Abstract. Data on the chemistry of strained tetrasubstituted alkenes with skeletal and polycyclic fragments are surveyed. A systematic account is given of information concerning the methods of their synthesis and data are presented on the deformation of their molecular geometry relative to the usual geometry. The characteristic features of the reactivity of skeletal compounds of this type are considered — the formation of unusual adducts and substitution products in reactions with electrophiles. The oxidation reactions of the alkenes are discussed and their value as starting materials for the synthesis of stable dioxetanes, which have found practical application as chemiluminescent labels and probes in immunology and molecular biology, is demonstrated. The bibliography includes 152 references.

I. Introduction

Effective routes to the synthesis of many organic substances proceed via reactions involving addition to alkenes, and this has been a permanent stimulus for the expansion of the available range of the latter. Each year there is a growth in the number of new and saturated compounds involved in practical organic synthesis; apart from the usual, unstrained alkenes, strained compounds are beginning to be used with increasing frequency in synthesis, including sterically hindered alkenes (SHA). The atoms involved in the SHA double bond have substituents comprising bulky groups or strained fragments shielding the bond. The presence of such substituents induces a steric strain in the molecule and can lead to definite structural deformations. The group of SHA includes substituted ethenes with branched alkyl substituents, polycyclanes, and skeletal compounds with an exocyclic double bond incorporated in a rigid polycyclic system as well as alkylidenepolycyclanes with bulky substituents in the side chain, and α-octamethyl-substituted cycloalkylidenecyclanes.

SHA occupy a special place in the chemistry of unsaturated compounds. They are less readily available than the usual alkenes and their synthesis therefore constitutes an independent synthetic problem. The reactivity of the shielded double bond in SHA differs significantly from that of the corresponding bond in the usual alkenes; the specificity of the reactions involving it is also different, especially in the case of skeletal SHA.

The unusual chemical properties of skeletal SHA have attracted considerable attention by investigators during the last decade. Nevertheless, the chemistry of SHA was not duly described in the review[1] devoted to strained organic molecules; its individual aspects (as regards the state in 1977) have been examined by Tidwell[2] in a review of sterically hindered molecules. Even in the familiar review of the chemistry of alkenes[3] as well as monographs[4,5] and reviews[6–8] devoted to the chemistry of skeletal compounds, very little attention has been devoted to the chemistry of SHA.

In the present review, an attempt is made to survey data on the synthesis, structure, and chemical properties of polycyclic and skeletal SHA with a tetra-substituted double bond and also the applications of the dioxetanes obtained from these compounds (in the discussion of the limits of the applicability of synthetic methods, of the degree of deformation of the molecules, and of the relative strain in SHA, data on aliphatic and aromatic compounds are quoted).

II. Methods of synthesis of sterically hindered alkenes

Only a few of the synthetic approaches known for the usual alkenes are used to obtain SHA. These are mainly methods which lead to the creation of the carbon skeleton with simultaneous introduction of the double bond; they are based on the dimerisation (coupling) of ketones or their derivatives. Numerous modifications of these methods, involving a transition to increasingly more reactive synthons, have expanded their possibilities and have made many SHA available.

Another route to strained alkenes of this type is via the Diels–Alder synthesis. Novel methods of synthesis, involving elimination, the use of sulfur-containing synthons, the participation of organometallic reagents, etc. have been proposed for individual SHA.

1. Synthesis of sterically hindered alkenes by the reductive coupling of ketones (the McMurry method)

Certain steric SHA with a symmetrical structure can be obtained in one stage by the McMurry reaction via the intermolecular reductive coupling of ketones under the influence of low-valence titanium reagents.[9–12] The latter are obtained in situ from $TiCl_3$ or $TiCl_4$ on treatment with reductants and are used in the

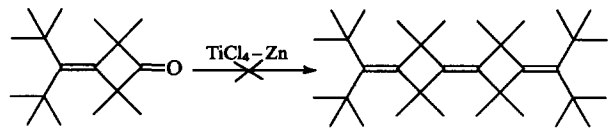
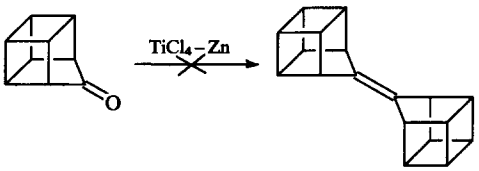
form of $TiCl_4-Zn$, $TiCl_3-K$, $TiCl_3-Li$, $TiCl_3-LiAlH_4$, etc. systems.†



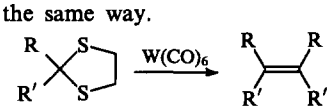
The tetraalkylethenes **1**–**7** and the polycyclic and skeletal alkenes **8**–**16** have been synthesised in this way. The reagents employed for the synthesis of the alkenes and the yield of the latter are presented in Table 1. It is seen from the table that the method is particularly effective for the synthesis of adamantylideneadamantane (2,2′-bisadamantylidene) **10**, for which an almost quantitative yield has been achieved. The yield of other SHA depends significantly on the extent to which the double bond is sterically hindered, diminishing with increasing branching of the substituents at the bond itself (tetrasubstituted ethenes) or following the introduction of alkyl substituents in the α-position relative to the bond (dialkyladamantylideneadamantanes). The choice of the system as a whole — the nature of the reductant and the solvent — has a significant influence on the yield of the SHA. This can be seen in relation to 1,1,2,2-tetraisopropylethene **1** and adamantylideneadamantane **10**. High stereoselectivity — the formation of only the *trans*-isomer — is characteristic of reactions leading to dimethyladamantylideneadamantane **11** and diethyladamantylideneadamantane **12**. The ratio of the (*E*)- and (*Z*)-isomers of 1,2,-di-*tert*-butyl-1,2 dimethylene **3** depends on the nature of the reductant.



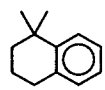
The limitations of the method are associated mainly with the difficulty of the introduction into the reductive coupling reaction of ketones with branched alkyl substituents — *tert*-butyl isopropyl ketone, di-*tert*-butyl ketone, *tert*-butyl neopentyl ketone,[16] and also 3-(di-*tert*-butylmethylene)-2,2,4,4-tetramethylcyclobutanone **17**.[31]

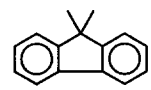
The attempt to achieve the single-stage synthesis of the diskeletal alkene **18** from homocubanone was unsuccessful.[32]

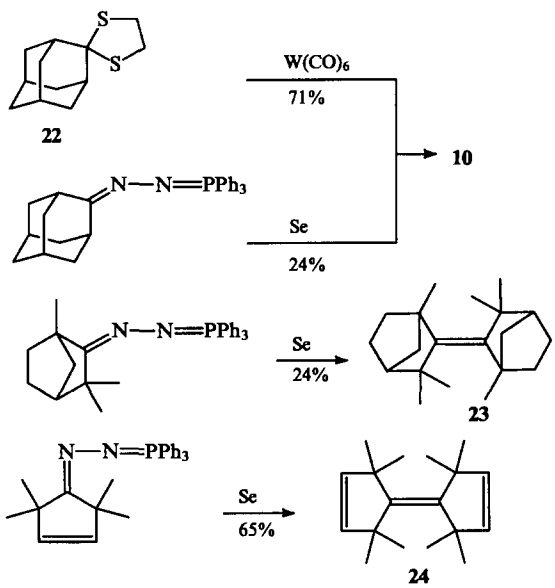
† Various aspects of the preparation of these reagents, the mechanisms of their action, and their applications in organic synthesis have been described in Lenoir's review.[13]



17





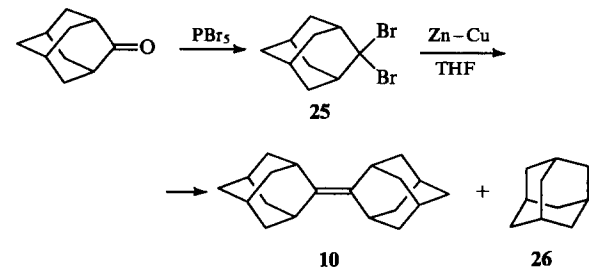


18

Together with the reductive coupling of the ketones themselves, examples of similar reactions have been described for the thio- and seleno-derivatives. Thus the desulfurisation of aromatic dithioketals by $W(CO)_6$ leads to the corresponding alkenes **19–21**, while the analogous reaction of the adamantanone dithioketal **22** affords adamantylideneadamantane **10**.[33] The latter has also been obtained in the reaction of adamantanone triphenylphosphorylidenehydrazone with selenium. Fenchylidenefenchane **23** [34] and 1,1′-bis(2,2,5,5-tetramethylcyclopent-3-enylidene) **24** [35,36] have been synthesised in the same way.

19–21

R, R′ = Ph, Me (**19**);  (**20**);  (**21**)

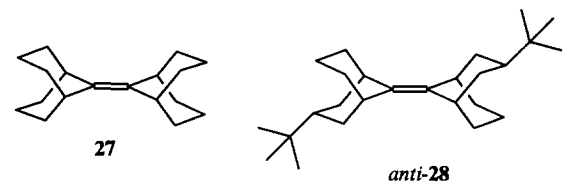


22

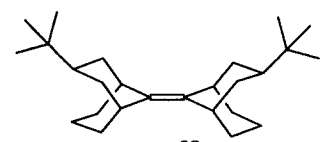
23

24

2. The 'carbenoid' method of synthesis of sterically hindered alkenes



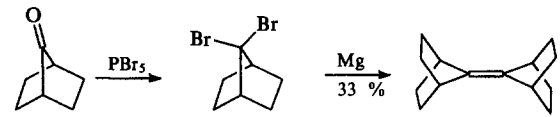
The synthesis of one of the best known SHA—the alkene **10**—from adamantanone via 2,2-dibromoadamantane **25** with subsequent debromination of the latter by the zinc–copper couple has been proposed by Geluk.[37] This method was used widely for a long time as a preparative procedure. The low yield of adamantylideneadamantane (60%–75%) owing to the side reaction **25**→**26** in the second stage and the need for the numerous repetitions of this stage must be regarded as its disadvantages. The yield of the target product depends on the quality of the zinc and the activity of the zinc–copper couple. Subsequently this method came to be called the 'carbenoid' method.



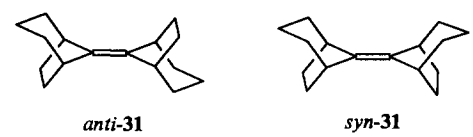
25

10 26

Bis(bicyclo[3.3.1]non-9-ylidene) **27** as well as its di-*tert*-butyl derivative **28** have been synthesised similarly in the form of a mixture of two stereoisomers.[39]

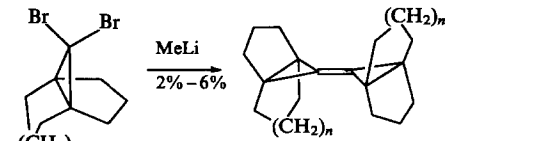


27 *anti*-**28**

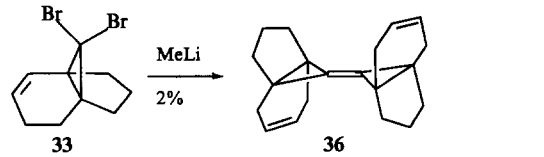


syn-**28**

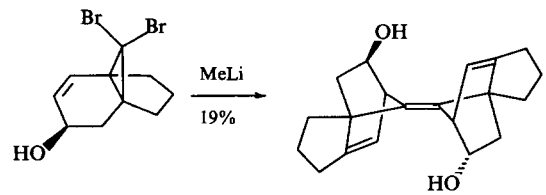
The use of magnesium instead of the zinc–copper couple made it possible to increase the yield of the alkene **10** to 83%.[40] Bis(bicyclo[2.2.1]hept-7-ylidene) **30** [40] and bis(bicyclo[3.2.1]oct-8-ylidene) **31** have been synthesised in the same way in the form of a mixture of the *syn*- and *anti*-isomers.[41]



29 30

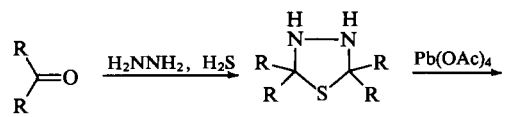


anti-**31** *syn*-**31**

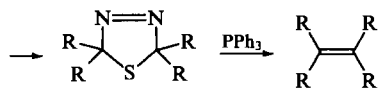


The SHA **35–37** are formed as side products (2%–19%) in the reactions of MeLi with *gem*-dibromo-substituted tricyclanes and tricyclenes with the propellane structure. The carbene dimers **35a, b** and **36** with fragments of the initial propellane structure have been obtained from the corresponding dibromo-derivatives **32a, b** and **33**, while the dimer **37** with a rearranged structure has been synthesised from the dibromo-derivative **34**. The structure of the dimer **37** has been confirmed by X-ray diffraction.[42,43]

32a, b **35a, b** *n* = 1 (**a**), 2 (**b**)



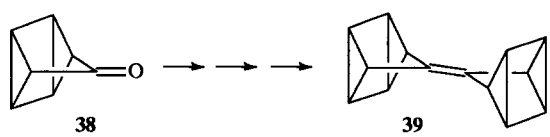
33 36



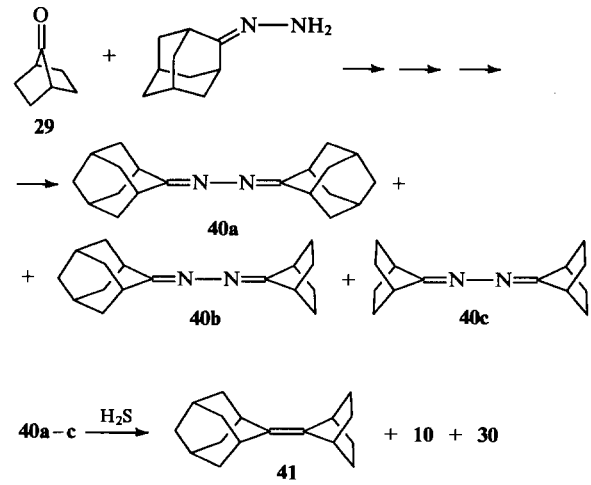
34 37

3. Double elimination (the thia- and selena-diazoline method) in the synthesis of sterically hindered alkenes

The thiadiazoline method has been used to obtain a series of asymmetric and strained symmetrical SHA. The method is based on the double elimination principle proposed by Barton and Willis[44] — the elimination of nitrogen and sulfur from synthons having the general formula **B**.[44]

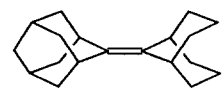


A



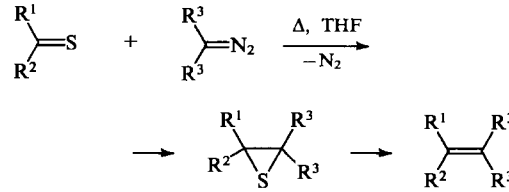
B

In the version proposed initially, the thiadiazolidine **A** was obtained from the corresponding ketone by treatment with hydrazine or H_2S (or as a result of the treatment of an azine by the latter). The oxidation of compound **A** by $Pb(OAc)_4$ led to Δ^3-1,3,4-thiadiazoline **B** and the latter was converted by treatment with PPh_3 into the alkene. Bisquadricyclene **39** has been synthesised[45] by this procedure from the ketone **38** as well as a series of symmetrical alkenes: the yield of the alkene **10**, obtained by the thiadiazoline method, is then the same as that of the products synthesised by the carbenoid method,[46] while the yield of the alkenes **27**, **28**, and **30** is significantly lower.[39]



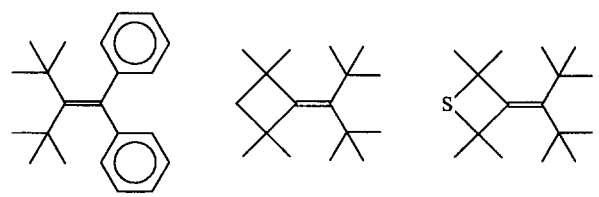
38 **39**

The use of the thiadiazoline method in order to obtain asymmetric alkenes has been demonstrated in relation to bicyclo[2.2.1]heptylideneadamantane.[41] The mixture of the azines **40a–c** formed on interaction of the ketone **29** with adamantanone hydrazone was treated with hydrogen sulfide and then oxidised and subjected to the elimination reaction. The alkene **41** was isolated by preparative gas–liquid chromatography (GLC) from its mixture with the alkenes **10** and **30**.

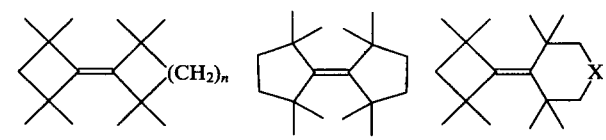


41

Bicyclo[3.3.1]nonylideneadamantane **42** has been obtained similarly.[39]

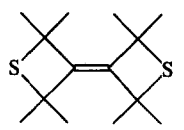


42

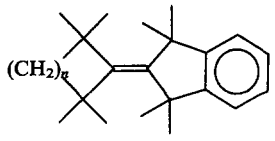


Certain more hindered asymmetric alkenes, which could not be obtained in accordance with the scheme indicated above, have been synthesised via a two-stage version in which a thione and a diazo-compound were used as synthons.[47]

The strained di-*tert*-butyldiphenylethene **43** has been obtained by this procedure from di-*tert*-butyl thioketone and diphenyldiazomethane (or from thiobenzophenone and di-*tert*-butyldiazomethane).[48] This route proved to be effective also for the synthesis of strained SHA such as 1,1,2,2-tetra(methylcyclopropyl)ethene **6**,[49] 2-(di-*tert*-butylmethylene)-1,1,3,3-tetramethylcyclobutane **44** and its thia-analogue **45**,[50] the keto-alkene **17**,[31] the octamethylbicycloalkylidenes **46–50** and their hetero-analogues **51–53**, the cycloalkylideneindans **54** and **55**, the triene **24**,[52,53] cyclobutylidene-Δ^1-pyrazoline **56**, and di(Δ^1-pyrazolylidene) **57**.[54,55]

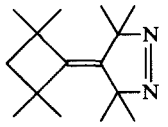


43 **44** **45**

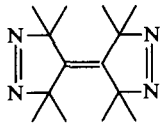


46–49 **50** **51, 52**

n = 1 (**46**), 2(**47**), 3(**48**), 4(**49**)

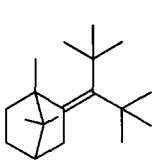


51: X = S,
52: X = O

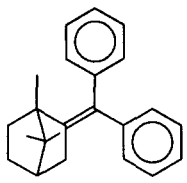


53

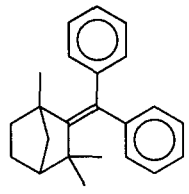
54, 55
54: n = 1,
55: n = 2



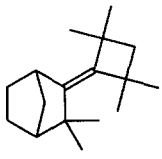
56



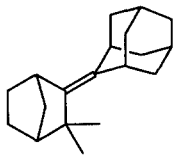
57



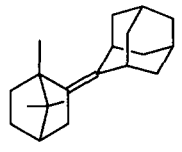
Di-*tert*-butylmethylenecamphane **58** has been obtained by means of this two-stage scheme from (±)-thiocamphor and di-*tert*-butyldiazomethane, while (±)-diphenylmethylenecamphane **59** has been obtained from the same thione and diphenyldiazomethane.[47] (±)-2-Diphenylmethylenefenchane **60**[48] and its individual (+)- and (−)-forms[47] as well as camphenylidenetetramethylcyclobutane **61**, camphenylideneadamantane **62**, adamantylidenecamphane **63**, camphenylidenecamphenylene **64**,[56] and the alkene **23**[52,53] have been synthesised similarly.



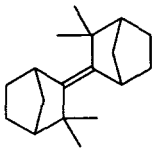
58



59

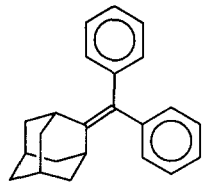


60

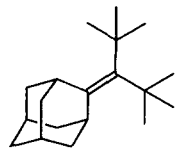


61

62

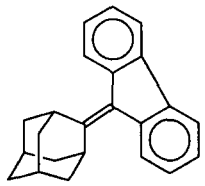


63

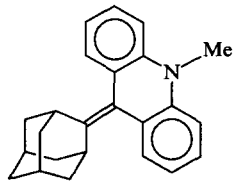


64

A series of methyleneadamantanes such as diphenylmethyleneadamantane **65**[57] and di(*tert*-butylmethylene)adamantane **66**,[58] adamantylidenefluorene **67**,[58] and adamantylidene-*N*-methylacridine **68** have been synthesised in accordance with the same scheme.[59]

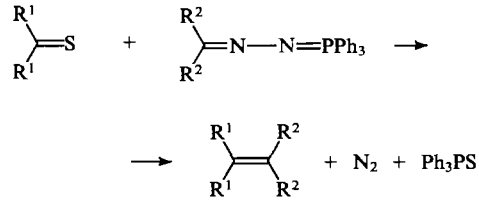


The preparation of the adamantane **66** in the thiadiazoline decomposition stage is complicated by the formation of adamantylideneadamantane **10**, the content of which in a mixture with the adamantane **66** reaches 53%.

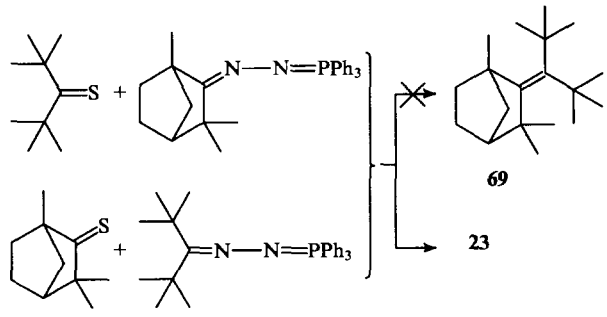


65

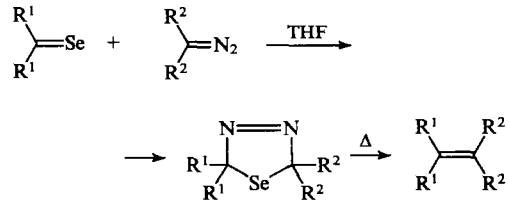
66



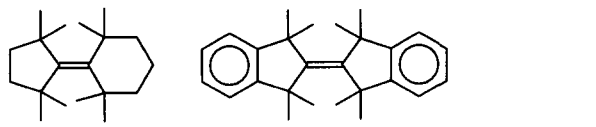
67



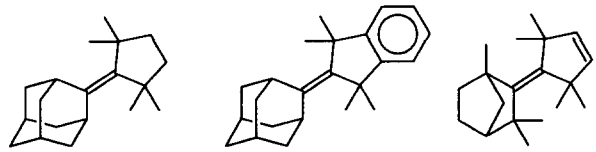
68



The possibility of using phosphorylidenehydrazones instead of diazo-compounds in the reactions considered has been demonstrated in the synthesis of the alkenes **58**–**60**. This version makes it possible to obtain the alkenes **58**–**60** in one stage but the yield of the product is then lower than in the two stage synthesis via diazo-compounds.[47]

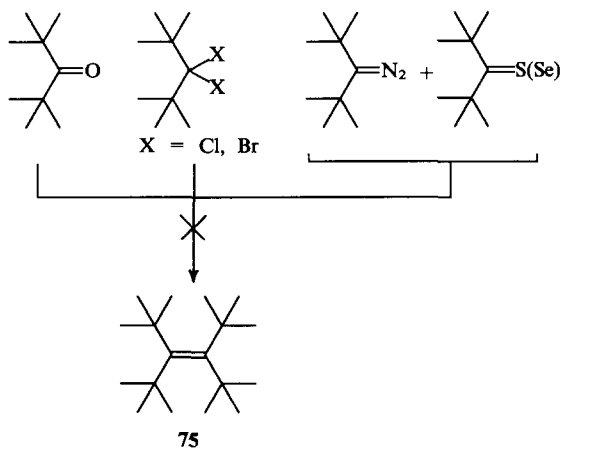


The attempts to obtain the strained di-*tert*-butylmethylenefenchane **69** in this way were unsuccessful and only the alkene **23** was isolated.[47]



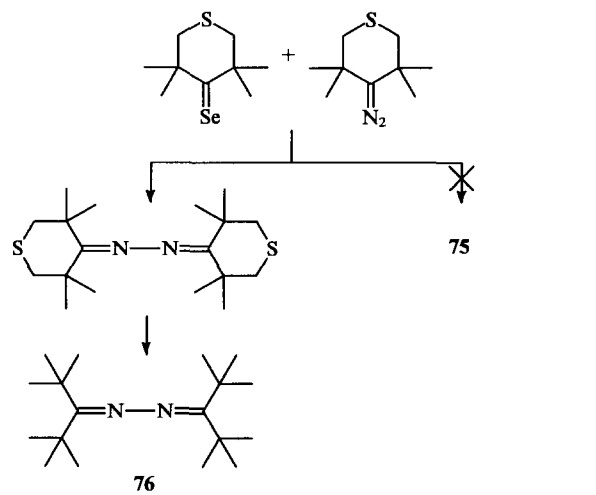
The selenadiazoline method proved to be effective for the synthesis of a series of SHA which could not be obtained by the thiadiazoline procedure. The corresponding thia- and selenadiazolines are formed under the same conditions. More severe conditions are necessary for the synthesis of the alkene **42** from the thiadiazoline than for its synthesis from the selena-analogue.[60]

The alkene **24**,[36] the octamethylbicycloalkylidenes **70** and **71**,[51] and the adamantane-containing alkenes **72** and **73**[39] have been synthesised by means of the selenadiazoline method. The preparation of 1,1'-bis(2,2,5,5-tetramethylcyclopent-3-enylidene)fenchane **74** by the procedure indicated is complicated by the formation of side products (60%) — the alkene **23** and the triene **24**.[36]

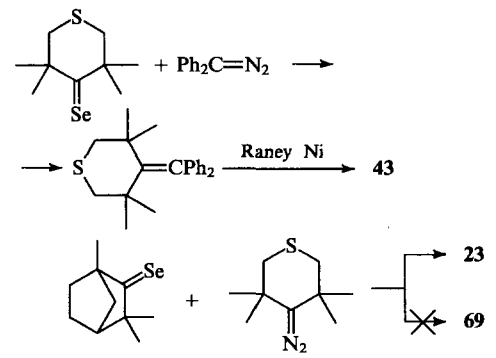


70 **71**

72 **73** **74**



However, the attempt to obtain strained tetra-*tert*-butylethene **75** by the methods indicated above proved unsuccessful.[36,47,48,51,52] The alkene **75** could not be synthesised by the photolytic decomposition of di-*tert*-butyldiazomethane either.[61]

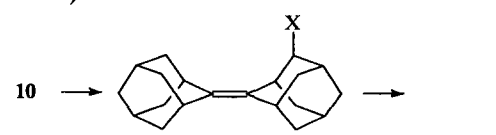


75

The unusual strategy combining the selenadiazoline method and the use of sulfur-containing synthons (synthons bound 'from the rear') also failed to afford the alkene **75**: instead of alkene **75**, the di-*tert*-butyl ketone azine **76** was isolated. This approach had been used successfully in a previous synthesis of the alkene **43**.

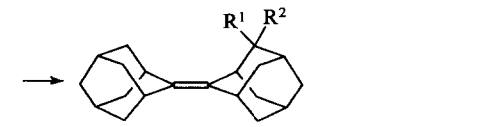
The sterically hindered alkene **69** could not be synthesised by this procedure either and the alkene **23** was obtained instead.[62]

76



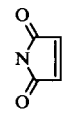
Thus the synthesis of compound **75** still remains an attractive and hitherto unattained aim.

4. Syntheses as a result of the modification of sterically hindered alkenes

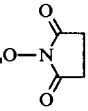


Certain alkenes, which can be obtained by the methods examined above, served in their turn as precursors in the synthesis of more strained SHA. Thus a series of 4-substituted adamantylideneadamantanes have been obtained from adamantylideneadamantane **10** in accordance with schemes involving the halogenation of the alkene **10** with formation of 4*e*-haloketenes **77** and **78**[63,64–67] and further synthetic transformations in the side chains. The ketoalkene **79**[63] and the maleimido-derivatives **80**, **81a–c**, and **82** have been obtained in this way (see Scheme 1).[68]

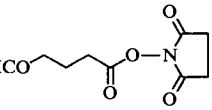
Scheme 1



77–78

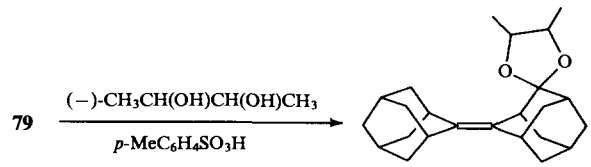


X = Cl (**77**), Br (**78**)



79–82

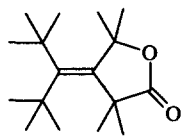
79: $R^1 + R^2 = O$;



80: R^1 =  , R^2 = H;

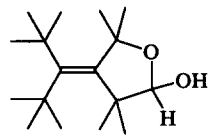
81a–c: $R^1 = OCO(CH_2)_nO-$  , R^2 = H;

n = 2 (**a**), 3 (**b**), 4 (**c**)



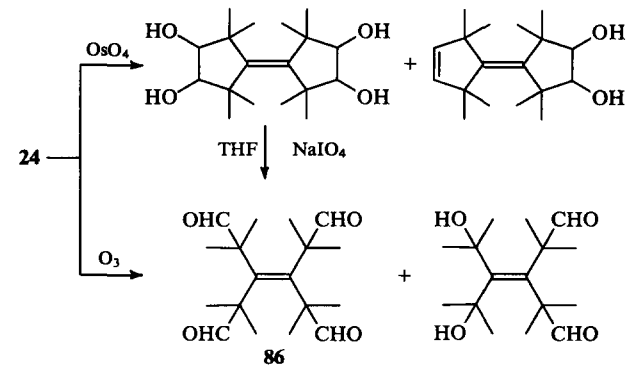
82: R^1 = NHCO  , R^2 = H.

A mixture of the diastereoisomeric ketals (+)-**83** and (−)-**83** has been synthesised from the ketalkene **79** and the optically active pure (−)-butane-2,3-diol. The ketal (−)-**83** was isolated from this mixture with 95% purity.[69]

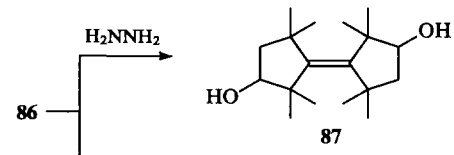


(+)-**83**, (−)-**83**

Highly strained di-*tert*-butylalkenes with lactone (compound **84**) and lactol (compound **85**) fragments have been obtained from the ketoalkene **17** via ring expansion reactions.[31]

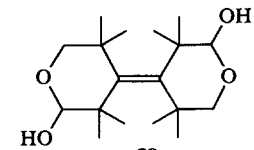


84



85

In the search for approaches to the hypothetical alkene **75**, the triene **24** has been used as the synthon. The triene was converted into the tetraaldehyde **86** by ozonolysis or hydroxylation with subsequent oxidative ring opening. The attempts to convert the tetraaldehyde **86** into the alkene **75** were unsuccessful and only the dilactol **87** and the diol **88** were obtained.[52,53]



A series of SHA without quadricyclane fragments have been obtained from bisquadricyclylidene **39**. The transformation of one or both quadricyclane fragments into methylenenorbornene fragments was achieved via the diene synthesis reaction employing dienophiles such as dimethyl ethynedicarboxylate [acetylenedicarboxylate (DEAC)], dicyanoethyne, maleic anhydride, vinylidene carbonate, and dimethyl azodicarboxylate (see Scheme 2). The 1:1 adducts **89–92** and the 2:1 adducts **93–98** obtained constitute two new structural types of SHA. In addition, SHA of a third structural type (compound **99**) can be obtained from the 1 : 1 adducts as a result of the isomerisation of the quadricyclane fragment to the norbornadiene fragment.[70]

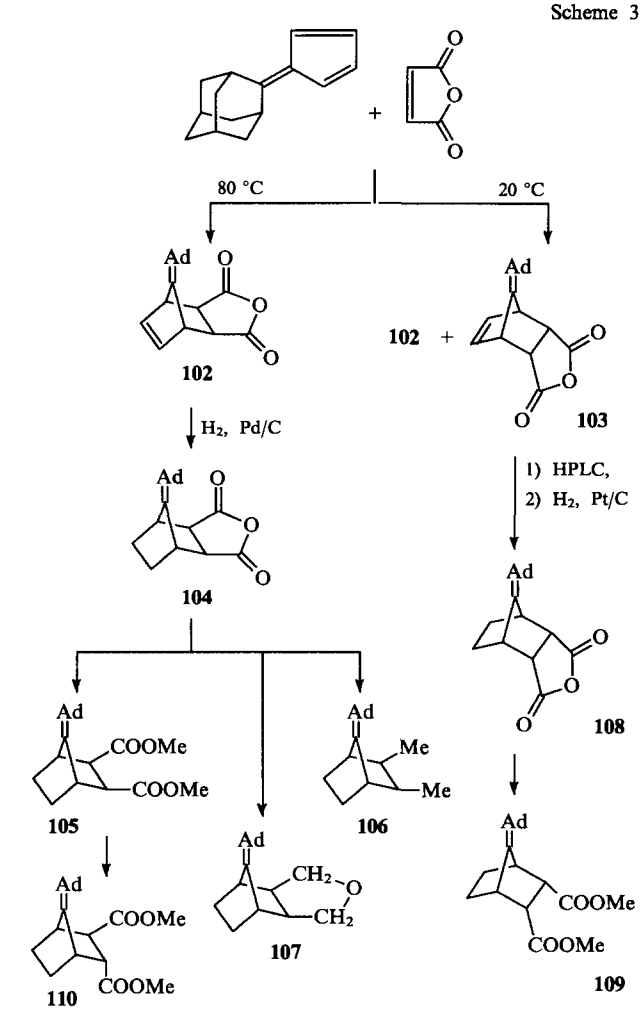
Scheme 2

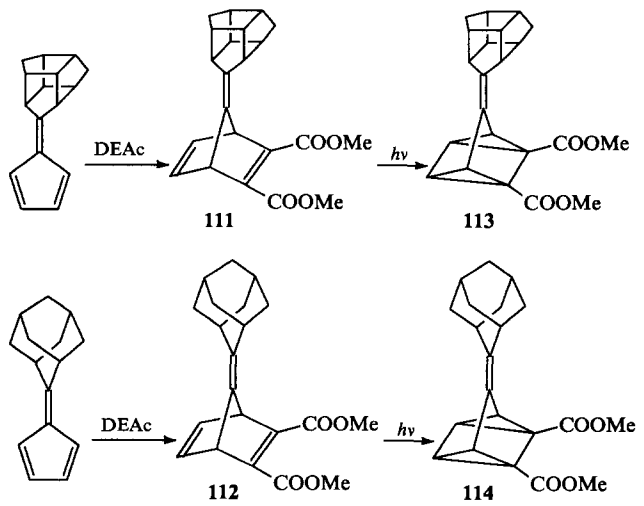
5. Sterically hindered alkenes obtained by diene synthesis with participation of 1,3-dienes and fulvenes

The syntheses of SHA based on the diene synthesis reactions of cyclo-1,3-dienes and skeletal fulvenes with various dienophiles are considered in this subsection. *syn*-Sesquinorbornene **100** and *anti*-sesquinorbornene **101** have been obtained in this way. The scheme for the synthesis of the norbornene **100** includes the stereospecific cycloaddition of phenyl vinyl sulfone to isobicyclopentadiene and the subsequent reductive desulfonation of the adduct.[71,72] The alkene **101** was synthesised by the cycloaddition of cyclopentadiene to the anhydride of norbornenedicarboxylic acid and the subsequent hydrogenation and decarboxylation of the adduct.[73]

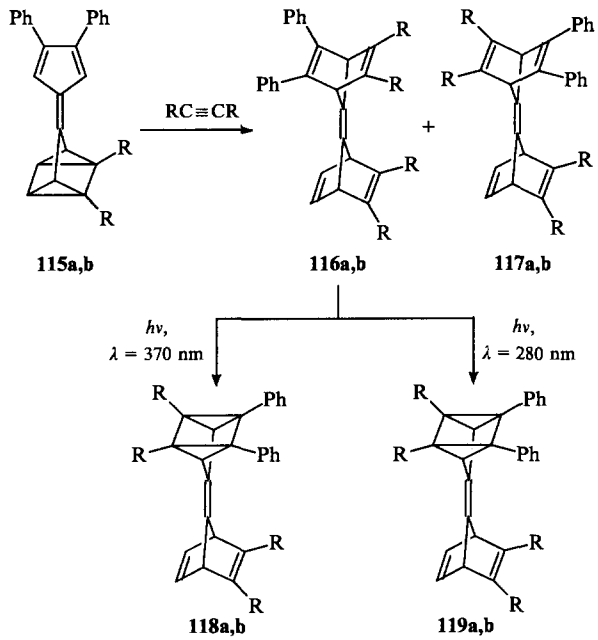


The second group of SHA which can be obtained by diene synthesis comprises asymmetric alkenes with functional-group substituents and an exocyclic double bond incorporated in the polycyclic and skeletal fragments. These compounds are obtained from skeletal fulvenes. When maleic anhydride is used as the dienophile, the monocyclic fragment in the above fulvenes is built up to the norbornene fragment and when the dienophile is DEAC or hexafluorodimethylethyne, it is built up to the norbornadiene fragment. Further synthetic transformations of the adducts (hydrogenation, photocyclisation) make it possible to achieve a transition to SHA with norbornane and quadricyclane fragments respectively.

A series of isomeric 2,3-disubstituted 7-adamantylidenenorbornanes have been obtained in accordance with the scheme involving the diene synthesis reaction of cyclopentadienylideneadamantane with maleic anhydride (Scheme 3). The *exo, exo*-adduct **102** is formed at 80 °C, while a mixture of the *exo, exo*- and *endo, endo*-isomers **102** and **103** in proportions of 1 : 1 is produced at 20 °C. Subsequently, the *endo, endo*-isomer is isolated from the mixture. The alkenes **104**–**107** can be obtained from the *exo, exo*-adducts as a result of appropriate synthetic transformations, while the alkenes **108** and **109** can be formed from the *endo, endo*-adducts. The isomerisation of the *exo, exo*-diester **105** leads to the formation of the *exo, endo*-diester **110**.[74]

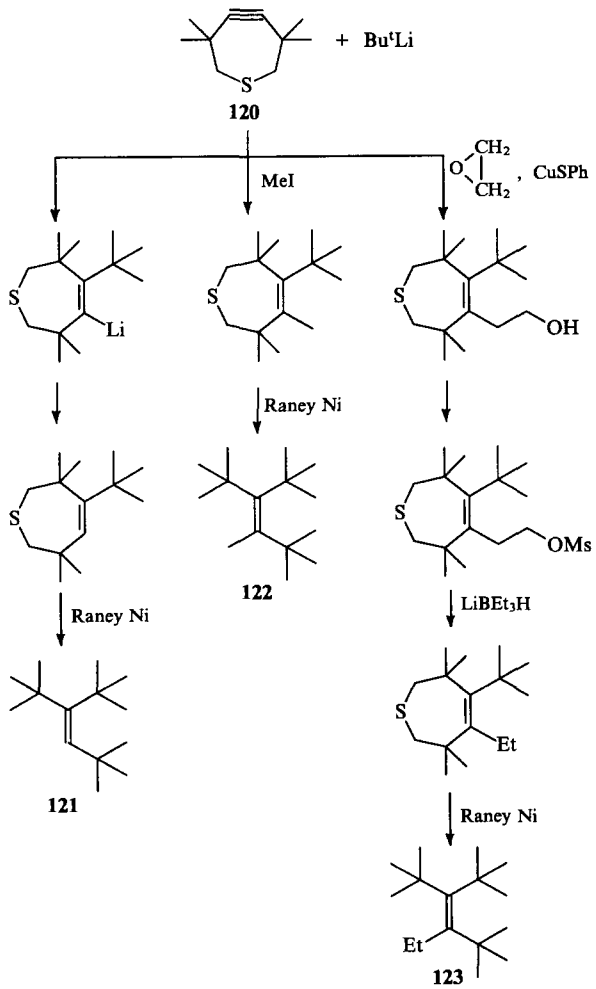


The biskeletal trienes **111** and **112** have been obtained by the diene synthesis reaction of DEAC with the corresponding skeletal fulvenes. The subsequent photocyclisation of the trienes **111** and **112** leads to the SHA **113** and **114** with a quadricyclane fragment.[75]

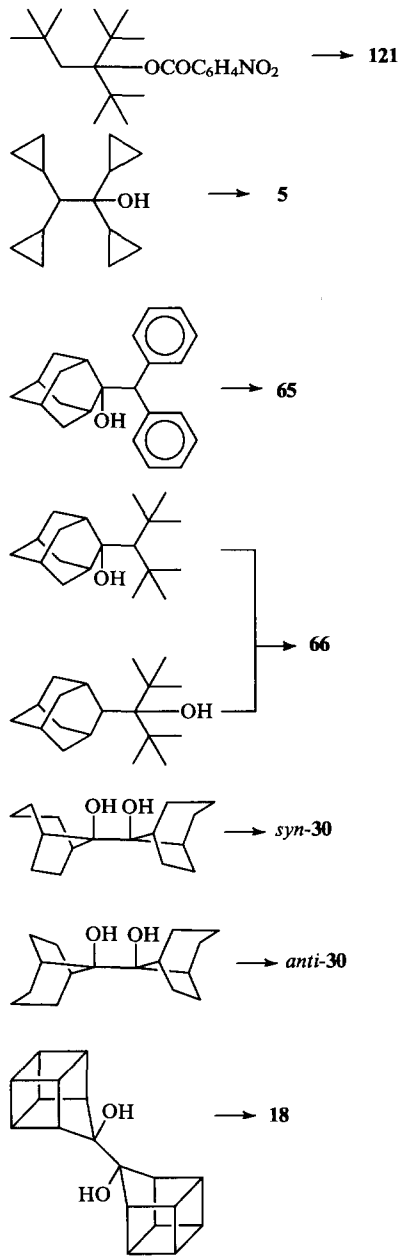


The reactions of tetrasubstituted cyclopentadienylidenequadricyclanes **115a, b** with DEAC or hexafluorodimethylethyne are accompanied by the isomerisation of the quadricyclane fragment and lead to mixtures of the corresponding isomeric SHA (**116a, b** + **117a, b**) with the bisnorbornadiene structure. The subsequent photocyclisation in one or both norbornadiene fragments leads to polysubstituted derivatives of quadricyclylidenenorbornadiene (**118a, b**) and bisquadricyclylidene (**119a, b**) respectively.[46] We have already spoken above about the involvement of similar adducts in diene synthesis with formation of new SHA.

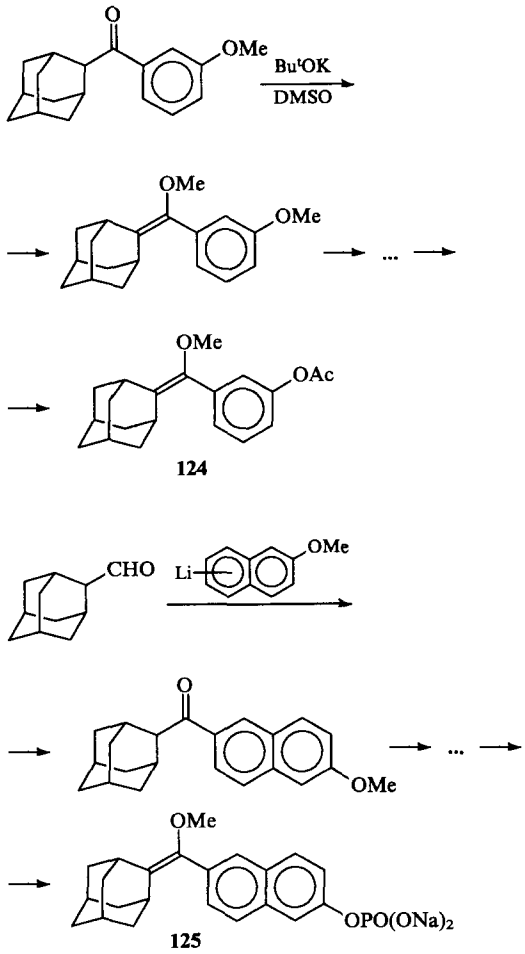
Scheme 3



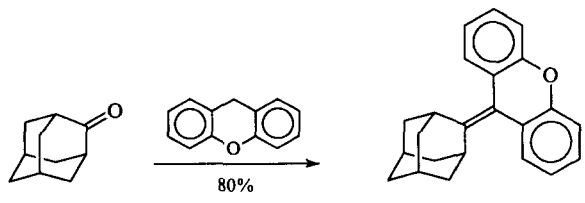
Here and henceforth the designation Ad has been retained for adamantylidene



6. Other syntheses

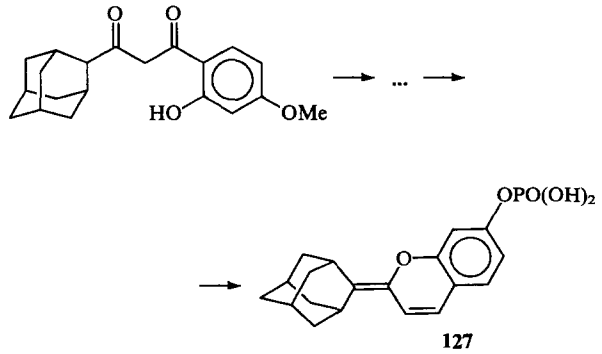


Other synthetic approaches, different from those examined above, have been proposed for certain types of SHA or their individual representatives. Thus tri-*tert*-butylethene **121** and its homologues **122** and **123** have been synthesised from the sulfur-containing synthon **120** in accordance with the schemes below:[52,53]



The syntheses of a series of SHA, including reactions involving the elimination of hydroxylated intermediates or their derivatives, have been described. Thus the alkene **121** has been obtained by the pyrolysis of the branched tetradecyl *p*-nitrobenzoate,[76,77] the alkenes **5**, **65**, and **66** have been synthesised by the dehydration of the corresponding carbinols,[78,79] and the *syn*- and *anti*-alkenes **30** and the biskeletal alkene **18** have been prepared by the dehydroxylation of diols.[32,41]

The synthesis of methoxyarylmethylideneadamantanes (enol ethers), based on the *O*-alkylation reaction of adamantyl allyl ketone, is presented below in relation to 2-[methoxy-(3′-acetoxyphenyl)methylidene]adamantane **124**[80] and the disodium salt of 2-[methoxy-(6′-phosphoryloxy)-2-naphthylmethylidene]adamantane **125**.[81]



9-Xanthylideneadamantane **126** has been obtained in one stage from adamantanone and xanthene by the Peterson reaction involving conversion into an alkene.[82]

126

The scheme for the synthesis of adamantylidenechromene phosphate **127** includes intramolecular cyclisation in the corresponding diketone as the key stage.[83]

127

III. Geometrical and thermodynamic parameters of sterically hindered alkenes

The presence in SHA of bulky substituents at the double bond or the incorporation of the latter in a rigid polycyclic system lead to appreciable intramolecular repulsive interactions and hence to a significant steric strain. The study of the influence of this factor on the structural parameters and thermodynamic characteristics of SHA is of considerable theoretical interest.

X-Ray diffraction data for strained SHA are presented in Table 2 (see next page). These compounds have a distorted (compared with the usual alkenes) molecular geometry primarily in the geometry of the double bond, the bond itself being extended up to 1.358 Å (in ethene, the bond length is 1.313 Å). Furthermore, the C–C bonds adjoining the double bond are lengthened and the angles are distorted. In the most strained SHA the double bond is twisted and the largest values of the torsional angle (24.0° – 37.5°) are characteristic of alkenes with *tert*-butyl substituents and of compound **86** — a structural analogue of the hypothetical tetra-*tert*-butylethene (for the latter, this value can be 44° according to calculated data). According to the same data, the structural analogues of the alkene **75** — the polysubstituted cycloalkylidenecycloalkanes **46** – **57** — are significantly less strained (Table 3, see p. 14). Evidently, the degree of structural deformations in this series depends on the structure of the cyclic fragments in which the double bond has been included.

There are considerable synthetic difficulties which must be overcome on the way to individual representatives of SHA. The failure of the attempts to synthesise the alkane **75** aroused considerable interest in the thermodynamic parameters of SHA. Calculations have been made of the strain energies and enthalpies of formation of a series of polyalkyl-substituted ethenes, adamantanes, and adamantylideneadamantanes (Table 4, see page 15). As can be seen, in the series of skeletal alkenes it is possible to trace clearly an increase in the energy of the double bond due to the increase in the degree of substitution in the admantane ring.

IV. Reactions of sterically hindered alkenes

The structural characteristics of SHA are responsible for the significant differences in the chemical behaviour of these compounds compared with the usual alkenes. Thus the successful hydrogenation of the double bond in SHA has been described only in relation to the alkene **121**.[95] Many alkenes of this type are inert to electrophiles; skeletal SHA are an exception, but their reactions lead as a rule to products other than those of the analogous reactions of the usual alkenes. Thus SHA with a highly shielded double bond are inert to oxidising agents; the ozonisation of skeletal SHA leads to epoxides instead of ozonides.

1. Reactions of skeletal sterically hindered alkenes with electrophiles

In most of the studies of the reactions of SHA with electrophiles, the synthetically available adamantylideneadamantane **10** was used as the model compound. Only individual examples of the involvement of other skeletal SHA in the reaction under discussion have been described.

Table 2. Torsional angles and bond lengths in sterically hindered alkenes (X-ray diffraction data).

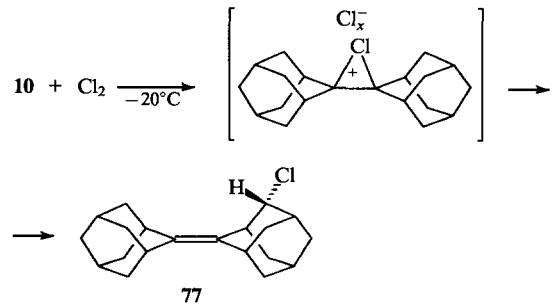
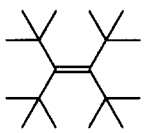
	0.0	1.307	43

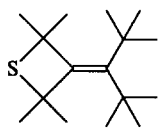
The reaction of the alkene **10** with bromine leads to the formation of an unusual adduct — the stable bromonium salt **128**.[96] The structure of the latter has been confirmed by X-ray diffraction data.[97] The structure found became a true scientific sensation because it had been postulated for many years that the reactions of the usual alkenes with bromine proceed precisely via intermediates of this kind.[98,99] The complex behaviour of the **10** + Br_2 system in solution has been investigated.[100]

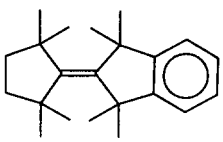


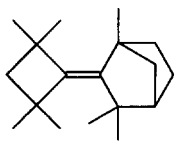
128

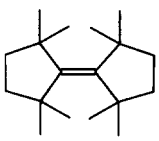
A bromonium salt — the adduct $C_{22}H_{33}Br_4$ insoluble in ether and hexane[26] — was also obtained in the reaction of *trans*-1,1′-dimethyladamantylideneadamantane **11** with bromine. In contrast to the alkenes **10** and **11**, the alkene **30** reacts with bromine to form the usual 1,2-adduct — the dibromo-derivative **129**.[40]

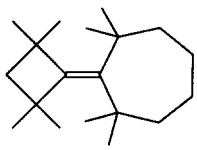


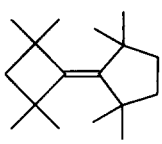


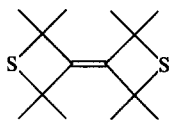


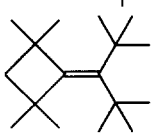


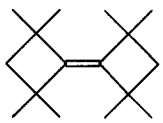


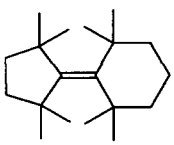






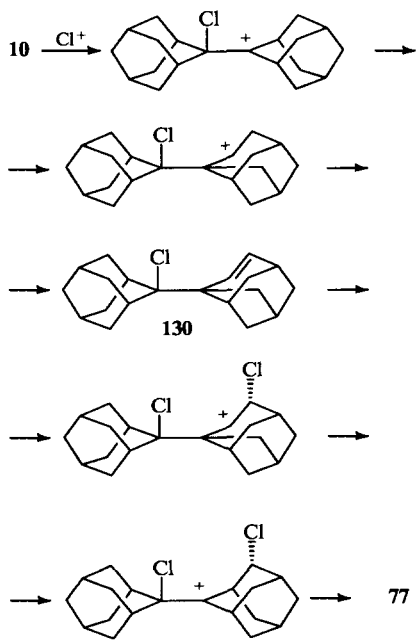






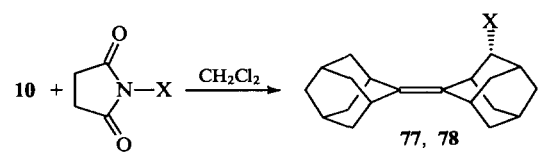
129

A substitution product — the chloroalkene **77** — has been obtained in a quantitative yield in the interaction of the alkene **10** with chlorine. In the initial stage of the chlorination reaction, the precipitation of the chloronium salt was observed visually. It was not possible to isolate it from the reaction mixture in view of its instability.[63]



77

Table 3. Torsional angles and bond lengths in sterically hindered alkenes (calculated data[92]).



Compound	C=C torsional angle/deg	C=C bond length/A	Compound	C=C torsional angle/deg	C=C bond length/A

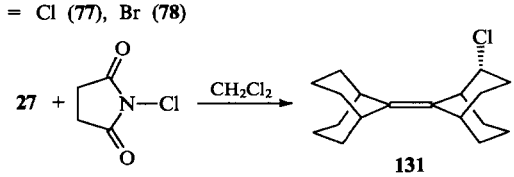
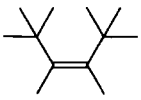
	12.1	1.369		3.5	1.347
	5.5	1.371		1.0	1.370
	5.1	1.351		0.1	1.344
	5.0	1.366		0.05	1.330
	4.9	1.379			

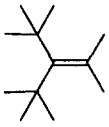
A mechanism, the key stage of which is the formation of the protoadamantene-like intermediate **130**, has been proposed for this reaction.

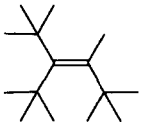


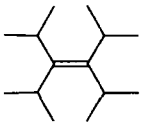
The formation of an iodonium salt in the reaction of the alkene **10** with the ICN–SbF_5 (1:1) system in SO_2 has been detected spectroscopically.[101]

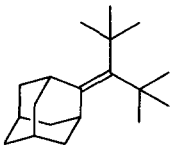
The radical-chain type of halogenation of the alkenes **10** and **27** has been described. The reaction of the alkene **10** with *N*-chlorosuccinimide leads quantitatively to the halo-derivatives **77** and **78**; this reaction constitutes the simplest and preparatively the most convenient method of synthesis of the chloroalkene **77**. Similar haloalkenes are formed on chlorination with *tert*-butyl hypochlorite or the NaOCl–MeCOOH system. The reaction of the alkene **27** with *N*-chlorosuccinimide leads to the chloroalkene **131**.[64–67]

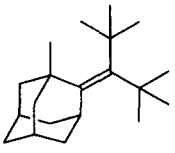


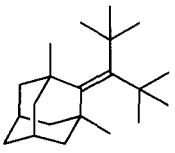


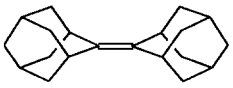


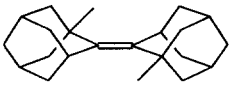


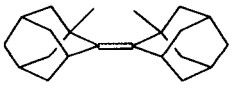


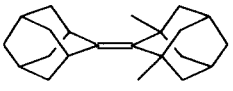


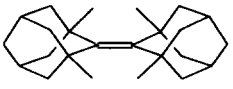




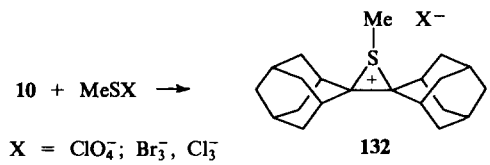






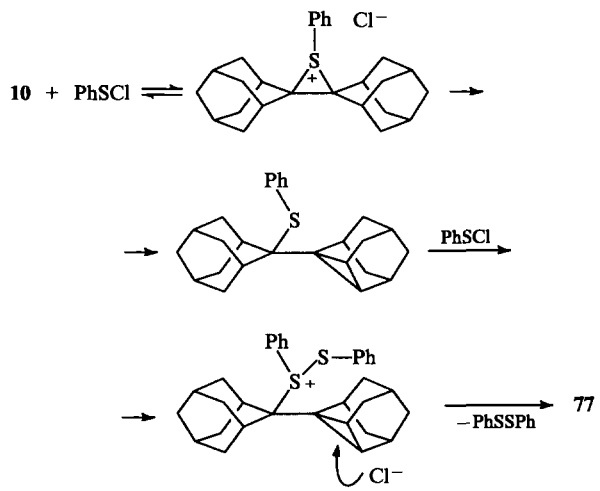


X = Cl (**77**), Br (**78**)



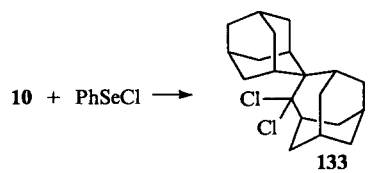
The reactions considered take place as selective homoallyl halogenation, whereas the usual alkenes afford the products of allyl halogenation on treatment with the same reagents.

Table 4. Thermodynamic parameters of sterically hindered alkenes (calculated data).



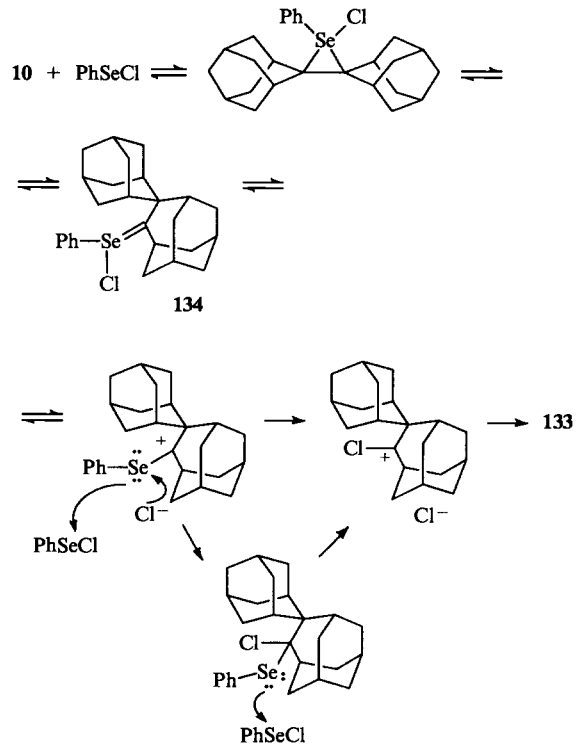
Compound	Standard enthalpy of formation/kcal mol^{-1}	Strain energy/kcal mol^{-1}	Ref.
	—	11.1	93, 94
	—	12.0	93, 94
	—	32	93, 94
	—	18	93, 94
	−28.92	46.14	58
	−17.73	66.20	58
	−6.16	86.64	58
	−30.36	13.54	26, 37, 58
	−26.10 (26.49)	35.54	27
	−18.20	43.44	26, 27
	−24.34	37.30	26, 27
	−61.07	75.31	26, 27

The reactions of adamantylideneadamantane **10** with electrophiles containing both a halogen and sulfur or both a halogen and selenium take place in an unusual manner. Thus the reactions of the above alkene with methanesulfenyl halides lead to the formation of the stable episulfonium salt **132**.[102] The formation of such compounds as intermediates was postulated previously in reactions involving the addition of alkanesulfenyl halides to the usual alkenes.



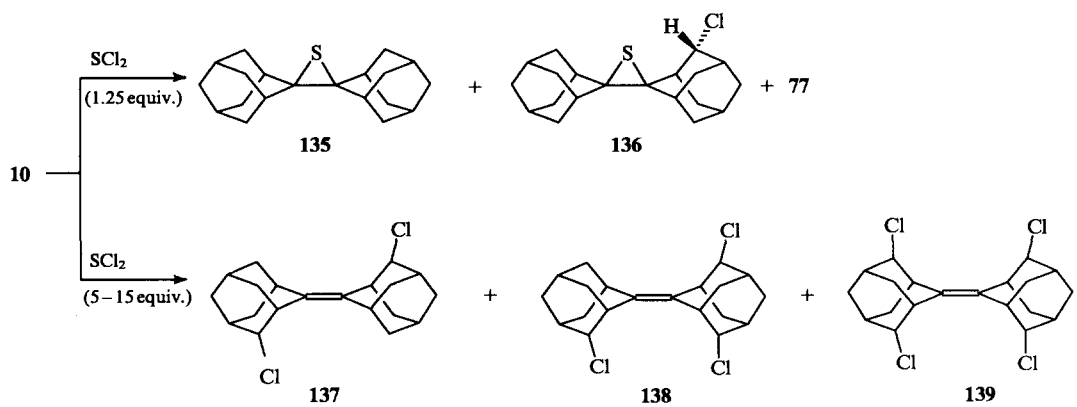
132

The reaction of the alkene **10** with 2 equiv. of PhSCl leads to the chloroalkene **77**.[103]



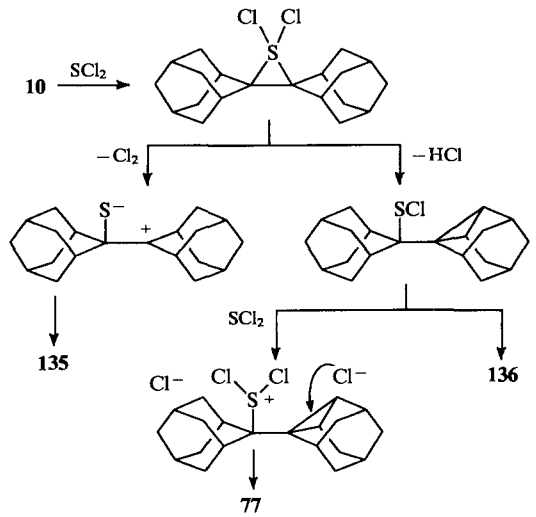
As in the interaction with chlorine, a substitution product is formed in this reaction instead of the 1,2-adduct.

The reaction of the alkene **10** with PhSeCl leads to an unexpected product — 3,3′-dichlorospiro(adamantane-2,2-homoadamantane) **133**.[104]

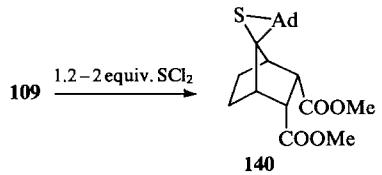


133

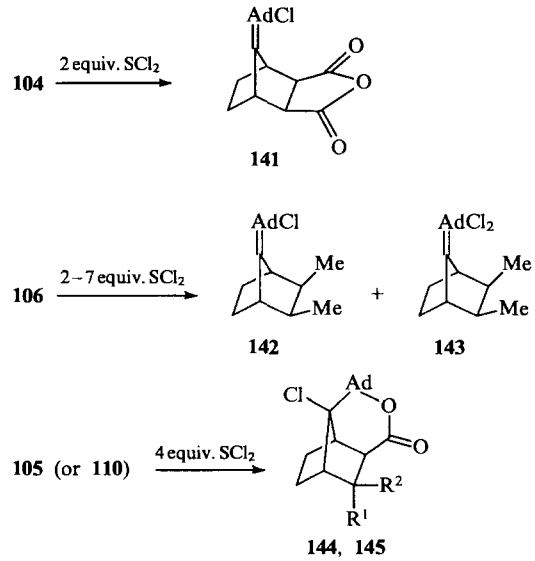
The proposed mechanism for this reaction includes a skeletal rearrangement in the intermediate **134**, the interaction of the rearranged derivative with a second molecule of the reagent, and cleavage of the salt formed.



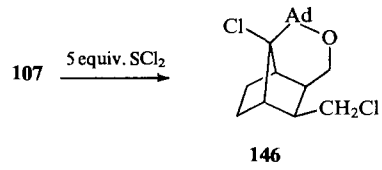
The reaction of the alkene **10** with SCl_2 leads to the epithio-compounds **135** and **136** and the (poly)chloroalkenes **77** and **137**–**139** (Scheme 4). Compounds **77**, **135**, and **136** are formed for an alkene : reagent ratio of 1 : 1, when the thiirane **135** is obtained predominantly in $CHCl_3$, the chlorothiirane **136** in CH_2Cl_2, and the chloro-derivative **77** in hexane. The specific synthesis of (poly)chloroalkenes **137**–**139** has been achieved in CH_2Cl_2 in the presence of a fivefold, sevenfold, and 15-fold excess of the reagent respectively.[105–106] The reaction of the alkene **10** with S_2Cl_2, in which the same epithio-compounds and chloroalkenes are obtained, is distinguished by a lower selectivity relative to the epi-compounds and by the formation of less chlorinated products than the reaction with SCl_2 occurring under the same conditions.[107] The structure of the chlorothiirane **136** has been confirmed by X-ray diffraction data.



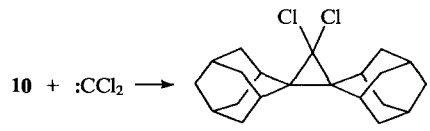
Scheme 4



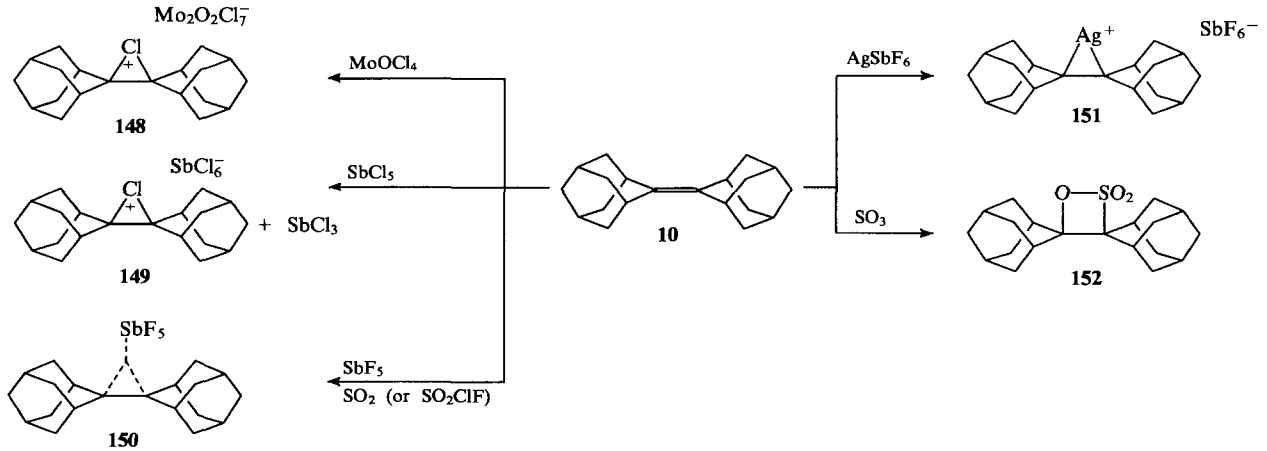
The diversity of the products formed in the reactions of the alkene **10** with SCl_2 and S_2Cl_2 may be explained by the existence of several versions of the stabilisation of the key intermediates — the primary sulfurane and sulfenyl chloride — and also by the successive chlorination of the unsaturated reaction products.



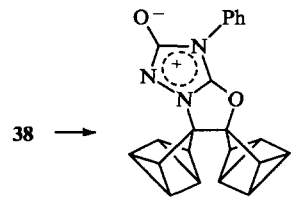
In the reactions of a series of disubstituted adamantylidenenorbornanes with SCl_2, the nature of the products depends significantly on the nature and the steric disposition of the substituents. Thus the reaction of SCl_2 with the *endo,endo*-diester **109** in $CHCl_3$ leads only to the thiirane **140**, while the reaction in CH_2Cl_2 leads to a complex mixture of products containing 17% of the latter. The chloroalkenes **141** and **142** have been obtained by the reactions of the *exo, exo*-adducts **104** and **106** respectively with 1.2–2 equiv. of SCl_2 in solution in CH_2Cl_2, while a mixture of five isomeric dichloroalkenes **143a–e** has been synthesised by the reaction of the alkene **106** with 7 equiv. of SCl_2.[74] The reactions of the *exo, exo*-diester **105** and the *exo, endo*-diester **110** with four equivalents of SCl_2 are accompanied by lactonisation, as a result of which the chlorolactones **144** and **145** respectively have been isolated in high yields. The dichloroether **146** has been obtained from the cyclic ether **107** as the product of the cleavage of the tetrahydrofuran fragment in the latter and subsequent etherification.[74]



105, **144**: R^1 = H, R^2 = COOMe;
110, **145**: R^1 = COOMe, R^2 = H



The normal cycloaddition product, the adduct **147**, is formed in the reaction of the alkene **10** with dichlorocarbene; this addition reaction takes place more slowly than with the usual alkenes, such as 2-methyladamantane (by a factor of 20) and 2-isopropylideneadamantane (by a factor of 200).[108]

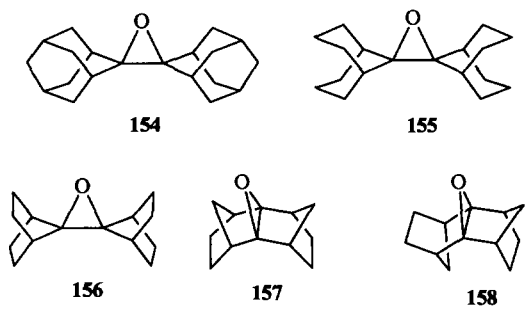


The reactions of the alkene **10** with $MoOCl_4$ and $SbCl_5$ in the presence of Lewis acids (Scheme 5) lead to the stable adamantylideneadamantanechloronium salts **148** and **149** respectively.[109]

Scheme 5

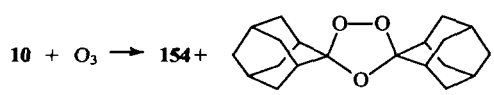
The adducts of the alkene **10** with SbF_5 and $AgSbF_6$—compounds **150** and **151** respectively[101]—as well as the β-sultone **152**[110] were detected in the reaction mixtures by ^1H and ^{13}C NMR.

The 1 : 1 adduct **153** has been obtained from the alkene **38** and *N*-phenyl-1,2,4-triazolinedione.[70]



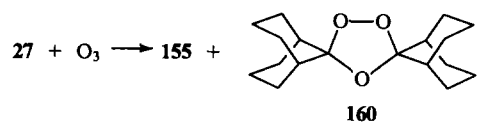
153

2. Oxidation reactions of sterically hindered alkenes



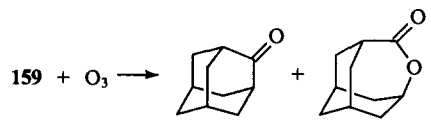
The behaviour of SHA in oxidation processes has been investigated on model reactions such as epoxidation, ozonisation, and 1,2-cycloaddition with participation of singlet or triplet oxygen.

The formation of epoxides from SHA on treatment with *m*-chloroperbenzoic acid has been described for the alkenes **9**,[24] **23**,[48] **42**,[48] and **50**.[90] The epoxides **154**,[111] **155**,[38] **156**,[40] **157**,[72] and **158**[73] have been obtained in the same way from the corresponding alkenes in satisfactory yields.



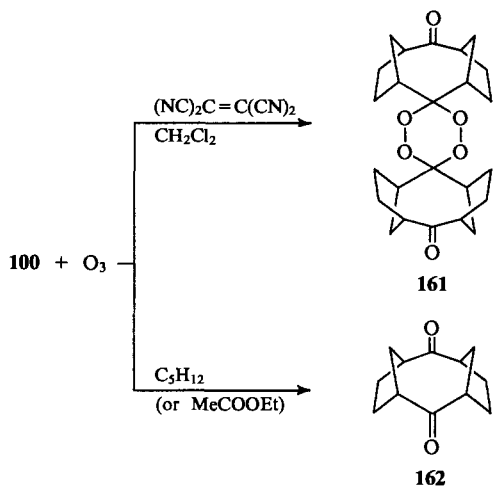
154 **155** **156** **157** **158**

The ozonisation of SHA in most cases does not lead to ozonides—the normal products of the usual alkenes with ozone. The alkene **121** is an exception. Its ozonisation proceeds normally and affords (after the appropriate treatment of the reaction products) di-*tert*-butyl ketone and pivalic aldehyde.[95] The reactions of other SHA with ozone proceed differently. Thus the reaction of the alkene **10** with ozone in nonpolar solvents leads to a mixture of the epoxide **154** and the ozonide **159** in proportions which depend on the nature of the solvent: the epoxide is formed exclusively in polar solvents. The reaction of O_3 with the alkene **27** proceeds similarly, leading to a mixture of the epoxide **155** and the ozonide **160** or only the former.[38,72] The thermal decomposition of the ozonide **159** results in the formation of a 1 : 1 mixture of adamantanone and a lactone.[38]



159

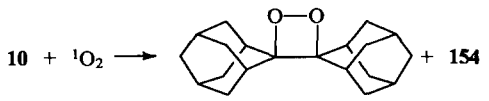
Solvent	Yield (%)	
	154	**159**
C_5H_{12}	60	33
C_5H_{12}–MeCOOEt	66	28
MeCOOEt	92	0



160

Solvent	Yield (%)	
	155	**160**
C_5H_{12}	77	18
MeCOOEt	100	0

Only the epoxide **156** has been obtained in the reaction of O_3 with the alkene **30**.[40] The ozonisation of the alkenes **23** and **100** is accompanied by the dissociation of the double bond; fenchone is formed from the first alkene,[48] while the peroxydiketone **161** or the diketone **162** is formed from the second (depending on the conditions).[72] The inertness of the alkenes **65** and **66** to O_3 has been noted.[112]



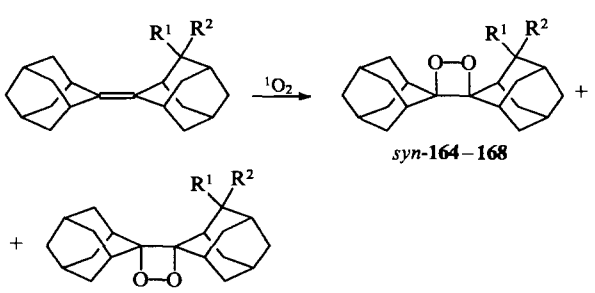
161 **162**

The oxidation of SHA of the 1,2-addition type leads to normal products—dioxetanes. The latter are more stable than the dioxetanes obtained from the usual alkenes. Thus the dioxetane **163**, synthesised from the alkene **10**, can be stored under the usual conditions. This feature of the dioxetanes obtained from SHA attracted considerable attention to them in connection with the problem of the strong chemiluminescence arising on thermal decomposition of compounds of this class.

Many SHA, especially adamantane-containing compounds, have been subjected to oxidation of the type of 1,2-addition. These alkenes have been involved in several types of reactions leading to dioxetanes: photosensitised oxidation by singlet oxygen and the radical-cation and electrochemical oxidation by oxygen. Mainly the synthetic possibilities and stereochemical characteristics of the above reactions are considered in the present review because the mechanisms of the latter and various aspects of the chemiluminescence of the dioxetanes on their decomposition have been described in detail in a monograph.[113] The synthesis and properties of various dioxetanes have been briefly considered in a review.[114]

Photochemical oxidation by singlet oxygen sensitised by dyes has been usually employed to obtain dioxetanes from SHA. The dioxetane **163** has been synthesised by precisely this method from the alkene **10**. Methylene Blue (MB) was used in this reaction as the sensitiser.[115] The structure of the above dioxetane was

confirmed by X-ray diffraction[116] (a method for the preparative synthesis of the dioxetane **163** has been described[117]).



