instead of PE,[138] is independent of the density of the network.

The question of the influence of hydrogen bonds on the microphase separation process in PU is extremely interesting. Bonart and Morbitger[139] believe that the degree of microphase separation depends on the affinity of the rigid segments for one another and also for the flexible segments. Owing to the affinity of the ester groups of the flexible segments for the urethane groups of the rigid segments, the degree of separation in UTEP of the ester type is systematically lower than in elastomers based on polyethers. Indeed, IR spectroscopic studies[140] have shown that mainly hydrogen bonds of the urethane–flexible segment type with inclusions of small self-associated species (dimers and trimers) exist at the beginning of the microphase separation. Subsequently the microphase separation is accompanied by the redistribution of the hydrogen bonds towards the occurrence of urethane–urethane interactions in the domains. As a consequence of kinetic and viscosity effects, this process is prolonged and it has been shown[141] that the time of attainment of equilibrium in the segregation process depends on the nature of the soft phase and is determined by molecular mobility and not thermodynamic parameters. Thus one must conclude that the greater the degree of hydrogen bonding in the system the less effective is the domain formation in it.[142,143] However, it has been shown[144,145] that the hydrogen bonds between the C=O group and the NH groups of the urea linkage intensify the phase separation effect in PU. All these facts show that the domain formation process is very complex and the ratio of the hydrogen bonds between rigid segments and also between rigid and flexible segments is not the least important factor on which it depends. The conclusion[146] that the flexible segments play the role of a diluent should be regarded not as a rule but rather as an exception to it. The hydrogen bonds between rigid and flexible units are responsible for the appearance of a transitional layer at the interface even in highly dilute systems.

Presumably the hydrogen bonds between rigid segments promote microphase separation, especially since the energy of the hydrogen bonds in polyesterurethaneureas can reach 50–100 kJ mol^{-1},[147] i. e. may be comparable to the energy of the covalent bonds and is the decisive factor in the free energy gain on microphase separation in PU.

In segmented PU with a rigid segment of the glycol diisocyanate type, the energy of the hydrogen bond is appreciably lower and microphase separation can also be caused by the thermodynamic incompatibility between the rigid and flexible segments and not only by the hydrogen bonds. This is supported by the occurrence of microphase separation on passing from PU with the –NHCOO– group to polymers without hydrogen bonds and containing >NCOO– or –COO-groups.[148]

The glass point T_g of UTEP is closely related to the question of microphase separation. A linear dependence of T_g on the concentration of urethane groups in the chain is characteristic of non-thermoplastic PU,[149] whereas for segmented PU containing an appreciable number of polar and primarily urethane or urea groups such a dependence becomes more complex. This is due to the dominant influence on T_g of the overall concentration of urethane groups and the character of their distribution along the macrochain. When all the rigid segments have been segregated into domains and there is no interaction between the rigid and flexible segments, two glass points should be observed theoretically: the glass point of the soft block in the low-temperature region, which is identical with the T_g of the initial polydiol, and the glass point of the rigid segment in the high-temperature region, equal to the T_g of the polymer obtained from the low-molecular-weight diol (and/or diamine) and the diisocyanate. However, the glass point in the low-temperature region is usually higher than for the initial PE, which indicates an increase in the rigidity of the PE macromolecules as a result of the interaction with the rigid segments.[150,151] A formula has been proposed[151] for the calculation of the mole fraction of the hydrogen bonds formed by the rigid and flexible blocks (X_b):

$$(T_{g,pe} - T_{g,pu})/T_{g,pu} = k \cdot X_b(1 - X_b),$$

where $T_{g,pe}$ and $T_{g,pu}$ are the glass points of PE and the soft PU segments and k = 1.2–1.5.

The mobility in the transitional regions formed by the flexible and rigid blocks as a consequence of their limited compatibility can be sometimes observed by the calorimetric method[152] from the heat change in the intermediate temperature range. This intermediate phase is observed especially clearly on the thermomechanical curves.[153] With increase in the MW of the PE, the individual sections of the flexible block emerge from the sphere of action of the domains, which lowers the T_g of the UTEP matrix.[154] An analogous picture is also observed when poly(isobutylene glycol) is used as the flexible block instead of the PE,[155,156] although the influence of the MW of the flexible block on the T_g is not so great.

The theoretical prediction of the temperature T_d of the reversible decomposition of the domain structure is extremely important for the practical utilisation of the UTEP of the first kind. A thermodynamic theory of UTEP with a domain structure has been proposed.[157] The equation for the calculation of the temperature T_d has the following form:

$$1/T_d = -(R/\Delta H_A) \ln [e^{\nu/Z}(\nu - 1)/N_A], \quad (1)$$

where ΔH_A is the enthalpy of the ordering of 1 mol of rigid units (the enthalpy of the phase transition), N_A the mole fraction of the rigid units (the enthalpy of the phase transition), N_A the mole fraction of the rigid units, ν the coordination number of the lattice, and Z the number of rigid and soft units of the macrochain forming the $A-B$ block.

The change in the disordering temperature on passing from the PU whose macrochains consist solely of rigid units (T_d^0) to the PU containing flexible segments is described by the formula

$$1/T_d - 1/T_d^0 = (R/\Delta H_A) \ln N_A. \quad (2)$$

Eqn. (2) is analogous in form to Flory's formula for the equilibrium crystallisation of polymers.

Analysis of Eqn. (1) shows that the decomposition temperature of the domain structure depends to a considerable extent on the chemical microstructure of the UTEP. Thermodynamic theory makes it possible to calculate the minimum number of rigid units Z_A^{min} in the block for which microphase separation is observed. It was found that Z_A^{min} should increase with increase in the MW of the flexible block (Fig. 2).

For the same MW of the flexible block, the increase in the continuous sequence of rigid units should lead to an increase in T_d.

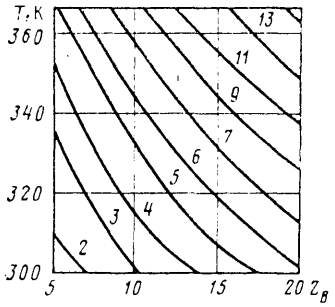

Figure 2. Dependence of Z_A^{min} on the number of units Z_B forming the flexible block and on the ambient temperature; ΔH_A = -9.8 kJ mol^{-1}; ν = 12.[157]

The conclusions of the theory have been confirmed by a series of experimental data. Thus UTEP with a specified chemical microstructure have been synthesised, the number of rigid units in the block varying from unity to three.[158] X-Ray diffraction study of the specimens showed that microphase separation is manifested following the attainment of a definite length of the rigid block. This conclusion agrees with other data,[159,160] which also reveal a 'critical' length of the rigid block, beyond which microphase separation is observed. The study of the dependence of T_d on the MW of POTMG of a urethane thermoelastoplastic based on MDI and BD showed[154] that the decomposition temperature of the domain structure shifts towards higher values with increase in the MW of the polyester. Analogous data have been obtained also in another investigation.[161] An increase in the length of the rigid block for the same MW of the PE entailed an increase in T_d.[162]

The marked dependence of the T_d for UTEP of the first kind on the chemical microstructure of the macrochains requires the development of quantitative methods for its calculation. We have suggested[163] that the theory of Markov chains be used for this purpose. It has been found that the chemical microstructure of the UTEP of both the first and second kinds can be defined fully with the aid of simple expressions involving the mole fractions of units of different types. It was found that the chemical microstructure of the UTEP of the first kind for a degree of conversion close to unity is almost independent of the relative reactivity of the hydroxylated monomers in the reaction with the diisocyanate and is determined by their initial molar ratio (Fig. 3). The microstructure of UTEP with allophanate or biuret branching and network nodes depends to a large extent on the rate constants for the branching process K_b. For a low value of K_b, the UTEP obtained contain virtually no cross-linking nodes and belong to the first type. On the other hand, for K_b comparable to the urethane formation rate constants the PU microstructure belongs to the UTEP of the second kind.

The chemical nature of the diisocyanates has a considerable influence on the properties of the UTEP. The asymmetry of the disposition of the isocyanate groups in 2,4-TDI leads to an amorphous structure of the domains, while symmetrical 2,6-TDI produces a crystalline rigid block.[7] It has been noted that the UTEP with the highest moduli of elasticity and tensile strengths are formed from symmetrical aromatic diisocyanates (MDI, 2,6-TDI, etc.). The symmetry of the structure of the diisocyanate influences also the degree of microphase separation. Koberstein[164] established by the small angle X-ray diffraction and small angle polarised light scattering methods that the PU specimens based on 2,4-TDI exhibit a smaller phase separation than the specimens obtained from MDI. However, the interface itself is more diffuse in the PU based on MDI.

Like the methyl substituent in the ring of the aromatic diisocyanate, the methyl side group in the diol also produces steric hindrance to the aggregation of the rigid segments into domains, which increases the T_g of the polymer.[165] On the other hand, apart from the increase in the fluidity temperature as a consequence of the decomposition of microregions with rigid blocks, the introduction of a polar substituent into the rigid blocks of polyurethanoureylenes

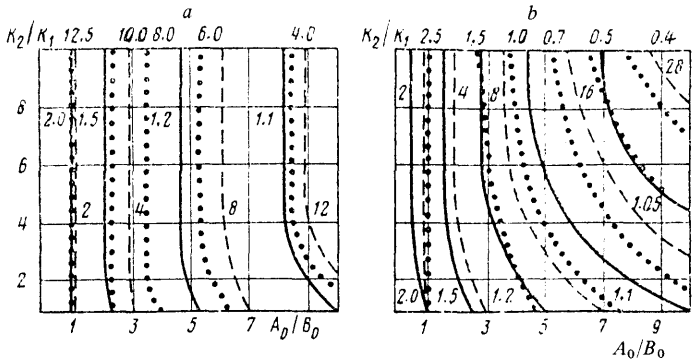

Figure 3. Dependence of the chemical microstructure of the UTEP macromolecules of the first kind $(A_mB_n)_c$ on the degree of conversion of the reaction system [*a*, α = 0.98; *b*, α = 0.90], on the initial molar ratio of the diol (A_0) and the polyester (B_0), and on the ratio of the rate constants for the interaction of the diol (K_2) and the polyester (K_1) with the diisocyanate; dashed line—*m*; continuous line—*n*; circles—*c*.

leads to an anomalous decrease in T_g owing to the manifestation of segmental mobility by the flexible oligoester blocks.[166]

During the past 10–15 years, many relations established previously as regards the influence of the molecular and chemical structures of the urethane formation process components and of the domain formation conditions on various properties of the UTEP have hardly changed significantly. They have all been described superbly in Kercha's monograph[7] and will not be considered in this review.

A series of novel investigations[30,31] devoted to the elucidation of the influence of the incompatibility of certain urethane formation process components with one another and of the rigid segments of different lengths on the structure and morphology of segmented polyurethanes have been published recently.

An interesting idea has been put forward by Teitel'baum et al.[167] According to their view, based on X-ray diffraction and thermomechanical investigations, the "kinetic limitation of the structure formation processes" can occur at a certain stage in the urethane formation process. The degree of perfection of the domain structure depends on the temperature of its formation. It has been shown that the ordering of the domain structure of amorphous polyesterurethanourea may be prolonged when it is heated above the hardening temperature. Analogous results have been obtained in the annealing or limited swelling of segmented polyesterurethanoureas in a series of low-molecular-rate solvents, which leads to further improvement of the microheterogeneous structure,[168] caused, according to the authors, by the orientational ordering of the rigid blocks.

A novel study of the influence of kinetic factors on the formation of the domain structure has been carried out.[169] By keeping PU based on POTMG, MDI, and PD at 190 °C, a specimen with microphase separation was obtained. This was followed by annealing at 120°, 90°, 80°, 60°, and 22 °C. With increase in annealing time, the glass point of the domain structure produced fell linearly with time in terms of semilogarithmic variables to a constant value and to a greater extent the lower the annealing temperature. The authors suggest that at low temperatures short and long sequences of rigid segments are rapidly segregated from the elastic phase, while at high annealing temperatures only the long sequences are segregated.

The significant influence of the number of stages in the synthesis of NPU on their parameters was already noted above. The two-stage synthesis of UTEP from POTMG, MDI, and ethylenediamine in solution with the reactants added in markedly different orders leads to the formation of sharply differing morphological structures.[170] UTEP with 50–80 Å crystalline domains has been obtained by adding ethylenediamine to the POTMG prepolymer and MDI. On the other hand, if ethylenediamine was added initially and then the product of its interaction with MDI was treated with POTMG, then the segmented PU formed had amorphous domains whose size reached 1000–2000 Å. The degree of phase separation was greater when POTMG was added gradually to MDI than for the converse addition.[171]

Studies by small angle X-ray scattering have shown[172] that the two-stage method of synthesis of UTEP from poly(tetramethylene glycol adipate) (PTMGA), MDI, and BD leads to a greater scattering intensity and width of the transition zone in the specimen than under conditions where it is synthesised by the single-stage method. When PTMGA is replaced by POTMG, the differences in the scattering intensity as a function of the methods of synthesis are significantly smaller. The observed behaviour can be explained by the greater degree of interaction of the flexible and rigid segments in the case of the polyester and the broadening of the distribution of the lengths of the rigid segments for the two-stage methods of synthesis of UTEP.

It has been suggested[173] that the UTEP based on POTMG, MDI, and BD, obtained in several stages, contains rigid blocks consisting predominantly of a single rigid diolurethane unit. In the segmented PU synthesised in one stage, the number of units forming the rigid block is greater than unity, which is the reason for the observed differences on deformation.

The physicomechanical properties of UTEP are greatly influenced by the MW and the MWD of the polyesters.[70] Segmented PU have been obtained by the reaction of poly(ethylene butylene glycol adipate) and BD with MDI. Two oligoesters with $\overline{M}_p$ = 1200 and 3000 were chosen for the investigation, a set of oligoesters with degrees of polydispersity ranging from 1.8 to 3.2 corresponding to each number-average molecular weight. The conventional tensile strength σ_t of PU-3000 proved to be greater and its relative elongation smaller than for PU-1200. In a series of PU-1200 specimens, σ_t fell with increase in polydispersity from 49.3 to 33.5 MPa. In contrast to PU-1200, σ_t for PU-3000 remained almost constant when the polydispersity was raised from 1.94 to 2.99. Deformation test calculations for the UTEP obtained using the model proposed by Kazama et al.[174] have led to the conclusion that the effective number of domains diminishes with increase in the polydispersity of the oligoester, which can be explained by the incompatibility of the rigid segment with the low-molecular-weight part of the polyester whose fraction is greater in specimens with a greater dispersity. With increase in dispersity, the boundary layer becomes more diffuse. It has been observed that phase separation takes place most effectively in PU-3000 specimens and improves as the polydispersity of the PU is reduced. Evidently this is the reason why the residual elongation and hysteresis losses are smaller by a factor of 2–3 for PU-3000 compared with PU-1200.

The present review has shown that in most cases it is possible to obtain network polyurethanes with the required set of properties by the specific regulation of the chemical, physical, and technological factors. The greatest advances in the control of the properties of network polyurethanes have been made as regards thermoelastoplastics, which makes this type of polyurethanes most promising in view of the relative ease of their synthesis and their capacity for being worked repeatedly.

The separation of stable isotopes of carbon

E D Oziashvili, A S Egiazarov

ABSTRACT. The present state of work on the separation of carbon isotopes by diffusion, fractional distillation, chemical isotopic exchange, and the selective excitation and dissociation of molecules in electrical discharges or in the field of laser radiation has been examined. The characteristics of new laboratory and industrial assemblies for separating carbon isotopes have been described. Promising directions of study aimed at developing effective technological processes for separating carbon isotopes have been noted.

The bibliography contains 148 references.

I. Introduction

Natural carbon consists of two stable isotopes: ^{13}C (1.11%) and ^{12}C (98.89%). The ^{13}C isotope is now widely used in various branches of science and technology.

The stable isotopes of carbon are used in physics to study nuclear reactions, to determine nuclear constants, to study the inelastic scattering of polarised protons, etc.[1–5] The heavy carbon isotope ^{13}C is particularly important for investigating the mechanisms of processes taking place in living organisms.

The development of NMR spectrometers and methods for determining the position of a ^{13}C tracer in complex organic compounds and even in biological materials without decomposing them has provided a powerful stimulus for devising effective methods for separating the stable isotopes of carbon and synthesising a wide range of isotopically substituted compounds, and for the development of different forms of ^{13}C NMR spectroscopy. It has made it possible to obtain rapidly valuable information on the structure and dynamics of the structural components and on the nature of the intracellular medium, the primary and secondary exchange paths in a culture medium, etc.[6]

A promising sphere of application of stable isotopes of carbon is in the identification of various types of functional breakdown in the organism: liver deficiency, breakdown of exchange processes in the liver, diabetes, oxygen starvation of the heart muscle, lung deficiency, etc. A large number of papers have been published on the diagnosis of metabolic breakdown due to the dysfunction of the endocrine and other organs, using compounds labelled with ^{13}C.[7–12] In the USA, 2.5 kg of the ^{13}C isotope are used annually for medical research and diagnosis alone.[6]

The wide interest in the use of stable isotopes to study processes in living organisms is indicated by the large number of published papers on this topic (see for example the bibliography in Ref. 13 and the published proceedings of special symposia and conferences).[6,14–17]

The extensive use of carbon isotopes in turn is stimulating the further development of methods and technology for their separation. Extensive material has accumulated on the separation of carbon isotopes by traditional methods such as the chemical exchange, fractional distillation, and diffusion of gaseous compounds of carbon, etc. In the last ten years, studies of the possible separation of carbon isotopes using lasers have shown that this method is highly effective for large-scale production.

II. Separation by diffusion

Methods for separating carbon isotopes by diffusion include diffusion through a porous membrane and diffusion in a stream of vapour.

The separation of isotopes using porous partitions results from the fact that the relative frequency with which the molecules of the components being separated enter the small openings is inversely proportional to the square root of their molecular weight. Since the separation effect of a single diffusion step is small, gas-diffusion cascades are usually employed, as illustrated schematically in Fig. 1. Part of the stream being separated, entering the gas-diffusion stage, passes through the partition, while the other part (the heavy fraction) does not. The heavy gas fraction, with the higher molecular weight, is taken to the next stage in the direction of the tail of the cascade. The light fraction, after moving through the partition into the higher-pressure region, is passed by the compressor to the next stage in the direction of the head of the cascade.[18]

Carbon-13 enrichment by a factor of 6.6 has been achieved by diffusion through a porous membrane in a cascade of 35 single stages.[19] The material used in the diffusion cascade was methane, whose molecules, containing different carbon isotopes, have a greater relative difference in mass than any other gaseous compound of carbon. Later,[20] a heavy methane fraction containing about 16% $^{13}CH_4$† was obtained in the assembly after operation for 12 h.

The porous partition can be replaced by a stream of mercury vapour, through which diffusion takes place.[21–23] The separate stages of this cascade are mercury diffusion pumps, which move the lighter component slightly faster than the heavy component. An advantage of this cascade is the use of the diffusion pump simultaneously as the generator of the original mixture, the assembly

† Here and subsequently the concentrations of the isotopes are given in at. %.

for the fractionation, and the pump for moving the richer and depleted fractions from one stage to another.

Separating pumps with an output of 1 cm^3 per day at a pressure of 266.6 Pa gave an enrichment in $^{13}CH_4$ of up to 12.4% relative to the natural concentration.[23] An experimental assembly consisting of 51 pumps has also been described.[24-26] The starting material was methane with the natural concentration of ^{13}C. At a pressure of 213–266 Pa after operation for 30 h at a rate of 300 cm^3 per day, a heavy methane fraction containing 30–32% $^{13}CH_4$ was obtained.

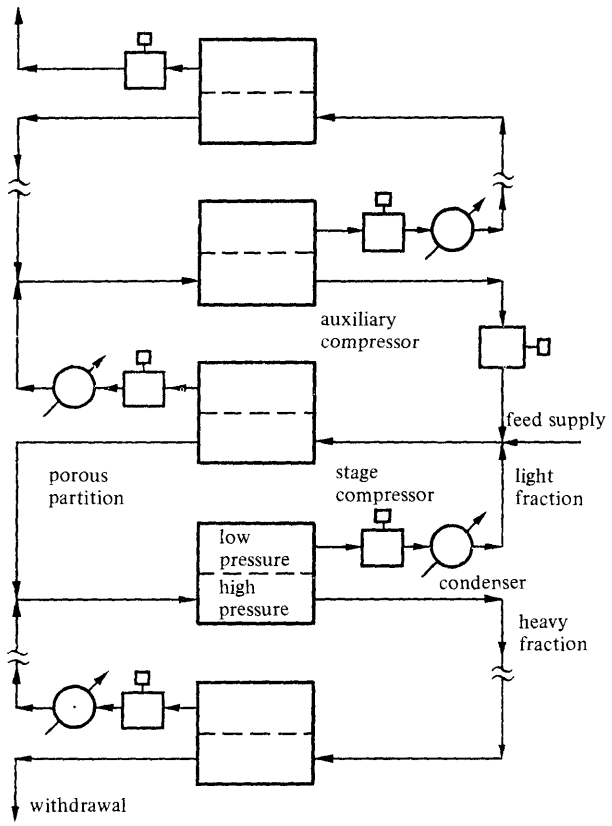

Figure 1. Schematic diagram of a gas-diffusion cascade.

The main disadvantage of the first diffusion cascade assemblies was their low output, which made it possible to obtain only tracer quantities of highly-enriched isotope fractions.