163

The above photochemical oxidation of the alkene **10** affords, together with the dioxetane **163**, also the epoxide **154**; the ratio of these products depends on the nature of the dye and the solvent (Table 5). Evidently, the dioxetane is formed selectively in the presence of MB or tetraphenylporphin (TPP).[118,119]

Table 5. Photochemical oxidation of adamantylideneadamantane **10** in acetone.[118,119]

Sensitiser	Yield of reaction products (%)	
	163	**154**
m-Tetraphenylporphin	95	traces
Methylene Blue	95	traces
Rhodamine B	95	5
Eosin	95	5
Fluorescein	90	10
Erythrosin	30	70
Rose Bengal	traces	95

The photochemical oxidation of 4-substituted adamantylideneadamantanes by singlet oxygen under the conditions of the selective synthesis of dioxetanes proceeds nonstereospecifically, affording a mixture of two isomeric dioxetanes. Thus a mixture of the *syn*- and *anti*-dioxetanes **164** in proportions of 3.1:1 has been obtained from the chloroalkene **77**.[120] Oxidation of the alkenes **80**–**82** with functional group substituents leads to the corresponding dioxetanes **165**–**167** in the form of mixtures of two isomers.[68] The analogous oxidation of the ketoalkene **79** gives rise to a 1:2 mixture of the *syn*- and *anti*-dioxetanes **168**,[121,122] while the optically active 1,2-dioxetane **169** has been obtained from the ketal (−)-**83** as the sole isomer.[69]

syn-**164**–**168**

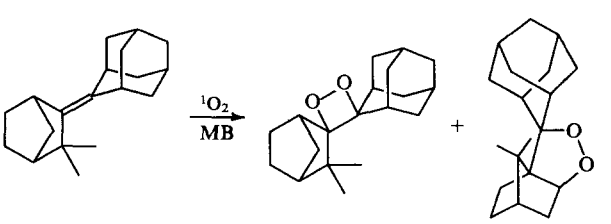
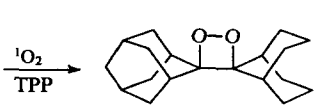
(−)-**169**

The photochemical oxidation of a series of isomeric 2,3-disubstituted 7-adamantylidenenorbornanes on treatment with $^1O_2$ was carried out in CH_2Cl_2 in the presence of MB. A 2:1 mixture of the dioxetanes *anti*-**170** and *syn*-**170** was obtained from the *endo,endo*-diester **109** in 90% yield, while the *exo,endo*-diester **110** afforded a 92% yield of 1.4:1 mixture of the dioxetanes *anti*-**171** and *syn*-**171**. The individual dioxetanes were isolated from the corresponding mixtures with the aid of high performance liquid chromatography (HPLC). The compounds of the *exo,exo*-series (**104**–**106**) are inert to singlet oxygen.[121–124]



109 → *anti*-**170** + *syn*-**170**

110 → *anti*-**171** + *syn*-**171**



The photochemical oxidation of the alkene **62** in the presence of MB leads to the formation of the dioxetane **172** and the dioxolane **173** in proportions which depend on the nature of the solvent.[56,125]

172 **173**

Solvent	172 : 173 ratio

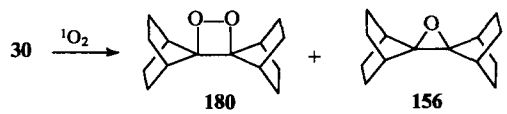
MeCN	3 : 7
Me_2CO	1 : 9

The photochemical oxidation of the alkene **42** in CH_2Cl_2 in the presence of TPP affords a high yield of the dioxetane **174**.[126]

174



The adamantane series dioxetanes **175**–**179**, containing the phenyl (compounds **175a**–**d**), naphthyl (compounds **175e**–**k**),[81] fluorene (compound **176**),[127,128] methylacridine (compound

177),[129-131] and xanthene (compound **178**)[82] fragments as well as the methoxy-group have been synthesised similarly from the corresponding alkenes. The phosphate derivative of the dioxetane **178** (compound **179**)[132] as well as the dioxetanes **175b**, **c**, **g**–**j**[80,133,134] have been obtained in the presence of Rose Bengal (RB) bound to a polymer.

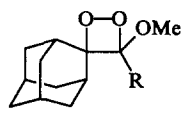


Table 6. Photosensitised oxidation of alkene **30** (see Ref. 40).

Sensitiser	Solvent	Yield of reaction products (%)	
		180	**156**
m-Tetraphenylporphin	CH_2Cl_2	60.3	39.7
	$t\text{-}C_4H_9COCH_3$	25.9	74.1
	1,4-dioxetane	24.8	75.2
	C_6H_6	18.2	81.8

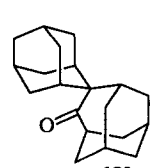
177

178, **179** R = H (**178**), $OPO_3^-H \cdot Py^+H$ (**179**)

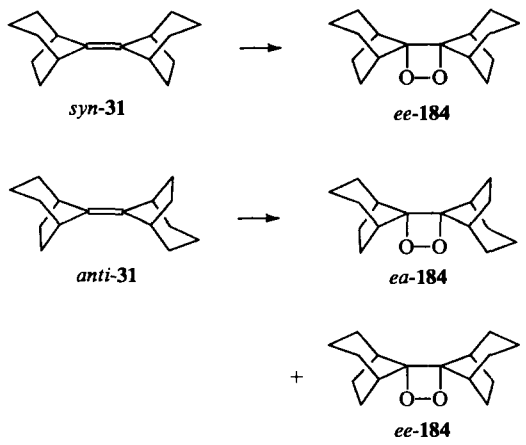


The oxidation of the *anti*-alkene **28** by singlet oxygen (with TPP as the sensitiser) afforded only the *cis,trans*-dioxetane **182**, whilst the oxidation of the alkene *syn*-**28** gave rise to a 2:1 mixture of the dioxetanes *trans,trans*-**182** and *cis,cis*-**182**.[39,126] The structure of the latter was established by X-ray diffraction.[51]

The alkenes inert to $^1O_2$ include the alkenes **23**, **64**, and **104**–**106**.[56] The attempts to obtain dioxetanes by the photochemical oxidation of the alkenes **100** and **101** were also unsuccessful. Only the epoxide **157** is formed from the alkene **100** in benzene in the presence of RB, while in acetonitrile in the presence of MB and in 1,2-dichloroethane in the presence of TPP the product is the diketone **162**.[77] Only the epoxide **158** has been obtained from the alkene **101** in benzene (with diacetyl as the sensitiser).[73]

The oxidation of SHA by oxygen under the conditions of a radical-cation chain process initiated by one-electron oxidants also leads to the formation of dioxetanes together with photochemical oxidation by singlet oxygen. Such oxidants are hexahaloantimonates of stable radical-cations: $(4\text{-}BrC_6H_4)_3N^{\cdot+}.SbCl_6^-$, $(2,4\text{-}Br_2C_6H_3)_3N^{\cdot+}.SbCl_6^-$, $(2,4\text{-}Br_2.C_6H_3)_3N^{\cdot+}.SbF_6^-$, and $NO^+PF_6^-$, $NO_2^+PF_6^-$, as well as sensitisers capable of generating radical-cations from the alkene on photoirradiation, such as, for example, 9,10-dicyanoanthracene (DCA) The radical-cations are also generated on electrochemical oxidation by oxygen.

The oxidation of the alkene **10** by oxygen in the presence of $(2,4\text{-}Br_2C_6H_3)_3N^{\cdot+}.SbCl_6^-$ results in the selective formation of the dioxetane **163**,[135] while in the presence of other oxidants the product is a mixture of the dioxetane **163** with the epoxide **154** and the spiroketone **183** in proportions which depend on the nature of the oxidant and the conditions (Table 7).[136]



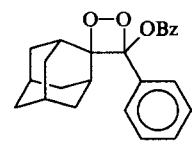
183

Table 7. Oxidation of adamantylideneadamantane **10** by oxygen in CH_2Cl_2 in the presence of oxidants.[136]

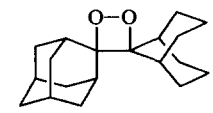
Oxidant	Content of oxidant (mol.%)	Time/min	Yield of reaction products (%)			
			163	**154**	**183**	**26**
MBPA.$SbCl_6$[a]	11.1	260	42	—	—	57
$NO^+PF_6^-$	103	2.5	6	86	—	—
$NO^+PF_6^-$	12.5	30	21	55	—	—
$NO_2^+PF_6^-$	3.5	180	40	7	—	40
$NO^+PF_6^-$	1.6	80	15	—	—	84
$NO_2^+PF_6^-$	95	2	—	—	73	—
$NO_2^+PF_6^-$	2.7	30	24	33	—	38

[a] MBPA = tris(*p*-bromophenyl)amine.

The oxidation of a series of enol ethers by the above procedure [in the presence of $(4\text{-}BrC_6H_4)_3N^{\cdot+}.SbCl_6^-$] leads to quantitative yields of the corresponding dioxetanes **175a** and **175g**.[137] A 25:1 mixture of the *syn*- and *anti*-dioxetanes **164** has been obtained similarly from the chloroalkene **77** in the presence of $(2,4\text{-}Br_2C_6H_3)_3N^{\cdot+}.SbF_6^-$.[118] A higher selectivity is attained in this reaction than in the photochemical oxidation of the above alkene by singlet oxygen. The oxidation of the isomers of the alkene **31** by oxygen in the presence of $(2,4\text{-}Br_2C_6H_3)_3N^{\cdot+}.SbCl_6^-$ resulted in the formation of only the *ee*-dioxetane **184** from the *syn*-isomer and a 4:1 mixture of the *ea*- and *ee*-dioxetanes from the *anti*-isomer.[138]



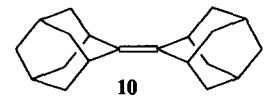
syn-**31** → *ee*-**184**

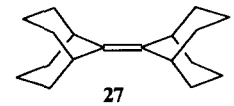


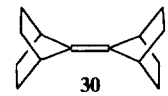
anti-**31** → *ea*-**184** + *ee*-**184**

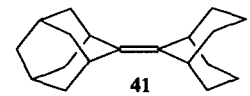
The synthesis of dioxetanes from SHA via the DCA-sensitised photochemical oxidation by oxygen has been described in relation to the alkenes **10**, **27**, **28**, and **42**. The oxidation of the alkene **28** stereoisomers by this procedure afforded the same products as their oxidation by $^1O_2$, but the ratio of the *cis,cis*- and *trans,trans*-dioxetanes is in this case 27:22. A dioxetane is not formed from the alkene **30** under these conditions.[39,126] The sensitised photochemical oxidation of a series of enol ethers afforded high yields of the corresponding dioxetanes **175a**, **e**, **g**, **l** and **185**.[139]

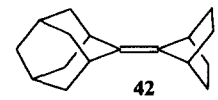
The electrochemical oxidation by oxygen is also used together with the oxidation method described above for the synthesis of dioxetanes from the alkenes **10**, **27**, **28**, and **42**; the ratios of the relative reactivities of the alkenes **10**, **27**, and **42** are then 1:0.74:0.06. The formation of mixtures of *cis,trans*-, *cis,cis*-, and *trans,trans*-dioxetanes **182** in proportions of 34:24:21 (from the *anti*-isomer) and 23:51:11 (from the *syn*-isomer) from the *syn*- and *anti*-stereoisomers of the alkene **28** is evidence in support of a different reaction mechanism than in other types of oxidation. The dioxetane **186** has been obtained in the same way from the alkene **41**, while the alkene **30** is inert to oxygen under the conditions indicated.[39,126,140]











185

186

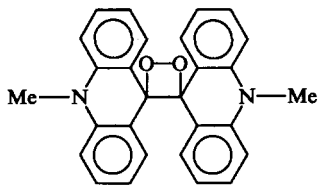
Comparison of three oxidation methods (singlet, DCA-sensitised, and electrochemical) in relation to the alkenes **10**, **27**, **30**, **41**, and **47** showed that oxidation by singlet oxygen is most effective for the preparation of dioxetanes from the above alkenes (Table 8). Among all the alkenes examined, the alkene **30**, is the most reactive.[126]

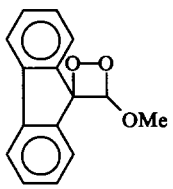
Table 8. Singlet, DCA-sensitised, and electrochemical oxidation of a series of alkenes.[39,126]

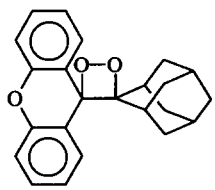
Alkene	Yield of dioxetane (%)		
	$^1O_2$	DCA	$^3O_2$
 **10**	98	66	87
 **27**	100	21	80
 **30**	15	does not react	does not react
 **41**	—	—	69
 **42**	92	59	72

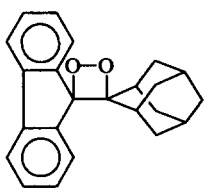
The higher relative thermal stability of the dioxetanes based on SHA compared with those based on the usual alkenes is illustrated by the data in Table 9, which lists the activation energies E_a for the thermolysis of a series of dioxetanes (this is one of the characteristics of the stability of compounds of this type). The table shows that the adamantane and bridging bicyclic fragments increase the stability of dioxetanes and that, of the two stereoisomers, the *anti*-isomers are more stable than the *syn*-isomers.

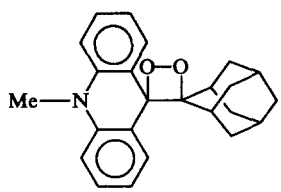
Table 9. Activation energies for thermal decomposition in the chemiluminescent thermolysis of dioxetanes.

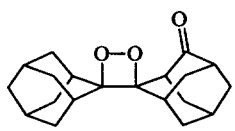


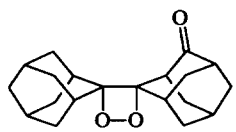


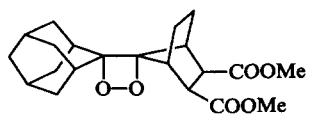


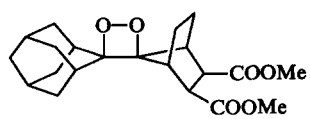


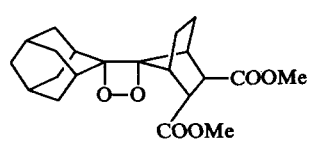


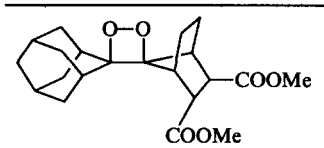


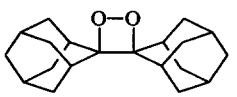


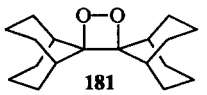












Dioxetane	E_a/kcal mol^{-1}	Ref.
	18.7	141, 142

V. Applications of dioxetanes based on sterically hindered alkenes

It has been discovered in the last decade that adamantane-containing dioxetanes with functional group substituents are likely to find applications as chemiluminescent labels and probes in labelling systems and in the determination of DNA, hormones, and other biological substances. Different aspects of the use of dioxetanes in molecular biology, immunology, and biotechnology have been described in detail in reviews[146,147] and patents.[80,83,148–152]

The glow in the systems under discussion is generated under the influence of enzymes — alkaline phosphatase (in the presence of disodium phosphates), aryl esterase (in the presence of acetates) — and of the fluoride ion (in the presence of trialkylsilyl ethers). The glow is excited as a result of the splitting off of the corresponding functional group, which leads to an unstable intermediate. The latter undergoes in its turn spontaneous decomposition in the dioxetane ring accompanied by chemiluminescence.[132,134] These transformations are illustrated below in relation to the dioxetane **175d** — 3-(2′-spiroadamantane)-4-methoxy-4-(3″-phosphoryloxy)phenyl-1,2-dioxetane (AMPD) (Scheme 6).

Scheme 6

It has been suggested that dioxetanes based on 4-substituted adamantylideneadamantanes **165** and **166**,[68] adamantylidene-(hetero)tricyclanes **176–179**,[82,127–132] compounds of the methoxyarylmethylideneadamantane series **175d–i**,[80,81,83,148] and others be employed as chemiluminescent labels. A system incorporating AMPD and alkaline phosphatase has found nowadays a real practical application. This system is manufactured by the Tropix Company. An advantage of systems of this kind is the combination of a high rate of assay with a high sensitivity (an order of magnitude higher than in the case where the usual luminescent reagents are employed), safety (compared with radioactive labelling), and diversity of applications.

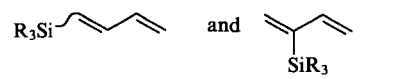
Silicon-containing alka-1,3-dienes and their functional derivatives in organic synthesis

M D Stadnichuk, T I Voropaeva

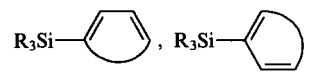
Contents

I. Introduction 25
II. Synthesis of 1- and 2-triorganosilylalka-1,3-dienes and their functional derivatives 25
III. Chemical properties of 1- and 2-triorganosilylalka-1,3-dienes and their derivatives 35



Abstract. Data on the synthesis and chemical reactions of silicon-containing 1,3-dienes are surveyed for the first time in the present review. It is shown that the addition reactions of 1- and 2-triorganosilylalka-1,3-dienes and their derivatives are the most interesting and promising in fine organic synthesis. The application of the trialkylsilyl group as a protecting group and as a new reaction centre, which makes it possible to obtain carbon—carbon or carbon–heteroatom bonds, is examined. It has been found that the double bonds remote from the silicon atom are the most reactive in addition reactions and that regardless of the nature of the reagent the attacking species always binds to the terminal carbon atom of the buta-1,3-diene fragment. The bibliography includes 329 references.

I. Introduction



1,3-Diene hydrocarbons and their derivatives have long served as convenient and readily available intermediates in the synthesis of complex aliphatic, carbocyclic, and heterocyclic compounds as well as polymers with useful properties. Silicon-containing derivatives of 1,3-diene hydrocarbons were first obtained in 1954.[1] The authors suggested that the product of the catalytic hydrogenation of 1-trimethylsilylbut-3-en-1-yne is 1-trimethylsilylbuta-1,3-diene. However, it was later established that the product is a mixture of 1-trimethylsilylbut-1-yne and the isomeric 1-trimethylsilylbuta-1,2-diene and 1-trimethylsilylbuta-1,3-diene.[2–4] Judging from gas–liquid chromatographic (GLC) data, the fraction of the 1,3-diene isomer in the mixture does not exceed 36%.[4]

2-Trialkylsilylbuta-1,3-dienes[5] and 1-trialkylsilylbuta-1,3-dienes[6] were first obtained in a pure state as late as 1956 to 1957 by the dehydration of the corresponding alcohols. Subsequently the chemistry of unsaturated organosilicon compounds began to develop in two directions. The first is associated with the development of the methods of synthesis of silicon-containing hydrocarbons — model compounds for the investigation of the relation between structure and reactivity and also of the delocalisation of the π-electrons of the multiple bonds with participation of unoccupied *d* orbitals of silicon ($d_\pi - p_\pi$ interaction); the second direction is associated with the development of methods of synthesis of carbofunctional derivatives of 1,3-diene silicon-containing hydrocarbons and with their application as synthetic units in the synthesis of natural products and their synthetic analogues, including silane analogues.[7,8]

Representatives of virtually all possible types of silylalka-1,3-dienes have now been synthesised, but the present review surveys the results of studies on only 1- and 2-organosilylalka-1,3-dienes containing the fragments

In view of the specificity of the methods of synthesis and of the characteristic features of their structure and reactivity, silylcyclo-1,3-dienes

silacyclo-1,3-dienes

and aliphatic compounds of the type

$n > 0$,

are not analysed in the present review.

Special reviews, including a full analysis of the chemistry of silicon-containing alkadienes and their functional derivatives, are lacking although compilatory[9–13] and narrow-profile[14–23] reviews, as well as certain monographs[24–26] include data also on the chemistry of 1,3-diene organosilicon compounds.

II. Synthesis of 1- and 2-triorganosilylalka-1,3-dienes and their functional derivatives

All the methods of synthesis of silicon-containing 1,3-dienes known at present can be divided into two groups. The first includes all the methods in which the initial compounds already contain the required carbon skeleton and the task of the investigator reduces either to the introduction of the organosilyl group into the organic molecule or to the creation of silyl-substituted 1,3-diene structures as a result of the chemical transformation of the corresponding unsaturated organosilicon compounds. The second group consists of methods involving the

Uspekhi Khimii **64** (1) 28–49 (1995); translated by A K Grzybowski

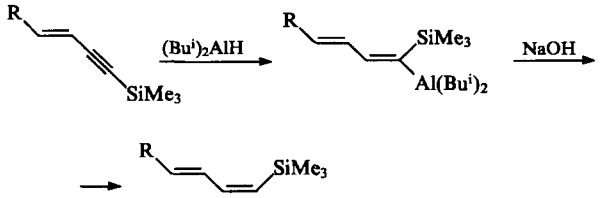
creation of silicon-substituted 1,3-diene structures from simpler synthetic units. The methods include the obligatory formation of new carbon–carbon bonds.

1. Synthesis of silicon-containing 1,3-dienes from the corresponding alkenynes

Catalytic hydrogenation of the available 1,3-enyne silicon-containing hydrocarbons and their derivatives is one of the promising methods of synthesis of the corresponding dienes.[26] According to Petrov et al.,[1] catalytic hydrogenation of 1-trimethylsilylbut-3-en-1-yne in the presence of palladium on barium sulfate actually takes place chemoselectively at the triple bond.

$$Me_3SiC{\equiv}C{-}CH{=}CH_2 + H_2 \xrightarrow{Pd/BaSO_4} Me_3SiCH{=}CH{-}CH{=}CH_2$$

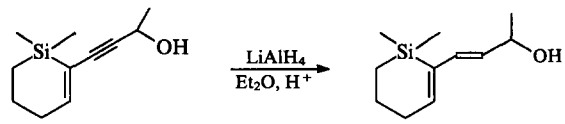
Other workers who investigated the catalytic reduction of silicon-containing vinylethyne ethers[27] and glycols[28] arrived at a similar conclusion.



$$Me_3SiC{\equiv}C{-}CH{=}CHOR + H_2 \xrightarrow{Pd+Pt} Me_3SiCH{=}CH{-}CH{=}CHOR$$

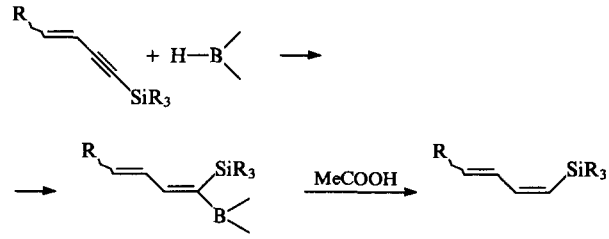
$$Me_2C(OH)C{\equiv}C{-}CH{=}C(SiEt_3){-}C(OH)Me_2 \xrightarrow{Pd/BaSO_4} Me_2C(OH)CH{=}CH{-}CH{=}C(SiEt_3){-}C(OH)Me_2$$

It has been noted that the alkenyne ethers are not hydrogenated in the presence of palladium on calcium carbonate or platinum on charcoal, but readily combine with catalytically activated hydrogen when a mixture of these catalysts is employed.



However, it was later shown[2–4] that the hydrogenation of silicon-containing alkenynes is a nonselective process: apart from the corresponding 1,3-diene, silicon-containing hydrocarbons and ethyne and allene products are formed. Since conclusions concerning the mode of hydrogenation were reached in the above investigations[1,27,28] on the basis of spectroscopic data (Raman or IR spectra) and the ability of the hydrogenation products to form cyclic adducts with maleic anhydride (which is possible also when the mixture contains 20%–30% of the 1,3-diene), the authors' conclusion[1,27,28] that catalytically activated hydrogen adds chemoselectively to the triple bond of silicon-containing 1,3-enyne hydrocarbons must be regarded as erroneous.

According to the available data, silicon-containing alk-1-en-3-ynes combine chemospecifically with diisobutylaluminium hydride at the triple bond. The corresponding (*Z*, *E*)-alkadienes were obtained by the protodemetallation of the adduct and the interaction with donors of the electrophilic halogens (chlorosuccinimide, bromocyanogen, and iodine) afforded the corresponding halo-derivatives of silicon-containing dienes.[29–33]



R = C_6H_{13}, C_6H_{11}, Bu^t, Me_3Si.

The reduction of the triple bond by lithium tetrahydroaluminate is known only for the corresponding alkenyne alcohols (a stereo-, regio-, and chemospecific reaction).[7]

The hydroboration of 1-trialkylsilylalk-3-en-1-ynes as well as their hydroalumination proceed chemo-, regio-, and stereo-specifically with formation of (*Z*)-adducts. The configuration of the 3,4-double bond is not altered.[32,34–37] Treatment of the adducts with acetic acid afforded the corresponding (1*Z*)-alkadienes.

The addition of hydrosilanes to 1,3-enyne compounds is nowadays one of the most important methods of synthesis of silicon-containing alka-1,3-dienes despite the fact that in many cases these reactions are characterised by a relatively low chemo- and regioselectivity. A 0.1 N solution of chloroplatinic acid in isopropyl alcohol (the Speier catalyst) is usually employed as the reaction catalyst; platinum on charcoal or other compounds of platinum group metals are more rarely employed.

It has been reported that conjugated alkenynes[38–47] and their functional derivatives[48,49] containing terminal ethyne groups combine with hydrosilanes exclusively at the triple bond with the silyl group becoming attached to the α-carbon atom. The nature of the R^1 and R^2 substituents does not affect the mode of the reaction and the yield of its products. In the interaction of trichlorosilane with vinylethyne, no individual adducts could be isolated.[43]

$$CH{\equiv}C{-}CR^1{=}CHR^2 + Cl_nR_{3-n}SiH \longrightarrow Cl_nR_{3-n}SiCH{=}CH{-}CR^1{=}CHR^2$$

R^1 = H, Me; R^2 = H, Me, OMe, NEt_2.

Judging from the yields, the reactivity of haloalkylhydrosilanes decreases in the sequence $Me_2ClSiH > MeCl_2SiH > Cl_3SiH$, which differs from that obtained previously in Greber's study.[45]

However, it was later established[50,51] that alkenynes with a terminal triple bond interact with hydrosilanes chemo- and regio-specifically: apart from 1-trialkylsilylalka-1,3-dienes, the products of the addition of hydrosilanes to the double bond also in the 1,4-positions as well as 2-trialkylsilylalka-1,3-dienes are formed. The yields of these compounds are low and they can be removed by fractionation.

Judging from the available data,[52–56] 1-trialkylsilyl alk-1-en-3-ynes also combine with hydrosilanes preferentially at the triple bond. However, considerable amounts of allene adducts are also formed in these reactions, their fraction in the mixture being determined by the structure of the enyne fragment and the hydrosilane.

$$Me_3SiC{\equiv}C{-}CR^2{=}CHR^3 + R^1_nCl_{3-n}SiH \longrightarrow$$

$$\longrightarrow Me_3SiCH{=}C(SiCl_{3-n}R^1_n){-}CR^2{=}CHR^3$$

$$\xrightarrow{H^+}$$

$$\longrightarrow Me_3SiCH{=}C{=}CR^2{-}CHR^3SiCl_{3-n}R^1_n$$

Trialkylhydrosilanes add to 1-trialkylsilylbut-3-en-1-ynes ($R^2 = R^3 = H$) exclusively in the 1,4-positions, while 3-methyl-1-trimethylsilylbut-3-en-1-yne ($R^2 = Me$) reacts with the same reagents to form almost exclusively the products of addition to the triple bond.

Alkylchlorohydrosilanes react with 1-trialkylsilylalk-3-en-1-ynes almost always at the triple bond regardless of the structure of the enyne fragment. It has been established that allene adducts readily isomerise in an acid medium to 1,3-diene adducts with migration of the trialkylsilyl group. These results enabled the authors [52,55] to postulate that the reactions proceed in all cases as 1,4-addition. The adducts obtained under these conditions isomerise to 1,3-dienes already under the conditions of the addition reaction. Chloroplatinic acid or hydrogen chloride, which is always present in chlorohydrosilanes, function as isomerisation catalysts. The isomerisation most probably proceeds via a quasi-cyclic transition state stage. [53]

It has been shown for the hydrosilylation of 1,2,4-tris-(trimethylsilyl)but-1-en-3-yne that the nature of the catalyst [H_2PtCl_6, $PtCl(PPh_3)_3$, $Pt(PPh)_4$, $PdCl_2(PPh_3)_2$, and $Pd(PPh_3)_4$] and the structure of the hydrosilane ($PhMeSiH_2$, Ph_2SiH_2, and Et_3SiH) affect the yield and structure of the adducts. [55]

The interaction of alkenes with trialkylhydrosilanes in the presence of chloroplatinic acid is optimal for the preparation of 1,3-dienes. [55]

Regardless of the structure of the reactants and the nature of the catalyst (chloroplatinic acid or platinum on charcoal), hydrosilanes add exclusively to the triple bond of vinylethyne alcohols [57-62] and their ethers [63-65] and esters [66] in the hydrosilylation reaction.

$$R^1R^2C(OR^3)C{\equiv}C{-}CH{=}CH_2,$$

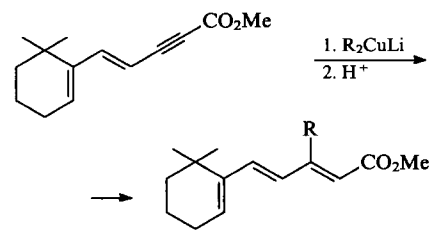
R^3 = H, Me, CH_2CH_2CN, MeCO, $CH_2CH{-}CH_2$ (O).

On the grounds that the adducts did not undergo "β-cleavage" on heating, a type **A** structure was initially attributed to them, but later the structure **B** was proposed on the basis of ^1H NMR spectroscopic data.

$$R^1R^2C(OR^3){-}C(SiR_nCl_{3-n}){=}CH{-}CH{=}CH_2$$

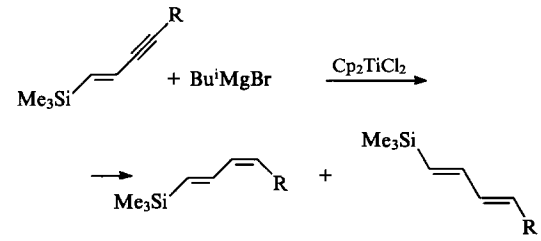
A

$$R^1R^2C(OR^3){-}CH{=}C(SiR_nCl_{3-n}){-}CH{=}CH_2$$



B

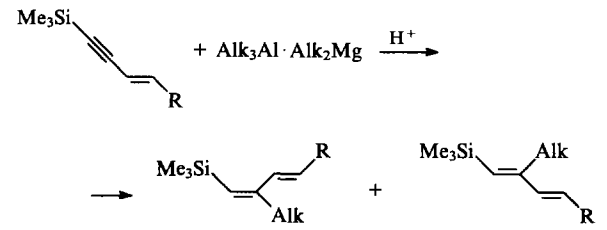
Ethyne and allene adducts have also been found in some investigations, [62,64] but the conclusions reached by the authors concerning the structure are open to doubt.



According to the data of Kakhniashvili and coworkers [67-69] and Shikhiev and coworkers, [70] alkenynes of the type *p*-$ROC_6H_4C(Me)_2C{\equiv}C{-}CH{=}CH_2$ give rise to a mixture of the corresponding 1,3-diene regioisomers, with type **B** adducts predominating (80%-90%), on interaction with trialkylhydrosilanes in the presence of chloroplatinic acid.

Analysis of the available data shows that hydrosilanes add to the triple bond of alkenynes with a high degree of selectivity and that in the case of terminal ethynes the silicon-containing group is attached predominantly to the α-carbon atom of the triple bond, while in reactions with internal triple bonds this group is attached to the β-carbon atom.

The addition of organometallic compounds to the double bond and in the 1,4-positions in alkenynes is of no interest as regards the synthesis of silicon-containing dienes with conjugated double bonds. [21] Only the reactions of silicon-containing lithium cuprates are an exception. Judging from the available data, these add chemo-, regio- and stereo-specifically to the triple bond of the methyl ester of the corresponding alkadienynoic acid. [71]



Under the usual conditions, Grignard reagents do not interact with silicon-containing alkenynes, but in the presence of catalytic amounts of dichloro(dicyclopentadienyl)titanium a reaction in which hydrogen and magnesium add to the unsaturated compound takes place. [32]

The overall yield of 1,3-diene silicon-containing hydrocarbons formed on demetallation with water does not exceed 30% and the isomer ratio is $E:Z = 42:58$.

Trialkylaluminium adds to 1-trialkylsilylalk-3-en-1-ynes only on heating. When a complex of trialkylaluminium with dialkylmagnesium is used as the reagent, the reaction takes place under milder conditions (the isomer ratio is $E,E:E,Z = 95:5$). [72,73]

The addition of mixed alkylaluminium chlorides in the presence of Cp_2TiCl_2 takes place similarly (the isomer ratio is $E,E:E,Z = 50:50$). [74]

The dealumination of the adducts formed can be carried out with iodine, whereupon one obtains 1-iodoalkadienes, which are difficult to obtain otherwise.

Judging from the data of Petrov et al., [1] the bromination of 1-trialkylsilylbut-3-en-1-ynes takes place exclusively at the triple bond and can be a convenient preparative method of synthesis of the corresponding 1,3-diene silicon-containing dibromo-derivatives. It was shown later that the 1,2-dibromo-derivatives are obtained as a result of the thermal isomerisation of the 1,4-dibromo-derivatives formed initially. [75]

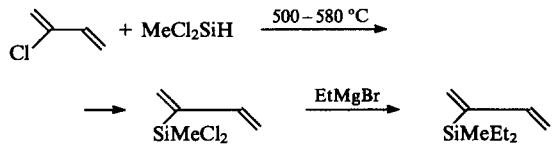
$$R_3SiC{\equiv}C{-}CH{=}CH_2 + Br_2 \longrightarrow$$

$$\longrightarrow R_3SiCBr{=}C{=}CHCH_2Br \xrightarrow{\Delta}$$

$$\longrightarrow R_3SiCBr{=}CBr{-}CH{=}CH_2$$

The functional derivatives of the silylalkenynes $Me_3SiC{\equiv}C-CH{=}CRX$ (X = CN, COR, CO_2R) combine with bromine at the double and triple bonds. The ratio of the dibromo-derivatives formed is ~1:1.[76] The introduction of a methyl group in the α-position relative to the functional-group substituent promotes the formation of dibromo-1,3-dienes.[76]

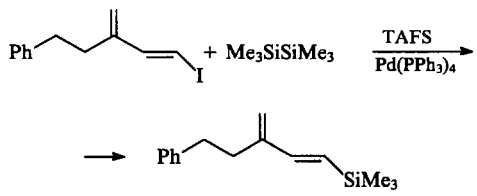
In contrast to the halogens, sulfinic acid halides, and other electrophiles[21] which add to silicon-containing alkenes at the double bond and in the 1,4-positions, sulfenic acid chlorides and bromides and their selenium-containing analogues react exclusively[77] or preferentially[78-82] at the triple bond.



$$Me_3SiC{\equiv}C-CR^1{=}CHR^2 + R^3XY \longrightarrow$$
$$\longrightarrow Me_3SiC(XR^3){=}CY-CR^1{=}CHR^2$$
$$+ Me_3SiC{\equiv}C-CR^1YCHR^2XR^3$$

X = S, Se; Y = Cl, Br.

Other reagents (secondary amines[83] and thiols) add to the double bond and in the 1,4-positions under the conditions of free-radical initiation,[84,85] the content of 1,3-diene adducts not exceeding 5%. Therefore these reactions are of no interest as methods of synthesis of polyfunctional derivatives of silicon-containing 1,3-diene hydrocarbons.



2. Silylation of derivatives of alka-1,3-dienes

Only two examples of the direct silylation of haloalkadienes, leading to the synthesis of the corresponding silicon-containing alka-1,3-dienes, are known. Thus 2-triorganosilylbuta-1,3-diene has been obtained in a low yield by the high-temperature (500–580 °C) condensation of dichloromethylsilane and chloroprene.[86]

Under milder conditions in the presence of a palladium catalyst and tris(diethylamino)sulfonium difluorotrimethylsilicate (TAFS), hexamethyldisilane interacts stereospecifically with 1-iodoalkadienes (Scheme 1).[87]

Scheme 1

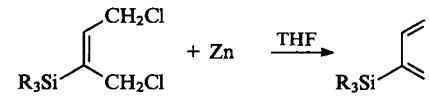
The use of potassium or caesium fluoride as the fluoride anion donor is ineffective.[87]

Silicon-containing 1,3-diene ethers are formed readily and in satisfactory yields on condensation of lithium alkoxydienides with triorganosilanes.[14,88-92]

$$R^1OCH{=}CH-CH{=}CHR^2 \xrightarrow{BuLi}$$
$$\longrightarrow [R^1OC{=}CH-CH{=}CHR^2]^-Li^+ \xrightarrow{Me_3SiCl}$$
$$\longrightarrow R^1OC(SiMe_3){=}CH-CH{=}CHR^2$$

R^1 = Me, Et, $MeOCH_2$, $Me_3SiOCH_2CH_2CH_2$;

R^2 = H, Me, Pr^i.

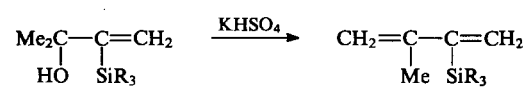


The lithium or sodium alkadienides interacting with Me_3SiCl can be obtained by metallating the corresponding halogen compounds[93] or as a result of the opening of the ring in furan derivatives[94] and cyclic acetals,[91] by transmetallation,[95,96] and by other procedures.[97-103]

TBS = Bu^tMe_2Si.

3. 1,2- and 1,4-Elimination reactions

Judging from the available data,[18,104-106] 1,4-dechlorination is the easiest method of synthesis of 2-triorganosilylbuta-1,3-dienes.

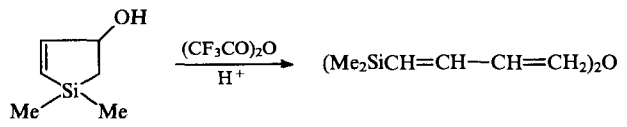


The initial 1,4-dichloro-2-triorganosilylbut-2-enes are obtained by hydrosilylating 1,4-dichlorobut-2-yne.

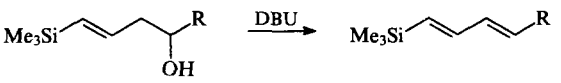
1,2-Dechlorination[107] can also be recommended as a convenient preparative method of synthesis of the corresponding derivatives of silicon-containing 1,3-dienes.

$$CF_2ClCFCl-CH{=}CHSiMe_3 + Zn \longrightarrow$$
$$\longrightarrow CF_2{=}CF-CH{=}CHSiMe_3$$

Another method of synthesis of 2-triorganosilylalka-1,3-dienes involves the 1,2- and 1,4-elimination of water from silicon-containing ethene alcohols. However, owing to the relatively low hydrolytic stability of the silicon–carbon bond towards strong inorganic acids and bases, the reaction must be carried out in the presence of acid potassium sulfate. It has been shown that tertiary and secondary alcohols are dehydrated under these conditions.[5,6,108-110]



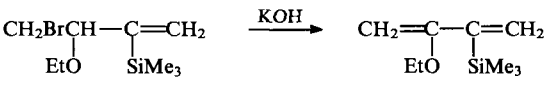
$$R_3SiCH_2\underset{OH}{C}H-CH{=}CHR^1 \xrightarrow{KHSO_4}$$
$$R^1 = H \longrightarrow R_3SiCH{=}CH-CH{=}CHR^1$$
$$R^1 = Me \longrightarrow R_3SiOSiR_3 + CH_2{=}CH-CH{=}CHR^1$$



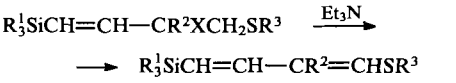
In all the cases investigated, tertiary alcohols are dehydrated under milder conditions than secondary alcohols. The dehydration of 1-trimethylsilylpent-3-en-2-ol takes place with almost complete desilylation. Heating the dihydric alcohols $R_2Si[CH_2CR^1(OH)-CH{=}CH_2]_2$ with $KHSO_4$ affords the corresponding bisbutadienylsilanes in low (~20%) yields.

Toluene-*p*-sulfonic acid began to be used later for the dehydration of secondary[111,112] and tertiary[113-116] silicon-containing alcohols.

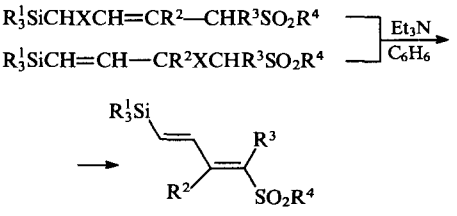
The dehydration of 1,1-dimethyl-1-silacyclopent-2-en-4-ol by trifluoroacetic acid anhydride takes place with the opening of the ring and the formation of the corresponding siloxane.[117]



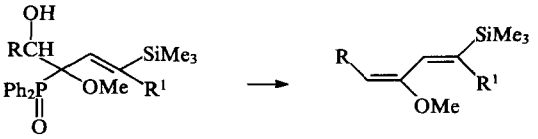
Examples of the dehydration of secondary silicon-containing alcohols on treatment with 1,8-diazabicyclo[5.4.0]undecane (DBU) are also known.[118]



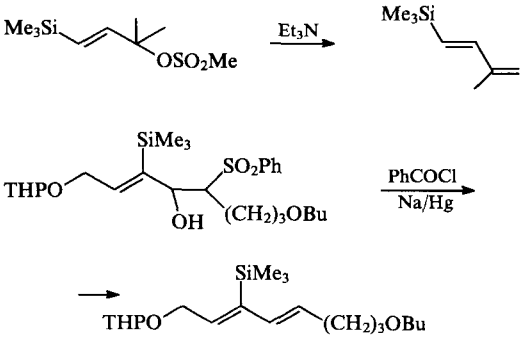
Thus, by varying the structure of the silicon-containing ethene alcohols and dehydrating agents synthesised by traditional methods, it is possible to obtain any silicon-containing conjugated alkadienes.



The 1,2- and 1,4-elimination of hydrogen halides and other acids proceeds as a rule only in a highly alkaline medium at high temperatures. This is apparently the reason why there are no data on the synthesis of silicon-containing 1,3-dienes by this procedure. However, it is known that, when carbonyl derivatives of silicon-containing ethene hydrocarbons contain a halogen and electron-accepting substituents, they readily split off hydrogen halides, the rate of reaction depending on the nature of the halogen (I > Br > Cl). Thus, according to the data of Shchukovskaya and coworkers,[119] β-bromoethers are dehydrobrominated by solid alkali at 90–120 °C.

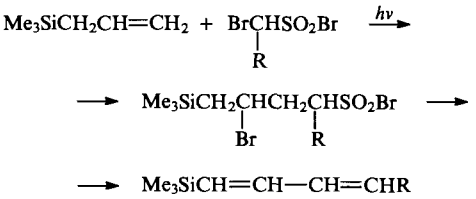


It was shown at the same time that silylchloro- and silylbromoalkyl sulfides containing a halogen in the allyl position readily split off the corresponding halogen halides even on treatment with triethylamine.[120] DBU was later used for similar purposes.[121–123]

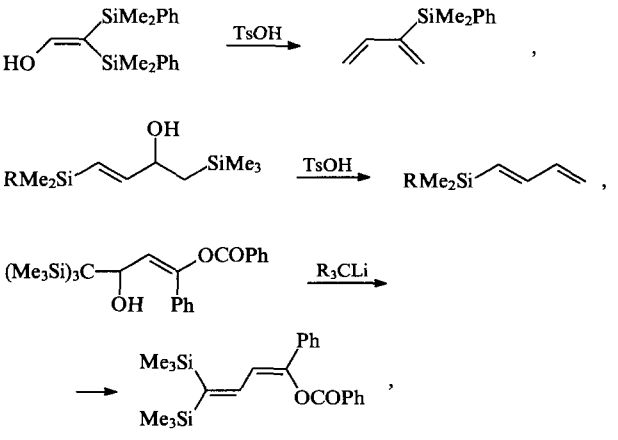


On treatment with triethylamine, the 1,2- and 1,4-dehydrohalogenation of unsaturated silicon-containing sulfones takes place at room temperature.[124–127] The 1,3-dienyl sulfones obtained under these conditions have the (*E*,*E*)-configuration.[128]

The 1,2-elimination of diphenylphosphonic acid takes place readily on treatment with butyllithium, lithium diisopropylamide,[129,130] or sodium hydride.[131]

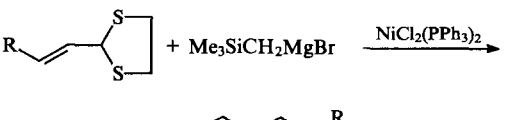


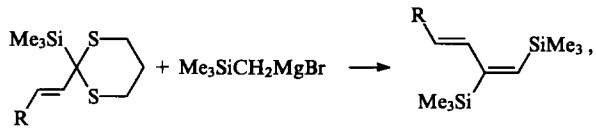
Examples of the synthesis of silicon-containing dienes as a result of the elimination of organic sulfonic acid from the corresponding esters[112] or sulfones[132] are known.



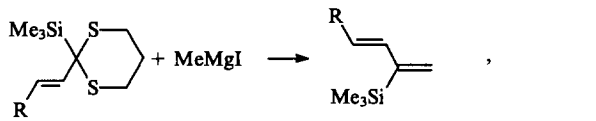
THP = 2-tetrahydropyranyl.

Block[133,134] proposed a novel method of synthesis of silicon-containing 1,3-diene hydrocarbons from readily available allylsilanes, which includes a stage in which hydrogen bromide and a sulfonic acid are eliminated.

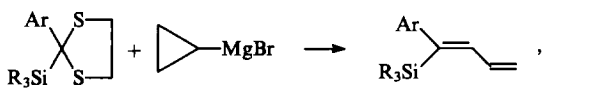




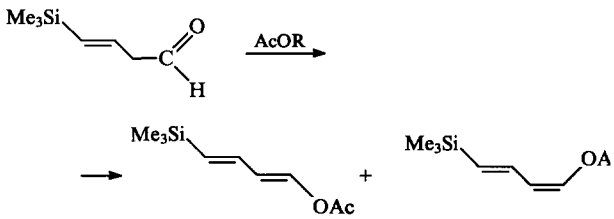
The replacement of triethylamine by 1,5-diazabicyclo [4.3.0]nonene does not affect the yields and the stereochemical result of the reaction. The employment of lithium or caesium *tert*-butoxide lowers somewhat the stereoselectivity of the reaction.[134]

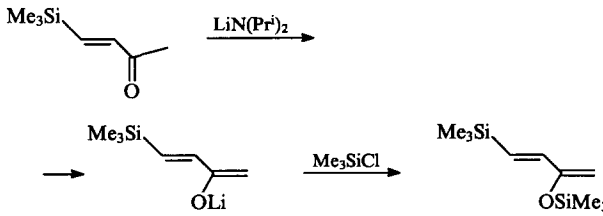


The synthesis of silicon-containing dienes as a result of the 1,2- or 1,4-elimination of silanols (on treatment with toluene-*p*-sulfonic acid[19,111,112,135] or bases[136])



or of thiols from the products of the interaction of organomagnesium compounds with unsaturated dithioacetals[136,137]

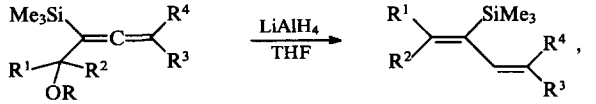




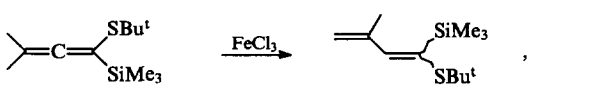
formally also belongs to the group of methods considered.

4. Isomerisation and ring opening

The keto–enol tautomerisation of silicon-containing aldehydes [138] and ketones [139,140] with subsequent fixation of the enol structure in the form of the corresponding ene-ethers has been widely used in the synthesis of acyloxy- and siloxy-buta-1,3-dienes. [112,138–141] Esters or anhydrides of the corresponding carboxylic acids may be used as the fixation reagents.

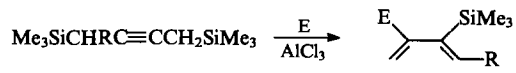


Siloxy-derivatives with a similar structure are obtained by treating an enolate (synthesised from a α,β-unsaturated ketone and lithium diisopropylamide [112] or dimethyllithium cuprate [142]) with chlorotrimethylsilane. [112]

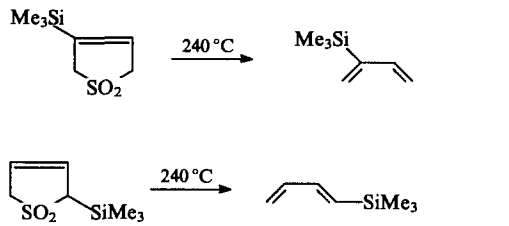


An instance of the photoinitiated isomerisation of non-conjugated unsaturated trialkylsilyl ketones to the conjugated ketones has also been described. [143]

The base-catalysed reactions of allene alcohols [144] and ethers, [145] i.e.

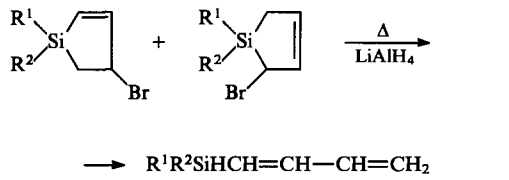


as well as the isomerisation of silicon-containing allenyl sulfides under the influence of $FeCl_3$, [146] i.e.

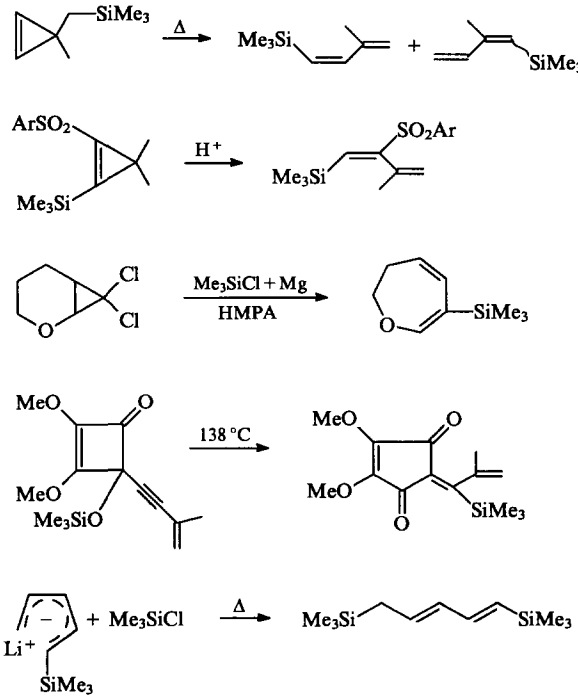


lead to the corresponding derivatives of silicon-containing 1,3-diene hydrocarbons. In certain cases, the base-catalysed isomerisation is combined with subsequent silylation. [144]

A novel method of synthesis of 2-trialkylsilylalka-1,3-dienes from the corresponding 1,4-bis(trialkylsilyl)alk-2-ynes is used in the treatment of an ethyne substrate by an electrophile (E = acetone, isobutyraldehyde, or trifluoroacetic acid) in the presence of anhydrous aluminium chloride. [147] The reaction involves a stage with a 1,2-shift of the trimethylsilyl group.

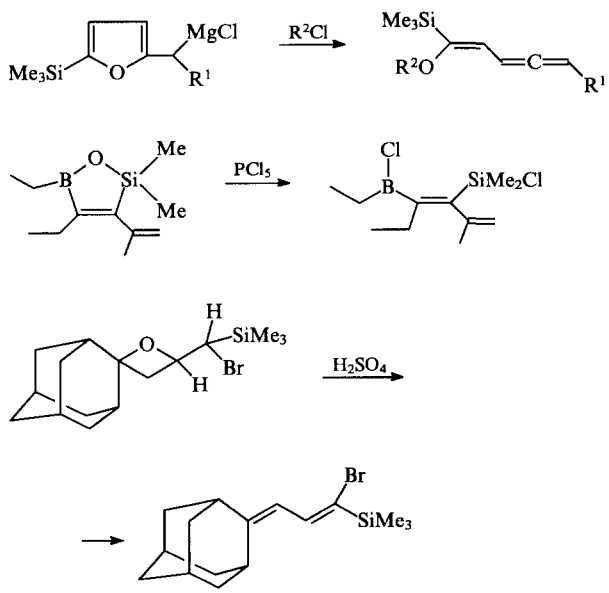


Pyrolysis of silicon-containing sulfolenes can also be included in the group of methods involving the isomerisation of the starting materials. This entails the cleavage of the heterocycle with formation of 1- or 2-trialkylsilylbuta-1,3-dienes, depending on the position of the trialkylsilyl group. [148–150]

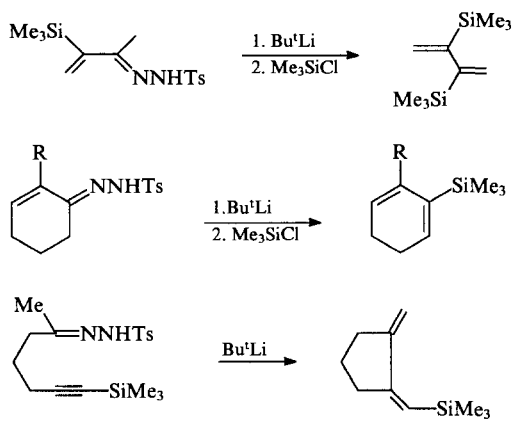


Mono- and di-alkyl-substituted silicon-containing sulfolenes afford mixtures of isomeric dienes under these conditions. [151]

Pyrolysis of silacyclopentenes and silacyclopentadienes ultimately also leads to silicon-containing alka-1,3-dienes. [152–156]

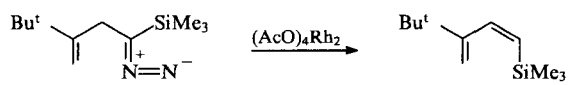


The opening of carbacycles is, under certain conditions, a very convenient preparative method of synthesis of conjugated silicon-containing 1,3-diene hydrocarbons and their derivatives. [99,157–161]



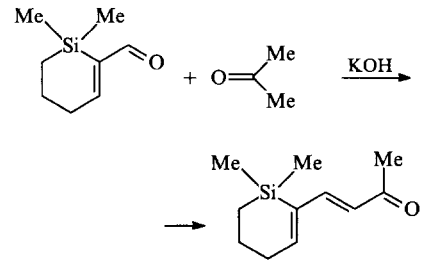
The methods of photochemical synthesis of silicon-containing 1,3-diene hydrocarbons and their derivatives are of interest.[162-165]

The opening of oxygen-containing heterocycles has been investigated only for isolated examples and has nowadays hardly any preparative interest.[166-169]

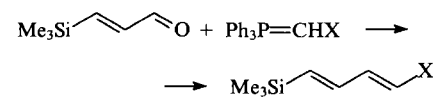


5. Synthesis of silicon-containing 1,3-diene hydrocarbons by the decomposition of tosylhydrazones or diazo-compounds

On treatment with lithium alkyls, tosylhydrazones decompose even at low temperatures with formation of the corresponding organolithium compounds, which give rise to the corresponding silicon-containing 1,3-diene hydrocarbon on interaction with trialkylchlorosilanes.[170-172]

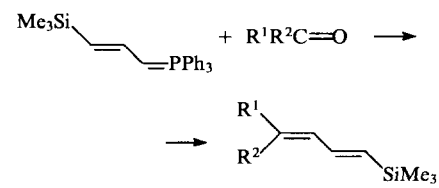


A stereoselective synthesis of (1*Z*)-isomers has been developed on the basis of the decomposition of the available aliphatic diazo-compounds by dirhodium-tetraacetate.[173]

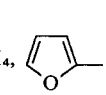


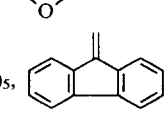
6. Methods for the construction of 1,3-diene fragments

In the synthesis of 1,3-diene fragments, the most important methods are those which presuppose their construction from simpler synthetic units. The corresponding reactions can occur as the condensation of two vinyl fragments, including silicon-containing fragments, or as the interaction of two fragments with the simultaneous formation of one or two double bonds. Owing to the low availability and the characteristic features of the spectra of α,β-unsaturated silicon-containing aldehydes and ketones, the latter are hardly used in the synthesis of silicon-containing 1,3-diene hydrocarbons and their derivatives. However, an example of the preparation of a ketone by the reaction of the corresponding aldehyde with acetone is known.[8] It was subsequently used in the synthesis of a sila-analogue of retinol.



The Wittig reaction and its phosphonate (the Horner–Emmons reaction) and silyl (the Peterson reaction) modifications constitute nowadays a well developed method of synthesis of silicon-containing 1,3-dienes and their derivatives. The Wittig method was first applied in the synthesis of carbofunctional derivatives of silicon-containing 1,3-diene hydrocarbons in 1971 in the reaction of silicon-containing α,β-ethene aldehydes with phosphoranes.[174]

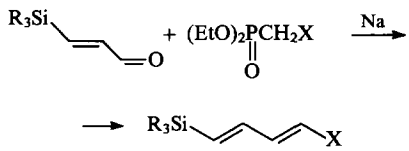




X = COMe, COOMe, CN.

It was later shown that the replacement of ether or THF, in which the Wittig reaction was usually carried out, by hexane simplifies significantly the purification and tends to increase the yield of the target products. (*Z*)- and (*E*)-aldehydes were introduced into the reaction.[175] The ethene fragment formed as a result of the condensation has predominantly or exclusively the (*E*)-configuration.[174-178] The introduction of a chlorine atom into the α-position relative to the silicon atom of the carbonyl component does not affect the yield and stereochemical result of the synthesis.[179]

An alternative version of the Wittig reaction, involving the interaction of a silicon-containing allylphosphorane with aldehydes and ketones, can also be used to obtain 1-trialkylsilylalka-1,3-dienes and their derivatives.[180,181]

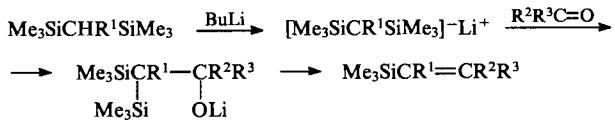


R^1 = H; R^2 = C_6H_{13}, PhCH=CH, 4-$NO_2C_6H_4$, 4-MeC_6H_4,  ;

R^1 = R^2 = Me, Ph; R^1 = R^2 = $(CH_2)_5$,  .

In such cases, the configuration of the 1,2-double bond does not change and the configuration of the newly formed ethene fragment depends in a complex manner on the structure of the carbonyl component and consists to the extent of 50% – 100% of the (*E*)-isomer.[181] The yields of the target products are 70% – 90%.

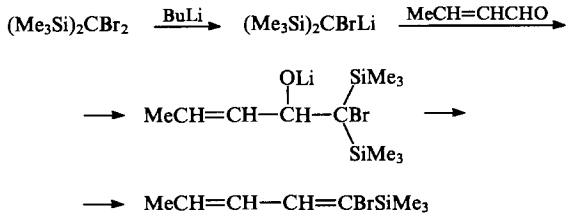
Judging from the available data, the phosphonate modification of the phosphorane synthesis (the Horner – Emmons reaction) also gives rise to satisfactory results in the synthesis of silicon-containing 1,3-diene compounds.[175,182-184]



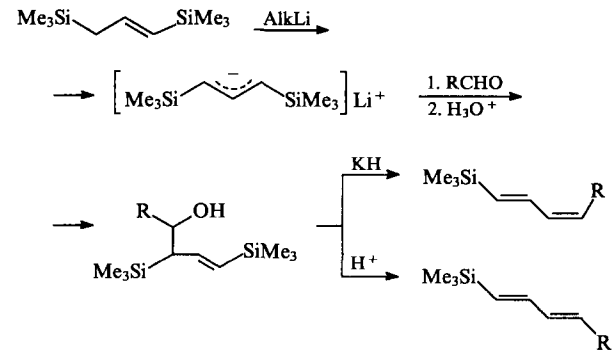
X = COOMe, COMe, CN.

The configuration of the double bond at the silicon atom does not change, as in the Wittig reaction, while the newly formed bond has predominantly the (*E*)-configuration. In the synthesis of ketones, the stereoselectivity of the reaction is higher when the Wittig method is used, while that of the reaction in the synthesis of nitriles is higher when the Horner – Emmons method is employed.[175]

The silyl modification of the Wittig reaction (the Peterson reaction) can be achieved in two ways: (1) by the reaction of the carbanions obtained from bis(trialkylsilyl)methanes with α,β-ethene aldehydes[11,136,185-188] and (2) by the reaction of the mesomeric carbanion of 1,3-bis(trialkylsilyl)prop-1-ene with carbonyl compounds (Scheme 2).[189-192]



Scheme 2

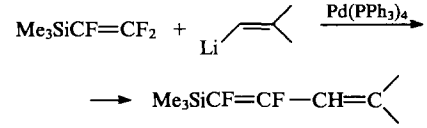


R^2 or R^3 = CH =CHX.

The carbanions needed in this reaction may be obtained also by the addition of lithium alkyls to 1,1-bis(trimethylsilyl)alk-1-enes.[185]

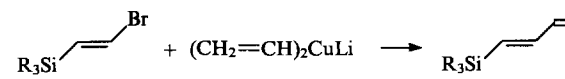
The interaction of dibromobis(trimethylsilyl)methane in succession with butyllithium and crotonaldehyde leads to a satisfactory yield of 1-bromo-1-trimethyl-silylpenta-1,3-diene [a mixture of the (1*E*)- and (1*Z*)-isomers in proportions of 2:1].[193]

A second version of the Peterson reaction in the synthesis of silicon-containing 1,3-diene hydrocarbons and their derivatives also includes a stage with formation of a carbanion and its condensation with the carbonyl compound.[118,189-192,194,195]



The stereochemical result of the reaction is determined by the nature of the silanol reagent split off.[189,192] In the presence of potassium hydride, the ethene fragment formed has predominantly the (*Z*)-configuration (60% – 90%) and in an acid medium the (*E*)-configuration (90%). The addition of magnesium bromide or trimethoxyboron to the reaction mixture reduces the stereoselectivity of the condensation and the isomer ratio *E,E*: *E,Z* is (60 – 70) : (40 – 30).[192] In the presence of silicates, (1*E*,3*E*)-trialkylsilylalka-1,3-dienes [R = H, Me, Bu^i, iso-C_5H_{11}, C_6H_{13}, Ph, $Ph(CH_2)_3$, $(CH_2)_nCH=CH_2$, n = 3,4] are formed exclusively;[190] in the presence of dicyclopentadienyltitanium chloride, the stereochemical result depends on the nature of the reagent promoting the elimination of trialkylsilanol. In an acid medium (sulfuric acid in THF), the (1*E*,3*E*)-isomers are formed exclusively, while on treatment with KF in THF the exclusive products are the (1*E*,3*Z*)-isomers.[191]

The data presented show that, in the synthesis of the (1*E*,3*E*)-isomers, preference should be given to the methods involving the Wittig or the Horner – Emmons reaction, while in the synthesis of the (1*E*,3*Z*)- or (1*Z*,3*Z*)-isomers the second version of the Peterson reaction is preferable.

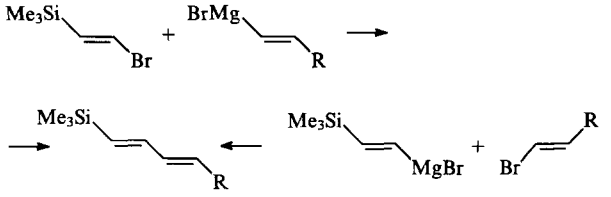


7. Organometallic synthesis

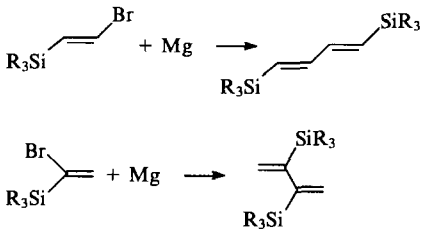
All the known methods including a stage in which a new carbon – carbon bond is formed with participation of classical organometallic compounds containing metal – carbon σ-bonds and the methods of synthesis of 1,3-diene structures as a result of the reacitons of unsaturated (including silicon-containing) compounds in the presence of metal complex catalysts are combined in this group. These reactions presuppose the formation of organometallic compounds of transition metals with classical or donor – acceptor carbon – metal bonds as an obligatory stage.

Organolithium α,β-ethene compounds do not alkenylate β-halovinylsilanes under the usual conditions. However, it is known that, in the presence of a palladium catalyst, trimethylperfluorovinylsilane reacts with vinyllithium to form the corresponding 1,3-dienes.[196-199]

Lithium vinylcuprates react similarly with β-bromovinylsilanes.[200]

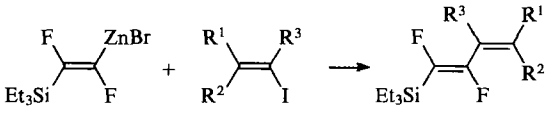


The interaction of vinylcuprates with halovinylsilanes afforded not only the corresponding silicon-containing 1,3-diene hydrocarbons but also their halo-[201] and amino-derivatives.[202]



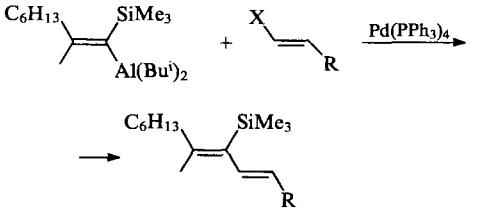
Mixed organomagnesium α,β-ethene compounds (the Norman reagent) interact with the corresponding vinyl halides also only in the presence of nickel and palladium complexes — $Ni(dppm)_2Cl_2$,[203,204] $Ni(dppe)_3Cl_2$, $Ni(dppp)_2Cl_2$,[205,206] $Ni(acac)_2AlMe_3$,[207] $NiCl_2(PPh_3)_2$,[136] and $PdCl_2(PPh_3)_2$,[203,204] where dppm = $Ph_2PCH_2PPh_2$, dppe = $Ph_2PCH_2CH_2PPh_2$, and dppp = $Ph_2PCH_2CH_2CH_2PPh_2$.

Both possible combinations have now been tested: organosilicon bromide–vinyl-magnesium halide and silicon-containing organomagnesium compounds–vinyl halide.

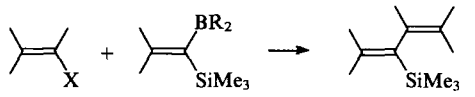


The stereoselectivity of the reaction in the synthesis of the (*E*, *E*)-isomers is about 90%[204] and in the synthesis of the (*E*, *Z*)-isomers it is somewhat lower (in the range 70%–80%).[203]

The 1,4- and 2,3-bis(trimethylsilyl)buta-1,3-dienes have been synthesised from the corresponding bromovinylsilanes and metallic magnesium without the preliminary preparation of the corresponding organomagnesium compounds.[208]

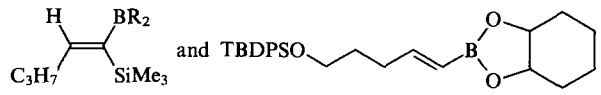


Mixed α,β-unsaturated organozinc compounds stereoselectively alkenylate vinyl halides in the presence of a palladium catalyst [$Pd(PPh_3)_4$[209,210] or $PdCl_2(PPh_3)_2$[211–213]].



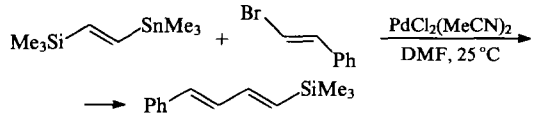
The target silicon-containing 1,3-diene hydrocarbons are obtained in satisfactory yields (80%–90%).

α,β-Unsaturated or organoaluminium compounds also react readily and stereospecifically with vinyl halides. The reaction is catalysed by the palladium complex $Pd(PPh_3)_4$.[199,214]

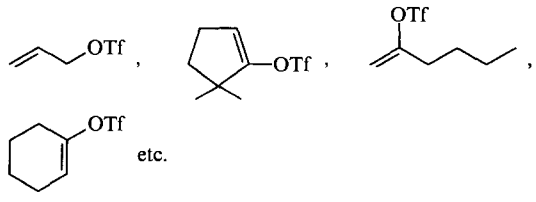


It has been shown in relation to 2-bromo-1-trimethylsilylethenes[214] that the (*E*)-isomer is more reactive than the (*Z*)-isomer.

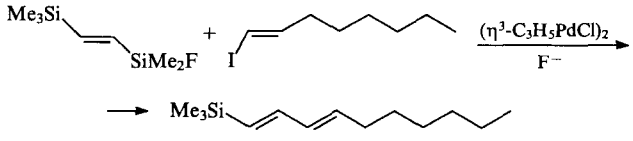
In the presence of tetrakis(triphenylphosphine) palladium, α,β-unsaturated boranes interact with vinyl halides [CH_2=$CH(CH_2)_2$.$CH(OBz)CH$=$CBr(SiMe_3)$, Me_2C=$CHBr$, CH_2=$CHCH_2CH(OBz)CH$=$CI(SiMe_3)$] to form the corresponding silicon-containing conjugated dienes.[215–217]



The boron-containing reagents investigated were

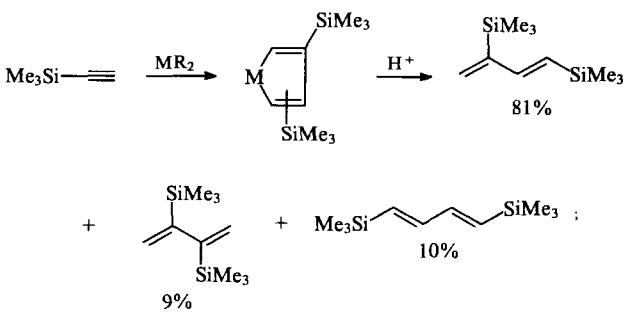


TBDPS = *tert*-butyl diphosphite-silane.



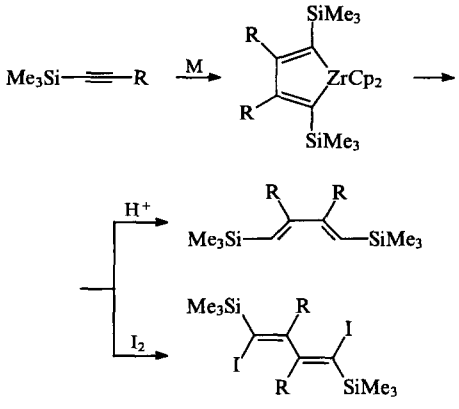
α,β-Unsaturated stannanes alkenylate vinyl halides under the conditions of the Stille reaction.[218]

The advantage of this method is manifested in the interaction of unsaturated stannanes with functional derivatives of vinyl halides containing as substituents groups which are reactive in relation to organolithium, organomagnesium, or organoaluminium compounds. Triflates can be used instead of halides.[219–223]



The ability of vinylsilanes to function as alkenylating agents in the synthesis of the corresponding silicon-containing 1,3-diene hydrocarbons has been recently discovered.[224]

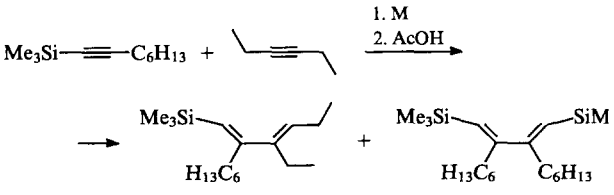
The successful occurrence of this reaction requires fluoride anion donors [in the study quoted, the donor employed was tris(diethylamine)sulfenyl difluorotrimethylsilicate (TASF)]. Bis(trimethylsilyl)ethene does not react with vinyl iodides.



8. Dimerisation of ethynes and their codimerisation with ethenes catalysed by transition metal complexes

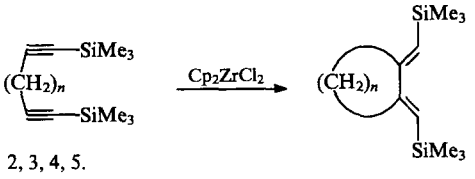
On interaction with zirconium complexes [Cp_2ZrPh_2, $Cp_2Zr.(CH_2$=$CH)_2$,[225] $Zr(C_5Me_5)_2MeB(4\text{-}FC_6H_4)_4$[226]], trialkylsilylethynes afford 1,3-diene complexes of zirconium, the proto-demetallation of which gives rise to the corresponding silicon-containing 1,3-diene hydrocarbons, for example:

M = Cp_2Zr.



Disubstituted silylethynes behave similarly in this reaction.[227-229]

M = Cp_2ZrCl_2.

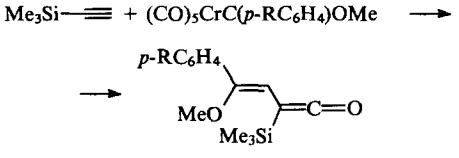


Zirconium compounds have been used as catalysts: Cp_2Zr(4-Me_2NPy).Z (Z = THF or CH_2=CHEt), Cp_2ZrCl_2,[229] and Cp_2ZrHCl,[227] while the demetallating agents were organic acids or iodine.

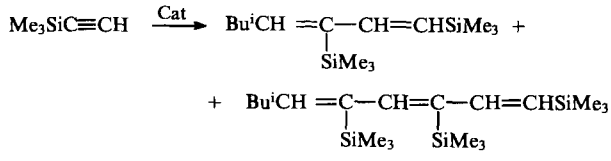
The codimerisation of disubstituted silylalkynes and dialkylethynes[227,228] leads to a cross-dimer and a dimer of the silicon-containing alkyne in proportions of 1:1.

It is striking that the 'head to head' principle operates in all cases in the dimers.

Nonconjugated silicon-containing alkenynes behave in this reaction as disubstituted ethynes,[230] while nonconjugated diethynes give rise to the corresponding cycloalkanes with conjugated endocyclic double bonds.[231-233]

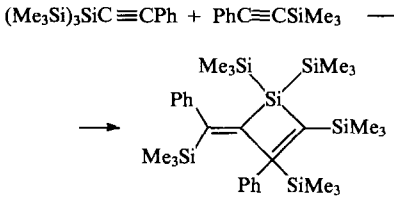


n = 2, 3, 4, 5.

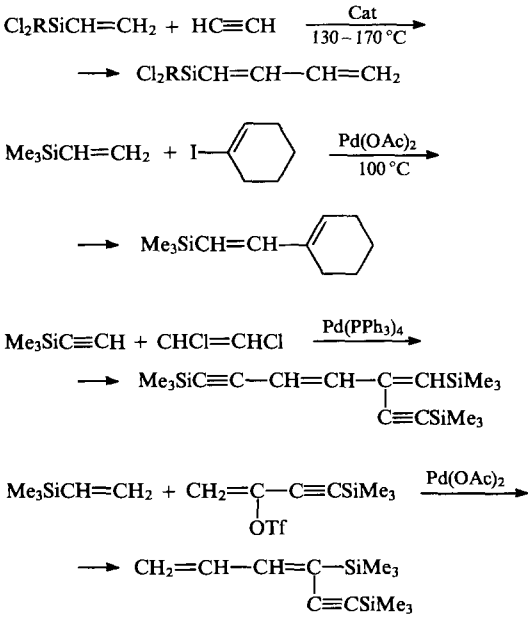


Nonconjugated diynes react similarly also in the presence of the palladium complexes $Pd_2(DBA)_3$ [234] and $PdCl_2Py_2$.[235]

The codimerisation of nonconjugated alkenynes with bis-(trimethylsilyl)ethyne in the presence of a cobalt catalyst leads to silicon-containing cyclohexadienes.[236]



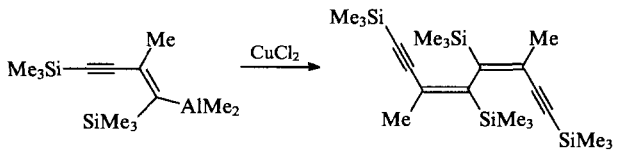
The interaction of trialkylsilylethynes with the pentacarbonyl[aryl(methoxy)carbene]chromium complexes $(CO)_5CrC.(p\text{-}RC_6H_4)OMe$ (R = H, Me, OMe, CF_3) proceeds in a more complex manner. The silylketenes formed indicate the involvement of the ligands forming part of the complex in the construction of the reaction product.[237,238]



The use of trialkylaluminium complexes[72,239] or the complexes of these compounds with metal chlorides [$Bu^i_3Al.MX_n$, where MX_n = $TiCl_4$, $VOCl_3$, $VO(acac)_2$, VCl_3, $NbCl_5$, $CrCl_3$, $MoCl_3$[240]] as catalysts of the dimerisation of silylethynes leads to the formation of a mixture of the corresponding dimers and trimers, the proportions of which are determined by the nature of the catalyst.

The codimerisation of silylethynes in the presence of $Ni(PEt_3)_4$ gives rise to conjugated dienes, one of the double bonds of which is in the silacyclobutene ring.[241]

The codimerisation of vinylsilanes with ethyne (catalysts — Pd/Al_2O_3, $Pd/CaCO_3$, Pd/C, or Pt/Al_2O_3[242,243]), haloalkenes,[244,245] or triflates[244] [catalysts — $Pd(OAc)_2$ or $Pd(PPh_3)_4$] leads to 1- or 2-silylalka-1,3-dienes.



The reactions proceed as a rule under relatively severe conditions and the yields of the target products are low.

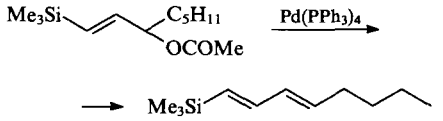
9. Other methods

A convenient preparative method of synthesis of disilylated alka-1,3-dienes involves the cleavage of the silylalkenyl derivatives of mercury,[246] silicon,[247] or aluminium[248] catalysed by transition metal compounds.

$$(Me_3SiCH{=}CH)_2Hg \xrightarrow{Pd(PPh_3)_4} Me_3SiCH{=}CH{-}CH{=}CHSiMe_3$$

$$K(Me_3SiCH{=}CHSiF_2) \xrightarrow{Ag\ or\ Cu} Me_3SiCH{=}CH{-}CH{=}CHSiMe_3$$

The catalytic reduction of ethynes with participation of hydrosilanes,[249-251] boranes,[252] or hydrogen[253] also leads to the formation of the corresponding alka-1,3-dienes, for example:



$$PrC{\equiv}CH + R_3SiH \xrightarrow{Cat} CH_2{=}CPr{-}CPr{=}CHSiR_3,$$

Cat = $Ni(acac)_2 \cdot AlEt_3$, $Ni(acac)_2 \cdot LiAlH_4$.

$$Me_3SiC{\equiv}CH + H_2 \xrightarrow{Cat} Me_3SiCH{=}CH{-}CH{=}CHSiMe_3,$$

Cat = $[(PPh_3)FeHX_2]BPy_4$.

Several examples of the synthesis of silicon-containing diene hydrocarbons and their aliphatic[254] and alicyclic[255,256] derivatives as a result of the [2+4]-cycloaddition reactions and subsequent isomerisation of the cyclic adducts as well as the β-elimination of carboxylic acids from the corresponding silicon-containing esters under the influence of a palladium catalyst[257,258] have been described.

Finally a comparatively interesting method of synthesis of 1-trialkylsilylalka-1,3-dienes has been developed by Japanese workers on the basis of the chromium(II) chloride-catalysed interaction of dibromomethyltrimethylsilane with cinnamaldehyde and its analogues.[259]

$$RCH{=}CH{-}CH{=}O + Me_3SiCHBr_2 \xrightarrow{CrCl_2} RCH{=}CH{-}CH{=}CHSiMe_3$$

The reaction takes place at room temperature and the yields of the dienes are ~80%.

III. Chemical properties of 1- and 2-triorganosilylalka-1,3-dienes and their derivatives

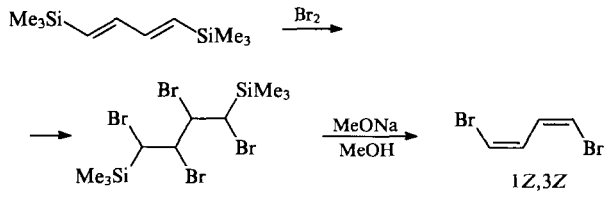
The chemical reactions of 1- and 2-triorganosilylalka-1,3-dienes and their carbofunctional derivatives known at the present time may be divided into three groups: (1) reactions with participation of multiple bonds — addition, polymerisation, and complex formation reactions; (2) reactions with participation of silicon–carbon bonds; (3) reactions with participation of functional groups.

The mode and selectivity of the addition of reagents of different nature are known to depend in a complex manner on the structure of the 1,3-dienes, their polarity, and their polarisability.[260] The study of the characteristic features of the variation of their reduction half-wave potentials,[56,208] the parameters of Raman and IR spectra,[175,261,262] as well as the bond lengths[263] and the enthalpies of formation of the bonds[264] on passing from 1,3-diene hydrocarbons and their derivatives to silicon-containing compounds with a similar structure permitted the conclusion that silicon-containing substituents at the double bond are weaker electron-donating agents than the analogous hydrocarbon groups. The measured molecular refractions indicate the high polarisability of the conjugated π-bonds in 1-trialkylsilylalka-1,3-dienes.[56,265]

Similar conclusions concerning the nature of the redistribution of electron density in silicon-containing dienes have been reached from the analysis of the ^1H and ^{13}C NMR spectra[125,175,266,267] and their dipole moments.[128,175,268]

In conformity with the existing tradition, the observed features of the electronic structure of the silicon-containing dienes have been explained by the delocalisation of the π-electron density of the multiple bonds to the unoccupied *d* orbitals of silicon ($d_\pi - p_\pi$ conjugation).

1. Addition of electrophiles



The interaction of silicon-containing 1,3-diene hydrocarbons and their derivatives with the halogens has been investigated only for reactions with bromine. Regardless of the structure of the substrates, it proceeds nonselectively in all cases. 1-Trialkylsilylalka-1,3-dienes combine with bromine at the double bond remote from the silicon atom and in the 1,4-positions,[50] the ratio of the dibromo-derivatives formed being ~1:1. On heating, the 1,4-dibromo-derivatives rearrange with migration of the double bond to the α,β-position relative to the silicon atom.

$$Me_3SiCHBrCH{=}CHCH_2Br \rightleftharpoons Me_3SiCH{=}CHCHBrCH_2Br$$

It is appropriate to recall that the allyl rearrangement of dibromo-derivatives obtained on bromination of 1,3-diene hydrocarbons is directed towards the formation of 1,4-dibromo-derivatives.[260] Silicon-containing dienes are brominated more slowly than hydrocarbons with a similar structure and the rate of reaction is described by a third-order kinetic equation.[269] The increase in the kinetic order of reaction to three is caused, according to the authors,[269] by the relative stability of the complexes $A_\pi \cdot Br_2$, where A_π is an alkene–bromine complex.

Ethyl 5-trimethylsilylpenta-2,4-dienoate also combines with bromine nonselectively at both double bonds. The 1,4-adducts were not detected.[175]

Exhaustive bromination of 1,4-bis(trimethylsilyl)buta-1,3-diene leads to the corresponding tetrabromo-derivative. On treatment with sodium methoxide in methanol, the latter affords 1,4-dibromobuta-1,3-diene in a satisfactory preparative yield.[270]

Judging from the available data,[271] the addition of the elements of hypohalites to silicon-containing 1,3-diene hydrocarbons proceeds chemo- and regio-specifically at the double bond remote from the silicon atom.

$$R^1_3SiCH{=}CH{-}CR^2{=}CHR^3 + \text{>N–X} \xrightarrow{R^4OH} R^1_3SiCH{=}CH{-}CR^2(OR^4)CHR^3X$$

X = Cl, Br.

The 1,3-diene was treated with the haloamide in an alcoholic medium.[271]

Alkyl hypohalites add to 3-*tert*-butyl-4-methyl-1-triethylsilylpenta-1,3-diene, containing a double bond subjected to a considerable steric hindrance, also only at the remote double bond.[272] This observation shows that the addition of alkyl hypochlorites and alkyl hypobromites to the double bond remote from the organosilicon substituents, which is unexpected from the standpoint of Ingold's classical ideas,[260] is due to nonsteric factors.

Organosulfenyl and organoselenyl halides also react at the double bond remote from the silicon atom with attachment of the electrophilic species to the terminal carbon atom of the 1,3-diene fragment.[120,273]

$$R^1_3SiCH{=}CH{-}CR^2{=}CHR^3 + R^4YX \longrightarrow$$
$$\longrightarrow R^1_3SiCH{=}CH{-}CR^2XCHR^3YR^4$$

X = Cl, Br; Y = S, Se.

The adducts containing mobile halogen atoms in the allylic position readily isomerise to 1,4-adducts, while on treatment with triethylamine they split off the hydrogen halide.[120,273]

On distillation, selenium-containing adducts are partly dehydrohalogenated, which hinders their isolation in a pure state.[273]

The addition of C-electrophiles has been investigated in relation to the interaction of 1-trialkylsilylbuta-1,3-dienes with chloromethyl ethers[118,274] or sulfides[142] catalysed by aprotic Lewis acids ($ZnCl_2$,[274] $ZnBr_2$,[142] $TiCl_4$[118]).

According to the data of Shikhmamedbekova and Khudieva, in the presence of zinc(II) chloride chloromethyl ether adds both in the 1,4-positions and to the double bond remote from the silicon atom in silicon-containing 1,3-diene hydrocarbons (the ratio of the adducts formed is 1:3:3).[274]

$$Me_3SiCH{=}CH{-}CH{=}CH_2 + ClCH_2OMe \xrightarrow{ZnCl_2}$$
$$\longrightarrow Me_3SiCHClCH{=}CHCH_2CH_2OMe$$
$$\longrightarrow Me_3SiCH{=}CH{-}CHClCH_2CH_2OMe$$

In the presence of titanium(IV) chloride, the interaction of dichloromethyl ether with 1-trialkylsilylalka-1,3-dienes leads to the corresponding silicon-free 1,3-diene aldehydes.[118]

$$R{-}\!\!\sim\!\!\sim\!\!SiMe_3 + Cl_2CHOMe \xrightarrow{TiCl_4}$$
$$\longrightarrow R{-}\!\!\sim\!\!\sim\!\!CHO$$

The possible paths in this interesting reaction are not discussed.

The reaction of 3-trimethylsiloxy-1-trimethylsilylbuta-1,3-diene with α-chlorosulfides results in the formation of the corresponding unsaturated carbonyl compounds, which presupposes the addition of the sulfide to the terminal double bond.[142]

$$Me_3Si{-}\!\!\sim\!\!\sim\!\!OSiMe_3 + ClCHRSPh \xrightarrow{ZnBr_2}$$
$$\longrightarrow Me_3Si{-}\!\!\sim\!\!\sim\!\!C(=O){-}\!\!\sim\!\!R$$

R = H, Pr.

2. Addition of nucleophiles

The interaction of 1-trialkylsilylalka-1,3-dienes with thiols in the presence of sodium thiolate had been described.[275] It has been shown that the reaction takes place only under severe conditions (100 °C, 70 h). The overall yield of the adducts does not exceed 20%. Chromatographic and spectroscopic analysis of the products showed that the thiol added to the 1,4-, 3,4-, and 4,1-positions (the yields of the corresponding products were 41%, 57%, and 2%).

The reactions of unsaturated organosilicon compounds with ammonia and amines are also nucleophilic addition processes, although their mechanism has not been investigated.

The attempts to add ammonia to 1-trialkylsilylbuta-1,3-dienes have not been successful: in the presence of metallic sodium, hydrogen undergoes 1,4-addition with formation of trialkylbut-2-enylsilane.[276]

Under the same conditions, secondary amines react with silicon-containing 1,3-dihydrocarbons, giving rise to mixtures of 1,4- and 3,4-adducts (~2:3) (Scheme 3).[277]

Scheme 3

$$R^1_3Si{-}\!\!\sim\!\!\sim\!\!C(R^2){=}CH{-}CHR^3 + R^4_2NH \xrightarrow{Na}$$
$$\xrightarrow{1,4} R^1_3Si{-}CH{=}CH{-}C(R^2)(NR^4_2){-}R^3$$
$$\xrightarrow{3,4} R^1_3Si{-}CH(R^2){-}CH{=}CH{-}NR^4_2\,(R^3)$$

The methyl group in the 3-position promotes addition in the 1,4-positions. The same group at the C(4) atom hinders the addition, but hardly affects the ratio of the isomeric products.[277]

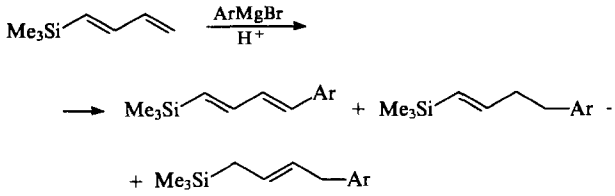
The interaction with organometallic compounds was first achieved by Sadykh-Zade[278] in relation to the reaction of 1-trimethylsilylbuta-1,3-diene with butyllithium.

According to the author, the silicon-containing hydrocarbon obtained after demetallating the adduct with water had the structure of *trans*-1-trimethylsilyloct-2-ene. It was established somewhat later that silicon-containing alka-1,3-dienes are formed after the demetallation of a mixture of alk-1-enes and alk-2-enes.[279] The ratio of the isomers formed hardly depends on the structure of the 1,3-diene fragment. It is not possible to isolate the adducts in the reactions of 1-trialkylsilyl-3-methylbuta-1,3-diene with lithium alkyls: regardless of the structure of the organolithium compounds and the experimental conditions, the diene polymerises.[279]

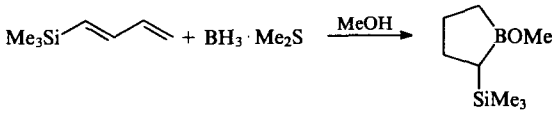
It is also noteworthy that the decrease in temperature and the replacement of the ether employed as the solvent by THF in the reactions of 1-trialkylsilylbuta-1,3-diene and 1-trialkylsilylpenta-1,3-diene promotes the formation of 1,4-adducts. In hydrocarbon solvents, the dienes polymerise.

Judging from the available data, 1-dimethylboryl-1-trimethylsilylbuta-1,3-diene combines with butyllithium at the double bond remote from the silicon atom. The adducts formed are readily alkylated.[37]

$$Me_3Si{-}\!\!\sim\!\!\sim\!\!BMe_2 \xrightarrow{BuLi} Me_3Si{-}CH(Li){-}CH{=}CH{-}Bu \xrightarrow{MeI}$$
$$\longrightarrow Me_3Si{-}CH(Me){-}CH{=}CH{-}Bu\;(BMe_2)$$



Mixed organomagnesium compounds add to 1-trialkylsilylbuta-1,3-dienes exclusively in the 1,4-positions.[280]

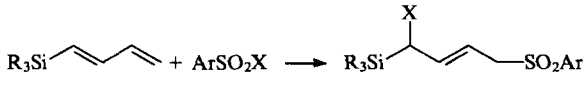


R^1 = Me, Et; R^2 = Et, Pr.

A change in temperature from −25 to 35 °C and of the solvent (Et_2O, glyme, THF) did not affect the mode of the reaction and the yield of its products.

On interaction with 1-trimethylsilylbuta-1,3-diene in the presence of transition metal complexes, arylmagnesium halides give rise to a mixture of products of substitutional arylation of the products of addition to the double bond and in the 1,4-positions.[281]

On interaction with 1-trimethylsilylbuta-1,3-diene, borane stabilised by trimethylsulfide gives rise to a cyclic adduct. The latter affords a satisfactory yield of (±)-1-methoxy-2-trimethylsilylborolane on treatment with methanol.[282]



3. Free-radical addition

The free-radical addition of thiols has been investigated only in relation to the interaction of 1-triethylsilylbuta-1,3-diene with ethanethiol. *tert*-Butyl peroxide was used as the initiator.[275] As in nucleophilic addition reactions, a mixture of 1,4-, 4,1-, and 3,4-adducts is formed in this process in proportions of 65 : 10 : 25.[275]

The interaction of organic sulfonic acids with acid halides, initiated by copper(I) halides (the Asher – Vovsi reaction) or thermally, is also included among the free-radical addition reactions.

It has been shown in relation to the reactions of 1-methyldiethylsilylbuta-1,3-diene that benzenesulfonic acid chloride adds to the above 1,3-diene on heating in the presence of the Asher – Vovsi catalyst — copper(I), triethylamine, and acetonitrile — exclusively in the 1,4-positions;[126] the reaction with the acid bromide proceeds also without a catalyst. The addition of the latter does not alter the mode of reaction. The acid iodide adds spontaneously and exothermically even at room temperature and also only in the 1,4-positions.

R_3Si = Me_3Si, $MeEt_2Si$, Et_3Si;

Ar = Ph, *p*-MeC_6H_4, *p*-$NO_2C_6H_4$; X = Cl, Br, I.

Toluene-*p*-sulfonic and *p*-nitrobenzenesulfonic acids behave similarly in this reaction.[124] The chlorides of methane- and ethane-sulfonic acids react with 1-trialkylsilylbuta-1,3-diene under more severe conditions to form a mixture of 1,4- and 3,4-adducts.[124,125] It is of interest that 5,5-dimethylhexa-1,3-diene, a hydrocarbon with a similar structure, combines with the chlorides of alkane- and arene-sulfonic acids under milder conditions exclusively in the 1,4-positions.[124] Specially formulated experiments established that the 1,4-adducts do not isomerise to the 3,4-adducts on heating in the presence of the Asher – Vovsi catalyst.[124]

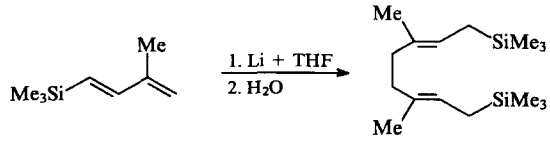
Within the limits of the accuracy of the method of competing reactions, the rate of addition is almost independent of the nature of the aromatic group (phenyl, *p*-tolyl, and *p*-nitrophenyl) attached to sulfur.[124] Variation of the alkyl groups at the silicon atom (R_3Si = Me_3Si, $MeEt_2Si$, Et_3Si) also does not affect the rate and mode of the reaction.[125]

1-Methyldiethylsilyl-3-methylbuta-1,3-diene reacts with the chlorides of alkane- and arene-sulfonic acids with much more difficulty than dienes without substituents in the 1,3-diene fragment.[127] A mixture of the 1,4- and 3,4-adducts and of the product of substitutional sulfonylation — 4-alkanesulfenyl-1-methyl diethylsilyl-3-methylbuta-1,3-diene (~10%) — has been obtained in an overall yield not exceeding 25%. Attempts to carry out the reaction of this silicon-containing diene with the chlorides or bromides of arenesulfonic acids were unsuccessful: the initial reactants which failed to react are recovered at low temperatures while at high temperatures charring takes place.

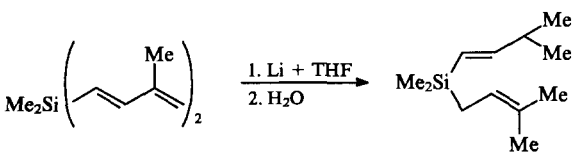
1-Trialkylsilylpenta-1,3-diene behaves similarly in the reaction with arene-sulfonyl halides.[127]

The above data combined with those obtained in the study of the influence of the nature of the catalyst components (metal, ligands) and the solvent (benzene, toluene, acetone, dibutyl ether, carbon tetrachloride, acetonitrile, chloroform, pyridine, methanol, dimethyl sulfoxide, hexamethylphosphoramide)[283] enabled the author to conclude that the thermally initiated addition of the bromides and iodides of sulfonic acids proceeds as a classical free-radical chain process.[282] The addition of the acid chlorides and bromides with participation of copper salts is a redox-initiated intracomplex reaction of the ligands in which the 1,3-diene participates as a bidentate ligand. In those cases where the interaction requires relatively high temperatures, the reagent – metal – diene complex decomposes and the reaction proceeds as the usual redox-initiated free-radical addition with formation of a mixture of the 1,4- and 3,4-adducts.[283]

4. Reduction and oxidation of 1- and 2-triorganosilylalka-1,3-dienes

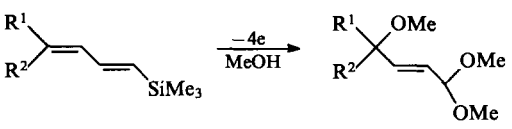


The catalytic hydrogenation of 1-trialkylsilylalka-1,3-dienes in the presence of platinum or palladium catalysts proceeds at room temperature and at atmospheric pressure with formation of a mixture of 1-triorganosilylalk-1-enes and 1-triorganosilylalk-2-enes.[41,42,284] The study of the composition of the hydrogenation products as a function of time has shown that 1-trialkylsilylalk-2-enes predominate in the mixture in the first stage, while 1-trialkylsilylalk-1-enes predominate in the concluding stage.[284] These results indicate that the alk-2-enes isomerise in the course of time with migration of the double bond towards the silicon-containing substituent.



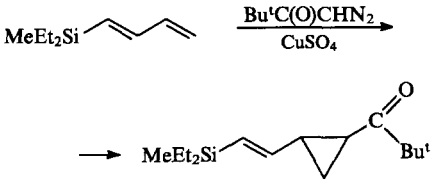
Under the same conditions in the presence of a palladium catalyst, 1,2-bis(trialkylsilyl)alka-1,3-dienes also combine with hydrogen in the 1,4-positions with formation of 1,2-bis-(trialkylsilyl)but-2-enes, which are not apparently hydrogenated further owing to steric factors.[52,53]

Exhaustive hydrogenation of 1-trialkylsilylalka-1,3-dienes and their functional derivatives in the presence of $Pd/CaCO_3$ or Pt/C afforded the corresponding saturated organosilicon compounds.[41,42,242,274]

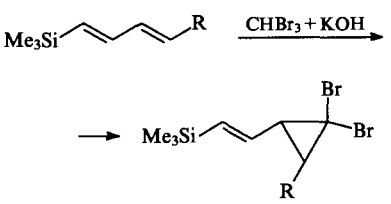


The interaction of 1-trimethylsilyl-3-methylbuta-1,3-diene with lithium in an aprotic medium results in the formation of hydrodimerisation products.[285]

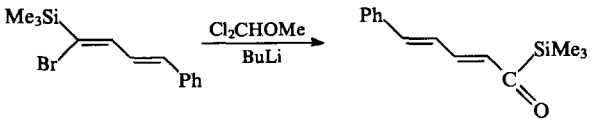
Under the same conditions, dimethylbis(3-methylbuta-1,3-dienyl)silane is hydrogenated in the 1,4- and 3,4-positions.[285]



There is only one communication which describes results of the electrochemical oxidation of 1-trialkylsilylalka-1,3-dienes in methanol.[194]

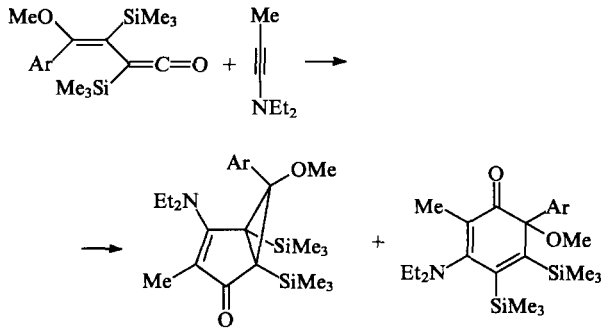


The reaction proceeds as the addition of methoxyl radicals accompanied by the substitution of the silyl group.



5. Cycloaddition reactions

The interaction with carbenes — [1+2]-cycloaddition — has been used as a method of synthesis of the corresponding alkenylcyclopropanes also in relation to silicon-containing dienes. Thus it is known that pivaloylcarbene[286] and dibromocarbene[22] add chemoselectively to the double bond of 1-trialkylsilylbuta-1,3-dienes remote from the silicon atom.

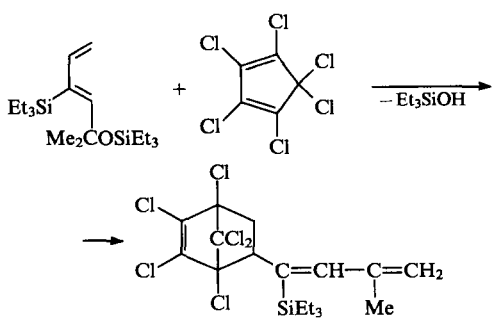


However, in the interaction of 1-bromo-4-phenyl-1-trimethylsilylbuta-1,3-diene with methoxymethylenecarbene a silicon-containing ketone was obtained instead of the expected cyclic adduct.[287]

The [2+2]-cycloaddition in the interaction of disilylated ketenes with 1-diethylaminoprop-1-yne takes place nonselectively (Scheme 4).[254]

Diene synthesis {[2+4]-cycloaddition} — the interaction of conjugated silicon-containing dienes with dienophiles — is one of the most thoroughly investigated reactions of 1- and 2-trialkylsilylalka-1,3-dienes and their derivatives. A considerable proportion of the studies in this field have been carried out in order to demonstrate the 1,3-diene structure of the silicon-containing

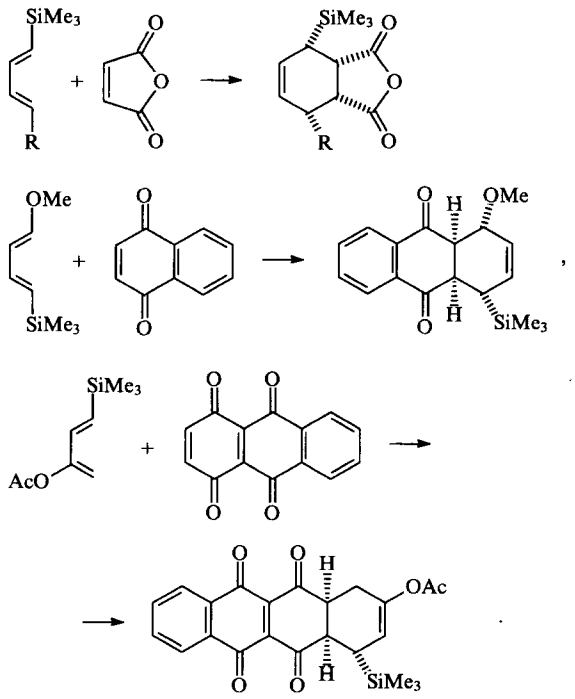
Scheme 4



compounds (see, for examples, Refs 6, 27, 52, 109, 129, 175, 208, 249, 274, etc.). However, the studies of the influence of the structure of the diene and the dienophile on the relative rates and the regio- and stereo-selectivity of the ring formation are of greater interest.[18,170,177,288–290] Diene synthesis is also a key stage in the multistage synthesis of compounds such as (±)-daunomycin, (±)-isodaunomycin[139,140,289,291,292] the aglucone of chlorotricin,[216] the agilactones A and F,[293] and other complex polycyclic biologically active substances.[20,93,216,217,289,294,295]

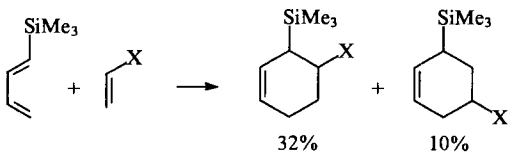
The importance of this aspect increased sharply after the development of methods for the protodesilylation (the removal of the silyl protecting group) of the cyclic adducts by potassium fluoride[20,160,209,296,297] and especially for the replacement of the triorganosilyl group by hydroxy-groups on treatment of silicon-containing compounds with lead(IV) tetraacetate[170,291,298] or perfluorotetraacetate.[140]

Diene synthesis with participation of organosilicon 1,3-diene compounds was first carried out in 1954 by heating a mixture of the products of the hydrogenation of 1-trimethylsilylbut-3-en-1-yne with maleic anhydride.[1] Maleic anhydride,[1,6,27,42,52,53,104,105,109,111,112,130,138,170,175,177,201,208,274,299–303] methylmaleic anhydride,[138,304] maleimides,[130,170,201,300] acrolein,[177] methylacrolein,[104,304] acrylonitrile,[177] methyl acrylate,[138,288,304] ethyl acrylate,[18,104,112] dimethyl maleate,[104,177,205] diethyl maleate,[177] 1,4-benzoquinone,[104,170,201] 2-methylbenzoquinone,[304] 3-methylbenzoquinone,[304] 2,6-dimethylbenzoquinone,[112] 2,3-dimethoxybenzoquinone,[290] 1,4-naphthoquinone,[100,130,138,300] quinizarinquinone and its derivatives,[139–141,290,291] tetracyanoethene,[180,184,249,301] and other compounds containing a dienophile group[100,112,205,298,300] were used later as dienophiles.



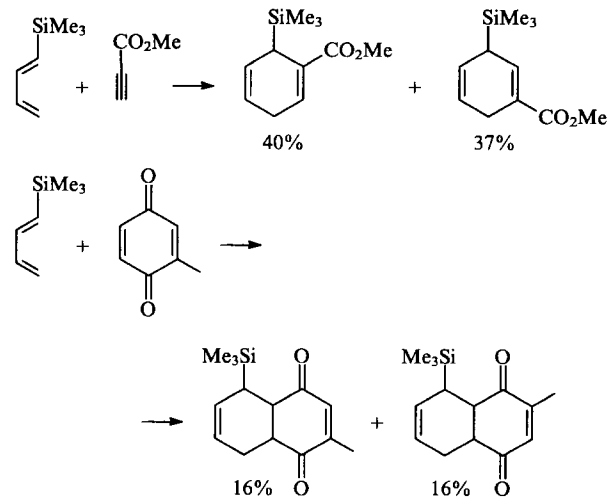
Examples of the cyclodimerisation of silicon-containing 1,3-dienes via the [2+4]-mechanism in which the diene itself plays the role of the dienophile are known.[305] The reaction is chemo- and regio-selective, but the preferred path involves condensation via the unsubstituted vinyl group of the 1,3-diene dienophile.

Hexachlorocyclopentadiene (diene) undergoes also an unusual condensation with the triethylsilyl ether of 2-methyl-4-triethylsilylhexa-3,5-dien-2-ol (dienophile):[116] the adduct formed splits off triethylsilanol under the conditions of the isolation process.

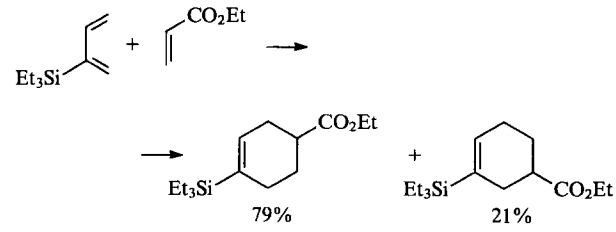


Compounds with activated triple bonds can also act as dienophiles: propiolic and methylpropiolic acids,[138,292,304] the nitrile[294] and ester[288,300,304] of propiolic acid, ethynedicarboxylic acid and its dimethyl ester,[100,104,170,300] and bis(trifluoro-methyl)ethyne.[35]

It has been noted that, in reactions with symmetrical dienophiles such as maleic anhydride, maleimide, etc., silicon-containing dienes condense with somewhat greater difficulty than silicon-free hydrocarbons.[112,305,306] Other conditions being equal, 2-silyldienes are more reactive than the isomeric compounds containing the organosilicon group at the first or fourth carbon atom of the conjugated fragment. The introduction of other substituents in the 1- and/or 4-position also hinders the cycloaddition. For example, 1,4-disubstituted dienes of the type $Me_3Si(CH{=}CH)_2X$ (X =COMe, COOMe) interact with the maleic anhydride only in the (*E*,*E*)-configuration on heating in a sealed tube.[112,175] As a rule, the reactions with symmetrical dienophiles are stereoselective: in relation to the plane of the ring, all the substituents are in the *cis*-positions, for example:



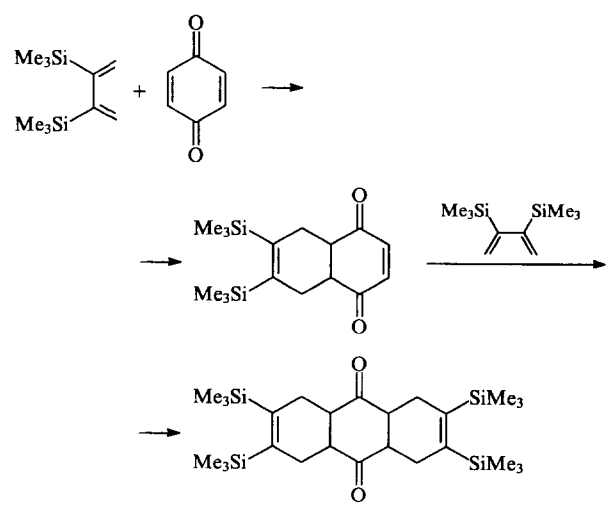
The acrylic dienophiles $CH_2{=}CHX$ (X = CHO, CN, COOR, etc.) can react with 1-trialkylsilylalka-1,3-dienes to form two regioisomers. The available data show that the reaction proceeds non-regioselectively, but 1,2-disubstituted cyclohexenes are formed in somewhat greater amounts (the *ortho*-effect).[112,304]



This difference virtually disappears in the reactions of silicon-containing dienes with methyl propiolate and methylbenzoquinone (Scheme 5).[304]

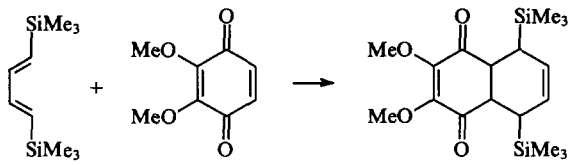
The isomeric 1,3- and 1,4-disubstituted cyclohexenes are formed in proportions of 1:3.3 in the interaction of ethyl acrylate with 2-triethylsilylbuta-1,3-diene. The use of catalysts (usually aprotic Lewis acids) promotes the formation of 1,4-isomers and increases the yield of cyclic adducts (Scheme 6).[18,104]

Scheme 5



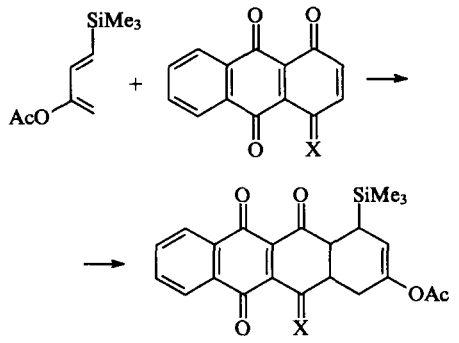
Scheme 6

In the presence of boron trifluoride etherate, the ratio changes to 1:7.3.[104]



A comparative study of the regioselectivity of the cycloaddition of the diene $Me_3Si{-}CH{=}CH{-}CR^1{=}CHR^2$ (R^1 =H, R^2 = Me; R^1 =Me, R^2 =H, Me_3SiO) to various dienophiles by Fleming showed that it is controlled to a larger extent by the nature of the substituents R^1 and R^2 than by the trialkylsilyl fragment at C(1).[288]

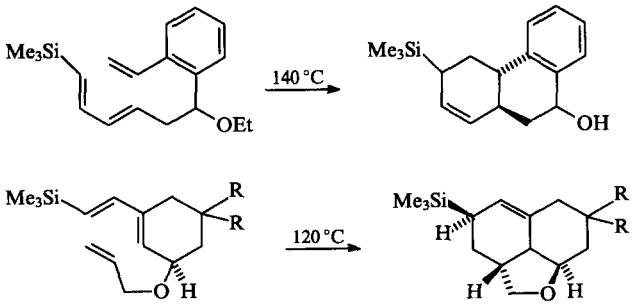
The formation of adducts with both multiple bonds is also possible in the reactions of silicon-containing dienes with benzoquinones, naphthoquinones, and quinizarinquinones. In most of the instances investigated, only one of the monoadducts is formed:[201,290,304] The possibility of obtaining the second isomer has not been discussed, although there are indications that it is absent.[201] The formation of an adduct via both double bonds of benzoquinone has been specially emphasised only in the study of Garrat and Tsotins.[170]



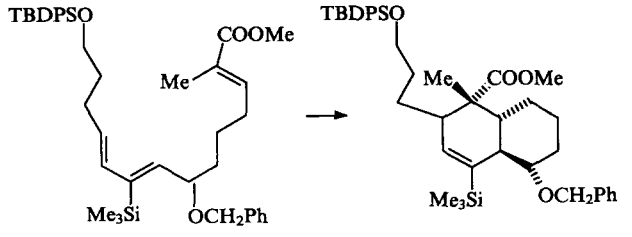
It is also appropriate to note that methyl-1,4-benzoquinone [304] and 2,3-dimethoxy-1,4-benzoquinone [290] combine with silicon-containing dienes only via the unsubstituted double bond (Schemes 5 and 7).

Scheme 7

Naphthoquinones, [130] quinizarinquinones, [139,140,289,291] and ketiminequinizarinquinones [289] form cyclic adducts exclusively via the 'external' double bond.



X = O, TsN.

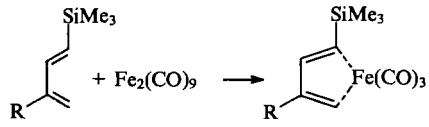


The high regio- and stereo-selectivity of the cycloaddition can be explained in terms of the perturbation of the frontier orbitals [306] of the electron-donating diene and the electron-accepting dienophile.

Examples of diene synthesis employing the dienes formed on pyrolysis of silicon-containing sulfolenes have been described. [148,151]

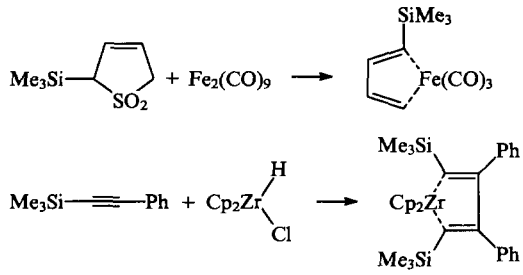
Intramolecular diene synthesis occupies a special place in the stereospecific synthesis of cyclic natural products.

1,3-Diene and dienophile fragments can be components of aliphatic [216,217] or alicyclic [20,105,131,293,295] compounds.



TBFDPS = *tert*-butyl diphosphite-silane.

This reaction is distinguished by a high stereoselectivity.

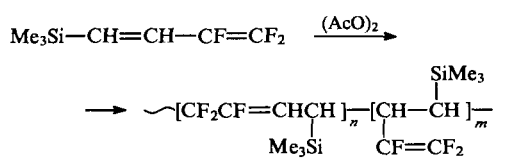


6. Synthesis of complexes with silicon-containing 1,3-diene ligands

Numerous iron, [96,106,167,190,307–310] cobalt, [311,312] zirconium, [313–315] and other transition metal [190,316] complexes of acyclic silicon-containing 1,3-dienes have now been obtained. In all cases, the 1,3-dienes behave as bidentate ligands.

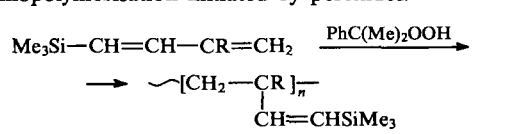
The synthesis of the complex may include both the interactions of silicon-containing 1,3-diene structures already formed with metal complexes (ligand exchange), i.e.

and the interaction of metal complexes with organic precursors of 1,3-dienes. [307,310,315] The method presupposes the synthesis of silicon-containing 1,3-diene compounds in the course of the formation of the complex.



In the vast majority of cases, the structure of the silicon-containing complexes has been demonstrated by X-ray diffraction.

The reactions of silicon-containing complexes with carboxylic acids, [226–229] their halides, [106,308,309] and ketones, [314] as well as photochemical isomerisation reactions [316] have been described.

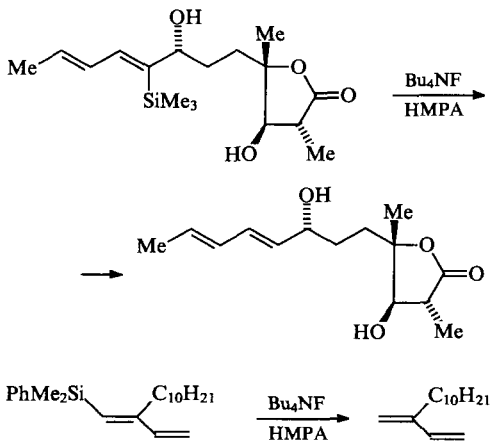


7. Polymerisation and copolymerisation of silicon-containing alka-1,3-dienes

The polymerisation of silicon-containing 1,3-dienes was first reported in 1956. According to the data of Shchukovskaya et al., [5] 3-methyl-2-triethylsilylbuta-1,3-diene gives rise to a viscous oil with a molecular mass of 9 000 on heating with *tert*-butyl peroxide. The structure and physicochemical properties of the polymer obtained were not investigated.

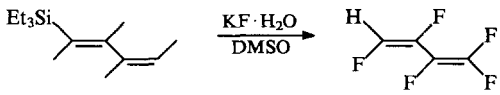
Somewhat later, Haszeldine and coworkers [107] showed that 3,4,4-trifluoro-1-trimethylsilylbuta-1,3-diene polymerises nonregioselectively under the influence of acetyl peroxide.

In contrast to fluorinated monomers, 1-trialkylsilylbuta-1,3-dienes and 3-methyl-1-trialkylsilylbuta-1,3-dienes give rise to high-molecular-mass compounds containing only 3,4-units on homopolymerisation initiated by peroxides. [317–319]



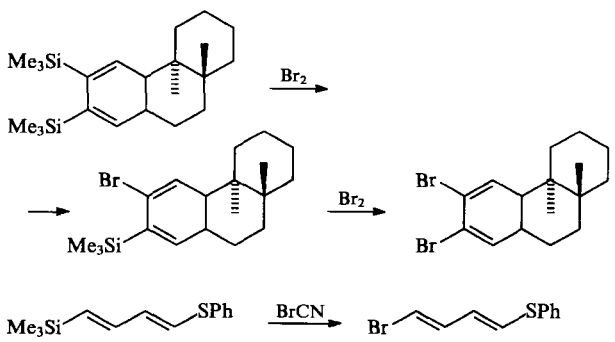
The copolymerisation of silicon-containing 1,3-diene hydrocarbons with vinyl monomers has also been investigated. [320,321] and the copolymerisation constants and activity factors have

been determined for 1-triethylsilylbuta-1,3-diene and styrene.[320,322,323] Similar high-molecular-mass compounds have been obtained by the copolymerisation of 1-triethylsilylbuta-1,3-diene with styrene on a cathode.[324] Copolymers having effective mechanical characteristics have been synthesised from arylvinyl monomers and 2-trimethoxysilylbuta-1,3-diene.[321]



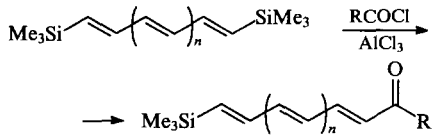
8. Reactions with participation of silicon–carbon bonds

The protodesilylation of 1- and 2-triorganosilylalka-1,3-dienes takes place with much greater difficulty than that of structurally similar 1-trialkylsilylalk-3-en-1-ynes.[26] This method has come to be fairly widely used only when the possibility of removing the silyl group from silicon-containing dienes by means of the fluoride anions had been demonstrated. Tetrabutylammonium fluoride[20,160,296,297] or potassium fluoride[168,169] are usually employed as fluoride anion donors. Both silicon-containing 1,3-diene hydrocarbons[296] and their derivatives[169,209,297] have been desilylated.



HMPA = hexamethylphosphoramide.

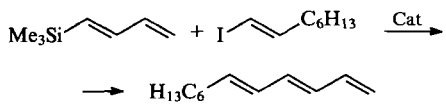
The protodesilylation by tetrabutylammonium fluoride is as a rule carried out in hexamethylphosphoramide or tetrahydrofuran[296,297] and that by potassium fluoride is performed in dimethyl sulfoxide.[209]



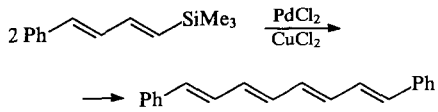
The use of alkalis or alkoxides as the nucleophile is relatively effective in the removal of the silyl protecting group, although it is known that dehydrohalogenation and desilylation take place on treatment of 1,2,3,4-tetrabromo-1,4-bis(trimethylsilyl)butane with sodium methoxide. (1*E*,4*E*)-dibromobuta-1,3-diene was first obtained by this method.[270]

Examples of the replacement of triorganosilyl groups by halogen on interaction of the corresponding 1,3-dienes with bromine[256] or bromocyanogen[204] are known.

The attempt to introduce iodine instead of the trimethylsilyl group by treating 1-trimethylsilylnona-1,3-diene with iodine was unsuccessful.[31]



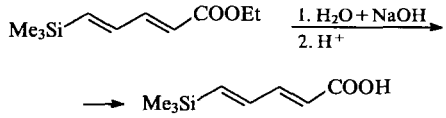
The reaction involving the replacement of the trialkylsilyl group by an acyl group in the presence of anhydrous aluminium chloride may be recommended as a convenient preparative method of synthesis of 1,3-diene ketones.[32,325,326]



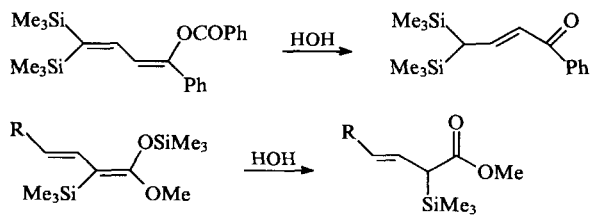
The use of dibasic acid dichloride in this reaction leads to the corresponding polyenepolyones.[325]

A similar acylation reaction is also known for complexes of 1-trialkylsilylalka-1,3-dienes with iron carbonyl.[106]

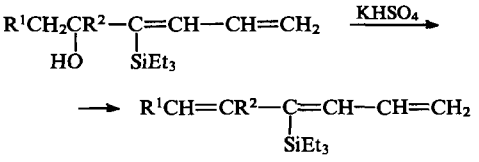
The alkenylation[327] and arylation[328] of silicon-containing 1,3-dienes by the corresponding halides occurs only in the presence of palladium catalysts — $Pd(OAc)_2.P(OEt)_3$, $PdCl(\eta^3\text{-}C_3H_7)$, etc.



Naso[204] described a very interesting 'dimerisation' reaction of 1-trialkyl silylalka-1,3-dienes on treatment with copper and palladium chlorides accompanied by desilylation.



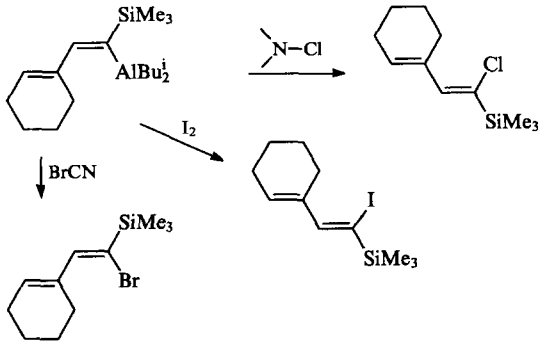
9. Reactions with participation of functional groups



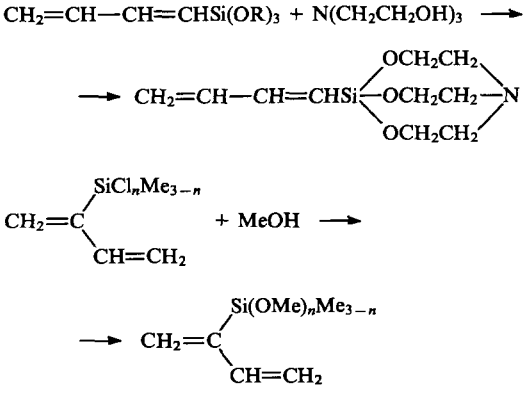
Reactions of this type of derivatives of silicon-containing 1,3-diene hydrocarbons have been least investigated. It has been reported that ethyl (5*E*,*E*)-trimethylsilylpenta-2,4-dienoate is hydrolysed by an aqueous alcoholic solution of sodium hydroxide without the cleavage of the silicon–carbon bond and a change in configuration.[175]

Hydrolysis of alkoxy-1,3-dienes,[14,131] acyloxy-1,3-dienes,[136] and mixed acetals[101] in an acid medium leads to unsaturated ketones or esters respectively.

Primary silicon-containing 1,3-diene alcohols give rise to the corresponding aldehydes in satisfactory yields on oxidation with pyridinium chlorochromate.[329] Tertiary silicon-containing alcohols are dehydrated on heating with acid potassium sulfate, but there is no elimination of the corresponding trialkylsilanols.[61,62]



Silicon-containing 1,3-dienyl sulfides are alkylated by organomagnesium compounds in the presence of palladium or nickel complexes.[204]



Derivatives of silicon-containing 1,3-diene hydrocarbons containing the BX_2 (X = Cl, Br, OAlk) group at the double bond lose boron on treatment with carboxylic acids[35] and are alkylated by mixed organozinc compounds or α-haloalkenes in the presence of palladium complexes.[210,211,213] On oxidation, these hydrocarbons give rise to silicon-containing ketones,[34] whilst their interaction with carbon monoxide in an alcoholic medium affords the esters of silicon-containing 1,3-dienoic acids.[212]

Organoaluminium derivatives of silicon-containing alka-1,3-dienes give rise to the corresponding halides on treatment with donors of the electrophilic halogens.[33]

Alka-1,3-dienes containing halogens or alkoxy-groups at the silicon atom enter into alcoholysis[105] or transalkylation (Scheme 8)[301] reactions.

Scheme 8

Analysis of the data examined in this review permits the following generalisations.

(1) The methods based on the Wittig, Horner–Emmons, Peterson, and dehydration reactions of silicon-containing alcohols make it possible to obtain any silicon-containing 1,3-diene hydrocarbons and their carbofunctional derivatives with a specified structure in a satisfactory preparative yield. In the synthesis of (1*E*,3*E*)-isomers, preference should be given to the methods based on the Wittig, Horner–Emmons, or dehydration reactions, whereas in the synthesis of (1*E*,3*Z*)- or (1*Z*,3*Z*)-isomers the second version of the Peterson reaction is preferred.

(2) Regardless of the structure of the substrate and the nature of the reagent, in the reactions of conjugated silicon-containing dienes the attacking species is almost always attached to the C(4) atom of the 1,3-diene fragment remote from the silicon atom. The occurrence of this reaction path in the addition reactions cannot be accounted for by the steric influence of the triorganosilyl group and is probably due to the stabilisation of the allyl intermediates containing the organosilyl group (formal analogy with 1-phenylbuta-1,3-diene).

(3) In terms of the overall electron-donating effect, the trialkylsilyl group occupy an intermediate position: $R_3C > R_3Si > H$.

Reduction methods in the synthesis of low-valence platinum and palladium complexes

N Yu Kozitsyna, I I Moiseev

Contents

I. Introduction	47
II. Synthesis of phosphine complexes of the type ML_n [M = Pt(0), Pd(0); L = PR_3; $n = 2-4$]	47
III. Synthesis of cluster compounds of platinum metals in the oxidation states $0 < n < 2$	51
IV. Conclusion	58

Abstract. The use of the reduction reactions of platinum(II) and palladium(II) complexes for the synthesis of compounds of these metals in the lowest oxidation states ($0 \leqslant n < 2$) with stabilising π-acceptor type ligands, such as phosphines, phosphides, phenanthroline, and bipyridyl, is discussed. The mechanisms of these reactions as well as the behaviour of tertiary phosphine ligands under the conditions of the reactions between the complexes and reductants are examined. The available structural data on the mononuclear and polynuclear compounds of platinum and palladium in the lowest oxidation states are surveyed. The bibliography includes 138 references.

I. Introduction

Among the known preparative methods of synthesis of complexes of metals in the nickel triad in the lowest oxidation states,[1,2] the following are most frequently employed: direct synthesis from the metals; substitution of the ligands in complexes with the metal in low oxidation states or addition of neutral ligands; reductive elimination; reduction reactions. The reduction reactions are simplest and possess extensive synthetic possibilities. Alkali metals, their alkoxides, hydrazine, sodium tetrahydroborate, carbon monoxide, and hydrogen are usually employed as reductants for the synthesis of complexes containing the metal atoms in the formal '0' oxidation state.

Among the compounds of platinoid metals, those with tertiary phosphines occupy a special place. Platinum(0) and palladium(0) compounds with aromatic tertiary phosphines and related ligands were obtained for the first time in 1957–1958 on reduction of phosphine complexes of platinum(II) and palladium(II) by hydrazine or an alcoholic solution of KOH.[3,4] In the 1970s–1980s, there was an appreciable growth of interest in the chemistry of transition metal complexes with ligands of the type PR_3 because many of them manifested a catalytic activity in processes such as hydrogenation, hydroformylation, and polymerisation. It was believed that these complexes are thermally fairly stable and do not undergo significant changes under the conditions of the catalysed reactions. An extensive set of ligands of the type PR_3 has been used to stabilise complexes in which the metal atom is bound to the H and C atoms as well as the atoms of other nontransition elements.

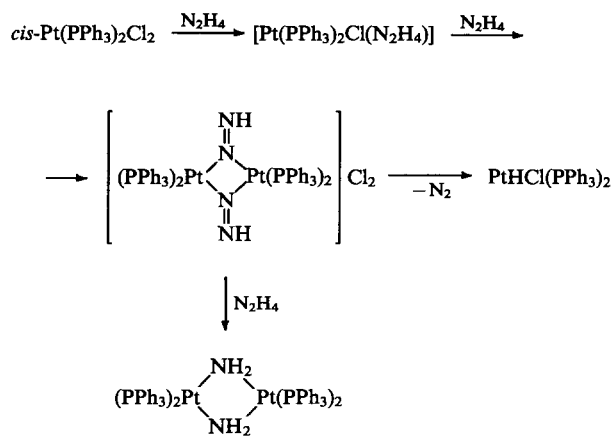
II. Synthesis of phosphine complexes of the type ML_n [M = Pt(0), Pd(0); L = PR_3; $n = 2-4$]

1. Reduction by metals

The reduction of halophosphinepalladium and halophosphineplatinum complexes by metallic sodium in liquid ammonia leads to the formation of the complexes $M(PF_3)_4$ (M = Pd, Pt).[5] This reduction method is not extensively used because of a series of disadvantages. These are principally experimental difficulties associated with the employment of metallic sodium in liquid ammonia and a low yield of the target product because of the insolubility of the reactants in the reaction medium. The same compounds have been obtained by the reaction of MCl_2 (M = Pt, Pd) with PF_3 and metallic copper at 100 °C and 100–300 atm. However, in this case one cannot rule out the possibility that not only the copper but also PF_3 behaves as the reducing agent.[6]



2. Reduction by hydrazine

This method is used successfully to reduce platinum(II) and palladium(II) compounds with tertiary phosphines, phosphites, and arsines.[3,4,7] The first studies on the reduction of platinum complexes by hydrazine led at first sight to contradictory results. Data were obtained indicating that, depending on: the reaction conditions, the nature of the ligands and the halogen atom bound to the metal, and the reaction time, it is possible to obtain both platinum(0) compounds and platinum(II) hydrides.[8] Furthermore, the unusual stability of the compounds described by Malatesta[4] as zero-valent complexes suggested that they are in fact platinum(II) hydrides.[9] However, later independent and careful studies definitely confirmed that platinum(0) compounds are formed in these syntheses.[7,10,11]

The interaction of metal complexes with hydrazine is as a rule a complex multistage process.[12] After the reduction of *cis*-$Pt(PPh_3)_2Cl_2$ at room temperature, certain stable intermediates were isolated. These are cationic dehydrodiimido- and amino-complexes soluble in the reaction medium (ethanol)[13] (Scheme 1).

The hydride complex *trans*-$Pt(PPh_3)_2HCl$ formed in the first stage of the reduction process is isolated from the reaction solution after several hours at room temperature or on heating the solution. This platinum(II) hydride is subsequently converted

Scheme 1

into a platinum(0) complex on treatment with an excess of hydrazine.[4,12]

$$cis\text{-}Pt(PPh_3)_2HCl \xrightarrow[PPh_3]{N_2H_4} Pt(PPh_3)_n$$

$n = 3, 4.$

Thus, by varying the amount of hydrazine, the time, and the reaction temperature, it is possible to obtain either a platinum(0) complex or a platinum(II) hydride. The reduction of *cis*-$Pt(PPh_3)_2Cl_2$ to $Pt(PPh_3)_2$ by an excess of hydrazine at 70–80 °C apparently proceeds via the same mechanism.[8]

The presence of an excess of the phosphine in the reaction solution makes it possible to obtain platinum(0) complexes with a maximum yield. The need for an excess of the phosphine arises from the ability of the zerovalent complexes to dissociate in solution, affording coordinatively-unsaturated compounds.[14]

$$M(PR_3)_4 \rightleftharpoons M(PR_3)_3 \rightleftharpoons M(PR_3)_2 \rightleftharpoons [M(PR_3)]_n$$

M = Ni, Pd, Pt.

The platinum complex of triphenylphosphine $Pt(PPh_3)_4$ is almost fully dissociated and the tricoordinate complex $Pt(PPh_3)_3$ exists in benzene. Further dissociation with formation of $Pt(PPh_3)_2$ takes place to a very slight extent—the equilibrium constant $[Pt(PPh_3)_2][PPh_3]/[Pt(PPh_3)_3]$ is $(1.6 \pm 1.1) \times 10^{-4}$ mol litre^{-1} in benzene at 25 °C.[14]

Such behaviour of the complexes $[M(PR_3)_4]$ in solution suggested that the PR_3 ligands in these compounds are non-equivalent. A later X-ray diffraction study of the tetrakis(triphenylphosphine)palladium complex $Pd[PPh_3]_4.0.5C_6H_6$ showed, however, that the coordination of the palladium atoms hardly differs from the ideal tetrahedral coordination;[15] admittedly, the average Pd–P bond length in this compound (2.443 Å) greatly exceeds the Pd–P distances in all other structurally characterised phosphine complexes.[16–18] This lengthening of the bond and also the extremely loose packing of the molecules in the crystal are apparently a consequence of the steric repulsion between the ligands in the complex. All these factors are responsible for the lability of the complex both in the solid state and in solutions.

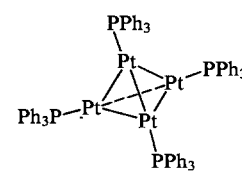
The influence of steric factors on the stability of complexes of zerovalent metals has been confirmed by X-ray diffraction data for the entirely stable complex $Pd[P(C{\equiv}CPh)_3]_4$,[19] where the bulk of the phenyl substituent are separated from the phosphorus atom by the C≡C groups, which creates more favourable conditions for unstrained spatial packing. Similar data have been obtained also for the complex $Pd[P(CH_2OH)_3]_4$.[20] The environment of the palladium atom is tetrahedral in both cases and the Pd–P distances are 2.28 and 2.32 Å respectively.

A series of relatively stable tricoordinate platinum(0) and palladium(0) compounds have been isolated in the solid state and have been reliably characterised by X-ray diffraction.[3,4] According to the X-ray diffraction data for the complex $Pt(PPh_3)_3$, the PtP_3 fragment has the form of a greatly flattened trigonal pyramid.[21] The Pt atom is located 0.1 Å above the plane in which the three phosphorus atoms are present. The $Pt(PPh_3)_3$ molecule is much less strained than the $Pt(PPh_3)_4$ molecule and the Pt–P distances in it are in the usual range 2.25–2.28 Å. In the analogous palladium complex $Pd(PPh_3)_3$, the palladium atom is raised by 0.16 Å above the P_3 plane.[22] The PtP_3 fragment in the complex $Pt(PCy_3)_3$ (Cy = cyclohexyl) is almost planar,[23] the platinum atom being displaced from the plane by only 0.04 Å. All the cyclohexane rings have the chair conformation.

The dicoordinate platinum and palladium complexes are extremely unstable. Only a few complexes with bulky phosphine ligands such as PCy_3, PBu^t_3, and PBu^t_2Ph have been isolated and characterised (see below).[24–27]

Complexes of the type PdL_4 and PtL_4 (L = $Ph_2PC{\equiv}CMe$) can also be obtained from solutions of K_2PtCl_4 or K_2PdCl_4 by reduction with hydrazine in the presence of an excess of the phosphine ligand.[28] Compounds containing methoxy- and n-butoxy-diphenylphosphine ligands $Ph_2P(OR)$ (where R = Me, Bu) have been synthesised similarly.[29] The complex $Pd(PPh_3)_4$ has been obtained by reducing $PdCl_2$ and PPh_3 at 140 °C in dimethyl sulfoxide (DMSO).[30] DMSO is also used as a convenient solvent in the synthesis of ML_4 with ligands such as *m*- and *p*-tolylphosphines from the corresponding platinum and palladium chlorides.[31]

3. Reduction by sodium tetrahydroborate



Apart from hydrazine, the reduction by sodium tetrahydroborate is used to synthesise platinum(0) and palladium(0) containing phosphines and tertiary diphosphines and diarsines.[11,32,33] The nature of the compounds obtained on reduction with sodium tetrahydroborate remained controversial for some time, but it has been shown that these are indeed compounds with the metal in the zero oxidation state and not hydrido-complexes.[11] $M(PPh_3)_4$ and $M[C_2H_4(PPh_2)_2]_2$ (M = Pd, Pt),[34] $Pd[C_3H_6(PPh_2)_2]_2$,[35] PtL_4 [L = $PMePh_2$, $PPhMe_2$, $PPh(OMe)_2$, $P(OPh)_3$, $AsPh_3$],[36,37] and $Pt(PMe_2C_6F_5)_4$[37] have been obtained by reduction with sodium tetrahydroborate.

$$Pt[C_2H_4(PPh_2)_2]_2Cl_2 \xrightarrow{NaBH_4/C_2H_5OH} Pt[C_2H_4(PPh_2)_2]_2$$

The synthesis of the tetramer of the monocoordinate compound $Pt(PPh_3)$ by reducing $Pt(PPh_3)_2O_2$ with sodium tetrahydroborate has been reported.[38]

$$Pt(PPh_3)_2O_2 \xrightarrow{NaBH_4/C_2H_5OH} \underset{\mathbf{1}}{[Pt(PPh_3)]_4} \qquad (1)$$

The data obtained in the determination of the molecular mass of this compound indicate the formation of the complex $[Pt(PPh_3)]_4$. The authors[38] proposed a tetrahedral structure of the complex.

The interaction of $[Pt(PPh_3)]_4$ with KCN leads to the displacement of free PPh_3 from the platinum complex, which agrees with the proposed interpretation of the experimental data.

Diphenylphosphine was not detected in the products of this reaction, but the conditions of reaction (1), in the course of which compound **1** was obtained (heating for 6 h at 90 °C),[38] and the fact that the formation of benzene or biphenyl were not monitored during the synthesis casts doubt on the view that complex **1** contains no phosphide or phosphene groups as ligands.[38]

The palladium(0) complexes formed on reduction are known to be incapable of catalysing the reduction of unsaturated hydrocarbons under mild conditions.[39] However, it has been shown in a series of studies that, after contact with air, solutions of $(PPh_3)_2PdCl_2$ treated with sodium tetrahydroborate acquire the capacity to absorb molecular hydrogen and to catalyse hydrogenation reactions in DMF, like solutions of authentic $Pd(PPh_3)_4$.[40,41] This effect can be accounted for by the formation of complexes with oxygen. Indeed a solution of $Pd(PPh_3)_2O_2$, obtained after the reduction of $(PPh_3)_2PdCl_2$ with sodium tetrahydroborate in air, proved to be catalytically active.[41] The increase in the reactivity of palladium compounds in relation to molecular hydrogen when oxygen-containing ligands are introduced into the coordination sphere agrees well with the reaction mechanism according to which the hydrogen molecule is cleaved heterolytically with simultaneous heterolysis of the Pd–X bond. Quantum-chemical analysis[42] of the interaction of the complexes *trans*-$XYPd(PH_3)_2$, where X = OH or OAc and Y = Cl, with molecular hydrogen showed that the presence of the oxygen-containing ligands facilitates the heterolysis of the hydrogen molecule.

The influence of oxygen and oxygen-containing ligands on the reactivity of palladium compounds in the reaction with hydrogen and on the formation of the centres responsible for the catalysis of the hydrogenation reaction has been observed not only for palladium complexes with organophosphorus ligands but also for systems containing N- or S-ligands. Thus it has been shown that the reduction of palladium complexes of pyridine, aliphatic amines, and sulfides or sulfoxides of petroleum origin by sodium tetrahydroborate or diisobutylaluminium hydride when the system is promoted by water or molecular hydrogen leads to highly active selective catalysts for the hydrogenation of conjugated dienes to alkenes.[43,44]

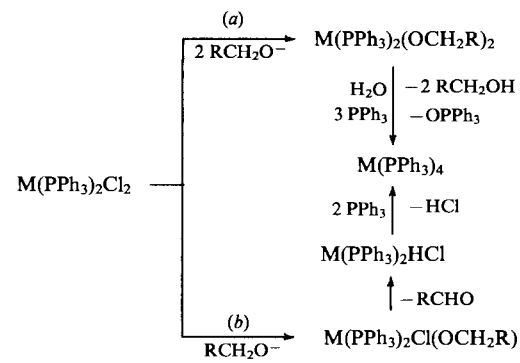
Systems obtained in the reduction of palladium salts by sodium tetrahydroborate in the presence of *o*-phenanthroline, α,α-bipyridyl, and polyethyleneimines in aqueous media may also be active in hydrogenation reactions,[45,46] but the composition of the complexes formed has not been investigated.

4. Reduction with an alcoholic solution of KOH

The reduction of platinum and palladium complexes with an alcoholic solution of KOH leads to the formation of compounds similar to those obtained with the aid of hydrazine and sodium tetrahydroborate. It was first used to synthesise the complex $Pt(PPh_3)_4$ by reducing $(Ph_3P)_2PtCl_2$.[4,47] Potassium tetrachloroplatinate in the presence of a phosphine ligand can also be used as the initial platinum compound. The complexes $Pt[P(OEt)_3]_4$,[48,49] $Pt(PMe_2Ph)_4$,[37] and $Pt(PMePh_2)_4$[50] have been obtained in this way. The combined reduction of K_2PtCl_4 by hydrazine and KOH in the presence of a tertiary phosphine has been used to synthesise $Pt[P(CH_2Ph)Ph_2]_4$.[50]

Depending on the reaction conditions, the reaction can proceed in accordance with the equations

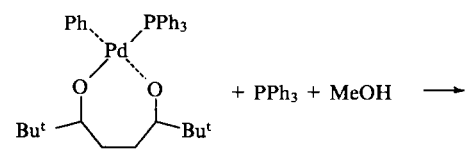
$$K_2PtCl_4 + 5\,PPh_3 + 2\,KOH \longrightarrow$$
$$\longrightarrow Pt(PPh_3)_4 + OPPh_3 + 4\,KCl + H_2O;$$



or

$$K_2PtCl_4 + 4\,PPh_3 + 2\,KOH + EtOH \longrightarrow$$
$$\longrightarrow Pt(PPh_3)_4 + 4\,KCl + MeCHO + 2\,H_2O.$$

In the former case, the reducing agent is the phosphine, while in the latter ethanol participates directly in the reaction, being oxidised to acetaldehyde.



Sodium propoxide may also be used as the reductant for the preparation of $Pt(PPh_3)_4$ from $Pt(PPh_3)_2Cl_2$. Secondary and tertiary alcohols and also phenols may be used instead of propanol.

The reduction of $Pd(PPh_3)_2Cl_2$ by sodium propoxide in propanol is carried out at room temperature in the presence of an excess of the phosphine.[51] The intermediates in this reaction were later investigated,[52] which made it possible to obtain a clearer picture of the process. The reaction apparently proceeds via two parallel routes:

In the case of route (*a*), the reducing agent is the phosphine, which gives up one or two electrons to the metal atom and is apparently subjected to inner-sphere nucleophilic attack by the hydroxide ion. For tertiary alcohols, this is the only possible pathway. Route (*b*) explains the formation of the products of the oxidation of primary and secondary alcohols. It has been shown that the contributions of both routes are approximately the same.[52] When the reaction was carried out in benzene, the intermediate $M(PPh_3)_2(OPh)_2$ was isolated and was then reduced in the presence of water to $M(PPh_3)_4$ with triphenylphosphine. In the first stage of this reaction, the hydroxo-complex $M(PPh_3)_2(OH)_2$ is probably formed [this complex has not been detected in the reaction of $M(PPh_3)_2(OC_6H_5)_2$ with water]. It has been shown that $Pt(PPh_3)_2(OH)_2$ is formed from $Pt(PPh_3)_2Cl_2$ and sodium propoxide in benzene in the presence of water and that its subsequent reaction with PPh_3 leads to the formation of $Pt(PPh_3)_4$ and triphenylphosphine oxide.

Treatment of phenylpalladium complexes with methanol in the presence of PPh_3 leads to the reductive dissociation of the Pd–C bond accompanied by the formation of $Pd(PPh_3)_4$ and benzene. In this case, methanol readily reduces the palladium, being oxidised to formaldehyde.[53]

$$\longrightarrow Pd[PPh_3]_4 + CH_2O + C_6H_6 + Bu^t{-}\overset{O}{\overset{\|}{C}}{-}(CH_2)_2{-}\overset{O}{\overset{\|}{C}}{-}Bu^t$$

Hydrides such as $[PtH(PPh_3)_3]HSO_4$ may be reduced to $Pt(PPh)_3$ by a solution of KOH in ethanol.[54] In essence, the platinum(II) compound is reduced in this reaction as a result of the deprotonation of a complex hydride on reaction with a base,

$$L_3PtH^+ + OH^- \longrightarrow L_3Pt + H_2O,$$

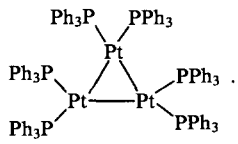
where the coordinated hydride ligand behaves as the 'reductant'.

The absence of an excess of the ligand from the solution makes it possible to obtain formally more coordinatively unsaturated compounds containing only two phosphine ligands at the central atom instead of four.

Attempts have also been made to synthesise coordinatively unsaturated complexes of the type ML_2 by creating conditions for the simultaneous reduction of the metal and the oxidation of the excess ligand. O_2 and H_2O_2 may be used as oxidants for the oxidation of PPh_3 to Ph_3PO. Thus Ugo et al.[24] reported the preparation of the yellow compound $Pt(PPh_3)_2$ in different ways. The first involved the addition of an alcoholic solution of KOH to an alcoholic solution of $[PtH(PPh_3)_3]HSO_4$ and subsequent treatment of the solution with oxygen.

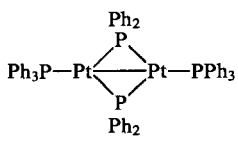
$$2\,[PtH(PPh_3)_3]HSO_4 + 2\,KOH + O_2 \longrightarrow$$

$$\longrightarrow 2\,[Pt(PPh_3)_2] + 2\,Ph_3PO + 2\,KHSO_4$$



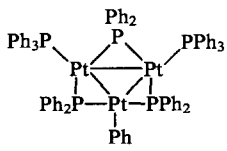
In the second procedure, stoichiometric amounts of H_2O_2 and KOH in alcohol were added slowly to an alcoholic solution of $[PtH(PPh_3)_3]HSO_4$.

$$[PtH(PPh_3)_3]HSO_4 + KOH + H_2O_2 \longrightarrow$$



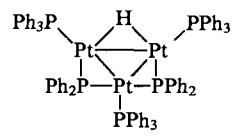
$$\longrightarrow [Pt(PPh_3)_2] + 2\,Ph_3PO + 2\,KHSO_4 + H_2O$$

The coordinatively unsaturated compound obtained as a result of these reactions was identified by elemental analysis. The molecular mass proved to be lower than the value calculated for the monomer $[Pt(PPh_3)_2]$.[24]



It has been reported that the isolation of pure $[Pt(PPh_3)_2]$ is extremely difficult as a consequence of its instability. A more stable red compound is formed on refluxing $[Pt(PPh_3)_2]$ in benzene under an argon atmosphere.[55] The results of the determination of the molecular mass indicate the existence of the complex $[Pt(PPh_3)_2]$ in the form of a trimer, for which the following structure has been proposed:

In 1966, when the study of Ugo and coworkers[55] was carried out, the ability of triphenylphosphine to undergo degradative reactions in the coordination spheres of platinum metals was not yet known. At the beginning of the 1970s, studies were published[56–66] in which doubt was cast on the postulate that the phosphine ligand is stable both under the conditions of the synthesis and under the conditions of the subsequent reactions of the phosphine complexes of platinum and palladium. In view of this, the above structure was re-examined.[63] It was observed[63] that, on heating $Pt(PPh_3)_4$ in benzene under an argon atmosphere, a dark-red solution is formed from which the two cluster complexes $[Pt_2(PPh_3)_2(PPh_2)_2].C_6H_6$ **2** and $[Pt_3(PPh_3)_2(PPh_2)_3(Ph)].C_6H_6$ **3** were isolated and characterised by X-ray diffraction.



2

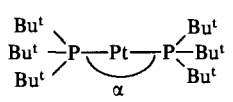
3

According to X-ray diffraction data, compound **2** is a dinuclear complex with a very short metal–metal distance (Pt–Pt = 2.604 Å), two bridging ligands PPh_2, and two terminal ligands PPh_3. The Pt_2P_2 skeleton is planar. Compound **3** is constructed as a trinuclear cluster with three Pt–Pt bonds and three bridging PPh_2 groups. The Pt–Pt distances (2.785 Å) are greater than in compound **2**, but are comparable to the bond lengths in the carbonylphosphineplatinum clusters. One of the platinum atoms is coordinated to two PPh_2 groups and to a σ-linked Ph group. This is one of the first compounds where a phenyl residue, formed as a result of the dissociation of the P–C bond, remains bound to the metal.[63]

The platinum complex $[Pt_3(PPh_3)_3(\mu\text{-}PPh_2)_2[\mu\text{-}H)]^+BF_4^-$ **4**, having a similar structure

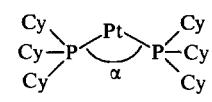
4

has been obtained on UV irradiation of $Pt(PPh_3)_2C_2O_4$ under a hydrogen atmosphere and subsequent precipitation with $NaBF_4$.[64] The Pt_3P_2 skeleton is significantly nonplanar. The Pt–Pt distance between the atoms linked by the bridging hydrogen atom (2.638 Å) is appreciably shorter than the other two (2.795 Å). The presence of the bridging hydrogen atom was established from ^{31}P NMR spectroscopic data.



Nevertheless, the mononuclear complexes $[ML_2]$ can be obtained in solution in the case of phosphine ligands containing 'bulky', frequently branched, aliphatic or aryl-substituted aliphatic substituents at the phosphorus atom (L = PCy_3,[25,67] PBu^t_3,[26] PPr^i_3, PBu^t_2Ph,[27] and PBu^t_2Me[68]) by substituting the ligands in platinum(0) and palladium(0) complexes.

$$Pd(\eta^5\text{-}C_5H_5)(\eta^3\text{-}C_3H_5) + 2\,L \longrightarrow PdL_2 + \text{hydrocarbons}$$



$$Pt(\eta^4\text{-}COD)_2 + 2\,L \longrightarrow PtL_2 + 2\,COD$$

L = PR_3, COD = cycloocta-1,5-diene.

Several such complexes have been characterised by X-ray diffraction (Table 1). It was found that the P–M–P angle in these compounds varies in the range from values close to 180° in the case of $Pt[PBu^t_3]_2$ **5**[26] to 160.5° for $Pt[PCy_3]_2$ **6**.[25]

5

6

The bent structure of the P–M–P fragment in the complex $Pt[PCy_3]_2$ cannot be a result of the packing effect in the crystal structure, since not one H...H packing distance shorter than 2.32 Å has been observed.[25] Nor can one account for the decrease in the angle α by electronic factors because the quasilinear geometry of the complex $Pt[PBu^t_3]_2$ does not fit within the framework of this scheme. Although the conical angle for the PBu^t_3 ligand is greater than for PCy_3 (Table 1),[69] the steric repulsion of the *tert*-butyl groups cannot exert a significant influence on the geometry of the complex because all the distances between the hydrogen atoms of the neighbouring groups are greater than 5.0 Å.[25]

For the less stable dicoordinate complexes with the triphenylphosphine ligand, the stable adducts $[Pt(PPh_3)_2].BCl_3$ with trichloroborane[70] or $[Pt(PPh_3)_2].SiF_4$ with tetrafluorosilane[71] are known.

Table 1. X-Ray diffraction data for the complexes $M[PR_3]_2$ and the conical angles of the PR_3 ligands.