The problem of developing highly efficient assemblies with a high specific productivity was solved by using high pressures (1333 Pa).[26,27] ^{13}C concentrations of 88% and 70.2% were obtained at take-off rates of 30 cm^3 per day and 200 cm^3 per day respectively in a cascade consisting of 70 separating pumps. The starting material was methane with a ^{13}C concentration of 2.7%. The average separation coefficient in one stage was 1.086, that is it was slightly lower than that of analogous assemblies operating at pressures of 133–266 Pa (usually 1.1).

A separating column using xylene vapour as auxiliary gas has been described.[28] On this column the enrichment in ^{13}C reached 2%. Subsequently, the combination of 10 diffusion columns of this type in a cascade gave an enrichment in $^{13}CH_4$ of up to 12% with an output of 500 cm^3 per day.[29]

Since the development of the first thermal diffusion column,[30] this method has been used fairly frequently to enrich natural methane for preparative purposes. The start of systematic studies in this field was probably made in Ref. 31, which gave the theoretical principles of the thermal diffusion method for the separation of a $^{12}CH_4-^{13}CH_4$ mixture. The essential feature of the thermal diffusion phenomenon is that when a temperature gradient is created in a mixture of several components, a concentration gradient is also produced.

The Clusius–Dickel thermal diffusion column consists of two vertically arranged surfaces, the space between which contains the mixture being separated. The temperatures of each surface are constant but different.[31] The temperature difference produces a concentration gradient in the horizontal direction. Simultaneously, as a result of the density difference in the mixture being separated, convective movement is produced close to the cold and hot surfaces; the less extensively heated stream of liquid or gas moves downwards, and the more extensively heated stream moves upwards, as shown schematically in Fig. 2. As a result, a counter-flow movement is established in the column, leading to repeated multiplication of the separation effect and to a change in the concentrations of the components of the mixture along the height of the column.

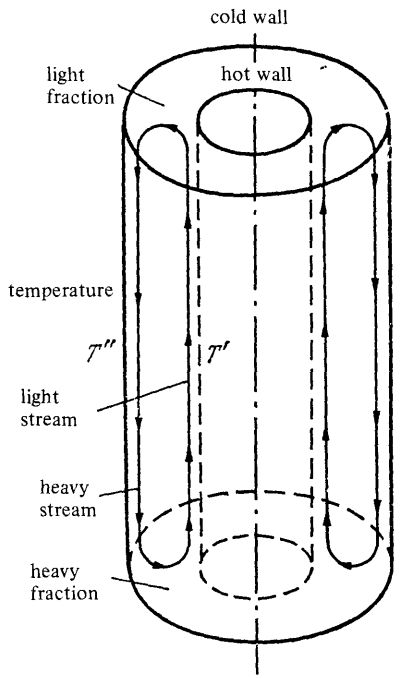

Figure 2. Diagram of a Clusius–Dickel thermal-diffusion column.

The principal gaseous compounds of carbon used to concentrate the ^{13}C isotope by thermal diffusion are methane and carbon monoxide (mainly the former).[32-42] The separation is carried out in thermal-diffusion columns with different dimensions at pressures from several Pa to atmospheric, and a temperature difference between the central tube (filament) and the outer wall of 573–673 K.

A high concentration of ^{13}C in methane (99.8%) was achieved[34] in 2 weeks using a cascade consisting of nine columns with a total length of 24 m. The starting material was methane previously enriched in ^{13}C to 55–73%.

In thermal diffusion processes, the purity of the working material is particularly important. In the design of a ten-stage cascade in Ref. 42, therefore, provision was made for the continuous removal of impurities from the last stage; the concentration of impurities was determined from the thermal conductivity. After operation for 300 d, the cascade gave methane with a ^{13}C concentration of 96%.

In Ref.42 it was proposed that carbon monoxide be enriched in the ^{13}C isotope and then hydrogenated with electrolytic hydrogen with a deuterium concentration lower than 5×10^{-5} % to eliminate the accumulation with the $^{13}CH_4$ molecules of the CH_3D impurity present at a concentration of 0.06% in natural methane.[43] An assembly consisting of eight glass columns with internal diameter 12.1 mm and length 2.85 m, connected in series, has been described.[44] The starting material was $^{13}CH_4$ containing 55–70% ^{13}C, obtained from enriched carbon monoxide. The process was carried out at a pressure of 94.5 kPa and a temperature of 673 K, and gave several litres of methane containing 99–99.8% $^{13}CH_4$. This complex separation scheme uses a large amount of energy, however, and is not justified economically.

In thermal diffusion, the separation factor depends on three main features: the temperature difference between the hot and cold walls, the molecular masses of the components of the gas being separated, and the properties of the molecules themselves. Methane has the highest relative differences in the masses of the isotopic molecules of all known gaseous compounds of carbon, but it is less thermally stable than carbon monoxide, and decomposes appreciably even at 700 °C. Thus the replacement of methane by carbon monoxide and hence an increase in the temperature difference should increase the efficiency of the thermal-diffusion column. Carbon monoxide was apparently first used instead of methane in thermal diffusion in Ref. 45. A column of length 5 mm and diameter 12 mm gave a separation factor of 5.85 at an optimum CO pressure of 71 581 Pa. Carbon monoxide was also used as the starting material in Refs. 46 and 47.

Comparison of the results obtained by the thermal diffusion of methane and carbon monoxide showed that the use of CO as the working gas makes it possible to decrease the volume of the assembly, but the consumption of electrical energy is appreciably higher.[47] Because of this the toxicity of CO, methane has definite advantages over carbon monoxide as the working gas. This probably explains why methane is used in the great majority of cases. Thermal diffusion has also been used to concentrate the ^{14}C isotope.[48–50]

Calculations of the cost of production[51,52] by thermal diffusion and the diffusion of methane through a porous partition showed that these methods are economically profitable only at a level of production of 100–200 g $^{13}CH_4$ with a concentration up to 60%.

Disadvantages of all methods for separating isotopes by diffusion are their low efficiency, which is related to the need to work at a low gas pressure, and the large amount of energy required by the process. According to Ref. 31, the power required to produce CH_4 enriched to 20% in the ^{13}C isotope by thermal diffusion is 6700 kW. h g^{-1} ^{13}C. It is therefore appropriate to use diffusion methods only in combined separation processes in the final stages of the concentration to obtain ^{13}C with an enrichment > 99%.

III. Fractional distillation

The separation of isotopes by fractional distillation is based on the isotopic effects appearing as a difference in the saturated vapour pressures of the components when the liquid–vapour equilibrium is

reached. The magnitude of the elementary separation factor α in fractional distillation (α is the ratio of the quantities of the isotopes present in the two phases in equilibrium) is determined chiefly by the properties of the isotopic molecules and by the nature of their interaction in the condensed phase. The lack of a well developed theory of the liquid state creates certain difficulties, however, in the selection of compounds suitable for separating isotopes by this method. Analysis of published data shows that the selection of carbon compounds giving acceptable values of α is restricted to the first members of the homologous series of saturated aliphatic hydrocarbons and carbon monoxide.[53-59] Table 1 gives the enrichment factors ($\varepsilon = \alpha - 1$) for carbon isotopes at the vapour pressure equilibrium. These data show that of the compounds studied, only methane and carbon monoxide are promising for separating carbon isotopes by fractional distillation. The factors α have been determined by Rayleigh distillation with equilibrium evaporation of the compounds C_2H_6, C_2H_4, CH_3OH, C_3H_8O, CH_3Cl, CCl_4, and C_6H_6.[60-65] The separation factors for methane, found by Rayleigh distillation, agree with one another, but their absolute values are greater than the values of α obtained by the differential method. These discrepancies may be due to the insufficient purity of the specimens used to determine α in Refs. 53 and 56.

The separation of carbon isotopes by the fractional distillation of carbon monoxide on a glass laboratory column with internal diameter 17 mm and height of the packed layer 134 cm at a pressure of 66 650 Pa and a reflux density of 7 $cm^3(cm.\ min)^{-1}$ has been studied.[58] The packing consisted of stainless steel spirals with dimensions 1.5 × 2 mm, prepared from wire with a diameter of 0.2 mm. A steady state was established in about 5 h. The lowest value of the height equivalent to a theoretical plate (HETP) was 4 cm. The HETP on a metal column with internal diameter 17 mm and height 370 cm with the same packing as in the experiments on the glass column was 2.7 cm. In the opinion of the authors cited,[58] the reason for this difference in the HETP values is that the process in the glass column was insufficiently adiabatic.

The results of the experiments on the metal column[56] agree with experimental data[66] on the separation of carbon isotopes on a column with the same geometric dimensions and the same packing. In Ref. 66 the steady state was established in 50 h, and the maximum separation factor (overall separation factor) was 3.67. The height equivalent to a theoretical plate, calculated from this value and $\alpha = 1.01$, is 2.82 cm. Experiments were also carried out on a 12-metre column consisting of an exhaustion section with length 2 m and diameter 25 mm and a lower concentration section. The concentration section consisted of two parts: a lower part with length 5 m and internal diameter 17 mm, and an upper part with length 5 m and diameter 25 mm. All the sections of the column were made of stainless steel, and the packing consisted of triangular spirals with dimensions 1.5 × 2 mm, prepared from wire with diameter 0.2 mm. For a separation factor of 67.8, achieved in 52 days, an approximate estimation of the HETP gave the value 2.2 cm. About 82 g of product with a ^{13}C concentration of 10–20% was obtained.

A three-column cascade with a total length of 36 m, with an output of 0.13 mol per day, for obtaining carbon monoxide with a ^{13}C concentration of 60% has been described.[67-69] Prolonged use of the experimental assembly revealed a number of unsatisfactory features, mainly in the system used to purify the original carbon monoxide. After purification, the concentration of CO_2 in the CO supply stream was only 0.003%, but even this amount gradually led to contamination of the packed part of the assembly. Experiments showed that for this assembly the optimum pressure was 86.6 kPa.

The parameters of a pilot plant for obtaining ^{13}C were also given in Ref. 69. The separation part consisted of a three-section cascade with a total length of 74 m and an output of 8.3 g ^{13}C per day. This cascade gave a ^{13}C enrichment of 90–92%. A period of use confirmed the high productivity and reliability of the assembly, resulting from the use of small-diameter columns connected in parallel in the first section and the positioning of the column of the third section among the columns of the first section (Fig. 3).

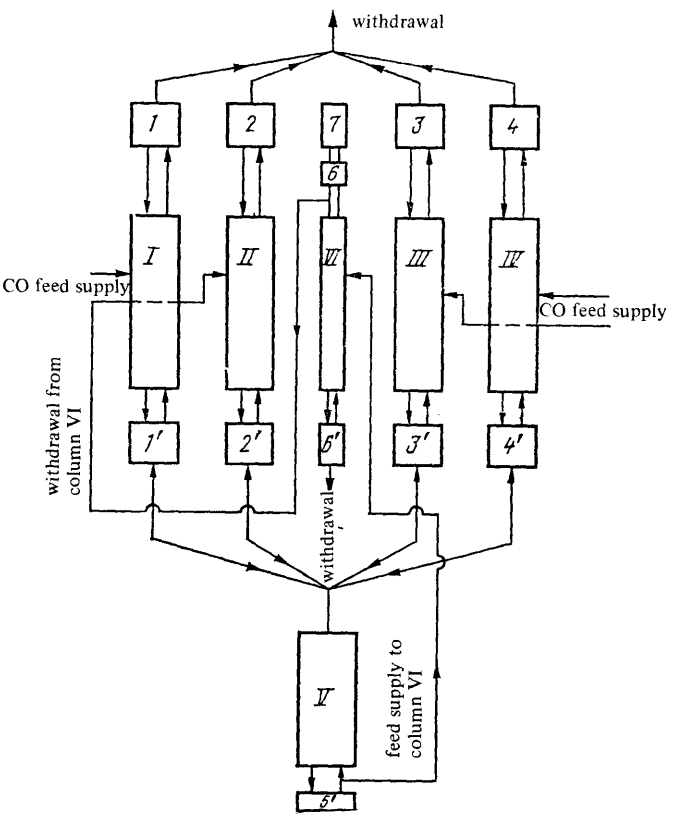

Figure 3. Schematic diagram of a pilot-plant assembly for obtaining the ^{13}C isotope by the fractional distillation of carbon monoxide: *I, II, III, IV*, columns of the first section; *1, 2, 3, 4*, condensers of the columns of the first section; *1', 2', 3', 4'*, evaporators of the columns of the first section; *V*, column of the second section; *5'*, evaporator of the column of the second section; *VI*, column of the third section; *6*, main condenser of the third section; *6'*, evaporator of the third section; *7*, intermediate condenser of the third section.

It is difficult to obtain high concentrations of ^{13}C by the fractional distillation of CO, because of the presence of the heavy oxygen isotope ^{18}O in the carbon monoxide.[67-69] Natural carbon monoxide is a $^{12}C^{16}O + {}^{13}C^{16}O + {}^{12}C^{18}O$ mixture. According to Ref. 56, the difference between the partial vapour pressures of

$^{12}C^{18}O$ and $^{13}C^{18}O$ is so small (α = 1.002 at 74.4 K) that fractional distillation in a column leads to the practical separation of only $^{12}C^{16}O$ from the binary $^{12}C^{18}O$ + $^{13}C^{16}O$ mixture. It can readily be shown that if it is assumed that the pressures of $^{12}C^{18}O$ and $^{13}C^{16}O$ are equal, the maximum enrichment in ^{13}C cannot exceed 95%. The further concentration of ^{13}C by this method requires an additional column. Thus on an industrial assembly with an annual output of 1.5 kg ^{13}C, further enrichment of the product from 95% to 97.7% was achieved by the fractional distillation of the enriched $^{12}C^{18}O$ + $^{13}C^{16}O$ mixture in an additional column.[70] It is possible to carry out the catalytic exchange reaction[56,71]

$$^{13}C^{16}O + {}^{12}C^{18}O \rightleftarrows {}^{13}C^{18}O + {}^{12}C^{16}O. \quad (1)$$

Up to the present, however, low-temperature catalysts for effective homomolecular exchange according to reaction (1) have not been found, so that on existing assemblies the ^{13}C concentration does not exceed 95%. Of these assemblies, mention must be made of a cascade operating in the Los Alamos research laboratory (USA), consisting of twelve parallel columns with diameter 2.54 cm and length 12 m (first stage), four parallel columns with diameter 2.54 cm and height 6.1 m (second stage), and one column with diameter 2.54 cm and length 24.4 m (third stage). The HETP for an input of 0.09 mol min^{-1} is 2.5 cm. The assembly produces 10.2 g of 92.4% ^{13}C per day.[51]

In Ref. 58, methane was used to separate carbon isotopes by fractional distillation. The experiments were carried out on the same column as the fractional distillation of CO, at a working pressure of 34 658 Pa. The steady state was reached in 7.5 h, and the HETP, calculated from α = 1.0108 and the maximum separation factor of 1.34, was 4.9 cm.

A comparative estimation of the efficiency of the fractional distillation of methane and carbon monoxide, carried out in Ref. 58 using the data from Ref. 46, showed that the use of methane to obtain ^{13}C with a concentration of 60–70% is economically less favourable. The applicability of this conclusion to the range of higher ^{13}C concentrations apparently requires special study. It may be noted that the use of methane requires the use of condensers of more complicated design, since the normal boiling point of liquid nitrogen is much lower than the freezing point of methane.

IV. Chemical isotopic exchange

Chemical isotopic exchange, proposed in the mid-nineteen-thirties,[72] is an effective method for separating the isotopes of light elements. It occupies a unique position, on the one hand because of the wide variety of reactions and compounds which can be used to separate isotopes and on the other hand because it is comparatively inexpensive. The production of isotopes by chemical exchange is based on the use of thermodynamically reversible separation processes in two-phase systems. In these systems there are deviations from the equally-probable distribution of the isotopes between the phases present in thermodynamic equilibrium. The isotopic effect is characterised quantitatively by the elementary separation factor α.

1. The bicarbonate method

One of the first reactions used to separate carbon isotopes was the exchange reaction between carbon dioxide and aqueous solutions of alkali metal bicarbonates:[73]

$$^{13}CO_2(\text{gas}) + H^{12}CO_3^-(\text{liquid}) \rightleftarrows {}^{12}CO_2(\text{gas}) + H^{13}CO_3^-(\text{liquid}). \quad (2)$$

At equilibrium, however, aqueous solutions of bicarbonates contain not only HCO_3^- ions but also carbonate ions and molecules of dissolved CO_2, so that the main exchange reaction (2) is accompanied by exchange reactions between the CO_2 in the gas phase and the CO_2 dissolved in the liquid phase, and also between CO_2 and carbonate ions.[74,75] At 298 K the separation factors for the carbon isotopes in these reactions are 1.013, 1.0008, and 1.0077 respectively.[75] The overall effective separation factor under different specific conditions depends on the mole fraction of each compound in the solution, and according to Ref. 73 is 1.012 at 298 K and a pressure P_{CO_2} = 101 308 Pa. With increase in temperature to 313 K, α decreases to 1.008.[75]

Despite the comparatively high separation factor and the simplicity of stream reversal, which is brought about by decomposing the bicarbonate with sulphuric acid, the bicarbonate method suffers from a serious disadvantage, namely the low rate of isotopic exchange.[73,76,77]

The influence of the material and geometric form of the packing on the efficiency of a column using the bicarbonate method has been studied.[78] At 293 K and a rate of supply of 20% potassium bicarbonate solution of 4 ml min^{-1}, in a two-metre column with diameter 16 mm filled with an aluminosilicate catalyst, the HETP was 53 cm. This agrees with the value obtained in another study[47] using a similar catalyst.

The addition to the aqueous potassium bicarbonate solution of acetone, in which the solubility of carbon dioxide is 7 times that in water, increases the separation of the carbon isotopes.[75,79,80] The optimum concentration of acetone in water is 5 vol.%.

The bicarbonate method uses large quantities of reagents for stream reversal. A method of separation using the bicarbonate of 2-aminoethanol instead of alkali metal bicarbonates does not suffer from this disadvantage.[81] Stream reversal in this case is achieved by simple thermal decomposition of the bicarbonate of 2-aminoethanol to the original CO_2 and 2-aminoethanol, and the 2-aminoethanol solution, saturated with CO_2 in an absorber, is returned to the cycle. This eliminates almost completely the irreversible consumption of reagents, and the expenditure on stream reversal reduces mainly to the cost of electrical energy. The effective carbon isotope separation factor when the bicarbonate of 2-aminoethanol is used is approximately the same as for isotopic exchange between CO_2 and alkali metal carbonates.[82]

The influence of temperature and the concentrations of the bicarbonate of 2-aminoethanol and the added catalyst carbonic anhydrase on the efficiency of the column was studied.[83] The experiments were carried out on a column with length 6 m and internal diameter 15 mm. The packing consisted of activated carbon and ShCM grade silica gel with a particle size of 2.5–3.5 mm. Neither silica gel nor activated carbon catalyses isotopic exchange between the bicarbonate of 2-aminoethanol and CO_2. With increase in temperature from 5 °C to 50 °C, the degree of separation passes through a maximum at 20 °C. The optimum 2-aminoethanol concentration is 0.9–1.0 M. The HETP decreases by a factor of 1.3–1.5 when an alcohol–chloroform specimen of carbonic anhydrase (1–10%) is added, and is 65–80 cm, depending on the catalyst concentration.

The bicarbonate method for separating carbon isotopes can compete with the fractional distillation of CO only when catalysts capable of giving comparable HETP are found.

2. The carbamate method

In the early nineteen-sixties it was established[84] that the salt-like carbamates formed by the reaction of secondary amines with CO_2 in anhydrous organic solvents may be promising for separating carbon isotopes by the isotopic exchange reaction:

$$^{13}CO_2(gas) + R_2N^{12}CO_2^-(liquid) \rightleftarrows R_2N^{13}CO_2^-(liquid) + {}^{12}CO_2(gas). \quad (3)$$

The product of the reaction of the amine with CO_2 is thermally unstable, so that stream reversal in the carbamate system is achieved by simple heating, and the separation can be carried out using the simple scheme shown in Fig. 4.

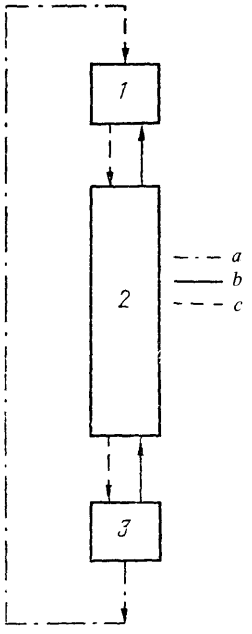

Figure 4. Schematic diagram of the separation of carbon isotopes by the carbamate method: *1*, absorber, *2*, exchange column, *3*, desorber, *a*, stream of complex former (amine + solvent), *b*, stream of gas (CO_2), *c*, stream of complex (amine + solvent + CO_2).

The presence of moisture in the solvent can produce a radical change in the nature of the product obtained by the reaction of CO_2 with a secondary amine. The reactions taking place in this case are probably accompanied by the reaction of water to give carbonates.

A column with length 196 cm and internal diameter 10 mm, containing stainless steel Helipak packing, was used to determine the degree of separation of carbon isotopes under identical conditions (reflux density, amine concentration, temperature) using fifteen different amine solutions in methanol.[85] The degree of separation of ^{13}C decreased in the order isobutylamine > 2-aminoethanol > n-butylamine. The optimum concentration of the solution of n-butylamine in methanol is 1–1.2 M, and the optimum temperature 298 K. Further increase in the n-butylamine concentration is inappropriate, because of the appreciable deterioration in mass transfer as a result of the increase in the viscosity of the solution.