Compound	M–P/Å	P–M–P angle/deg	Conical PR_3 angle[a]/deg	Ref.
$Pt[P(Bu^t)_3]_2$	2.249	180	182(2)	26
$Pt[P(Bu^t)_2Ph]_2$	2.25	177.0	170(2)	18
$Pt[PCy_3]_2$	2.23	160.5	179(10)	67
$Pd[PCy_3]_2$	2.26	158.4	179(10)	25
$Pd[P(Bu^t)_2Ph]_2$	2.28	175.7	170(2)	25

[a]The conical angles were taken from Tolman.[69]

5. Reduction by metal alkyls

The reduction of palladium(II) acetylacetonate by $AlEt_3$ in the presence of PCy_3 leads to the formation of a product described as $Pd(PCy_3)_2$.[72] The complexes $PdL_2(C_2H_4)$ [L = PPh_3, PCy_3, $P(OC_6H_4Me\text{-}o)_3$] have been obtained similarly in the presence of ethene and various phosphines.[73] HX can be removed from hydrido-complexes such as *trans*-$Pt(PPh_3)_2HX$ (X = halogen) by treating them with n-butyllithium. The complex $Pt(PPh_3)_2$, first synthesised by treating $[PtH(PPh_3)_3]HSO_4$ with alcoholic alkali,[24] has been obtained by this method.[54]

6. Reduction by phosphine ligands

Phosphine ligands may reduce the central metal atom in the absence of halide ions or other strongly coordinated ligands lowering the oxidation-reduction potential of the platinoid atom. The reaction is usually carried out in ethanol. This method has been applied successfully in the synthesis of PdL_4 [L = PPh_3, $P(OPh)_3$] by treating $Pd(NO_3)_2$ or freshly precipitated palladium oxide with an excess of the ligand.[3] When metal halides are used as the initial compounds, amines are added to the reaction mixture in order to displace the halide ions. $Pd[P(OEt)_3]_4$ has been obtained in this way.[74]

Phosphite ligands are capable of reducing palladium halides in the absence of an amine. The complexes $Pd[PhP(OR)_2]_4$ (R = Me, Et) have been synthesised in this way from $PdCl_2$ and the corresponding phosphite.[75]

$$PdCl_2 + 4\,PhP(OMe)_2 \longrightarrow Pd[PhP(OMe)_2]_4$$

The complex $Pd(PF_3)_4$ has been obtained by reducing $Pd(CO)_2Cl_2$[76] or $Pd(C_6H_5CN)_2Cl_2$[77] using PF_3 as the reductant at room temperature. The ability of PF_3 to reduce platinum group metals appears unexpected at first sight. However, one should bear in mind that the tendency of trivalent phosphorus to form bonds with oxygen, which are some of the strongest in inorganic chemistry, is very great. It would seem that powerful electronegative substituents (fluorine atoms) should diminish the electron-donating capacity of the phosphorus atom and its ability to give up a lone electron pair in order to form a bond with a 'singlet' oxygen atom. However, the effect of these substituents leads apparently to a very considerable lowering of the unoccupied *d* levels of the phosphorus atom, which is reflected by an increased electron-accepting capacity of the phosphorus atom in PF_3. As a consequence of this, the P–O π-bond in the corresponding (possibly hypothetical) oxide F_3PO should be very strong. In other words, the contribution of the covalent canonical structures

$$\overset{-}{O}\!-\!\overset{+}{P}F_3 \longleftrightarrow O{=}PF_3\,,$$

in the description of F_3PO should be extremely large.

As a consequence of the increased tendency towards the acceptance of electrons manifested by PF_3, the latter is believed to be the most powerful π-acceptor in coordination compounds and is superior to the cyanide ion, alkyl isocyanides, carbon monoxide, etc. Numerous complexes of PF_3 with metals in low oxidation states are known.[78] Thus both factors — the tendency towards the formation of stable complexes with the metal in a low oxidation state and the energy of the bond formed in F_3PO — play the role of the driving force by virtue of which PF_3 is able to function as a reductant in relation to platinum group metal complexes.

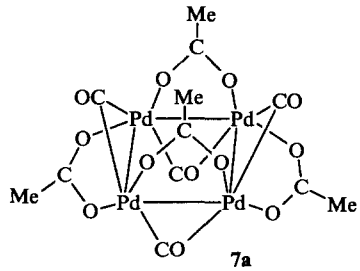
The platinum complexes PtL_4 [L = PF_3, CF_3PF_2, $(CF_3)_2PF$] have been synthesised by the reaction of platinum(II) chloride[79] or K_2PtCl_4[80] with phosphorus trifluoride.

In virtually all the reactions described above, mononuclear compounds were employed as the starting materials. The reaction was carried out in the presence of an excess of the phosphine ligand, coordinatively saturated mononuclear compounds of the type ML_4 with the metal in the zero oxidation state being obtained. Similar complexes have been frequently used as the initial form of the catalyst in a wide variety of catalytic reactions (oxidation, hydrogenation, isomerisation, etc.) of organic substrates.[81] The chemistry of these compounds suggests that they are unstable under the conditions of the catalytic reactions and undergo partial oxidation, elimination, and/or dehalogenation of the phosphine ligands usually with formation of aggregated species of cluster type. The latter are in fact apparently responsible for catalysis in most cases. We shall therefore consider in the next section the conditions for the reduction of platinum(II) and palladium(II) leading to the formation of platinum and palladium clusters in nonzero oxidation states.

III. Synthesis of cluster compounds of platinum metals in the oxidation states $0 < n < 2$

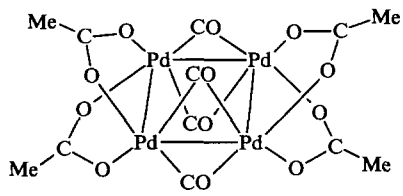
Polynuclear and cluster compounds of platinum metals in low oxidation states are formed when reductants such as carbon monoxide, formic acid, or hydrogen are used, while the initial compounds are platinum(II) or palladium(II) dinuclear or polynuclear carboxylate complexes. As a rule, the reaction is carried out for low concentration ratios L : M, where L is the stabilising ligand. When halide compounds, which are reduced by the above reductants under severe conditions, are the starting materials, sodium amalgam is employed.

1. Reduction by carbon monoxide



Treatment of solutions of palladium(II) salts with CO usually leads to the reduction of palladium to the metal. Thus the reduction of $Pd(OAc)_2$ by carbon monoxide in glacial acetic acid containing alkali metal acetates leads to the formation of metallic palladium, acetic anhydride, and CO_2.[82,83]

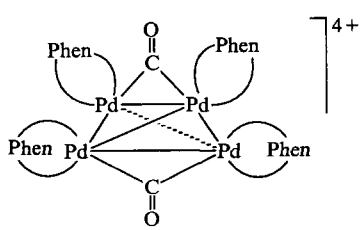
$$Pd(OAc)_2 + CO \xrightarrow{NaOAc} Pd^0 + Ac_2O + CO_2$$



However, in the absence of alkali metal acetates, palladium carbonyl acetate (PCA) having the composition $Pd_4(CO)_4.(OAc)_4.2AcOH$ was obtained from $Pd(OAc)_2$ and CO.[84,88]

$$4\,Pd(OAc)_2 + 8\,CO \longrightarrow Pd_4(CO)_4(OAc)_4 + 2\,Ac_2O + 4\,CO_2$$

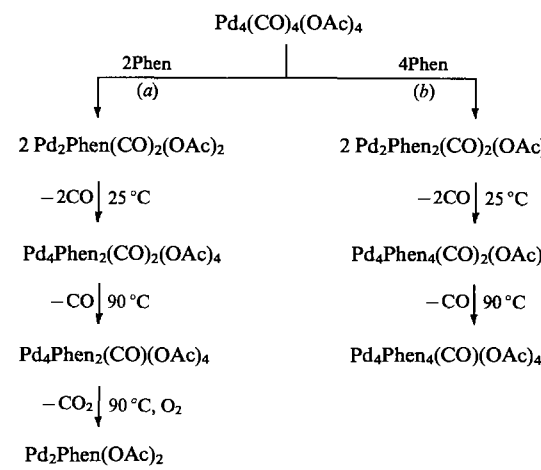
According to X-ray diffraction data,[85] crystals of this substance consist of tetranuclear clusters $Pd_4(CO)_4(OAc)_4$ **7** with a rectangular metal core (the Pd–Pd distances are 2.66 and 2.91 Å). However, according to EXAFS data complex **7** exists in the form of two isomers with a square metal core **7a** (the Pd–Pd distance is 2.72 Å) and a rectangular core **7b**.[86] The authors attribute their existence to the presence or absence of molecules of acetic acid of crystallisation in complex **7**.



7a

7b

Similar clusters having the composition $Pd_4(CO)_4(RCOO)_4$ have been obtained by reducing palladium(II) propionate and benzoate (R = Ph, Et) with carbon monoxide and also by the exchange of the carboxylate ligands by treating the PCA with the corresponding carboxylic acids (R = CF_3, CH_2Cl, Bu^t).[87-90] IR spectroscopic data for these compounds permit the conclusion that they all have similar structures. Nevertheless, their investigation by the EXAFS method revealed appreciable differences between the geometries of the metal cores for not very significant differences in the acido-ligand.[86] Thus the palladium carbonyl monochloroacetate complex (R = CH_2Cl) has a square metal core (the Pd–Pd distance is 2.70 Å), similar to one of the isomers of PCA. The metal core in the palladium carbonyl trifluoroacetate complex (R = CF_3) has the form of a rhombus with a side of 2.70 Å and diagonals of 3.75 and 4.08 Å. The observed Pd–Pd distances for palladium carbonyl benzoate (R = Ph) and carbonyl pivalate (R = Bu^t) correspond to a mixture of isomers with metal cores in the form of a square and a rectangle.[86] The causes of such sensitivity of the geometry of the metal core to the ligand environment require the analysis of not only steric but also electronic factors.



In contrast to the substitution of acido-ligands, the exchange of carbonyl groups for other neutral ligands and, what is more important the displacment of the acido-ligands from the inner coordination sphere of palladium lead to appreciable changes in the cluster metal core. Thus the interaction of the PCA with phenanthroline in the proportions [Pd]:[Phen] = 1:1 in acetic acids results in the formation of the complex $Pd_4Phen_4(CO)_2$.$(OAc)_4$ with a nearly tetrahedral metal core.[88]

This complex is also formed on the reduction of $Pd(OAc)_2$ by carbon monoxide in the presence of phenanthroline. According to X-ray diffraction data, the crystals of the complex contain the almost tetrahedral cluster cation $[Pd_4Phen_4(CO)_2]^{4+}$ as the main structural unit. On formation of this complex from the PCA, all the metal–metal distances change significantly: the Pd–Pd bonds in the Pd(μ-CO)Pd fragments are lengthened to 2.890 Å (in the PCA this distance is 2.663 Å) and become longer than the Pd–Pd bonds in the absence of ligands (2.718 Å). This ratio of bond lengths could be accounted for by the fact that, in terms of its disposition in space, each Pd(μ-CO)Pd bond is in fact bridging in relation to the opposite ligand-free Pd–Pd bond. The acetate groups are not coordinated to the Pd atoms, as in the PCA, but are located in the outer sphere in the form of AcO^- anions.[88]

The replacement of the CO groups by neutral ligands such as phenanthroline (Phen) or bipyridyl (Bipy) also takes place readily on interaction of the PCA with the free ligands at extremely low concentrations—$[L]_\Sigma:[Pd]_\Sigma \leqslant 1:1$. The extremely labile complexes formed under these conditions (Scheme 2) have been characterised on the basis of indirect data for the stoichiometry of the reaction, but have not been isolated in a pure form.[91,92]

Scheme 2

It has been shown[91-93] that the complete removal of the coordinated CO molecules requires heating under an oxygen atmosphere above 90 °C, the polynuclear palladium complexes formed exhibiting a catalytic activity in the oxidation of CO and in the oxidative acetoxylation of alkenes and alkylarenes (Scheme 2).

The combination of the effect of CO as a stabilising ligand and reductants such as alkali metals or their hydroxides, $Fe(CO)_5$, or cobaltocene on platinum compounds such as Na_2PtCl_6, $H_2PtCl_6.xH_2O$, Na_2PtCl_4, and $Pt(CO)_2Cl_2$ made it possible to obtain a series of dianions having the general formula $[Pt_3(CO)_6]_n^{2-}$ (n = 1–6, 10).[94]

$$3n[PtCl_6]^{2-} + (12n+1)\,CO + (12n+2)\,OH^- \longrightarrow$$

$$\longrightarrow [Pt_3(CO)_6]_n^{2-} + 18n\,Cl^- + (6n+1)\,CO_2 + (6n+1)\,H_2O$$

The structure of a series of platinum carbonyls $[Pt_3(CO)_6]_n^{2-}$ (n = 2, 3, 5) in the form of tetraphenylphosphonium salts has been determined by X-ray diffraction.[95] The Pt_3 triangles are linked by three bridging carbonyl ligands and are arranged one on top of the other, forming a layered structure. The Pt–Pt distances in the triangular Pt_3 fragment are 2.66 Å and those between the layers reach 3.01–3.04 Å. The layers have rotated relative to one another by angles ranging from 8.1° to 28.6°, which disturbs the regular prismatic packing of the platinum atoms.[95] This geometrical disorder is apparently a result of an increase in the distances between the CO ligands.

In the search for catalytically active complexes and, what is more important, complexes selective in hydrogenation reactions, studies have been made of phosphine and phenanthroline complexes of palladium, which are formed when $Pd(OAc)_2$ interacts with various reductants in the presence of the above ligands.[96-98]

2. Reduction of the complexes $[Ph_3PMX_2]_2$ (M = Pd, Pt) by sodium amalgam

Sodium amalgam is used as a reductant for palladium and platinum halide complexes because the latter are reduced by hydrogen only under very severe conditions.[99]

The interaction of the dinuclear complex $[Ph_3PPdCl_2]_2$ with sodium amalgam in CH_2Cl_2 at 20 °C leads to the formation of solutions from which a compound described as a dinuclear palladium(0) complex $(Ph_3P)_2Pd_2$ was isolated.[100]

$$[Ph_3PPdCl_2]_2 \xrightarrow{Na/Hg,\ CH_2Cl_2} (Ph_3P)_2Pd_2$$

A similar compound is obtained also when the carboxylate complex $[Ph_3PPd(OAc)_2]_2$ is used as the starting material.[100]

$$[Ph_3PPd(OAc)_2]_2 \xrightarrow{Na/Hg,\ CH_2Cl_2} (Ph_3P)_2Pd_2$$

The experiments on the synthesis of this compound are poorly reproducible, which may be associated with the characteristic features of the purification of the solvent.

The reduction of $[Ph_3PPtCl_2]_2$ by sodium amalgam in benzene at 20 °C leads to the dissociation of the P–Ph bond of the coordinated PPh_3 ligand and the formation of a phosphide complex, which is $[Ph_2PPtCl]_n$ according to elemental analysis and IR spectroscopy.[101]

$$[Ph_3PPtCl_2]_2 \xrightarrow{Na/Hg,\ C_6H_6} [Ph_2PPtCl]_n$$

The molecular mass of this compound corresponds to a polymer with $n = 16$ and it may be that the Pt atoms are linked to phosphide and chloride bridges.

In tetrahydrofuran (THF), the reaction of the platinum(II) chloride complex with sodium amalgam proceeds further and terminates with the formation of the complex $[Ph_2PPt]_n$, where $n = 6$. According to elemental analysis, the compound contains no chlorine and its IR and ^1H NMR spectra contain only the signals due to phosphide groups.[101]

$$[Ph_3PPtCl_2]_2 \xrightarrow[-C_6H_6]{Na/Hg,\ THF} [Ph_2PPt]_n$$

Gas–liquid chromatography of the reaction mixture revealed the presence of 1 mol of C_6H_6 per gram-atom of the platinum of the complex introduced into the reaction. Measurements of the electrical conductivities of the solutions in dimethylformamide showed that the compounds $[Ph_2PPtCl]_n$ and $[Ph_2PPt]_n$ are electrically neutral.

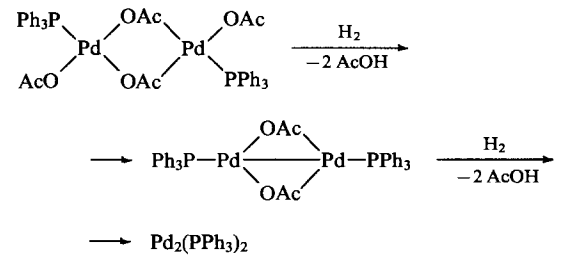
The complex $[Ph_2PPtCl]_n$ does not react with hydrogen under mild conditions, but, after the replacement of Cl^- by AcO^- (on treatment with AgOAc), it is reduced by hydrogen. Benzene was detected in the reaction product.

The platinum acetate complex $[Ph_3PPt(OAc)_2]_2$ is also reduced by sodium amalgam with formation of a platinum phosphide complex and benzene.[101]

$$[Ph_3PPt(OAc)_2]_2 \xrightarrow[-C_6H_6]{Na/Hg,\ THF} [Ph_2PPt]_n$$

3. Reduction of platinum(II) and palladium(II) carboxylate complexes with phosphine ligands by hydrogen

In connection with the study of the homogeneous hydrogenation of alkenes in systems containing a palladium carboxylate and PR_3, the reduction of palladium by molecular hydrogen has been studied in greatest detail. Analysis of literature data shows that both the mode of the reaction and the nature of the compounds formed depend greatly both on the nature of the acido-ligand coordinated to the metal atom and on the reaction conditions.[100,102]



Treatment of the palladium acetate trimer $[Pd(OAc)_2]_3$ with a phosphine ligand leads primarily to the rupture of the acetate bridges. Depending on the metal : ligand ratio, the following reactions can take place:[103]

$$2\,[Pd(OAc)_2]_3 + 6\,PPh_3 = 3\,[Ph_3PPd(OAc)_2]_2,$$

$$[Ph_3PPd(OAc)_2]_2 + 2\,PPh_3 = 2\,(Ph_3P)_2Pd(OAc)_2.$$

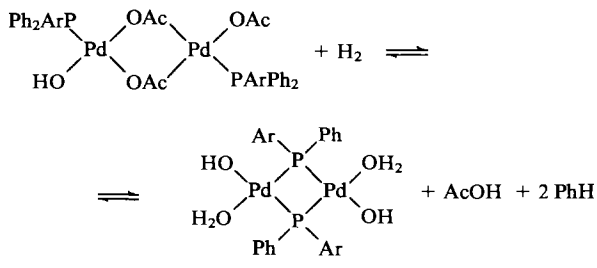
For the ratio $[PPh_3] : [Pd(II)] = 1$, predominantly dinuclear palladium(II) complexes exist in solutions in DMF and CH_2Cl_2.[104] These actually react with hydrogen in this system.

The interaction of molecular hydrogen with $[Ph_3PPd(OAc)_2]_2$ leads to the formation of palladium(I) and palladium(0) complexes.[41,100]

The presence of the bridging ligands coordinated as bidentate species in the initial compounds apparently creates favourable conditions for the formation of the metal–metal bond on reduction.

The final product of this reaction — tentatively bis(triphenylphosphine)dipalladium — combines reversibly with molecular hydrogen, but is incapable of catalysing the hydrogenation reaction. Solutions of this complex acquire catalytic activity only after contact with a gas containing at least traces of oxygen in addition to H_2. In the joint presence of oxygen and hydrogen, hydrogen peroxide is formed and oxidises part of this complex, affording phosphine oxide and palladium(II) acetate. The latter reacts with H_2 and with the $Pd_2(PPh_3)_2$ which failed to enter into the oxidation reaction, being converted into the cluster **8**.

$$n\,(Ph_3P)_2Pd_2 + n\,[Pd(OAc)_2]_3 + 5n\,H_2O \longrightarrow$$

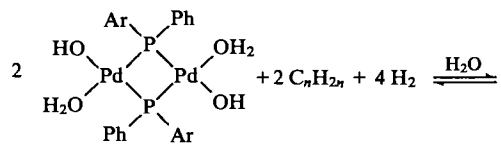


$$\longrightarrow [(PhP)_2Pd_5]_n + 6n\,AcOH + 4n\,C_6H_6$$

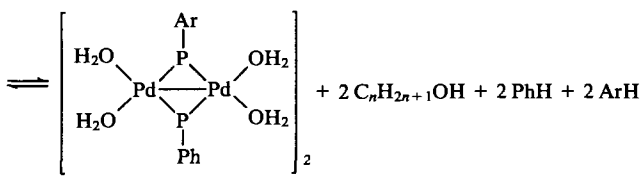
8

The kinetics and mechanisms of the hydrogenation of various organic substrates in the presence of the complexes described above have been investigated in detail.[96,105–112]

The use of the triarylphosphine ligand (L), containing the lyophilic SO_3Na group in the benzene ring, made it possible to synthesise by the above procedure phosphine complexes of the type (LPd_2X_2) (X = oxygen-containing acido-ligand). These compounds are soluble in water and may be used to hydrogenate unsaturated compounds in aqueous solution at 1 atm and 20 °C.[97,113–115]



In aqueous solutions, the palladium(II) complex of phosphine, containing the lyophilic SO_3Na group, reacts with hydrogen, affording complex **9** with a phosphide ligand.

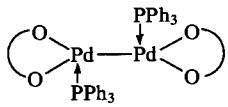


9

where Ar = *m*-$NaO_3SC_6H_4$.

Complex **9** in water is inert to molecular hydrogen, probably as a consequence of the influence of the strong electron-donating ligands — phosphide groups, which reduce the effective positive charge on the palladium atom. However, after the addition of an unsaturated hydrocarbon (propargyl or allyl alcohol, etc.) the absorption of hydrogen due to the reduction of the complex begins. Stoichiometric (in relation to the absorbed hydrogen) formation of an alcohol is observed simultaneously.[113,116]

9

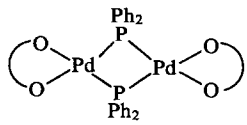


10

Under an argon atmosphere at 293 K, the cluster **10** catalyses the hydration of allyl alcohol to 1,2-propylene glycol and of propene to propan-2-ol.[115]

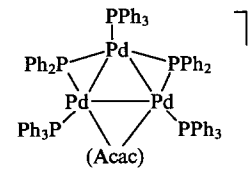
The clusters **8–10** have also been obtained as X-ray-amorphous powders and conclusions about their structures are based on the results of elemental analysis, IR and ^1H NMR spectroscopic data, and also the stoichiometry of the reactions involving them.

The formation of the complex $Pd(Acac)_2PPh_3$ is observed in the $Pd(Acac)_2$ + PPh_3 system. Therefore, in the study of the interaction of $Pd(Acac)_2$ with H_2 in the presence of PPh_3, the reduction of the complex already formed by hydrogen was in fact investigated.[98,117,118] In contrast to the palladium(II) acetate complex, the reduction of $Ph_3PPd(Acac)_2$ by hydrogen leads to the formation of the cluster $[(Pd_3P)_8.PPh_3]_n$.[122] In both cases, the palladium phosphide complexes are regarded as intermediates and the principal reaction products are obtained as a result of the far-reaching dephenylation of the triphenylphosphine ligands.

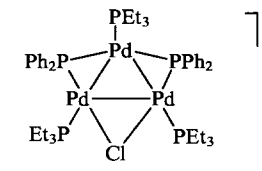


In the first stage of the reaction of $Pd(Acac)_2$ with H_2, the formation of an unstable intermediate was detected by IR and NMR spectroscopic methods. The formula **11** was proposed for it.[117]

11



The subsequent treatment with hydrogen leads to the appearance of benzene and the formation of the stable intermediate complex $[Ph_2PPdAcac]_2$, isolated in the solid state, in which the palladium atoms are assumed to be linked by two bridging diphenyl phosphide groups.



12

After the complete cessation of the absorption of hydrogen, complex **12** as well as the dinuclear cluster $[Pd_3(PPh_3)_3(PPh_2)_2.Acac]^+Acac^-$ [13] were detected in solution. The structures of complexes **12** and **13** were proposed on the basis of ^{31}P NMR spectroscopic data. In reaching conclusions about the structure of complex **13**, the authors were guided by the available data on the structure of the trinuclear palladium complex with diphenylphosphide ligands $[Pd_3(PPh_3)_3(PPh_2)_2Cl]^+Cl^-$ **14**,[119] containing chloride ions instead of acetylacetonato-groups. Complex **14** was first isolated together with *trans*-$Pd(Ph)Cl(PPh_3)_2$ when attempts were made to obtain $Pd(PPh_3)_2$ from $Pd(PPh_3)_4$ with $PdCl_2$ as the PPh_3 acceptor.[58] A series of analogues of this compound $[Pd_3(PPh_2)_2.(PR_3)_3X]^+BF_4^-$ (R = Ph, Et; X = Cl, Br, SCF_3) were later synthesised and the structure of the cluster $[Pd_3(PPh_2)_2.(PEt_3)_3Cl]^+BF_4^-$ **15** was determined by X-ray diffraction.[119]

13

15

The structure of this complex is based on a triangle made up of palladium atoms. The Pd_3P_2 skeleton is almost planar. The Pd–Pd bond lengths (2.89, 2.93, and 2.93 Å) are very similar and indicate a significant metal—metal interaction. The triangular Pd_3 fragment is almost equilateral in contrast to that observed in the cluster $[Pt_3(PPh_2)_3(PPh_3)_3Ph].C_6H_6$, where the metal atoms have the same formal oxidation state (4/3) as in the cluster **15**, but one Pt–Pt distance is longer than the other two.[63]

In the reaction of $Pd(Acac)_2$ with H_2 in the presence of PPh_3, a small amount of a product containing as the ligands P atoms or PPh groups, arising as a result of the removal of the phenyl group from the phosphorus atom of triphenylphosphine, is formed in addition to benzene and complexes **12** and **13**. This compound proved to be an active catalyst of hydrogenation, carbonylation, and arylation reactions.[98]

In order to increase the yield of the catalytically active substance, a study was made of the reduction of $Pd(Acac)_2$ in the presence of PPh_3 with the ratio Pd : P = 0.7–5.0. The substance obtained with the ratio Pd : P = 4 and having the composition $Pd_8P_3C_6H_{15}$ **16** proved to be most active in catalysing the hydrogenation of phenylethyne.[118]

According to ^{31}P NMR data, complex **16** contains phosphorus atoms, as an interstitial element, and triphenylphosphine ligands. According to small angle scattering data, the size of the particles is ~30 Å. EXAFS data for complex **16** were interpreted within the framework of a cluster model constructed from a set of trihedral Pd_6 prisms with a 2.54 Å edge and a height of 3.14 Å. The phosphorus atoms are located in their centres. In addition, about 11% of the initial PPh_3 is not dephenylated and is coordinated to the palladium phosphide Pd_3P formed. On the basis of the data obtained, the formula $[(Pd_3P)_8.PPh_3]_n$ was attributed to complex **16**.[102,118]

In contrast to platinum(II) chloride complexes, which are reduced by hydrogen only under very severe conditions,[99] platinum(II) acetate complexes are readily reduced by hydrogen, like the palladium(II) complexes. Treatment of the complex $[Ph_3PPt.(OAc)_2]_2$ with hydrogen (20 °C, 1 atm H_2) in acetic acid leads to the formation of the compounds $[Ph_2PPt]_n$ **17** (yield 85% with respect to platinum), $[Ph_2PPt(OAc)]_n$ **18** (yield 5% with respect to platinum), and a mixture of products of the far reaching dephenylation of triphenylphosphine having the general formula $[PhPPt]_m$ (yield 5% with respect to platinum).[101]

$$[Ph_3PPt(OAc)_2]_2 \xrightarrow[-C_6H_6]{H_2,\ AcOH} [Ph_2PPt]_n + [Ph_2PPt(OAc)]_n + [PhPPt]_m$$

17 **18**

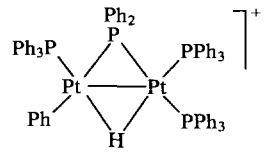
The reaction is accompanied by the formation of benzene, which indicates the cleavage of the P–C bond of the coordinated triphenylphosphine under the conditions of the reaction with H_2. Furthermore, the main bulk of the compounds isolated contain PPh_2 groups and even the product of the incomplete reduction of the acetate groups $[Ph_2PPt(OAc)]_n$ contains diphenylphosphide groups and not triphenylphosphine. Thus, in contrast to palladium, where the complex $[Ph_3PPd]_2$ is formed under analogous conditions,[104] in the reduction of the complex $[Ph_3PPt(OAc)_2]_2$ by hydrogen the dephenylation of triphenylphosphine apparently proceeds in parallel with the hydrogenolysis of the Pt–OAc bonds linking the acetate groups and the complex $[Ph_3PPt]_n$ cannot be synthesised under these conditions.

It was expected[101] that the formation of heteronuclear platinum and palladium phosphide complexes is possible in the reduction of $(\eta^3\text{-}C_3H_5)Pd(OAc)_3Pt(PPh_3)$ **19** by hydrogen in acetic acid. However, metallic palladium is formed almost simultaneously with the heteronuclear complex on contact of complex **19** with H_2 and then platinum(II) is reduced slowly with formation of benzene and a platinum complex. According to IR spectroscopic data and elemental analysis, the latter complex is analogous to the $[Ph_2PPt]_n$ obtained on reduction of $[Ph_3PPt(OAc)_2]_2$ by hydrogen.[101]

$$(\eta^3\text{-}C_3H_5)Pd(OAc)_3Pt(PPh_3) \xrightarrow[-C_6H_6]{H_2,\ AcOH} \underset{\mathbf{19}}{} \longrightarrow Pd^0 + \underset{\mathbf{17}}{[Ph_2PPt]_n}$$

The reduction of $[Ph_3PPt(OAc)_3Ag]_2$ **20** by hydrogen in acetic acid also leads to the partial dephenylation of the triphenylphosphine ligands. On reduction, 1–2 molecules of benzene are formed from two molecules of compound **20**. The silver is reduced quantitatively to the metal. According to elemental analysis and the determination of the molecular mass, the main reaction product is the complex $[Pt_2(PPh_3)(PPh_2)(OAc)]_3$ **21**. According to data obtained by transmission electron microscopy (TEM), the particle size is ~5 Å, which can be correlated with the size of the particle containing the Pt_6 group.[101]

$$\underset{\mathbf{20}}{[Ph_3PPt(OAc)_3Ag]_2} \xrightarrow[-C_6H_6]{H_2,\ AcOH} \underset{\mathbf{21}}{[Pt_2(PPh_3)(PPh_2)(OAc)]_3}$$



The acetate groups of complex **21** are manifested in the IR spectrum at 1580 and 1440 cm^{-1} and in the ^1H NMR spectrum at 2.09 p.p.m. (the hydride signals are not observed). A superposition of complex multiplet signals in the range 17–58 p.p.m. is observed in the ^{31}P NMR spectrum, which can be attributed to both Ph_2P and Ph_3P groups.

Complex **21** absorbs hydrogen reversibly in solutions in acetic acid (1 mol of H_2 per gram-atom of Pt). The cycles involving evaporation, admission of argon, and subsequent absorption of hydrogen may be repeated several times.

$$[Pt_2(PPh_3)(PPh_2)(OAc)]_3 \underset{-H_2}{\overset{H_2}{\rightleftharpoons}} \underset{\mathbf{22}}{[Pt_2(PPh_3)(PPh_2)(OAc)(H_2)_2]_3}$$

The reversible absorption of hydrogen is not characteristic of this complex alone. Thus, when $[Ph_3PPt(OAc)_2]_2$ and $(\eta^3\text{-}C_3H_5)$. $Pd(OAc)_3Pt(PPh_3)$ are reduced, more hydrogen is absorbed (2 mol and 1.5 mol per gram-atom of the metal respectively) than is required for the stoichiometric reduction reaction. The superstoichiometric amount of hydrogen is also absorbed reversibly in such cases. Similar results were obtained previously in the case of the palladium complex $Pd_2(PPh_3)_2$.[100] The signal due to the coordinated hydrogen in the ^1H NMR spectra was not recorded in all cases, which can probably be explained by the low stability of the complexes and the very large signal width, characteristic of complexes with molecular hydrogen.[120]

When a mixture of $Pt(1,5\text{-}C_8H_{12})_2$, [*trans*-PtPh(MeCOMe). $(PPh_3)_2]^+$, and PPh_3 was treated with hydrogen, the formation of the platinum phosphide complex **23** was also observed.[66]

23

The question of the origin of the phenyl group linked to the platinum atom was solved by replacing the initial cation by $[trans\text{-}Pt(p\text{-}MeC_6H_4)(MeCOMe)(PPh_3)_2]^+$. Since the cation **23** is in this case detected among the reaction products, it is evident that the phenyl group was formed as a result of the dissociation of the P–C bond involving the PPh_3 ligand.

4. Reduction of $Pd(OAc)_2$ by hydrogen in the presence of phenanthroline and bipyridyl

The products of the reduction of $Pd(OAc)_2$ by hydrogen in acetic acid containing phenanthroline or bipyridyl have been investigated.[121–123] The noncrystalline substances obtained are capable of catalysing the oxidation of alkenes, alcohols, and other organic substrates.

The product of the reduction of palladium(II) acetate by hydrogen in solution in acetic acid containing 0.5 mol of phenanthroline per gram-atom of palladium has the composition $Pd_4Phen(OAc)_2H_4$ **24.**

$$4\ Pd_3(OAc)_6 + 3\ Phen + 15\ H_2 = 3\ \underset{\mathbf{24}}{[Pd_4Phen(OAc)_2H_4]_n} + 6\ AcOH$$

The hydride nature of complex **24** was confirmed by ^1H NMR spectroscopic data. A broad band with a maximum in the range $\delta = -30$ to -50 ppm (width 5 kHz) was found in the broad-band spectrum (frequency range 250 kHz).[130] The appreciable broadening of the hydride signals was explained by the fact that the palladium atoms in these complexes form a polynuclear structure with a system of metal–metal bonds similar to the lattice of metallic palladium or its hydride phases.

The study of this substance by high-resolution transmission electron microscopy showed that its particles contain a nearly spherical metal core 20 ± 5 Å in diameter.[124] A radial distribution curve for the atoms (RDA), on which there is a single maximum corresponding to the Pd–N interatomic distance (2.1 ± 0.1 Å) and a single peak corresponding to the short Pd–Pd distance (2.62 ± 0.05 Å) was obtained from EXAFS data.

The sizes of the metal core of the hydrido-complex molecules found from TEM data enabled the authors to estimate the number n in the formula $[Pd_4Phen(OAc)_2H_4]_n$, which proved to be approximately 100 on the assumption that the packing density of the palladium atoms in the core of this cluster is the same as in the metallic palladium lattice.

The chemical properties of the hydrido-complex indicate its high reactivity.[125,126] Treatment of the polynuclear hydrido-complex with various electrophiles leads as a rule to unstable products, which decompose into monomeric or oligomeric palladium complexes. In contrast to this, the reaction with O_2 leads to the formation of clusters in which a massive metal skeleton is retained. These clusters proved to be effective catalysts for many oxidation reactions.[127,128]

5. Giant palladium clusters

On reaction with oxygen, the polynuclear hydrido-complex **24** loses its hydride atoms, which are bound to form H_2O. A small proportion of the palladium atoms are then oxidised to Pd(2+) complexes and the main bulk are converted into a cluster compound the simplest formula of which is $Pd_9Phen(OAc)_3$ **25**. Complex **25** is stable in air and is soluble, like the hydrido-complex **24**, in water and polar organic solvents.[127]

The molecular mass of complex **25**, which is $(1.0 \pm 0.05) \times 10^5$, was estimated from the measured rates of sedimentation in an aqueous solution under ultracentrifugation conditions. Such a large molecular size required the use of a set of analytical methods for the identification of these compounds. More definite information about the molecular size of compound **25** was obtained with the aid of small angle X-ray scattering methods, high-resolution transmission electron microscopy, and electron diffraction.[128-130]

The metal cores of the molecules of compound **25** are observed on the electron photomicrographs in the form of almost regular spherical particles 26.0 ± 3.5 Å in diameter with a unimodal size distribution. The packing of the palladium atoms in the cluster **25** was determined with the aid of EXAFS spectra.[128,129] The set of atomic Pd–Pd distances found (2.60 ± 0.04, 3.1 ± 0.1, 3.7 ± 0.1, 4.1 ± 0.1) agrees best with the icosahedral model of the packing of palladium atoms in the metal core of the cluster **25**. Taking into account the chemical composition, the idealised formula $Pd_{561}Phen_{60}(OAc)_{180}$ was proposed for the cluster **25**. This formula apparently corresponds to an average size and composition of the cluster and not to definite fixed dimensions and chemical composition, i.e. there is a distribution of the particles of the cluster **25** about an average value $d \approx 25$ Å and the idealised composition $Pd_{561}Phen_{60}(OAc)_{180}$.

In this structure, 60 Phen ligands are coordinated as bidentate species by the palladium atoms at the vertices and on the edges of the icosahedron. The overall formal charge on the metal core together with the electrically neutral Phen ligand is 180+ and is balanced by 180 anionic ligands OAc^-, which are distributed in the outer sphere of the cluster cation **25** (Fig. 1). A similar outer-sphere arrangement of acetate anions has been observed with the aid of X-ray diffraction in the tetranuclear cluster $[Pd_4Phen_4(CO)_2](OAc)_4$.[131]

The cluster **25** can be precipitated from aqueous solution by adding salts such as NaX or KX (X = Cl, Br, ClO_4, HSO_4, PF_6, AsF_6), which is accompanied by the substitution of the OAc^- anions by X^-. When compound **25** was treated with the salt KPF_6, a giant cluster having a similar composition and structure and represented by the idealised formula $Pd_{561}Phen_{60}O_{60}(PF_6)_{60}$ **26** was obtained.[130]

$$Pd_{561}Phen_{60}(OAc)_{180} + 60\,PF_6^- + 60\,H_2O$$

$$= Pd_{561}Phen_{60}(PF_6)_{60}O_{60} + 120\,AcOH + 60\,AcO^-$$

EXAFS data led to the conclusion that the packing of the metal atoms in the metal core of the cluster **26** is cubooctahedral and not icosahedral.

The giant clusters obtained serve as a bridge between the usual molecular clusters and colloidal metals and their homogeneous solutions are a model of the colloidal solutions of metals. The size of the metal core in giant clusters greatly exceeds the size of the larger molecular clusters, such as $Pd_{38}(CO)_{28}(PEt_3)_{12}$[132] and $Au_{55}(PPh_3)_{12}Cl_6$,[133] approaching the lower limit of the size of the colloidal particles of metals. In contrast to the latter, giant clusters have a distinct ligand environment with a definite stoichiometry characteristic of molecular clusters. However, in those cases where the number of metal atoms approaches several hundreds, a set of more or less imperfect metallopolyhedra is formed with a certain distribution with respect to size and chemical composition.

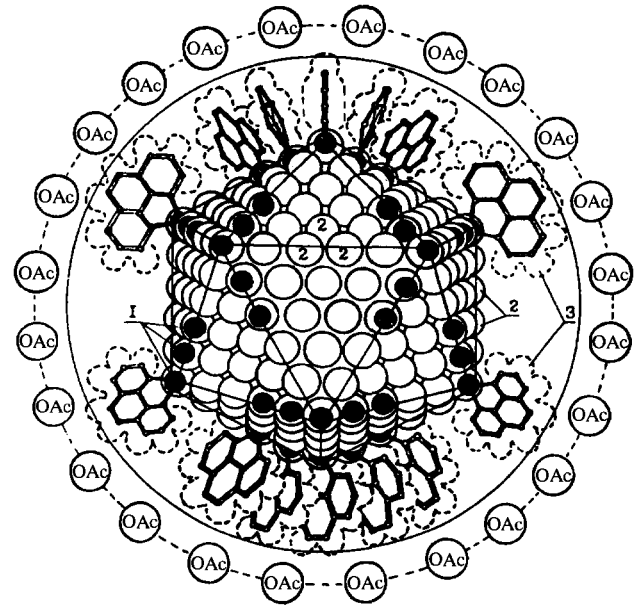


Figure 1. An idealised model of the cluster **25**: (*1*) palladium atoms coordinated to the Phen ligands; (*2*) palladium atoms accessible for the coordination of the AcO^- anion and substrate or solvent molecules; (*3*) the van der Waals volume of the coordinated phenanthroline molecules.

The clusters **25** and **26** behaved as catalysts in a series of reactions. Oxidative acetoxylation of ethene to vinyl acetate, of propene to allyl acetate, and of toluene to benzyl acetate takes place in the presence of acetic acid in solutions of these clusters.[130] They effectively catalyse the oxidation by molecular oxygen of primary alcohols to esters and of secondary alcohols to ketones.[134]

6. Reduction of platinum(II) and palladium(II) carboxylate complexes by formic acid

As shown above, the reduction of $[Ph_3PPd(OAc)_2]_2$ or $Ph_3PPd.(Acac)_2$ by molecular hydrogen leads to the final products $[Pd_5(PPh)_2]_m$ and $[(Pd_3P)_8.PPh_3]_n$ respectively.[100] These are formed as a result of the far reaching dephenylation of the triphenylphosphine ligands. In both cases, palladium phosphide complexes are regarded as intermediates. Presumably it will be possible to obtain palladium phosphide complexes by the reduction of palladium carboxylates with formic acid.

Indeed, the study of the interaction of $Pd(Acac)_2PPh_3$ with formic acid under an atmosphere of an inert gas or hydrogen showed that the initial complex is reduced much faster by formic acid than by hydrogen. The latter does not affect the course of the reaction and the composition of the products under these conditions.[98,117,135] In the first stage, all the acetylacetonate ligands are substituted by formate ligands.

$$Pd(Acac)_2PPh_3 + 2\,HCOOH \longrightarrow Pd(HCOO)_2PPh_3 + 2\,HAcac$$

Analysis of the gas phase revealed the presence of CO_2 and H_2, which is characteristic of the catalytic decomposition of HCOOH.[136] According to a number of investigators,[98,117,137,138] the dimeric complex $[PdPPh_3]_2$ should also be formed in the reduction of $Pd(HCOO)_2PPh_3$, similarly to what happens in the reduction of $[(Ph_3P)_2Pd(OAc)_2]_2$ by hydrogen.[41,100]

$$[Pd(HCOO)_2PPh_3]_2 \longrightarrow [PdPPh_3]_2 + 4\,CO_2 + 2\,H_2$$

However, the complex $[PdPPh_3]_2$ could not be detected. It is apparently unstable under the reaction conditions and interacts in accordance with the following scheme with the hydrogen formed:

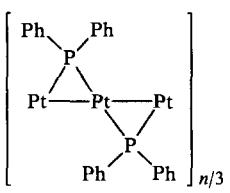
$$[PdPPh_3]_2 + H_2 \longrightarrow [PdPPh_2]_2 + 2\,C_6H_6.$$

The final product of the reduction reaction is a complex to which the formula $[Pd_4(PPh_3)_2(PPh_2)_2]_n$ was attributed on the basis of the results of elemental analysis and UV and IR spectroscopic data.[117] In this product, half of the PPh_3 ligands have been dephenylated. the complex obtained exhibits a high activity in the arylation of styrene by iodobenzene, but is inactive in the hydrogenation and oligomerisation of phenylethyne.[117]

The interaction of $[Ph_3PPt(OAc)_2]_2$ with HCOOH also begins with the replacement of all the acetate ligands by formate ligands (according to GLC data). After an induction period, the platinum(II) complex is subsequently reduced with formation of benzene and CO_2. According to the results of elemental analysis and IR spectra, the main reaction product corresponds to the composition $[Ph_2PPt]_n$ **27**. In addition, a small amount (~5%) of the product of more far reaching dephenylation $[PhPPt]_m$ **28** is formed (Scheme 3).[101,102]

Scheme 3

$$[Ph_3PPt(OAc)_2]_2 \xrightarrow[-AcOH]{HCOOH} [Ph_3PPt(OCOH)_2]_2 \xrightarrow{-CO_2}$$



$$\longrightarrow [Ph_3PPtH_2]_n \xrightarrow{-C_6H_6} [Ph_2PPt]_n \xrightarrow{-C_6H_6} [PhPPt]_m$$

27 **28**

The molecular mass of complex **27** in benzene corresponds to 10 $[Ph_2PPt]$ fragments, i.e. $n = 10$. According to the results of the study of complexes **27** and **28** by high-resolution transmission electron microscopy, their particle size does not exceed 6 Å, which corresponds to small clusters and does not conflict with the determination of the molecular mass.[101]

A very broad signal (50 mHz), apparently associated with the occurrence of rapid exchange in the system, is observed in the ^{31}P NMR spectra. A decrease in temperature to −90 °C in toluene or to the glass point (−60 °C) in DMF does not induce slow exchange conditions in this case. ^{31}P NMR spectra of a similar type have been observed for all platinum phosphide complexes.

According to EXAFS spectroscopic data, there is only one shortest Pt–Pt distance in complex **27**, amounting to 2.53 Å, while the next nonbonding distance is 3.01 Å; only one maximum also corresponds to the Pt–P distance (2.22 Å). Bearing in mind that the Pt:P ratio is 1:1 on the basis of the composition of complex **27** and that according to EXAFS spectroscopic data the intensity of the Pt–P peak exceeds significantly that of the Pt–Pt peak, the authors suggested that complex **27** is a linear chain polymer in which the platinum atoms are linked by the metal–metal interaction and by bridging phosphido-groups. In addition, the authors do not rule out the possibility of the existence of pentacoordinate phosphorus atoms in this structure.

The fixed long Pt–Pt distance can apparently be explained by the fact that the chain structure is bent and not linear. The bent form of the chain can be accounted for by the molecular packing effects in the solid phase (EXAFS spectra were recorded for the specimens). However, the EXAFS spectroscopic data for a solution of complex **27** are virtually identical with the spectra of solid specimens.

The size distribution and form of the particles of complex **27** have been investigated by the small angle X-ray scattering method (SAXS). According to SAXS data, the particles of complex **27** are nearly spherical with a diameter of 15.2 ± 0.5 Å.

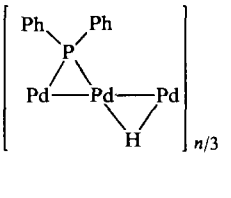
In contrast to platinum, treatment of the palladium acetate complex $[Ph_3PPd(OAc)_2]_2$ with formic acid leads to the formation of the polyhydride complex $[Pd_2(PPh_2)H_x]_n$ **29** as the main reaction product (60% and 70% relative to palladium). Furthermore, the complex $[Pd(\mu\text{-}O_2PPh_2)(Ph)(PPh_3)]_2$ **30** was obtained in 8%–10% yield relative to palladium. According to GLC data, the reaction also results in the formation of acetic acid (2 mol per mol of palladium) and benzene (0.9 mol per mol of PPh_3).[137]

$$[Ph_3PPd(OAc)_2]_2 \xrightarrow[-C_6H_6]{HCOOH}$$

$$\longrightarrow [Pd_2(PPh_2)H_x]_n + [Pd(\mu\text{-}O_2PPh_2)(Ph)(PPh_3)]_2$$

29 **30**

The dynamics of the variation of the volume of the gas phase of the system corresponds to the autocatalytic nature of the reaction, the volume of the gas exceeding the calculated value by a factor greater than 2.5. According to GLC data, the evolved gas is a ~1:1 mixture of CO_2 and H_2. Carbon monoxide was not detected even in trace amounts. The presence of hydrogen in the gas mixture and the volume of the evolved gas indicate that the reduction of the palladium(II) complex is accompanied by the decomposition of formic acid by the complex.



$$Pd(II) \xrightarrow{HCOOH} Pd(0) + CO_2 + 2\,H^+$$

$$HCOOH \xrightarrow{Pd^{0-1}} CO_2 + H_2$$

Nor can one rule out [the possibility] that the hydrogen formed on decomposition of formic acid is consumed on the reduction of the initial palladium(II).

The IR spectrum of complex **29** (the main reaction product) contains only the absorption bands of the phosphorus-containing ligands. Those of the OAc^- groups are absent (the Pd–H vibrations are inactive in the IR spectrum). In the ^1H NMR spectrum, the signal due to the aromatic protons is broadened and in addition a broad signal is observed (signal widths ~0.9 ppm) with the centre at −9.5 ppm and may correspond only to complexes with hydrogen. According to SAXS data (small angle scattering), the particles of complex **29** are spherical and their size is 15.6 ± 0.5 Å. The $[Pd_2(PPh_2)H_x]_n$ particle size is virtually the same as for the analogous platinum complex $[Ph_2PPt]_{10}$ (15.2 ± 0.5 Å). Thus the number of metal atoms in the palladium phosphide complex is apparently also close to ten.

The RDA curve for complex **29** was obtained from EXAFS data. It has a peak corresponding to a single shortest distance between the palladium atoms (2.55 Å), the next nonbonding distance being 3.66 Å. Only a single maximum corresponding to a Pd–P distance of 2.15 Å is also observed in the EXAFS spectrum. In conformity with these data, the authors[137] suggest that, like the platinum phosphide complex, complex **29** is a linear chain polymer in which the palladium atoms are linked by the metal–metal interaction, bridging phosphido-ligands, and, apparently, bridging hydrido-ligands.

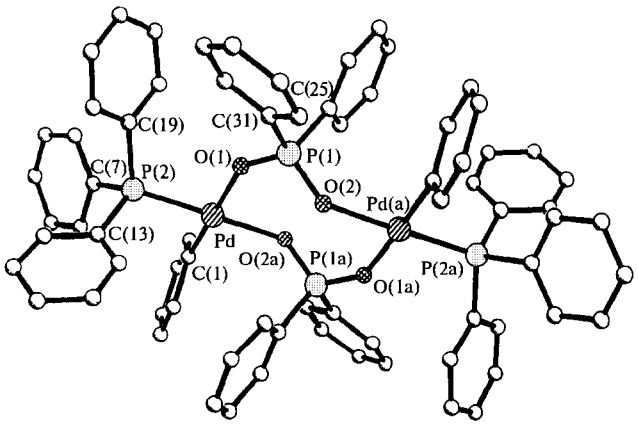


Figure 2. Molecular structure of $[Pd(\mu\text{-}O_2PPh_2)(Ph)(PPh_3)]_2$ **30**.

The structure of the second product of the interaction of $[Ph_3PPd(OAc)_2]_2$ with HCOOH — the dimeric complex $[Pd(\mu\text{-}O_2PPh_2)(Ph)(PPh_3)]_2$ **30** was established by X-ray diffraction.[138] The Pd^{2+} species of the centrosymmetrical dimeric complex **30** are linked by two bridging diphenylphosphinate groups. The Pd...Pd distance is 5.35 Å, which rules out the possibility of a metal–metal interaction (Fig. 2). The coordination of the palladium atoms is close to the ideal square-planar. The central eight-membered ring has the chair conformation and, as a consequence of its centrosymmetrical structure, the atoms of the central part of the ring P(1), O(2), P(1a), and O(2a) are strictly coplanar, while the plane comprising the atoms of the 'angular' fragment P(1), O(1), Pd, and O(2a) forms a dihedral angle of 47.3° with the plane of the central part.

The Pd–O(1) and Pd–O(2a) bonds in the *trans*-positions relative to the Ph and Ph_3P substituents at the metal atom are virtually the same [2.115(6) and 2.100(9) Å]. On the other hand, the P(1)–O(1) [1.482(6) Å] and P(1)–O(2) [1.516(9) Å] bond lengths differ by 0.034(9) Å, which justifies the assumption that the P(1)–O(1) bond is multiple, while Pd–O(1) is a coordinate bond. Nevertheless, the Pd–O bond lengths are equalised, which is apparently induced by the electronic influence of the Ph_3P and Ph groups in the *trans*-positions relative to these bonds.

It is noteworthy that the formation of complex **30** in the reaction of $[Ph_3PPd(OAc)_2]_2$ with HCOOH is the outcome of an unusual oxidation-reduction process because it indicates the oxidation of P^{III} to P^{V} in the presence of a powerful reductant (HCOOH) and in the absence of any kind of traditional oxidant. The only source of oxygen atoms, which become attached to the phosphorus atom of the phosphine ligand during the formation of complex **30** under the reaction conditions (Ar atmosphere, reagents carefully freed from O_2), is the carboxylate ligands.

The fact that the P–C bond dissociation reaction in the formation of complex **30** includes an intermediate decrease in the oxidation state of the metal is confirmed both by the very fact of the formation of complex **30** with a Pd–C(Ph) bond and by data on the reduction of palladium(II) by formic acid in the presence of hydroquinone and *p*-benzoquinone. The presence of hydroquinone, which is incapable of oxidising palladium(0), under these conditions merely shortens somewhat the induction period and hardly affects the form of the curve. On the other hand, the addition of *p*-benzoquinone increases sharply the induction period, at the end of which gas is evolved at a significantly higher rate. On the basis of these data, one may conclude that the low-valence palladium complex formed in the system is immediately oxidised by *p*-benzoquinone to palladium(II) and, as long as any amount of the quinone remains in the system, there is virtually no gas evolution.

IV. Conclusion

The extensive and independent field of the chemistry of cluster compounds such as the carbonylphosphineplatinum(0) and carbonylphosphinepalladium(0) compounds remains outside the scope of the present review.

Complexes with phosphine ligands have played an enormous role in the establishment and development of the modern chemistry of transition metals. The electronic properties of these ligands (their *n*-donor capacity and their fairly low-lying unoccupied *d* orbitals) as well as the steric factors which vary within wide limits have been used widely to stabilise labile complexes containing M–H, M–C, M–Si and other bonds and also to obtain numerous catalysts from them.

In the first stage of the study of complexes of this type, it appeared that the phosphine ligand can migrate, as a stable fragment, from one compound to another or can leave the coordination sphere without changing and without entering into any kind of reactions involving the P–C bonds.

The data examined above show that in reality tertiary phosphines lose their organic groups fairly readily under the conditions of reactions leading to a decrease in the oxidation state of the central atom. The dissociation of the P–C bond is observed when virtually any reductants are employed. It now appears surprising that these reactions remained unnoticed in the first stages of the development of the chemistry of complexes with tertiary phosphines when numerous mononuclear complexes of metals in the zero oxidation state were synthesised. Studies in later years showed that, when the M : L ratio is varied, it is possible to obtain in the same systems clusters in which the role of the bridging groups is assumed by phosphide or phosphene ligands, arising when the organic groups are removed from the molecule of the initial tertiary phosphine. The nature of these reactions is still insufficiently clear. There is no doubt about the role which the coordinative unsaturation of the metal atom in the corresponding intermediate plays in the dearylation and dealkylation of the tertiary phosphine. However, the comparative stability of the complexes containing only two phosphine ligands at the metal atom in the zero oxidation state suggests that, apart from the formal coordinative unsaturation, some other factors are also responsible for the course of these unusual processes.

The cluster formation reactions are a phenomenon characteristic not only of complexes with phosphine ligands. As can be seen from the concluding sections of the present review, palladium clusters are formed readily when palladium acetate is treated with reductants in the presence of stabilising ligands such as carbon monoxide and aromatic nitrogen-containing bases coordinated as bidentate species. The formation reactions of these clusters constitute the basis of the synthesis of catalytically active compounds exhibiting an unusual selectivity and activity under mild conditions. The interest of the authors in the topic to which this review is devoted is partly due to these factors.

Abstract. The structure of intermediate surface compounds in heterogeneous catalytic reactions involving H_2, CO, and NO is discussed. The relative reliability of the role of various structures in catalysis is discussed. Schemes for the reaction mechanism which have been developed from information on the surface complexes are described. The bibliography includes 248 references.

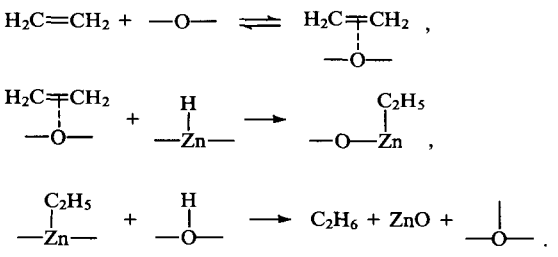
I. Introduction

We have previously discussed the intermediates which have been detected by spectroscopic measurements in situ in the simplest heterogeneous catalytic reactions of hydrocarbons.[1] This review is concerned with somewhat more complex reactions involving H_2, CO, or NO. In most cases two substances are the initial reactants, and the catalysts are metals or transition metal oxides. The hydrogenation of olefins and the dehydrogenation of paraffins are reaction of the general type

$$A + B \leftrightarrows AB .$$

In the forward direction we may observe the activation of both the olefin (A) and the hydrogen (B), and therefore possible intermediates formed from both the hydrocarbons and the hydrogen must be considered.

As in our previous review[1] we shall define three levels of reliability of the existence of intermediate substances: a low level (L), obtained from spectroscopic data recorded before and after the catalysis, a medium level (M), obtained from spectroscopic data in situ but without kinetic measurements, and a high level (H), from spectroscopic data in situ aimed at comparing the kinetics of the heterogeneous catalytic reactions with those of the change in concentration of the surface compounds.

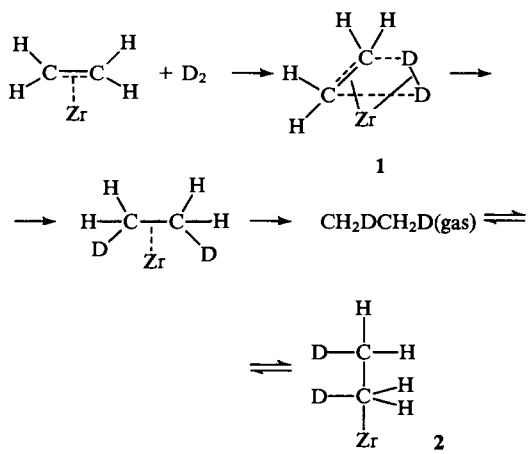


O V Krylov, V A Matyshak N N Semenov Institute of Chemical Physics, Russian Academy of Sciences, ul. Kosygina 4, 117 977 Moscow, Fax (7-095) 938 21 56

Received 4 April 1994
Uspekhi Khimii **64** (1) 66–91 (1995); translated by J I Carasso

In the reactions with H_2, CO, and NO the observed spectra are usually stronger than those seen in the reactions of the hydrocarbons. This effect is attributed to the high extinction coefficients of the C–O, O–H, and N–H bonds. Accordingly, the reliability of the results is also generally higher.

II. Hydrogenation of hydrocarbons

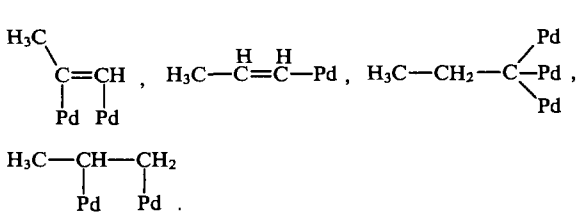


In our previous review,[1] devoted to the simplest reactions of the hydrocarbons, alcohols, and acids, we discussed the intermediate complexes formed by the isomerisation of the olefins on ZnO.[2,3] The same workers[4–6] used kinetic methods and IR spectroscopy to study the mechanism of the hydrogenation of C_2H_4 on ZnO. According to their results there are two types of adsorption of H_2 on ZnO: (1) a fast, reversible adsorption, with formation of Zn–H bonds (1710 cm^{-1}) and of O–H bonds (3510 cm^{-1}), and (2) a slow, irreversible adsorption, with diffusion of the hydrogen into the bulk of the catalyst. Adsorption of the first type occurs when C_2H_4 is hydrogenated at 300 °C. After the adsorption of C_2H_4 the Zn–H band persists in the IR spectra but the O–H band disappears. This led to the conclusion that hydrogen is adsorbed as a π complex on the oxygen atoms, with absorption bands (a. b.) at 1438, 1451, and 1600 cm^{-1}; the heat of adsorption is about 58 kJ mol^{-1}. A new band assigned to a π complex, appears when the C_2H_4 is hydrogenated in a flow reactor. When C_2H_4 is replaced by C_2D_4 the initial rate of disappearance of the C_2H_5 absorption bands is close to the stationary rate of hydrogenation: the step corresponding to this process may be rate-limiting. The proposed mechanism can be represented as

The adsorbed hydrogen can migrate over the oxygen centres of the surface towards the adsorbed C_2H_4.

The mechanism proposed[4-6] for the hydrogenation of C_2H_4 was subsequently confirmed.[7,8] However, the only deuteration products of C_3H_6, C_4H_8, and C_4H_6 were the deuterated hydrocarbons $C_3H_6D_2$, $C_4H_8D_2$, and $C_4H_6D_2$. This shows that the hydrogen takes part in the reaction in a molecular form rather than in the atomic form seen in the hydrogenation of ethylene: this difference can be attributed to the weaker chemisorption of C_2H_4 on ZnO as compared with C_3H_6, C_4H_6, and C_4H_8. Therefore C_3H_6 and C_4H_8 are adsorbed as π-allyl complexes.

The IR spectra of hydrogen adsorbed on ZrO_2 at 0-100 °C also indicate a heterolytic dissociation of H_2 with formation of Zr-H and O-H groups.[9] However, when bound in this way hydrogen does not react with ethylene from the gas phase, but is simply replaced by it: the intensity of the Zr-H band decreases, and the absorption bands of π-C_2H_4 (1446 cm^{-1}) and of the tightly bound C_2H_4 complex (1338 cm^{-1}) are formed. However, the hydrogenation of C_2H_4 is detectable even at −100 °C, when the heterolytic dissociation of H_2 is inconceivable. Under these conditions the adsorbed ethylene interacts with D_2 from the gas phase by the following mechanism:

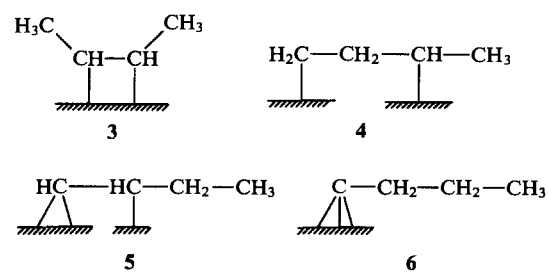


In this reaction the complex **1** is the intermediate and the complex **2** is a side product.

On clean Pd(111) and Pd-Cu(111) metallic surfaces π-C_2H_4 and ethylidene (=CH-CH_3) are observed[10] in the electron energy loss spectroscopy (EELS) spectra, whereas in the adsorption of C_2H_2 the corresponding species are π-C_2H_2 and ethylidyne (≡C-CH_3). At high temperatures (200 °C) even more highly dehydrogenated intermediates of composition Pd-C_xH_y are formed (where $x > y$). It was concluded that the hydrogenation reaction takes place through the formation of these complexes.

An IR spectroscopic study[11] of the interaction of C_2H_4 with Rh/SiO_2 and with VO_x-Rh/SiO_2 also suggested the formation of the ethylidene groups =CH-CH_3. In the presence of hydrogen these are hydrogenated to give alkyl groups, and beyond to CH_4 and C_2H_6.

An analysis[12] of the IR spectra obtained after the hydrogenation of propylene on Pd/ZrO_2 detected the formation of the surface compounds



The hydrogenation of butadiene on Pt(100), studied[13] by low-energy electron diffraction (LEED) and by Auger spectroscopy, was found to proceed through the formation of the intermediate C_4H_7:

$$C_4H_6 \rightleftharpoons C_4H_6\,(ads) \underset{-H^+}{\overset{H^+}{\rightleftharpoons}} C_4H_7\,(ads) \xrightarrow{H^+} C_4H_8\,(ads) \longrightarrow C_4H_8\,(gas).$$

The conversion of butadiene into butene is the rate-limiting step, characterised by an activation energy of 39 kJ mol^{-1}. The fact that the rate of H/D exchange is an order of magnitude greater than the rate of hydrogenation of C_4H_6 points to the same conclusion.

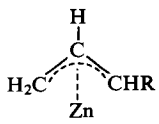
The IR spectra of butenes adsorbed on Ni/SiO_2 [14] and on Co/SiO_2 [15] revealed absorption bands denoting the formation of metal-butane

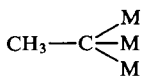
and of π-allyl complexes. The allyl complexes are probably the precursors of the metal butanes **3**-**5**. The complex **3** is loosely bound to the surface, and is easily hydrogenated to butane. The complexes **4** and **5** are tightly bound, and are probably hydrogenated through the intermediate formation of the complex **6**. The formation of butane is observed in the range 20-100 °C, but above 90 °C the hydrogenation is accompanied by some dissociation of the C-C bond.

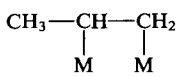
Data on the intermediate compounds taking part in the hydrogenation of the hydrocarbons are summarised in Table 1.

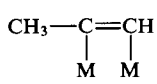
The hydrogenation of olefins on ZnO was studied by a combination of in situ spectroscopic and kinetic measurements, which unambiguously demonstrated the participation of the π-allyl complexes of C_3H_6 and of the π complexes of C_2H_4, and also the interaction of the H atoms with C_2H_4 and of the H_2 molecules with C_3H_6 and with C_4H_8. However, the kinetic parameters obtained by spectroscopic methods could not be compared with those obtained by analysing the gaseous products.[4-8]

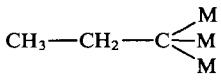
Adequately reliable data on the intermediate compounds taking part in the dehydrogenation of the paraffins do not appear to be available.

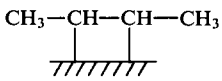












Addigo et al.[16] studied the IR spectra of the complexes of ethylbenzene and styrene adsorbed on iron oxide catalysts after the dehydration of the ethylbenzene to styrene. Under ordinary (non-reactive) conditions on non-promoted Fe_2O_3 the binding of the adsorbed styrene to the surface takes place through the aromatic ring, and the vinyl group suffers only a negligibly small perturbation. However, under the conditions favourable to the dehydrogenation reaction the interaction with the surface takes place through the vinyl group.[16]

III. Decomposition of ammonia

The synthesis of ammonia is carried out under high pressures. Spectroscopic measurements are difficult under these conditions, and therefore the reverse reaction (decomposition of NH_3) is often used in studies of the mechanism of the ammonia synthesis.

The decomposition of NH_3 on polycrystalline tungsten has been studied by Auger spectroscopy,[17] and on W(100),[18] Ru(001), and Ru(111)[19] it was studied by X-ray photoelectron spectroscopy (XPS). At 800 °C the tungsten surface (according to in situ Auger spectroscopy data) is covered with nitrogen atoms, and no NH_x species are found on the surface. The number of adsorbed

Table 1. Intermediate compounds in the hydrogenation of olefins.

N atoms is much greater than the number corresponding to equilibrium adsorption

$$N_2 \rightleftharpoons 2N(ads),$$

in the absence of NH_3 and H_2 but under otherwise similar conditions. A combined study (by Auger spectroscopy) of the kinetics of the decomposition of NH_3 and of the desorption of N_2 showed that an increase in the coverage of the surface by nitrogen (θ_N) lowers the rate of decomposition of NH_3 and increases the rate of desorption of N_2, which become identical under steady-state conditions. Hydrogen from the gas phase has no effect on the adsorption of N_2 or on the rate of the reaction.

These results show that the reaction takes place by the mechanism of 'dynamic equilibrium' between two successive rate-limiting steps: (1) the formation on the catalyst surface of a layer of N atoms as a result of the decomposition of the NH_3 molecules, and (2) the desorption of the N atoms with formation of the N_2 molecule. The nitrogen is not in equilibrium with the NH_3 and H_2, as it is in the well known Temkin–Pyzhev mechanism of NH_3 synthesis on iron,[20] and for this reason the hydrogen does not affect the rate of absorption of nitrogen or the overall reaction rate. At high pressures the iron penetrates into the bulk of the catalyst and forms a nitride.

The decomposition of ammonia on Fe, W, and Re catalysts has also been studied by the electron projector method under thermal desorption conditions.[21] Nitrogen and hydrogen atoms adsorbed under the reaction conditions were detected. The activated adsorption of N_2 was observed on iron, and on rhenium and tungsten non-activated adsorption of nitrogen took place in two different forms, one of which contributes to the decomposition reaction whereas the other does not.

Thus it has been reliably shown by spectroscopic methods that adsorbed nitrogen atoms are the intermediate species in the decomposition of NH_3. Obviously, nitrogen atoms must act as intermediate complexes also in the synthesis of ammonia.

IV. Water gas conversion

Reactions involving CO are most conveniently studied by spectroscopic methods because the C≡O vibrations have high extinction coefficients. The interaction of CO with water vapour

$$CO + H_2O \rightleftharpoons CO_2 + H_2,$$

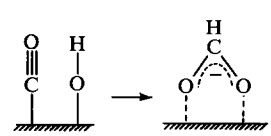
(the 'water gas conversion'), like its reverse reaction (the reverse water gas conversion'), is one of the simplest reactions involving CO. Both associative and dissociative mechanisms have been proposed for this reaction.

A purely dissociative mechanism was put forward on the basis of an IR spectroscopic study of this reaction on $Ni/(La_2O_3-MgO-Al_2O_3)$.[22] The vibration band of the bridging CO group

is shifted from 1960 to 1930 cm^{-1} after the adsorption of water, and under these conditions the linear form Ni–C≡O disappears. It was concluded that the adsorption of H_2O weakens the C=O bond in the bridging CO group (probably by shifting the electron density from H_2O towards the Ni) and thus favours its dissociation and disproportionation with formation of CO_2. The CO_3^{2-} and CH_3 groups, which do not take part in the conversion of CO, were also detected on the Ni surface. The following reaction mechanism was proposed:

$$H_2O(ads) \longrightarrow OH(ads) + H(ads),$$

$$CO(br) \longrightarrow C(ads) + O(ads),$$



$$CO(br) + O(ads) \longrightarrow CO_2(ads),$$

$$2\,H(ads) \longrightarrow H_2,$$

$$C(ads) + OH(ads) \longrightarrow CO(br) + H(ads).$$

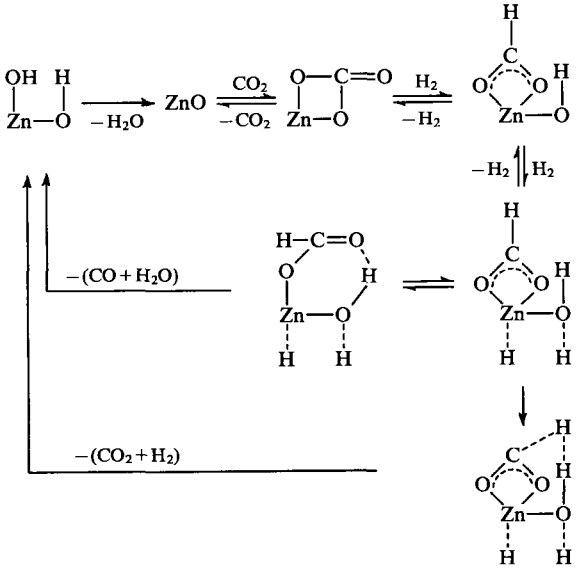
A dissociative mechanism for the reaction of CO with H_2O on Cu was proposed on the basis of IR spectroscopic data,[23] and for the same reaction on Co–Mo oxides by interpreting the results obtained by the response method.[24]

Most of the workers engaged in IR spectroscopic studies of the conversion of CO by water vapour observed the formation on the catalyst surface of formate groups (in addition to CO groups of various types). Therefore the formates are treated as intermediates in the mechanisms proposed for the reaction. The following formal mechanism was proposed after a study[25,26] of the conversion of CO on Cu–ZnO and $Cu-ZnO-Al_2O_3$ catalysts:

$$\rightleftharpoons H_2 + CO_2.$$

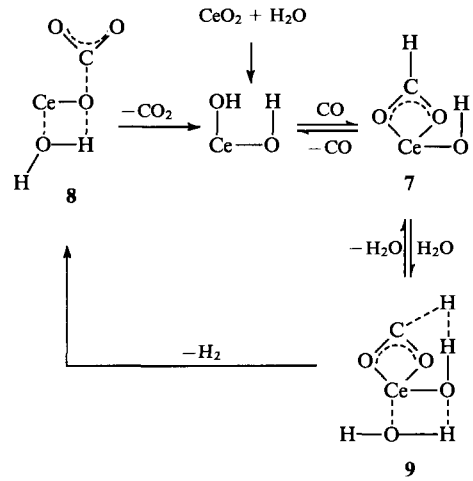
A similar mechanism was discussed for the reaction of H_2 with CO on Ru/NaY at 200–300 °C, but the observed first-order kinetics with respect to P_{H_2O} exclude the participation of tightly bound OH groups in the reaction.[27] An in situ study of the UV spectra allowed the valence state of the Ru to be determined: the results led to the reaction mechanism

$$Ru^+(H)(CO) + H_2O \longrightarrow Ru^{2+}(HCOO^-) + H_2,$$



$$Ru^{2+}(HCOO^-) \rightleftharpoons Ru^+(H) + CO_2,$$

$$Ru^+(H) + CO \rightleftharpoons Ru^+(H)(CO),$$



in which the formation of formate is the rate-limiting step.

On ZnO at 230 °C the rate of dissociation of the surface formate is equal to the rate of evolution of H_2O and CO into the gas phase after the hydrogenation of the CO_2.[28,29] On the other hand, if CO + H_2O is used as the initial mixture the production of formate is not observed. The opposite state of affairs is found on MgO:[28] formate is produced more easily from a mixture of CO + H_2O than from H_2 + CO_2. Under the conditions of the catalysis the MgO surface is covered mainly (90%) by carbonate, but the latter does not take part in the reaction.

The difference in structure between the surface complexes formed in the forward (CO + H_2O) and in the reverse reaction (CO_2 + H_2) on ZnO was reported also by Shido and Iwasawa.[30] By combining IR spectroscopy and labelled atom methods these workers showed that two types of formate complex exist on the surface. The first, formed from H_2 and CO_2, is 70% decomposed into H_2 and CO_2 at 250–300 °C, and 30% into H_2O (or surface OH groups) and CO. A different formate complex is obtained from OH and CO: this species is 70% decomposed with formation of OH and CO and 30% with formation of H_2 and CO_2. The activation energy for the decomposition of the formate complexes of the second type is 15–18 kJ mol^{-1} lower than for the first type. The rate of decomposition of the formate is much lower (by a factor of 10–30) in the presence of CO_2 than in a vacuum. Conversely, in the presence of H_2 the decomposition is faster. Under stationary conditions a balance is established between the promotion of the reaction by hydrogen and its suppression by CO_2. As reported,[30] the rate-limiting step is the dissociation of H_2 on a pair of Zn(HCOO)(OH). The overall reaction scheme can be written as follows.

The study of the interaction of CO and H_2O was extended to CeO_2 promoted by rhodium.[31] The activation energy for the decomposition of the formate complex produced from CO and OH was 56 kJ mol^{-1} (for the decomposition into H_2 + CO_2) and 122 kJ mol^{-1} (for the decomposition into OH + CO). In the presence of water vapour the rate of decomposition of $HCOO^-$ by the first path is increased 100-fold, and the activation energy falls to 33 kJ mol^{-1}. The rate-limiting step is assumed[31] to be the decomposition of the bidentate formate **7** into H_2 and the monodentate carbonate **8**. The evolution of CO_2 from the monodentate carbonate is promoted by H_2O through the intermediate complex **9**.

8 **7** **9**

The proposed mechanism differs from the mechanism of the same reaction on ZnO by the presence of the carbonate complex **8**. Rhodium itself is not active, but when added to CeO_2 it induces a rearrangement of the charges in the Ce–O pair which results in the activation of the C–H bond in the intermediate formate, in a closer approach of the formate to the neighbouring OH bridging group in the transition state **9**, and in a lowering of the activation energy.

Of the intermediates suggested above as participants in the water gas conversion the possible existence of the bridging carbonyl and carbonate complexes **8** can be assigned a reliability level L, and the existence of the formate complexes **7** a level M. However, the associative mechanism seems to be the most probable for the reaction: in this case the intermediate complex is not simply the formate but its associative complex with H_2O or H_2. The observation of various formate complexes, dissociating with different activation energies, suggests the possible migration of $HCOO^-$ from some centres to centres of other types.

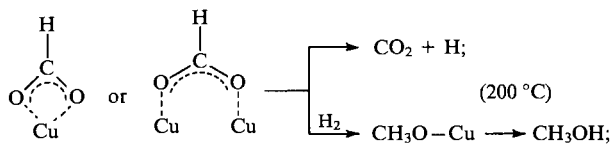
V. Synthesis and decomposition of methanol

Methanol is synthesised at high pressures from a mixture of CO + H_2. According to Rozovskii[32] the species hydrogenated is CO_2, and not CO. The carbon dioxide is formed in the first step of the water gas conversion discussed in the previous section. The mechanism of the synthesis of methanol from CO + H_2 and from CO_2 + H_2 has been studied extensively.[33–47] The reverse reaction (decomposition of CH_3OH) has also been studied, because it takes place at low pressures and is therefore experimentally easier.

The Cu–ZnO–Al_2O_3 system is the most generally used methanol synthesis catalyst: most of the reported spectroscopic studies have relied on the use of this catalyst and of its components. IR spectroscopy measurements on the catalyst surface have revealed the presence of formates,[29,33–46] carbonates,[33,37–39,41,43] methoxy groups,[29,34,35,44,47] and formyl groups HCO,[34,36,40,43,46] as well as adsorbed forms of CO and CO_2. Adsorbed CH_2O has also been reported.[47] Many of these workers have formally proposed the following series of transformations for these compounds:

$$H_2 + CO\,(ads) \rightleftharpoons HCO \rightleftharpoons HCOO^- \overset{H_2}{\rightleftharpoons}$$

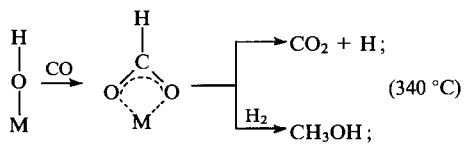
$$\rightleftharpoons CH_3O^- \overset{H_2}{\rightleftharpoons} CH_3OH.$$



The same sequence of reactions was assumed[48] for the synthesis of methanol from CO_2 and H_2 on $Cu-ZnO-SiO_2$, in which the IR spectra of the surface compounds were examined after the reaction.

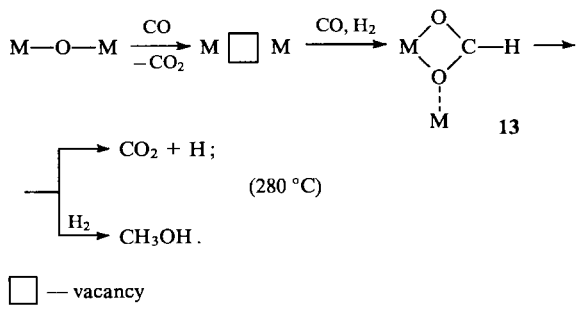
A detailed study[49] of the kinetics and of the mechanism of synthesis of CH_3OH on $Cu-ZnO-Al_2O_3$ led to the following scheme:

$$H_2 \rightleftharpoons 2\,H(ads),$$
$$CO_2 \rightleftharpoons CO_2(ads),$$
$$CO_2(ads) + H(ads) \rightleftharpoons HCOO(ads),$$
$$HCOO(ads) + 3\,H(ads) \rightleftharpoons CH_3OH + O(ads),$$
$$CO + O(ads) \longrightarrow CO_2,$$
$$H_2 + O(ads) \longrightarrow H_2O.$$



The location of these complexes is a problem of the greatest importance. Three types of adsorbed formate were detected by combining IR spectroscopic methods with temperature-programmed desorption (TPD) and with the method of chemical traps:

(1) formates adsorbed on Cu

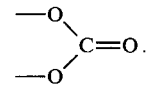


10 **11**

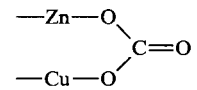
(2) formates adsorbed on Zn and Al atoms (with the participation of OH groups)

12

(3) formates produced after the partial reduction of the surface by carbon monoxide (evidently, near the boundary between Cu and ZnO)



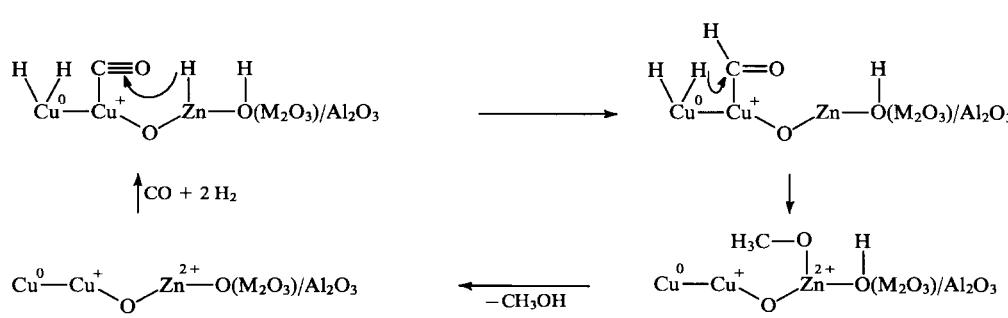
13



Many workers have detected a proportionality between the rate of the reaction of CO with H_2 (or of CO_2 with H_2), or of the amount of formate produced, and the copper content of the catalyst (or the surface area of the copper phase).[35,39,40,42] They concluded that the reaction takes place on the copper. There are also suggestions that $HCOO^-$ is formed near the Cu–ZnO boundary.[41,47] The hydrogenation of $HCOO^-$ to CH_3O (and even to CH_3OH) is treated as rate-limiting in the synthesis of CH_3OH from CO and H_2 (see Neophytides et al.[39]) or from CO_2 and H_2 (see Amenomiya and Tagawa[40]).

However, according to other workers[38,46,47] the formate is not an intermediate but a side-product of the methanol synthesis and decomposition processes. In a study of the synthesis of CH_3OH from CO and H_2 or from CO_2 and H_2 the IR spectra were obtained under high-pressure conditions.[38,48] At 200–220 °C both carbonate and formate complexes were detected on both Cu and ZnO. It was found that the formate complexes **10–13** are stable under the reaction conditions, and that upon further heating they decompose with evolution of CO (and not CO_2, as had been previously thought). Thus adsorbed CO is not a source of CH_3OH. On the other hand carbonate complexes are formed immediately after the adsorption of CO_2 and are converted into methanol during the subsequent hydrogenation. Thus it was concluded, in keeping with Rozovskii's views,[32] that the CH_3OH is formed from CO_2 and not from CO.

The role of carbonates in the synthesis of methanol was studied on the basis of IR spectroscopic measurements.[37,41,44] On ZnO the weakly bound bicarbonate HCO_3^- and the strongly bound carbonate CO_3^{2-} are formed, but on Cu we find the bidentate carbonate



On mixed Cu–ZnO catalysts an absorption band at 1615 cm^{-1} was also found, and assigned to the carbonate

located at the phase separation boundary (known to be an active complex in the synthesis of methanol).[41] The hydrogenation of this carbonate produces formate. The formation of CO_3^{2-} during the adsorption of CO_2 is associated with the $Cu^0 \rightleftarrows Cu^+$ transition. It was also found that the formation of carbonates is approximately eight times greater in the adsorption of a mixture of $CO_2 + 2H_2$ than in the adsorption of CO_2 only,[37] i.e. that the hydrogen not only assists the adsorption of CO_2 (associative mechanism) but it also regenerates the centre needed for the subsequent adsorption of CO_2.

The adsorption of H_2 on ZnO at low temperatures results in the formation of Zn–H and O–H bonds, but at higher temperatures these bonds are not formed.[46] On this mixed catalyst we observe the migration (spill-over) of the hydrogen from the Cu to the ZnO and backwards, and this hydrogen contributes to the hydrogenation of the carbonate groups.[42]

Scheme 1

The nature of the synergism observed in the synthesis of methanol on a $Cu-ZnO-M_2O_3$ catalyst (M = Sc, Cr, V) has been studied by in situ Raman spectroscopy.[45] The Cu–H, Cu–O–H, Cu–CO, and Cu–CHO groups were detected on the catalyst surface. The mechanism of this reaction is shown in Scheme 1.

According to the Raman spectra additions of N_2O promote the adsorption of CO.

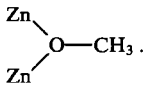
The simultaneous use of in situ IR spectroscopy and kinetic response methods showed that the formation of methanol from $CO + H_2$ and $CO_2 + H_2$ mixtures takes place by different mechanisms.[36] In the first of these mixtures surface formyl is produced from M–CO and M–H, and this step is rate-limiting, as shown by the appearance in the IR spectrum of an absorption band due to HCO immediately after the passage of a pulse through the $H_2 + CO$ mixture. In the $CO_2 + H_2$ mixture carbonates and formates are formed:

$$CO_2 + M \rightleftharpoons M{-}CO_2,$$

$$H_2 + M \longrightarrow M{-}H,$$

$$M{-}CO_2 + M{-}H \longrightarrow M{-}O{-}\overset{\overset{O}{\|}}{C}{-}H + M,$$

$$M{-}O{-}\overset{\overset{O}{\|}}{C}{-}H + 2\,M{-}H \longrightarrow M{-}O{-}CH_2{-}OH + 2\,M,$$



$$M{-}O{-}CH_2{-}OH + M{-}H \longrightarrow CH_3OH + M{-}OH + M,$$

$$M{-}OH + M{-}CO \longrightarrow M{-}O{-}\overset{\overset{O}{\|}}{C}{-}H + M.$$

In this case the rate-limiting step is (apparently) the dissociative adsorption of H_2 on ZnO and Cu and the migration of the hydrogen from the ZnO to the Cu. However, this dissociation is faster than the synthesis of CH_3OH from CO and H_2. Furthermore the CO_2 inhibits the disproportionation of CO into CO_2 and C, thus preventing the poisoning of the catalyst.

It has been shown[29] that the decomposition of the surface formates, which is very slow in the absence of a gas phase, is greatly accelerated by the presence of CH_3OH in the gas phase, i. e. the decomposition takes place by an associative mechanism.

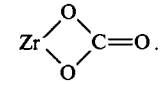
The mechanism of the decomposition of CH_3OH on a $Cu-ZnO/Al_2O_3$ catalyst has been studied also by in situ ^{13}C and ^1H NMR methods.[50] The methanol is adsorbed on Al_2O_3 as $Al-OCH_3$, and on ZnO as

When heated on copper the OCH_3 group is oxidised to the symmetrical formate and beyond (to HCO_3^- and CO_3^{2-}), and CO_2 is evolved when the system is further heated to 250 °C. Under the conditions of the synthesis of CH_3OH many intermediate substances are adsorbed on ZnO and Al_2O_3, but in order to contribute to the synthesis these must migrate towards the copper. Experiments on the adsorption of CH_2O also show that this species can participate in the reaction, for example by disproportionation into CH_3O^- and $HCOO^-$, though in the synthesis process CH_2O is not adsorbed on the surface. Carbon dioxide is easily adsorbed on $Cu-ZnO/Al_2O_3$, giving a carbonate, whereas CO is adsorbed to a much smaller extent. The carbon monoxide also is converted into a carbonate during the oxidation. This indicates the participation of CO_2 (rather than CO) in the synthesis of methanol.

An NMR study[51] of the decomposition of CH_3OH on $Cu-ZnO/Al_2O_3$ detected methoxy among the adsorbed compounds.

Fu and Somorjai[52] studied the interaction of CH_3OH with Cu–ZnO by a combination of XPES, LEED, and temperature-programmed reaction (TPR) methods. The methanol reduces the ZnO and removes the adsorbed oxygen from the copper centres. The formate produced on clean copper decomposes into CH_2O and H_2. On Cu–ZnO also we observe the decomposition of $HCOO^-$ into $CO_2 + CO + H_2O$ at 380 °C and the decomposition of CH_3O^- into CH_2O and H_2 at 280 °C. The decomposition of $HCOO^-$ on ZnO produces a mixture of $CO + CO_2 + H_2O + CH_4$.

The formation of compounds on the individual components of the catalyst was studied in parallel with the mechanism of the synthesis of CH_3OH on $Cu-ZnO/Al_2O_3$. It was found that copper can catalyse all the stages. Nevertheless under the conditions of the synthesis of CH_3OH many compounds formed as intermediates are found on the support phases (ZnO and Al_2O_3): we should therefore stress the important role of synergism and spill-over effects in this process.



Spectroscopic methods have been used also in the study of other catalysts. For example, in situ IR spectroscopy was used to study the synthesis of CH_3OH on a K–Cr–Zn–O catalyst.[53] After the reaction CH_3O^- and $HCOO^-$ fragments were detected on the surface. In the presence of potassium we note a large increase in the $HCOO^-:CH_3O^-$ ratio. Methyl formate ($HCOOCH_3$) is formed at low temperatures on catalysts containing potassium, evidently as a result of the interaction of the unstable $HCOO^-$ with methane. The methyl formate can then take part in the synthesis of higher alcohols.

$HCOO^-$ and CH_3O^- groups were detected[17] during the decomposition of CH_3OH on Cr_2O_3. The adsorbed formate groups are stable in a vacuum, but in the presence of $^{13}CH_3OH$ vapour the ^{13}C isotope is easily incorporated into the $HCOO^-$ surface groups and hence into the reaction products. At the same time, according to IR spectroscopic data, the concentration of formate stays constant. This shows that the decomposition of CH_3OH takes place by an associative mechanism through 'desorption at the expense of adsorption', (in Tamaru's terminology[17]).

The synthesis of CH_3OH from CO and H_2 on ZrO_2 has been studied by IR spectroscopy and temperature-programmed desorption (TPD) methods.[54,55] It is accelerated by the presence of water, but ^{18}O atoms from $H_2{}^{18}O$ water do not penetrate into the CH_3OH. The following sequence of reactions is suggested:

$$CO(ads) \xrightarrow{OH^-} HCOO^- \xrightarrow{2\,H^+} OCH_3^- \xrightarrow[-OH^-]{H_2O} CH_3OH.$$

Thus, water is needed for the desorption of the methanol. A similar sequence of reactions was proposed by Onishi et al.[56] on the basis of an IR spectroscopic investigation, but these workers stipulated the formation of a bidentate carbonate group as the first stage after the adsorption of CO:

Formate is produced (with the participation of an oxygen atom from the oxide) in the interaction of H_2 with CO on MgO, CaO, La_2O_3, ThO_2, and ZrO_2 at 200–300 °C.[57] Comparing the IR with the TPD spectra showed that the formation of $HCOO^-$ is preceded by the formation (as an intermediate) of the formyl group HCO^-. The main product of the reaction was CH_3OH on La_2O_3 and ZrO_2, and CH_2O on MgO.

On Pd or Rh catalysts supported on SiO_2, Al_2O_3, or ZrO_2 (promoted with LiCl, NaCl, or KCl) formate was observed[58,59] by IR spectroscopy after the admission of a mixture of $CO + H_2$ at 180 °C. It was found that the higher the concentration of

adsorbed $HCOO^-$, the greater is the rate of the synthesis of CH_3OH. No absorption bands could be seen in the IR spectra of nonpromoted samples. The rate of formation of C_2H_5OH on $Rh-Na-Al_2O_3$ was approximately proportional to the intensity of the CH_3COO^- bands. These results led to the suggestion that the active centres contain oxidised compounds which stabilise the acetates and formates.[58]

Studies of the mechanism of the formation reaction of CH_3OH and C_2H_5OH at 240–280 °C on platinum catalysts prepared from $Pt_9(CO)_{18}.2NEt_4$ clusters supported on MgO, ZrO_2, and Al_2O_3 revealed the CO_2^{2-}, CO_3^{2-}, and CH_3O^- fragments stabilised on the carrier.[60] They are apparently formed by the interaction of Pt–CO with the OH groups (or the O^{2-} groups) of the carrier. Their hydrogenation produces the alcohols.

The decomposition of CH_3OH into CO and H_2 on Fe, Ni, or Pd foil was studied by molecular beam relaxation spectrometry.[61] The process was divided into several stages, and the kinetic parameters of each stage were determined:

$$CH_3OH \xrightarrow{(1)} CH_3OH(ads) \xrightarrow{(2)} CH_3O(ads) \xrightarrow{(3)}$$

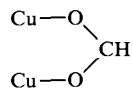
$$\longrightarrow CH_2O(ads) \xrightarrow{(4)} \ldots \longrightarrow CO(ads) + 2\,H(ads),$$

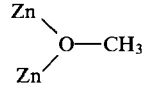
$$CO \rightleftharpoons CO(ads),$$

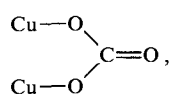
$$H_2 \rightleftharpoons 2\,H(ads).$$

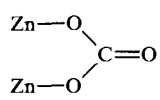
The reality of some of these stages was confirmed by the XPES method. On Ni the slow step was the third, with an activation energy of 104 kJ mol^{-1}. On Pd the desorption of CH_3OH could not be observed because its conversion into the subsequent products is very fast. In this case the desorption of CO becomes the rate-limiting step. On Fe the adsorbed CH_3OH can be converted into CO and H_2 through intermediate products, but it can also pass into another, unreactive form (CH_3OH^{II}):

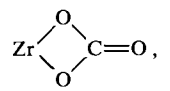
$$CH_3OH^{I}(ads) \begin{cases} \longrightarrow CH_3OH^{III}(ads) \longrightarrow \ldots \longrightarrow CO + H_2, \\ \longrightarrow CH_3OH^{II}(ads). \end{cases}$$











The activity of the Fe is determined by the relative probability of the reaction taking place by these two pathways. In terms of their activation energy (E_a) these metals can be arranged in the series Ni ≫ Pd > Fe, i.e. the highest E_a values are observed when the intermediates appear in the later stages of the reaction.

According to XPES and TPR data the decomposition of alkoxy groups on Fe(100) can follow one of three paths: (1) with formation of CO + H_2; (2) with formation of CH_3OH; (3) with full breaking of the C–H and C–O bonds. The last of these paths has been reported also by Benziger and Madix.[62]

Data on the intermediate compounds taking part in the synthesis and decomposition of CH_3OH are summarised in Table 2.

To conclude this section we note that, in spite of the large number of publications in which spectroscopic methods are used to study the synthesis and decomposition of CH_3OH, information on spectro-kinetic studies of these systems is almost totally absent (with a few exceptions[36,38,48,61]). The detection of the $HCOO^-$, CO_3^{2-}, CH_3O, and HCO groups on the catalyst surface is often interpreted as a proof that these species take part in the reaction as intermediates. However, direct kinetic confirmations of this conclusion are seldom put forward. Most probably the $HCOO^-$ groups contribute not to the synthesis or the decomposition of CH_3OH but to the corresponding conversion of water gas. A contribution from intermediate carbonates to the synthesis of CH_3OH is a more realistic suggestion. Furthermore, $M-CO_3$ complexes are formed simultaneously on the various phases of a complex catalyst, and it is essential to establish which of these contribute to the main reaction and which are a blind end-product or a reservoir for the former. Obviously, the spill-over phenomenon plays a very important role in the reaction mechanism. In many cases it has been established that the reaction follows an associative mechanism.

VI. Synthesis of hydrocarbons from carbon monoxide and hydrogen

The hydrogenation of CO to hydrocarbons (or Fischer–Tropsch synthesis) takes place on metals. Iron catalysts are most widely used for this reaction. However, they were studied mainly from the standpoint of their structural phase transformations under the reaction conditions. Less attention has been devoted to the forms adsorbed on the surface.

The state of the carbon on the iron surface was studied by XPES,[63–65] Raman,[66,67] and IR spectroscopy methods,[68] and also by the kinetic and the isotopic response method.[63,69–71] Three main forms of carbon were detected: graphite (which is universally known to be inactive in the Fischer–Tropsch synthesis), carbide carbon (which contributes to the synthesis of methane and of higher paraffins), and partially hydrogenated carbon CH_x (which can be hydrogenated further to give CH_4 and C_nH_m). There are also reports[64,69] of the formation of an amorphous, relatively porous form of carbon which can also be hydrogenated by hydrogen. According to Tan and Bennet[71] the real intermediate in the Fischer–Tropsch synthesis is the CH species. By using the method of 'interception' (with pyridine) of intermediate substances it was shown that alkyls can act as intermediate species of this type. Surface formates, carbonates, and carboxylates have also been detected: these are probably formed from the CO_2 produced by the disproportionation of CO.[72]

There are two contrary mechanisms for the hydrogenation of carbon monoxide by hydrogen: a dissociative and an associative mechanism.[73,74] According to the former the CO produces carbidisation of the metal (or other forms of carbon attributed to the dissociation of CO):

$$2\,Fe + CO + H_2 \longrightarrow Fe_2C + H_2O,$$

and

$$2\,Fe + 2\,CO \longrightarrow Fe_2C + CO_2,$$

and the carbide then interacts with hydrogen to give hydrocarbons

$$Fe_2C + 2\,H_2 \longrightarrow 2\,Fe + CH_4.$$

According to the associative mechanism the CO and H_2 from the gas phase react with atoms of the metal, forming complexes: for example[75]

$$H(ads) + CO(ads) \rightleftharpoons HCO(ads) \longrightarrow H_2CO(ads) \longrightarrow CH_3O(ads) \longrightarrow CH_3(ads) + O(ads).$$

The CH_3 group can be hydrogenated to methane or it can add on a CH_2 group, forming C_2 (and higher) hydrocarbons.

According to results from our laboratory[74] on iron catalysts this reaction involves oxides and carbides. The following mechanism can be proposed for the reaction at the metal–oxide boundary:

$$MO + CO = M\square_O + CO_2,$$

$$M\square_O + CO = C + MO,$$

$$2\,M + H_2 \longrightarrow 2\,M{-}H,$$

$$4\,M{-}H + C \longrightarrow 4\,M + CH_4.$$

$\square_O$ — oxygen vacancy on the catalyst surface

Here the hydrogenation of the carbon monoxide takes place mainly by a dissociative mechanism:

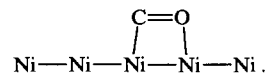
$$2\,CO + 2\,H_2 = CH_4 + CO_2.$$

An alternative reaction path for the hydrogenation of CO,

$$2\,CO + 3\,H_2 = CH_4 + H_2O,$$

is probably realised by an associative mechanism, involving the formation of HCO complexes in the presence of an excess of H_2 and a deficit of CO:

$$M'CO + M{-}H = M'COH + M,$$



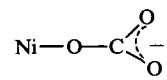
$$M'COH + 2\,M{-}H \longrightarrow M'OCH_3 + 2\,M,$$

$$M'OCH_3 + M \longrightarrow MO + M'CH_3 \xrightarrow{H_2} CH_4 + H_2O + M' + M.$$

It may be assumed that the activation of H_2 and CO takes place on different active centres: M and M'.

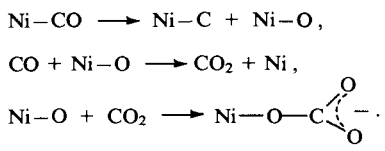
Nickel (unlike iron) is mainly a catalyst for the formation of methane from CO and H_2. Different forms of carbon (carbide, and hydrogenated) have been detected on a Ni surface by IR spectroscopy,[76–86] XPES,[87] and Auger spectroscopy.[88]

Bands corresponding to linear and to bridging CO groups were observed in the IR emission spectra for the interaction of CO and H_2 on 10% Ni/Al_2O_3; HCO groups were not detected.[82] It has been suggested[79] that the shift of the CO band in the IR spectra measured on Ni/SiO_2 and Ni/Al_2O_3 can be attributed to the formation of an associative HCHO complex. The preadsorption of H_2 on Ni(111) produces a shift in the bands of the adsorbed linear carbonyls (Ni–C≡O) towards the positions corresponding to the bridging C=O groups.[83] Evidently this can be explained by the formation of a surface carbonyl hydride in which the energy of the C–O bond is low and the dissociation of the carbonyl into carbide and oxide is facilitated. A possible precursor of the dissociated forms could be the 'recumbent' carbonyl



The 2050 cm^{-1} band in the IR spectrum of CO adsorbed on Ni/SiO_2 has been assigned to this form.[86]

Active carbon exists on the Ni surface in the relatively narrow temperature range between 200 and 450 °C. Above 450 °C it is rapidly converted into the inactive graphite, and below 200 °C there is no dissociation of the CO.[76,77] The following sequence of conversions of the carbon during its hydrogenation on a Ni plate has been established by in situ XPES[87] and 'absorbance-reflectance' IRS[81] methods:



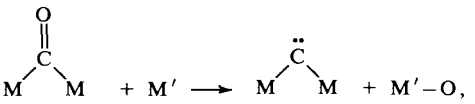
$$C \rightleftharpoons CH \longrightarrow CH_2 \rightleftharpoons CH_3 \rightleftharpoons CH_4.$$

Under reaction conditions the Ni surface is mostly covered with CH groups (Ni–CH), and their hydrogenation is probably rate-limiting.[81,87] At low temperatures we also find Ni–CH_2–Ni bridging groups, but these are lost from the surface even before the methanation temperature is reached. It is assumed[82] that under different conditions the rate-limiting step can be either the rate of formation of the CH_x species or the rate of their hydrogenation.

It has been reported[88] that the rate of methanation on Ni(100) increases with the concentration of carbon on the surface, whereas the yield of higher hydrocarbons increases with the oxygen concentration. The oxidised forms $HCOO^-$ and CH_3O^- are also found[76,77] on a Ni surface treated with a mixture of H_2 and CO, but they are hydrogenated less actively than the surface carbon. The appearance of carbonate

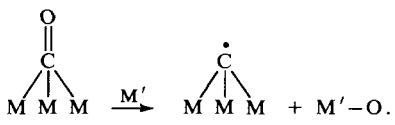
is apparently associated with the CO disproportionation reaction:[81]

The hydrogenation of CO to hydrocarbons on a cobalt film also includes the dissociation of CO, and probably takes place through carbide formation.[89]



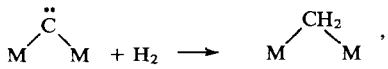
Cobalt favours the dissociative adsorption of CO more markedly than nickel.[90] This accounts for the preferential formation of methane on Ni and of methane with higher hydrocarbons on Co. However, if the Co is supported on metallic gold the rate of the hydrogenation reaction increases, the character of the CO adsorption changes, and the process takes place through the formation of HCHO complexes (or other 'associative' complexes) without dissociation of the CO.

Carbonyl groups, as well as hydrocarbons, formates, and carbonates, have been detected[91] by IR spectroscopy on Co/SiO_2 and Co/Al_2O_3 under conditions compatible with the hydrogenation of CO at 200–250 °C. The time-changes in the intensity of the bands show that these are reaction products accumulating on the surface.

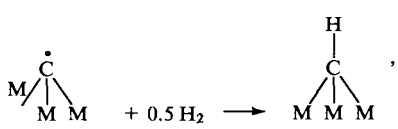


According to Loran et al.[92] the hydrogenation of CO on Ni, Ru, and Fe goes mainly via the breaking of the C–O bond in carbon monoxide, whereas on Rh and Mo it goes mainly via the breaking of the same bond in the HCHO complex.

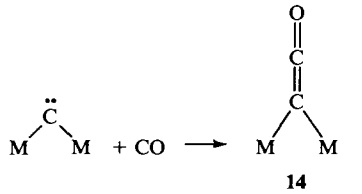
The behaviour of bimetallic catalysts (for example, Ni–Fe and Co–Fe) towards the same reaction has also been studied.[74] The activity of the latter catalyst is attributed to the presence of cobalt, and the selectivity of the formation of olefins to the presence of iron. Obviously, the more active component contributes to the activation of H_2, and the less active to the activation of CO. It has been assumed, on the basis of IR spectroscopic data,[93] that the CO is more easily activated at the boundary between the oxidised and the reduced phase.



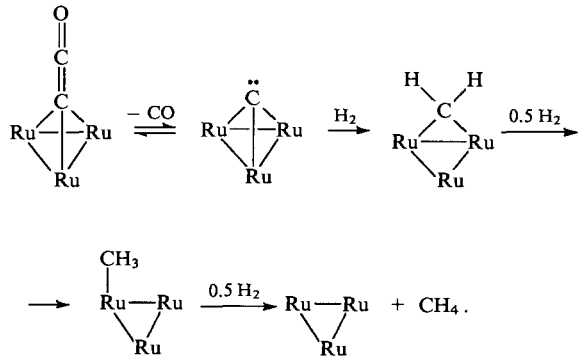
Also according to IR spectroscopic data[94] the most stable form of CO on Fe or Co is the bridging CO ($\nu_{CO} = 1800-1900$ cm^{-1}), retained until the reaction temperature is reached. Its dissociation is accompanied by the formation of carbide and oxide:



or



The surface carbides can then undergo hydrogenation or carbonylation.



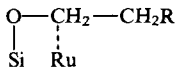
or

14

The transformations of the keten complex of ruthenium **14** supported on SiO_2 have been studied under the conditions of hydrogenation of CO at 200–300 °C:[91]

The reaction takes place by a dissociative mechanism: the associative mechanism, including (for example) the hydrogenation of the keten, is not observed.

We note that the dissociation of the C=C bond in the keten $CH_2=C=O$ added to a mixture of CO + H_2 in the hydrogenation of CO to hydrocarbons was observed by isotopic labelling more than 30 years ago.[95] The radioactivity of the hydrocarbons was found to be proportional to their carbon content. It was concluded from these results that the CH_2 species contribute to the chain initiation.



The transformation of the dissociative form of adsorption of CO into the molecular form during the carbidisation of the V(110) surface[96] is also of interest. As shown by an analysis of the EELS spectra, the C–C bond is produced during the adsorption of CO on VC, and this could be the initial stage in the subsequent synthesis of hydrocarbons.

On the platinum group metals (Ru, Rh, Pd) compounds containing oxygen are formed in addition to hydrocarbons. This is attributed to the high dissociation energy of CO on these metals.[97] On the platinum group metals (unlike iron) the energy of formation of the M–C and M–O bonds is of the same order of magnitude as the dissociation energy of CO. Many workers have studied the mechanism of the Fischer–Tropsch reaction by using a combination of physical methods. Ruthenium[97–119] and rhodium catalysts[102,120–134] were investigated most extensively.

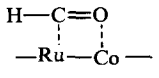
According to IR spectroscopic measurements linear and bridging forms of CO and of the dicarbonyl $Ru(CO)_2$ are formed[97,102,104,105,108,116] on Ru/Al_2O_3. Under the catalysis conditions the linear CO groups are hydrogenated almost exclusively: the dicarbonyl groups do not contribute to the hydrogenation. Disproportionation of the CO by Boudart's reaction has also been observed.[109,123] The hydrogenation of CO takes place (apparently) through the intermediate dissociation of the linear form Ru–CO.[97,109] In the absence of H_2 the activation energy of the dissociation of CO is much higher than in its presence. The promoting action of H_2 is explained by the formation of H_2O, O(ads), and H(ads), which suppress the recombination of C and O and shift the equilibrium towards the dissociation of CO.[115] An alternative explanation of the decrease in the activation energy of the dissociation of CO in the presence of H_2 is the formation of the HCO complex.[99,117]

By using IR [97,111,114] and NMR [97,108,109] spectroscopy in conjunction with kinetic and isotopic response methods it was found that carbon is adsorbed on the surface of ruthenium in two forms: C_α and C_β. The first of these consists of adsorbed carbon atoms which are rapidly hydrogenated to CH_4 (few of these are found on a surface in a stationary state). The rate of formation of methane is directly proportional to the concentration of the C_α surface form. The C_β form consists of CH groups which accumulate on the surface and do not contribute significantly to the yield of CH_4. They are hydrogenated much more slowly than C_α CO groups are also found on the ruthenium surface, but practically no H(ads), since this is rapidly removed [98] as H_2O.

Further studies by NMR of the adsorption forms of carbon revealed the presence of four distinct forms on Ru: C_α (carbon atoms), and $C_{\beta1}$, $C_{\beta2}$, $C_{\beta3}$ (different alkyl groups). [99,101,108] The $C_{\beta1}$ form is a possible intermediate in the formation of the C_2 product. The $C_{\beta2}$ form apparently acts as a source for the formation of long hydrocarbon chains, most of which remain on the surface, and $C_{\beta3}$ is a source of branched products. The intensity of the CH_2 bands observed in the in situ IR spectra is not correlated with the rate of the reaction: evidently, these bands are due to the accumulation of reaction products on the surface. [106,107] Under the synthesis conditions (at high pressures) the hydrocarbons accumulated on the Ru surface are also bound to the support: [112]

The oxygen compounds HCO and $HCOO^-$ are also formed on the surface of supported ruthenium catalysts. [114,117] On Ru(001) promoted by potassium we find carbonate and formate:

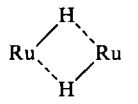
$$CO \longrightarrow CO_2 + C,$$



$$CO_2 + K_2O \longrightarrow K_2CO_3 \xrightarrow{H_2} KHCOO.$$

The conversion of water gas under the influence of alkaline additives also takes place through formate as an intermediate:

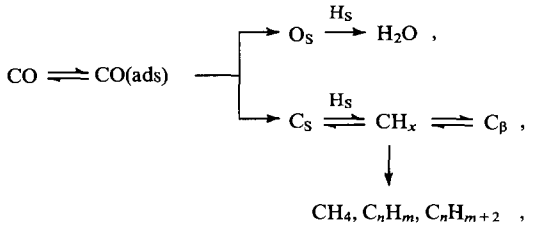
$$CO + H_2O \longrightarrow HCOO^- + H^+ \longrightarrow CO_2 + H_2.$$



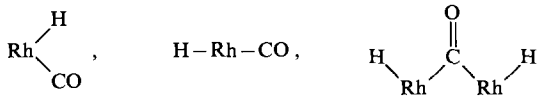
The formate is then hydrogenated to CH_4 and CH_3OH. In the absence of potassium only methane is formed.

According to calculations [94] the activation energy for the hydrogenation of HCO is smaller than for the dissociation of HCO. Therefore HCO can be hydrogenated to H_2CO(ads), CH_3O(ads), and beyond (to alcohols and hydrocarbons). As reported, the intensity of the 1584 cm^{-1} HCO band is correlated with the rate of the synthesis of oxygenated compounds. [117,134] On $Ru-Co/SiO_2$ catalysts this absorption band corresponds to the complex

The conversion of HCO into $CH_3C{=}O$ and $C_mH_nC{=}O$ groups bound to Ru and Co has been studied spectroscopically.



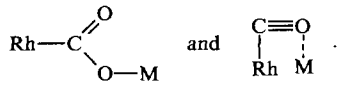
The role of carbides in the hydrogenation of CO has been studied by IR and EXAFS spectroscopic methods in the case of $[Ru_6C(CO)_{16}(CH_3)]^-$ complexes supported on MgO, ZnO, La_2O_3, TiO_2, ZrO_2, and Al_2O_3. [118,119] Whereas the carbide complex of Ru takes part in the synthesis of oxygenates, hydrocarbons and CH_4 are formed on the ordinary (carbonyl) Ru complex. It has been shown [118,119] that the central carbide atom in the cluster determines the structure of the intermediate complex, enabling it to add reversibly 8 – 11 molecules of CO onto each cluster. Under these conditions the cluster continuously expands or shrinks. The presence of a large number of adsorbed CO molecules in the bridging form (Ru_2CO) suppresses the dissociation of CO and favours the synthesis of the oxygenated compounds CH_3OH, CH_3OCH_3, and CH_2O. The expanded Ru_6C structures are more active than the compressed structures because they favour the dissociative adsorption of H_2:



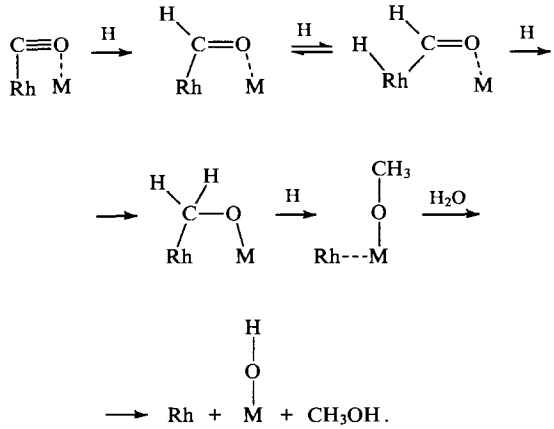
The H/D isotope exchange on the Ru_6C/MO carbide cluster is 3000 times faster than the stationary synthesis of oxygen compounds.

The low activity of rhodium towards the dissociation of CO accounts for its high activity towards the synthesis of the higher hydrocarbons (the Fischer – Tropsch reaction) and of oxygenated compounds. The Rh^0 form plays an important role in the synthesis of hydrocarbons, and Rh^+ in the synthesis of alcohols. [132] Obviously, the Rh^0-Rh^+ pairs in catalysts such as Rh/ZnO and Rh/TiO_2 can assist both the dissociation of carbon monoxide and the introduction of CO into the growing chain. [132,133]

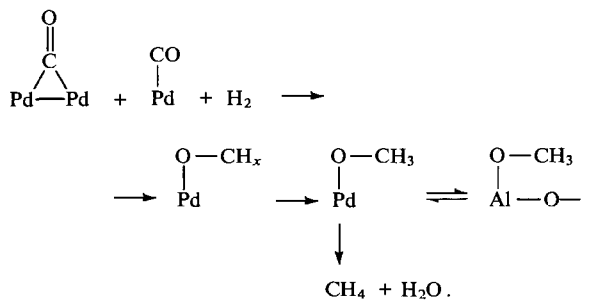
The analysis of the IR [102,121,127] and NMR spectra [124] of the products adsorbed on supported Rh catalysts also indicates the formation of different carbonyl groups, and also of the C_α and C_β forms of carbon. The following reaction scheme was proposed: [206]



(the subscript S denoting surface atoms) according to which the form C_β does not take part in the hydrogenation of CO. The presence of H_2 assists the adsorption of CO on Rh as a result of the formation of complexes of the CH_2O type. In the methanation of CO on Rh/Al_2O_3 the formation of carbonyl hydrides has been reported: [123]



15



The formation of the complex **15** and the synthesis of hydrocarbons take place below the temperature of the Boudart reaction, i. e. the dissociation of CO is not observed under these conditions. The oxygenated groups OCH_3, OC_2H_5, HCOO, HCO, CH_3CO, CH_3COO, and CO_3 were detected on the rhodium surface by IR [127–130] and NMR spectroscopy. [124] The formate is produced mainly on the support: under the catalysis conditions it is fairly stable and it cannot act as an intermediate, whereas $HCOO^-$ adsorbed on metallic rhodium can play this role. [120,127] The same is true of the carbonates and acetates, which are also adsorbed mainly on the support. [128] Evidently, the active centres for the formation of oxygen compounds are on the boundary between Rh and the support. [122] Two adsorption complexes of CO, formed at the metal – support interface, have been observed [130] on Rh and Mo catalysts supported on ZrO_2:

Their dissociation is facilitated in the presence of hydrogen by the formation of the intermediate complex Rh–CHO, which is then (apparently) converted into $Rh{=}CH_2$ and methane. Methanol is obtained by the series of reactions

The properties of palladium are similar to those of Ru and Rh.[102,135–140] A scheme for the methanation of CO on Pd, involving the fully dissociated forms C(ads), H(ads), and O(ads), has been proposed.[131] The maximum coverage of the Pd/TiO_2 surface by linear carbonyls is 1%, and the maximum coverage by bridging carbonyls is 0.1%. Carbonyl groups and CH_3O, HCOO, and HCO groups, stabilised mainly on the carrier, have been observed[137] in the hydrogenation of CO on Pd/Al_2O_3. Spill-over of these species between the palladium and the Al_2O_3 was also noted. According to these workers[137] the source of the formation of CH_4 are the $CH_3–O–Pd$ groups:

According to Hindermann et al.[138] the key intermediate in the hydrogenation of CO on $Pd–MgO–SiO_2$ is the formyl group HCO. This was confirmed by the chemical interception method with dimethyl sulfate. The presence of surface formate was also noted. Its hydrogenation has been stated[140] to be the rate-limiting step.

No correlation between the catalytic activity and the concentration of CO groups on the surface was observed[141] in a study of the hydrogenation of CO on Pt/TiO_2 by IR spectroscopy. It was concluded that only a very small part of the surface CO contributes to the hydrogenation. The active centres are, apparently, the steps or kinks on the platinum crystallites, which do not appear in the spectra.

The formation of CH_3O, which is rapidly hydrogenated to methane, was observed[142] during the hydrogenation of CO on Pt/Al_2O_3. Most of the CH_3O is adsorbed on the carrier, and the H(ads) species can move from the Pt to the Al_2O_3 (and hydrogenate the CH_3O) by the spill-over effect.

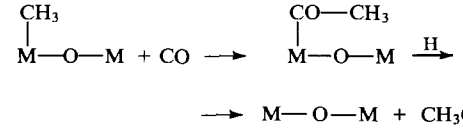
According to in situ IR spectroscopic data[76] on supported iridium the reaction proceeds by the scheme

$$CO \rightleftharpoons CO(ads),$$

$$H_2 \rightleftharpoons 2\,H(ads),$$

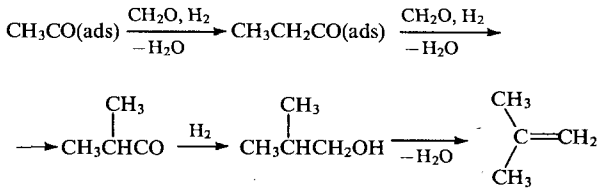
$$CO(ads) + H(ads) \longrightarrow C(ads) + OH(ads),$$

$$2\,CO(ads) \longrightarrow C(ads) + CO_2(ads),$$



$$C(ads) + H(ads) \longrightarrow CH(ads) + CH_4,$$

$$OH(ads) + H(ads) \longrightarrow H_2O.$$



The contribution of the disproportionation of CO to the overall transformation is not substantial (only 0.8% of CO_2 is detected for a 60% conversion of the CO). The rate of hydrogenation of the adsorbed carbon is much higher than that of CO, but the adsorbed carbon is formed not by the direct dissociation of CO but by the interaction of CO with the adsorbed hydrogen (possibly through the HCO stage) by an associative mechanism.

A similar dissociative mechanism has been proposed for the hydrogenation of CO on $Ir_4(CO)_{12}$ clusters supported on α-Al_2O_3.[143] The formation of carbide, carbonyl, and oxide surface compounds has been observed by IR spectroscopy when the reaction was carried out at 250–300 °C. The rate-limiting step is the hydrogenation of the carbonyls. The formation of $Ir_xC(CO)_y$ carbide–carbonyl clusters under the reaction conditions has also been suggested, but these clusters have not been observed directly.

The hydrogenation of CO on ZrO_2 can lead to the selective synthesis of isobutene. HCOO and CH_3O groups were observed on the surface by using in situ NMR and IR spectroscopic methods.[144,145] The presence in the reaction of CH_3 and CH_2 species was also demonstrated by the kinetic interception method, using special acceptors. The introduction of the CO group into the $M–CH_3$ bond results in the formation of a new C–C bond:

The synthesis of isobutene can also take place by the aldol condensation mechanism[145]

The HCOO, CO_3, and CH_3O groups have been observed[146] by in situ IR spectroscopy at 200–400 °C on the catalyst surface during the hydrogenation of CO on Sm_2O_3. This led to the suggestion of a chain of transformations leading to the formation of methanol at temperatures below 300 °C and of hydrocarbons above that temperature.

Table 3 lists the data on the intermediate compounds which take part in the hydrogenation of CO to hydrocarbons (the Fischer–Tropsch synthesis and methanation).

In spite of the many reported studies of the CO hydrogenation mechanism by spectroscopic and kinetic methods very few truly spectroscopic investigations can be found. The best publications[97,98,104,108,109] show that the hydrogenation of CO on ruthenium catalysts takes place through the dissociative (C_α) forms of carbon. However, even these results were based on an

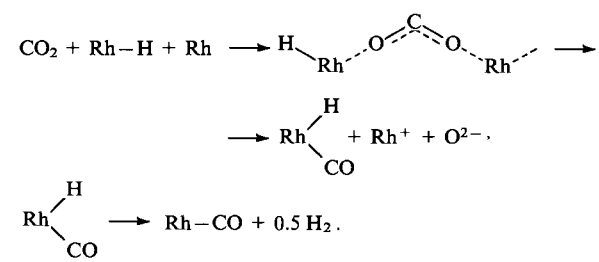
analysis of NMR spectra, which cannot always be obtained directly under the experimental conditions because of experimental difficulties. The existence of the intermediate compound HCO seems very likely, but a direct spectroscopic proof of this assumption is still not available. The HCOO, CH_3O, and other groups observed under catalysis conditions are usually stabilised on the carrier and not on the active phase of the catalyst.

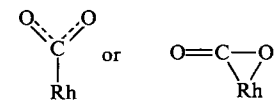
Most of the results point to a dissociative mechanism for the hydrogenation of CO, but associative mechanisms cannot be excluded.

VII. Hydrogenation of carbon dioxide



We have already discussed the hydrogenation of CO_2 as the reverse reaction of the conversion of water vapour (see Section IV), and also in connection with the synthesis of methanol on zinc–copper catalysts (see Section V). In this section we shall examine some data on the methanation of CO_2 on metallic catalysts.

The methanation of CO_2 on Rh/Al_2O_3 has been studied [147–151] by IR spectroscopy. An analysis of the IR diffuse reflectance spectra revealed HCOO groups on Rh/Al_2O_3 and HCOO and CH_3O groups on $Rh/Lu-Al_2O_3$.[147] In the first case the activation energy for the formation of CH_4 is 67 kJ mol^{-1}, and in the second case 96 kJ mol^{-1}. When CO_2 is added to the catalyst it is dissociated into CO and O(ads), and the further addition of H_2 produces formates. Stopping the addition of CO on Rh/Al_2O_3 lowers the intensity of the CO bands in the IR spectra to zero, whereas the intensity of the HCOO bands also falls but not to zero. On $Rh/Lu-Al_2O_3$ the concentration of CO groups decreases rapidly, but that of HCOO decreases slowly. From this evidence the authors conclude that the formates contribute to the conversion of water gas rather than to the synthesis of methane: the HCOO decomposes with formation of CO, which is then hydrogenated to CH_4.



The CO, HCOO, and HCO_3 surface groups have been observed [148–151] by IR spectroscopy and EELS in the reaction of $H_2 + CO_2$ on Rh/Al_2O_3. On the unsupported catalyst HCOO groups are not formed, and on the catalyst with a carrier they appear mainly as a result of the spill-over of hydrogen from the Rh onto the carrier. The dissociation of CO_2 on Rh is assisted by the presence of H_2 because in the bent structure

an electron can be transferred from the adsorbed H_2 through the Rh to the π orbital of CO_2:

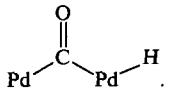
The formate group produced by the hydrogenation of Rh–CO is transferred (by spill-over) to the Al_2O_3, where it is stabilised. On the $K-Rh/SiO_2$ catalyst the band of the CO_2^- anion bound to potassium can be seen: this group is then hydrogenated to give $HCOO^-$.[151] In the absence of K or Rh no formate is produced. On massive Rh a weakly bound molecular form was observed by the EELS method during the adsorption of CO_2:

In the presence of potassium the following reactions take place:[152]

$$2\,CO_2^- \longrightarrow CO_3^{2-} + CO,$$

$$2\,CO_2^- \longrightarrow C_2O_4^{2-},$$

$$K^+ + CO_2^- \longrightarrow KO^- + CO(ads).$$



In the hydrogenation of CO_2 on $Rh-Mo/ZrO_2$ linear and bridging carbonyl forms are produced, as well as carbonate and formate, on the ZrO_2.[153]

CO(ads) and $HCOO^-$ have been detected on Ru/TiO_2 under the CO_2 hydrogenation conditions by IR diffuse reflectance spectroscopy.[154,155] The stationary concentration of CO(ads) is correlated with the rate of formation of CH_4. It was shown by the response method that the concentration of $HCOO^-$ is rapidly suppressed by the removal of H_2 from the gas mixture, but unfortunately these workers [154,155] did not provide a quantitative comparison of the concentrations of $HCOO^-$ and H_2. The formate

(or even HCOOH) produced can decompose into H_2O and CO (i. e. it can undergo a reaction which is the reverse of the conversion of water gas), or it can be hydrogenated to $CH_4 + H_2O$ in several stages. The hydrogenation of CO takes place only on a small number of Ru centres, and therefore the direct spectroscopic observation of the formation of CH_4 is experimentally difficult.

On $Ru-RuO_x/TiO_2$ the formation of various carbonyls has been observed by IR spectroscopy after the adsorption of CO_2, and after exposure to a $CO_2 + H_2$ mixture the complexes RuO_x-CO and $H-Ru-CO$ were observed.[156] Under these conditions the H or O atoms adsorbed on Ru facilitate the dissociation of the C–O bond. The much lower methanation temperature of CO_2 (as compared with CO) has been stressed: this effect is ascribed[154] to the high reactivity of the carbonyls at the instant of the dissociation of CO_2 (and also, possibly, to the formation of CO free radicals), which are subsequently converted into active carbon and methane. At high temperatures the hydrogenation mechanism of CO can include the formation of CO_2 by the Boudart reaction and its subsequent dissociation.

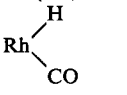
A study[149] of the hydrogenation of CO_2 on Pd supported on SiO_2, MgO, TiO_2, and Al_2O_3 showed that the interaction of CO_2 with Pd is facilitated in the presence of H_2 by the formation of the complex

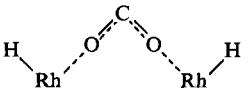
On an iron foil the only product of the hydrogenation of CO_2 is CH_4, i. e. the process has a high selectivity.[157] On the other hand in the presence of surface oxide some CO is formed by a process which is the reverse of the water gas conversion. The high selectivity is attributed to the rapid coverage of the surface by a layer of carbon: the reaction then proceeds on the active Fe and FeC_x centres.

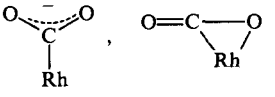
Magnetic studies have shown[158] that in the hydrogenation of CO_2 on Ni the carbide Ni_3C is produced by the scheme

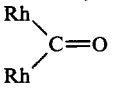
$$CO_2 + Ni \rightleftharpoons Ni_xCO(ads) + NiO(ads),$$

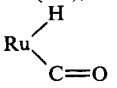
$$Ni_xCO(ads) \rightleftharpoons Ni_3C + NiO(ads).$$

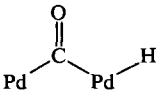












The carbide is then hydrogenated to CH_4. The methanation of CO_2 on Ni is faster than the methanation of CO.

The formates observed by IR spectroscopy during the hydrogenation of CO_2 on $La_{1-x}M_xCoO_3$ perovskites are probably intermediates in the equilibrium of the water gas conversion and of its reverse reaction. The hydrogenation of CO_2 to hydrocarbons takes place through the dissociated forms of CO_2 and H_2.[159]

Table 4 shows some data on the compounds proposed as intermediates in the hydrogenation of CO_2 to methane.

Some attempts to use spectrokinetic methods in studies of the hydrogenation mechanism of CO_2 have been reported,[154,155] but they gave ambiguous results (evidently because of the low

sensitivity of the method). The only conclusion from this work was that adsorbed carbonyl is a likely intermediate in the hydrogenation reaction, whereas formate is an intermediate in the reverse water-gas formation reaction, i. e. in the reduction of CO_2 to CO.

VIII. Carbonylation and hydroformylation

The mechanism of carbonylation on heterogeneous catalysts containing rhodium or iridium is similar to the homogeneous carbonylation mechanism. In the homogeneous carbonylation on carbonyl complexes of Rh, Ru, Ir, and Co, intermediate compounds including carbonyl hydrides were detected, and in some cases CH_3OH and CH_3 species were found in the form of ligands bound to a metal atom.[160] Zeolites, which can be treated as solid quasihomogeneous systems, are mostly used as heterogeneous catalysts.

In situ IR spectra were obtained under methanol carbonylation conditions on zeolites containing rhodium at 150–200 °C.[161] On RhNaX we observe the conversion of CO under the influence of water vapour:

$$Rh^{3+} + H_2O + 3\,CO \longrightarrow Rh^{+}(CO)_2 + CO_2 + 2\,H^{+}.$$

During the interaction of CO with CH_3OH bands corresponding to CH_3COOCH_3, $(CH_3)_2O$, H_2O, CH_3O^-, and perhaps also to adsorbed CH_3COOH can be observed.

The following reaction has been studied[162] on IrNaY and RhNaY in the presence of CH_3I:

$$2\,CH_3OH + CO \longrightarrow CH_3COOCH_3 + H_2O.$$

It was found that initially the active species $[I_2Rh(CO)_2]^-$ is formed on RhNaY. The rate-limiting step of the reaction is the oxidative addition of CH_3I

$$[I_2Rh(CO)_2]^- + CH_3I \longrightarrow [I_3Rh(CO)_2CH_3]^-,$$

followed by the fast rearrangement of $[I_3Rh(CO)_2CH_3]^-$ into the rhodium acetyl derivative $[I_3Rh(CO)(COCH_3)]^-$, accompanied by the evolution of methyl acetate (in methanolysis) or of acetic acid (in hydrolysis). The rate of the reaction on rhodium catalysts is described by the equation $v = kP^{1}_{CH_3OH}P^{0}_{CO}P^{0}_{CH_3I}$, whereas in homogeneous carbonylation the rate equation is $v = kP^{0}_{CO}P^{0}_{CH_3OH}P^{1}_{CH_3I}$. On the IrNaY catalyst the rate of the reaction is described by the equation

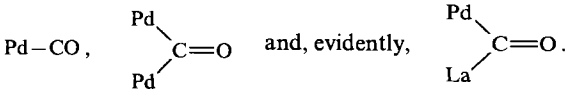
$$v = k\frac{P_{CH_3OH}}{1 + k'P_{CH_3OH}}.$$

The rate-limiting step of the reaction is the adsorption of CH_3OH. Subsequently, under the influence of CH_3OH, the methyl group in $I-Ir(CH_3)(COOCH_3)(CO)_2$ is converted into the alkoxycarbonyl group, forming methyl acetate. The mechanism of the reaction can be described by the scheme

$$Ir + 3\,CO \longrightarrow [Ir(CO)_3] \xrightarrow{CH_3I} [I-Ir(CH_3)(CO)_3].$$

The hydroformylation or oxo-synthesis, i. e. the reaction of olefins with CO and H_2 (by which aldehydes are produced), also takes place on homogeneous and on heterogeneous catalysts. A study of the hydroformylation of C_2H_4 on Rh/SiO_2 by in situ IR spectroscopy has shown the presence of various forms of adsorbed CO. The introduction into adsorbed ethylene of the linear form of adsorbed CO produces the acyl group C_2H_5CO. The addition of CO takes place more readily than the synthesis of hydrocarbons from CO and H_2.[163–165] A study of some special features of the reaction kinetics[165] showed that acyl is not the main intermediate in the reaction.

According to in situ IR spectroscopy results[166] the CO group in the $Rh_6(CO)_{16}/SiO_2$ complex bound to the terminal Rh atom (1805 cm^{-1}) is more difficult to introduce into the Rh–C bond than the dicarbonyl group and the lienar form of CO on Rh crystallites. The low activity of this group is attributed to the absence of the rhodium centres needed for the adsorption of C_nH_{n+1}, C_2H_4, and H_2 from the surrounding of the rhodium atom. In the stationary state the rhodium is in the oxidised form Rh^+, and the limiting step is the hydrogenation of C_2H_5CO into C_2H_5CHO.



Two carbonyl complexes of rhodium, $Rh_6(CO)_{16}$ and $Rh(CO)_2$, have been detected[167] under the conditions of hydrocarbonylation of C_2H_4 on RhY. When the first complex is dissociated it is converted into CH_3CH_2CHO by the loss of several CO molecules. The second complex becomes active after lengthy exposure to a $C_2H_4 + H_2$ mixture. A likely intermediate compound in the hydroformylation of ethylene is $HRh(CO)_x$.

According to Natio and Tanimoto[168] the hydroformylation of propene on Rh/SiO_2 and Pd/SiO_2 takes place by the scheme

$$H_2 + 2\,Z \overset{(1)}{\rightleftharpoons} 2\,HZ,$$
$$CO + Z \overset{(2)}{\rightleftharpoons} COZ,$$
$$C_3H_6 + Z \overset{(3)}{\rightleftharpoons} C_3H_6Z,$$
$$C_3H_6Z + HZ \overset{(4)}{\rightleftharpoons} C_3H_7Z + Z,$$
$$C_3H_7Z + COZ \overset{(5)}{\rightleftharpoons} C_3H_7COZ + Z,$$
$$C_3H_7COZ + HZ \xrightarrow{(6)} C_3H_7CHO + 2\,Z,$$
$$C_3H_7Z + HZ \xrightarrow{(7)} C_3H_8 + Z.$$

where Z is an active surface centre. The competition between the stages (*5*) and (*7*) determines the selectivity of the reaction. On palladium step (*5*) is limiting, and on rhodium step (*6*). The activation energy of the hydroformylation is 57 kJ mol^{-1} on Rh/SiO_2 and 69 kJ mol^{-1} on Pd/SiO_2, i. e. the activation energy of step (*6*) is lower than that of step (*5*).

Bridging and linear carbonyls are observed on the surface under the conditions of the hydroformylation of propene and hex-1-ene on Pd/SiO_2 and $Pd-La/SiO_2$ at 250 °C and 10 atm:

Carbon monoxide adsorbed on La and on Pd does not contribute to the addition reaction on the $Pd-C_3H_7$ bond.[169] Spill-over of hydrogen between the Pd and the SiO_2 has been observed by the programmed temperature desorption (PTD) method. The magnitude of the spill-over is well correlated with the yield of reaction products.[169]

The hydroformylation of C_2H_4 and C_3H_6 has also been studied on the $RhFe_2$, $PtFe_2$, and $PdFe/SiO_2$ clusters.[170] A possible reaction mechanism is

A summary of the data on the intermediate compounds taking part in the carbonylation and hydroformylation reactions is shown in Table 5.

Thus definite reaction sequences have been established from IR spectroscopic data for the carbonylation and hydroformylation reactions: their reliability is confirmed (essentially) by comparing the sequences with those of the analogous homogeneous reactions. Some stages of the process can take place by associative mechanisms involving hydrogen. It is stated that the intermediates in these reactions are adsorbed carbon monoxide and the alkyl and acyl groups. Spectro-kinetic studies have not been reported.

IX. Reduction of NO_x with CO

The interaction of NO_x with CO has been widely studied by spectroscopic methods because of the high sensitivity of the C–O and N–O absorption bands in the IR spectra. This reaction is of great practical importance in relation to the problem of removing CO and NO_x from the exhaust gases of automobile engines. The reaction can follow two paths: with formation of N_2 and CO_2 or with formation of N_2O and CO_2. The first mechanism is usually predominant on metals, the second on oxides.

The NO + CO reaction on platinum foil was studied by absorbance-reflectance IR spectroscopy.[171] It was established that below 150 °C the surface is covered with CO, and that the activation energy for desorption is 14.2 kJ mol^{-1}. Above 150 °C the activation energy is governed by the dissociation of NO and is equal to 36 kJ mol^{-1}. The reaction follows a dissociative mechanism:[171]

$$CO + Z \overset{(1)}{\rightleftharpoons} COZ, \qquad NO + Z \overset{(2)}{\rightleftharpoons} NOZ,$$
$$NOZ + Z \overset{(3)}{\longrightarrow} NZ + OZ,$$
$$COZ + NOZ \overset{(4)}{\longrightarrow} CO_2 + NZ + Z,$$
$$2\,NZ \overset{(5)}{\longrightarrow} N_2, \qquad COZ + OZ \overset{(6)}{\rightleftharpoons} CO_2 + 2\,Z.$$

The rate of removal of CO (calculated from IR spectra) is determined by the kinetics of step (*4*).

On Rh(100) the reaction of NO_x with CO with studied by LEED, Auger spectroscopy, and TPD.[172] A dissociative mechanism similar to that described by Skarf and Benziger[171] was proposed. A study of the interaction of CO with NO on a Rh(331) surface has also been reported.[173] The changes in the 520 cm^{-1} absorption band (assigned to adsorbed oxygen) show that the oxygen atoms formed by the dissociation of the NO molecules are immediately removed from the surface and interact with CO molecules. The oxygen atom formed by the dissociation of the NO molecule on the surface is less active towards the adsorbed CO molecule than the oxygen atoms produced by dissociatively adsorbed O_2.

The oxygen formed on the surface by the decomposition of NO_2 under the conditions of the reaction of NO_2 with CO has properties similar to those of the oxygen formed by the decomposition of O_2. Thus, NO and CO_2 are formed on platinum at temperatures below 430 °C under the conditions of this reaction.[174] The rate of formation of CO_2 is an order of magnitude higher than the rate of interaction of CO with NO, and is almost equal to the rate of the reaction of CO with O_2.

Most of the studies have been devoted to the reaction between NO and CO on metals of the platinum group supported on SiO_2, Al_2O_3, and other carriers.[175–194] The formation of isocyanate groups (NCO) on the surface was invariably observed. For example, in the interaction of a mixture of CO and NO on Pt, Rh, and Ir supported on TiO_2, MgO, Al_2O_3, and SiO_2 carriers the IR spectrum was found to include bands at frequencies between 2180 and 2318 cm^{-1}, assigned to the NCO vibrations on the surface of both the metal and the carrier.[175] The isocyanate groups are formed by the interaction of adsorbed nitrogen atoms and CO molecules:

$$Pt–N + Pt–CO \rightleftharpoons Pt–NCO.$$

It should be noted that cyanides adsorbed on platinum or palladium absorb in the same spectroscopic region (1980–2200 cm^{-1}).[181–183] Detailed spectroscopic studies using nitrogen, oxygen, and carbon isotopes have shown that two different forms of the complex can exist on the platinum metal surface: isocyanates Rh–NCO (2172 cm^{-1}) and cyanates Rh–OCN (2225 cm^{-1}). The migration of NCO from the metal to the carrier is very fast. Its driving force is the formation of a stronger bond with the Lewis-acid centres on the carrier.

Several forms of adsorbed CO, including bridging forms (at 1875 cm^{-1}), have been observed on a binary $Pt–Rh/SiO_2$ catalyst. NCO groups are adsorbed on the Rh, but they are not observed on the Pt.[177]

Studies in situ by IR spectroscopy of the reaction of CO + NO on $Pt–WO_3/SiO_2$ at 280 °C showed that the slow step in this case is the dissociation of NO. The CO groups on Pt are rapidly replaced by NO groups, and therefore the absorption bands of the NO groups are predominant in the in situ IR spectra. Bands corresponding to CO groups are observed also on WO_x; NCO, NO_3, or NO_2 groups were seen only under the conditions of the experiment, and they were assigned[177] not to intermediates but to side-products of the reaction, because they are formed in large quantities under conditions which suppress the reaction of carbon monoxide. The active centres are located at the boundary between Pt and WO_3.

The most active of the platinum metals (rhodium) has been studied the greatest detail.[178–184] According to Hecker and Bell[178,179] the reaction of NO_x with CO on Rh/SiO_2 takes place by the scheme

$$NO + Rh \overset{(1)}{\rightleftharpoons} RhNO, \qquad CO + Rh \overset{(2)}{\rightleftharpoons} RhCO,$$
$$NORh + Rh \overset{(3)}{\longrightarrow} NRh + ORh,$$
$$NORh + NRh \overset{(4)}{\longrightarrow} N_2O + 2\,Rh,$$

$$NORh + NRh \xrightarrow{(5)} N_2 + {}^1/_2O_2 + 2\,Rh,$$

$$CORh + ORh \xrightarrow{(6)} CO_2 + 2\,Rh,$$

$$NRh + CO \overset{(7)}{\rightleftharpoons} RhNCO,$$

$$NRh + CORh \xrightarrow{(8)} RhNCO + Rh,$$

$$2\,RhNCO \xrightarrow{(9)} N_2 + 2\,CO + 2\,Rh.$$

The absorption bands of NCO on Rh (2170 cm^{-1}) appear during the catalysis; they are strongest if the reaction is carried out at 230 °C. However, there is no proof that their formation determines the rate of the catalytic reaction. The coverage of Rh by NCO groups is low as compared with the coverage by NO groups (1685 cm^{-1}) and by N atoms (1610 cm^{-1}). A high concentration of NCO is found on SiO_2 (2300 and 1960 cm^{-1}); the CO groups are observed on the carrier as a result of migration from the metal. Under the reaction conditions these groups are stable, and apparently do not contribute to the catalysis. The exposure of Rh/SiO_2 to a mixture of $N_2 + H_2 + CO$ also produces bands corresponding to the NH and NH_2 groups.[180] The activation energy for the reduction of NO in the presence of H_2 is very substantially lowered (from 34 to 23 kJ mol^{-1}). An intermediate compound [urea, $(NH_2)_2CO$] is formed on the reduced catalyst, probably by the reaction

$$HNCO + NH_3 \longrightarrow NH_4OCN + (NH_2)_2CO.$$

HNCO is formed on an oxidised catalyst.

When the reaction of NO_x with CO is carried out on Rh/Al_2O_3 Rh–NCO complexes are not formed, but Rh(CO)(NO) groups have been observed[186] and suggested as the source of the reduction of NO. The formation of dicarbonyls suppresses the reaction. However, Dictor[181] has noted the formation of $Rh(CO)_2$, but was unable to detect Rh(CO)(NO) groups. The $Rh-NO^-$, Rh–NO, $Rh-NO^+$, Rh–CO, Rh_2CO, Rh–CN, and a large number of NCO groups adsorbed mainly on the Al_2O_3 were also detected. It is suggested that NO dissociates on the reduced Rh and easily oxidises the catalyst. The NCO groups are probably formed at the Rh – carrier boundary (but not on the Rh^+).

It has also been shown[182] that the stability of NCO increases in the presence of O_2, and therefore isocyanate could be an intermediate in the catalytic reaction of NO + CO + O_2.

The NO + CO + O_2 reaction has been studied[186] on Pt/SiO_2. At low coverages of the surface by CO groups the CO + O_2 reaction takes place much more readily than the CO + NO reaction. A dissociative mechanism is suggested, with the dissociation of chemisorbed NO as the rate-limiting step.

The forms $NO-Ru^{2+}$ and NO_2-ZnO have been observed[188] on the Ru/ZnO catalyst. Carbon monoxide adsorbed on Ru reacts with NO when the latter is dissociated, forming NCO and CO_3. As a result of spill-over the NCO and CO_3 species move from the metal to the carrier, where they are stabilised even for temperatures above the catalysis temperature.[188]

Under catalytic conditions the formation of NCO groups and their migration towards the carrier have been observed[185] on Ir catalysts supported on SiO_2, Al_2O_3, TiO_2, or MgO. As reported, the dissociation of NO takes place on reduced iridium centres by the scheme

$$Ir(CO)(NO) \longrightarrow IrN + CO_2.$$

NNO groups, which are intermediates in the formation of N_2O, are formed in parallel with NCO:

$$IrN + NO \longrightarrow IrNNO \longrightarrow Ir + N_2O.$$

On an oxidised Ir surface no interaction between NO and CO was detected.

The only systematic spectroscopic investigation of the interaction of CO and NO on supported platinum group metals appears to be a group of studies from our laboratory.[189–194] This work involved the simultaneous measurement of the rate of conversion of the surface compounds [CO(ads), CO_2^{2-}, and NCO] and of the rate of formation of the reaction products (N_2, N_2O, and CO_2). As a result we were able to establish the following series of steps in the interaction of CO with NO:

$$CO + M \overset{(1)}{\rightleftharpoons} M-CO,$$

$$NO + M \overset{(2)}{\rightleftharpoons} M-NO,$$

$$M-NO + M \xrightarrow{(3)} M-N + M-O,$$

$$M-N + M-CO \xrightarrow{(4)} M-NCO + M,$$

$$M-NCO + M-NO \xrightarrow{(5)} M-CO_2 + N_2 + M,$$

$$M-CO + M-O \xrightarrow{(6)} M-CO_2 + M,$$

$$M-CO_2 \xrightarrow{(7)} CO_2 + M,$$

$$M-N + M-NO \xrightarrow{(8)} N_2O + 2\,M,$$

$$O_2 + 2\,M \xrightarrow{(9)} 2\,MO.$$

I: $2\,CO + 2\,NO = 2\,CO_2 + N_2$,

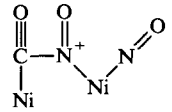
II: $CO + 2\,NO = N_2O + CO_2$,

III: $2\,CO + O_2 = 2\,CO_2$.

It was found that this sequence is identical for all the catalysts examined.[189–194]

The NO + CO reaction was studied on a Ni/SiO_2 catalyst by IR spectroscopy and microgravimetrically.[195] The adsorbed NO [mainly in the form of $Ni(NO)_2$] reacts with CO, giving NiNCO + CO_2. The stoichiometry of the reaction corresponds to the equation

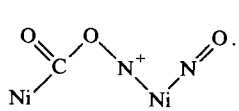
$$4\,NO(ads) + 3\,CO \longrightarrow$$
$$\longrightarrow NCO(ads) + 2\,O(ads) + 3\,N(ads) + 2\,CO_2.$$



Weakly adsorbed CO is formed also by the interaction

$$NiNCO + Ni \longrightarrow NiN + NiCO.$$

In the absence of CO the following reaction takes place;



$$Ni + Ni(NO)_2 \longrightarrow 2\,NiNO \longrightarrow 2\,N(ads) + 2\,O(ads).$$

A correlation between the decomposition of NO and the formation of NCO is established 10 min after the beginning of the reaction. The possible formation of associative intermediate complexes has been suggested:[195]

16

or

17

The formation of NCO in the reaction of surface nitride NiN (after the dissociation of NO) with CO has not been observed.

The same reaction (NO + CO) has been studied on a reduced copper catalyst (Cu/Al_2O_3) by in situ IR spectroscopy and TPD.[196] The products (CO_2 and N_2) are formed in a single elementary step. The adsorption of CO groups on Cu^0 and Cu^+ centres has been observed. The action of NO on the reduced

surface leads to the reoxidation of the copper and subsequently to the formation of NCO, probably on the carrier. The following reaction mechanism has been suggested:

$$NO \rightleftharpoons NO(ads) \longrightarrow N(ads) + O(ads),$$

$$N(ads) + N(ads) \longrightarrow N_2,$$

$$N(ads) + NO(ads) \longrightarrow N_2O,$$

$$NO(ads) + NO(ads) \longrightarrow N_2O + O(ads),$$

$$O(ads) + 2\,Cu^0 \longrightarrow Cu_2O,$$

$$Cu_2O + CO \longrightarrow 2\,Cu + CO_2,$$

$$N(ads) + CO(ads) \longrightarrow NCO(ads),$$

$$NCO(ads) + NO(ads) \longrightarrow N_2 + CO_2.$$

The last step is rate-limiting. The possible spill-over of N particles from the copper towards the carrier and their interaction with CO on the carrier have also been suggested.[196]

Absorption bands corresponding to the complexes $Cu^{2+}-NCO$, $Cu^{+}-NCO$, $Cu^{+}-NO$, $Cr^{2+}-NO$, $Cu^{2+}-CO$, $Cu^{2+}-NO$, and $Cu^{+}-CO$, and also absorption bands from carbonates, carboxylates, nitrites, and nitrates, have been observed in the IR spectra obtained under reaction conditions on a $Cu-Cr/Al_2O_3$ catalyst.[197,198] The NCO group is formed by the NO + CO reaction, and also by the sequential exposure of the catalyst first to NO and then to CO. However, not all the NCO takes part in the catalysis. Its formation and decomposition on the copper are also possible:

$$Cu^{+}-N + CO \longrightarrow Cu^{+}-NCO,$$

$$Cu^{+}-NCO + NO \longrightarrow Cu^{+} + N_2 + CO_2.$$

NCO groups are obtained also in the CO + NO reaction on oxide catalysts, for example on Cr_2O_3 [199] and on $LaMO_3$, where M = Cr, Mn, Fe, Co, or Ni.[200]

The interaction of CO and NO has also been studied[201,202] on CuO supported on Al_2O_3. Bands from carbonate–carboxylate complexes (1200–1650 cm^{-1}), from adsorbed CO_2 (2350 and 2370 cm^{-1}), and from CO bound to the reduced copper ions ($Cu^{+}-CO$, 2130 cm^{-1}) have been observed in the spectra for the adsorption of CO on Cu/Al_2O_3. The adsorption of NO produces nitrate–nitrite structures (1200–1660 cm^{-1}) and NO complexes bound to the Cu^{2+} ions (1880 cm^{-1}). $Cu^{+}-NO$ complexes (1740–1780 cm^{-1}) can also be formed. After the adsorption of a CO + NO mixture bands at 2130 ($Cu^{+}-CO$), 1880 ($Cu^{2+}-NO$), and 1780 cm^{-1} ($Cu^{+}-NO$), were observed in the spectra, and also bands at 2270, 2240, and 2140 cm^{-1} which were assigned to vibrations of the isocyanate complex. The role of the latter in the reaction was not examined. A scheme for the interaction of CO and NO in which $Cu^{+}-NO$ is the intermediate complex was proposed on the basis of spectroscopic data.

A quantitative proof that the surface carbonyl $Cu^{+}-CO$ is the intermediate complex in the interaction of CO and NO was produced[203,204] by simultaneous measurements of the diffuse reflectance spectra in the IR region and of the reaction rate on CuO/Al_2O_3.

Reports of simultaneous measurements of the rate of transformation of surface compounds and of the rate of the reaction on copper catalysts are few. In particular, one investigation of this type on CuO/SiO_2 has been described.[205,206] Comparing the spectroscopic and the kinetic results produced a scheme in which the adsorbed NO form acts as an intermediate in the formation of nitrogen. Under the reaction conditions weak adsorption bands from the isocyanate complex were observed. This suggests the possibility of the dissociative adsorption of NO:

$$Cu + NO \rightleftharpoons CuNO,$$

$$CuNO + Cu \longrightarrow CuN + CuO,$$

$$CuNO + NO \longrightarrow Cu + N_2O,$$

$$Cu^{+} + CO \rightleftharpoons Cu^{+}-CO,$$

$$Cu + N_2O \rightleftharpoons CuONN,$$

$$CuONN \rightleftharpoons CuO + N_2,$$

$$Cu_2O + CO \longrightarrow Cu^{+} + CO_2,$$

$$CuO + CO \longrightarrow Cu + CO_2,$$

$$CuN + CO \rightleftharpoons CuNCO.$$

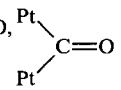
The existence of centres of different types on the surface has been proposed: Cu, Cu^{+}, and Cu^{2+}. The dissociation and the formation of the isocyanate complex take place on the reduced centres.

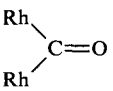
A similar study was carried out on Cr_2O_3/SiO_2.[207] The activity of the catalyst was measured in a gradient-free reactor which also allowed simultaneous spectroscopic measurements. A correlation was observed between the rate of formation of CO_2 and the intensity of the absorption band at 1735 cm^{-1}, corresponding to the vibrations of NO adsorbed in the dinitrosyl form.

The interaction of NO and CO with formation of N_2O and CO_2 was studied[208] on an Au–ZSM-5 catalyst at 70 °C. Under the reaction conditions the $Au^{+}-CO$, $Au^{+}-NO$, $Au^{+}-(NO)_2$, and $Au^{+}-NO_2$ bands were observed.

It should be noted that studies in which the measurements of the reaction rate were accompanied by simultaneous measurements of the rate of conversion of surface complexes were more generally reported than in previous work.

The N_2O + CO reaction on MgO was studied by IR emission spectroscopy and by the response method.[209] An intermediate formate complex was observed, and found to be removed by the reaction





$$HCOO^{-} + N_2O \longrightarrow CO_2 + N_2 + OH^{-}.$$

On oxidation-reduction catalysts the N_2O + CO interaction follows a different path, involving an alternation of oxidation and reduction processes.

Table 6 lists the intermediate compounds observed in the study of the CO + NO reaction on different catalysts. Compounds such as **16** or **17**, which were proposed but not experimentally observed, are not included in the table.

To conclude the present section we note that many surface species have been considered in in situ studies of the CO + NO reaction by IR spectroscopic methods, but few direct kinetic confirmations of the reality of their contribution to the catalysis have been put forward. Both a dissociative mechanism (with dissociation of the CO and NO molecules) and an associative mechanism [with formation of NCO, NNO, and M(CO)(NO) species] have been suggested by different workers. There have been extended discussions of the participation in the catalysis of the NCO isocyanate species, which can be adsorbed on both the metal and the carrier. The most widely held view is that NCO adsorbed on the carrier does not contribute to the catalysis whereas NCO adsorbed on the metal. The rate of its transformation on the metal is fairly high, and after the reaction this species is not usually observed. There are also assumptions of the formation of more complex associative complexes such as **16** and **17**.

Table 6. Intermediates in the NO + CO reaction.

X. Reduction of NO_x with other reducing agents

The reduction of NO_x with other reducing agents has been studied intensively in recent years with the aim of removing nitric oxide impurities from oxygen-containing exhaust gases from industry and transport. Ammonia is often used as a reducing agent to purify industrial gases and gases from electrical power stations, and the $V_2O_5-TiO_2$ system usually provides the catalyst.