The hydrodynamic characteristics of the system were improved using a whole series of non-aqueous solvents[86,87] having a lower viscosity and greater solvent power for carbamate, compared with methanol. The best of these was triethylamine (TEA). Of the amines, di-n-butylamine (n-DBA) has the most favourable characteristics. In the Mound Laboratories (USA), data obtained for solutions of n-DBA in TEA were used to construct and operate a five-stage cascade in which CO_2, previously enriched to 20% in ^{13}C, gave 4 g ^{13}C per day with 90% enrichment.[88] The incomplete stream reversal when TEA is used as solvent lowers considerably the efficiency of the separation of the isotopes in the carbamate system.[51]

Pyridine and triethylamine have been used as solvents, and dibutylamine as the amine.[89] Experiments showed that solutions of dibutylamine in triethylamine with a water concentration $\geqslant 0.1\%$ are unsuitable for the separation, because of the formation of an insoluble precipitate in the desorber and in the column. On a column with diameter 2.5 cm and length 100 cm, the greatest separation factor (1.77) was achieved using a 1 M solution of n-DBA in TEA. With increase in the molarity of the solution, the separation deteriorated, due to the increase in the viscosity of the liquid phase. Triethylamine has a number of disadvantages as solvent: 1) the high saturated vapour pressure of TEA under the working conditions in a prolonged separation process leads to extensive loss of solvent and requires the use of special assemblies to keep the composition of the liquid phase constant; 2) preliminary drying of the solvent is essential; and 3) quantitative stream reversal in the desorber cannot be achieved when TEA is used.

A search has therefore been carried out for a more effective solvent which would satisfy the following requirements: low viscosity and boiling point; good solvent power for carbamate; low surface tension; chemical inertness and thermal stability; comparatively low vapour pressure; low physical solvent power for CO_2 and low solvent power for water; low cost; and availability. From these properties, octane was selected as solvent for di-n-butylamine.[89] On a column with length 100 cm and diameter 2.5 cm, using a 1 M solution of n-DBA in octane, the separation factor was 1.93, which is slightly greater than that for triethylamine, for which the separation factor was 1.77. Moreover, when octane was used, the time taken for the assembly to reach the steady state was reduced by 30%. The dependence of the degree of separation on the reflux density for the 2 M n-DBA–octane–CO_2 system was studied on a large-scale metallic laboratory assembly (length of packed column 250 cm, diameter 56 mm). The highest separation factor, 2.4, was achieved at a reflux density of 1 ml cm^{-2} min^{-1}.

Table 2. Influence of temperature on the value of α and the degree of separation of carbon isotopes in the system formed by CO_2 and a solution of n-DBA in octane.[90]

Temperature, K	α	Reflux density ml cm^{-2} min^{-1}	Degree of ^{13}C separation	Time to reach steady state, h	HETP, cm
298	1.0100±0.0003	0.840	1.67	48	1.94
318	1.0075±0.0004	1.070	1.60	30	1.62
333	1.0060±0.0003	1.170	1.46	25	1.61

When the separation was carried out for 60 d using the same working mixture, the concentration of moisture in the liquid phase did not increase, and remained at 0.03%. Thermal phase reversal at

the lower end of the assembly was achieved by boiling the liquid phase at 131 °C. The loss of CO_2 did not exceed 5 μg ml^{-1}.

The influence of temperature on the separation of carbon isotopes using the system formed by CO_2 with a solution of n-DBA in octane was studied on a column with diameter 2.5 cm and length 100 cm at different reflux densities calculated to give the same carbon dioxide flux at all temperatures.[90] Table 2 shows that α decreases regularly with increase in temperature. Increase in temperature above 318 K is not appropriate. Because of the appreciable dependence of the HETP on temperature in the range 298–318 K, the decrease in α is compensated by the decrease in the HETP and by the decrease in the accumulation time of the isotopic product.

The results of published studies[89,90] were used to calculate versions of a cascade assembly for obtaining highly concentrated ^{13}C. To obtain a ^{13}C concentration of 99% with α = 1.01, approximately 1400 theoretical separation stages are required. It was found most suitable to use a four-column cascade, with minimum total volume and minimum time to reach the steady state (about 53 d). It was shown that for a calculated assembly operation time of 300 days per year, half of the expenditure is for the starting materials (amine and solvent).

3. The cyanide method

The exchange between hydrogen cyanide and alkali metal cyanide solutions is one of the most effective methods for separating carbon isotopes. The concentration of ^{13}C by the reaction

$$H^{12}CN(gas) + Na^{13}CN(liquid) \rightleftarrows H^{13}CN(gas) + Na^{12}CN(liquid) \quad (4)$$

takes place in the gas phase, and the calculated separation factor α is 1.026–1.030 at 298 K.[91–93] A slightly higher value of α (1.035) is obtained for the separation of ^{12}C and ^{14}C.[94] The effective separation factor is lowered to 1.013[91] as a result of exchange between gaseous HCN and hydrogen cyanide absorbed by the NaCN solution. For this last reaction, α = 0.995.

A two-stage cascade with a total length of 19.5 m gave 20 g of carbon containing 25% ^{13}C.[93] The column diameter was 22 mm in stage I, and 10 mm in stage II. The working pressure in the lower part of the column was 166 652 Pa. The column of stage I was supplied with sodium cyanide formed by neutralising the ascending stream of HCN with NaOH solution in the absorber.

A cascade consisting of two columns was used to study the influence of pressure and the NaCN concentration on the efficiency of the separation.[95] The diameters of the columns of stages I and II were 24.8 mm and 14.4 mm respectively, and the height of each column was 2.5 m. The optimum concentration of the solution was 4.5 M, and the optimum pressure 166 625 Pa. Later,[96] the data from Ref. 95 were used to construct a four-stage cascade with a total length of 13 m, with packing consisting of Fenske glass spirals with diameter 4 mm. The output of the cascade was 0.16 mol ^{13}C per day.

The exchange reactions taking place in a liquid–liquid system between cyanohydrins in the organic phase and aqueous potassium cyanide solutions have also been studied:[97]

$$R_2C(OH)^{12}CN + K^{13}CN \rightleftarrows R_2C(OH)^{13}CN + K^{12}CN. \quad (5)$$

The high lability of the cyanide groups of the cyanohydrins leads not only to high separation factors (1.035–1.040) but also to a fairly high rate of isotopic exchange.

In addition to its advantages (a high separation factor and medium HETP), the cyanide method also has a number of significant disadvantages, primarily the extreme toxicity and the high cost of cyanides, and their tendency to polymerise with blockage of the packing. Moreover, the need to work at a reduced pressure reduces the carrying power of the column and hence its productivity. Changing to columns with a large diameter leads to a sharp increase in the HETP. These disadvantages make the process unsuitable for obtaining ^{13}C on the industrial scale.

4. Ion exchange and other methods of separation

The first publications on the separation of isotopes on ion exchange resins appeared in the mid-nineteen-fifties,[98] when a carbon isotopic effect was detected in the separation of ^{14}C-labelled amino-acids on cation exchange resins. The effect depended significantly on the position of the tracer in the aminoacid molecule. The presence of the ^{14}C isotope in a position at a distance from the ionogenic groups had no influence on the ion exchange properties of the acid.

In the separation of carbon isotopes using hydrogen cyanide, a separation factor close to 1.01 was obtained.[99] The process was carried out by depositing a band of cyanide ions on Dowex-2 anion exchange resin and displacing the band with dilute solutions of hydrochloric and acetic acids. No further studies were carried out, however, because of the high volatility and toxicity of hydrogen cyanide.

Subsequently, carbon isotopes were separated using formate ions,[100,101] deposited on the strongly basic Dowex-2 resin in the acetate form. When the band was displaced with hydrochloric acid solution, its leading edge was enriched in the heavy isotope. With increase in temperature from 279 K to 308 K, α decreased from 1.0062 to 1.0032.

Analysis of the experimental data showed that the use of ion exchange resins with a very high degree of cross-linking does not always lead to an increase in the efficiency of the separation, since there is a simultaneous increase in the dehydrating action of the resin on the ions. Moreover, increase in the degree of cross-linking (the concentration of divinylbenzene in the resin) may lead to a deterioration in mass transfer. In the separation of sulphur isotopes in a band of bisulphite ions in a column of Dowex-2 × 10 anion exchange resin in the acetate form, carbon isotopes were also separated at the boundary between the bisulphite and acetate ions.[102] The heavy ^{13}C isotope was concentrated in the solution. The separation factor α was approximately 1.0016.

A combined method for the simultaneous separation of sulphur and carbon isotopes on Wofatit-150 [?Ambeslite IR-20 (Ed. of Translation)] ion exchange resins with displacement of CN^- and HSO_3^- with sulphuric acid solution has been described .[103,104]

The use of ion exchange processes to separate carbon isotopes has not yet gone beyond laboratory studies. Nevertheless, in a number of cases, ion exchange can probably compete with traditional methods, particularly for isotopes of elements of medium mass, whose separation by chemical exchange or fractional distillation is difficult. The most promising methods involve ion exchange using counter-current movement of the phases analogous to that in the two-phase separation processes of fractional distillation and chemical isotopic exchange.

Of other chemical exchange systems used to separate carbon isotopes, mention may be made of systems based on carbonyl complexes. The complexes of CO with Ag_2SO_4 (in concentrated H_2SO_4), CuCl (in concentrated HCl), $CuSO_4$ (in concentrated H_2SO_4), di-n-propylamine, $Cu_2Cl_2.8NH_4Cl$, etc. have been tested.[105] The most suitable for the exchange reaction was found to be the $Cu_2(CO)Cl_2.8NH_4Cl-CO$ system, for which at 20 °C α = 1.016 and the half-exchange time is ~5 s. The stream reversal in the desorber

at 140 °C was quantitative (>99.99%).[105] A characteristic feature of the liquid phase of this system is the formation, on contact with atmospheric oxygen, of a sparingly soluble precipitate which blocks the packing in the column and disrupts its operating conditions. Technological difficulties probably represent the main obstacle to the industrial application of this system.

The simultaneous separation of carbon and sulphur isotopes by chemical exchange between carbon disulphide and potassium xanthate ($S=C<^{OR}_{SK}$) [106,107] has not found practical application, probably because of its high cost.

V. Isotopic effects in electrical discharges

In many countries in recent years, considerable attention has been paid to methods for separating stable isotopes based on the selective excitation of atoms and molecules in electrical discharges.[108,109]

Isotopic effects in the synthesis and dissociation of molecules in gas discharges had been observed even earlier, but they were slight. Thus it was shown[110–112] that in the dissociation of carbon dioxide in a silent discharge, the heavy ^{13}C isotopes of carbon accumulate in the undissociated CO_2 molecules. The degree of separation is independent of the power of the discharge and the rate of flow and pressure of the gas in the discharge tube, and its average value is 1.028 ± 0.008. A study of the redistribution of the isotopes in the dissociation of carbon dioxide in a glow discharge showed that, as in the silent discharge, the carbon monoxide formed has a lower concentration of the heavy ^{13}C isotope, and the undissociated carbon dioxide fraction is enriched in ^{13}C by an average factor of 1.020 ± 0.008.[113] Analysis of the mechanisms of the dissociation of carbon dioxide in glow[114] and silent[115–118] electrical discharges indicates that the dissociation passes through a number of stages with the formation as intermediate products of oxygen and ozone, which also accumulate in appreciable quantities in the final products.

A method has been proposed for separating isotopes by chemical reactions taking place under thermodynamically non-equilibrium conditions,[109,119] when the difference in the rate constants of the reactions involving different isotopic forms of the molecules may be considerable.[119]

The possibility of separating carbon isotopes in the reaction CO + CO taking place in an electrical discharge under different conditions (pulse, direct, alternating) has also been studied.[120,121] The chosen duration of the discharge pulse was much shorter than the vibrational-relaxational relaxation time. The pulse repeat frequency was 0.3 Hz, and its duration 5 μs. The experiments were carried out in a stream of gaseous CO at 298 K and 77 K in a reaction vessel consisting of a discharge tube with diameter 20 mm, length 300 mm, with molybdenum electrodes. The gas pressure in the reactor was varied from 133 Pa to 1330 Pa, and the flow rate from 10^{-2} litre s^{-1} to 1 litre s^{-1}. The composition of the mixture before and after the reaction was determined mass-spectrometrically. The measurements showed that in the pulse discharge with the walls of the reactor cooled to liquid-nitrogen temperature, the average concentration of ^{13}C in the C_2O formed reached 3.5%. No significant enrichment in ^{13}C was observed in the alternating and direct current discharges.

The presence of C_2O in the reaction products apparently indicates that the mechanism of the reaction CO + CO in the pulse electrical discharge is analogous to that of the photolysis of CO using an iodine lamp (wavelength 2064 Å):[122]

$$CO^* + CO \rightarrow CO_2 + C, \quad (6)$$

$$C + CO \rightarrow C_2O, \quad (7)$$

$$C_2O + CO \rightarrow C_3O_2 \quad (8)$$

(CO^* represents an excited CO molecule). Reaction (6) can take place in two directions:

$$^{13}CO + {}^{12}CO \rightarrow {}^{12}CO_2 + {}^{13}C \quad (9)$$

and

$$^{13}CO + {}^{12}CO \rightarrow {}^{13}CO_2 + {}^{12}C. \quad (10)$$

Since the experiments showed ^{13}C enrichment in the compound C_2O, which is formed with the participation of C, and not CO_2, reaction (9) apparently predominates.

The degree of separation of ^{12}C and ^{13}C in an electrical discharge is much greater than that in other single-stage processes. Because of the complexity of the accumulation of the products of the separation in the reactions in electrical discharges, and the large quantities of energy required for these processes, however, they still remain at the stage of laboratory studies.

VI. Separation of isotopes using lasers

In the last ten years, the laser separation of isotopes (LSI) has been intensively studied in the Soviet Union and other countries. This is related to a number of potential advantages of the LSI method over traditional methods, namely the high selectivity of the elementary act of separation ($\alpha \gg 1$) resulting from the monochromatic nature of the laser radiation and the possibility of its preferential action on one isotopic form; the fairly low expenditure of energy per atom of the isotope separated (energy is required practically only to isolate the required isotope); the rapid attainment of the steady state of the process; and its universal character.

Of the forms of the LSI method known at present, the most suitable for practical application is the isotopically selective multiphoton dissociation (MPD) of molecules, based on the phenomenon of the selective decomposition of molecules under the influence of resonance infrared radiation. Experiments on isotopically selective MPD have been carried out for many isotopes, from the light (hydrogen) to the heavy (osmium) elements.[123]

The selectivity coefficient of the dissociation, which corresponds to the separation factor, is usually defined as the ratio of the effective rate constants of the dissociation of the molecules with different isotopic compositions in a single irradiation. This definition is close to that adopted in traditional methods for separating isotopes;[124] in both cases the value of α is a measure of the selectivity of the elementary act of the separation.

Although the processes of multiphoton excitation and dissociation of molecules under the influence of infrared radiation have potentially a high isotopic selectivity, there are a number of factors which may lower the separation factor considerably. One of the main factors is vibrational relaxation, as a result of which high selectivity is achieved at low pressures (not higher than 133 Pa).

The study of the isotopically selective dissociation of the CF_3I [125] and CF_3Br [126] molecules shows that carbon LSI has promising possibilities. These molecules are of interest since the dissociation energies of the weak C–I and C–Br bonds are only 2.3 eV and

2.8 eV respectively. The high isotopic selectivity is preserved at a comparatively high gas pressure (up to 670 Pa).[127] Since it is desirable to carry out the process at increased gas pressures to increase the productivity, the dependence of the selectivity of the MPD on pressure was studied for CF_3I,[125,128,129] CF_3Br,[130] CF_2Cl_2,[131] and C_6H_5F.[132] In all cases the selectivity of the dissociation decreased regularly with increase in the pressure of the gas used.

Experiments have shown that it is better to use molecules which are not too complex for separation by the LSI method, since the MPD of polyatomic molecules gives numerous fragments, and the isotopic selectivity is decreased. At the same time, complex molecules dissociate more readily under the influence of laser radiation, and higher energy densities are required for molecules containing few atoms.[123] In molecules containing few atoms, the density of the levels up to the dissociation energies is small. This, firstly, restricts the possibility of attaining an energy sufficient for decomposition of the molecule, and, secondly, decreases the rate of the intramolecular redistribution of the excitation energy. Collisions with the buffer gas, however, may change the rotational state of a molecule in the ground or excited state. Since simple molecules (HFCO, CHF_3, CF_3I, CF_3Br) may be promising for carbon LSI, the MPD of these compounds in the presence of large quantities of buffer gases (Ar, He, NO, N_2) has been studied.[133–135] The dependence of the effective rate constant of the dissociation on the pressure of the buffer gas has been studied. An appreciable decrease (by an order of magnitude or more) in the rate of the MPD of these molecules was observed with increase in the pressure of the buffer gases from 1.33×10^3 Pa to 26.6×10^3 Pa.

Even with the fairly high selectivity coefficients of the MPD of molecules, one enrichment cycle is insufficient to achieve a high concentration of the required isotope, and a multistage process is necessary.[129,133,134,136–138] In the field of a pulse CO_2 laser, CF_3X molecules decompose by the reaction

$$CF_3X \rightarrow CF_3 + X \quad (X = I, Br, Cl)$$

to give molecules of C_2F_6 and halogen as final products. Since the C_2F_6 molecule does not absorb in the range of the radiation of the CO_2 laser, and its chemical transformation into CF_3X is fairly complicated, the dissociation of CF_3X may be carried out in the presence of, for example, acceptors of CF_3 radicals such as HBr and NO.[136] This gives CF_3H and CF_3NO molecules, which are then easily reconverted into the original compound CF_3X. When CF_3NO is heated with an excess of Br to 200 °C, CF_3Br is formed quantitatively in several minutes, so that one or several additional enrichment stages can be carried out.

Another method for cascading the laser separation process involves the use of I_2 and Br_2 molecules as acceptors. Thus the MPD of CF_3I mixed with Br_2 led to the complete conversion of the original molecules to CF_3Br, and, on the other hand, the dissociation of CF_3Br in the presence of I_2 led to the complete conversion of CF_3Br into CF_3I.[133,134,137,138] The experiments showed that in the presence of acceptors the yield of the dissociation and the selectivity of the MPD may be not only preserved but in many cases increased. The dependence of the yield of the MPD of CF_3I (CF_3Br) on the pressure of the acceptor is not monotonic, and has a clearly defined maximum, close to which the yield of the dissociation is higher than in the absence of the acceptor.

In principle, a high enrichment in the required isotope can be achieved by using laser radiation to 'burn off' from the starting material the molecules containing the isotope which is not required. In this separation scheme, the required isotope is concentrated in the residual products. For carbon, this method can effectively concentrate only the ^{12}C isotope, by 'burning off' from the mixture the small quantity of molecules containing the ^{13}C isotope. Gram quantities of CF_3I with a ^{12}C concentration of 99.99% have been obtained in this way.[139]

To obtain a highly enriched ^{13}C fraction, a two-stage scheme is best. In the first stage, the $^{13}CF_3I$ molecule is dissociated, and in the presence of an acceptor a new compound CF_3X is formed (X = Br, NO) with 20–30-fold enrichment in ^{13}C. The CF_3X is then transformed either into the original compound[137] or into a compound which undergoes isotopically selective dissociation under the influence of a CO_2 laser (for example CF_3Br).[133] The second stage involves the dissociation of the $^{12}CF_3X$ molecules. In this way it is possible to obtain a product with a ^{13}C enrichment of 90–99%.

The above results were obtained under single-pulse conditions. They were later reproduced[140,141] on a specially constructed assembly consisting of a pulse-periodic CO_2 laser with a kilowatt power level and a laser separating cell with transverse pumping of the working gas. The results obtained make it possible to proceed to the development of an industrial assembly for carbon LSI by isotopically selective MPD using CF_3I or CF_3Br molecules as the starting material.[140]

Analysis of the experimental data shows, however, that in addition to their advantages (the low dissociation energy of the carbon–halogen bond, and the high isotopic selectivity at a comparatively high gas pressure up to 600 Pa), halogen-substituted methane molecules have certain disadvantages: they decompose by a radical mechanism, and the primary act of dissociation of the CF_3X molecules (X = I, Br) to a CF_3 radical and halogen is followed immediately by the start of secondary chemical reactions which lower the selectivity and the yield of the required isotope. Moreover, the isotopically enriched halogen-substituted hydrocarbons obtained as final products in these processes may find only limited application. The conversion of CF_3X molecules into simple molecules (CO, CO_2) convenient for subsequent application involves technological difficulties and additional expense. A search has therefore been carried out for molecules whose isotopically selective dissociation will give products widely used in the synthesis of labelled compounds, and also in traditional methods of separation by low-temperature fractional distillation and exchange.[142] In particular, for carbon LSI it has been suggested that carbonyl-containing compounds, many of which give CO and CO_2 on decomposition, may be used. Moreover, in carbonyl-containing compounds, the C=O bond stretching vibrations (1700–1800 cm^{-1}) show large isotopic shifts (40–50 cm^{-1}),[143] and this is important for achieving a high isotopic selectivity in the MPD process.