On pure V_2O_5 the mechanism of the reduction of NO_x was first studied by Takagi et al.[210] An analysis of the IR spectra recorded at room temperature showed that in the absence of oxygen NO is not adsorbed on V_2O_5, but in the presence of oxygen it is adsorbed [as NO_2(ads)]. Upon adding ammonia they observed NH_4(ads). From these results they proposed the following reaction mechanism:

$$NO + {}^1/_2O_2 \longrightarrow NO_2(ads),$$

$$ZOH + NH_3 \longrightarrow ZO^- + NH_4^+(ads),$$

$$ZO^-...NH_4^+(ads) + NO_2(ads) \longrightarrow N_2 + 2\,H_2O + ZO^-,$$

$$ZO^- + H_2O \longrightarrow 2\,ZOH.$$

On TiO_2 the following forms of adsorbed NO_x were observed by IR spectroscopy: NO on Ti^{4+} ions (Lewis centres), N_2O on Ti^{3+} (through the reduction of NO), and NO_3^- on Ti^{3+} (through the oxidation of NO).[211] In the adsorption of NO_2 nitrates are formed, and in the adsorption of NH_3 we find coordinatively bound ammonia (on the Ti^{4+} Lewis centres), which is stable up to 300 °C. The ammonia displaces NO from the surface, but does not react with it.

Another communication from the same authors[212] describes a study of the reaction between NO_x and NH_3 on the $V_2O_5-TiO_2$ system. In the adsorption of NO the surface is rapidly covered with nitrosyl groups and slowly with NO_3 and NO_2. NH_4^+ and coordinatively bound ammonia are formed on the V–OH centres as a result of the adsorption of ammonia. At 250 °C the intensity of the coordinated ammonia bands in the IR spectra decreases, and the NH_4^+ bands disappear, but they are replaced by NH_2 bands. Heating a surface covered with ammonia in an NO atmosphere leads to the reaction

$$VO^{2+} + NH_3 \longrightarrow [HO-V-NH_2]^{2+},$$

$$NO + [HO-V-NH_2]^{2+} \longrightarrow \underset{\textbf{18}}{[HO-V-NH_2-NO]^{2+}},$$

$$[HO-V-NH_2-NO]^{2+} \longrightarrow N_2 + H_2O + [VOH]^{2+},$$

$$[VOH]^{2+} + {}^1/_4O_2 \longrightarrow VO^{2+} + {}^1/_2H_2O.$$

The overall reaction is

$$NH_3 + NO + {}^1/_4O_2 = N_2 + 1\,{}^1/_2H_2.$$

Thus the reaction of NO_x with NH_3 on V_2O_5 takes place through the decomposition of the associative complex **18**. NO or NO_2 can contribute to the reoxidation stage instead of O_2:

$$[VOH]^{2+} + {}^1/_2NO \longrightarrow VO^{2+} + {}^1/_2\,H_2O + {}^1/_4\,N_2,$$

$$2\,[VOH]^{2+} + {}^1/_2NO_2 \longrightarrow 2\,VO^{2+} + H_2O + {}^1/_4\,5\,N_2.$$

Data obtained[213] by Fourier transform IR spectroscopy and by electrical conductivity methods lead to a similar conclusion:

$$3\,V_2O_5 + 2\,NH_3(ads) \longrightarrow N_2 + 3\,H_2O + V_2O_4,$$

NH_3 reduces the V^{5+} by the reaction

$$2\,V_2O_4 + NO \longrightarrow N_2 + 2\,V_2O_5.$$

and NO reoxidises the V^{4+} to V^{5+}:

At 200 °C the formation of the intermediate complex $V^{5+}-ONH_4$ was observed:

$$2\,V^{5+}-ONH_4 + V^{5+}-O-V^{5+} + 2\,NO \longrightarrow$$

$$\longrightarrow 2\,N_2 + 3\,H_2O + 2\,V^{5+}-OH + V^{4+}\square V^{4+}$$

A study of the reaction[214] by Auger spectroscopy and by TPD showed that NH_3 is adsorbed on both TiO_2 and V_2O_5, but NO is adsorbed only on TiO_2.

Ammonia reduces V_2O_5 by a reaction which produces N_2O. In the presence of N_2O, NO, and O_2 the V_2O_5 surface is reoxidised, and N_2 is evolved. NO and NH_3 molecules adsorbed on TiO_2 do not interact, but they interact on $V_2O_5-TiO_2$. The reaction apparently takes place near the Ti–V interface. Of all the possible intermediates the NH_2 groups are adsorbed on the V_2O_5:

$$V_2O_{5-x} + x\,NH_3 \longrightarrow V_2O_5 + 1^1/_2\,x\,(NH_2)_x + {}^1/_2\,x\,H_2O,$$

$$V_2O_5 + 1^1/_2\,x\,(NH_2)_x + x\,O_2 \longrightarrow V_2O_{5-x} + {}^1/_2\,x\,N_2O + H_2O,$$

$$V_2O_{5-x} + x\,N_2O \longrightarrow V_2O_5 + x\,N_2.$$

The interaction of NO with NH_3 has been studied also on metallic catalysts. On Pt(111) at low temperatures the IR spectra include a band at 1280 cm^{-1} assigned[215] to the associative complex NH_3NO. Upon being heated to 350 °C the system again breaks down into NH_3 + NO. Absorption bands due to adsorbed NO and NH_3 have also been observed. The NH_3 + NO reaction begins only at temperatures above 400 °C, stimulated by the dissociation of NH_3 into NH_2 and H.

When the NO + NH_3 reaction was carried out on FeY zeolite the bands corresponding to NH_3(ads) and NH_4^+ appeared in the IR spectra.[216] Contributions to the catalysis from HNO and N_2O species have also been suggested.

Several papers have dealt with the mechanism of the reduction of NO by hydrogen on metals, including the faces of Pd,[217] Rh,[218] and Ru monocrystals.[219]

An analysis of the EELS spectra obtained uring the reaction of NO with H_2 on Pt(III) under stationary conditions (100–350 °C, pressure $10^{-9}-10^{-8}$ Torr) showed[220] that with an excess of NO the main product of the reaction is N_2, whereas with an excess of H_2 it is NH_3 (in the temperature range 20–200 °C) or N_2 (at higher temperatures). The same precursor appears in both reactions. The NH_3NO complex which is observed (a wide band at 1280 cm^{-1}) inhibits the reaction; when heated it dissociates into NH_3 and NO. At low temperatures the Pt surface is covered with linear and with bridging NO groups, but the NO apparently contributes to the reaction in its dissociated form.

The reaction of NO + H_2 on Pt(111) under the same conditions ($10^{-9}-10^{-8}$ Torr) was studied by EELS and thermosorption methods.[221,222] Two forms of linear NO and two of bridging NO were detected in the low-temperature adsorption of NO: on the (111) plane and on defects (atomic steps). The α form of NO is desorbed at temperatures close to 100 °C, and the β form dissociates at 200–250 °C with formation of N_2. The HNO, N, NH, NH_2, and NH_3 groups are also observed on the surface.

The following mechanism is proposed for the reduction:

$$NO \xrightarrow{(1)} \alpha_1\text{-}NO(ads),$$

$$H_2 \xrightarrow{(2)} 2\,H(ads),$$

$$H(ads) + \alpha_1\text{-}NO(ads) \xrightarrow{(3)} HNO(ads),$$

$$HNO(ads) + H(ads) \xrightarrow{(4)} N(ads) + H_2O,$$

$$N(ads) + 3\,H(ads) \xrightarrow{(5)} NH_3,$$

$$2\,N(ads) \xrightarrow{(6)} N_2.$$

The NO + H_2 reaction has been studied also on supported metal catalysts. A mechanism in which the first stage is the adsorption of NO and the dissociation of H_2 was proposed[223] for the reaction on Rh/SiO_2. Nitrogen is formed by the interaction of N(ads) and NO rather than by the recombination of adsorbed N atoms. On other centres this interaction leads to the formation of N_2O:

$$NO \overset{(1)}{\rightleftharpoons} NO(ads),$$

$$H_2 \overset{(2)}{\rightleftharpoons} 2\,H(ads),$$

$$NO(ads) + H(ads) \xrightarrow{(3)} N(ads) + OH,$$

$$NO(ads) + N(ads) \xrightarrow{(4)} N_2O,$$

$$NO(ads) + N(ads) \xrightarrow{(5)} N_2O + O(ads),$$

$$O(ads) + H(ads) \xrightarrow{(6)} OH(ads),$$

$$OH(ads) + H(ads) \xrightarrow{(7)} H_2O,$$

$$N(ads) + H(ads) \xrightarrow{(8)} NH(ads),$$

$$NH(ads) + H(ads) \xrightarrow{(9)} NH_2(ads),$$

$$NH_2(ads) + H(ads) \xrightarrow{(10)} NH_3.$$

The Rh–NO and Rh–N=O···Sn complexes, and also Rh–O–Sn, were observed by IR spectroscopy and XPES under the conditions of the reaction of NO with H_2 at 100 °C on a $Rh-Sn/SiO_2$ catalyst. Their interaction with hydrogen produced N_2, N_2O, and H_2O.[224]

A study of the reaction of NO with H_2 on Au/SiO_2 and Au/MgO by in situ Fourier transform IR spectroscopy[225] revealed a wide band at 2400–2700 cm^{-1}, which could not be identified. It was assumed that the reaction includes the intermediate dissociation of NO and involves adsorbed atomic nitrogen.

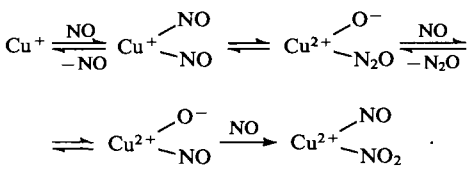
With one exception[223] none of the studies mentioned above was spectroscopic, amd therefore the proposed mechanisms must be treated as tentative. Obviously, associative and dissociative steps are combined in the mechanism of the NO reduction reaction: the NO molecule takes part (as a whole) in the interaction with NH_3 or with H_2. The formation of the $NO{\cdot}NH_3$ complex assists the formation of N–N bonds and the dissociation of the NO molecule.

Reactions leading to the selective reduction of NO_x to nitrogen by using the hydrocarbons contained in the 'lean' mixtures (i.e. mixtures with an excess of oxygen)[226] characteristic of the exhaust gases of Diesel engines were recently discovered on the Cu–ZSM-5 zeolite catalyst. These have stimulated a new series of studies[227–231] aimed at establishing the mechanism of this reaction and the mechanism of the decomposition of NO_x on zeolites.

The state of the copper in the zeolites was studied by ESR (including under reaction conditions[227–229]), XPES, Auger spectroscopy,[230] and IR spectroscopy.[231] All these workers point out that the zeolite contains bivalent and univalent copper, but that the Cu^+ is predominant under the reaction conditions. As reported,[227,231] the reaction

$$2\,Cu(OH)^+ \rightleftharpoons [Cu-O-Cu]^{2+} + H_2O$$

takes place on Cu–ZSM-5. However, the formation of paired copper clusters raises some doubts, since the H^+ ions in the H–ZSM-5 zeolite are located too far from each other to allow a paired cluster to be retained near these centres. A mechanism for the autoreduction of Cu^{2+} with formation of free-radical centres has been proposed:[229]

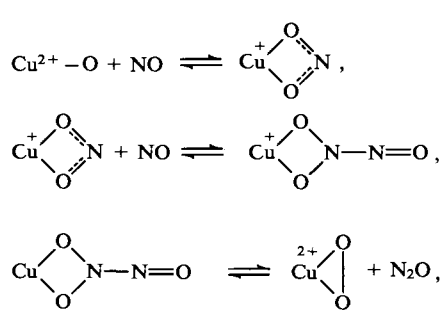


$$Cu(OH)^+ = Cu^+ + \dot{O}H,$$

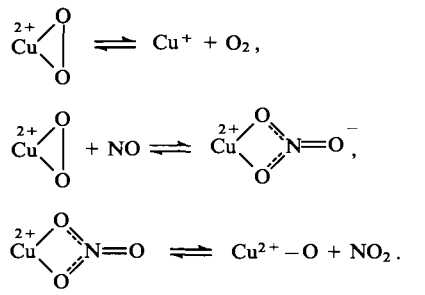
$$Cu(OH)^+ + \dot{O}H = CuO + H_2O,$$

$$2\,Cu(OH)^+ \rightleftharpoons Cu^+ + CuO + H_2O.$$

According to this scheme the water oxidises the Cu^+ centres. We know[232] that water acts as a catalyst poison in the reaction between NO and hydrocarbons in the presence of oxygen. Therefore it follows that the Cu^+ centres are the active centres under the catalysis conditions.



The decomposition of NO on Cu–ZSM-5 takes place at the same temperatures as its reduction by hydrocarbons. Therefore the decomposition of NO has been widely studied by spectroscopic methods.[227–229,232–234] In almost every case the formation of dinitrosyl complexes $Cu^+(NO)_2$ was observed. The following sequence of these complexes, leading to the formation of N_2O, has been proposed:[236]



N_2 and O_2 are evolved during the dissociation of the last of these complexes. Complexes of the species $NO^{\delta+}$, $NO^{\delta-}$, $(NO)_2^{\delta-}$, and $NO_2^{\delta-}$ with Cu^{2+} have been detected.[233] During the decomposition of NO the intensity of the $NO^{\delta-}$ and $(NO)_2^{\delta-}$ bands decreases, and that of $NO^{\delta+}$ increases. The decomposition accompanied by the formation of nitrate ($NO_3^{\delta-}$), nitrite ($NO_2^{\delta-}$), and associative ($NO_2 \cdot NO$) complexes:[234]

$$NO_2(ads) + NO(ads) \longrightarrow [NO_2 \cdot NO] \longrightarrow O(ads) + N_2 + O_2.$$

Many different complexes have been observed in an analysis[229] of the IR spectra of the products of the reaction of NO with H_2. Bands corresponding to the following complexes were found after the adsorption of NO on Cu–ZSM-5 at room temperature: $Cu^{2+}-N=N$ (2156 cm^{-1}), $Cu^{2+}-NO$ (1910 cm^{-1}), Cu^+-NO (1811 cm^{-1}), $Cu^+(NO)_2$ (1734, 1827 cm^{-1}), and $Cu^{2+}-O-N=O$ (1631 cm^{-1}). At higher temperatures, and under conditions corresponding to the onset of the decomposition of NO, bands assigned to the following complexes were observed: $Cu^{2+}-NO_2$ (2130 cm^{-1}), $Cu^{2+}-NO$ (1910 cm^{-1}), Cu^+-NO (1811 cm^{-1}), $Cu^{2+}-O-N=O$ (1616, 1590, 1574 cm^{-1}) and $Cu^{2+}-NO_3$ (1502 cm^{-1}). The following scheme for the transformations of these complexes during their adsorption and decomposition was proposed:[229]

$$Cu^+ + N_2O \rightleftharpoons Cu^{2+}-O + N_2,$$

The mechanism of the interaction of hydrocarbons with NO in the presence of O_2 has been studied by spectroscopic methods.[235–241] In most cases propene was used as the reducing agent, but propane[237] and isobutane[241] were also used. Ideas on the intermediate forms of the hydrocarbons taking part in the reaction are not so definite as the ideas on the forms of NO. According to one suggestion, based on experiments in a TAP (temporal analysis of products) reactor,[236] the product obtained from the hydrocarbons is coke, which is a reducing agent for NO_x on Cu–ZSM-5 in the presence or in the absence of oxygen. The zeolite has a positive effect on both the formation of coke and on keeping the copper in the Cu^+ state.

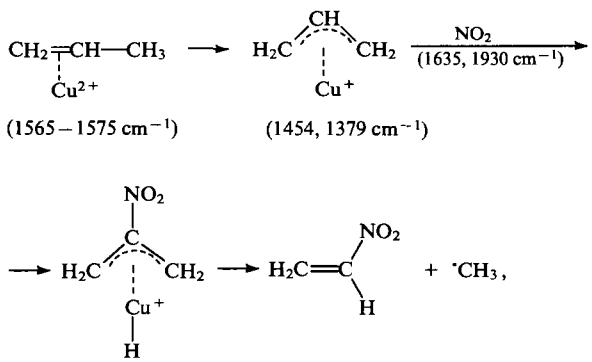
Some workers have observed the formation under the reaction conditions of isocyanate[238–240] and of cyanide complexes.[240] The isocyanate groups can be bound both to the Cu and to an Al atom in the zeolite. As reported,[239] the process takes place by the following scheme:

$$C_xH_y \rightleftharpoons C_xH_y(ads),$$

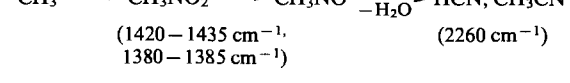
$$C_xH_y(ads) + O_2 \longrightarrow C_mH_nO + CO_2 + H_2O,$$

$$C_mH_nO + m\,NO \longrightarrow m\,NCO + z\,H_2O,$$

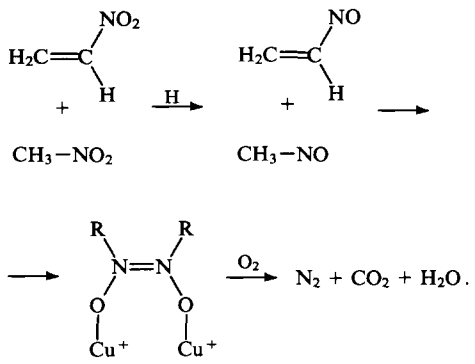
$$NCO + NO \longrightarrow N_2 + CO_2 \text{ (rate limiting)},$$



$$2\,NCO + O_2 \longrightarrow N_2 + 2\,CO_2,$$



$$C_xH_y(ads)\,(\text{or } C_mH_nO) + NO \longrightarrow N_2O + CO_2 + H_2O,$$



$$C_xH_y(ads) + O_2 \longrightarrow x\,CO_2 + y/2\,H_2O,$$

$$C_mH_nO + O_2 \longrightarrow m\,CO + n/2\,H_2O.$$

There is also a more detailed scheme, based on in situ IR spectroscopic studies:[240]

In this scheme cyanides are dead-end compounds, and isocyanates are not formed.

The interaction of NO with hydrocarbons in the presence of O_2 was studied by spectroscopic methods also on other zeolites of the ZSM-5 type (containing ion-exchange cations). The reaction of $C_3H_6 + NO + O_2$ on Ce–ZSM-5 was studied by in situ spectroscopy combined with the kinetic response method using gas-phase analysis.[242, 243] The absorption bands of the NO_2, NO_3, NCO, and CH_3NO_2 species adsorbed on the surface were detected in the IR spectra under the catalytic conditions. According to these workers[242] the reaction takes place by the mechanism

$$CH_3NO_2 + NO \longrightarrow N_2 + CO_2 + H_2O\,.$$

The Ga–ZSM-5 catalyst was found to be very selective in the processes associated with the interaction of NO with methane and ethane.[242–244] Its unique properties are attributed to the dissociative adsorption of methane on Ga–ZSM-5 (in contrast to its adsorption on Cu–ZSM-5. This was confirmed, in particular, by isotope exchange experiments between CH_4 and CD_4 on Ga–ZSM-5.

The reduction of NO_x by hydrocarbons in the presence of O_2 has been studied also on other catalysts. Thus, in particular, the $C_3H_6 + NO + O_2$ reaction takes place on Rh/Al_2O_3.[247] According to published data NO_2^- and NO_3^- are formed in an excess of O_2, and they subsequently react with C_3H_6 giving the $^{\cdot}C_3H_5$ radical and HNO_x. The weakly bound $^{\cdot}C_3H_5$ radical is rapidly oxidised to CO_2 by nitrates and nitrites.

The species $R-NO_x$, NO_x, NCO, nitrate, and nitrite were detected[248] spectroscopically in a study of the reduction of NO by hydrocarbons on various zeolites, and also on modified ZrO_2 and on complex oxides supported on γ-Al_2O_3.

We should stress that studies of the reduction of NO_x by hydrocarbons began only 2 or 3 years ago. Nevertheless there are already numerous reports of the spectroscopic detection of various surface forms, though only few spectro-kinetic studies could be traced. The existence of adsorbed intermediate forms of NO is most convincingly established, that of the complexes of NO with hydrocarbons is still arguable. The NCO species observed by several workers may play a key role in the reduction of NO both by CO and by hydrocarbons, though detailed schemes are still to be developed.

Table 7 gives a summary of data on the intermediate compounds which take part in the reduction of NO by ammonia, hydrogen, and hydrocarbons.

XI. Conclusion

The reactions discussed in this review had been more carefully studied than those which were examined in our previous article.[1] This is because the extinction coefficients of the C – O, N – O, O – H, and N – H bonds are substantially higher than those of the C – H and C – C bonds. As a result, in reactions involving CO and NO (and sometimes also hydrogen) the sensitivity of the spectrokinetic measurements is higher, but the measured characteristic times of the elementary processes are lower. However in this case, as can be seen from the above tables, the confidence level of the great majority of the reported studies is only moderately high. We consider the studies of the catalytic reduction of NO by carbon monoxide, ammonia, and hydrocarbons to be the most reliable. These reactions began to be studied relatively late, but for this reason the methods used for the detection of surface compounds were more sensitive and up-to-date than the methods used in the earlier work.

In many cases the observed surface compounds (carbonates, formates, NCO) were stabilised on the carrier rather than on the active phase. They could be dead-end compounds, but they could also take part in the catalytic reaction as a result of their migration (spill-over) towards the active surface or towards the phase separation boundary.

A generalising analysis of all the reactions so far considered will be given in the third (closing) part of the present series of reviews.

Abstract. The results of studies of the radical polymerisation of acrylamide and of its derivatives in the presence of inorganic salts (Lewis acids) in various solvents are correlated. It is shown that the effect of inorganic salts on the polymerisation of acrylamide depends to a large extent on the nature of the solvent. During polymerisation in water the addition of Lewis acids has no effect on the rate of the process. The effect of Lewis acids is most marked when the reaction is carried out in organic solvents of relatively low polarity. It is shown that the change in the overall rate of the process in the presence of Lewis acids is due to a change in the rate constants of the chain growth and chain breaking reactions, induced by the formation of a complex between the amide group of the propagating radicals and/or monomers and the inorganic salt. The introduction of substituents into the acrylamide suppresses the formation of a complex with the salt, and therefore the effect of the salt on the polymerisation of substituted acrylamides is less marked than in the polymerisation of acrylamide itself. The bibliography includes 52 references.

I. Introduction

Studies reported during the past 15–20 years have convincingly established that in the radical polymerisation of vinyl monomers the nature of the reaction medium has a strong influence on the overall rate of the process, on the rate constants of the elementary propagation and termination reactions of the polymer chains, and on the molecular characteristics of the resulting polymers. Changing the nature of the solvent or introducing various complexing additives into the reaction mixture can significantly affect the kinetic parameters of the homogeneous radical polymerisation reaction.

Solvent effects are especially marked in the polymerisation of water-soluble monomers. Thus, in the polymerisation of monomers such as acrylamide, acrylic acids, *N*-vinylpyrrolidone, and the tertiary salts of the aminoesters of (meth)acrylic acid the chain propagation rate constant (k_p) is increased 50–100-fold[1–6] when the homogeneous polymerisation in organic solvents is replaced by polymerisation in an aqueous solution. The nature of the solvent has a smaller effect on the polymerisation of nonpolar and moderately polar vinyl monomers such as styrene and methyl methacrylate. But even in this case the overall rate of the reaction can be varied by a substantial factor by changing the nature of the solvent, and the k_p value for the homogeneous polymerisation of styrene varies by 50%–70% depending on the nature of the solvent. These effects have been discussed in depth in several monographs and reviews (see, for example, Refs 1 and 7–14). An analysis of published data suggests that the principal causes of the influence of the nature of the solvent on the kinetic parameters of the homogeneous radical polymerisation of vinyl monomers are the formation of specific complexes between the reacting species (the monomer, and the polymeric radicals) and the solvent molecules, the hydrophobic interactions stimulated by the polymerisation of water-soluble monomers in aqueous solutions, and also the change in the quality of the solvent as compared with the growing polymer. In the case of low-polarity hydrocarbon monomers of the styrene type the factor which mainly determines the effect of the solvent on k_p is the formation of donor–acceptor complexes between the solvent molecules and the growing polymer radicals, leading to a decrease in the activity of these radicals.

The formation of donor–acceptor complexes between the vinyl monomers and/or their radicals (on the one hand) and inorganic salts acting as Lewis acids (on the other) can also affect the radical polymerisation of the vinyl monomers. Detailed analyses of the reported studies of polymerisation in the presence of Lewis acids can be found in several publications.[15–22] Their results, correlated in those reviews, show that the addition to the reaction system of Lewis acids such as zinc chloride, aluminium bromide and chloride, stannic chloride, lithium chloride, and also various organoaluminium compounds leads to marked changes in the kinetics of the homopolymerisation of vinyl monomers (acrylonitrile, methacrylonitrile, methyl acrylate, methyl methacrylate, etc.) and of the copolymerisation of these monomers. Under these conditions substantial changes in the molecular masses of the polymers also take place. Most of the authors explain the observed kinetic effects in terms of complex formation between the components of the reaction mixture and of the influence of these complexes on the rate constants of the elementary propagation and termination reactions of the polymer chains. The formation of complexes in systems containing vinyl monomers and various Lewis acids has been established experimentally by spectroscopic methods: in many cases the complexes between the monomer and the Lewis acids were isolated in a pure state. A study of the effect of the complexing

agent on the radical polymerisation of (meth)acrylonitrile and methyl(meth)acrylate[23] showed that (depending on the strength of the Lewis acid, its concentration, and the donor–acceptor properties of the monomer) the complex-forming salts can both accelerate and inhibit this process.

Thus we have very extensive and convincing evidence of the effect of the nature of the solvent and of added complexing salts on the radical polymerisation of a large number of vinyl monomers. One of the sources of the observed effect is the formation of various types of complex between the components of the reaction system. Furthermore, the nature of the resulting complexes and their influence on the polymerisation kinetics may be different if the polymerisation is carried out in different solvents or in the presence of Lewis acids. Therefore information on the effect of the nature of the solvent on the radical polymerisation in the presence of complexing salts could be useful in establishing the mechanism by which the composition of the reaction medium affects the kinetic parameters of the polymerisation. The aim of the present review is to generalise the results of studies of this problem.

Studies of the influence of the nature of the solvent on the polymerisation in the presence of complex-forming salts were carried out mainly on acrylamide and on some of its derivatives. The polymers of acrylamide offer a wide range of important properties for practical applications.[24–26] They are used as efficient flocculants in the purification of potable water and of effluents from metallurgical, mining, and other industrial plants, to improve the performance of petrol engines, to decrease the hydrodynamic resistance to the motion of water along pipelines and to the motion of various objects in water, in the textile and the food industry, etc. Therefore studies of the polymerisation mechanism of acrylamide and its derivatives in the presence of salt additives are of great interest not only in establishing the fundamental rules governing the radical polymerisation process but also for practical purposes.

II. Polymerisation of acrylamide and its derivatives in the presence of Lewis acids

We know that the amide group has a planar configuration, the *trans* form being the most favourable:[27,28]

In the absence of metal ions the amide group is almost neutral; in an acid medium it can add on a proton, the protonation taking place mainly at the oxygen atom.[28,29]

Complex formation with metal ions lengthens the C = O bond and shortens the C–N bond. Experimental and theoretical studies have identified an increase in the double-bond character of the carbon to nitrogen bond, due both to metallisation and to the protonation of the amide group in an acid medium.[27]

These results suggest that in the polymerisation of amide monomers a specific interaction should exist between the amide group of the monomer (and/or the polymeric radical) and the metal atoms of the Lewis acid, leading to a change in the reactivity of the reacting species and therefore also of the kinetic parameters of the polymerisation of these monomers. A partial confirmation of these changes is provided by data on the copolymerisation of acrylamide with other vinyl monomers in the presence of Lewis acids. Thus, in the copolymerisation of acrylamide with acrylic acid the addition of zinc chloride strongly influences both the copolymerisation constant and the overall rate of the process.[30] Whereas in the absence of the salt the copolymerisation of these monomers in benzene produces a random copolymer, and the system is characterised by the copolymerisation constants $r_1 = 1.38$ and $r_2 = 0.36$, the addition of zinc chloride (at all concentrations of the initial mixture of monomers) produces an alternating copolymer of equimolar composition. The changes in the copolymerisation constants of acrylamide with vinyl acetate and methacrylic acid in the presence of a Lewis acid are also confirmed by independent results.[31]

Several studies of the complex formation of acrylamide and some of its derivatives with the halides of various metals (in particular, with zinc chloride and bromide) in the solid state and of the polymerisation of these solid complexes were reported in the early 1980s.[32–35] The polymerisation of several *N-tert*-alkylacrylamides in solution under the influence of zinc chloride was also studied. The formation of solid complexes of acrylamide, methacrylamide, and their *N*-substituted analogues with zinc, cadmium, and mercury halides has been investigated.[32] The ability of these systems to form complexes depends both on the structure of the amide and on the nature of the salt. The presence of bulky *tert*-alkyl substituents near the nitrogen atom of the amide group strongly suppresses the complex-forming properties of the monomer. Furthermore methacrylamide is less effective in complex formation than acrylamide. A study of the structure of the *N-tert*-butyl- and *N-tert*-amylacrylamide complexes with zinc chloride in dioxan showed that in this case the electrophilic attack of zinc chloride takes place at the oxygen atom of the carbonyl group in the amide.[33]

The complex formation of *N-tert*-butyl- and *N-tert*-hexylacrylamide with zinc chloride increases the rate of radical polymerisation of these amides in the solid state. In most cases the formation of complexes of these amides with zinc bromide is accompanied by a decrease in the reactivity of the monomers.[34] At a given polymerisation temperature an increase in the size of the alkyl substituent on the nitrogen atom increases the rate of solid-phase polymerisation of the complexed monomer. However, at a given reduced temperature (i.e. for a fixed $T:T_m$ ratio) we observe the opposite activity sequence of the complexed monomers. It is important to note that the activation energy for the polymerisation of the complexed monomers is higher than the value for the free amide monomers.

In the presence of zinc chloride *N-tert*-alkylacrylamides (*N-tert*-butyl- and *N-tert*-amyl-) are polymerised at 60 °C even without a radical initiator if the reaction is carried out in solvents of low polarity (benzene, dioxan).[35] The yield of the polymers depends on the strength of the interaction between the salt and the solvent (Table 1). When this interaction is very strong (with polar solvents like pyridine, ethyl acetate, and especially water) the influence of the Lewis acid on the reactivity of the monomer is slight, and the rate of polymerisation is low. Adding water to a solution of the monomer in dioxan breaks the bond between the monomer and the salt and thus lowers the yield of polymer.

Table 1. Polymerisation of *N-tert*-butylacrylamide (I) and *N-tert*-amylacrylamide (II) under the influence of zinc chloride.[35]

Solvent	Yield of polymer (%)	
	I	II
Water	—	0.85
Pyridine	0.81	1.80
Dioxan	45.80	23.57
Ethyl acetate	0.81	2.52
Benzene[a]	60.00	40.00
Methanol	0	0
Acetone	0	0

Note. Reaction conditions: concentration of amide 0.2866 M, of salt 0.1433 M; temperature 60 °C; polymerisation time 1 h.
[a]During the polymerisation in benzene the polymer is partially precipitated as a separate phase.

The effect of Lewis acids on the polymerisation of acrylamide has been examined in much greater depth. The polymerisation of this monomer was studied in detail in various solvents and in the presence of inorganic salts of different types, thus allowing a well founded mechanism of the process to be developed.

1. Effect of the nature of the solvent on the polymerisation of acrylamide in the presence of Lewis acids

The radical polymerisation of acrylamide in water and in various organic solvents and water–organic mixtures in the presence of Lewis acids has been studied in our laboratory.[36–40] In every case the reaction was carried out under UV radiation in the presence of the dinitrile of azoisobutyric acid (DAA) as a photosensitiser. The polymerisation of acrylamide (AA) in an aqueous solution in the presence of lithium bromide has also been discussed.[36,39] It can be seen from the results in Fig. 1 that at relatively low rates of initiation the addition of the salt (lithium bromide) produces a marked decrease in the overall rate of the reaction. However, at higher rates of initiation the effect of the salt becomes less marked and the reaction no longer depends on the additions of salt. An analysis of these results (and in particular the study of the effect of the salt on the order of the polymerisation reaction with respect to the initiator, which varies from 1 to 0.5 as the salt concentration is increased) leads to the conclusion that the lithium bromide additive has no effect on the rate constants of the chain propagation and chain termination reactions in the polymerisation of acrylamide in aqueous solution.[36,39] On the other hand the decrease in rate observed at low rates of initiation is entirely due to the presence of additives in the system. The conclusion that additions of Lewis acids have no effect on the rates of the propagation and termination reactions of the chains during the polymerisation of amide monomers (and also of acrylonitrile) in aqueous solutions is also consistent with other results.[35,41]

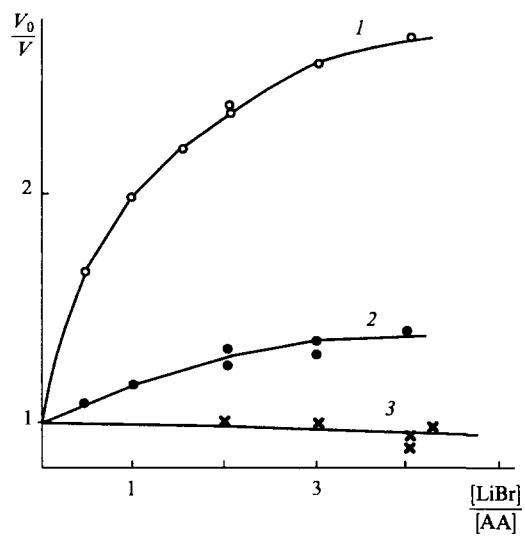

Figure 1. Dependence of the relative rate of polymerisation of acrylamide in water on the concentration of lithium bromide. Concentration of acrylamide 0.5 M; $T = 20$ °C; V_0 and V are the reaction rates in the absence and in the presence of the salt respectively. Concentration of DAA, M: 0.5×10^{-4} (*1*), 0.8×10^{-3} (*2, 3*); intensity of incident UV light, arbitrary units: 1 (*1, 2*), 2.5 and 4.0 (*3*).

It should be noted that some studies have revealed a change in the rate of polymerisation of acrylamide under the influence of several oxidation–reduction initiating systems after the addition of sodium, potassium, iron, manganese, and other salts (see, for example, the monograph by Finch[26]). However, this effect is fully explained by the influence of those salts on the rate of the oxidation–reduction initiation, and is not dependent on any interaction of the salts with the monomer and/or the growing radicals.

A different state of affairs is found in the polymerisation of acrylamide in less polar solvents. The addition of lithium bromide to a solution of acrylamide in dimethyl sulfoxide (DMSO) leads to an increase in the total rate of polymerisation, which reaches a maximum at a molar ratio of [salt] : [monomer] = 1.5, followed by a slight decrease when the salt concentration is increased beyond this value (Fig. 2). The order of the reaction with respect to the initiator is 0.5, both in the absence of salt and in the presence of a [salt] : [monomer] ratio of 1.5. When the concentration ratio of salt to monomer is kept constant the order of the reaction with respect to the monomer increases from 1.0 (in the absence of the salt) to 1.96 (at a ratio of 1.5). Increasing this ratio to 2.0 produces a decrease in the order of the reaction with respect to monomer.[37,39]

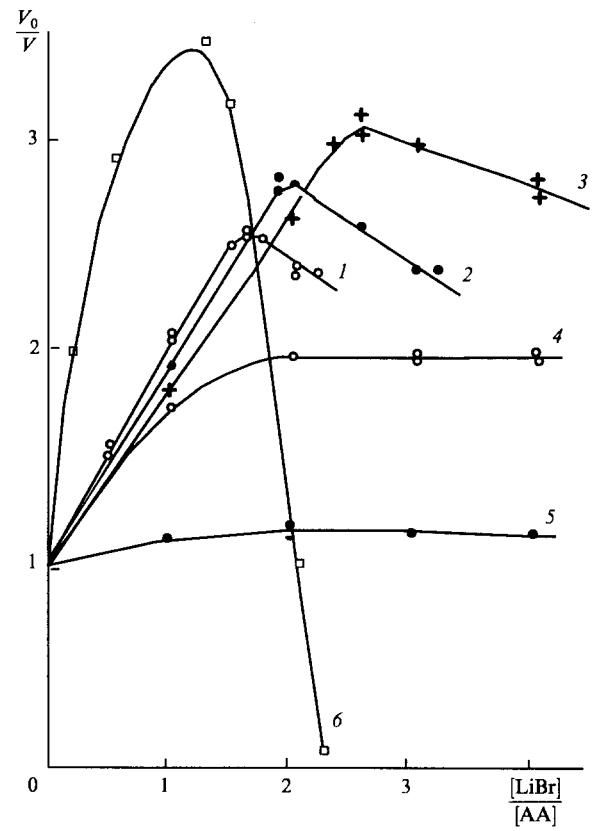

Figure 2. Dependence of the relative rate of polymerisation of acrylamide in DMSO (*1*), in a water–DMSO mixture (*2–5*), and in tetrahydrofuran (THF) (*6*) on the concentration of lithium bromide. Concentration of acrylamide 0.5, concentration of DAA 3×10^{-3} M; $T = 30$ °C; concentration of water in the mixture with DMSO mol %: (*2*) 8.4, (*3*) 20, (*4*) 65, (*5*) 85.

Adding water to the DMSO produces a gradual decrease in the effect of the salt on the rate of polymerisation of acrylamide. For small additions of water (8.4 and 20 mol% of the DMSO) the plots of the overall rate of polymerisation (V) against the concentration of the salt show a maximum at higher concentrations than in the polymerisation in the absence of water (Fig. 2, curves *2* and *3*). Under these conditions the effect of the salt on the rate of polymerisation (i.e. the ratio V/V_0, where V_0 is the rate of polymerisation in the absence of water) is greater in the presence of water than when the polymerisation takes place in dry DMSO. For higher water concentrations in the mixed solvents (65 and 85 mol%) the maximum effect of the salt is less marked than in pure DMSO (Fig. 2, curves *4* and *5*). Furthermore at high

water contents there is practically no decrease in the reaction rate beyond the lithium bromide concentration at which the maximum value is reached.

The effect of lithium bromide on the polymerisation of acrylamide is strongest in THF. In this solvent the reaction takes place with precipitation of the polymer from solution, and therefore the rate of photopolymerisation was determined in the earliest stages of the process, when the loss of transparency of the reaction system produced by the precipitation of the polymer was not too serious, i.e. the rate of photoinitiation was practically constant. The results in Fig. 2 show that, as in DMSO, in the polymerisation in THF (curve *6*) the reaction rate reaches a maximum at a well defined concentration of the salt, and that in this case the maximum V/V_0 ratio is much higher than in the polymerisation in DMSO and the maximum is observed at a lower concentration ratio of the salt and the monomer. However, at higher concentrations of lithium bromide the rate of polymerisation of acrylamide falls off steeply.

The addition of saturated acetamide to a reaction system containing lithium bromide and acrylamide lowers the rate of polymerisation in DMSO, and this effect increases with the concentration of acetamide.[39, 40] In the absence of the salt, adding acetamide has no effect on the rate of polymerisation of acrylamide. When acrylamide is polymerised in DMSO in the presence of acetamide, salt additions increase the rate of the reaction but in this case the accelerating effect of lithium bromide is less marked than in the absence of acetamide (Fig. 3).

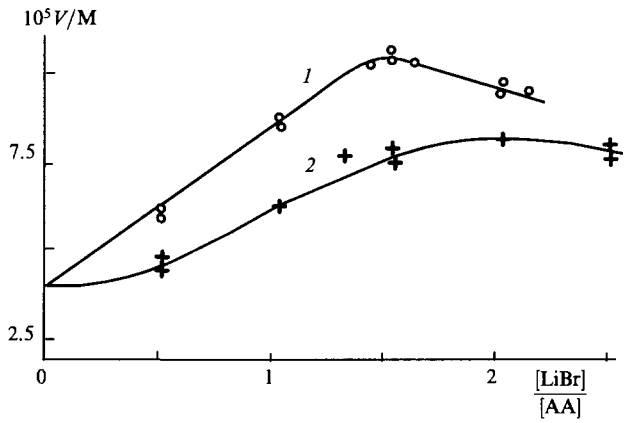

Figure 3. Effect of the concentration of lithium bromide on the rate of polymerisation of acrylamide in DMSO in the presence (*1*) and in the absence of 1.0 M of acetamide (*2*). Concentration of acrylamide 0.5, of DAA 3×10^{-3} M, $T = 30$ °C.

2. Effect of the nature of the inorganic salt on the polymerisation of acrylamide

The effect of the nature of the Lewis acid on the polymerisation of acrylamide has been studied for the reaction in DMSO.[38-40]

Lithium, calcium, and zinc chlorides were used as the Lewis acids. The reaction was carried out under the conditions used in the presence of lithium bromide. In every case the reaction proceeds (without a period of induction) with a constant initial rate. The polymerisation in the presence of lithium and calcium salts produces a maximum in the plot of the overall rate of the process against the concentration of the salt (Fig. 4). However, the position of the maximum varies with the nature of the salt. With respect to their influence on the overall rate of polymerisation of acrylamide the salts can be arranged in the following series: LiBr < LiCl < $CaCl_2$. The rate of polymerisation of monomers such as acrylonitrile and methyl methacrylate,[42] and also *N*-alkylacrylamides,[35] increases markedly in the presence of zinc chloride, but the addition of this salt has

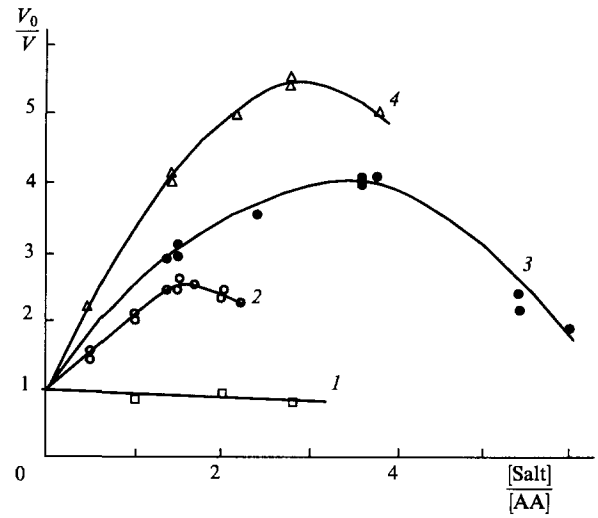

Figure 4. Dependence of the relative rate of polymerisation of acrylamide in DMSO on the salt concentration. Concentration of acrylamide 0.5, concentration of DAA 3×10^{-3} M; $T = 30$ °C; salt (*1*) $ZnCl_2$, (*2*) LiBr, (*3*) LiCl, (*4*) $CaCl_2$.

almost no effect on the rate of homogeneous polymerisation of acrylamide under the conditions of these experiments.

The rate of polymerisation of acrylamide in the presence of lithium bromide or calcium chloride depends on the nature of the solvent in which the reaction is carried out: the accelerating effect of small additions of salt on the polymerisation process increases as the polarity of the solvent decreases (Fig. 5).[40] It should be noted that (as in the polymerisation of *N-tert*-alkyl substituted acrylamides in a low-polarity medium[35]) the polymerisation of acrylamide in *N*-methylpyrrolidone (the least polar of the solvents used in that work[40]) with [salt]:[monomer] ratios between 0.35 and 0.40 takes place even in the absence of radical initiators. The spontaneous polymerisation of acrylamide (in the

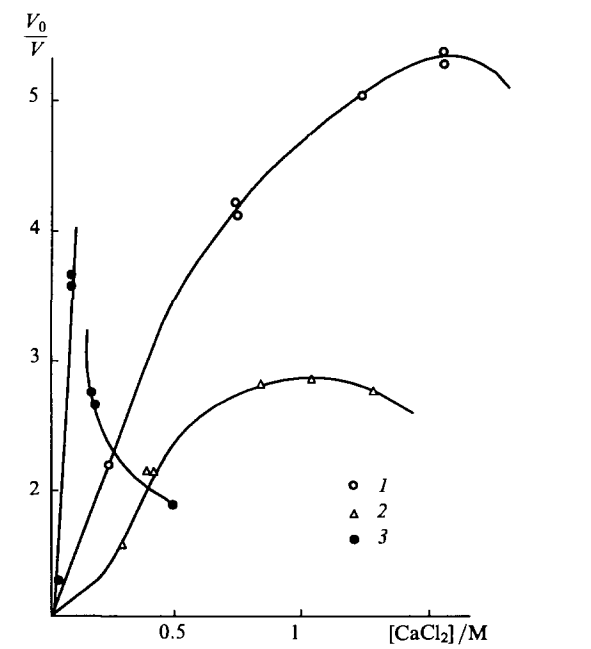

Figure 5. Dependence of the relative rate of polymerisation of acrylamide in DMSO (*1*), formamide (*2*), and *N*-methylpyrrolidone (*3*) at 30 °C (*1*) and 20 °C (*2, 3*) on the concentration of calcium chloride. Concentration of acrylamide 0.5, concentration of DAA 3×10^{-4} M.

Table 2. Order of the reaction with respect to the monomer in the polymerisation of acrylamide in DMSO for different concentration ratios of salt to monomer.[38,39]

Salt	[Salt]:[Monomer]	n	Relative viscosity of salt solution in DMSO	n' (see [a])
LiBr	0.5	1.3	1.4	1.3
	1.0	1.6	1.6	1.3
	1.5	1.9	2.0	1.7
LiCl	0.5	1.4	1.4	1.2
	1.5	2.2	2.0	1.9
$CaCl_2$	1.5	2.8	4.0	2.2
	3.0	3.6	19	2.5

Notes. Reaction conditions: concentration of acrylamide 0.5, of DAA 3×10^{-3} M; $T = 30$ °C.
[a] n' was calculated from the rates of polymerisation reduced to a fixed viscosity of the reaction system equal to the viscosity of DMSO.

absence of UV radiation) was not observed at other salt concentrations in *N*-methylpyrrolidone.

The kinetic order with respect to the initiator in the polymerisation of acrylamide in DMSO is 0.5 in the presence of lithium and calcium chlorides (as it is in the presence of lithium bromide). On the other hand the order of the reaction with respect to the monomer (n) at a constant ratio between the salt and the monomer varies with this ratio between 1.3 and 3.6 (Table 2). The addition of salts to a solution of acrylamide in DMSO produces a large increase in the viscosity of the reacting solution. Thus, at a salt concentration of 0.75 M the viscosity of the solution increases 2-fold with lithium chloride and bromide and 4-fold when calcium chloride is added. As was pointed out,[43] an increase in the viscosity of the reaction medium should be accompanied by an increase in the overall rate of polymerisation. Therefore the reaction rates were recalculated for a fixed viscosity of the reaction solution, equal to the viscosity of DMSO, and the order of the reaction with respect to the monomer was then redetermined (n'). It was assumed that the rate of the reaction was proportional to the viscosity of the reaction system to the power 0.5. The results (see Table 2) show that the order of the reaction with respect to the monomer was greater than 2.0 in the presence of calcium chloride at high [salt]:[monomer] ratios, whereas it approached this value during polymerisation in solutions containing lithium chloride or bromide.

Additions of inorganic salts (Lewis acids) affect not only the overall rate of polymerisation but also the molecular mass of the polymers, which is much greater than the molecular mass of the polyacrylamide synthesised in the absence of salts.[38-40] Thus, the intrinsic viscosity of the polymer produced in DMSO at a monomer concentration of 0.5 M is 0.88 dL g^{-1}, whereas the polymers synthesised in the presence of 1.0 M of lithium bromide or chloride or of calcium chloride have an intrinsic viscosity of 2.9, 3.5, and 4.1 dL g^{-1} respectively.

The change in reactivity of acrylamide and/or its radical in the presence of Lewis acids also results in changes in the overall rate of the process and in the copolymerisation constants of acrylamide with styrene in DMSO. It has been shown[40] that the rate of polymerisation of acrylamide decreases rapidly with small additions of styrene, the effect depending on the presence of a Lewis acid in the reaction system. Thus, adding 5 mol% of styrene lowers the rate of polymerisation in the absence of the salt by a factor of 17, whereas in a system containing lithium bromide ([salt]:[acrylamide] = 1.5) the rate falls by a factor of 32, and in the copolymerisation under similar conditions but in the presence of lithium chloride it falls by a factor of 40. The copolymerisation constants of acrylamide with styrene in DMSO are $r_1 = 0.21$ and $r_2 = 2.35$ in the presence of lithium chloride and $r_1 = 0.40$ and $r_2 = 2.0$ in the absence of the salt.[44]

3. Mechanism of the effect of salts on the polymerisation of acrylamide

The results discussed above denote a specific interaction between the reacting species and the salts (Lewis acids) in the polymerisation of acrylamide. The IR and PMR spectra of acrylamide–salt systems in DMSO were analysed in order to confirm the presence of this interaction.[38-40] In the IR spectra the absorption band which characterises the NH group of the monomer is shifted towards lower frequencies in the presence of lithium bromide (Fig. 6). The PMR spectrum also reveals a small shift of the signal due to the protons of the NH_2 group towards lower energies.[36,40] A more substantial shift is observed when lithium chloride is added to a solution of acrylamide in DMSO, and an even stronger shift when calcium chloride is added. On the other hand the addition of zinc chloride to the acrylamide–DMSO system does not produce a significant shift of this signal. Thus the spectroscopic results point to the formation of a complex between the amide group of acrylamide and the inorganic salts (except zinc chloride). The C=C vinyl group does not take part in complex formation. A similar result was obtained in a study[45] of the interaction between methyl methacrylate and Lewis acids. The formation of complexes between the amide group of acrylamide and the salt is confirmed by kinetic data on the effect of acetamide on the polymerisation of acrylamide in DMSO in the presence of lithium bromide. If the vinyl group had contributed to the formation of a complex between acrylamide and the salt, the rate of polymerisation of the acrylamide would not have been affected by the addition of acetamide. Evidently acetamide (like acrylamide) forms a complex with lithium bromide, and the addition of a saturated amide to the reacting system creates a competition between the acrylamide and the acetamide for the formation of a complex, which lowers the rate of polymerisation. The fact that even small additions of acetamide (as compared with the acrylamide) produce a marked decrease in the rate of polymerisation is evidence that the formation of a complex between the salt and a saturated amide has a higher probability than the same reaction with the unsaturated acrylamide. PMR spectroscopy results[36,40] lead to the same conclusion: under otherwise identical conditions the signal which characterises the protons of the amide group is shifted by the addition of lithium bromide by 0.30 and 0.23 ppm for acetamide and acrylamide respectively.

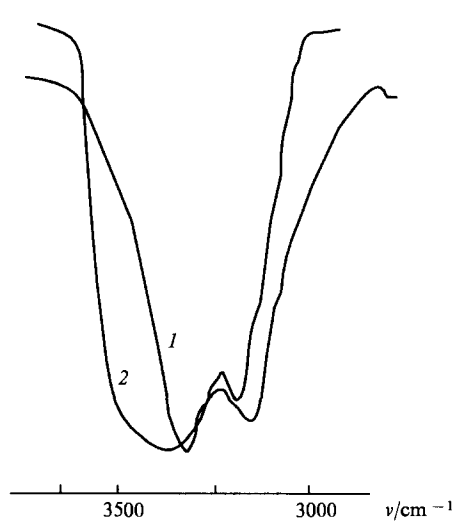

Figure 6. IR spectra of solutions in DMSO (*1*) and in DMSO + LiBr (*2*). Concentration of acrylamide 0.5 M, of salt 0.75 M.

The PMR spectroscopy data indicate an increase in the double-bond character of the C–N bond in acrylamide after the addition of the Lewis acid. It may be assumed that the presence of a C=C double bond undergoing conjugation with the C=O bond of the amide lowers the probability of complex formation between the acrylamide and the salt as compared with acetamide.

According to the IR and PMR spectroscopy data the amount of monomer complexed in the reaction mixture is small. Therefore we may assume that the complexed radicals (which have a high activity) and not the complexed acrylamide play the key role in the change in the rate of polymerisation of acrylamide in the presence of Lewis acids.

The stability constants of the complexes formed by acrylamide with salts (K) in various solvents have been calculated[36,38–40] from PMR data. The K values for 27 °C calculated by the Hildebrand–Benes method[46] from the dependence of the shift of the PMR signal at 7.50 ppm on the concentration of acrylamide at constant salt concentration are shown below:

Solvent	DMSO	DMSO	THF	Water
Salt	LiBr	$CaCl_2$	$CaCl_2$	LiBr
K/L mol^{-1}	0.066	0.14	0.23	0

As in the case of lithium bromide, in systems containing lithium chloride or calcium chloride the complexed radicals play the main part in the polymerisation process. However, at high salt concentrations the contribution from the complexed monomer cannot be ignored. This is specially true of polymerisation in a DMSO solution of calcium chloride, since the power to form complexes with acrylamide is highest in this salt.[36–40]

The following kinetic scheme for the formation of a complex between the reacting species (monomer and radical) and the salt and also for the polymerisation of acrylamide in the presence of Lewis acids was derived[36–40] from the reported kinetic and spectroscopic data.

If $R_c^{\cdot}$ radicals bound in a complex take part in the polymerisation process their concentration in the reaction system is determined by the reaction

$$\text{Salt} + R^{\cdot} \xrightarrow{K} R_c^{\cdot}.$$

If the concentration of the salt is much greater than the concentration of the radicals we have

$$[R_c^{\cdot}] = K[\text{Salt}]([R^{\cdot}]_0 - [R_c^{\cdot}]).$$

and

$$[R_c^{\cdot}] = \frac{K[\text{Salt}][R]_0}{1 + K[\text{Salt}]}.$$

On the assumption that the chain propagation reaction is characterised by the constant k_p when the participating radicals are not complexed and by the constant k_p' in the case of complex-bound radicals we can write the following equation for the overall rate of polymerisation in the presence of a complex-forming salt:

$$V = [M]\{k_p([R^{\cdot}]_0 - [R_c^{\cdot}]) + k_p'[R_c^{\cdot}]\}. \quad (1)$$

After substituting for $R_c^{\cdot}$ we find

$$V = [M][R^{\cdot}]_0\left(\frac{k_p}{1 + K[\text{Salt}]} + \frac{k_p'K[\text{Salt}]}{1 + K[\text{Salt}]}\right). \quad (2)$$

If $K[\text{Salt}] \ll 1$ the overall rate of polymerisation is

$$V = [M][R_0^{\cdot}](k_p + k_p'K[\text{Salt}]). \quad (3)$$

For a polymerisation process involving not only radicals bound in a complex but also complexed monomer molecules the following rate equation for the polymerisation has been obtained:

$$V = [M][R^{\cdot}]_0(k_p + k_1[\text{Salt}] + k_2[\text{Salt}]^2). \quad (4)$$

Here k_1 and k_2 are constants which characterise the rate of the chain propagation reaction of the corresponding complexed species and the stability constant of the complex. The term $k_2[\text{Salt}]^2$, which does not appear in Eqn (3), results from allowing for the interaction of complexed radicals with the monomer.

It follows from Eqn (4) that the overall rate of polymerisation should increase linearly with the concentration of the monomer, and that the order of the reaction with respect to the salt as a function of the relative values of k_p, $k_1[\text{Salt}]$, and $k_2[\text{Salt}]^2$ should vary from 0 to 1 if only complexed radicals contribute to the polymerisation [see Eqn (3)], or from 0 to 2 if both complexed radicals and the monomer bound in a complex are involved. Therefore the overall order of the polymerisation reaction with respect to the monomer and the salt (i.e. when the concentrations of the salt and of the monomer are both changing, but the ratio of these components of the reaction mixture is held constant) should increase from 1 to 2 or from 1 to 3 respectively with the salt concentration. The experimental data shown in Table 3 agree satisfactorily with these predictions. They also confirm the participation of the complexed monomer in the polymerisation of acrylamide in a DMSO solution containing calcium chloride. This is not surprising, since the concentration of complexed acrylamide in this system is approximately 15%–20% of the total concentration of monomer under the conditions corresponding to the maximum rate in curve *4* of Fig. 4.

In order to explain the mechanism of the effect of inorganic salts on the radical polymerisation of acrylamide the absolute values of the rate constants of the elementary reactions for the propagation and termination of the polymer chains were determined for the reaction in DMSO in the presence of various salts.[38–40] It was found that the changes in the rate of polymerisation of acrylamide can be attributed almost entirely to changes in the rate constants for the propagation (k_p) and termination (k_t) of the chains, and are not dependent on changes in the rate of initiation produced by the addition of salts (see Table 3 and Fig. 7). A similar state of affairs was observed in the polymerisation of acrylonitrile in the presence of Lewis acids.[42]

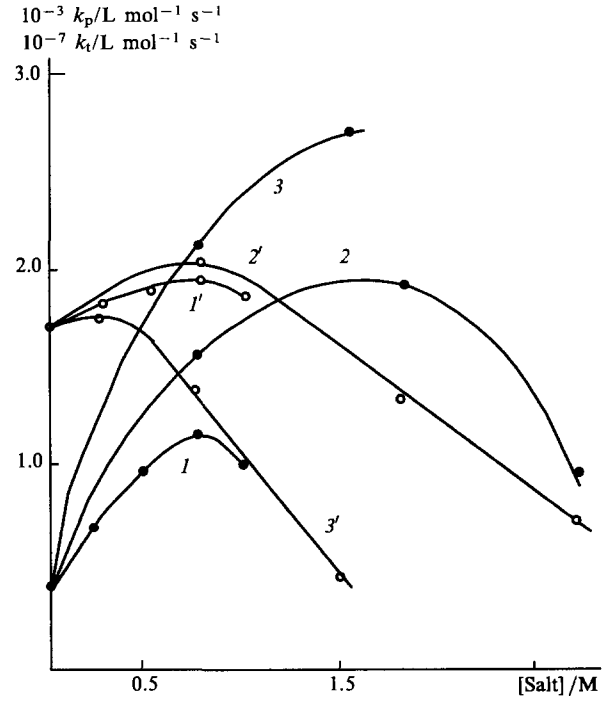

Figure 7. Dependence of the rate constants for the propagation (*1*–*3*) and for the termination of the chains (*1′*–*3′*) on the salt concentration during the polymerisation of acrylamide in DMSO at 30 °C. Salt: (*1*) LiBr, (*2*) LiCl, (*3*) $CaCl_2$.

The changes in the overall rate of polymerisation observed after the addition of lithium bromide to a solution of acrylamide in DMSO are due mainly to changes in k_p (since the changes in k_t are only slight). Additions of this salt lower the activation energy of the chain propagation reaction, and this effect is associated with a decrease in the complex formation constant with temperature. Thus an increase in temperature is accompanied by a decrease in the stability constant of the complex, and therefore also in the concentration of complexed radicals, and this leads to a less steep temperature dependence of the rate of chain propagation.

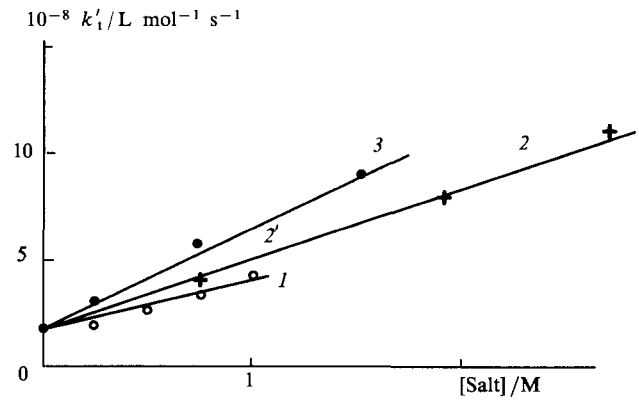
The complex formation constant decreases as the polarity of the solvent increases. This accounts for the influence of the nature of the solvent on the polymerisation of acrylamide in the presence of lithium bromide or calcium chloride. The effect of the salt on the polymerisation is greatest in tetrahydrofuran ($K = 0.23$ L mol^{-1}), whereas in an aqueous solution no acceleration is produced by the salt (the stability constant of the complex in water is zero).

In the presence of complexing salts the constant k_p varies in the same sense as the change in the overall rate of polymerisation (see Table 3). The experimentally observed dependence of the chain termination rate constant on the salt concentration is due to the diffusion control of the polymer chain propagation reaction. We know[43] that the chain termination rate constant is directly proportional to the fluidity of the reaction system. Therefore we used the formula[40]

$$k_t' = \eta k_0$$

(where k_t' is the experimental value, and η is the viscosity of the initial reaction mixture relative to DMSO) to calculate the k_t' values for a viscosity equal to that of pure DMSO. It was shown that the k_t' values are directly proportional to the salt concentration (Fig. 8), which suggests an increase in the reactivity of the polymeric radicals with increasing salt concentration and confirms the concept of complex formation by polymeric radicals.[36-40]

The difference in the chain propagation rate constants observed in the homogeneous polymerisation of acrylamide in DMSO containing various salts can be attributed to different degrees of complex formation between the active centres and the salt. It should not be forgotten that free radicals both bound and not bound in a complex contribute to the polymerisation. An increase in the complex formation constant results (not surprisingly) in an increased number of complexed active centres and therefore in an increase in the effective rate coefficient of the chain propagation reaction. Since the complex formation constant for potassium chloride with acrylamide in DMSO is higher than for lithium bromide we may suggest that the complex formation constants of these salts with polymeric radicals vary in the same sequence. Therefore the propagation of chains should have its highest specific rate in the presence of calcium chloride and its lowest in the presence of lithium bromide, as is indeed observed experimentally. It follows from PMR spectroscopy data that zinc chloride does not form a complex with acrylamide in a DMSO solution. Therefore the addition of this salt to a solution of acrylamide in DMSO does not affect the overall rate of polymerisation.



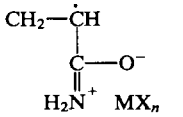


Figure 8. Plots of the rate constant of the chain termination reaction reduced to a single viscosity for the polymerisation of acrylamide in DMSO at 30 °C against the salt concentration. Salt: (*1*) LiBr, (*2*) LiCl, (*3*) $CaCl_2$.

The formation of a complex between the acrylamide molecules and the salts is accompanied by an increase in the distance between the signals in the PMR spectra which characterise the protons of the amide group in the monomer. Whereas the signal at 7.0 ppm is almost unaffected by the addition of salts the signal at 7.5 ppm is shifted towards lower

energies, indicating an increase in the double-bond character of the C–N bond in acrylamide as a result of the formation of a complex with the salt.[36,38]

The higher reactivity of the complexed acrylamide radical, which produces an increased rate of polymerisation of acrylamide in the presence of Lewis acids, can be attributed to the formation of the structure

whose most important feature is the localisation of an unpaired electron on the carbon atom.

In the PMR spectrum the distance between the signals which characterise the protons of the amide group in acrylamide decreases at higher temperatures, and both signals (at 7.0 and 7.5 ppm) become broader. At a well defined temperature the two signals merge together. This temperature is determined by the energy of the rotation round the C–N bond, and depends on the degree of double-bond character between these two atoms. The merging temperature of the singlets is strongly dependent on the nature of the complexing salt, and increases on changing from lithium bromide (80 °C) to lithium chloride (92 °C) and to calcium chloride (106 °C) (Fig. 9). This sequence shows that the double-bond character of the C–N bond is more marked in acrylamide complexed with calcium chloride than in acrylamide complexed with lithium salts.

The presence of a single signal in the PMR spectrum of acrylamide denotes free rotation round the C–N bond. In this case the presence of a Lewis acid in the system does not affect the reactivity of the acrylamide radical, and therefore also the rate of polymerisation of acrylamide. Thus, in the polymerisation of acrylamide in the presence of lithium bromide in DMSO at 80 °C, i.e. under conditions which produce only one signal from the protons of the amide group in the PMR spectrum of acrylamide, the addition of salt (in the region of the maximum in curve *1* of Fig. 2) does not affect the rate of polymerisation as compared with the polymerisation of acrylamide without the salt.

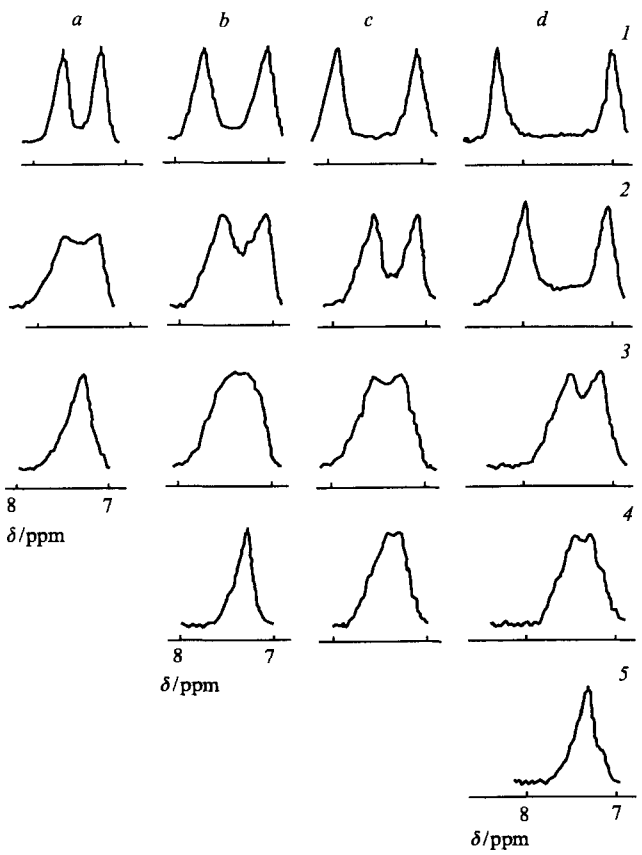

Figure 9. Effect of temperature on the shape of the PMR spectrum of acrylamide in DMSO in the presence of various salts. Salt: (*a*) none, (*b*) LiBr, (*c*) LiCl, (*d*) $CaCl_2$; *T*, °C: (*1*) 27, (*2*) 50, (*3*) 70, (*4*) 90, (*5*) 106.

The decrease in the overall rate of polymerisation and in the rate constants of the chain propagation and termination reactions beyond their maxima may be due to a change in the conformational characteristics of the macromolecules in the solution at high salt concentrations. The addition of a large quantity of salt probably degrades the thermodynamic quality of the solvent, and therefore it lowers the rate coefficients of the propagation and growth of the chains (as is found in the homogeneous radical polymerisation of acrylamide in the absence of salts[6,47,48]). Therefore the maximum in the plots of the overall rate of polymerisation and of the rate coefficient for the growth of the chains against the concentration of the salt is probably due to the competing effects of complex formation (leading to an enhanced rate of polymerisation and to an increased rate coefficient for the propagation) and of the conformation of the macromolecules (i.e. of the salting-out effect of the salts). The greater complex-forming capacity in lithium chloride and in calcium chloride (as compared with lithium bromide) produces a shift in the maximum rate towards higher salt concentrations (see Fig. 4).

We know that in the radical polymerisation of hydrocarbon monomers the reactivity of the radicals and that of the monomers change in opposite directions.[23] Therefore the decrease in the rate of polymerisation in the presence of high concentrations of salt could also be due to the participation in the polymerisation reaction of monomer molecules bound in a complex, whose activity may be lower than the activity of noncomplexed acrylamide molecules. This approach was proposed earlier to account for the maxima on the plots of the overall rate of the process against the salt concentration in the polymerisation of methyl methacrylate.[23] The participation of complexed monomer molecules in the reaction can make a substantial contribution, since at high salt concentrations (and in spite of a relatively low complex formation constant) the number of complexed monomers should be appreciable. Thus, at 30 °C and a molar ratio of 4.0 between the calcium chloride and the acrylamide the fraction of complexed monomer should be ~30%. However, if allowance is made only for the change in reactivity of the complexed monomer and for its relative concentration the maximum in the dependence of the overall rate of polymerisation on the salt concentration should be found at lower concentrations for calcium chloride than for lithium bromide, since the complex formation constant of acrylamide is lower for the lithium salt than for calcium chloride.

III. Polymerisation of *N*-substituted acrylamides in the presence of calcium chloride

These ideas on the effect of the complex formation by the amide group of the monomer with the complexing Lewis acids on the polymerisation kinetics were confirmed by studies of the polymerisation of derivatives of acrylamide (methacrylamide and *N-tert*-butylacrylamide) in various solvents in the presence of calcium chloride. The photopolymerisation of *N-tert*-butylacrylamide in *N*-methylpyrrolidone and that of methacrylamide in formamide have been studied.[49] The polymerisation of these monomers takes place under homogeneous conditions both in the absence of a salt and in the presence of calcium chloride. In every case the initial rate of the polymerisation becomes constant immediately after the application of UV light. The dependence of the overall rate of the polymerisation on the salt concentration is shown in Fig. 10. For comparison the figure also shows data for

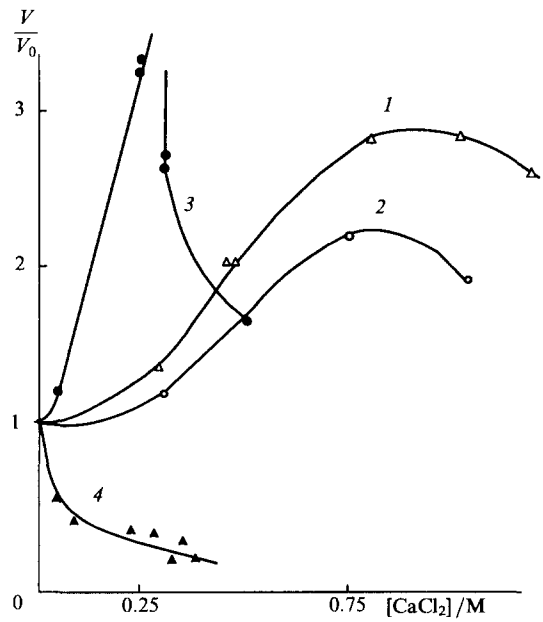

Figure 10. Dependence of the relative rate of polymerisation of acrylamide and its derivatives in various solvents on the concentration of calcium chloride at 20 °C. Concentration of monomer 0.5, concentration of DAA 3×10^{-3} M. System: (*1*) acrylamide in formamide, (*2*) methacrylamide in formamide, (*3*) acrylamide in *N*-methylpyrrolidone, (*4*) *N-tert*-butylacrylamide in *N*-methylpyrrolidone.

the polymerisation of acrylamide in formamide and in *N*-methylpyrrolidone. It follows from these results that in the polymerisation of acrylamide in both these solvents and in the polymerisation of methacrylamide in formamide additions of calcium chloride initially produce a large increase in the reaction rate, which goes through a maximum at a definite concentration of the salt before falling off again. The initial rate of polymerisation in these systems is proportional to the square root of the rate of initiation; the order of the reaction with respect to the monomer is close to unity. The $k_p/k_t^{1/2}$ ratios were calculated from the overall rate of polymerisation and from the rate of initiation, determined by measurements in the presence of an efficient radical polymerisation inhibitor (2,2,6,6-tetramethyl-4-oxopiperidine-*N*-oxyl). In the polymerisation of acrylamide this ratio increases from 0.61 in the absence of the salt to 2.0 when calcium chloride is added ($[CaCl_2]:[\text{acrylamide}] = 1.8$). In the case of methacrylamide the parameter $k_p/k_t^{1/2}$ increases from 0.06 to 0.14 when the same amount of salt is added. Comparing the overall rates and the $k_p/k_t^{1/2}$ values for these systems shows that the changes in the rate of polymerisation produced by the addition of calcium chloride are almost wholly due to changes in the rate of the chain propagation and termination reactions.

The effect of calcium chloride on the polymerisation of methacrylamide in formamide is less marked than in the case of acrylamide. This difference is due partly to a decrease in the complex formation constant between methacrylamide and its radical, and partly to a decrease in the same parameter for calcium chloride. PMR spectroscopy data also confirm that the complex formation of methacrylamide with lithium bromide is weaker than the corresponding reaction of acrylamide. The addition of lithium bromide (0.75 M) to a solution of acrylamide in DMSO (0.5 M) increases by 0.30 ppm the spacing of the signals which characterise the protons of the amide group. On the other hand with methacrylamide the increase in the spacing of the signals from the protons of the amide groups is 0.20 ppm under similar conditions. Other results[32] also confirm that methacrylamide is less reactive towards the formation of complexes with Lewis acids.

In contrast to acrylamide and methacrylamide no increase in the rate of the process is observed when calcium chloride is added to *N-tert*-butylacrylamide. Conversely, the addition of even small amounts of this salt (0.04 M at a monomer concentration of 0.5 M) markedly lowers the rate of homogeneous polymerisation of this monomer in *N*-methylpyrrolidone. An increase in the salt concentration produces a further decrease in the rate of polymerisation of *N-tert*-butylacrylamide (see Fig. 10). Most probably, the formation of a complex between the amide group and the salt is seriously hindered (if not completely suppressed) by the presence of a bulky *tert*-butyl substituent on the nitrogen atom of *N-tert*-butylacrylamide. As a result the addition of calcium chloride to a solution of *N-tert*-butylacrylamide does not increase the rate of polymerisation but only produces a 'salting-out' effect which degrades the thermodynamic quality of the solvent and is accompanied by a decrease in the overall rate of polymerisation. It should be noted that the results published from our laboratory[49] are consistent with the report[35] that in polar solvents the spontaneous polymerisation of *N-tert*-butylacrylamide in the presence of Lewis acids takes place slowly or not at all.

IV. Complex-radical polymerisation of acrylamide in the presence of zinc chloride

It is of interest to examine the causes of the difference in behaviour of salts such as lithium chloride and bromide, and calcium chloride (on the one hand) and zinc chloride (on the other) in the homogeneous polymerisation of acrylamide in DMSO. Zinc chloride is a Lewis acid of moderate strength, and it effectively accelerates the polymerisation of several other vinyl monomers such as acrylonitrile, methyl methacrylate, and other esters of acrylic and methacrylic acid. Since metal ions are involved[27,28] in complex formation between inorganic salts and amides it could be suggested that the different effects of salts on the polymerisation of acrylamide in DMSO are related to differences in their degree of dissociation in the relatively basic solvent DMSO.[36-40]

In order to test this hypothesis the dissociation of various salts in DMSO was measured, and the polymerisation of acrylamide in the presence of zinc chloride was also studied in another solvent.[50] The dissociation of the salts was determined by studying the dependence of the electric conductivity of their solutions in DMSO on the salt concentration, and the equivalent conductivity at infinite dilution (λ_∞) was obtained. To simplify the calculation all the salts were treated as 1:1 electrolytes. The λ_∞ values found in this way for lithium chloride and bromide and for calcium chloride lie in the range of 33–39 Ω^{-1} cm^2 (g-equiv)$^{-1}$, in good agreement with published data.[51] The degree of dissociation of the salts (α) was calculated as in the case of weak electrolytes: from the ratio of the specific to the equivalent conductivity. The results thus obtained showed that at concentrations of lithium salts and of calcium chloride between 0.2 and 0.3 M their dissociation is not less than 30%.

The conductivity of zinc chloride solutions in DMSO was almost constant at salt concentrations between 0.01 and 0.32 M, and did not exceed 1.0 Ω^{-1} cm^2 (g-equiv)$^{-1}$. Therefore the dissociation of this salt in the concentration range examined is ~1%–2%. It appears that the interaction of DMSO with zinc chloride produces an adduct which suppresses the dissociation of this salt in a solution of DMSO.

We know[52] that zinc chloride is partially dissociated in a mixed solution of water and tetrahydrofuran containing 77.5 mol% of water. The dissociation of the salt in that solution at concentrations of 0.1–0.5 M is 30%–12%, i.e. it is close to the dissociation of lithium salts and of calcium chloride in DMSO. The photopolymerisation of acrylamide in a mixture of THF and water was therefore studied in the presence of various concentrations of zinc chloride.[50] As can be seen from the results in Fig. 11 these polymerisation conditions produce a

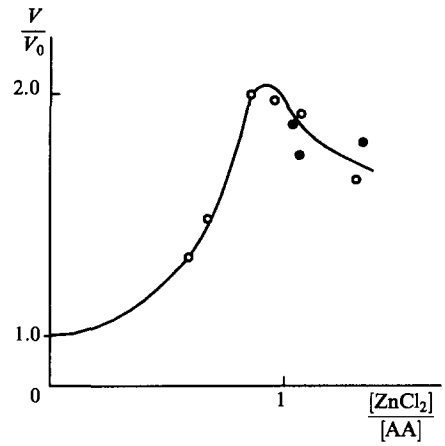

Figure 11. Dependence of the relative rate of polymerisation of acrylamide in a mixture of tetrahydrofuran and water containing 77.5 mol% of water on the concentration of zinc chloride at 20 °C. Concentration of acrylamide 0.5 M.

dependence of the overall rate of polymerisation on the concentration of the salt similar to the dependences observed in the polymerisation of acrylamide in DMSO in the presence of lithium salts or of calcium chloride (see Figs 2 and 4).

As in the case of the other salts, the changes in the kinetic parameters of the polymerisation of acrylamide in the presence of zinc chloride are due to complex formation between the reacting species and the salt. The formation of a complex between the monomer and zinc chloride in a mixture of water and tetrahydrofuran is confirmed by IR spectroscopy results: the 1695 cm^{-1} absorption band, characteristic of the C=O group in acrylamide, is shifted by 10 cm^{-1} towards lower frequencies by the addition of the salt.

The largest change in the overall rate of polymerisation of acrylamide in the presence of zinc chloride is somewhat smaller than for the polymerisation in DMSO in the presence of the other salts which have been studied. The lower effect of the salt during polymerisation in a mixture of water and tetrahydrofuran may be due (at least partially) to the influence of the water on the complex formation between the salt and the acrylamide, and/or its growing radical. Thus the addition of water should markedly lower the formation constant of the complex between the amide group and the salt.

Further evidence of the participation of the salt in an ionised state in the complex formation process was obtained during the study of the acrylamide–tetrahydrofuran–zinc chloride system. Additions of zinc chloride to a solution in tetrahydrofuran do not affect the IR spectrum of acrylamide, showing that in this solvent no complexes are formed between zinc chloride and the monomer.

The participation of lithium chloride (in an ionised form) in the complex formation with acrylonitrile radicals, leading to an increase in their reactivity and therefore also to an increase in the overall rate of polymerisation of acrylonitrile in the presence of lithium chloride, was first suggested by Bamford.[19] We may therefore assume that the influence of the nature of the solvent on the complex-radical polymerisation of vinyl monomers in the presence of inorganic Lewis acids is determined by the effect of the solvent on the dissociation of the Lewis acid, and also on the constant which defines the formation of a complex between the metal ions and the reacting species (the monomer and the polymeric radicals).

V. Conclusion

Available data show that (as in the polymerisation of vinyl monomers) inorganic Lewis acids have a substantial influence on the polymerisation of acrylamide and its derivatives. In every case the effect of inorganic salts such as metal halides is the result of their formation of a complex in the ionic form with the monomer, and also with the growing polymeric radicals, and of the change in the reactivity of the reacting species produced by this complex formation. The formation of complexes between the salts (Lewis acids) and the functional groups of the monomers and/or the growing polymeric radicals is strongly dependent on the polarity of the solvent in which the reaction is carried out. The acid–base characteristics of the solvent also have a definite effect. For this reason the Lewis acids show their strongest kinetic effect in polymerisations carried out in solvents having a relatively low polarity and no basic properties. In the radical polymerisation of acrylamide in aqueous solutions the addition of Lewis acids does not affect the kinetic parameters of the process or the molecular characteristics of the resulting polyacrylamide.

The results discussed in this review show that (as in the radical polymerisation of vinyl monomers such as acrylonitrile, methyl methacrylate, and the vinylpyridines) the addition of various Lewis acids to the reaction system can be used to control the radical polymerisation of acrylamide and its derivatives. In this way a change in the composition of the reaction medium can be used to carry out the polymerisation of acrylamide at different rates and to obtain polymers having different molecular masses and the required operational properties.

Abstract. New data on the thermal and photochemical reactions between hexa-1,3,5-trienes and cyclohexadienes as well as their heteroanalogues are surveyed. The bibliography includes 283 references.

I. Introduction

Electrocyclic reactions include the rearrangement of linear alkenes with a conjugated system of π-bonds accompanied by the formation of a new σ-bond and ring closure as well as the reverse rearrangements involving the dissociation of a σ-bond in a cyclic unsaturated compound and the formation of compounds with a conjugated system of π-bonds. The study of such reactions began as early as the beginning of this century.[1–3] Among them, an important place is occupied by 1,6-electrocyclic reactions (1,6-ER), which are six-electron electrocyclic processes. These include the cyclisation reactions of hexatriene, its derivatives, and its heteroanalogues as well as the ring opening in cyclohexadiene. The cyclisation of hexatriene to cyclohexadiene was first achieved in 1964.

After the theory of pericyclic processes had been developed,[1–3] these studies began to develop vigorously. The details of the mechanism of the cyclisation of hexatriene were investigated and numerous theoretical studies of 1,6-electrocyclic reactions involving quantum-chemical calculations were published.

More than 800 communications on 1,6-ER have now been published and half of them appeared during the last decade. They include a series of reviews devoted to individual questions of 1,6-ER or problems associated with these reactions. Marvell's book,[4] in which the literature on thermal ER published up to 1979 is surveyed, appeared in 1980. Unfortunately it does not include photochemical electrocyclic reactions, which are of enormous interest for the understanding of the characteristic features of electrocyclic processes.

Among the latest advances in this field, mention should be made of the development of a new approach to the synthesis of cyclic systems: electrocyclic and other pericyclic reactions, occurring successively, making it possible to obtain a whole series of highly effective antibiotics; a series of investigations demonstrating that the 1,6-ER of trienes is one of the stages in the mechanism of the action of a series of highly active antitumour preparations; the development of new photochromic systems on the basis of the ER of hexatriene hetero-analogues.

The present review deals with the continuation of the present author's investigations[5,6] and contains data on thermal and photochemical 1,6-ER.

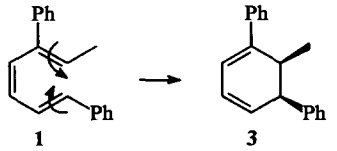
II. Theoretical investigations

There have been relatively few studies on the cyclisation of hexa-1,3,5-trienes and their hetero-analogues. Lewis and Steiner[7] calculated the activation parameters for this reaction by the method of Evans and Polanyi.[8] Marvell[9] used a modified Hendrickson method for the determination of the influence of substituents on the rate of reaction.

Attempts have been made to predict and explain the reactivity of hexa-1,3,5-trienes by Hückel's method[10] and by various semiempirical methods: PPP,[11] MINDO/2,[12] MINDO/3,[13–16] MNDO,[17] CNDO/2S,[18] and AM1,[19] as well as ab initio methods with the 3-21G, 6-31G, and 6-31G + MP2 basis sets.[20]

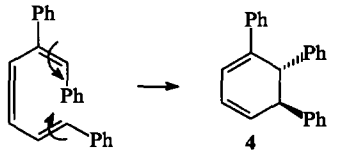
The activation energies for the thermal cyclisation of hexa-1,3,5-triene, determined by the MINDO/2 and MINDO/3 methods, are 24.6 kcal mol^{-1},[12] and 33.2 kcal mol^{-1},[16] respectively, which are close to the experimental value (29.4 kcal mol^{-1}).[1–3]

It has been shown that true transition states (TS) correspond to both the 'allowed' and 'forbidden' paths in the thermal reaction.[16] However, the transition state corresponding to the conrotatory path is asymmetric.[16] The authors[16] showed that, when the hydrogen atoms at the C(2) and C(5) atoms of the hexatriene system are located on one side of the molecular plane, a disrotatory transition state is indicated, while their location on each side of the molecular plane is evidence for a conrotatory transition state.[16]



Gatti et al.[21] used the topological theory of molecular structures to investigate the reactions of cyclic systems. Baldwin et al.[22] calculated the kinetic isotope effect in the cyclisation of hexa-1,3,5-triene with the aid of semiempirical calculations in terms of the 6-31G basis set. The values obtained proved to be close to the experimental data.[22]

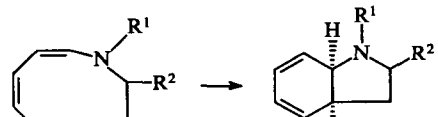
Bock et al.[23] presented data on the interconversion of benzene oxide and oxepine—the oxa-analogues of cyclohexadiene and hexa-1,3,5-triene. The calculations were performed by the AM1 and ab initio methods in terms of the 6-21G, 6-31G, and 6-31G + MP3 basis sets.[23] The authors showed that the best agreement between the calculated and experimental data is attained when third-order perturbation theory is used to perform the calculations.[23]



Calculations have been performed for the photochemical isomerisation of cyclohexadiene to hexatriene by means of the MRDCI method.[24]

III. Stereochemical characteristics of 1,6-electrocyclic reactions

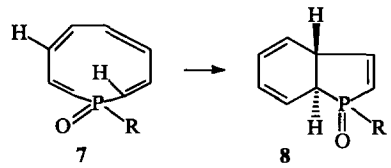
According to the rules for the conservation of orbital symmetry, the cyclisation of hexa-1,3,5-trienes should be disrotatory in the ground state and conrotatory in the excited state.[1-3] This conclusion has been confirmed by numerous theoretical and experimental studies.[1-3] According to MINDO/3 calculations, the disrotatory path to the cyclisation of hexa-1,3,5-triene is preferred to the conrotatory path to the extent of 14.5 kcal mol^{-1}.[13] Padwa et al.[25] showed that, on heating in toluene, the trienes **1** and **2** undergo disrotatory cyclisation to the cyclohexadienes **3** and **4**. The products of the conrotatory cyclisation were not detected under these conditions.



1 **3**

2 **4**

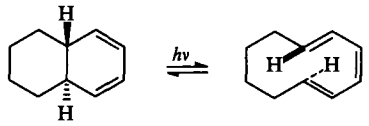
In a study of the thermolysis of *cis*-5,6-dimethylcyclohexadiene and 1-phenylhepta-1,3,5-triene, it was shown that the yield of the products of the conrotatory cyclisation is less than 0.5%.[4] The cyclic trienes **5** give rise to the bicyclic compounds **6** with a *cis*-disposition of the substituents at the bridging carbon atoms, which is also evidence for a disrotatory process.[26,27]



5a,b **6a,b**

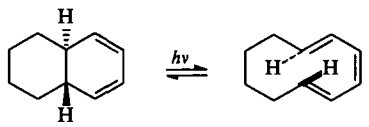
R^1 = CO_2Me, R^2 = CH_2Ph (**a**);

R^1 = Ph, R^2 = CH_2Ph (**b**).



However, it is essential to note that experiments indicating disrotatory cyclisation of compound **5** are not very convincing, since the bicyclic compounds **6** are formed from initial compounds having a specific geometry.

The experiment of Quin et al.[28] is especially interesting in this connection. They showed that the tetraene **7**, the geometry of which should promote conrotatory cyclisation, actually cyclises to the bicyclic product **8** with a *trans*-disposition of the hydrogen atoms at the bridging carbon atoms.[28]



7 **8**

The most striking examples confirming the conrotatory mechanism of the photocyclisation of the cycloala-1,3,5-trienes[21] is provided by experiments with the optically active dienes **9**. When the dienes **9** are irradiated, the ring opens with retention of the chirality and the photocyclisation of the resulting trienes **10** leads to the exclusive formation of the initial enantiomers.[29]

(−)-**9** (+)-**10**

(+)-**9** (−)-**10**

IV. Thermodynamic and kinetic investigations

The energy of activation for the formation of cyclohexa-1,3-diene from *cis*-hexa-1,3,5-triene is 29 kcal mol^{-1}.[4] Thermochemical determination of the heats of formation of cyclohexa-1,3-diene and *cis*-hexa-1,3,5-triene (25.38 and 40.58 kcal mol^{-1}) has made it possible to calculate the heat of formation of the transition state in this reaction (69.6 kcal mol^{-1}) and the energy of activation for the opening of the cyclohexa-1,3-diene ring (44.2 kcal mol^{-1}).[4]

The difference between the allowed disrotatory and forbidden conrotatory paths is 5 kcal mol^{-1} according to the authors' estimate[4] and 14.5 kcal mol^{-1} according to calculations by the MINDO/3 method.[13]

Kinetic studies have been carried out on the cyclisation of acyclic[4] and cyclic[4,29-39] hexatrienes as well as their heteroanalogues.[37-39]

Kinetic data have been published recently for photochemical 1,6-ER.[40,41] The most complete set of activation parameters for 1,6-ER has been presented in a monograph.[4] Treatment of the experimental data with the aid of CAMEO† programs permitted the following generalisations:[42]

1. When the triene system is incorporated in a ring, the activation energy diminishes by 2 kcal mol^{-1}.

2. *cis*-Substituents in the terminal positions of the conjugated systems increase the corresponding activation energy, apparently as a result of the deviation from planarity by 2 kcal mol^{-1}.

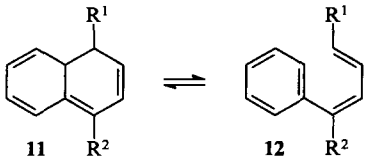
3. The activation energy for the cyclisation of trienes in which the terminal atom is part of a cumulene system is reduced by 10 kcal mol^{-1}.

4. The activation energy for the ER involving cyclic π-systems should be apprreciably lower than in the case of acyclic analogues. If the triene is part of a ring in which the number of atoms is more than six, then E_a diminishes by 10 kcal mol^{-1}.

5. If the cyclisation of trienes results in the formation of a three- or four-membered ring, then E_a increases by 10 kcal mol^{-1}.

6. If the cyclisation disturbs or generates aromaticity, E_a increases or diminishes by 8 kcal mol^{-1}.

† CAMEO = Computer-assisted mechanistic evaluation of organic reactions.

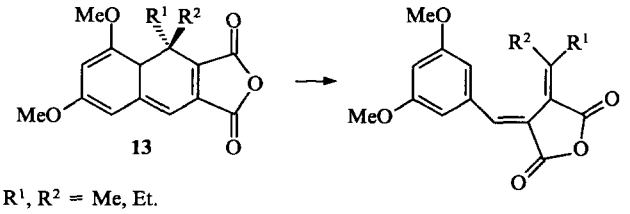


Unfortunately, the authors [42] did not include all the literature data then available in the information which they interpreted. Because of this, the well established fact that the cyclisation of 1,3,5-trienes is accelerated by the introduction of substituents in the 2- or 5-position remained outside the limits of their assessment. [4] Marvell [4] explained this effect by the decrease in the steric interactions of the substituent with the triene system in the transition state having the *cis*-(*Z*)-*cis*-conformation, compared with the initial compound which exists predominantly in the *cis*-(*Z*)-*trans*-form. [4]

V. Thermal processes

1. Reactions of acyclic compounds

It has been already noted that cyclohexadienes are more stable than hexatrienes, but if the opening of the cyclohexadiene ring results in the formation of an aromatic ring then this may alter and facilitate the process.

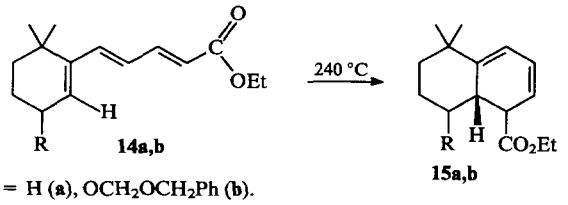


With the aid of deuterium labels, Lamberts and coworkers [43–45] showed that the flash thermolysis of the dihydronaphthalenes **11** results in the opening of the cyclohexa-1,3-diene ring and the formation of the butadiene derivatives **12**. The authors [45] established that only compounds where the recyclisation leads to the formation of an aromatic ring enter into the reaction.

11 **12**

R^1, R^2 = H, Ph, 4-MeC_6H_4.

The formation of an aromatic ring may be the cause of the ready opening of the cyclohexadiene ring in the tricyclic compound **13**. The reaction takes place even at 28 °C. [46]



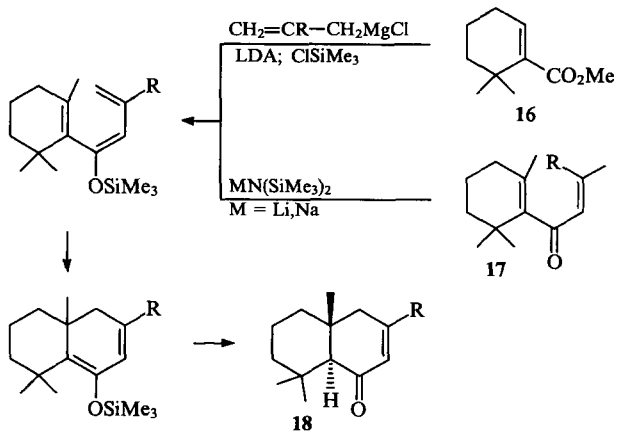
13

R^1, R^2 = Me, Et.

Trienes cyclise to hexadienes as a rule at elevated temperatures. [4] This is associated with the high energy barrier in the isomeric interconversions between the *cis*- and *trans*-isomeric forms of hexatriene. Thus compounds **14** cyclise only at temperatures above 240 °C. [47]

It has been shown [47] that the cyclisation of compound **14b** results in the formation of only one diastereoisomer **15b**, which indicates an effective stereocontrol by the OCH_2OCH_2Ph group. This implies the possibility of carrying out asymmetric syntheses of compounds **15**, which are the starting materials for the synthesis of forskolin — an oxygen-containing diterpene exhibiting a broad spectrum of physiological activity. [47]

240 °C



14a,b **15a,b**

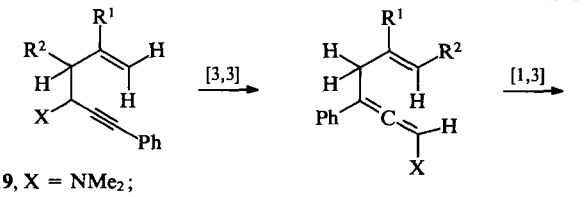
R = H (**a**), OCH_2OCH_2Ph (**b**).

The introduction of the electron-accepting carbamoyl groups in the 2- and 5-positions in the hexatriene system greatly facilitates the cyclisation and the process takes place smoothly already at 200 °C. [4]

The photochemical reaction involving the opening of the cyclohexadiene ring is frequently employed to obtain trienes with a *cis*-(*Z*)-*cis*-configuration. [4]

An interesting method for the generation of trienes by the Grignard reaction from methyl β-cyclogeranate **16** or by the deprotonation of the enone **17** has been described. [48]

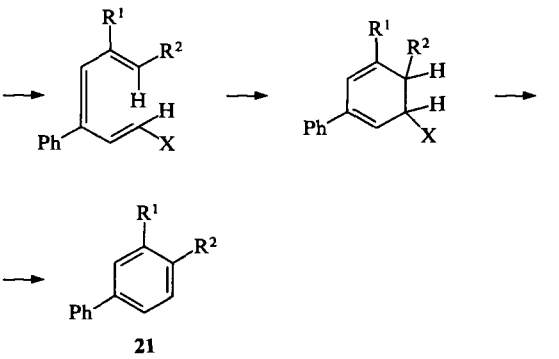
16 **17** **18**



R = H, Me;

LDA = $(Pr^i)_2NLi$.

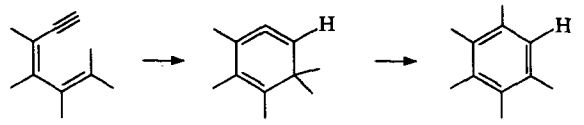
This process and the subsequent electrocyclisation constitute a new method of synthesis of the cyclic enone **18**.



It has been shown [49] that the ynamine **19** and the thioether **20** can serve as sources of hexatrienes. Moderate thermolysis of these compounds leads to the formation of the benzene derivative **21** (Scheme 1).

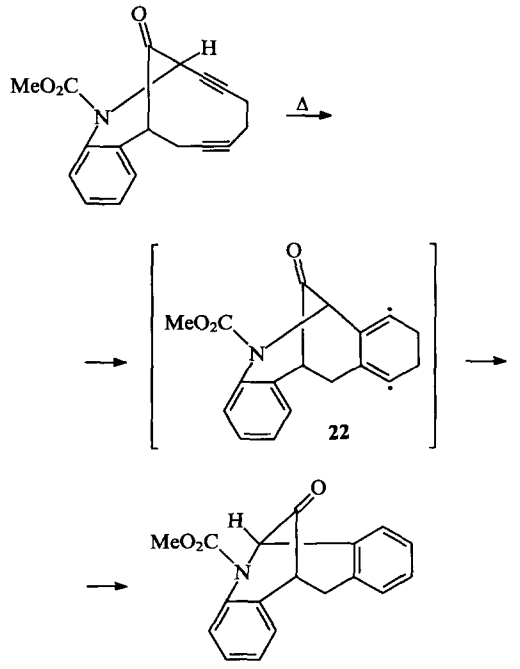
Scheme 1

19, X = NMe_2;



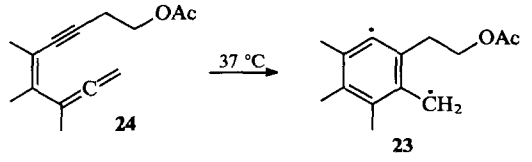
20, X = SMe.

21



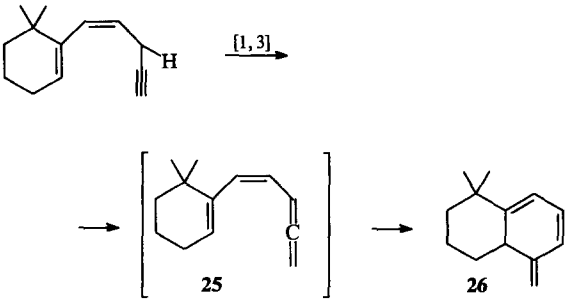
The substitution of one or both terminal double bonds in the hexa-1,3,5-triene by triple bonds does not prevent the cyclisation. [4]

The thermal cyclisation is carried out at elevated temperatures (~300 °C), but in the presence of strong bases it is possible to carry out this reaction at 80 °C. The rate-limiting stage is apparently the migration of hydrogen, but it has been shown that other groups can also migrate. [50]

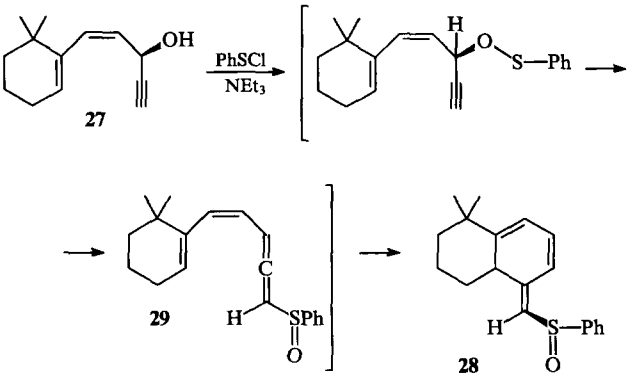


Systems of conjugated multiple bonds enter into the composition of the molecules of daunomycin, neocarzinostatin, and esperamicin–antibiotics with a high antitumour activity.[51–55]

It has been suggested[53,54] that the mechanism of the biological action of these compounds is associated with the formation of the tricyclic biradical **22**, which can abstract hydrogen from DNA and thus damage its helix. It has been demonstrated by kinetic investigations that the rate of cyclisation of such systems increases with decrease in the distance between the terminal atoms of the conjugated π-system.[51,52]

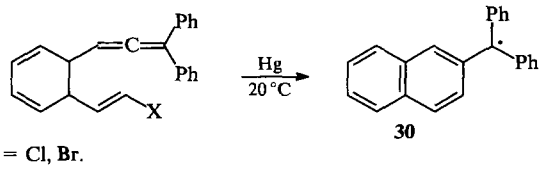


Ethynyldienes in which the terminal π-bond is part of an allene group are also biologically important. They are part of the molecules of antibiotics of the enediyne series.[56,57] It has been suggested that Bergman type electrocyclisation of these compounds, which leads to the biradical **23**, plays an important role in the cleavage of the DNA helix by antibiotics of the enediyne series.[56]



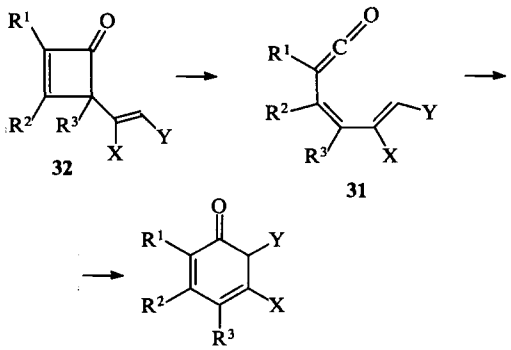
The activation energies E_a have been determined[56] for the cyclisation of a series of type **24** compounds and it has been shown that steric factors affect its rate to a greater extent than electronic factors.

The trienes **25**, in which one π-bond enters into the composition of an allene group, are unstable and are readily transformed into compounds **26**.[58]



It has been demonstrated[58] that the electrocyclic reaction takes place with a lower value of E_a than the 1,3-sigmatropic shift of hydrogen.

The interaction of the optically active *cis*-propargyl alcohol **27** with benzenesulfenyl chloride leads exclusively to the diastereoisomer **28**.[58] The authors[58] claim that this reaction is a stereospecific tandem centre–axis–centre transfer and that the cyclisation of compound **29** takes place via a disrotatory mechanism.

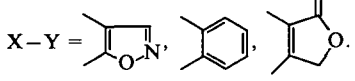


It is of interest to note that the cyclisation of butadienylallenes in the presence of elemental mercury leads to the stable triarylmethyl radical **30**.

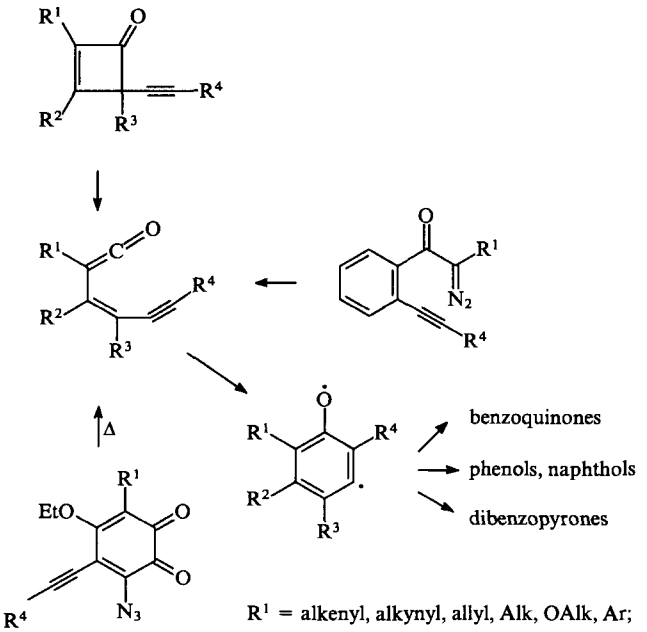
X = Cl, Br.

When one double bond of the 1,3,5-triene system is part of a ketene group, the rate of electrocyclisation increases greatly.[4]

The butadienylketenes **31** can be generated in the vacuum flash thermolysis of 5-(3-indolinylmethylene)-2,2-dimethyl-1,3-dioxane-4,6-dione[60] and on opening the ring in the cyclobutenes **32** having a vinyl group in the 3-position[60–67] including the case where the group forms part of the composition of the benzene system[65,66] or a heterocyclic system.[65,67]



32 31



R^1 = Alk, Ar, alkynyl; X = H, Me_3Si;

R^2 = OAlk; Y = OMe, H;

R^3 = H, Cl, OAlk, OH, SPh;

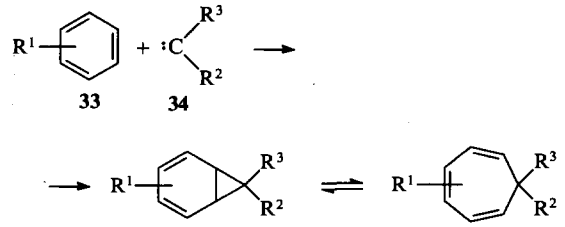
X–Y = 

The replacement of the vinyl group by the ethynyl group does not prevent cyclisation.[61,65,68–73]

R^1 = Cl, R^4 = Ar.

R^1 = alkenyl, alkynyl, allyl, Alk, OAlk, Ar;

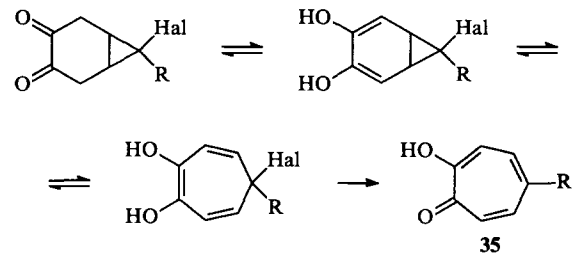
R^2 = Alk, OAlk, Ar;



R^3 = OH, OAlk, CN;

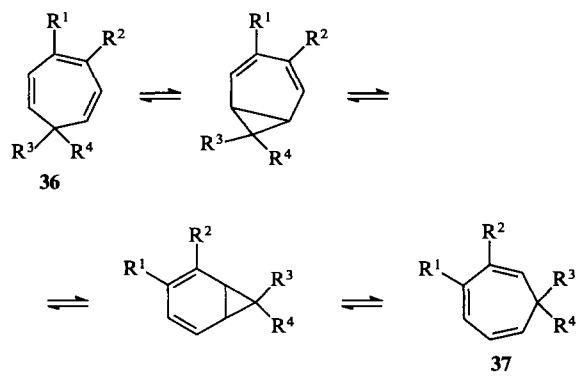
R^4 = Alk, Ar.

The reactions of cyclobutenes described constitute general and flexible methods of synthesis of benzoquinones, phenols, naphthols, and related compounds, which are constituents of many biologically important substances. Thus the methods have been used in the synthesis of a nonsteroid antiinflammatory agent—(±)-naproxen.[74]



2. Reactions of cyclic compounds

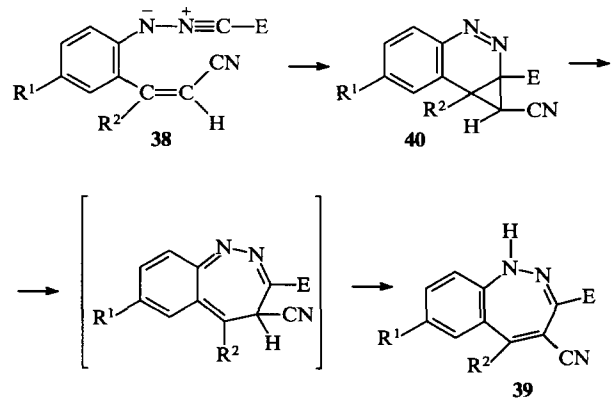
In the general case, ER in cyclic systems are facilitated compared with acyclic systems. As a consequence of the high strain energy of the three-membered ring, the interconversions between cycloheptatrienes (CHT) and norcaradienes (NC) occupy a special place in this series. The opening of the norcaradiene ring is one of the stages in the syntheses of cycloheptatrienes from the benzene derivatives **33** and from the carbenes **34**[4,75,76] and of the hydroxytrienes **35**[77] and also in the rearrangements of the cycloheptatrienes **36** and **37**.[78,79]



33 34

R^1, R^2, R^3 = H, Alk, Ar, CO_2Alk, CN.

35



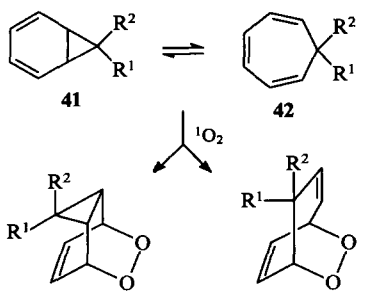
Hal = Cl, Br; R = Hal, H, Me_3Si.

36 37

R^1 = CO_2Me; R^2 = H, D; R^3 = Me, R^4 = CH_2OMe.

The rearrangement of the nitrile imines **38** to the benzodiazepines **39** also involves the 1,6-ER involving the opening of the norcaradiene ring.[80] The 2,3-diazanorcaradiene **40** formed in this reaction is stable; it is converted fully into the benzodiazepine **39** only on refluxing in benzene.[80]

38 40 39



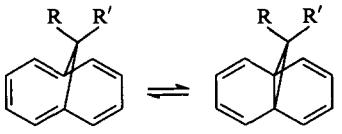
R^1 = H, R^2 = H;

R^1 = Cl, R^2 = Ph;

E = electron-accepting group.

The equilibrium between the norcaradienes and the cycloheptatrienes is as a rule appreciably displaced towards the latter and the concentration of the norcaradienes‡ in the mixture is low. Therefore, a very sensitive method is essential for the determination of the influence of the substituents on the equilibrium in the system.

The limitations in the use of NMR spectroscopy for these purposes have been noted by Adam et al.[82] At the same time, the method which they proposed for the determination of the position of equilibrium between the norcaradiene **41** and the cycloheptatriene **42** by using cycloaddition of singlet oxygen is inapplicable to the determination of equilibrium constants. It is in essence a variant of the method of competing reactions and makes it possible to determine the influence of substituents on the relative reactivities in the cycloaddition of the norcaradiene and the cycloheptatriene.[83,84]

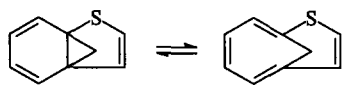


41 **42**

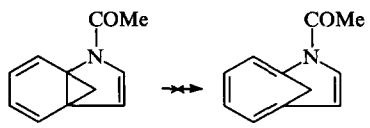
R^1, R^2 = H, Me, CO_2Me, Ph, 4-$MeO_2CC_6H_4$.

Kinetic studies have been made and quantum-chemical calculations of the activation parameters for this reaction have been performed.[85,86] According to kinetic data, the activation energy is only 7.7 kcal mol^{-1}.[83] Ab initio calculations in terms of the 4-31G basis set yield 7.3 and 2.3 kcal mol^{-1} for the forward and reverse reactions respectively in the cyclisation of the annulenes **43** to the norcaradienes **44**.[86]

The conversions of compounds **43** into compounds **44** are of great theoretical interest in connection with the aromatic properties manifested by the annulenes **43**, which contain 10 π-electrons.



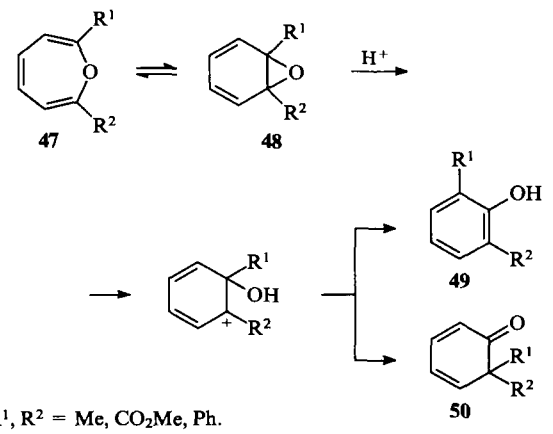
43 **44**



A topological approach has been applied to the study of the properties of 11-R, 11-R'-1,6-methano(10)annulenes.[21]

The existence of a critical bonding point in the 11,11-dicyano-derivative of compound **44** and in the β-phase of the crystals of the 11-cyano-11-methyl derivative of this annulene indicates a tricyclic structure for these substances. The authors[21] showed that the crystals are made up of two molecules; one has the norcaradiene structure **44** but with a low bond order, while the other has the annulene structure **43**. It is of interest to note that the bonds of the cyclopropane ring in compound **44** and the bridging bonds in compound **43** have an appreciable π-character and are conjugated with the π-system.[95]

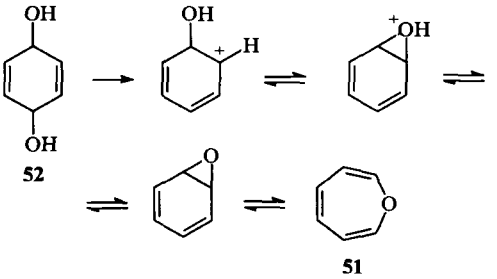
The data concerning the influence of substituents on the equilibrium position between cycloheptatrienes and norcaradienes have been compiled by Marvell[4] and in subsequent publications.[87-92] The introduction of electron-accepting substituents in the 7-position, the inclusion of the π-bonds of the norcaradiene structure in the aromatic rings, and the introduction of bulky substituents in the 3- and 5-positions are all factors stabilising the structure of the norcaradiene. It has been shown that the insertion of yet another bridge between the 1- and 6-positions increases the stability of the norcaradiene form.[4,93-96] This feature is illustrated particularly clearly by the heteroatomic systems **45** and **46** incorporating sulfur and nitrogen atoms.[95,96] Thus the content of the tricyclic compound **45** in the equilibrium mixture is 84%, while that of compound **46** is 100%.



45

46

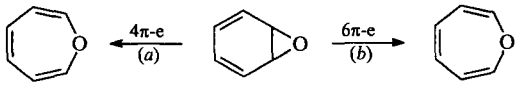
The interconversions of the heteroanalogues of the norcaradienes and cycloheptatrienes containing nitrogen,[97] oxygen,[98-100] sulfur,[101] phosphorus,[102] and boron[103] atoms instead of the methylene group have been described. The reactions of the oxygen-containing analogues have been most thoroughly investigated. It has been shown that arene oxides are the products of the metabolism of monocyclic and polycyclic aromatic compounds in plants, animals, and microorganisms[104,105] and that the reverse ring opening reaction to give oxepines is associated with their carcinogenic activity.[104,105]



The conversion of the oxepines **47** into arene epoxides **48** is the first stage of the rearrangement of the oxepines **47** into the phenols **49** and the cyclohexadienones **50**[106,107] and also in the reactions of the aza-analogues of these compounds.[107]

47 **48** **49** **50**

R^1, R^2 = Me, CO_2Me, Ph.

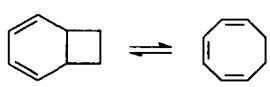


Conversely the retro-ER of the arene epoxides into oxepines is the last stage in the synthesis of type **51** compounds from compounds **52**.[108]

52 **51**

‡ The presence of the norcaradienes has been confirmed by NMR spectroscopy at low temperatures[81] and by X-ray diffraction of the xylene derivatives of this series.[93]

Benzene epoxide was first synthesised by Vogel et al.[109] about thirty years ago. It was shown that benzene epoxide is a little more stable than oxepine. The arene epoxide–oxepine equilibrium position is influenced by various factors: temperature, conjugation with the aromatic ring, the nature of the substituents, protonation, or complex formation. In the main, an analogy can be traced with the reactions of norcaradienes and cycloheptatrienes. The influence of various factors on the equilibrium between arene epoxides and oxepines has been examined in detail in a number of studies.[97,110–112] Two possible mechanisms of the conversion of aromatic arene epoxides into oxepines have been demonstrated[106] — the conrotatory opening of the oxirane ring (*a*) and the disrotatory opening of the cyclohexadiene ring (*b*).

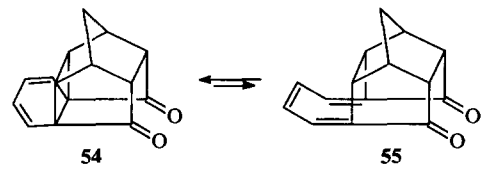


The choice in favour of the disrotatory 1,6-ER was made on the basis of the positive entropy of activation for the process determined from kinetic measurements and the lower activation energy than for the opening of the ring in oxiranes§ to give carbonyl ylides.[110–112] Kinetic studies on the 1,6-ER of arene epoxides and oxepines have been performed only for several compounds. This is associated mainly with the difficulty of determining the rates of fast reactions. The method for the determination of the rates of isomerisation of arene epoxides and oxepines involving the study of the degenerate racemisation of chiral arene epoxides at low temperatures, proposed by Jennings et al.,[112] is therefore a major achievement.

The relative stabilisation energies of arene epoxides and oxepines have been calculated with the aid of perturbation theory. The calculations explained the differences between the rates of racemisation of optically active polynuclear arene epoxides.[113]

Calculations for arene epoxides and oxepines by the AM-1 method and ab initio methods with various basis sets have been published quite recently. It has been shown that only the ab initio calculations in terms of the 6-31G basis set and involving the use of the third-order perturbation theory yield satisfactory heats of formation of benzene epoxide and oxepine.[23]

As a result of the lower strain energy of the cyclobutane ring compared with the cyclopropane ring, bicyclooctadienes are much more stable than bicycloheptadienes. The equilibrium between the bicyclooctadienes **52** and the octatrienes **53** and the rate of ER are influenced by various factors: electronic[4–35] and steric properties of the substituents,[114] the strain energy of dienes and trienes with cisoid double bonds, conjugation of double bonds with aromatic π-systems,[32] etc.



52 **53**

Apart from their theoretical interest, the 1,6-ER of cyclic trienes have also a considerable practical importance. Thus they have been used in the synthesis of vitamin A[115] and of endiandric acids.[116,117]

An increase in the size of the ring condensed with the cyclohexadiene leads to a greater stability of the bicyclic form compared with the monocyclic form,[4] which promotes the cyclisation of isomeric trienes. Thus compound **5a** cyclises at 75 °C,[26] while compound **5b** cyclises at room temperature.[27,28] The transoid trienes **10** cyclise even more readily (at −55 °C).

§ The isomerisation of the optically active *trans*-2-phenyl-3-(*p*-tolyl)-oxirane (conrotatory opening of the oxirane ring) takes place at high temperatures (180–247 °C) and has E_a = 35.9–41.1 kcal mol^{-1} and ΔS = −2 to +2 kcal mol^{-1} K^{-1}.

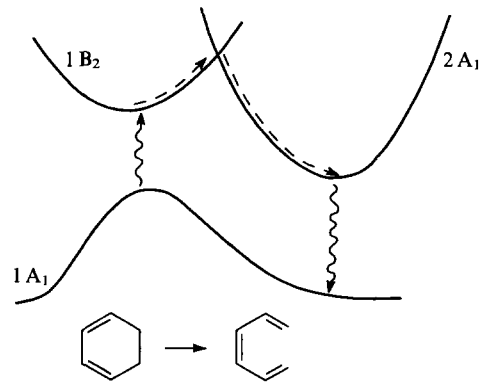
In conclusion of this section, we may note that in a later study[118] the authors were able to observe the 1,6-ER in the propellane systems **54** and **55**.

54 **55**

VI. Photochemical processes

It has been shown by means of a large number of examples that the interconversions between cyclohexa-1,3-dienes and hexa-1,3,5-trienes are effected photochemically as conrotatory processes.[4] However, it is claimed[16] that the cyclisation process does not involve the retention of the C_2 symmetry axis. The transition state on the potential energy surface (PES) in the ground state and the state corresponding to the minimum on the PES for the excited state are asymmetric.

It has been shown that these processes proceed via a ππ* excited state and are photochemical singlet reactions.[1–3,14,40,41] Kinetic[40,41] and quantum-chemical studies[14,41] permitted the conclusion that the photochemical opening of the ring in cyclohexadienes does not take place adiabatically and constitutes a more complex process. The first stage involves photoexcitation and transition from the ground state ($1A_1$) to the excited state ($1B_2$), in the second stage there is a transition (with a small energy barrier) to the next excited state ($2A_1$), then there is a nonadiabatic transition onto the potential surface for the conrotatory reaction, and the final stage involves the formation of the triene in the ground state (Fig. 1).



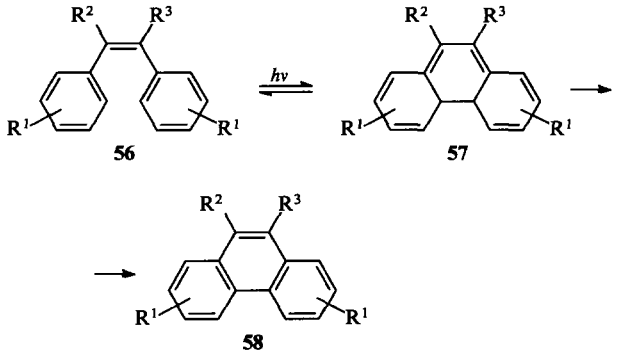


Figure 1. The mechanism of the photochemical opening of the ring in cyclohexadienes. The potential surfaces for the $1A_1$, $2A_1$, and $1B_2$ states are shown.

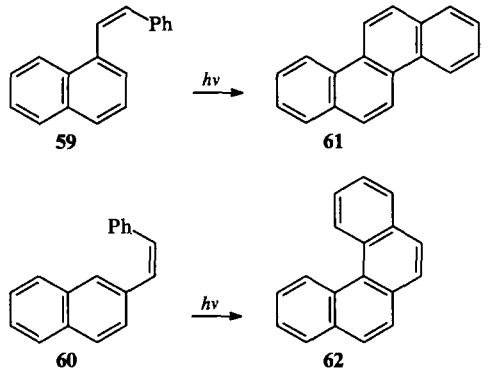
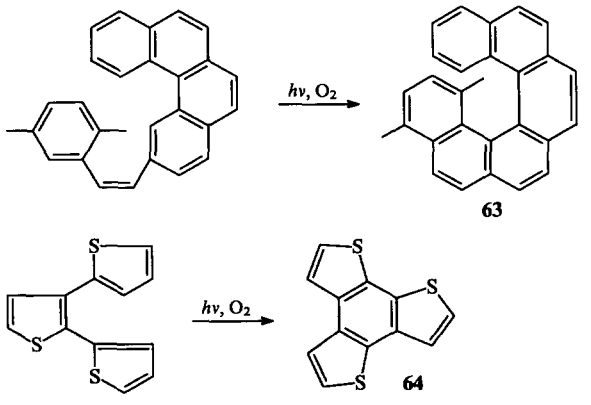
The photochemical reactions of simple cyclohexadienes and hexatrienes described by Havinga and coworkers[119–121] and also by their successors[122–124] have been the subject of a series of reviews[4,124–126] and we shall therefore not consider them in detail.



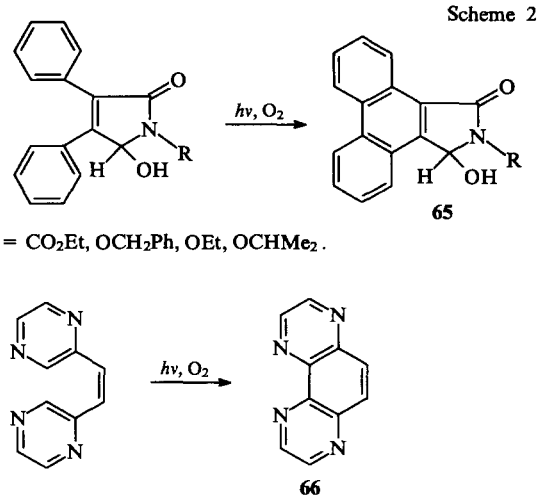
In describing thermal 1,6-ER, it was noted that the processes proceeding with breakdown of the aromaticity of the rings incorporating the double bonds of the triene or hexadiene system are hindered. In contrast to the thermal reactions, the opening of the cyclohexadiene rings and the cyclisation of hexatrienes are readily effected photochemically also in the case when one of the double bonds enters into the composition of an aromatic cyclic system.[17]

The photocyclisation of the substituted *cis*-stilbenes **56** to 4*a*, 4*b*-dihydrophenanthrenes **57**, which are unstable and are converted into the polynuclear arenes **58** in the presence of atmospheric oxygen or iodine, has been thoroughly investigated and is widely used in organic synthesis.[4]



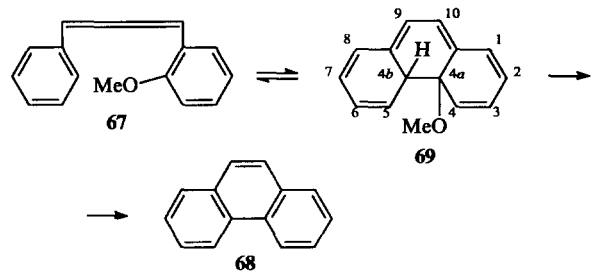
R^1, R^2, R^3 = H, Alk, Ar, OAlk, and others.

This reaction has been extended also to other arylhexatrienes. Thus the cyclisation of α- or β-(phenylvinyl)naphthalenes **59** and **60** leads to the formation of chrysene **61** and benzo[*c*]phenanthrene **62**.



Photocyclisation is used to obtain the helicenes **63** (including the optically active compound),[127] the heterocyclic compound benzotrithiophene **64**,[128] the phenanthropyrrolines **65**, and 1,4,5,8-tetraazaphenanthrene **66** (Scheme 2).[129,130]

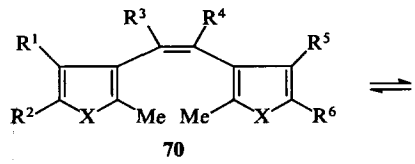
Scheme 2



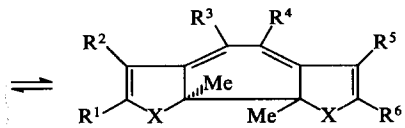
Scheme 2 (cont.)

R = CO_2Et, OCH_2Ph, OEt, $OCHMe_2$.

Mallory et al.[131] note that *meta*-substituted stilbenes give rise to mixtures of isomers which are difficult to separate into their components. They showed that the introduction of the methoxy-group leads to the regioselective cyclisation of compound **67** with participation of the substituted atom; the subsequent elimination of methanol, which is facilitated by the addition of a solution of sulfuric acid in *tert*-butyl alcohol, gives the individual phenanthrene **68**.



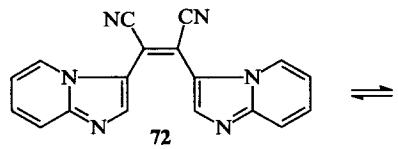
When amines are used in the absence of oxygen, aromatic dihydro-compounds of type **69** are obtained.[132] It has been shown that the amine behaves as a base and interacts with the 4*a*, 4*b*-dihydrophenanthrene formed initially, promoting proton transfer from the C(4*a*) atom to the C(4) atom. Propanethiolate promotes proton transfer to the 9-position, whilst sodium methoxide promotes such transfer to the 2-, 4-, and 9-positions, which leads ultimately to the formation of 1,4- and 9,10-dihydrophenanthrenes.[133]



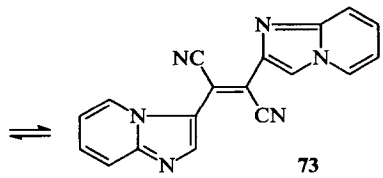
In connection with the discovery of the photochromic properties of 1,2-diheteroarylethenes, a number of studies on the synthesis of a wide variety of compounds of this series have been carried out.[16,134-137] It has been shown that 1,2-diheteroarylethenes **70** undergo a photoinduced thermally irreversible cyclisation to the coloured compound **71**. It is interesting to note that the acquisition of a colour–decolorisation cycle may be repeated more than 10 000 times without appreciable loss of efficiency.[116]

In contrast to other representatives of this series, compounds **71** [X = NMe; R^1, R^2 = $-(CH{=}CH)_2-$; R^3 = R^4 =CN; R^5 = R^6 = Me] have no thermal stability, like dihydrophenanthrenes,[4] while compounds of type **72**, containing imidazo[1,2-*a*]-pyridine residues, do not cyclise, undergoing the photoinduced *Z*–*E* isomerisation to compounds **73**[135] and are therefore of no interest as photochromic materials of this type.

The replacement of one imidazopyridine fragment in compound **72** by a thiophene fragment facilitates the 1,6-electrocyclic reaction.[135]



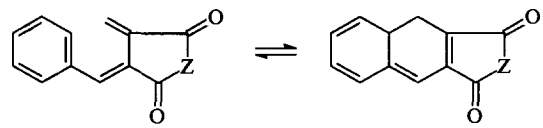
70



71

$R^1+R^2 = R^5+R^6 =$ 

R^3, R^4 = CN,  ; X = S, Se.

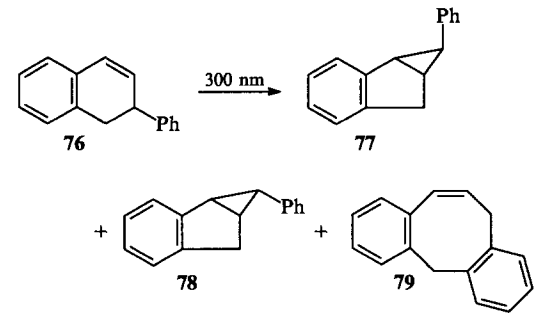


72

73

Nakamura and Irie[17] analysed the results of semiempirical calculations in terms of the MNDO approximation carried out for 1,2-di(3-furyl)-, 1,2-di(3-thienyl)-, 1,2-di(3-pyrrolyl)-, and 1,2-diphenyl-ethenes and showed that the energy barrier in the ring opening reaction is correlated with the difference between the energies of the ground states of the cyclic and open-chain forms; the smaller this difference, the higher the barrier.[17] The difference between the energies of the cyclic and open-chain forms is in its turn correlated with the aromatic stabilisation energy of the cyclic substituents. Thus the higher thermal stability of 1,2-diheteroarylethenes compared with 1,2-diarylethenes can be explained by the lower aromaticity of the heterocyclic compounds compared with benzene.[17]

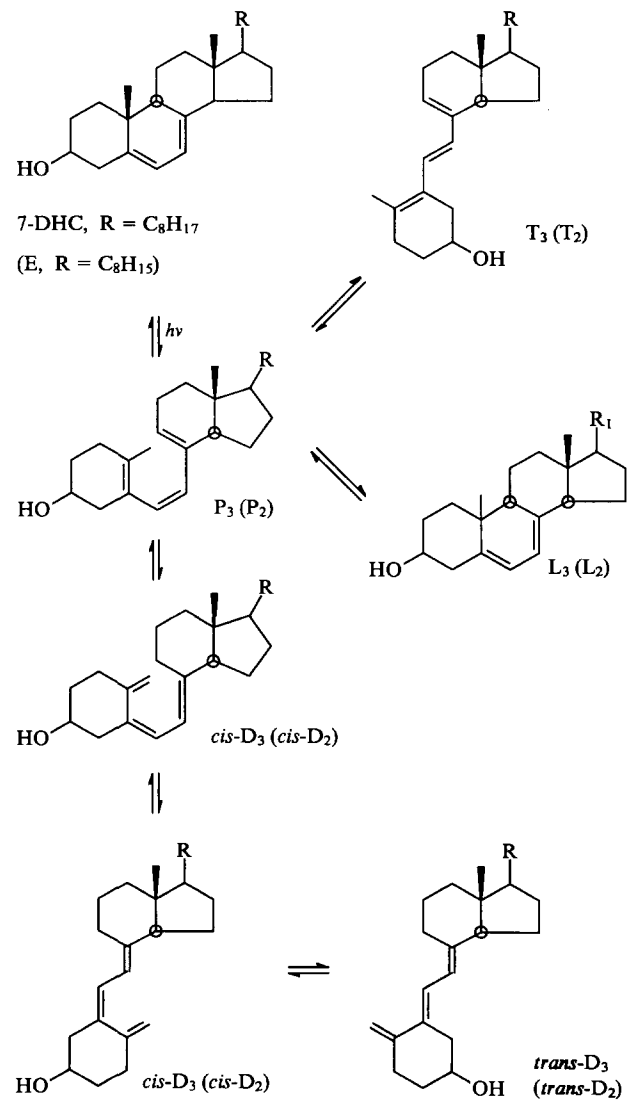
The phenomenon of photochromism in the fulgides **74** and fulgimides **75** is also due to the 1,6-ER of hexatrienes.



74, Z = O. **75**, Z = NR (R = Ph, Bz, Alk).

Reactions of this type have been described in a review[138] and those of the hetero-analogues of fulgides and fulgimides have been described in a number of other communications[139-144] and are therefore not considered here.

The ring opening reaction of cyclohexadienes, which occurs on UV irradiation, is used to synthesise trienes in the *cis*-(*Z*)-*cis*-conformation.[4] The ring-opening process is usually accompanied by side reactions — *Z*–*E* isomerisation, sigmatropic shifts of hydrogen atoms, and also 1,4- and 1,6-cyclisation.[122]



Thus irradiation of 2-phenyl-1,2-dihydronaphthalene **76** with UV light at a wavelength of 300 nm leads to three primary photoproducts: *endo*- and *exo*-6-phenylbenzobicyclo[3.1.0]hex-2-enes **77** and **78** and 7,12-dihydrodibenzo[*a*,*b*]cyclooctatetraene **79**.[44]

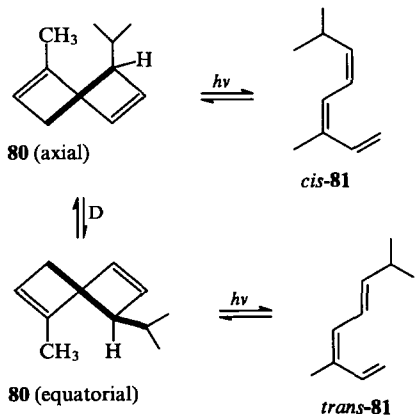
76 **77** **78** **79**

It has been shown[44] by means of experiments with 3,4-d_2-labelled specimens of compound **76** that the two isomers (compounds **77** and **78**) are formed via two paths — via the mechanism of the di-π-methane rearrangement and as a result of the electrocyclic ring opening with subsequent photocyclisation.

The complex photochemistry of 7-dihydrocholesterol (7-DHC) and ergosterol (E) became understood as a consequence of the studies of Havinga and coworkers.[119,120] Together with the electrocyclic ring opening and the formation of the (*Z*)-trienes P_2 and P_3, *Z*–*E* isomerisation, 1,4-ER, dimerisation, and sigmatropic transformations take place. The ratios of the products formed depend on the temperature, the diene concentration, and the wavelength of the irradiating light. The following scheme gives an idea about the photochemistry of the process (at a temperature below 0 °C):

It was shown that the singlet and triplet transformations of 7-DHC lead to different products.[119] Photolysis in the range 271–310 nm gives relatively high yields of P_3 (provitamin D); irradiation at shorter wavelengths leads to the predominance of tachysterone (T_3), while irradiation at longer wavelengths gives rise to compound L_3.[145,147]

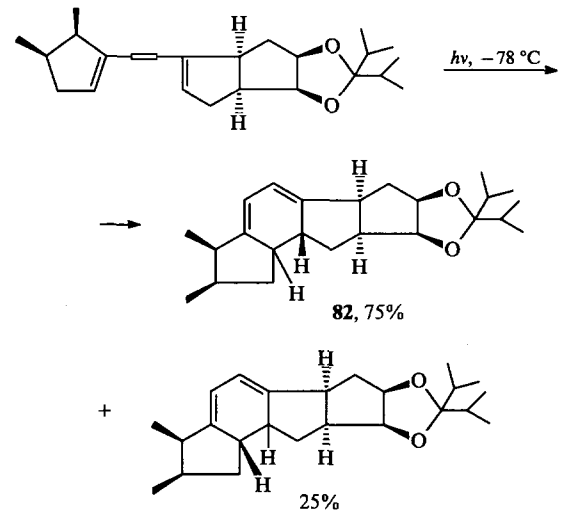
In the synthesis of vitamin D, the photochemical reaction is usually arrested at 50% conversion of 7-DHC and provitamin D (P_3) is isolated by fractional crystallisation. The provitamin is then converted into the target product as a result of a 1,7-sigmatropic shift.



It has been noted[145,148] that, when the technique involving laser photolysis with subsequent irradiation by light at wavelengths of 248 and 473 nm, 248 and 353 nm, and 254 (300) and more than 330 nm is used, predominantly P_3 (P_2) is formed.

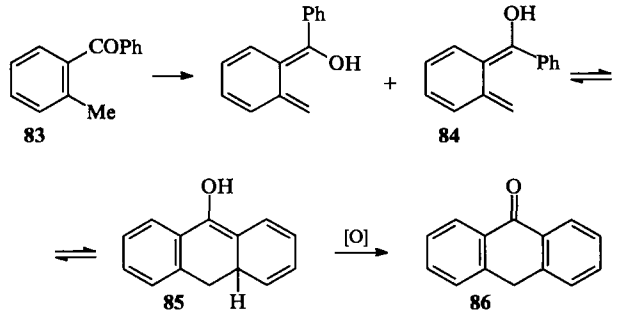
The photochemistry of vitamin D stimulated studies on the photochemical reactions of simple hexa-1,3,5-trienes and related systems. The principle of Non-Equilibriation of Excited-state Rotamers (NEER) was developed as a result of these investigations.[119,149,150] According to this principle, the lifetime of the singlet state is not long enough for the isomerisation of different conformers, so that conformers of each type give rise to their own assortment of products.

Thus the ratios and compositions of the substances formed on photolysis of hexatrienes are determined by the isomeric compositions of the conformers of the initial compound in the ground state.[119]

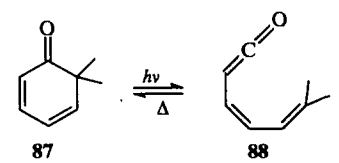


Later the NEER principle was extended to simple hexatrienes. It was shown that an increase in the bulk of the substituents in the 2- and 5-positions in the triene system increases the fraction of the *cis*-(*Z*)-*cis*-isomer and therefore promotes cyclisation.[151]

In their study of the influence of the conformational control on the ratio of the products formed on photolysis of α-phellandrene **80**, Baldwin and Krueger[152] demonstrated the applicability of the NEER principle to retro-ER.[152] They showed that the fraction of the isomer with the axial isopropyl group increases with decrease in reaction temperature and there is a consequent increase in the fraction of the *cis*-isomer of compound **81**.

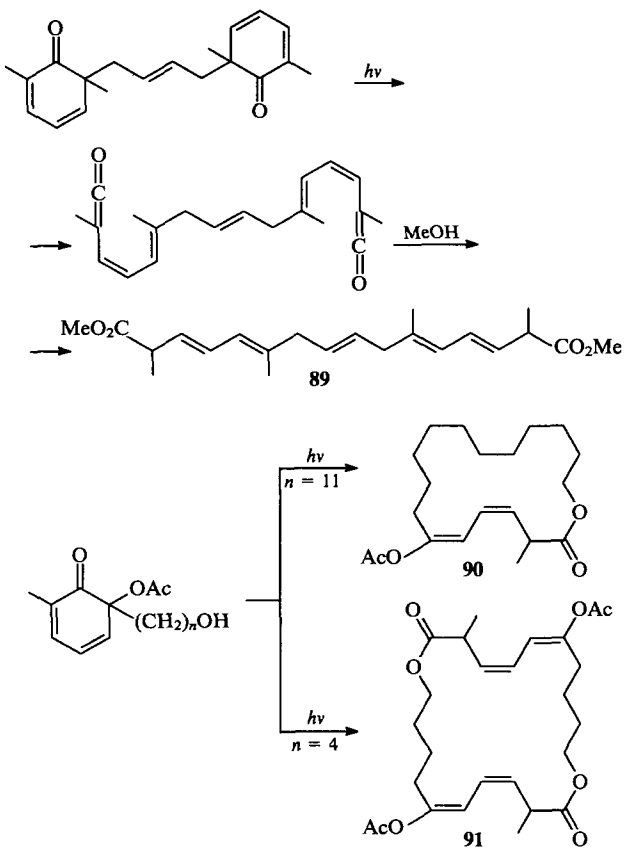


It is essential to note that, in conformity with the orbital symmetry conservation rules, the formation of both *cis*- and *trans*-**81** from the axial isomer of compound **80** is allowed. The preferential formation of *cis*-**81** from the axial isomer of compound **80** and of *trans*-**81** from the equatorial isomer served as a basis for the principle, formulated by Baldwin,[152] which states that the mode of the reaction corresponds to the conformation of the diene in the ground state. When a triene is formed via the 'corresponding' path (the formation of *cis*-**81** from the axial **80**), the *p*-orbitals generated began to overlap with the existing π-system in the early stages of the reaction, whereas in the operation of the 'noncorresponding' path (the formation of *trans*-**81** from the axial **80**), they should pass through the node in the plane of the π-system. The concepts introduced by Baldwin are very closely related to the term 'torquoselectivity' introduced by Houk in a study of the thermal opening of the ring in cyclobutenes.[7–9]



By using the correspondence principle, Whitesell et al.[150] achieved the stereoselective synthesis of the principal fragment in ikarugamycin **82**.

Hexatrienes containing a hydroxy-group in the 5-position are unstable owing to their conversion into the keto-form. However, by irradiating 2-methylbenzophenone **83**, Wilson et al.[153] were able to generate compound **84**, which cyclises, following the absorption of a second photon, to compound **85**, which is oxidised to anthrone **86**.[153]



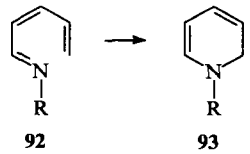
The photochemical opening of the ring in cyclohexa-2,4-dienone **87** results in the formation of the triene **88** containing the ketene group.[154,155]

The reaction proceeds via a n,π^* excited singlet state. The ketene **88** is thermally unstable and is reconverted into the initial compound,[156] but it may be 'trapped' by different nucleophiles.

Since the initial cyclohexadienones **87** are readily available, this reaction constitutes a valuable synthetic method for the preparation of diverse organic compounds with unusual structures.[157]

The most striking examples illustrating the effectiveness of this method are the syntheses of dimethylcrocetin **89**, the pigment saffron,[158] and the macrocyclic lactones **90** and **91**.[159]

VII. 1,6-Electrocyclic reactions in heteroatomic systems



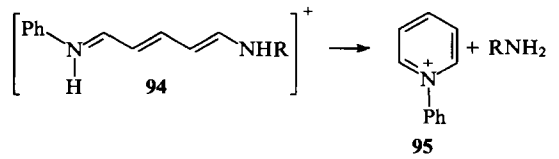
The introduction of heteroatoms into a conjugated π-system hardly alters the symmetry and mechanism of the cyclisation. The substitution of the terminal methylene group by a heteroatom diminishes the exothermicity of the reaction and lowers the barrier to the cyclisation process.[4,16] It has been noted that the introduction of heteroatoms into the terminal positions in the triene system diminishes the difference between the activation energies for the processes proceeding via allowed and forbidden paths.[16] When two heteroatoms are introduced into the terminal positions, the cyclic form is strongly destabilised and the open-chain structure becomes more stable.[4,16] Analysis of the correlation diagrams for the electronic states of the cyclic and open-chain forms leads to the conclusion that the cyclisation of 1,6-dioxatrienes is prohibited in the ground state in both ways — disrotatory and conrotatory.[160] The data on the 1,6-ER of heteroatomic systems are divided arbitrarily into subsections depending on the type (nitrogen, oxygen, sulfur) and number of heteroatoms.

1. Reactions of nitrogen-containing compounds

A nitrogen atom may be introduced into any position in hexa-1,3,5-triene without a significant alteration of the π-system. ER have been described in the literature for all the isomeric mono-azatrienes.[4]

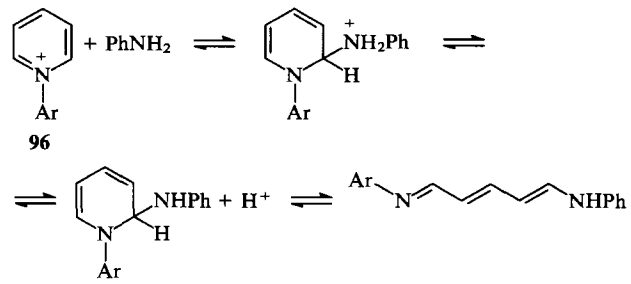
In the general case, the 1-azahexatrienes **92** are less stable than their cyclic isomers — 2-dihydropyridines **93** (Scheme 3).[4]

Scheme 3



R = H, Alk, Ar.

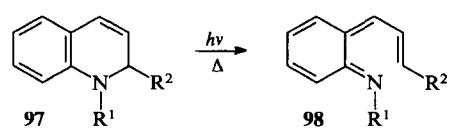
Reactions involving the opening of the rings in pyridinium salts by nucleophiles,[4] the cyclisation of Konig's salts,[161] rearrangements of the Dimroth[162] and Kost–Sagitullin[163] types, the transformation of oxazines into pyridines,[164] and nucleophilic substitution in heteroaromatic compounds via the ANRORC mechanism[165] have been thoroughly investigated. All these reactions include at least one 1,6-ER of 1-azahexatrienes.



It has been shown that the cyclisation of Konig's salts **94** to the pyridinium salts **95** is catalysed by both bases and acids.[4]

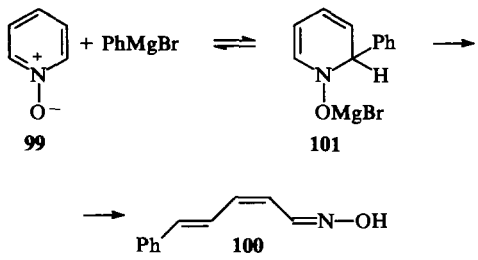
The *cis–trans* isomerisation of compound **94** takes place very readily; E_a is only 6 kcal mol^{-1}.[4] Unfortunately all the atoms in compounds **94** and **95** are located in one plane and their structure does not therefore yield information about the stereochemistry of the process.

Numerous studies, surveyed in Marvell's book,[4] have been devoted to the reactions involving the opening of pyridinium rings by nucleophiles.



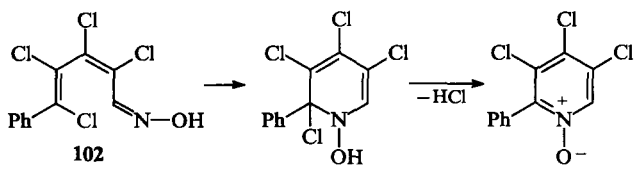
Kinetic investigations indicate the acceleration of the reaction after the introduction of electron-accepting substituents into the *para*-position in the phenyl group. Thus the opening of the ring in dinitrophenylpyridinium **96** by sodium hydroxide is 10^6 times faster than in the unsubstituted phenylpyridinium.[4] It has been noted[166] that the reaction mechanism may change when the pH of the medium is altered. The ring opening reaction is apparently fast and is not the rate-limiting stage in the overall process.

Ar = 2,4-$(NO_2)_2C_6H_3$.



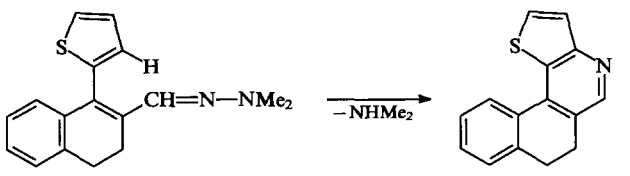
It has been observed that the Schiff bases of retinal analogues cyclise extremely readily to dihydropyridine analogues.[167] It has been shown[167] that the rate of the process is influenced by steric and conformational factors. Data concerning the use of retinal azomethines as models simulating the spectroscopic and chemical properties of certain pigments of halobacteria, particularly bacteriorhodopsin, were analysed in the same communication.[167]

When the dihydroquinolines **97** are irradiated with UV light at 196 °C, the monocyclic compounds **98** are formed. These cyclise slowly to the initial compounds at room temperature.[4]



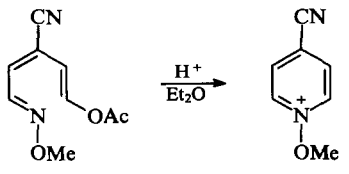
R1 = COOEt, CN; R2 = CN, OH.

On interaction with a Grignard reagent, pyridine *N*-oxide **99** affords the dienyloxime **100**.[4] The last stage of this process is the electrocyclic opening of the ring in the intermediate dihydropyridine **101**.



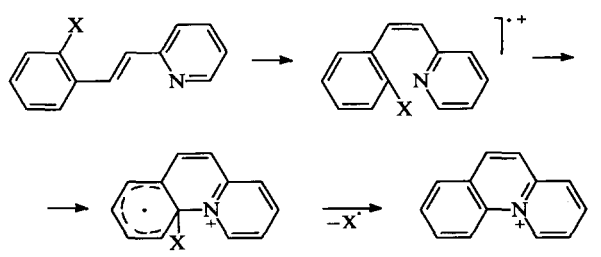
99 **101** **100**

Like the hydrazones **103** having double bonds in the *cis*-positions, the dienyloximes **102** are capable of being converted into dihydropyridines. The latter may be stabilised by the abstraction of a water or hydrogen chloride molecule[4] and, in the case of the hydrazone **103**, by the abstraction of dimethylamine.[168,169]



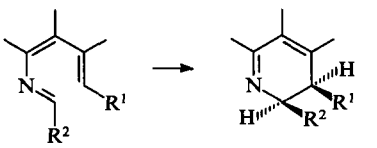
102

103



The cyclisation reactions of the trienes **102** and **103** apparently take place with a low activation energy E_a and the rate of the overall process is limited by other stages.

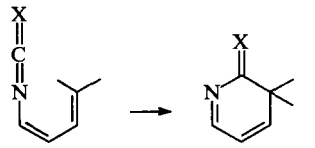
The formation of the pyridinium salts **104**, additionally stabilised as a consequence of their aromatic properties, is the driving force in the cyclisation of compounds **105** in acid media.[170]



105 **104**

A single study[171] of 1,6-ER with participation of radical species containing the 1-azahexatriene system has been published.

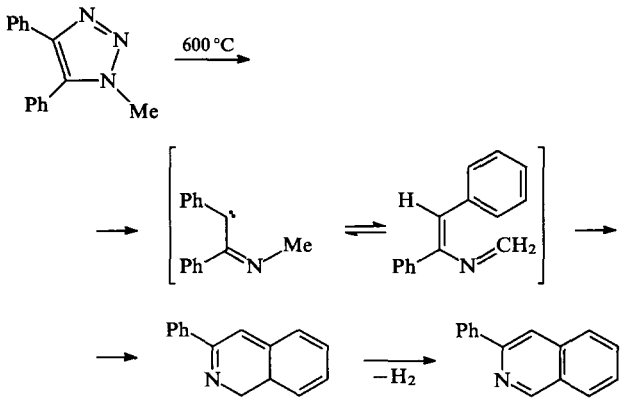
X = H, Me, F, Cl.



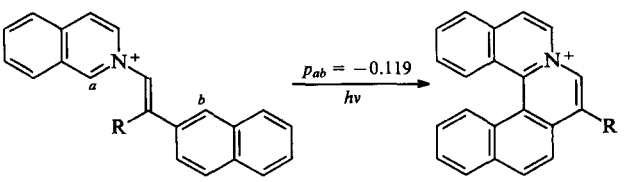
The introduction of a nitrogen atom in the 2- and 3-positions in the hexatriene system 'perturbs' the orbitals only slightly and should not alter the cyclisation mechanism. The results of calculations and experiments[4] confirm this conclusion and indicate a disrotatory mechanism for the cyclisation of 2-aza-hexa-1,3,5-trienes **106**.

106

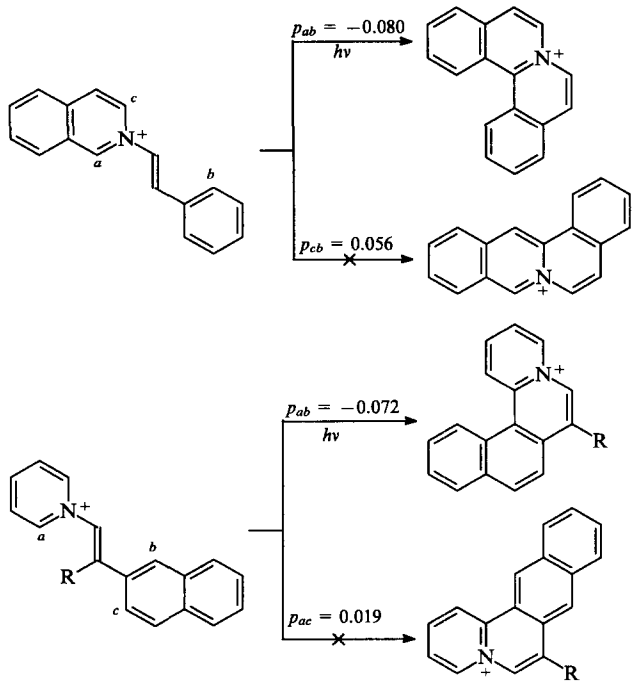
R^1, R^2 = Alk.



The cyclisation of the dienyl isocyanate **107**[172] and of the carbodiimide **108**[173,174] can take place without rotation relative to the N=C bond by analogy with the 1,4-ER of iminoketenes.[5]

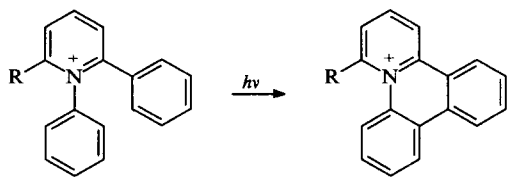


107, X = O.



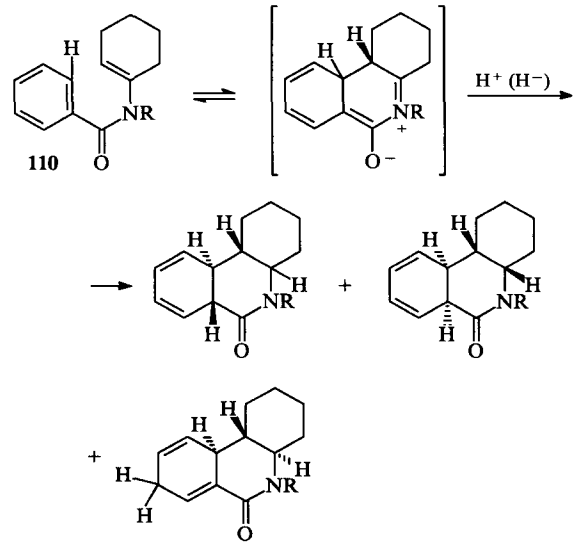
108, X = NPh.