It should be emphasised that the frequency of the C=O stretching vibration lies in the range of the generation of the CO_2 laser, which has not yet been used to separate isotopes, although its specific energy characteristics and the broad spectral composition of the radiation makes this a realistic possibility.[144–146] Carbonyl chloride $COCl_2$ enriched in ^{13}C and ^{18}O has been used to study MPD under the influence of pulse CO_2 laser radiation and to determine the yield of products and the selectivity with respect to carbon and oxygen simultaneously. The isotopic analysis of the dissociation product (CO) and the residual product ($COCl_2$) was carried out by mass spectrometry. The energy of the lasing pulse was ~0.5 J, and its duration ~5 μs. The irradiation of carbonyl chloride at a pressure of 66 Pa gave a selectivity of 4 with respect to carbon and oxygen.[147,148]

VII. Summary

At the present time, the principal industrial method for obtaining the ^{13}C isotope is the low-temperature fractional distillation of carbon monoxide. Extensive studies of the fractional distillation of CO in counter-current laboratory, pilot-plant, and industrial packed columns with different diameters have given the optimum parameters of the technological separation process, providing a reliable basis for increasing their productive capacity and making it possible to arrange cascades of columns to reduce the time taken to achieve a given ^{13}C concentration. At the same time, the method involving low-temperature fractional distillation of CO has a number of disadvantages, of which the most significant are the comparatively low separation fator α and the high energy consumption associated with the large quantities of coolant used, the complexity of the technological equipment for the process, and the rigorous requirements for pure CO. These disadvantages, particularly the first, become important when the scale of ^{13}C production is increased.

Promising technical and economic characteristics are shown by processes for obtaining carbon isotopes by chemical isotopic exchange between carbon monoxide or dioxide and their molecular compounds with organic ligands. The main advantages of these systems, in addition to the comparatively high values of the factor α, are the possibility of thermal enrichment of the streams and the fact that the separation can be carried out at room temperature. The carbamate system appears promising. The efficiency of the carbamate method of separation can be increased by using aliphatic hydrocarbons as solvents for the amines. The disadvantages of this method are, firstly, the need to use a large quantity of inert solvent, which requires an increase in the cross-section of the mass-exchange assembly and the processing of large streams. The main volume of the assembly and most of the material expenditure are associated with the first two stages of the cascade, where the ^{13}C concentration is increased to only 10%.

Another promising direction for the large-scale production of carbon isotopes is the laser method. The laser separation of carbon isotopes may in the near future compete with traditional methods such as fractional distillation and chemical isotopic exchange. An important task in the development of a technological LSI process is to find effective starting materials. To obtain a highly enriched required isotopic product, several cycles of the laser separation are usually required. After each separation stage it is necessary to convert the enriched product into the starting material or into compounds which absorb the energy of the CO_2 laser; this is often difficult and always requires the expenditure of energy and materials.

A method of separation using only lasers is probably not always the optimum method. It may be technologically appropriate to combine carbon LSI with traditional methods of separation, in particular chemical exchange and fractional distillation. In this combination, simple carbon-containing molecules (CO, CO_2, etc.) with a low degree of enrichment (up to 10–15 at.%), obtained in a single laser-separation cycle, can be subjected to further enrichment by traditional methods. This would make it possible to eliminate from cascade separating assemblies the first two stages, in which, as noted above, the greatest quantities of energy and materials are used, and this should lead finally to a significant decrease in the cost of carbon isotopes.

Important directions in the separation of carbon isotopes are still the development of rational technological schemes for combining separation processes and the search for less expensive starting materials, taking account of the possibility of using industrial waste products to give ecologically clean processes.

Chemiluminescence in cryogenic matrices

S V Lotnik, V P Kazakov
Institute of Chemistry, Bashkir Branch of the USSR Academy of Sciences

ABSTRACT. The literature data on chemiluminescence (CL) in cryogenic matrices have been classified and correlated for the first time. The role of studies on phosphorescence and CL at low temperatures in the development of cryochemistry is shown. The features of low-temperature CL in matrices of nitrogen and inert gases (fine structure of spectra, matrix effects) and the data on the mobility and reactivity of atoms and radicals at very low temperatures are examined. The trends in the development of studies on CL in cryogenic matrices, such as the search for systems involving polyatomic molecules and extending the forms of CL reactions, are followed. The reactions of active nitrogen with hydrocarbons that are accompanied by light emission and CL in the oxidation of carbenes at $T \geqslant 77$ K are examined.

The bibliography includes 112 references.

I. Introduction

During the last three decades a separate new branch of chemistry has been formed—cryochemistry. The impressive results obtained in low-temperature chemistry have been correlated in a number of monographs and review articles.[1-10] There are quite a number of theoretical models that examine the mechanisms of low-temperature reactions; but in representing the kinetics of such processes a number of problems still occur, which cannot be resolved without the collection and classification of experimental material. The kinetics and mechanism of low-temperature solid-state reactions have mainly been studied using spectroscopic methods, among which chemiluminescence (CL) plays an important role.

Every year hundreds of reports on new CL reactions, investigations of their mechanisms, and applied aspects of the phenomenon are published. In this stream of information, some studies on low-temperature solid-state CL, comparatively few in number but very interesting, get lost. It is appropriate to recall here that the CL method can be used to measure directly the rate of a chemical process. When the high sensitivity of the CL method, which under favourable conditions permits the monitoring of changes down to only thousands or even hundreds of molecules per second, which are inaccessible to calorimetry, EPR, and absorption spectroscopy, is taken into consideration, it becomes clear that there is future potential in using low-temperature CL to study those solid-state processes which, as a rule, occur at a low rate. It is a favourable circumstance that in cryogenic systems temperature quenching of luminescence is suppressed to a considerable degree, and there is a substantial increase in the number of particles which can exist in electronically excited states during the time required to record them.

Low-temperature CL reactions do not constitute an exotic class; they occur over a wide range of temperatures and in various media—from cryogenic matrices of nitrogen and inert gases to frozen aqueous[11,13-15,17,18] and nonaqueous[12,16,19,20] solutions. Chemiluminescence at low temperatures accompanies radical recombination, atom transfer reactions, and a number of redox reactions such as oxidation of sulphur with ozone,[11] uranium(IV) sulphate complexes with ozone and xenon difluoride and trioxide,[12] luminol with oxygen and hydrogen peroxide,[13,15,18] triethylaluminium with xenon difluoride,[16] and reduction of $[Ru(bipy)_3]^{3+}$ with sodium borohydride,[14] the hydrolytic reduction of XeF_2,[17] and several other reactions.[12,19,20]

In this review we will not examine frozen solutions but will confine ourselves to CL in cryogenic matrices. The CL method is used to study the stabilisation of free radicals in nitrogen and inert gas matrices, to simulate under laboratory conditions the photochemical reactions that occur on the surface of dust particles in interstellar space, and to monitor the course and kinetics of chemical reactions in low-temperature matrices. Up to the present time, however, there have been no reviews in the world literature on studies devoted to low-temperature CL.

The present article serves a double purpose: firstly, to draw the attention of cryochemists to the unique possibilities of the CL method and, secondly, to alert the specialists in the field of gas-phase and liquid-phase CL to a new extensive region for application of efforts—low-temperature solid-state chemical reactions.

II. Early studies of phosphorescence and chemiluminescence at low temperatures

Investigations into the problems relating to the phenomenon of low-temperature CL were undertaken by Becquerel, Dewar, Lewis, and Rayleigh. The progress made by the end of the last century in the preparation and storage of liquid gases made it possible to widen the scope of studies in low-temperature chemistry and physics. Phosphorescence was detected at the temperature of liquid air for a large number of organic compounds, such as alkaloids, hydrocarbons, acids, alcohols, ethers,[1] but the mechanism of the phenomenon remained uncertain up to the 1940's, when as a result of the efforts of Jablonski,[21] Lewis,[22] Terenin,[23] and Kasha[24] it was

established that phosphorescence spectra are due to triplet-singlet electronic transitions from the lowest excited triplet states of molecules.

It was Dewar[25] who first observed the phosphorescence of a number of compounds at the boiling point of hydrogen. Back in 1903 in conjunction with Moissan he carried out a study of the reaction of liquid hydrogen with solid fluorine at 20.5 K.[26] Dewar was the first to use low-temperature traps cooled with liquid air for the preservation of unstable compounds.[27,28] Moreover, in conjunction with Jones he was the first to observe flashes of light accompanying the low-temperature explosive polymerisation of carbon monosulphide, whose spectrum contained cyanogen lines and sulphur and hydrocarbon bands.[27,28] Even earlier, in 1894, Dewar had detected the accumulation of ozone in liquid oxygen when exposed to electric discharge and he observed the luminescence of molecular and atomic oxygen produced by electron bombardment.[29] In the luminescence spectrum of oxygen he recorded, in particular, a green line (557.7 nm), which caused many disputes 34 years later in attempts to determine the nature of the aurora borealis and the luminescence of the night sky.

In 1924 Vegard[30] put forward the suggestion that the aurora borealis is caused by the luminescence of crystals of nitrogen present in the upper atmospheric layers when exposed to intense cosmic radiation. In attempting to confirm experimentally his hypothesis about the mechanism of this natural phenomenon, Vegard detected and studied in detail the luminescence of solid nitrogen condensed on a surface cooled to 20.5–4.2 K and then subjected to bombardment with electrons or positive ions. He considered that the green line that he observed with wavelength 557.738 nm was due to radiation from an excited nitrogen molecule. Vegard's hypothesis proved to be incorrect. McLennan and co-workers[31] measured the wavelength of the green line of oxygen with a Fabry–Perot interferometer and obtained a value of 557.7341 ± 0.0004 nm, which was in excellent agreement with the value of 557.7350 ± 0.0005 nm determined from astronomical measurements by Babcock.[32] Thus, it was demonstrated that the green line at 557.7 nm was due to the radiative $^1S \rightarrow {}^1D$ transition of an oxygen atom formed in the upper atmosphere as a result of solar radiation on molecular oxygen.[33]

Vegard was responsible for a remarkable observation which to a large degree assisted an extensive study of free radicals started three decades later. He found that after bombardment of solid nitrogen has ceased, a bright luminescence occurs for several minutes. On increasing the temperature of the sample the luminescence appears again, and its intensity and spectroscopic composition undergo changes during warming. The luminescence is not phosphorescent in nature, as was clear even after the first experiments of Vegard, who observed the emission of light from the sample when it was warmed several hours after electron bombardment had ceased. Consequently, it was shown that the luminescence produced by warming an irradiated nitrogen matrix is CL caused by the recombination of nitrogen atoms. Thus, Vegard was the first to observe CL in cryogenic matrices and to undertake a spectroscopic study of it under experimental conditions with good reproducibility.

Also to Vegard's credit is that he was in fact the first to use the method of matrix isolation in low-temperature spectroscopy. A pioneer in the concept of matrix isolation was Schmidt.[34] By assuming that the phosphorescence of compounds in liquid solution is considerably reduced as a result of the loss of excitation energy through molecular collision, he attempted to reduce the deactivation effect of excited particles by diluting them with inert molecules, placing the compound being studied in a rigid matrix or crystal (gelatine, sugar, papaverine). It was the experiments of Schmidt that served as an impetus for studying the effect of temperature and viscosity of the solvent on phosphorescence.

At the end of the 1920's many spectroscopists who had tried to obtain radicals by electrical discharge observed an unusual luminescence in the low-temperature traps protecting vacuum pumps. In some cases condensed ozone, hydrogen peroxide, and other compounds were detected.[1] At that time radical chain reactions were of considerable interest to research workers, so evidently they made considerable efforts to elucidate the role of radicals in the luminescence observed in traps and in detonation of frozen products. Thus, Lavin and Bates[35] reported a blue-green luminescence in a trap at 93 K to which was admitted ammonia that had previously passed through a discharge zone. It was concluded that the luminescence was due to the formation of NH and NH_2 particles. Lunt and Mills[36] reproduced these experiments and observed CL by interacting the decomposition products of gaseous ammonia in an electrical discharge on a solid surface of NH_3 at 93 K, having thus confirmed the results of Lavin and Bates.[35] The authors[36] considered that the reaction of metastable NH particles with hydrogen molecules in the ground state was the most probable source of CL

$$2\ {}^1\Delta\,NH + {}^1\Sigma H_2 = N_2^*H_4 \rightarrow 2\overset{*}{N}H_2.$$

The reaction product—an excited hydrazine molecule—dissociates to give two electronically excited NH_2 particles, which emit the CL.

III. Chemiluminescence in solid nitrogen

In 1954 Broida and Pellam[37] detected considerable luminescence accompanying the condensation of active nitrogen on a surface cooled to 4.2 K. It was suggested that the solid inert gases and nitrogen could be used as media for matrix isolation.[38,39] Their selection was determined not only by their considerable inertness but also by their transparency over a wide range of wavelengths (from the far infrared region of the spectrum to the vacuum ultraviolet) and by their adequate rigidity at 4.2–20 K. The reader can find detailed information about the method of matrix isolation, the properties of the matrices, condensation of solid deposits, and generation of highly active particles in several studies.[2,6–9,40–47]

After the report of Broida and Pellam,[37] extensive studies were carried out on luminescence spectra recorded not only by depositing the products of microwave discharge in gaseous nitrogen[48–56] but also by stimulation of luminescence through a high-voltage discharge using a Tesla transformer,[57] electron bombardment,[58,59] and the action of X-ray emission.[60]

Problems concerning the stabilisation of nitrogen atoms were studied by Fontana.[61,62] He came to the conclusion that if the condensing gas contains more than 1–2 mol % of nitrogen atoms virtually all of them recombine when the solid condensate is formed. It transpired that not more than 0.01–0.04 mol % of nitrogen atoms were stabilised in the nitrogen matrix.

Subsequently, Edwards[2] attempted to interpret the main characteristics of CL in solid nitrogen. He suggested that when the condensate is warmed up, diffusion of nitrogen atoms is initiated, and they migrate and undergo recombination to form nitrogen molecules in the ground ($X^1\Sigma_g^+$) and electronically excited ($A^3\Sigma_u^+$) states:

$$N(^4S) + N(^4S) \rightarrow N_2; \quad N(^4S) + N(^4S) \rightarrow \overset{*}{N}_2.$$

It was later suggested that the heat evolved from these reactions causes an increase in temperature of the sample and thus stimulates subsequent chemical processes. It was therefore assumed[2] that the β-lines in the CL spectrum are due to oxygen atoms formed in an excited state by the reaction:

$$N+NO\rightarrow N_2+O^*;\ O^*\rightarrow O+h\nu.$$

The transfer of energy from an excited N_2^* molecule to an oxygen atom is also allowed

$$O+N_2^*\rightarrow O^*+N_2^{\neq};\ O^*\rightarrow O+h\nu\ (\beta\text{-line});$$
$$O^*(N_2^{\neq})\rightarrow O+N_2+h(\nu_{el}\pm\nu_{vib})(\beta\text{-, }\beta'\text{- and }\beta''\text{-lines}),$$

where $N_2^{\neq}$ is a vibrationally excited nitrogen molcule, $O^*(N_2^{\neq})$ is an intermediate state which decomposes with emission of β-lines. The appearance of α-lines was accounted for by the occurrence of similar processes, except that, instead of an oxygen atom, a nitrogen atom was assumed to take part in the reactions:

$$N+N_2^*\rightarrow N^*+N_2^{\neq};\ N^*\rightarrow N+h\nu\quad(\alpha\text{-line});$$
$$N^*(N_2^{\neq})\rightarrow N+N_2+h(\nu_{el}\pm\nu_{vib})(\alpha\text{-, }\alpha'\text{- and }\alpha''\text{-lines}).$$

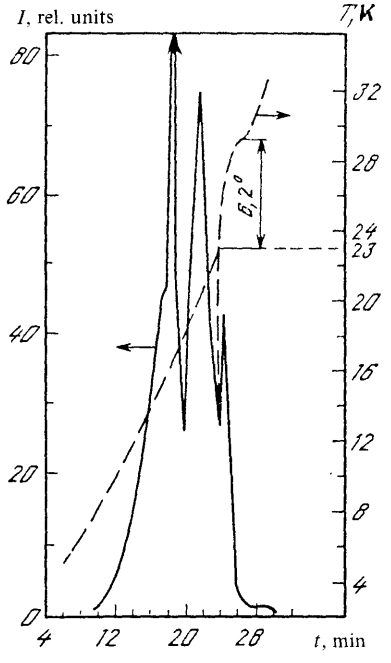

Figure 1. Dependences of the intensity of the α-band in the chemiluminescence spectrum (solid line) and the temperature of the sample (broken line) on time during the warming of a solid condensate of the products of ultra-high frequency discharge in gaseous nitrogen.[63]

In the mechanism examined a direct connection between CL and heat processes accompanying the recombination of atoms was assumed. Hemstreet and Hamilton[63] did not agree with such a treatment. They interpreted the dependence of the intensity of CL on time when the sample was warmed up (Fig. 1) by assuming the possible stabilisation of nitrogen atoms occurring not in the ground state but in an electronically excited state in the N_2 matrix.[63] This type of hypothetical stabilisation of excited particles, the life-time of which is several tenths of a second (we should remember that the radiative life-time of nitrogen atoms in the ^2D-state in a vacuum amounts to ~20 h, and in the ^2P-state to about 4 s), occurred, according to Hemstreet and Hamilton, via the formation of a weak complex between an electronically excited nitrogen atom and an N_2 molecule in the ground state. It was suggested that this complex inhibited the spontaneous deactivation of nitrogen atoms until it was destroyed on warming the matrix.

The presence of two maxima on the intensity curve (Fig. 1) was accounted for by Hemstreet and Hamilton[63] on the basis that there were two types of trap in ordered and disordered parts of the matrix respectively. It transpired that the maxima for CL and heat liberation did not necessarily coincide in time. Hemstreet and Hamilton saw that there was a discrepancy in the model of Edwards mainly because according to their data the luminescence peak occurred earlier than the heat liberation processes resulting from the recombination of nitrogen atoms in the ground state were recorded.

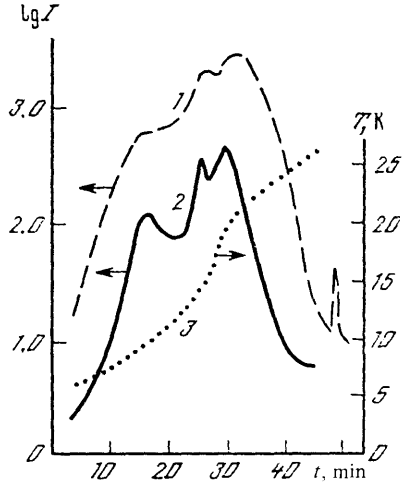

Figure 2. Dependence of the logarithm of the intensity of chemiluminescence on time (curves *1* and *2*) during warming and a thermogram of the sample in the case of irradiation with annealing (curve *3*). *1*, irradiation without annealing; *2*, irradiation with initial annealing.[64]

However, the results of Brocklehurst and Pimentel[64] based on quantitative thermometric and spectroscopic studies of solid nitrogen subjected to electron bombardment at 4.2 K contradicted the theory of Hemstreet and Hamilton. When the sample was warmed up the authors[64] observed three broad CL peaks and light emission at 35 K—the phase transition temperature (curve *1*, Fig. 2). When there was initial annealing of the sample, curve *2* was obtained with good reproducibility. The peaks were better resolved in the case of the annealed sample of solid nitrogen, which made it possible to exclude any of the observed CL maxima from being attributed to a process involving the ordering of imperfections in the crystal lattice

that develop when the condensate is formed. Thus, it remained to Brocklehurst and Pimentel to propose a mechanism for CL which would account for the presence of not two, as found by Hemstreet and Hamilton,[63] but three luminescence peaks.

In order to try and explain the presence of three luminescence peaks using the model of Hemstreet and Hamilton, it would be necessary to admit the existence of three complexes of excited atoms with molecules of the matrix, each of which would decompose irreversibly at a given temperature. Therefore, Brocklehurst and Pimentel returned to the model of Edwards, having modified it slightly. They proposed that each CL peak was due to the same active particles—this followed directly from the lack of change in the luminescence spectrum of a sample when its temperature was varied from 4–20 K. Subsequently, the authors,[64] by assuming that the given luminescence maxima were initiated by diffusion, postulated that the $N(^4S)$ nitrogen atoms were stabilised in the nitrogen matrix in three different positions (relative to the matrix environment), each of which was characterised by one of three values for its enthalpy of activation of diffusion. This model satisfactorily explained a number of features of CL in a nitrogen matrix, since the recombination reaction of $N(^4S)$ nitrogen atoms provides sufficient energy (225 kcal mol^{-1}) to excite the nitrogen atoms to the ^2D (54.7 kcal mol^{-1}) or ^2P (86.4 kcal mol^{-1}) states by exciton transfer.

However, despite the progress achieved by the beginning of the 1960's in understanding the nature of the CL of solid nitrogen, there were still considerable difficulties in attempts to interpret the fine structure of emission spectra. Complications arose because in order to obtain sharp and intense nitrogen luminescence spectra a very pure gas without contamination with oxygen was necessary since the latter quenches the luminescence of nitrogen and gives a series of broad emission bands in the exact spectroscopic region for observing nitrogen lines. In the study of Brocklehurst and Pimentel,[64] where the most complete theoretical analysis of the spectroscopic characteristics of the luminescence of solid nitrogen was carried out, gas of 99.995% purity was used.

In solid nitrogen that is free of impurities, the most intense band in the visible region of the spectra is the α-band. This component of luminescence is attenuated very slowly, and is caused by a very striking green afterglow with $\lambda = 523$ nm, due to the $^2D \rightarrow {}^4S$ transition of the nitrogen atom. The α′-band, as designated by Bass and Broida,[49] is much weaker than the α-band. It was established[52,54] that the difference in frequencies $\Delta\nu = \nu(\alpha)-\nu(\alpha') = 2300$ cm^{-1} is close to the vibration frequency of an N_2 molecule in the ground electronic state. On the basis of this, the α′-band was interpreted as the combination of a $^2D \rightarrow {}^4S$ electron transition of a nitrogen atom and a concurrent vibrational transition $v = 0 \rightarrow v = 1$ in a neighbouring N_2 molecule.

In the near IR region of the spectrum, the most intense emission comes from the so-called δ-band at 1044 nm, as detected by Peyron and co-workers,[55] and which they attributed to the $^2P \rightarrow {}^2D$ transition of an N atom.

Earlier, the fine structure of the α-band had been studied using spectrograms obtained photographically.[49,55,58] The difficulties which arose in the interpretation of this structure were overcome by Dressler and co-workers,[65] who for the first time obtained a photoelectric record of the α-band in the emission spectrum of solid nitrogen bombarded by electrons at 4.2 K (Fig. 3). It was shown that the spectrum of the α-band may be made up by a series of modified Lorentzian curves. The intensity ratio of lines *1–5* remains constant for different conditions of excitation and condensation of the samples. The overall pattern of these lines was interpreted as a dynamically induced electron-phonon band containing asymmetric molecular vibrations in the ground state, and the O_A and O_B lines were attributed to an unsymmetrically broadened, induced phonon-free band. This assignment was confirmed by a frequency analysis of the satellite vibration lines α′, α″, and α‴.

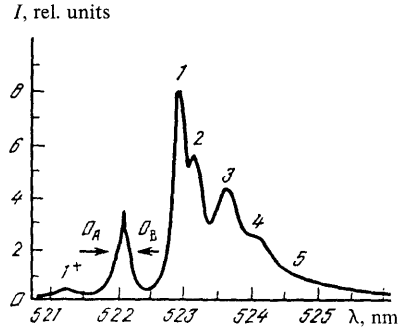

Figure 3. Structure of α-bands caused by the $^2D \rightarrow {}^4S$ transition in the low-temperature (4.2 K) luminescence spectrum of the nitrogen atom.[65]

Information about the structure of the traps containing active particles is of considerable importance for the correct interpretation of CL processes that occur when cryogenic matrices are warmed up. Such information was obtained even in the early studies on the EPR spectra of N atoms in a nitrogen matrix.[66,67] There is an interesting study,[68] in which in order to obtain data on the possible molecular environment of nitrogen atoms, an investigation was made as to how the EPR spectra were affected by the temperature of condensation of the products formed in an ultra-high frequency discharge in gaseous nitrogen. The occurrence of a single group of lines (spectrum *A*) at 7 K and three groups of lines (spectra *A*, *B*, and *C*) in the EPR spectrum of solid nitrogen at 14 K was related by Delannoy and co-workers[68] to the existence of one and three types of trap respectively in the matrix of molecular nitrogen. In an N_2 matrix the nitrogen atoms can occur in different stabilisation sites as a result of three processes (the position is characterised by the distance *R* between the centre of the structural defect occupied by the N atom and one of the adjacent nitrogen molecules):

1) substitution ($R_\alpha = 0.4$ nm);
2) insertion with an octahedral matrix environment ($R_\beta = 0.282$ nm)
3) insertion with a tetrahedral matrix environment ($R_\gamma = 0.244$ nm)

The capture centres of the $N(^4S)$ nitrogen atoms in an N_2 matrix were investigated in the study of Adrian.[69] With the theory he proposed it is possible to establish an interrelationship between the value of the hyperfine splitting constant and the number of neighbouring molecules and also the distance from the latter to the centre of the stabilised atom.

The next stage in studying the phenomenon of CL observed when condenstates of active nitrogen are warmed up was undertaken by Faure and co-workers.[70] Having used a combination of EPR and optical spectroscopy, they studied the effect of temperature on the capture of nitrogen atoms in traps of various types. When the condensate was warmed up from 5 to 40 K they observed three CL

peaks from the main component of the α-band for the $^2D \rightarrow {}^4S$ atomic transition (at 15.9, 20.3, and 23.5 K), which was consistent with earlier results.[63]

By analysing the changing features of the fine structure of the emitting α-band on varying the temperature, which revealed a different behaviour of the two components of luminescence in the region of the phonon-free band—O_A and O_B (Fig. 4)—Faure and co-workers[70] were able to conclude that N atoms were captured in two different types of trap. In fact, it is very clear from Fig. 4 that there is a relative decrease in intensity of the O_A lines (λ = 522.13 nm) when the temperature of the sample is increased. When a temperature of 18–20 K is reached, line O_A disappears. The observed changes in the spectra correspond, according to Dressler and co-workers,[65] to a change in the background structure due to an exchange of the types of trap in which the nitrogen atoms are stabilised.

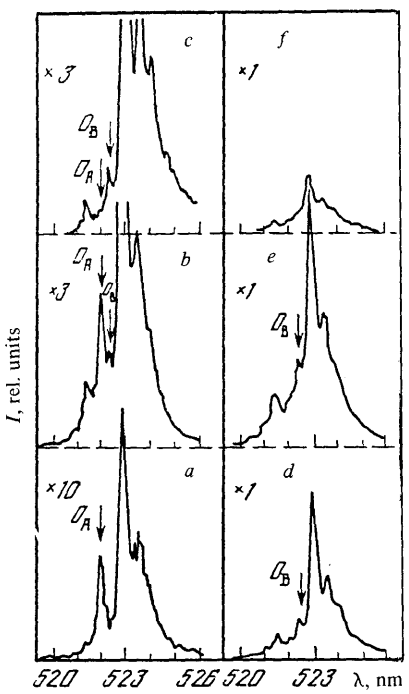

Figure 4. Fine structure of the $^2D \rightarrow {}^4S$ α-band emission obtained at different decomposition temperatures during warming (0.7 deg/min) of the condensate of products of gaseous nitrogen when exposed to ultra-high frequency discharge.[70] The rate of scanning the spectrum was 32 Å/min.
Temperature, K: *a*, 10–11.5; *b*, 14–15.5; *c*, 16–17.5; *d*, 20–21.5; *e*, 24–25.5; *f*, 26–27.5.

The studies started by Faure and co-workers[70] were continued by Tribbollet and Valadier,[71] who analysed the changes that occur in the fine structure of the α-band in the luminescence spectrum recorded during condensation of nitrogen at different fixed temperatures. The observed changes in the relative intensity of lines O_A, O_B, and O_C were interpreted on the basis of the existence of the three types of trap identified previously.[65]

The temperature dependencies of the intensity of the individual lines *1*, O_{AB} and O_C, as shown in Fig. 5, indicate that there can be several possible energy of activation values for each type of trap. Tribollet and Valadier[71] proposed that low-temperature CL is due to two different processes for excitation of nitrogen atoms: firstly, the recombination of atoms situated near each other (this process is responsible for the formation of the first maximum on the temperature curve of CL intensity and occurs in a similar manner to the recombination of electron–hole pairs by a tunnel mechanism); and secondly, the recombination of atoms with a diffusion mobility that is provided by thermal activation (the formation of the second CL peak is due to this mechanism, which has a bimolecular nature).

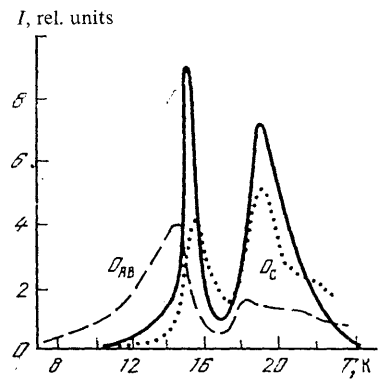

Figure 5. Temperature dependences of the intensity of three lines: *1*, O_{AB} and O_C, present in the luminescence spectrum of the nitrogen atom for $\alpha(^2D \rightarrow {}^4S)$.[71] O_{AB} is the sum of lines O_A and O_B.

In this study[71] the first event in the mechanism for stimulation of CL is assumed to be the recombination of two $N(^4S)$ atoms. The energy of the excited triplet molecule of N_2 is then transferred to nitrogen atoms, which emit light.

The suggestion that there were two mechanisms for excitation of nitrogen atoms was based on the results of an investigation of the kinetics of liberation of N atoms from traps at different temperatures. It transpired that in no single case could the attenuation of CL on removing the heating and stabilising the temperature of the nitrogen matrix containing nitrogen atoms be represented by an exponential decay typical of a first-order kinetic reaction. The decrease in luminescence at 20.3 K corresponds closely to $1/(1 + at)^2$. The intensity of CL at 15.9 and 23 K varies according to a hyperbolic relationship, $1/t$, which is characteristic of the recombination of electron-hole pairs occurring by a tunnel mechanism.

Tribbollet and Valadier[71] proposed two equations to represent the temperature dependencies of intensity obtained in their study for one of the components of the α-band (designated by them as line *1*) in the CL spectrum recorded on warming nitrogen which had condensed at 5 K after passage through a zone of ultra-high frequency discharge. The first expression was obtained by assuming

that the CL reaction occurs by a first-order kinetic mechanism, the second was obtained for the kinetics of a bimolecular reaction:

$$I_1 = n_0 S \exp(-E/kT) \cdot \exp\left(-\frac{S}{B}\int_{T_0}^{T} \exp(-E/kT')\,dT'\right),$$

$$I_2 = n_0 S' \exp(-E/kT) \cdot \left(1+\frac{S'}{B}\int_{T_0}^{T} \exp(-E/kT')\,dT'\right)^{-2},$$

where n_0 is a factor proportional to the number of particles responsible for luminescence at temperature T_0; E is the energy of activation; S is the pre-exponential factor; B is the rate of warming; T_0 is the initial temperature.

It may be mentioned that the theoretical curve that is plotted using the second expression is a better approximation to the experimentally obtained curve.

The problem of stabilising atoms and free radicals that occur in significant concentrations in solid matrices at low temperatures also remains important at the present time. The development of low-temperature physics has revived interest in metastable systems containing atoms stabilised at helium temperatures because of the possibility of finding unique quantum properties in such systems, namely, quantum diffusion, tunnel chemical reactions involving exchange of an atom with a molecule, superfluidly doped atoms, and superconductivity. These questions are among the most interesting and important problems of contemporary physics.

The fact that in the 1950's to 1960's it was only possible to stabilise atoms and radicals in very low concentrations was due to the thermal instability of systems containing considerable quantities of high-activity particles. It was suggested that atoms or free radicals were stabilised in structural traps in the matrix and the thermal instability was due to an increase in their diffusion capabilities caused by a temperature wave coming from the centre of a random recombination. This accounted for the weak dependence of the limiting concentrations of the stabilised atoms on the temperature of the matrix and depth of the structural traps.

Experiments carried out by a group of Soviet research workers[72–77] in which an original method was used for stabilisation of atoms based on the introduction of atom-molecule clusters into superfluid helium (He *II*) through its surface[72] showed that under good heat-exchange conditions and at a low temperature ($T_0 \approx 1.5$ K) the concentration of stabilised nitrogen atoms can reach 10%,[77] and the N atoms do not recombine for at least 1.8×10^3 s. It may be concluded from this that there is virtually complete stabilisation of the nitrogen atoms in He *II*. It was found that on increasing the temperature a significant proportion of the nitrogen atoms that accumulated at T < 2 K recombined in an explosive manner at the λ-point ($T_\lambda \simeq 2.19$ K). A powerful emission of CL is recorded at the same time.[72,73] Since at the λ-point there is only a sudden change in the thermal conductivity of liquid helium, the authors concluded that the effect was due to thermal explosion of particles of molecular nitrogen containing N atoms that were suspended in the liquid.

An analysis of the thermal stability of systems containing stabilised atoms was carried out by Gordon and co-workers.[73] They came to the conclusion that the limiting concentrations of the atoms stabilised at very low temperatures (T < 4 K) are determined by the stability of the system towards temperature-wave explosion and at higher temperatures towards thermal explosion. In the first case, the conditions for stabilisation require that the temperature wave coming from the centre of a random recombination does not succeed during its existence in inducing the recombination of neighbouring atoms in the matrix; in the second case the conditions require that the rate of heat removal from recombination provides a constant temperature of the medium.

The mechanisms examined above concerning the excitation of condensates of active nitrogen assumed the occurrence of two successive processes: the diffusion-controlled recombination of $N(^4S)$ atoms on the surface or in the bulk of a solid sample and the resonant transfer of energy from the $N_2(A\,^3\Sigma_u^+)$ molecule formed to an $N(^4S)$ atom, which is converted in the process to the electronically excited ^2D state.

Gordon and co-workers[74,75] studied the effect of isolating active nitrogen in a neon matrix on the fine structure of the α-band in the luminescence spectrum of solid nitrogen condensed in superfluid helium from a region of microwave discharge. They came to the conclusion that the α-emission of the nitrogen atoms at the moment of condensation was not due to the recombination of $N(^4S)$ atoms but to the de-excitation of excited $N(^2D)$ atoms trapped from the gas phase in the matrix of molecular nitrogen. The authors made use of the fact that even the lowest energy level of an excited neon atom (E = 16.6 eV) cannot be populated using the recombination reaction of $N(^4S)$ atoms (E = 9.8 eV). Consequently, the resonant transfer of energy from the triplet $N_2(A\,^3\Sigma_u^+)$ nitrogen molecule through the neon matrix is impossible. Therefore, if the mechanism for excitation of condensates of active nitrogen includes the recombination of nitrogen atoms in the ground state followed by transfer of energy from $N_2(A\,^3\Sigma_u^+)$ through the nitrogen matrix to an $N(^4S)$ atom, as N_2 is replaced by Ne the intensity of luminescence of the nitrogen atoms due to the $^2D \rightarrow {}^4S$ transition must decrease. If the main reason for the development of $N(^2D)$ atoms in the condensate is their capture from the gas phase, the matrix isolation with neon should not affect the intensity of the α-band in He *II*.

It transpired that when the ratio Ne/N_2 was varied from 0 to 20 the intensity of luminescence due to the transition $N(^2D \rightarrow {}^4S)$ in the nitrogen–neon condensate did not change.

In one study[76] the fine structure of the α-band in the luminescence spectrum of active nitrogen condensed in superfluid helium was examined, and it was concluded that the line with $\lambda \geqslant 523$ nm was due to a phonon wing transition and the I^+ line (λ = 521.2 nm) was not due to an anti-Stokes transition[65] but corresponded to the luminescence of nitrogen atoms captured on surface traps of a molecular nitrogen matrix.

IV. Chemiluminescence in cryogenic matrices of inert gases

A large contribution to the study of reactions in cryogenic matrices was made by Pimentel and co-workers. Back in 1958 Milligan and Pimentel[78] made a visual observation of the red luminescence during the warming up of solid nitrogen which had been subjected to UV photolysis at 20 K and which contained diazomethane. It was suggested that the CL was caused by one of three reactions:

Reaction	$-\Delta H$, kcal mol^{-1}
a) $CH_2 + CH_2N_2 = C_2^*H_4 + N_2$	101
b) $CH_2 + CH_2 = C_2^*H_4$	122
c) $CH_2N_2 + CH_2N_2 = C_2^*H_4 + 2N_2$	80

Subsequently, Goldfarb and Pimentel[79,80] undertook a more detailed spectrographic and visual study of the orange-red CL recorded at 20–40 K during the warming of a nitrogen or argon

matrix containing reactive residues of diazomethane or its deuterated analogues. On increasing the temperature the intensity of CL changed substantially—from a luminescence scarcely visible to the eye adapted to darkness to a bright orange-red emission which could be discerned even in a light sufficient for reading.

It should be noted that the photolytic method for obtaining active particles stabilised in cryogenic matrices proved very convenient and the majority of the subsequent studies concerned with low-temperature CL were carried out using UV photolysis. One of the studies of Goldfarb and Pimentel[79] is also of interest as a complex method for studying the mechanism of solid-state CL was used in it—IR absorption spectroscopy and emission spectroscopy and isotope substitution. Many subsequent studies were carried out using a similar approach.

Two decades after the discovery of CL in ethylene, Pimentel returned to cryogenic matrices containing diazomethane in order to study once again the luminescence spectrum, to elucidate the role of oxygen impurities, to obtain additional evidence for the presence of CH_2 radicals in a photolysed matrix, and to identify the emitter of chemiluminescence and the electronic transitions responsible for the emission of light.[81] During the intervening period there had been a considerable increase in the scope for recording low-temperature CL and knowledge about the energy levels of the excited states of ethylene had broadened. With the use of EPR and photoelectron spectroscopy new information about CH_2 radicals was obtained and an attempt was made to identify the possible products from the photolysis of diazomethane in matrices of inert gases.

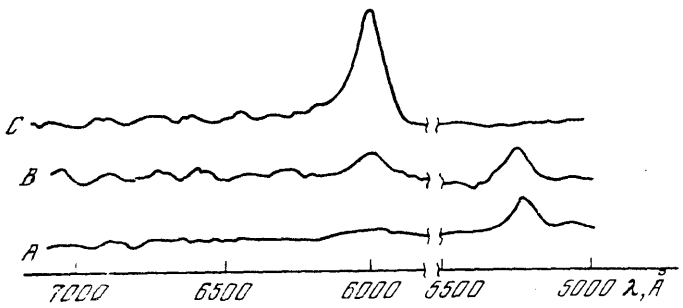

Figure 6. Luminescence spectrum recorded on warming a UV-irradiated nitrogen matrix containing CH_2NN (CH_2NN/N_2 = 1/300).[81]
Temperature, K: *A*, 8–10; *B*, 11–12; *C* 15–16.

Samples obtained by coprecipitation of diazomethane and argon (CH_2N_2 : Ar = 1 : 300) on a copper sheet at 6 K were irradiated with the full light of a medium-pressure mercury lamp for 2.5 h, and the CL spectra were recorded at a slow rate of warming (1–2 deg/min).[81] The early observations[79–80] were confirmed, and with better resolution of the spectroscopic apparatus used, additional structural features were detected in the spectrum. Below 10 K, a broad band with a maximum at 522.0 ± 0.4 nm (Fig. 6, spectrum *A*) predominated in the spectrum. At 11–12 K, a broad band appeared in the region 598.7 ± 0.5 nm, and there were also weak bands over the range 600–760 nm (Fig. 6, spectrum *B*). When the temperature was increased further the emission at 522.0 nm decreased and at 15 K was no longer recorded. At the same time the intensity of the band at 598.7 nm increased, reaching a maximum value at 18 K. This luminescence could be recorded up to about 35 K (Fig. 6, spectrum *C*).

The determination of the nature of the CL emitter was given prominence in this study.[81] Each of the maxima in the luminescence spectrum at 522.0 and 598.7 nm is a separate broad peak without any signs of vibrational structure. This type of spectrum is typical for a monoatomic emitter or a molecular transition between states with almost the same molecular geometry. The nitrogen atom and N_2, CH_2NN, CH_2NH, and C_2H_4 molecules were examined as probable sources of CL. The authors[81] considered the most probable CL emitter to be the ethylene molecule formed in reactions (a) and (b). This interpretation was confirmed not only by the observed correlation between the brightness of luminescence and the concentration of ethylene in the sample but also by the existence in a C_2H_4 molecule of electronic transitions between states with the same geometry. The latter circumstances accounts for the frequencies of the observed spectroscopic bands and the absence of vibrational structure in the CL spectrum. An argument in favour of a C_2H_4 molecule participating in the chemiluminescent reaction was the band detected in the IR region at 1115 cm^{-1}, which corresponded to the deformational vibration of the ground state of CH_2.[81] Consequently, on warming the matrix either diffusion and subsequent recombination of CH_2 radicals was possible or they could react with diazomethane [reactions (b) and (a) respectively]. The authors proposed that the long-wavelength CL maximum at 598.7 nm was due to electronic transitions from the second singlet ($^1A_1$, 43 000 cm^{-1}) or the first singlet ($^1B_2$, 43 769 cm^{-1}) state to the triplet ($^3A_2$, 24 700 cm^{-1}) state of the ethylene molecule. No definite conclusion was reached about the nature of the CL with a maximum at 522.0 nm.

At the start of the 1970's, owing to the efforts of inorganic chemists and organometallic chemists interest was once again stimulated in processes occurring in low-temperature matrices. The focus in studies of this type was shifted from the physical aspects of the chemistry towards synthesis, structure, and reactivity. Laser Raman spectroscopy, Mössbauer spectroscopy, magnetic circular dichroism, developed for application in matrix studies, proved a useful addition to the methods of EPR, absorption, and emission spectroscopy. CL also underwent further development.

Starting in 1974 a whole series of studies was published on low-temperature solid-state CL reactions involving sulphur atoms. In one of the first reports[82] there is information about a blue luminescence observed during the warming of Ar, N_2, or CO matrices which had previously been photolysed at 20 K and which contained hydrogen sulphide. The observed phenomenon was attributed to the formation of HS radicals, and hydrogen and sulphur atoms during photolysis. It was assumed that at 30 K diffusion of sulphur atoms starts, leading to their recombination and radiative deactivation of the excited sulphur molecule formed. The correctness of such an interpretation was confirmed by experiments involving photolysis of OCS.[83,84]

Direct evidence for the formation of S(^1S) atoms by photodecomposition of OCS in an argon matrix at 4 K on exposure to light with λ = 147 nm was obtained by Brom and Lepak.[83] They observed a broad emission band with a maximum at 775 nm, which was readily identified as the $^1S \rightarrow {}^1D$ transition in a sulphur atom.

The chemiluminescence of SO_2 on warming cryogenic matrices that had been irradiated with UV light and which contained SO_2 was first observed by French research workers,[85] who proposed that

the luminescence developed as a result of the reactions S + O_2 and O + SO. Long and Pimentel[86] interpreted the CL spectrum recorded on warming an argon matrix that had been photolysed at 8.5 K and which contained OCS and O_2 molecules by comparing it with the spectrum of the gas-phase phosphorescence of SO_2 and also by measuring the isotope shifts of the vibrational bands of the CL spectrum when $^{16}O_2$ was replaced by $^{18}O_2$. It was concluded that CL develops during the reaction of sulphur atoms with an oxygen molecule, which occurs with an energy of activation almost equal to zero at 10–40 K:

$$S(^3P_2) + O_2(X\,^3\Sigma_g^-) \rightarrow S{\cdot}O_2 \rightarrow SO_2(X\,^1A_1) + h\nu.$$

French research workers[84] detected a considerable diffusion of sulphur atoms in an argon matrix even at 6 K. This study was the extension of a previous one,[85] in which the occurrence of CL on warming a matrix containing SO_2 was attributed exclusively to the emission of SO_2 formed in an electronically excited state as a result of reaction in the lattice $S(^3P) + O_2(X^3\Sigma_g^-)$. However, the high intensity of SO_2 phosphorescence could have masked the emission of $S_2(B^3\Sigma_u^-)$ and in order to detect CL of the sulphur molecule, the French research workers turned to other sulphur-containing compounds giving sulphur atoms by photodissociation. In their later study[84] they observed two clearly distinguishable types of luminescence—the photoluminescence during photolysis at 5–6 K of Ar matrices containing OCS or CS_2 molecules, and CL when the temperature of the sample was increased after the completion of irradiation with light of wavelength 147 nm. Since the energy of the photons (8.3 eV) was insufficient for photoionisation of CS_2 or OCS, the observed luminescence was not due to recombination of charges, as occurs in radiothermoluminescence, but was due to the recombination of atoms, forming molecules in an electronically excited state, in other words, it was CL by its very nature.

It was also established that the CL emitter in matrices containing both OCS and CS_2 was an electronically excited molecule of sulphur, which emits light from the transition $(B^3\Sigma_u^- \rightarrow X^3\Sigma_g^-)$. As well as emission from S_2, emission of SO_2 was recorded in the matrices containing OCS, which was borne out by the similar shape of the temperature curves of intensity of luminescence for S_2 and SO_2 molecules,[84,86] which was an indication of the identity of the particles responsible for luminescence (Fig. 7). In the case of CS_2, bands relating to CS particles $(a^3\Pi \rightarrow X^1\Sigma^+)$ were observed in the CL spectrum. These results indicate that carbon atoms can also diffuse for a considerable distance to form $CS(a^3\Pi)$ particles according to the reaction

$$C(^3P) + S(^3P) \rightarrow CS(a\,^3\Pi),$$

and the rate of diffusion of the carbon atoms is higher than that for the sulphur atoms—Cs bands are observed at lower temperatures than for S_2 bands.

The reliably established evidence for the formation of S_2[83,84] and O_2[87] molecules in an electronically excited state as a result of solid-state chemical reactions stimulated the study undertaken by Lee and Pimentel[88] on low-temperature matrices aimed at obtaining SO molecules in an electronically excited state; there was no information about the existence of these molecules in the gas phase. The authors introduced NO_2, O_2, and SO_2 molecules into an argon matrix for the photogeneration of oxygen atoms, and to obtain sulphur atoms they introduced OCS and SO_2. When the photolysed matrices ($OCS/O_2/Ar$; $OCS/NO_2/Ar$; SO_2/Ar) were warmed up, they observed CL, with a spectrum containing two emission bands—in the region 390–520 nm, due to the transitions $SO_2(\tilde{a} \rightarrow \tilde{X})$, and a progression in the region 520–770 nm. In the system $OCS/O_2/Ar$ the $S_2(\tilde{c}^1\Sigma_u^- \rightarrow \tilde{a}^1\Delta_g)$ was also observed.[89]

The progression in the region 520–770 nm was identified by Gordon and co-workers[74] as SO emission, which was identified from the proximity of ω_e'' to the vibrational frequency of the progression and arose from the low electronically excited states of the SO molecule. Experiments with $^{18}O_2$ showed that the CL emitter contained oxygen.

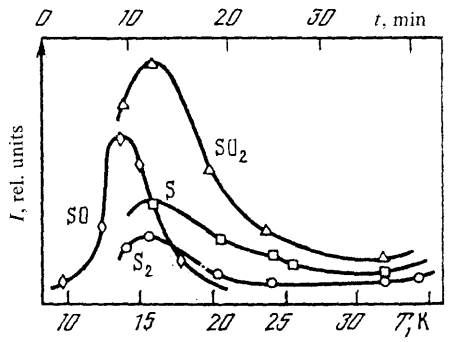

Figure 7. Dependences on temperature and time for the intensity of chemiluminescence of SO, S_2, S, and SO_2 molecules, recorded on warming UV-irradiated Ar matrices containing O_2 and COS ($COS:O_2:Ar = 1:1:200$).[88]

By analysing the experimentally obtained and calculated data on the energy levels of the SO molecule, Lee and Pimentel[88] were able to conclude that the chemiluminescence of SO was due to the radiative transition $\tilde{c}^1\Sigma^- \rightarrow \tilde{a}^1\Delta$. The $\tilde{c}^1\Sigma^-$ state is populated as a result of the reaction $S(^3P_2) + O(^3P_2)$ taking place either directly or via the higher $\tilde{A}''$ and/or $\tilde{A}'$ states, which rapidly relax to the $\tilde{c}$ state. Thus, in this study[88] spectroscopic information about the $\tilde{c}^1\Sigma^-$ state of the SO molecule was obtained for the first time.

In all the studies examined above CL spectra were recorded either photographically or by using a photoelectron multiplier (PEM). The main disadvantage of the latter system is the variation in the light flux, the intensity of which is proportional to the concentration of emitting particles such as SO_2^* or S_2^* during the interval of time necessary to record the spectrum. Consequently, the ratio of intensities of the bands at the limits of an emitting system can only be determined approximately.

This difficulty is eliminated when a photographic method is used, when all the emission distributed in the spectrum is recorded at the same time. However, because of the relatively low sensitivity and the logarithmic dependence of the degree of darkening of photoemulsions on the duration of exposure, it is only possible to use this method successfully with bright CL systems. These disadvantages are eliminated by an optical multichannel analyser in which the integral (multichannel) resources of a photographic plate are combined with the high sensitivity and linear characteristics of the PEM.

By using an optical multichannel technique it was possible for the first time to record simultaneously low-temperature CL spectra on warming cryogenic matrices.[90] The time of scanning a section of the spectrum with width 275 nm was 32.8×10^{-3} s. In each experiment up to 1000 individual scans were carried out using 500 channels. The studies were carried out over the spectroscopic range 200–650 nm. Frozen mixtures of inert gases (Ar, Kr, Xe) with added amounts of O_3, $H_2S + O_2$, and $O_3 + H_2S$ at 8 K were irradiated with UV light. The successive warming up of the irradiated samples over the range 8–20 K led to the appearance of intense chemiluminescence in the visible region of the spectrum.

In the CL spectrum observed on warming an irradiated matrix containing ozone there was the Herzberg I system due to $O_2(A\,^3\Sigma_u^+ \rightarrow X\,^3\Sigma_g^-)$ emissions. This system (340–640 nm) was observed by Broida and Peyron[56] when they studied the luminescence of solid condensates from ultra-high frequency discharge in gaseous N_2 containing traces of oxygen. However, in contrast to Broida and Peyron, who postulated an excitation mechanism that included the transfer of energy from an electronically excited N_2 molecule, Smardzewski[90] considered that excitation of O_2 occurred as a result of diffusion and emissive recombination of oxygen atoms formed by photolysis of ozone:

$$O(^3P) + O(^3P) + M \rightarrow O_2(A\,^3\Sigma_u^+ \rightarrow X\,^3\Sigma_g^-) + M.$$

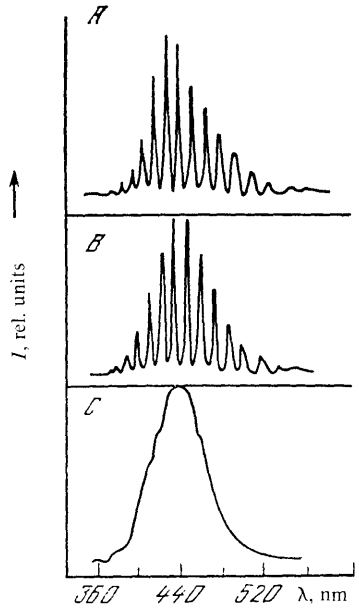

Figure 8. Chemiluminescence spectra observed on warming (from 8 to 13–15 K) H_2S-containing matrices subjected to UV-photolysis during their condensation at 8 K.[90] $M : H_2S = 100 : 1$; *A*, M = Ar; *B*, M = Kr; *C*, M = Xe.

By using different inert gases as matrices it was possible to study the effect of the matrix environment on the CL spectra. There could be two causes of such an effect—diffusion effects and the interaction of trace particles and atoms or molecules of the cryogenic matrix. In densely packed structures of solid inert gases, the dimensions of the interstices and vacancies increase with atomic weight. If the dimensions of trace particles having a low atomic (molecular) weight are comparable with the dimensions of the vacancies in the matrix, diffusion of such particles can take place at an appreciable rate.

It was shown,[90] in fact, that the $(A \rightarrow X)$ emitting system of O_2 molecules formed in an excited state by recombination of oxygen atoms has high intensity in solid argon, low intensity in krypton, and is not recorded at all in solid xenon. This was attributed to the fact that in matrices of heavy inert gases (Kr, Xe) the diffusion mobility of oxygen atoms is quite high even at the temperature of photolysis (8 K) so that even before the sample is warmed up the oxygen atoms have time to react with each other to give O_2 or O_3. Such an interpretation is consistent with an earlier study,[59] in which the radiative $(A\,^3\Sigma_u^+ \rightarrow X\,^3\Sigma_g^-)$ transition of molecular oxygen was observed during electron bombardment of Kr and Xe matrices containing O_2.

In experiments with matrices containing H_2S, Smardzewski[90] observed CL, the spectra of which are shown in Fig. 8. In the case of the Ar and Kr matrices, CL was due to $S_2(B\,^3\Sigma_u^- \rightarrow X\,^3\Sigma_g^-)$ emission in the region 365–560 nm. The same type of emission was observed[83,84] when photolysed Ar matrices containing OCS and CS_2 molecules were warmed up.

The recombination of sulphur atoms in the ground state was considered to be a fundamental part of the CL mechanism by both Smardzewski and other authors.[83,84] However, it was known from gas-phase studies that the $B\,^3\Sigma_u^-$ state of S_2 is not populated by direct reaction of two $S(^3P)$ atoms. In order to overcome this difficulty, it was assumed that when the $S(^3P)$ atoms recombine, S_2 is formed in the predissociative state 1_u, whose potential curve intersects the potential curve of the $B\,^3\Sigma_u^-$ state. The $B\,^3\Sigma_u^-$ state is then formed as a result of a nonradiative transition:

$$S(^3P) + S(^3P) \xrightarrow{M} S_2(1_u) \xrightarrow{M} S_2(B\,^3\Sigma_u^-,\ v' = 0).$$

The results of the study by Smardzewski[90] indicate that the effect of the matrix on the course of reactions involving recombination of O and S atoms varies substantially. In fact, the product of mass times radius of the sulphur atom is more than four times the corresponding value for an oxygen atom, and so naturally a lower mobility of S atoms compared to O atoms is to be expected. The diameter of the oxygen atom is ~1.2 Å, in other words, approximately equal to or slightly less than the average diameter of an interstice in solid krypton (1.28 Å) and considerably less than the corresponding distance in solid xenon (1.39 Å) at 4 K. The size of the sulphur atom (2.54 Å) and also its large mass impede the diffusion of the latter in all three matrices before the process of warming up the sample. Thus, the occurrence of chemiluminescence for S_2 and the absence of luminescence for O_2 in solid Xe is due to the different rate of diffusion of the S and O atoms in a Xe matrix at low temperatures.

Matrix effects of the second type, which are due to interaction of trace particles with the matrix material, are quite complex. Thus, in experiments concerned with studying CL in S_2 molecules, structured spectra were observed in Ar and Kr matrices, while for the Xe matrix an unexpected result was obtained—instead of a progression of sharp bands, the CL spectrum comprised a broad featureless band in the region 365–532 nm (Fig. 8, spectrum *C*).

Two possible causes of the broadening of the band were investigated.[90] One of these was fluorescence from vibrationally nonrelaxed states. In the Xe matrix, where the diameter of vacancies reaches 4.34 Å, two sulphur atoms could recombine on

warming the matrix to form an excited S_2 molecule, whose dimensions in the $B^3\Sigma_u^-$ state ($\sim$4.2 Å) would be less than the space occupied by a vacancy. If the radiative lifetime of such a particle is small, highly excited vibrational states ($v' \leqslant 9$) would not be attenuated and they would contribute to the emission spectrum. The absence of low-frequency bands and the short lifetime of S_2^* (45.0 $\pm$ 0.6 ns) are evidence for the possibility that $S_2(B^3\Sigma_u^- \rightarrow X^3\Sigma_g^-)$ fluorescence takes place at the same time as nonradiative vibrational relaxation. In this particular case, superposition of $(n + 1)$ Franck–Condon emission maxima from each of the excited v_n' levels would give a total effect of broadening the S_2 fluorescence into the blue region of the spectrum. In the case of Ar and Kr matrices, which have smaller diameters for vacancies amounting to 3.76 and 3.99 Å respectively, vibrationally excited states will be attenuated as a result of collisions.

The alternative explanation for the broadening of the fluorescence lines, as proposed by Smardzewski,[90] assumes the formation of an S_2^*–Xe Van der Waals complex.

The CL emitters and electronic transitions that are responsible for the emission of bands in the regions 490–870 and 385–600 nm on warming matrices containing sulphur and oxygen atoms were established by Tevault and Smardzewski.[91] It was found that luminescence was due to the transitions $c\,^1\Sigma^- \rightarrow a\,^1\Delta$ and $A'\,^3\Delta \rightarrow X^3\Sigma^-$ from SO molecules formed in reactions involving recombination of sulphur and oxygen atoms. The interpretation of the spectra was based on the results of experiments with $^{18}O_2$ and ^2H isotopes, which showed that the emitting molecule did not contain hydrogen atoms and had one oxygen atom. An optical multichannel analyser was used as the primary photodetector,[91] so that it was possible to follow several CL systems simultaneously over a practicable time-scale.

Lee and Pimentel[89] extended the spectroscopic range for observing CL caused by reactions involving sulphur atoms to the near IR region. In the CL spectrum observed over the range 8–44 K on warming photolysed Ar, Kr, and SF_6 matrices containing CS_2 and COS molecules, three progressions were recorded. The progression in the region 340–552 nm was due to the familiar[83,84,86,90] $B^3\Sigma_u^-$ $(B''\,^3\Pi_u) \rightarrow X^3\Sigma_g^-$ radiative transition of the S_2 molecule, while the two new bands in the regions 558–689 and 668–875 nm were identified as $A'\,^3\Delta_u \rightarrow X^3\Sigma_g^-$ and $c\,^1\Sigma_u^- \rightarrow a\,^1\Delta_g$ transitions respectively.

Fluorescence spectra and recombination emission of S_2 molecules, recorded on photolysis with light at $\lambda = 257.3$ nm (frequency doubled pulsed Ar^+ laser) of CS_2/Ar mixtures frozen at 15 K were observed by Hamaguchi and Tasumi.[92] These spectra contained two series of vibrational bands attributed to transitions of the S_2 molecule—$B^3\Sigma_u^- \rightarrow X^3\Sigma_g^-$ and $B''\,^3\Pi_u^- \rightarrow X^3\Sigma_g^-$. The excitation mechanism includes the primary photodissociation of CS_2 molecules:

$$CS_2 + h\nu \rightarrow CS\,(a\,^3\Pi) + S\,(^3P)$$

followed by a process involving recombination luminescence:

$$S\,(^3P) + S\,(^3P) \rightarrow S_2^*\,(B''\,^3\Pi_u) \rightarrow S_2\,(X\,^3\Sigma_g^-) + h\nu.$$

CL systems containing nitrogen oxides[93] and carbon oxides[94,95] have been detected. When a photolysed argon matrix containing NO_2 and O_2 molecules was warmed up, two emitting systems from NO_2 and O_2 were recorded. Irradiation at 7.5 K of an Ar matrix containing N_2O with light of wavelength 147 nm was accompanied by emission of Vegard–Kaplan bands of the N_2 molecule $(A\,^3\Sigma_u^+ \rightarrow X\,^1\Sigma_g^+)$ and fluorescence of oxygen atoms $(^1S \rightarrow {}^1D)$ and nitrogen atoms $(^2D \rightarrow {}^4S)$.[94] It follows from this that the primary processes in the photolysis of N_2O are:

$$N_2\,(X\,^1\Sigma_g^+) + O\,(^1S); \quad N_2\,(A\,^3\Sigma_u^+) + O\,(^3P);$$
$$NO\,(X\,^2\Pi_{1/2}) + N\,(^2D).$$

On warming the irradiated samples, starting at 9 K, CL, resulting from the recombination of oxygen atoms was recorded

$$O\,(^3P) + O\,(^3P) \rightarrow O_2\,(A\,^3\Sigma_u^+ \rightarrow X\,^3\Sigma_g^-).$$

Under the experimental conditions of the study,[94] the distance between the oxygen atoms was estimated to be 50 Å; it would be necessary for the oxygen atoms to complete about 170 random jumps in order to cover the space separating them and undergo reaction.

In the presence of CO the CL spectrum changes. Instead of a radiative O_2 transition, a continuum is recorded in the region 380–500 nm, due to emission of CO_2 molecules excited in the reaction

$$CO\,(X\,^1\Sigma^+) + O\,(^3P) \rightarrow C^*O_2\,(^3B_2 \rightarrow X\,^1\Sigma_g^+).$$

The photolysis of CO_2 in Ne, Ar, and Kr matrices at 4.5 K with UV light ($\lambda = 147$ nm) and the reactions occurring when the samples were subsequently warmed up were studied.[95] The CL spectrum consisted of four bands of an $O_2(A\,^3\Sigma_u^+ \rightarrow X^3\Sigma_g^-)$ Herzberg system, which were absent in the photoluminescence spectrum. It was shown that the recombination of $O(^3P)$ atoms on irradiation of CO_2 in solid Ar or Kr did not take place even when photolysis was carried out at 30 or 40 K. Increasing the temperature of the samples was a necessary condition. At the same time, in a Ne matrix the recombination of oxygen atoms, appearing as CL, took place under isothermal conditions even at 4.5 K. It was not possible to account for this behaviour on the basis of differing rigidities of the matrices since they are the same for Ne at 4.2 K and for Kr at 20 K. Fournier and co-workers[95] proposed a model according to which the oxygen atoms in the Ne matrix do not interact with the atoms of inert gas while in the case of Ar, Kr, and Xe matrices they are stabilised by formation of oxides of the respective inert gas.

The suggestion about the formation of Van der Waals complexes had been put forward previously,[96] when the luminescence stimulated by synchrotron irradiation was attributed to radiative transitions of ArO and KrO. The formation of XeO was detected in an argon matrix containing Xe, CO_2, or O_2 when it underwent UV photolysis with light at $\lambda = 121.5$ nm.[97] In the photoluminescence spectrum of a frozen mixture of Ar/Xe/CO_2, a system of bands was observed, corresponding to a XeO transition $(d^1\Sigma^+ \rightarrow a^1\Sigma^+)$ in the region 520–570 nm and Cameron bands due to CO.

The range of CL systems in cryogenic matrices is constantly expanding. There are interesting studies on the laboratory simulation of processes occurring in dust clouds in interstellar space. Studies of this type have theoretical importance for our understanding of chemical and prebiological evolution.[10] Thus, on warming argon matrices containing water vapour and/or ammonia which had been irradiated at 10 K with light from a hydrogen lamp ($\lambda = 150$–170 nm), CL from O_2, NO, N_2, and NH molecules was detected.[98] The occurrence of electronically excited diatomic molecules on warming the photolysed matrices for all cases except NH and the β-bands from NO was attributed to the diffusion and subsequent recombination of nitrogen and oxygen atoms in the

ground state. In similar experiments with $Ar/CH_4/H_2O$ mixtures, which also simulated the "dirty ice" on dust particles in dense nebulae, as well as an O_2 system in the CL spectrum, Cameron bands were observed, caused by $a^3\Pi \rightarrow X^1\Sigma^+$ transitions of CO, as were unidentified bands, which were later[99] identified as radiative $d^3\Pi_g \rightarrow a^3\Pi_u$ transitions from C_2 molecules.

There are many unresolved problems in the chemistry of atomic carbon, which is mainly due to the difficulty of obtaining C atoms and their high reactivity. The rate of a chemical process can be considerably reduced by cooling the reaction system. Krogh and co-workers[99] did precisely that, having used the method of matrix isolation to study the dynamics of reactions involving products from the UV photolysis of cyanazide. The highly active intermediates formed were identified from the results obtained using IR spectroscopy and low-temperature CL. The source of carbon atoms was NCN_3 which dissociated when photolysed. The first report about CL from warming an Ar matrix containing products from the photolysis of NCN_3 was produced by Milligan and co-workers,[100] who established that the primary product of the photodissociation of cyanazide is the NCN radical.

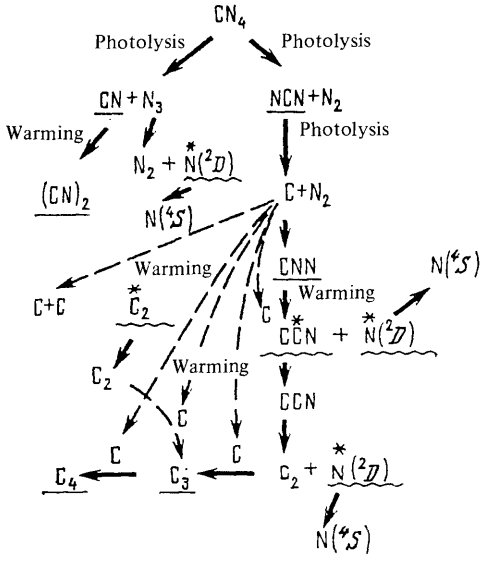

Figure 9. Mechanism for the reaction involving the photolysis products of NCN_3 in an argon matrix.[99] The data of IR measurements are emphasised with a straight line, the curved lines indicate the results obtained using an optical multichannel analyser.

In the CL spectrum[99] recorded using an optical multichannel analyser when a photolysed argon matrix containing NCN_3 was warmed up, 5 Swan bands from $C_2(d^3\Pi_g \rightarrow a^3\Pi_u)$ and bands due to emission by the CCN radical ($A^2\Delta_i \rightarrow X^2\Pi_i$) and the nitrogen atom ($^2D \rightarrow {}^4S$) were detected. It was shown that $N(^2D)$ atoms were mainly formed during thermal decomposition of N_3 radicals formed as a metastable cyclic isomer by photolysis. The reaction scheme occurring on photolysis of NCN_3 followed by warming of the matrix is depicted in Fig. 9. Krogh and co-workers[99] concluded that despite the complexity of the process, photolysis of cyanazide could serve as a powerful source of carbon atoms.

During the last ten years low-temperature solid-state chemiluminescence has been detected for several diatomic (O_2, S_2, CO, CS) and triatomic (NO_2, SO_2, CO_2, CCN) molecules which are formed as a result of the thermally induced diffusion and subsequent interaction of highly active particles stabilised in cryogenic matrices. There is a clear trend towards extending the CL method to study low-temperature reactions involving polyatomic molecules. The first results in this direction have already been obtained. Thus, in one study examined above[81] CL was detected in ethylene. Subsequently, when an Ar matrix which had undergone UV irradiation at 8 K and which contained diazomethane and oxygen was warmed up, CL was detected,[101] and in the spectrum two new progressions in the regions 310–360 and 390–490 nm were detected together with the known $O_2(A'^3\Delta_u \rightarrow X^3\Sigma_g^-)$ emission.

By analysing isotope shifts in experiments with $^{18}O_2$ it is possible to interpret the vibrational numbers v'' in two ways for both emission systems. The spectroscopic parameters obtained indicate that the observed progressions belong to the $a^3A'' \rightarrow X^1A'$ and $A'^1A' \rightarrow A^1A''$ transitions of the HCOOH molecule. This is the first observation (not only as luminescence but also when using any other methods of excitation) of such transitions in formic acid, whose molecules are excited in an argon matrix according to the reaction:

$$CH_2(^3B_1) + O_2(^3\Sigma_g^-) \rightarrow HCOOH.$$

In all of the previously examined reports on low-temperature CL in cryogenic matrices, reactions whose initial stage was recombination of radicals were studied. The recently discovered chemiluminescence of BaO, which is excited in the reactions

$$Ba + N_2O \rightarrow Ba^*O + N_2 \text{ and } Ba + O_3 \rightarrow Ba^*O + O_2,$$

presents a new class of CL reactions, with a mechanism that involves atom transfer.[88]

In the case of an argon matrix containing barium atoms and an oxidising agent (N_2O or O_3) a sharp increase in temperature of the sample is found when it is warmed up. Matrices containing Ba and N_2O (or O_3) at about 15 K warm up unexpectedly rapidly to 40 K, which results in evaporation of the sample. Chemiluminescence is usually recorded, starting at 8 K, then its intensity increases steadily as the temperature is raised. In the region 13–15 K a sharp increase in the intensity of luminescence occurs and the subsequent sudden jump in temperature of the sample is accompanied by an extremely bright emission. In the opinion of Pimentel and co-workers[102] the rapid rise in the temperature of the matrix is caused by decomposition of the unstable oxidising agents N_2O and O_3, catalysed by barium oxide or barium atoms.

Local warming and evaporation of even small sections of the matrix in such exothermic processes leads to a loss of vacuum in the space surrounding the sample and consequently results in warming and evaporation of the whole matrix. This phenomenon restricts the temperature region for recording CL spectra to 10–13 K. However, it transpired that emission spectra obtained during condensation of a sample were identical to the CL spectra from warming the matrix. Two molecular progressions of BaO with ν_{00} = 17 035 and 17 195 cm^{-1} and ω_e'' = 657 and 651 cm^{-1} were detected in the CL spectrum. They were related to radiative $\tilde{a}^3\Sigma^+ \rightarrow \tilde{X}^1\Sigma^+$ transitions of the BaO* molecule stabilised in different positions relative to the matrix environment. The possibility of an $\tilde{A}^1\Sigma^+ \rightarrow \tilde{X}^1\Sigma^+$ transition occurring was also not

ruled out. The proposed mechanism for excitation of BaO molecules involves population as a result of the chemical reactions of one or two singlet states ($\tilde{A}\,^1\Sigma^+$ and/or $\tilde{A}'\,^1\Pi$) followed by a rapid intercombination transition to the $\tilde{a}\,^3\Sigma^+$ state. The $(6s6p\,^1P) \rightarrow (6s^2\,^1S)$ radiative transition of the Ba atom was also observed. Excitation occurs by transfer of energy from the electronically excited BaO* molecule to a barium atom:

$$Ba^*O(\tilde{A}\,^1\Pi) + Ba(6s^2\,^1S) \rightarrow BaO(\tilde{X}\,^1\Sigma^+) + Ba^*(6s6p^1P).$$

There is a considerable difference between atom transfer reactions and radical recombination reactions. For the former the selection rules are less strict, which ensures the existence of several reaction pathways. In the case of a radical reaction the total excess of energy is concentrated in the excited product, while in an atom transfer reaction a redistribution of energy takes place between the products. The relaxation pathways of such excited products can be studied directly by CL.

V. Chemiluminescence in hydrocarbon matrices at 77 K and above

In addition to the investigation of CL reactions in cryogenic matrices, CL has also been studied in low-temperature systems. A series of studies has been published on CL occurring as a result of the interaction of a stream of active nitrogen on the surface of hydrocarbons frozen at 77 K.[103-103]

When the surface of frozen benzene, fluorobenzene, and chlorobenzene was treated with active nitrogen, Devolder[103,104] observed CL, with spectra that matched the phosphorescence spectra of benzonitrile, a mixture of the three isomers of fluorobenzonitrile, and an isomeric mixture of chlorobenzonitriles respectively.

Studies were also made on the CL spectra of polycrystalline benzene with added amounts of naphthalene, carbazole, acetonitrile, and benzaldehyde, for which the energy of the phosphorescent triplet state was lower than the corresponding energy for benzonitrile. The CL spectra observed were dependent on the concentration of the added components (guests). At high concentrations of guests ($\sim 10^{-1}$ M), only the phosphorescence spectrum of the guest was observed, whereas at low concentrations ($\sim 10^{-4}$ M), phosphorescence due to both the guest and benzonitrile was recorded. This indicates that the triplet states of the guests and benzonitrile are populated in concurrent processes and that the guest can play the role of quencher relative to the triplet state of benzonitrile. Since the intensity of CL proved to be proportional to the square of the concentration of $N(^4S)$ nitrogen atoms in a stream of active nitrogen and from the known fact that the $A\,^3\Sigma_u^+$ state of the N_2 molecule is a very effective energy donor the following two-stage mechanism for CL stimulation was proposed. Recombination of N atoms occurs on the cold surface of benzene with the formation of $N_2(A\,^3\Sigma_u^+)$ molecules in the triplet state followed by the transfer of energy to a phosphorescent state of the guest or to benzonitrile formed from benzene in a chemical reaction.

The initial studies[103,104] of CL reactions of active nitrogen with hydrocarbons were continued with a spectroscopic investigation.[105] The correlation of the CL spectra carried out in the earlier studies[103,104] was confirmed by the results of a parallel study of the reactions of active nitrogen with mixed polycrystals (an aromatic polycrystalline substrate activated with the corresponding benzonitrile derivatives). It was proposed that when benzonitrile is formed during reaction, a phenyl radical appears as an intermediate.

In another study[107] there is an investigation into the nature of the so-called delayed luminescence occurring as a result of the reaction between nitrogen and polycrystalline mixtures of aromatic compounds at 77 K. When hydrocarbons initially condensed on a cold surface are treated with a stream of active nitrogen, CL similar to that reported previously[103-105] is observed. If the supply of nitrogen is then cut off and a vacuum ($\sim 10^{-2}$ mm Hg) is created in the system, the luminescence diminishes exponentially for several minutes until a very low but still finite level is reached. This residual luminescence was called delayed luminescence by analogy with the very familiar delayed luminescence that occurs after ionisation of solids with UV or γ-radiation.

Three types of delayed luminescence were studied: isothermal luminescence at 77 K; isothermal luminescence stimulated by visible or IR light; and thermoluminescence.

The following mixtures (guest + matrix) were studied: naphthalene + benzene, naphthalene + benzene-d_6, acetonitrile + benzene-d_6, benzonitrile + fluorobenzene, *p*-cyanotoluene + toluene. It was found that the delayed luminescence spectrum matched the phosphorescence spectrum of the guest molecules.

When efficient electron acceptors—CCl_4 or benzyl chloride—were introduced into the sample, neither the intensity nor the composition of the CL spectrum obtained when active nitrogen was reacted with hydrocarbons changed, whereas the isothermal luminescence was very considerably reduced and the stimulated luminescence was not observed at all. The experimental results obtained were interpreted on the basis of ideas about the ionisation of mixed polycrystalline samples at 77 K during the primary reaction of active nitrogen with a cooled surface of hydrocarbons. Two possible mechanisms for chemiluminescence were proposed: either by energy transfer from high vibrational levels of $^3\Sigma_u^+$ nitrogen molecules to a high-energy triplet level (T_i) of molecules of the matrix (M) or guest (G):

$$N + N \rightarrow N_2(^3\Sigma_u^+, \text{high } \nu);$$
$$N_2(^3\Sigma_u^+, \text{high } \nu) + M \rightarrow N_2(^1\Sigma_g^+) + M(T_i)\ [\text{or } G(T_i)];$$
$$M(T_i)\ [\text{or } G(T_i)] \rightarrow M^+ (\text{or } G^+) + e^-,$$

or as a result of triplet-triplet annihilation of the guest with an $N_2(^3\Sigma_u^+)$ molecule which has relaxed to a state with low vibrational levels:

$$N_2(^3\Sigma_u^+, \text{low } \nu) + G(T_1) \rightarrow G^+ + e^- + N_2(^1\Sigma_g^+).$$

In a study by Devolder and co-workers,[107] together with the results already discussed in previous reports[103-106] there are additional data on the reactions of active nitrogen with hydrocarbons using chemiluminescence and EPR. It was established that the phase state of the matrix plays a substantial part in the mechanism for excitation of the triplet state in the guest. Thus, in polycrystalline matrices—both in aromatic (benzene, toluene, pyridine) and aliphatic (cyclohexane) matrices—the CL spectrum consists of phosphorescence from the guests (in the case of toluene, fluorescence from the benzyl radical was observed at the same time as phosphorescence from toluene). In vitreous matrices (ethanol, methylcyclohexane, isopentane) CL did not occur. In the EPR spectra mainly cyclohexadienyl-type radicals were detected.

The main difficulty in establishing the mechanism for the reaction of active nitrogen with organic compounds is principally connected with the existence of several reactive particles in active nitrogen generated by ultra-high frequency discharge in gaseous N_2. These particles are long-lived $N(^4S)$ atoms and $N_2(A\,^3\Sigma_u^+)$ molecules. There is one report[108] on a simple method for obtaining "pure" $N_2(A\,^3\Sigma_u^+)$ by passing active nitrogen through a trap filled with

liquid nitrogen. The removal of nitrogen atoms from $N_2(A^3\Sigma_u^+)$ is achieved in this method as a result of the recombination of the former on the cold surface of the trap. Dessaux[108] observed CL in the reaction of $N_2(A^3\Sigma_u^+)$ with benzene, chlorobenzene, and fluorobenzene at 77 K. The CL spectrum obtained in experiments with benzene matched the phosphorescence spectrum of benzene displaced to lower frequency, from which it was concluded that the CL emitter in this case is a charge transfer complex $N_2(A^3\Sigma_u^+)^{\pm} \ldots C_6H_6^{\mp}$.

This interpretation of the phenomenon was questioned by Mitsumori and Hiraoka.[109] They investigated the CL spectrum recorded at 77 K in reactions of $N_2(A^3\Sigma_u^+)$ with benzene and toluene, and also with given matrices containing biacetyl. If the luminescence emitter were the charged intermediate complex $N_2(A^3\Sigma_u^+)^{\pm} \ldots C_6H_6^{\mp}$ formed on the surface of solid benzene, as proposed by Dessaux, deactivation of its electronically excited state by energy transfer to guest molecules would be inefficient because of localisation of the complex in the benzene matrix. It was shown, however, that introduction of biacetyl into solid benzene substantially quenches the luminescence of pure benzene and leads to the appearance of characteristic phosphorescence from biacetyl.[109] This result indicates that there is migration of triplet excitation energy over a considerable distance in solid benzene. Mitsumori and Hiraoka[109] came to the conclusion that the CL accompanying the reaction of $N_2(A^3\Sigma_u^+)$ with solid benzene was caused by several products formed in the benzene matrix, possibly benzene isomers.

The absence of CL in reactions of $N_2(A^3\Sigma_u^+)$ with solid hexane or cyclohexane at 77 K and also the very weak (1000 times less than in benzene) phosphorescence of biacetyl (0.1 mol %) indicate either that there is no transfer of energy from $N_2(A^3\Sigma_u^+)$ to alkanes or that migration of triplet excitation energy does not occur in the solid matrices studied.

Chemiluminescence in a vitreous hydrocarbon matrix at temperatures above 77 K was first observed by Trozzolo and co-workers.[110] On warming a UV-irradiated glass containing diphenyldiazomethane and oxygen, emission of blue light was observed, with a spectrum that matched the phosphorescence spectrum of benzophenone. In samples that contained no oxygen, luminescence was absent. On the basis of the results obtained and also the fact that the matrices were warmed up several hours after irradiation, it was concluded that the observed luminescence belonged to CL accompanying the reaction of oxygen with the photolytically obtained diphenylmethylene. This CL reaction was observed on warming a 10^{-4} *M* solution of diphenyldiazomethane in 2-methyltetrahydrofuran which had been photolysed at 77 K.[111] Although the suggestion was made in these studies that the CL emitter was benzophenone in the triplet state, the CL spectrum was not published.

On freezing vitreous freon-113 (chosen because of the high solubility of oxygen in it) containing diphenylcarbene obtained photolytically at 77 K, Turro and co-workers[112] were the first to observe emission of light lasting 5–15 s which was visibie to the eye in a darkened room. Using an optical multichannel analyser it was established that CL occurs not only in the reaction between O_2 and diphenylcarbene but also in the oxidation of phenyltrifluoromethylcarbene or phenylchlorocarbene.

The CL spectrum corresponds qualitatively with the phosphorescence spectrum of the ketone which is a source of the carbene: benzophenone in the photolysis of diphenyldiazomethane, tetraphenyloxirane, 2,2,4,4-tetraphenyloxetanone, or diphenylketene; trifluoroacetophenone in the photolysis of phenyltrifluoromethyldiazirene; chlorobenzaldehyde in the photolysis of phenylchlorodiazirene. The CL spectra have an anomalous distribution of intensities of the components as compared with the photoluminescence of the corresponding ketones. The nature of this interesting phenomenon has not been determined, but in the opinion of Turro and co-workers[112] the rigid matrix of fluorocarbon glass, which inhibits the (0,0) transition because of the particular geometry of the chemically excited ketone, may be the cause.

It was established that CL may also occur at 77 K and not only when a vitreous matrix is warmed up.[112] This indicates that there is a low energy of activation for the process. It has been proposed that the reaction takes place via the formation (by a reaction between carbene and oxygen) of a $Ph_2C{=}O^+O^-$ Criegee intermediate, which reacts with oxygen to give the ketone (including that in an electronically excited state) and ozone. The latter has not been detected but is only postulated.

It was concluded[112] that CL from the reaction of carbenes with O_2 is a general phenomenon which does not depend on the multiplicity of the carbene or the source used to prepare it.

---o0o---

Thus, in the studies on low-temperature CL important results have been obtained on the mobility and reactivity of a number of atoms and molecules at very low temperatures. The ability to diffuse proved very high for nitrogen, oxygen, sulphur, carbon, and barium atoms in matrices of inert gases; even at 5–10 K they diffuse over a distance of several tens of Ångstroms within comparatively short intervals of time (minutes-tens of minutes).

The increased interest shown in recent years towards CL in cryogenic matrices is due to the possibility of obtaining unique information. This primarily relates to the spectroscopic identification of new electronically excited states which often cannot be observed by other methods. It should be noted that CL spectra in matrices of inert gases have a fine structure that is similar to the spectra of gas-phase luminescence. This feature of low-temperature solid-state CL makes it possible to determine the luminescence emitter and reaction pathway and energetics with great accuracy. Chemiluminescence provides information on the population of excited states and makes it possible to assess the most precise details of the elementary event of a reaction and also the effect of matrices of varying types on relaxation processes. Thus, studies on low-temperature CL make a considerable contribution to the understanding of the role of excitation in exothermic reactions in solid matrices.

Progress in the chemistry of thio derivatives of trivalent phosphorus acids

O G Sinyashin, E S Batyeva, A N Pudovik
Arbuzov Institute of Organic and Physical Chemistry, Kazan' Branch of the USSR Academy of Sciences, Kazan'

ABSTRACT. The methods for synthesising thio derivatives of P(III) acids and their chemical behaviour in substitution and addition reactions are examined.

The bibliography includes 199 references

Contents

I. Introduction 352
II. Synthesis 352
III. Chemical properties 356

I. Introduction

Thio derivatives of trivalent phosphorus acid (TTPA) have until recently remained one of the least studied classes of organophosphorus compounds. Although the first examples of this class of compounds were obtained more than 100 years ago, there were virtually no systematic studies of the chemical behaviour in their class for a long time. Only at the end of the 1950's and the beginning of the 1960's did TTPA start to attract more attention from research workers. This occurred because several TTPA were found to have practical application and continue to be of use as additives for lubricating oils,[1,2] stabilisers of polymeric materials,[3–6] heat-stable additives for organic products,[7,8] vulcanisation accelerators of rubbers,[9] etc. Moreover, with the discovery in the 1950's of the reaction between elemental phosphorus and disulphides,[10,11] the industrial synthesis of trialkyl phosphorotrithioites became a possibility. At the same time, the problem of finding ecologically preferable, 'chlorine-free' methods for synthesising various organophosphorus compounds based on phosphorotrithioites became important. Evidently the solution to these practical problems was not possible without a detailed study of the reactivity of TTPA.

By the mid-1970's investigations had been carried out on the synthesis and some chemical properties of esters and acid halides of P(III) thioacids had been studied, so that it was possible to find the first examples of the difference in chemical behaviour between TTPA and their oxygen analogues. These specific aspects of the chemistry of TTPA were partially covered in monographs[12,13] and a review[14] of that period and received the most attention in the review of Krasil'nikova,[15] which dealt with problems on the dual reaction of esters of P(III) thioacids with alkyl and acyl halides.

However, about 10 years has passed since it was published and during this time the chemistry of TTPA has undergone a new stage of development. Previously unknown classes and types of TTPA have been discovered, and an abundance of synthetic material has been collected on essentially new reactions involving TTPA, so it has been possible to establish the general mechanisms of these reactions. A wide range of physicochemical methods has been involved in structural and stereochemical studies of this class of compounds, which have recently been reviewed in a monograph.[16] Also at the present time it has become necessary to correlate and, as far as possible, classify the abundant and interesting material collected during the last few years in the world chemical literature.

In the review presented here, the findings of the last ten years, concerned with synthetic methods and properties of TTPA, have mainly been used.

II. Synthesis

By analysing the considerable flow of literature on the synthesis of TTPA, we have considered it practicable to limit ourselves to an examination of preparative methods based on those chemical conversions which lead to the formation of a P(III)–S bond in the molecule. The reactions which use trivalent phosphorus compounds that already contain a P(III)–S bond as starting materials will be examined when problems of the reactivity of the latter are discussed.

1. Synthesis based on elemental phosphorus

The direct synthesis of trialkyl phosphorotrithioites from elemental phosphorus and disulphides was developed back in the early 1950's:[10,11]

$$P_4+6RSSR\rightarrow 4(RS)_3P\,.$$

It was later shown[17,18] that phosphorotrithioites can be obtained in high yield by reaction of white phosphorus with thiols in the presence of sodium thiolate in CCl_4.

$$P_4+6RSH+6RSNa+6CCl_4\rightarrow 4(RS)_3P+6CHCl_3+6NaCl\,.$$

By using perfluorochloromethylsulphenyl chlorides in a reaction with elemental phosphorus it was possible to achieve the direct synthesis of perfluorochloromethyl phosphoromono- and phosphorodi-chloridothioites:[19]

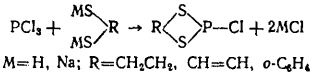
$$P_4+CF_nCl_{3-n}SCl\rightarrow(CF_nCl_{3-n}S)_xPCl_{3-x}+(CF_nCl_{3-n}S)_2$$
$x=1, 2$ when $n=1, 2$; $x=1-3$ when $n=3$.

However, up to the present time phosphorylation of sulphur-containing compounds has continued to remain the most common method for obtaining TTPA.

2. Phosphorylation of sulphur-containing compounds

In recent years this method has been developed on the one hand by improving the reactions of this type that were already known and on the other hand by modifying them through expanding the range of both phosphorylating agents and reactants being phosphorylated.

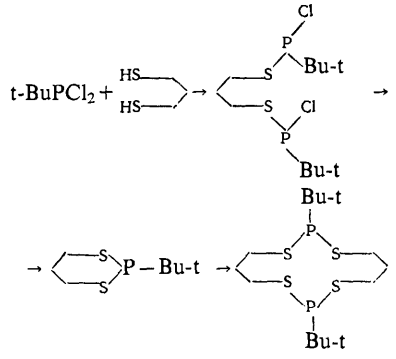
The most widely used process is the phosphorylation of metal thiolates[20,21] and thiols[21–26] with P(III) acid halides.



$$R_{3-n}PX_n + nR'SM \rightarrow R_{3-n}P(SR')_n + nMX$$

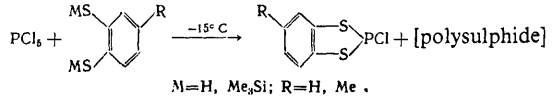
R = alkyl, aryl, RO, RS, Me_2N; X = Cl, Br, M = H, Na, Pb .

In the latter case a base is generally used, and in order to avoid an induction period in the reaction of P(III) halides with thiols it was proposed that the phosphorylation should be carried out in the presence of formamide[23] or other nitrogen-containing catalysts.[24]



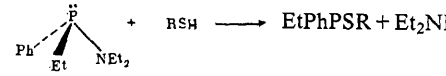
By using this reaction it was possible to obtain new types of bis-phosphorylated methylamines[27,28] and functionally substituted TTPA, including silicon-containing P(III) thioesters,[5,29,30] of γ- and ω-chloro-substituted phenylphosphonochloridothioites,[31] phosphorus(III)-containing dithiolothiadiazoles,[32] and *S*-phosphorylated derivatives of thioglycolic acid esters[33,34] and amides.[33]

By introducing *o*-dithiolobenzene, ethane- and *cis*-ethylene-dithiols, or their metal derivatives into a reaction with PCl_3, it was possible to synthesise a number of 1,3,2-dithiaphospholanes[35] and 1,3,2-dithiaphospholenes[36] containing an exocyclic P–Cl bond:



M = H, Na; R = CH_2CH_2, CH=CH, *o*-C_6H_4

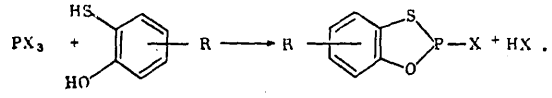
At the same time, it is necessary to use a base in order to obtain 1,3,2-dithiaphospholanes with a P–C bond.[37] In the absence of the former the reaction of t-butyldichlorophosphine with 1,3-propanedithiol results in the formation of a twelve-membered ring containing phosphorus and sulphur atoms together with 2-t-butyl-1,3,2-dithiaphosphorinane.[38] The process takes place via an intermediate acyclic product:



Recently[35,39] PCl_5 has also been used successfully as a phosphorylating agent for the synthesis of acyclic and cyclic TTPA:

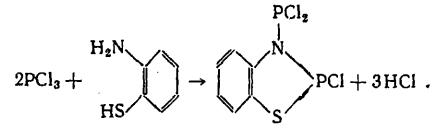
$$PCl_5 + (C_6F_5S)_2Pb \rightarrow [(C_6F_5S)_5P] \rightarrow (C_6F_5S)_3P + (C_6F_5S)_2$$

M = H, Me_3Si; R = H, Me .



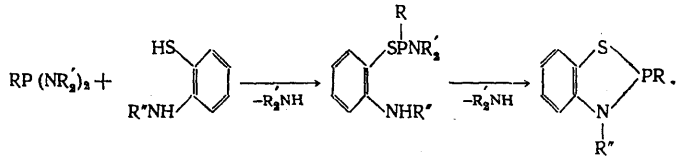
An attempt was made to utilise the phosphorylation of thiols with P(III) acid amides[40] in order to obtain optically active phosphinothioites.[40] However, when the optically active ethylphenylphosphinous diethylamide was treated with thiols, only the racemic thioester of this acid was formed:

When this reaction was extended to bis(trimethylsilyl) aminophosphine it was possible to synthesise the first example of a new class of TTPA—ethylthiophosphine:[41]

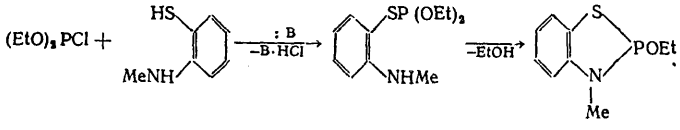


$$(Me_3Si)_2NPH_2 + EtSH \rightarrow EtSPH_2 + (Me_3Si)_2NH .$$

During the last ten years there has been a development of the phosphorylation of bifunctional reactants that have other proton-containing substituents in the molecule in addition to the thiol group; this is due to the growing interest of research workers in the chemistry of heterocycles. The reaction of phosphorus trihalides with certain 2-thiolophenols on heating gives the corresponding 2-halo-4,5-benzo-1,3,2-oxathiaphospholanes:[42,43]

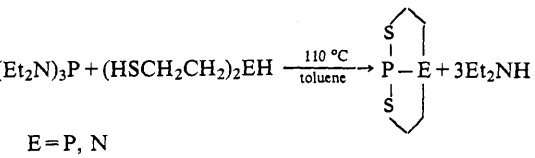


X = Cl, Br; R = H, alkyl, t-alkyl, OMe



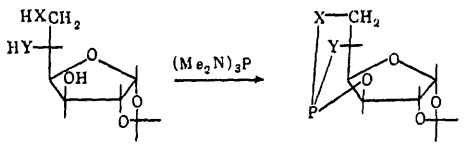
At the same time, attempts to synthesise 2-chloro-4,5-benzo-1,3,2-thiazaphospholane by phosphorylation of *o*-aminothiophenol with PCl_3 proved unsuccessful. In the presence of a base only a four-coordinate phosphorus derivative was isolated,[44] while in the absence of a base a halogenated *N*-phosphorylated 4,5-benzo-1,3,2-thiazaphospholane was formed:[45]

More successful was the use of alkyl- and aryl-phosphono-diamidites[46] and diethyl phosphorochloridite,[47] which made it possible to obtain a number of 1,3,2-thiazaphospholanes by reaction with *o*-aminothiophenol and its *N*-methyl derivative:



R = Me, Et, Ph; R′ = Me, Et; R″ = H, Me

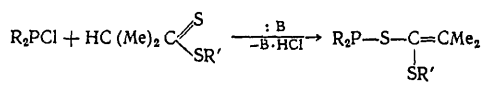
It should be noted that in most cases the process takes place via the formation of linear products which are phosphorylated on the thiol group. In this case the factors (structure of reactants, temperature, presence of acidic catalysts, etc.) that affect the formation of products with a linear structure as well as cyclisation products have been determined.[46,47]



The temperature conditions of the reaction also govern the ratio of *S*- and *N*-phosphorylation products formed by reaction of indole-3-thiols with P(III) acid amides and chlorides,[48,49] the thiol group of indole-3-thiols being more active in reactions with chlorides.[49]

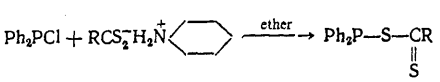
By using the reactions of polyfunctional compounds, in particular bis(β-thioloethyl)phosphine or bis(β-thioloethyl)amine, with triaminophosphine, a method has been developed for the preparation of bicyclic eight-membered heterocycles—2,8-dithia-1,5-diphospha- or 2,8-dithia-1-phospha-5-aza-bicyclo[3.3.0]octanes[50]

E = P, N



The reaction of thiolodeoxy-1,2-alkadiene-α-*D*-glucofuranose with PCl_3 [51] or hexamethyltriaminophosphine[52] was used for the synthesis of sugar bicyclophosphorothioites:

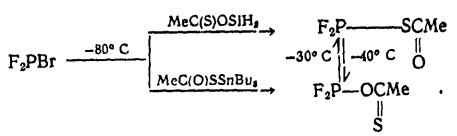
X = S, Y = O



X = O, Y = S .

Phosphorylation has also been widely used to obtain TTPA that contain electron-withdrawing substituents on the sulphur atom. Thus, because the high mobility of the α-hydrogen atoms in dithiocarboxylic acid esters makes it possible to phosphorylate the latter on the sulphur atom of the thiocarbonyl group, a method based on the reaction of P(III) acid chlorides with dithioisobutyrate esters in the presence of a base could be developed for the synthesi of the previously unknown vinyl phosphorothioites:[53,54]

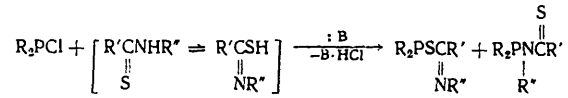
R = Cl, Et, EtO, Et_2N; R′ = Me, Et .



Piperidine salts of dithiocarboxylic acids proved to be convenient for the synthesis of the first examples of mixed anhydrides of diphenylphosphinothious acid and the respective dithiocarboxylic acid:[55]

R = Et, *p*-R′C_6H_4; R′ = Cl, Me, MeO.

These reactions were subsequently extended to dialkyl phosphorochloridites.[56]

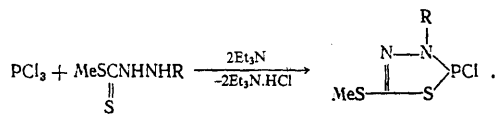


In a study of the phosphorylation of metal derivatives of thioacetic acid it was found[57] that *S*-acetyl phosphorodifluoridothioite is only formed when phosphorus difluorobromide reacts with the silyl ester of thioacetic acid at −80 °C:

At the same time, the reaction of phosphorus difluorobromide with tributylstannyl thioacetate gives the *O*-phosphorylation product—*O*-thioacetyl phosphorodifluoridite—which on heating to −30 °C is partially isomerised to *S*-acetyl phosphorodifluoridothioite.[57]

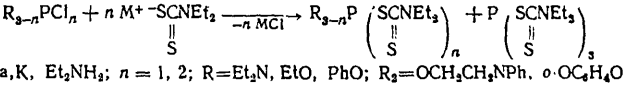
Phosphorylation of free thioacetic acid with PCl_5 only occurs on the sulphur atom and triacetyl phosphorotrithioite is formed.[58] The reaction of thioacetic acid with chlorophosphines in the presence of a base takes place in a similar manner.[58,59]

Taking into account the tendency of thiocarboxamides to form thiolimidoyl structures, studies were made of their phosphorylation with P(III) acid chlorides in the presence of a base.[60,61] While dialkyl phosphorochloridites react smoothly with thioacetamide to give only the *S*-phosphorylation product,[60] the reaction of diethyl phosphorochloridite with thiobenzoic acid *N*-methylamide gives *S*- and *N*-phosphorylation products in approximately equal proportions.[61] The phosphorylation of *N*,*N*′-diphenylthiourea occurs in a similar manner to that for the latter:[61]



R = EtO, PrO, Et_2N; R′ = Me, Ph, NHPh; R″ = H, Me, Ph .

Reaction of phosphorodiamidochloridite with thiobenzoic acid *N*-methylamide again gives an imidoyl phosphorothioite as the sole product.[61]

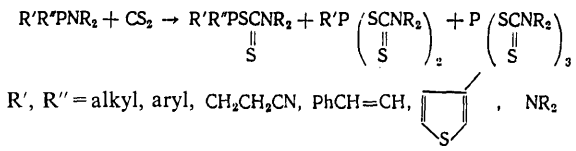


The products of *S*-phosphorylation-2-benzthiazolyl phosphorothioites—are also the only ones when Captax is reacted with trivalent phosphorus acid amides.[62]

Examples of new types of phosphorus-containing heterocycles—2-phenyl- and 2-acetyl-1-chloro-4-methylthio-1,5,2,3-phosphathiadiazoles—were synthesised by phosphorylation of the methyl esters of 3-substituted dithiocarbazic acids in the presence of triethylamine:[63]

R = Ph, MeCO

Treatment of alkali metal[64–66] or diethylammonium[66] *N*-diethyldithiocarbamates with P(III) acid chlorides gives phosphorylated derivatives of *N*-diethyldithiocarbamic acid:



M = Na, K, Et_2NH_2; *n* = 1, 2; R = Et_2N, EtO, PhO; R_2 = OCH_2CH_2NPh, *o*-OC_6H_4O

It should be noted that compounds with a single dithiocarbamate group were only obtained in the case of 2-chloro-3-phenyl-1,3,2-oxaphospholane.[65,66]

Phosphorylated derivatives of dithiocarbamic acid can also be synthesised by reaction of P(III) acid amides with carbon disulphide, as was reported in detail back in 1963.[67] At the beginning of the 1980's this reaction once again drew the attention of research workers because a number of phosphorylated dithiocarbamates obtained from it proved to be effective vulcanisation accelerators for rubbers with polyfunctional action.[68–71] By studying new types of acyclic P(III) acid amides in reactions with carbon disulphide it was possible on the one hand to extend considerably the range of organophosphorus compounds containing one, two, or three dithiocarbamate groups[65,66,69,70] and on the other hand to determine the factors (nature of substituents, ratio of initial reactants, presence of acidic catalysts, etc.)[66,72] affecting the rate and direction of

reaction as well as the structure of the products formed and the composition of the reaction mixture:

R′, R″ = alkyl, aryl, CH_2CH_2CN, PhCH=CH, , NR_2

R = alkyl, $R_2=(CH_2)_n$, $(CH_2CH_2)_2O$; $n = 4,5$.

In the case of cyclic phosphoramidites containing both an exo- and endo-cyclic P–N bond, carbon disulphide is inserted selectively into the exocyclic phosphorus–nitrogen bond.[64,65]

In the last ten years a whole series of studies has been published on the synthesis of TTPA containing the heterosystem P–S–E (E = Si, Ge, P), information about which was previously restricted to individual studies.[73,74]

The possibility of forming *S*-silyl esters of P(III) thioacids was shown[75] when the reactions of different silylphosphines with elemental sulphur dissolved in hydrocarbons were studied:

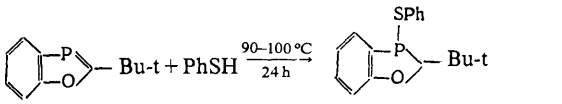
$$RR'PSiMe_3 \xrightarrow{[S]} RR'PSSiMe_3$$

R=R′=Me, Me_3Si; R=Me_3Si, R′=Me, $P(SiMe_3)_2$.

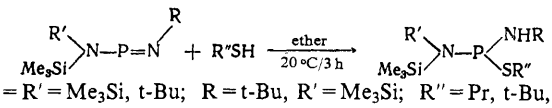
In a study of the reaction of *bis*(difluorophosphine) sulphide with chlorogermane, *S*′-germyl phosphorodifluoridothioite was obtained for the first time:[76]

$$(F_2P)_2S + ClGeH_3 \xrightarrow{20^\circ C} F_2P{-}S{-}GeH_3 + F_2PCl\ .$$

However, it is not possible to synthesise the *S*-silyl or *S*-stannyl analogues of the latter by phosphorylation of disilathiane or bis(tributylstannyl) sulphide with difluorohalophosphines due to the high rate of the second stage of the reaction, resulting in the formation of bis(difluorophosphine) sulphide:[77]



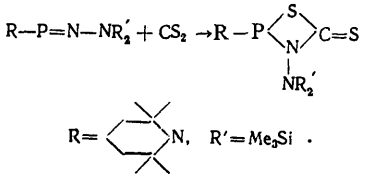
$$F_2PX + S(ER_3)_2 \xrightarrow[-XER_3]{} [F_2PSER_3] \xrightarrow[-XER_3]{F_2PX} F_2P{-}S{-}PF_2$$



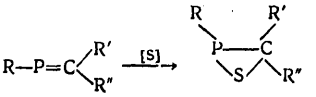
X = Cl, Br; E = Si, Sn; R = H, Bu.

Reaction of disilathiane with tetramethylphosphorodiamidochloridite also takes place in a similar manner.[78]

3. Synthesis of TTPA from bicoordinated phosphorus compounds



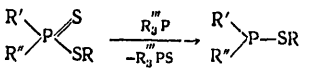
A new approach to the synthesis of previously unknown types of TTPA is opened up by the addition reactions of thiols to phosphaalkenes[79,80] and imidophosphenous acid amides:[81]



R = R′ = Me_3Si, t-Bu; R = t-Bu, R′ = Me_3Si; R″ = Pr, t-Bu, Ph.

It was possible to obtain a four-membered phosphorus-containing heterocycle by [2+2]-cycloaddition of carbon disulphide to 1-aminodiazaphosphene.[82]

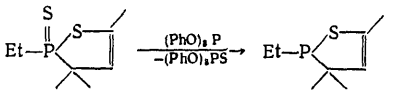
R= , R′ = Me_3Si .



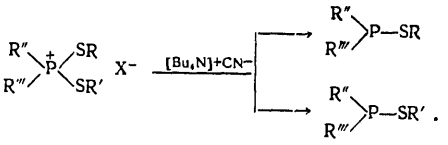
Certain phosphaalkenes reacted smoothly with sulphur by a [2+1]-cycloaddition to give the previously unknown 1,2-λ^3-thiaphosphiranes.[83,84]

R = $Me_3Si-C\equiv C$, R′ = R″ = Me_3Si; R = R″ = Bu-t, R′ = H.

4. Other methods for obtaining TTPA

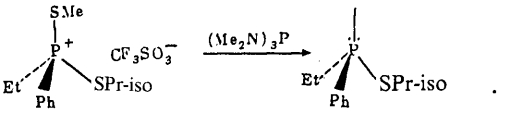


During the last ten years processes involving desulphurisation of four-coordinated phosphorus derivatives by treatment with tertiary phosphines and other P(III) derivatives have been used to an increasing extent for the synthesis of TTPA. Thus, the elimination of sulphur from phosphinodithioate esters,[85] including those that were optically active, with trialkylphosphines was successfully carried out, resulting in the isolation of the corresponding phosphinothioite esters:



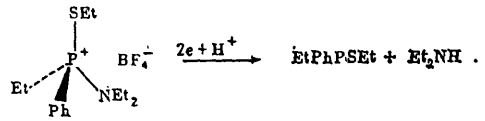
R = Me, R′ = R″ = Ph; R = *p*.$MeOC_6H_4$, R′ = Me, R″ = Ph; R‴ = Me, Bu .

However, optical activity cannot be retained in the reaction products due to the low pyramidal inversion barrier of phosphinothioites.[85]



By using triphenyl phosphite to reduce 3,3,5-trimethyl-2-thione-2-ethyl-1,2-thiaphosphol-4-ene it was possible to synthesise the corresponding phospholene with a tricoordinated phosphorus atom:[86]

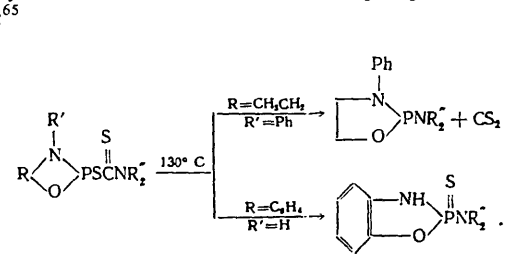
Phosphinothioite esters were obtained by P–S cyanolysis of quasiphosphonium salts containing an alkylthio group on the phosphorus atom:[87]



When this method was modified using hexamethyltriaminophosphine as the nucleophilic reagent it was possible to carry out the stereoselective synthesis of optically active phosphinothioites:[88]

For this reaction it was established in two studies[87,88] that, depending on the nature of the RS group, both its selective elimination giving only one phosphinothioite and the formation of a mixture of phosphinothioite esters were possible.

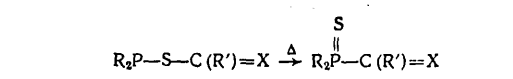
At the same time, electrochemical reduction of optically active ethylphenyl(diethylamino)ethythiophosphonium tetrafluoroborate in acetonitrile at 20 °C gives ethyl ethylphenylphosphinothioite that is optically inactive:[85]



The formation of alkyl phosphorodichloridothioite occurred[89] on decomposition of certain diazadiphosphetidines, and a number of diphenylphosphinothioite esters were obtained by thermal decomposition of phosphorylated semimercaptals,[90] being accelerated in the presence of acidic catalysts.

III. Chemical properties

At the beginning of the 1970's the chemical conversions of TTPA were studied in the greatest detail in the case of reactions with alkyl and acyl halides, and in the course of these studies dual reactivity of P(III) acid thioesters was found.[15] In the last ten years the range of both electrophilic and nucleophilic reagents has been considerably extended, so it has been possible to determine the general mechanisms governing the chemical behaviour of TTPA in substitution and addition reactions and to establish the differences between the reactivity of the system $\geq\ddot{P}-\ddot{S}$ and that of other ambident systems with a heteroatom (N, O) on trivalent phosphorus.



1. Thermal stability and isomerisation of TTPA