The thermal transformation of 1-methyl-4,5-diphenyl-1,2,3-triazoles into 3-phenylisoquinolines can apparently also include the 1,6-electrocyclic closure of the 2-azatrienyl system.[175,176]



There are examples of the cyclisation of 2-azatrienes containing a quaternary nitrogen atom in the molecule.[4,177,178] It has been shown[177,178] that the order of the bond (p) between the atoms being linked (C_a, C_b, and C_c) must be negative for cyclisation to occur.

The photocyclisation of compounds **109**, containing the azoniahexa-1,3,5-triene system, has been studied in detail by Dorofeenko and coworkers[179] and their successors[180] and constitutes yet another example of 1,6-ER.

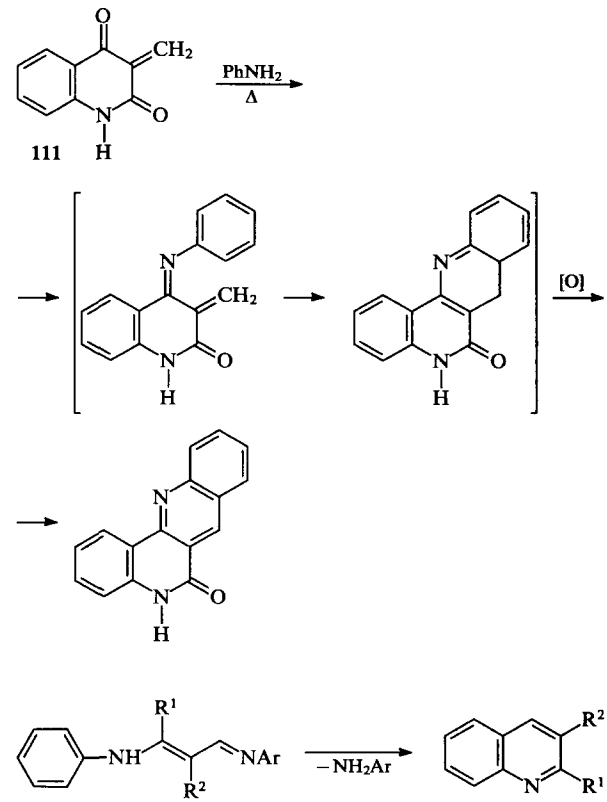


109

R = Me, COOH, Ph.

There exists a single study[181] on the basis of which one may reach a conclusion concerning the mechanism of the cyclisation of 3-azahexatrienes. The authors[181] showed that reductive photocyclisation of the enamides **110** takes place in a conrotatory manner in conformity with the orbital symmetry conservation rules (Scheme 4).[1-3]

Scheme 4

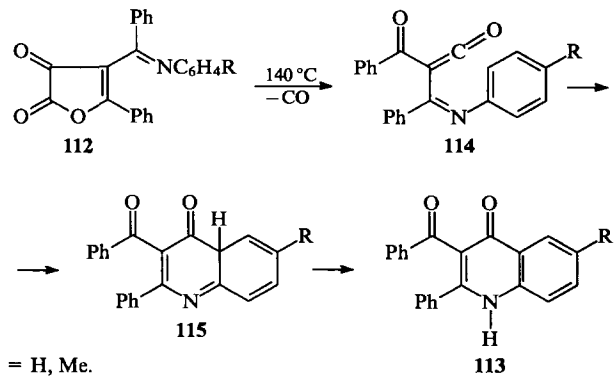


110

R = Alk, Ar.

The photocyclisation of enamides[182] has been used by the same workers to synthesise the alkaloid naucleficine.

The dihydropyridines **111**, formed on thermal cyclisation of 3-azahexatrienes, are converted into aromatic compounds as a result of the oxidation or elimination of low-molecular-mass products, which hinders the study of the stereochemistry of this reaction (Scheme 5).[4,183]



Scheme 5

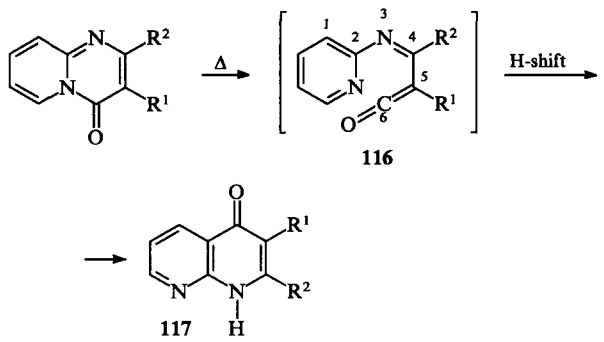
111

R¹, R² = H, Me.

The transformation of the furandione **112** into the quinolinone **113** apparently involves the cyclisation of the iminoketenes **114** to the hydropyridine **115**. The latter is stabilised as a result of the 1,3-sigmatropic shift of a hydrogen atom.[184]

112 **114**

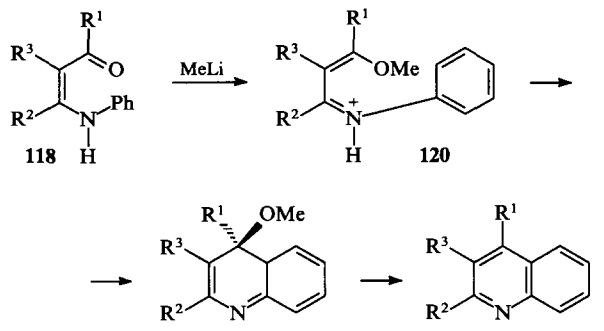
115



R = H, Me.

113

The formation and 1,6-ER of the iminoketenes **116** constitute the basis of the rearrangement of pyrido[1,2-*b*]pyrimidines to pyridopyridones **117**.[185]

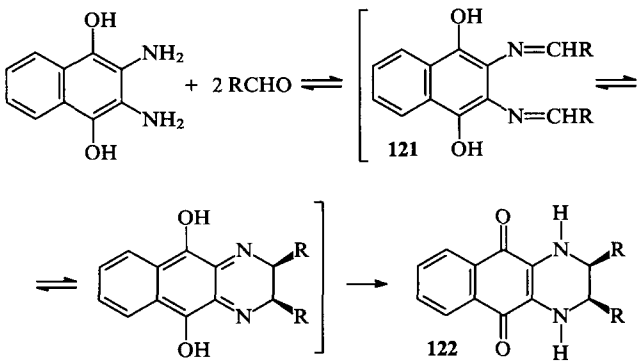


It has been shown[186] that the methylation of the ketoenamines **118** by dimethyl sulfate leads to the quinolines **119**.

It has been suggested[186] that the reaction proceeds via the intermediate cation **120**. Taking this into account, one may conclude that the cyclisation of 3-azoniahexatrienes may be achieved not only photochemically but also thermally.

116

117

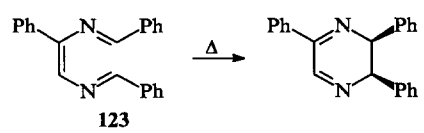


118 120 119

R^1, R^2, R^3 = H, Me, Bu^t.

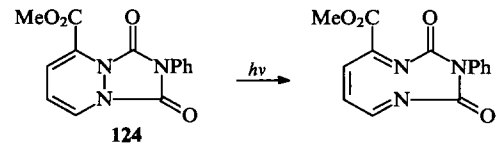
It has been demonstrated with the aid of quantum-chemical calculations that the substitution of two CH groups in the 2- and 4-positions and also in the 2- and 5-positions in the hexatriene system should not alter the mechanism of the cyclisation reaction.[171] Experimental data fully support these conclusions (Scheme 6).[4]

Scheme 6



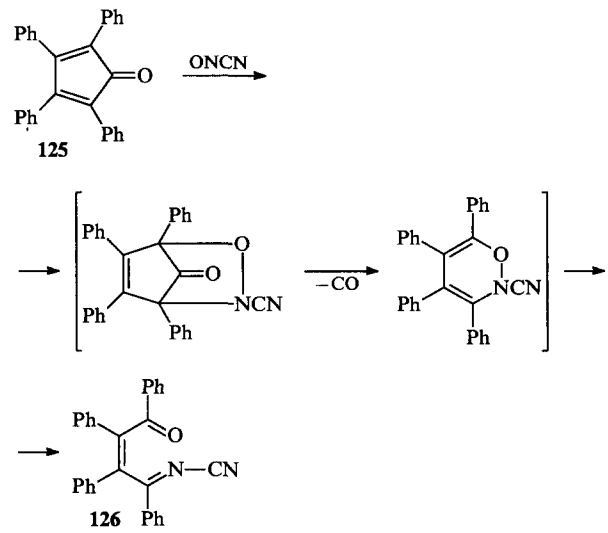
121 122

R = 2-HOC$_6$H$_4$, 2-OH-3-MeOC$_6$H$_3$,
2-OH-4-MeOC$_6$H$_3$, 2-OH-5-MeOC$_6$H$_3$,
4-MeC$_6$H$_4$, 4-NH$_2$C$_6$H$_4$.



It has been shown[187] that the azomethine imines **121** cyclise via a disrotatory process with the ultimate formation of the quinones **122**. Freeman and Kim demonstrated the possibility of the occurrence of this reaction for the acyclic 2,5-diaza-1,3,5-trienes.[188]

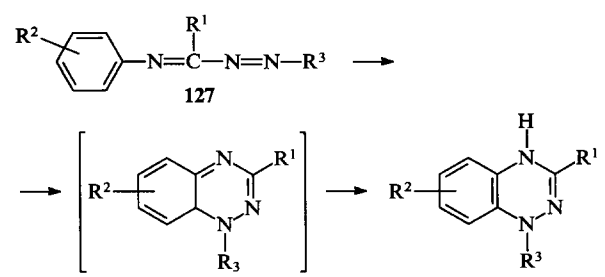
A more rigorous demonstration of the disrotatory cyclisation mechanism has been achieved by Padwa et al.[189] in a study of the cyclisation of the triene **123**.



123

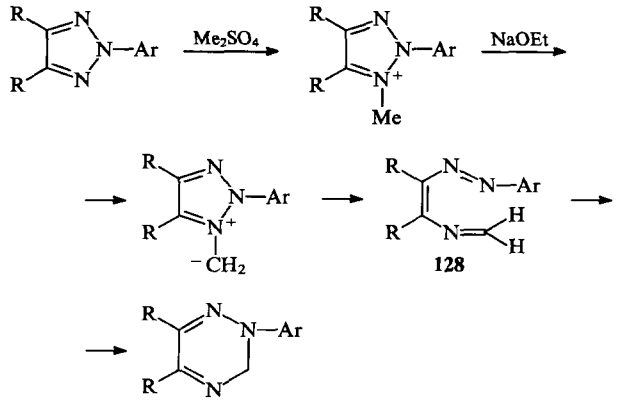
The photochemical opening of the ring in the dihydropyridazine **124** is an example of a reaction involving the 1,6-diazahexatriene system.[190]

124



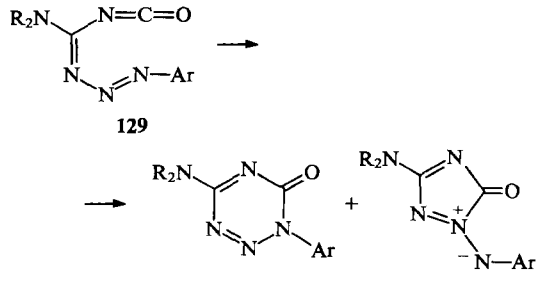
1,6-Diazahexa-1,3,5-trienes are more stable than their cyclic isomers. This apparently applies also to systems having other heteroatoms with lone pairs in the terminal positions. Thus the reaction of the cyclopentadienone **125** with nitrosocyanogen leads to the formation of 1-oxa-6-azahexa-1,3,5-triene **126** in a pure form and in a high yield.[191]

125 126



Nucleophilic substitution in pyramidines, which proceeds via the ANRORC mechanism and has been discovered and studied in detail by van der Plas and coworkers,[165,192] includes the 1,6-ER of 1,5-diazahexatrienes as one of the stages.

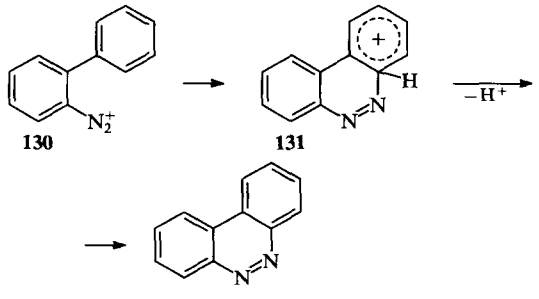
The cyclisations of 1,4-diaryl-1,2,4-triaza-1,3-dienes **127**,[193] 1-aryl-1,2,5-triazadienes **128**,[175,176] as well as aromatic and heteroaromatic diazonium salts belong to the class of 1,6-ER of triene systems with three nitrogen atoms. They will be examined in the next section.



127

R^1, R^2, R^3 = H, Me, Ar, COMe, COPh, CO_2Alk.

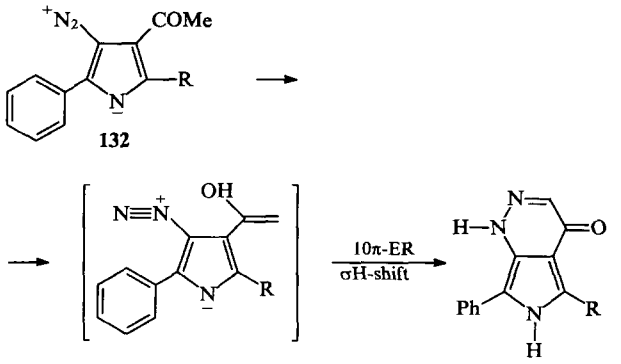
The cyclisation of the isocyanates **129** is an example of the ER of trienes with four nitrogen atoms.[194]



2. Cyclisation of heterocyclic diazo-compounds and diazonium salts

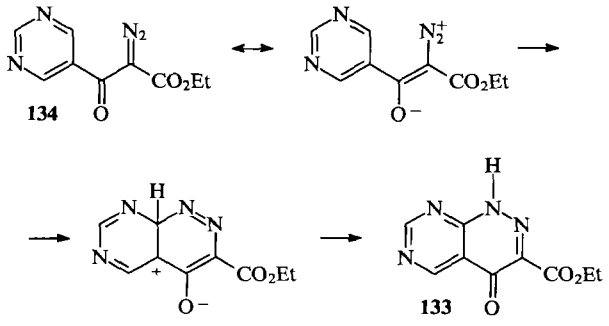
One of the possible mechanisms of the cyclisation of aromatic diazonium salts and heterocyclic diazo-compounds, in the *ortho*-positions of which there are groups containing multiple bonds, involves a monorotatory 1,6-electrocyclic reaction. This reaction is used widely in the synthesis of a wide variety of six-membered heterocyclic compounds such as pyrazines, v-triazines, and thiadiazines.

Since these processes have many features in common, they are described in a separate subsection.



a. The formation of the N–C bond

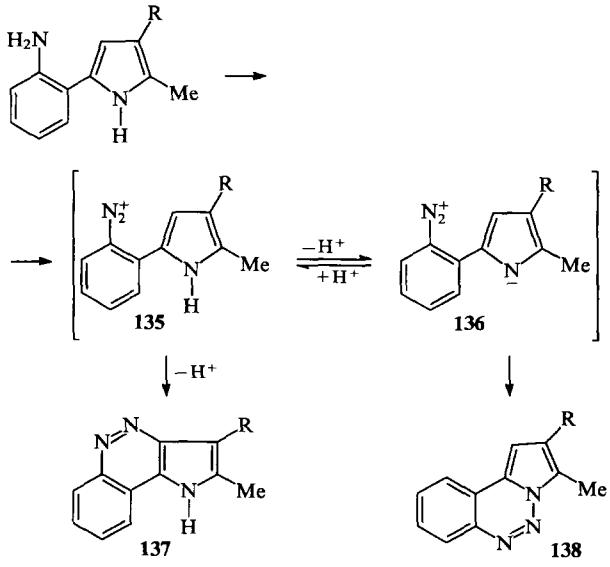
The cyclisation of diazonium salts and heterocyclic diazo-compounds containing a vinyl group in the β-position (the Widman–Stoermer reaction) is treated as an intramolecular azo-coupling for the aryl derivatives **130**.[195–198]



Unfortunately, experimental and theoretical studies on the mechanisms of this reaction are not described in the literature; the intermediate complexes **131** have not been characterised, the influence of the π-system on the energy relations of the cyclisation reaction has not been elucidated, and kinetic studies have not been carried out.

Presumably, the diazoketones **132** cyclise via a similar mechanism. It is of interest to note that the methylketo-group, tentatively in the enolic form, and not the aromatic ring, participates in the reaction.[199]

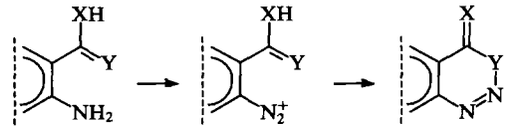
R = H, Me.



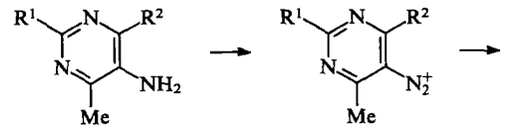
The occurrence of this reaction requires the presence of sulfuric acid. Thus, on heating in DMF, the initial compound **132** remains unaltered.[199]

The condensed pyridazines **133** are also formed on cyclisation of pyrimidinyl diazoketones **134**.[200,201]

If the molecule of the diazo-compound contains a pyrrole ring in the *ortho*-position relative to the diazonium group, the reaction can proceed via two paths, depending on the pH of the medium, with formation of a C–N or N–N bond.[202,203]

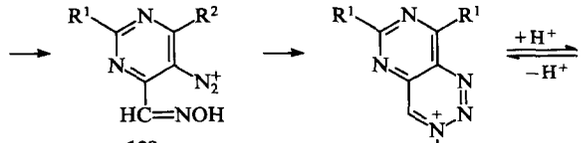


These results have been explained[203] by the existence of an acid–base equilibrium between the diazo-compounds **135** and **136**, each of which gives rise to its own cyclisation product — compounds **137** and **138** respectively.

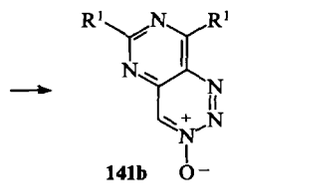


R = COMe, CO_2Et, H.

b. The formation of N–N and N–S bonds

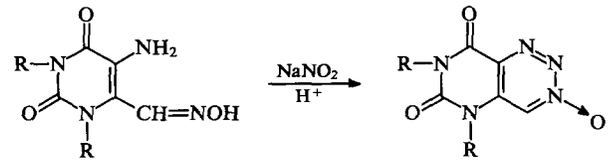


The diazotisation of heterocyclic and aromatic amines containing amide, amidine, and thioamide groups in the *ortho*-positions takes place via intermediate diazo-compounds with formation of condensed 1,2,3-triazines and thiadiazines.



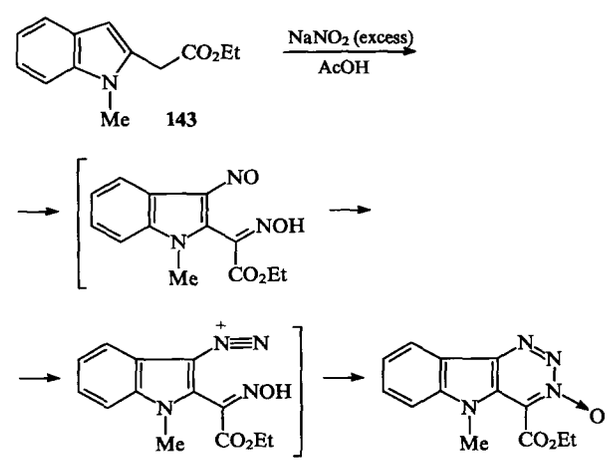
X, Y = O, S, NR.

140



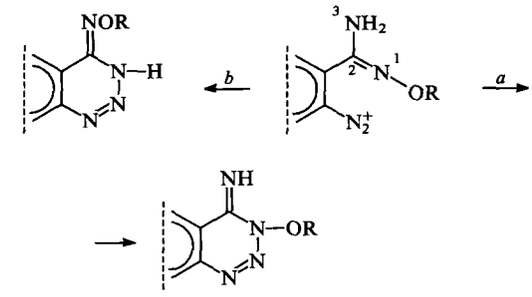
139 **141a**

141b



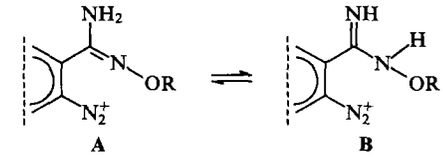
Thus the diazooximes **139**, formed from the amines **140** as a result of diazotisation and nitrosation reactions, cyclise to pyrimido[4,5-*d*]-1,2,3-triazines **141**.[196,204]

The interaction of the amines **142**[196] and indoles **143**[205] with nitrous acid affords analogous results.



142

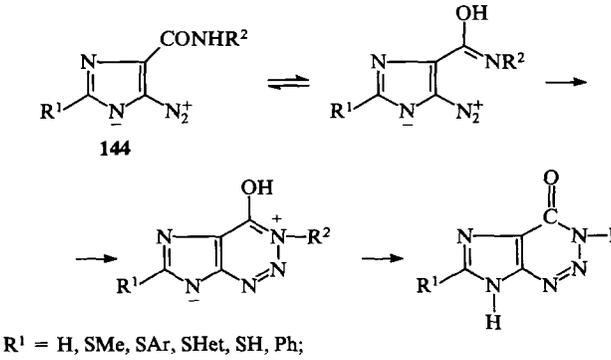
R = H, Alk.



Diazo-compounds containing an amidinoxime group can cyclise, in principle via two paths — with participation of the N(1) and N(3) atoms.

However, it has been shown[196,206] that this reaction involves the formation of a N–N bond with the N(1) atom linked to the oxygen atom (route *a*).

R = H, Alk.



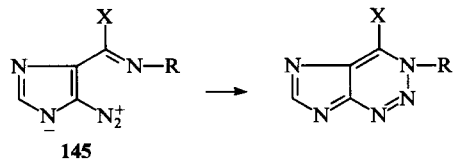
The higher reactivity of the nitrogen atom linked to the oxygen atom can be accounted for either by the α-effect of the lone pair of the oxygen atom or by the existence of amidinoximes fully in the tautomeric form **A** and by the high energy barrier to the conversion of form **A** into form **B**.

A **B**

R = H, Alk.

Data indicating a higher reactivity of the amide nitrogen atom linked to the heteroatom with a lone pair are confirmed by the series of studies of Mokyushin and coworkers[192–195] on the cyclisation of heterocyclic diazo-compounds containing an amide¶, hydroxyamide, and hydrazide group in the *ortho*-positions.[207–210] The authors showed that, despite their tendency to cyclise, the diazo-compounds **144** (R^2 = H, Alk, Ar) may be isolated and characterised spectroscopically. However, this does not apply to compounds **144** with R^2 = OH, NH_2, or N=CHAr.

144



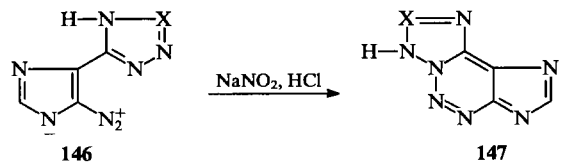
R^1 = H, SMe, SAr, SHet, SH, Ph;

R^2 = H, Alk, Ph, OH, NH_2, NCH_2Ar.

They cyclise already during their synthesis, which indicates their higher reactivity compared with other representatives of this series.

¶ The cyclisation of diazo-compounds with the *o*-amide group as a method of synthesis of condensed triazinones has been described in numerous publications.[207–215]

The heterocyclic diazo-compounds **145**, containing the amidine and imidate groups, also cyclise to triazines under the conditions of the synthesis.[196]

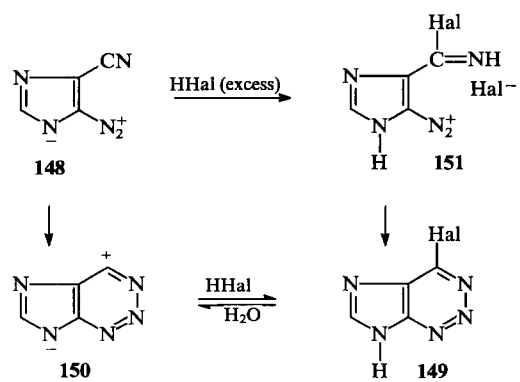


145

X = OAlk, NH_2, SMe.

Nevertheless, Mokrushin and coworkers[216] were able to isolate and characterise spectroscopically the diazo-compounds **145** (X = SMe).

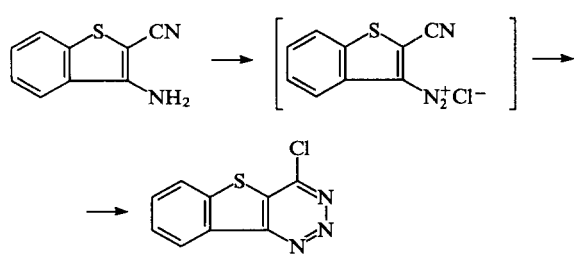
The cyclisation of the diazo-compounds **146**, in which the amidine group is represented by a triazole or tetrazole ring, leads to the formation of the tricyclic compounds **147**.[217-219]



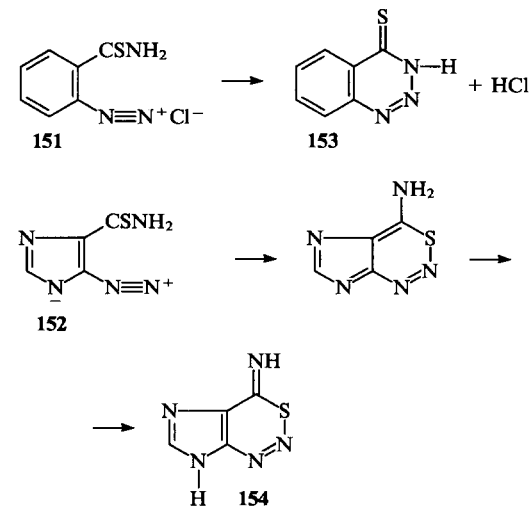
146 **147**

X = CH, N.

The diazo-compounds **148**, containing a cyano-group in the *ortho*-position, are converted into the imidazotriazines **149** on treatment with hydrogen chloride or bromide.[220,221] In aqueous media, the reaction proceeds in the opposite direction.



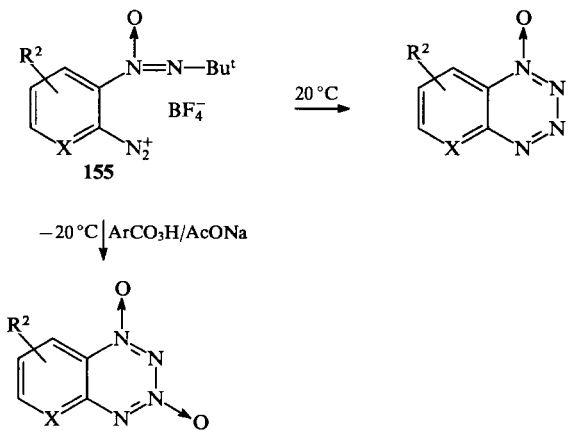
The authors[220,221] suggested that this reaction is achieved via the intermediate compound **150**. However, in our view, the mechanism involving the diazoimine **151** as an intermediate is more probable.



148 **151** **150** **149**

Hal = Cl, Br.

Beck and Yahner observed a similar reaction but in other systems.[222]



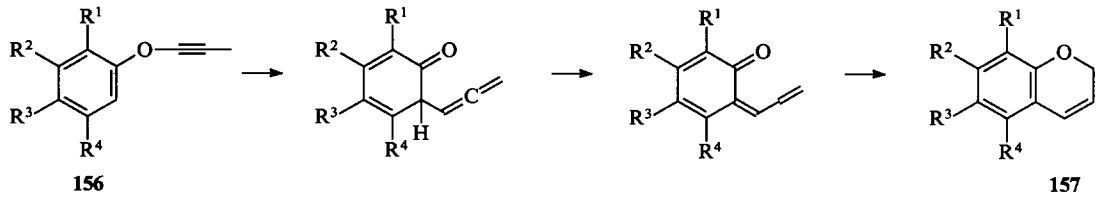
It is of interest to note that the cyclisation of the aromatic diazonium salts **151** and of the heterocyclic diazo-compounds **152**, containing a thiocarbamoyl group in the molecule, takes place via different paths with formation of 1,2,3-triazinethiones **153**[223,224] and thiadiazines **154**.[225,226]

151 **153** **152** **154**

It is not understood whether this is associated with the different reactivities of the diazo- and diazonium groups or with the different thermodynamic stabilities of the imidazo- and benzo-thiadiazines.

The cyclisation of the diazonium salts **155**, containing an azoxy-group in the *ortho*-position, leads to the *N*-oxides of heterocycles with four nitrogen atoms — tetrazines.[227,228]

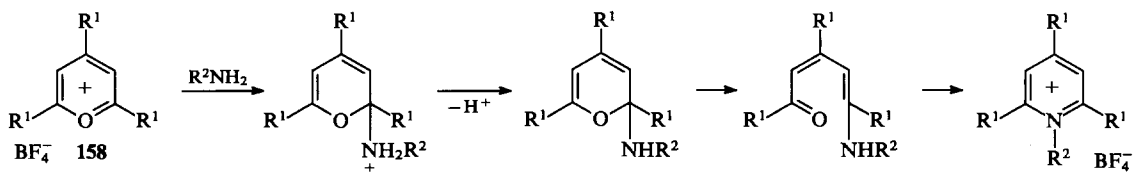
155



3. Reactions of oxygen-containing compounds

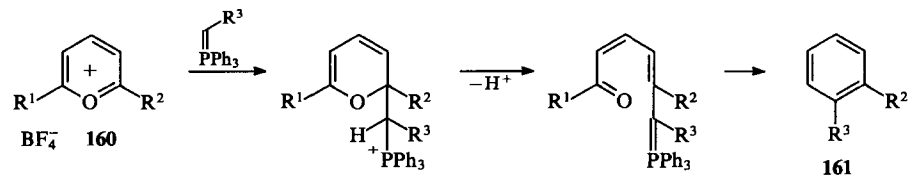
a. Compounds with one oxygen atom

The 1,6-ER of dienones to pyrans, which is extremely interesting from the standpoint of theoretical studies and practical use, belongs to processes of this type. It constitutes the basis of the manifestation of the photochromic and thermochromic properties by spiropyrans,[229] chromenes,[230,231] and spirooxazines[232] and is one of the stages in a wide variety of chemical transformations of, for example, the propargyl ethers **156** into the benzopyrans **157**,[4] of the pyrylium salts **158** into the pyridinium salts **159**[233,234] (on treatment with aliphatic and aromatic amines), of compounds **160** into the benzene derivatives **161** (on treatment with phosphoranes[235] and enamines[236]), and also of the isoxazolium salts **162** into the 1,3-oxazines **163**[237] (Scheme 7).



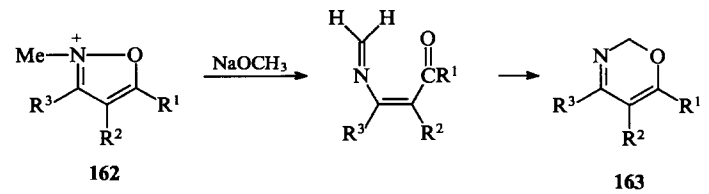
It has been shown that, on heating with diethyl ethynedicarboxylate, the dithioacetal **164** gives rise to the thiapyranone **165**. This illustrates a series of consecutive pericyclic reactions: cycloaddition (CP), 1,4- and 1,6-ER and sigmatropic rearrangements (Scheme 8).[238]

Scheme 7



156 157

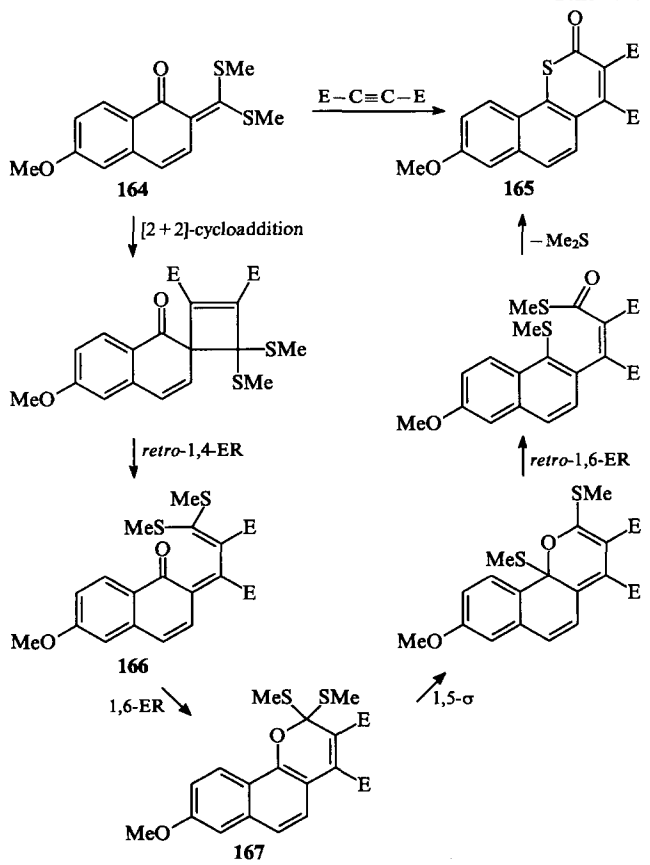
R^1, R^2, R^3, R^4 = H, Me, Cl, OMe.



158 159

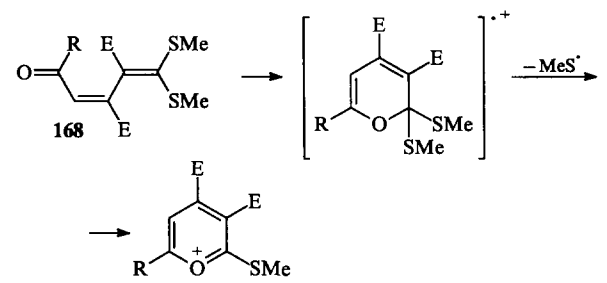
R^1 = Ph, 4-FC_6H_4; R^2 = Bu, Bz, C_6H_{11}, Ph.

160 161



R^1, R^2 = Me, OMe; R^3 = CO_2Et.

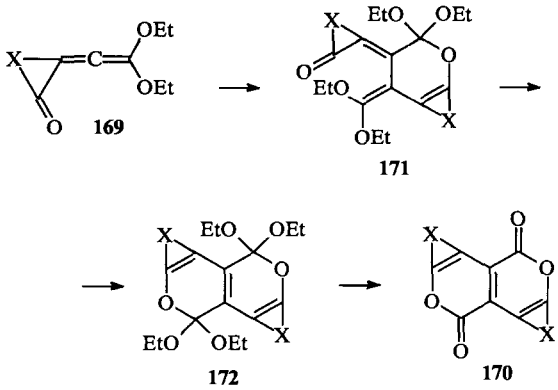
162 163



R^1, R^2, R^3 = H, Ph.

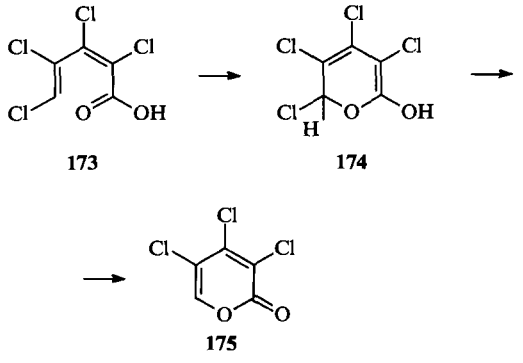
Scheme 8

E = CO_2Et.



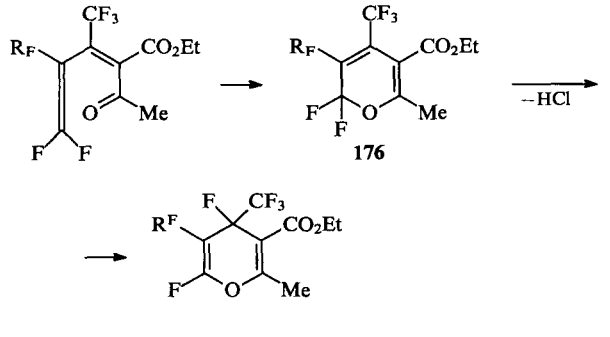
It has been shown[238] that the 1,6-ER of compound **166** to compound **167** is analogous to the mass-spectrometric decomposition of compound **168**.

E = CO_2Et.



Saalfrank et al.[239] showed that compound **169**, which is stable at moderate temperatures, gives rise to the pyranone **170** on thermolysis, probably as a result of the consecutive [4 + 2]-cycloaddition and 1,6-ER reactions of the intermediate dienone **171** and the hydrolysis of the diacetal **172**.

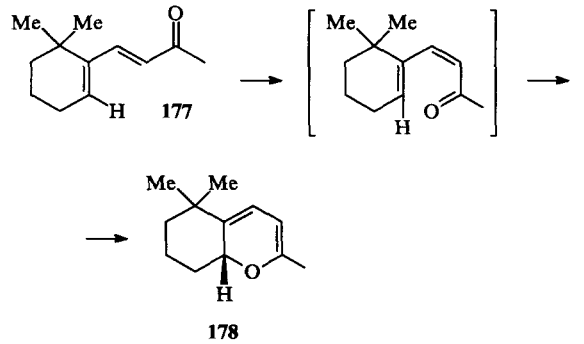
The cyclisation of the polyhalodienone **173** does not stop at the ER stage. The 2*H*-pyran **174** formed is stabilised as a result of the elimination of a hydrogen halide molecule and is converted into the pyran-2-one **175**.[240,241]



169 171 172 170

X = $(CH{=}CH)_2$.

173 174 175

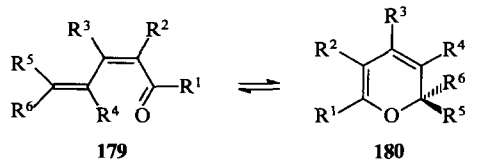


The polyfluorinated pyrans **176** are stabilised by the 1,3-sigmatropic shift of a fluorine atom.[242]

176

R_F = $(C_2F_5)_2CCF_3$, $C(CF_3)_3$, C_2F_5, F.

A study of the products of the irradiation of the *trans*-dienone **177** (to which the structure of the pyran **178** had been initially attributed) by ^{1}H NMR spectroscopy showed that at 55 °C the products consist of 18.8% of the dienone **177** and of 82.2% of the 2*H*-pyran **178**.[4]



177 178

It has been shown that the ring closure in *cis*-β-ionone is a rapid unimolecular reaction which is relatively insensitive to the solvent.[4] The enthalpy and entropy of activation for this process are 20 kcal mol^{-1} and −5 entropy units, whereas the corresponding quantities for the cyclisation of *cis,cis*-1-cyclohexenylpenta-1,3-diene are 34 kcal mol^{-1} and −5 entropy units respectively. Thus the substitution of the terminal methylene group by an oxygen atom lowers the activation energy by 14 kcal mol^{-1}. Several causes accounting for this phenomenon have been put forward in Marvell's book.[4]

The available literature data did not permit conclusions concerning the influence of the electron-donating and electron-accepting properties of the substituents on the rate of this 1,6-ER.

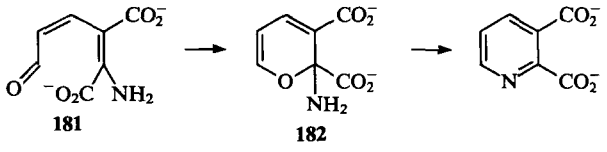
According to Benson's data,[4] the difference between the enthalpies of formation of *cis*-pentadienes and α-pyrans is −0.1 kcal mol^{-1}. In the absence of other strong interactions, the equilibrium between the dienones and pyrans is therefore determined by entropy factors.

179 180

R^1–R^6 = H, Alk, OAlk, NHAlk, COOAlk, COAlk, CN, Ar.

A systematic and detailed study of the influence of the structure on the equilibrium between dienones and the isomeric 2*H*-pyrans has been carried out by Krasnaya and co-workers.[243–248] They showed that the intensification of the steric interactions between the substituents in the α- and γ-positions as well as the introduction of a dimethylamino-group in the β-position displace the equilibrium towards the pyran form, whereas an increase in the capacity of the solvent for specific solvation entails an increase in the fraction of the diene form. Among compounds **179** (R^4 = Br, OEt), containing bromine or the ethoxy-group, solvatochromism is most pronounced. In hexane or tetrachloroethene, they exist in the form of 2*H*-pyrans, whilst in water or in a water–methanol mixture they are present as the dienones.

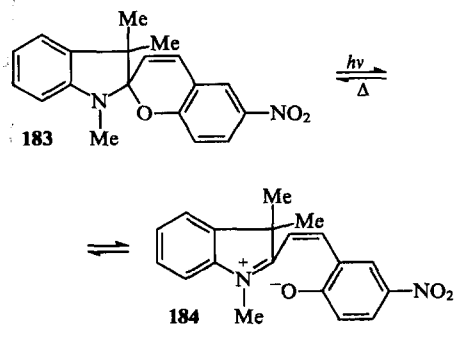
It is of interest to note that the content of valence isomers may depend on the state of aggregation of the given substance. Thus compound **179** [R^1, R^2 = $-(CH_2)_4-$, R^4 = OEt] exists in the crystalline state as the dienone **179**, whilst in solution or in the melt it is present as two isomers — the dienone **179** and the pyran **180**.



The authors[242–249] explain their findings by the fact that, with increase in the steric hindrance between the substituents R^5 and R^3 and also between R^4 and CO, the equilibrium shifts towards *cis*-form of the dienone, which is favourable for cyclisation. Their explanations are similar to those used by Duperrier and Dreux,[250] who showed that the steric interaction between R^3 and R^5 and also between R^4 and CO can be important for the cyclisation reactions, while the groups R^4 and R^6, conjugated with the π-system, displace the equilibrium towards the dienone.

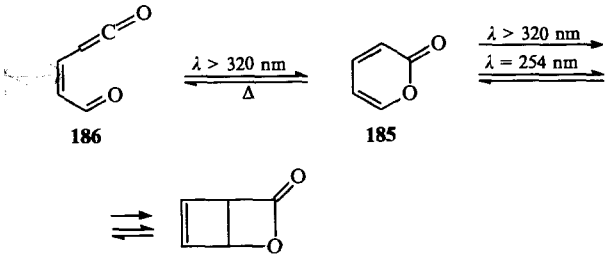
In connection with the manifestation of photochromic properties by chromenes and spiropyrans, a series of theoretical and experimental studies have been carried out on the photochemical reactions of these compounds.[251–260] It has been shown[258] that $^1(\pi\pi^*)$ singlet state of the spiropyran is decisive in this process but that in the photochemical reaction a crossing of the type $^1(\pi\pi^*)-{}^3(n\pi^*)$ or $^1(n\pi^*)-{}^3(\pi\pi^*)$ takes place.

However, Khlomanskii and Dyumaev[259] believe that these processes do not fully account for the nature of the primary photochemical step in spiropyrans.



The rapid reactions of dienones and 2*H*-pyrans are the cause of the ready isomerisation of retinal relative to the double bonds.[261,262] It has been shown that pyrans are reduced via the dienones initially formed.[263,264]

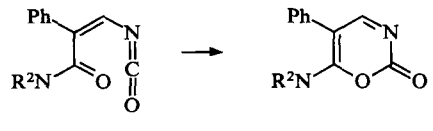
In connection with the high sensitivity of the equilibrium between dienones and 2*H*-pyrans to the influence of the pH of the medium, temperature, and irradiation by light, it has been suggested[18] that this ER plays an important role in biochemical processes in living organisms. The study by Keys and Hamilton[265] constitutes a confirmation of this hypothesis. It was shown in the latter that one of the key stages in the biosynthesis of pyridine-2,3-dicarboxylate in animals is the cyclisation of 2-amino-β-carboxymuconate ε-semialdehyde **181** to the pyran **182**.



181 **182**

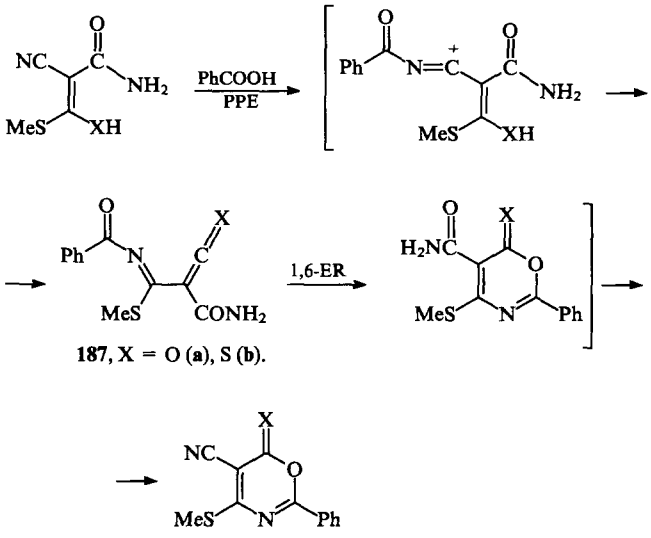
In this connection, one should also note that the system **183**↔**184** functions as an agent transferring aminoacids through liposomes.[266]

183 **184**



The replacement of the terminal double bond by the ketene group in the dienone leads to the displacement of the equilibrium towards the cyclic form.[4] The low-temperature photolysis of the pyranone **185** makes it possible to identify the ketene **186**, which is converted irreversibly into the initial compound after the cessation of UV irradiation.[267–269]

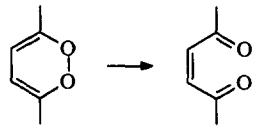
186 **185**



This fact made it possible to carry out a kinetic study of the cyclisation of the ketene **186**. The activation energy for the ketene is 9.4 kcal mol^{-1} and its lifetime at 26.5 °C is only 2.4 μs.

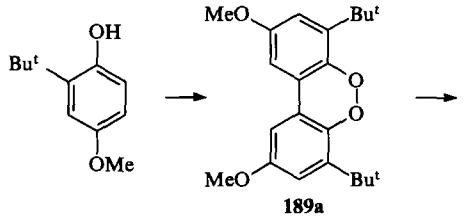
Isocyanates containing the 2-azadienone system also readily cyclise to oxazinones.[270–272]

R = Alk, R_2N —  .



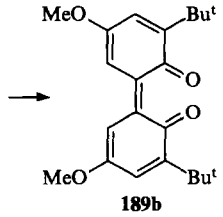
It has been shown that the 1,6-ER of the aza-analogues of compound **186** — the ketenes **187a** and the thioketenes **187b** — is one of the stages in the double O,N- and N,N-rearrangements.[273,274]

187, X = O (**a**), S (**b**).



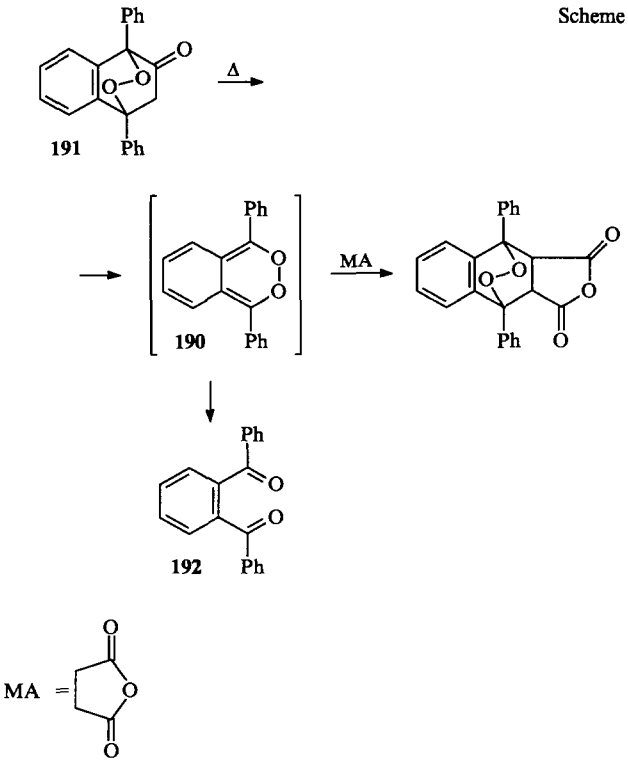
b. Compounds with two oxygen atoms

The reaction involving the opening of the ring in the potential 1,2-dioxine **188** should have a low activation energy and should be largely exothermic according to Marvell.[4]



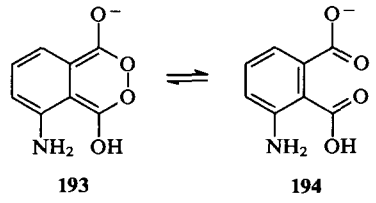
188

Nevertheless, Baltes and Volbert[275] were able to obtain its derivative — the dioxine **189a** — by oxidising 2-*tert*-butyl-4-methoxyphenol. The colourless compound **189a** acquires a deep blue colour on dissolution in nonpolar solvents, apparently as a result of its conversion into the diketone **189b**.



189a

189b



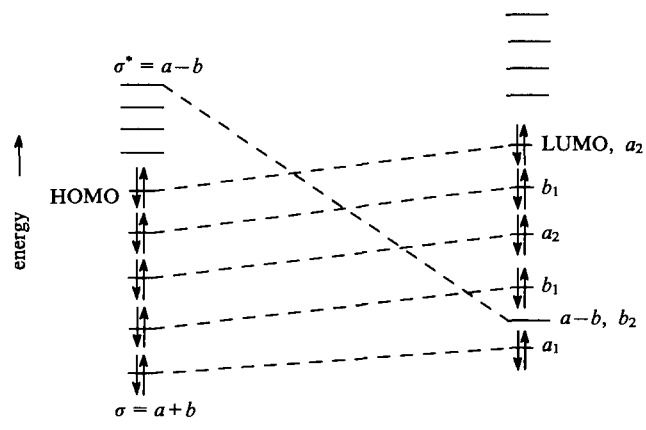
Proof of the existence of *o*-xylylene peroxide **190** as an intermediate in the decomposition of compound **191** was obtained chemically in its reaction with maleic anhydride (MA). In the absence of MA, electrocyclic opening of the dioxine ring and the formation of *o*-dibenzoylbenzene **192** take place (Scheme 9).[276]

Scheme 9

Chemiluminescence is observed during the formation of compound **192**, which indicates its existence in an excited state.

In a discussion of the chemiluminescence, Michl[277] suggested that the endoperoxide **193** is a direct precursor of the luminescent phthalate ion **194** and put forward qualitative arguments explaining why the dissociation of the O–O bond leads to chemical excitation.

Michl's model is most clearly illustrated by a qualitative correlation MO diagram (Fig. 2).



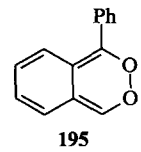


Figure 2. Qualitative correlation diagram for the MO of compounds **193** and **194**.

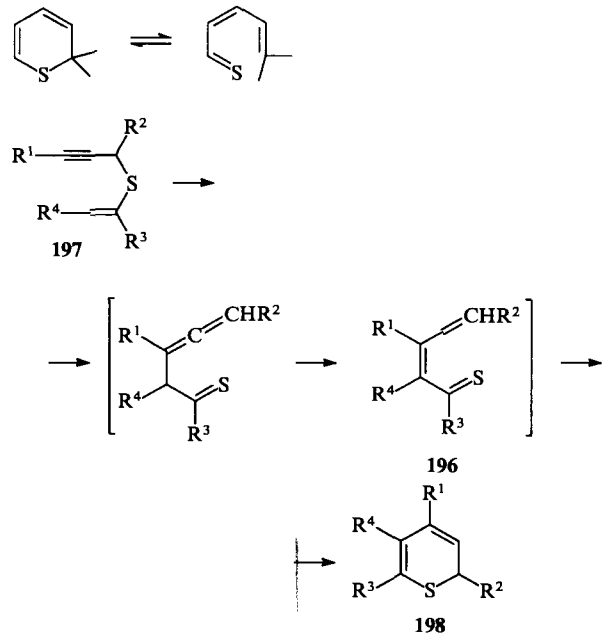
In the endoperoxide **193**, $a + b$ is a bonding orbital and $a - b$ is an antibonding orbital. With increase in the O–O distance, the energies of the two orbitals approach one another. In a rapid nonadiabatic reaction, the electrons do not have sufficient time to pass to an orbital with a different symmetry. This entails the failure to fill the $a - b$ orbital, whereas the LUMO becomes doubly occupied, i.e. we arrive at a doubly excited state, the transition from which to the ground state is accompanied by chemiluminescence.

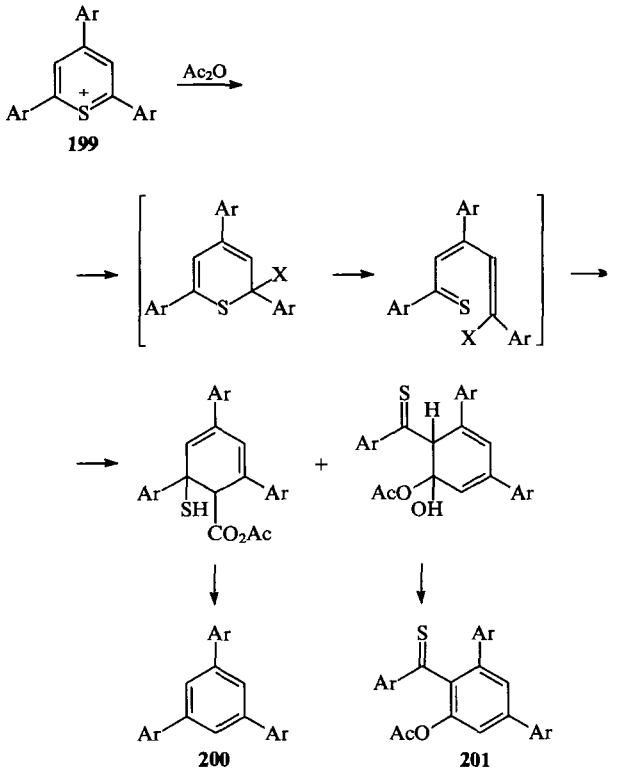
Michl's qualitative model has been developed and refined by means of quantum-chemical calculations in terms of the HAM (Hydrogen Atom in Molecule) approximation.[160]

The authors[160] showed that two intersections on the correlation MO diagrams are important for the manifestation of the phenomenon of chemiluminescence. The activation energy for the opening of the endoperoxide ring in compound **193** is only 6 kcal mol^{-1}. Schuster and coworkers[278] demonstrated the unexpected stability of the *o*-xylylene peroxide **195**.



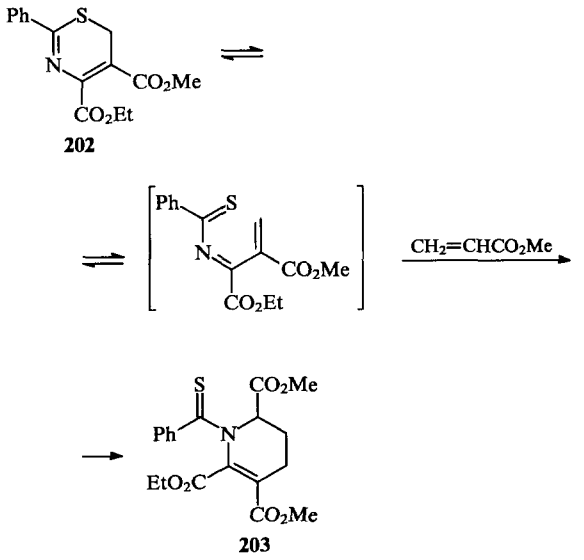
Calculations in terms of the HAM approximation explain such behaviour in the following way: the replacement of the phenyl group by an OH group increases the energy of the HOMO and lowers that of the LUMO, which diminishes the energy gap and promotes the nonadiabatic transition, lowering thereby the activation energy for the ring opening process.[160]

On the basis of calculations for the conversion of butene-1,4-dione into 1,2-dioxacyclohexadiene in terms of the MINDO/3 approximation, Pichko[138] concluded that cyclisation of this compound has a 'disrotatory' mechanism.



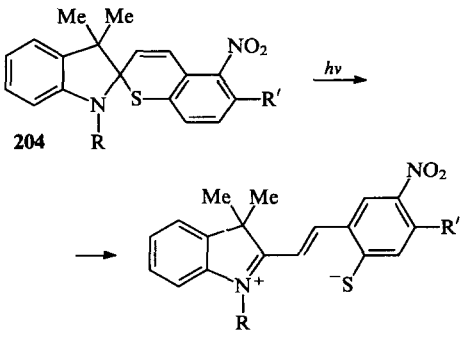
4. Reactions of sulfur-containing compounds

It has been shown by MINDO/3 calculations that thiopyrans are much more stable than their open-chain isomers.[254] Experimental data are fully consistent with the calculated results. Thus, the 1-thiahexatriene **196**, formed from the sulfide **197**, cyclises to the thiopyran **198** under the conditions of its synthesis.[4]



R^1, R^2, R^3, R^4 = Me, Et.

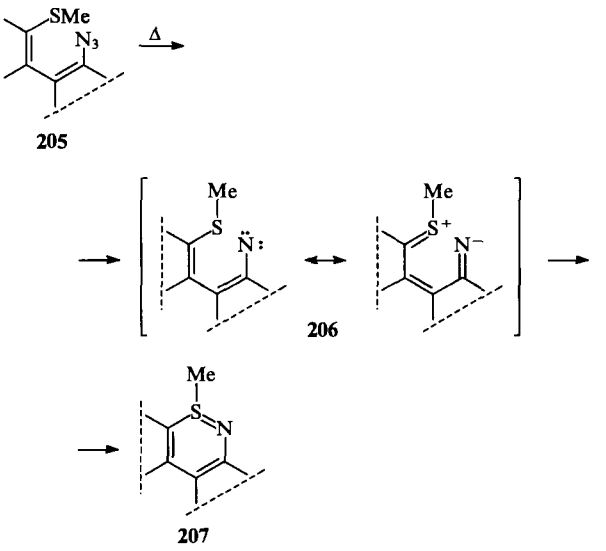
Nevertheless, the transformations of the thiopyrylium salts **199** into compounds **200** and **201** on treatment with acetic anhydride, described by Zimmermann and Fischer,[279] and of the thiazine **202** into the pyridine **203** in the presence of a dienophile[280] confirmed the possibility of the electrocyclic opening of the thiopyran ring.



X = CH_2COOAc.

Ar = RC_6H_4, R = Ph, 4-Me, 4-MeO, 4-Cl, 4-Br.

Data concerning the manifestation of photochromic properties by the spirothiopyrans **204** — structural analogues of the spiropyrans **183** — have been published.[281] The authors[281] suggest that the photochromism of these compounds is associated with the electrocyclic opening of the thiopyran ring.



R = Me, Pr^i, $C_{18}H_{37}$,

R′ = $CH_2O_2CCMe{=}CH_2$, $CH_2OC(CH_2)_{20}Me$.

Theoretical and experimental studies[282] have demonstrated that, like thiopyrans, 1,2-dithiines are more stable than the isomeric 1,6-dithiahexatrienes.

The thermolysis of aryl, heteroaryl, and vinyl azides **205**, containing the thioether group, entails the initial formation of the nitrenes **206**, which then cyclise to the thiazines **207**.[283]

Compounds **206** may cyclise via the electrocyclic mechanism or as a result of the interaction of the lone pair of the nitrogen atom and the unoccupied orbital localised on the nitrogen atom, i.e. the heteroelectrocyclic mechanism.[5] Unfortunately, there have been no theoretical studies on this reaction.

* * *

Together with the striking advances in the application of 1,6-electrocyclic reactions in the synthesis of a whole series of different substances of practical importance and its application to achieve an understanding of the processes occurring in living nature, there have been only a few publications dealing with the study of the details of the mechanism of the 1,6-ER by computational methods.

So far it is not clear what causes the low activation energy in the reactions of hexa-1,3,5-trienes the double bond of which forms part of allene and heteroallene groups and the anomalous stability of the heteroanalogues of norcaradiene. The role of the π-system in the cyclisation of aromatic diazonium salts containing vinyl and azomethine groups in the *ortho*-position has not been discovered.

There is no doubt that the solution of these problems will lead to a fuller understanding of the characteristics of electrocyclic reactions.

IV. High-temperature electrochemical synthesis of multicomponent high-melting compounds 129

Abstract. The present state of research in the field of high-temperature electrochemical synthesis of the carbides, borides, and silicides of Group IV–VI metals in ionic melts is reviewed. Modern problems in electrochemical synthesis and possible future developments are discussed. The results of recent studies of high-temperature electrochemical synthesis are reported. The bibliography includes 103 references.

I. Introduction

An increasing interest in the development of new and effective methods of preparing high-melting compounds (the carbides, boride, and silicides of Group IV–VI metals) has been stimulated by the ever increasing number of applications of these compounds in modern technology. A comparative analysis of currently available methods of synthesis of quasimetallic high-melting compounds (QHC) showed that the high-temperature electrochemical synthesis (HES) in ionic melts,[1] though inadequately investigated to date, is one of the most promising methods.

The HES of quasimetallic high-melting compounds is based on multielectron processes leading to the electrodeposition of metals and nonmetals from ionic melts.[2–4] Lack of information on the theoretical basis and on the controlling principles of both the multielectron processes and the HES had initially prevented the practical application of electrosynthesis methods. This explains the original lack of interest in these methods. However, the systematic data on the multielectron processes leading to the deposition of high-melting metals and nonmetals obtained during the last two decades have provided a scientific basis and understanding which have stimulated an increasing interest in the problems of HES.[2,5–21]

II. Methods of high-temperature electrochemical synthesis

1. Variants of the method of high-temperature electrochemical synthesis

The high-temperature electrochemical synthesis of QHC is based on the simultaneous or the sequential generation of multielectron electrochemical reactions resulting in the formation and deposition of the required product (carbide, boride, silicide) on the cathode. It should be noted that the presence of electronic conduction in the deposited compound is a necessary condition for the realisation of electrochemical synthesis.

There are two methods of achieving HES.[1] In the first variant the molten electrolyte contains one of the components in a molecular or an ionic form which is discharged on the electrode (consisting of the other component). The species to be discharged is either a compound of carbon, silicon, or boron which can be reduced to the elemental state on a high-melting metal cathode (electrochemical carbidisation,[22,23] silicidation,[24,25] boridation[26–28]) or an oxyanion of a high-melting metal which is reduced to the metal on a graphite cathode.[29,30] All these processes are slow even at relatively high temperatures, and they yield only compounds of variable composition in the form of coatings.

In the second variant the electrolyte contains both components, which are discharged simultaneously or sequentially on an indifferent electrode: the discharge products can then react chemically. Both theoretically and practically this variant seems more promising than the first, because it allows QHC of the required composition to be produced, either as coatings or as finely divided powders, simply by varying the electrolysis conditions (composition and temperature of the electrolyte, and current density).

2. Synthesis of the carbides of high-melting metals

The electrochemical synthesis of molybdenum and tungsten carbides was first reported by Andrieux and Weiss,[31] who obtained powders of the carbides by electrolysing a melt of composition $LiF-NaBO_2-Na_2CO_3-MO_3$ (where M = Mo, W). The stoichiometric composition of the deposited powders depended on the $[CO_3^{2-}]:[MO_3]$ concentration ratio.

The further development of the HES of carbides involved the choice of new electrolyte compositions. The conditions used in the synthesis of high-melting metal carbides are shown in Table 1. It is noteworthy that in every case the molten mixtures invariably contained fluoride, borate, or carbonate components. The high-melting metal was introduced as an oxide or as an alkali metal oxy-salt.

Table 1. Electrochemical systems and conditions for the HES of the carbides of high-melting metals.

Electrolyte	Component with high-melting metal	Component with carbon	Electrolysis parameters		T/K	Cathodic product	Ref.
			U/V	$10^{-2}i_k$/A m^{-2}			
$LiF-NaBO_2$	WO_3, MoO_3	Na_2CO_3	3		1050–1100	WC, W_2C (Mo_2C)	31
$NaF-KF-Na_2B_4O_7$	Na_2MoO_4	Na_2CO_3		86	1300	Mo_2C	32
$NaCl-NaF-NaOH-B_2O_3$, ($NaBO_2$, $Na_2B_4O_7$)	Na_2WO_4	Graphite anode		10–150	1300	WC	33
$NaF-KF-Na_2B_4O_7$	Ta_2O_5, Nb_2O_5	Na_2CO_3	0.3–0.8		1100	TaC, NbC	34
$LiF-NaF-KF$	K_2TaF_7	K_2CO_3	0.4–0.9		1023–1073	Ta_2C	34
$NaF-KF$ $LiF-NaF$ $LiF-KF$ $LiF-NaF-KF$	K_2TiF_6, R_2HfF_6, K_2ZrF_6, K_2NbF_7, K_2TaF_7, K_2CrF_6 K_3MoCl_6	K_2CO_3	1.5		973–1023	Cr, Mo, W, Nb, Ta, Ti, Zr, Hf carbides	35–41
$LiF-NaF-KF$	Na_2WO_4 or tungsten anode	K_2CO_3	1.0–1.5	2–7	973–1023	W_2C	39, 40, 45
$LiF-KF$	K_2SiF_6	Li_2CO_3		3–5		SiC	45
$LiF-NaBO_2$	K_2SiF_6	Na_2CO_3		3–5		SiC	45

An interesting method of preparing metal carbides was disclosed in an American patent.[33] Its most important feature is the omission of carbonate ions from the melt, using a dissolvable graphite anode as the source of carbon. However, the potential use of this method is limited by anodic effects on the carbon electrode and by the corrosiveness of the molten medium.

In an attempt to extend the method[33] to other carbides it was noted[36] that if the fluorides were thoroughly dried the graphite anodes did not lose mass, and no carbides were formed. This was attributed[36] to the fact that carbon can react electrochemically with the melt only in the presence of water, and therefore a variant of the HES of carbides based on the Mellors–Senderoff method was proposed.[41–49] The following are its most characteristic features: the electrolyte contains only fluoride anions; the proportion of alkali metal cations varies from 15% to 75% of the total number of cations; the melt does not contain complex formers.

These requirements are satisfied by the ternary LiF–NaF–KF eutectic. By adding potassium carbonate and oxides or halides of the high-melting metal to it, Stern and coworkers[35–40] obtained coatings of the carbides of Group IV–VI metals. However, it is doubtful whether the carbonate ion and the fluoride complexes K_2TaF_7, K_2NbF_7, K_2CrF_6, K_2TiF_6, K_2ZrF_6, and especially K_3MoCl_6 are compatible and can coexist with a LiF–NaF–KF melt. Indeed, in a later paper[44] Stern describes only the preparation of tungsten carbide using Na_2WO_4.

It has been reported[45] that silicon carbide (SiC) can be deposited electrolytically from a $NaF-KF-K_2SiF_6-Li_2CO_3$ melt in the form of powders, coatings, or dendrites.

Only one attempt to develop theoretical foundations for the electrochemical synthesis of carbides has been reported.[36] However, the mechanism of these processes was not discussed in sufficient depth.

3. Synthesis of the silicides of high-melting metals

The HES of silicides was first achieved by Dodero,[46] who synthesised the silicides of titanium, zirconium, and chromium by the electrolysis of molten mixtures of Na_2SiF_6 and K_2SiF_6 with the oxides and fluorides of titanium, zirconium, and chromium.

$TiSi_2$ was synthesised by the electrolysis of an $NaCl-KCl-K_2SiF_6-K_2TiF_6$ melt.[47] These workers[47] studied the cathodic processes involved in the deposition of $TiSi_2$ from chloride–fluoride melts.

The electrodeposition of Group IV–VI silicides from a melt containing a eutectic mixture of alkali metal fluorides, silicon (in the form of potassium silicofluoride), and the high-melting metal (in the form of its fluoride) has been described in a patent.[48] A more detailed description of the electrodeposition of tantalum silicide coatings has also been published.[49]

The conditions used in the preparation of the silicides of high-melting metals are summarised in Table 2.

4. Synthesis of the borides of high-melting metals

In 1929 Andrieux[50] described the preparation of borides by the electrolysis of molten fluorides and oxides of alkali and alkaline earth metals containing the oxides of boron and of a high-melting metal. He synthesised 17 borides, including TiB_2, ZrB_2, TaB_2, NbB_2, VB_2, and CrB_2. According to Andrieux and Barletty[51] the oxides of the high-melting metal and boron are reduced by the lithium, magnesium, or calcium initially deposited at the cathode.

More recently Andrieux and Weiss[52] reported the preparation of MoB and WB by the electrolysis of mixtures of the fluorides, oxides, and borates of alkali and alkaline earth metals containing the oxide of the transition metal.

Table 2. Electrochemical systems and conditions for the HES of the silicides of high-melting metals.

Electrolyte	Component with high-melting metal	Component with silicon	U/V	T/K	Cathodic product	Ref.
Na_2SiF_6 (K_2SiF_6)	TiO_2, ZrO_2, Cr_2O_3, fluorides Ti, Zr, Cr	Na_2SiF_6 (K_2SiF_6)	1.9–2.1	1273	$TiSi_2$, $ZrSi_2$ $CrSi_2$	46
$NaCl-KCl$	K_2TiF_6	K_2SiF_6	1.3–1.5	973	$TiSi_2$	47
$LiF-KF$	K_2TaF_7	K_2SiF_6	1.2	1023	$TaSi_2$, $TiSi_2$, $ZrSi_2$	48, 49
$NaF-KF$	K_2TiF_6					
$LiF-NaF-KF$	K_2ZrF_6					

Table 3. Electrochemical systems and conditions for the HES of the borides of high-melting metals.

KF	WO_3 (MoO_3)	KBF_4			1173–1273	W_2B_5, WB (Mo_2B_5, MoB)	68

The synthesis of a series of chromium borides of different composition has also been reported.[53] These compounds were obtained by gradual changes in the Cr_2O_3 content of the fluoride–borate melts.

The HES of borides was subsequently developed in three directions: electrolysis from purely oxide melts, from purely halide melts, and from mixed oxide–halide melts. The conditions used in the preparation of the borides of high-melting metals are summarised in Table 3.

Pure oxide melts were studied by Schlain and coworkers[54–57] in the preparation of coatings of titanium boride. They used melts of alkali and alkaline earth metal borides with added titanium oxide. Titanium or sintered TiB_2 were used as anodes. The TiB_2 anode offered more stable electrolysis conditions. The rate of deposition of the coatings was between 20 and 220 μm h^{-1}.

A method of preparing coatings of vanadium, niobium, and tantalum borides has been disclosed.[58] The authors suggest the use of a purely oxide melt based on borates: the bath was made of graphite or heat-resistant steel, the anode was the body of the bath or an electrode made of graphite, heat-resistant steel, or an alloy of vanadium, niobium, or tantalum.

Another patent[59] claims the electrodeposition of titanium and zirconium diborides (though the method is equally applicable to other borides) from the fluoride–chloride melt NaCl–KCl–K_2TiF_6(K_2ZrF_6)–KBF_4. A method of preparing coatings of TiB_2 by the electrolysis of molten salts using a soluble anode or an anode of pure boron in the presence of BF_4^- ions (introduced as gaseous BF_3 has also been disclosed.[60] The composition of the bath must include an alkali metal fluoride. A method of depositing TiB_2 coatings on various items by the electrolysis of LiF–KF–K_2TiF_6–TiF_3–KBF_4 melts has been developed.[61]

The electrosynthesis of tantalum boride from the chloride–fluoride melt KCl–K_2TaF_7–KBF_4 has been achieved,[62] and an attempt has been made to identify the mechanism of the process. A mixture of tantalum mono- and diboride or only one of these borides could be obtained by varying the composition of the electrolyte, the anodic current, and the cell voltage.

An analysis[63] of the current–voltage curves for the electrolytic dissociation of TiO_2 and B_2O_3 showed that the direct deposition of the boride TiB_2 from a fused borate–fluoride bath is the primary process. Substantial depolarisation of the cathodic process through the formation of TiB_2 is possible.

Another patent[64] proposes a method of synthesising the borides ZrB_2 and TiB_2 from melts of sodium chloride, fluoride, borate, and carbonate. A detailed description of the electrolytic preparation of metal diborides from their oxides and ore concentrates has also been given.[65]

A method of preparing zirconium diboride from a fluoride–oxide melt has been patented.[66] ZrF_4 can replace K_2ZrF_6 as the source of zirconium. Zirconium diboride has been prepared also from a fluoride–oxide melt containing only zirconium and boron components.[67] In this case the process is controlled by the concentration of B_2O_3 in the melt, and at high current densities metallic zirconium is deposited as well as the diboride.

Aleonard[68] extended Marion's method (described by Hagenmüller[53]) to the preparation of molybdenum and tungsten borides. He also used fluoride–oxide melts.

III. Modern problems in high-temperature electrochemical synthesis

An analysis of the state of problems in the HES of quasimetallic high-melting compounds has shown that (as a rule) electrosynthesis is carried out by a purely empirical choice of melt composition and of experimental conditions. The very small number of publications (approximately thirty) devoted to this problem is noteworthy.

Most of these publications dealt with the HES of titanium and zirconium borides, titanium silicides, and molybdenum and tungsten carbides. There are also a few unrelated papers on the preparation of tungsten and molybdenum borides, and of compounds of Group V metals. No information at all is available on the electrosynthesis of molybdenum and tungsten silicides, and of three-component high-melting compounds. However, in the whole of this work no reference can be found to the mechanism and to the controlling principles of the HES processes, without which the practical exploitation of the method is severely limited.

Because of these limitations studies in depth have been pursued in our laboratories during the past 15 years: their aim has been to create theoretical foundations for the HES and for the principles underlying the realisation and control of multielectron reactions, and to explain their mechanism. The following problems were formulated in order to achieve these objectives:

(1) to develop a thermodynamic basis for the high-temperature electrosynthesis of QHC, and to use it to identify possible variants and regimes of the electrosynthesis and to choose the components for the synthesis;

(2) to establish the mechanism of the electrolytic reduction of large complex anions of high-melting metals and nonmetals, and to develop the principles underlying the realisation and control of multielectron processes;

(3) to develop methods of approximating and identifying the conditions for reconciling the potentials of different processes for the deposition of the components;

(4) to define methods for controlling the form (powders, or coatings) of the cathodic deposits.

Table 4. Electrochemical systems and conditions for the HES of multicomponent high-melting compounds.

Electrolyte	Component with high-melting metal	Component with nonmetal	Electrolysis parameters		T/K	Cathode product	Ref.

The high-temperature electrochemical synthesis of QHC can take place in two regimes: the thermodynamic (or quasi-equilibrium) or the kinetic regime. According to a theoretical analysis of the electrochemical preparation of alloys[5] the thermodynamic regime is established when the deposition potential of the components are similar ($\Delta U \leqslant 0.2$ V). Under these conditions the composition of the alloy is independent of the current density over a wide range. In the opposite case ($\Delta U > 0.2$ V) we meet the kinetic regime, and the composition of the alloy is independent of the potential difference. In order to deposit carbides, borides, and silicides with a greater interaction energy the range of values of the potential for the thermodynamic regime is increased by G_f/zF, where G_f is the Gibbs free energy of formation of the QHC from the elements in their standard state; z is the total number of electrons contributing to the electrosynthesis of the QHC (for Mo_2C this number is $z = 16$).

The thermodynamic foundations of the HES of quasimetallic high-melting compounds and of the choice of systems for the synthesis were established by an analysis of the equilibrium potentials (voltages) for the decomposition of various compounds of high-melting metals of Groups IV–VI and of nonmetals (C, B, Si) at high temperatures (900–1200 K), using thermodynamic data obtained for these compounds.[69,70] Bartlett and Johnston[71,72] carried out a similar analysis of electrochemical processes involving the carbonate ion and carbon dioxide.

A comparison of the temperature dependences of the deposition potentials of the Group IV–VI metals and of carbon, boron, and silicon shows that those of the high-melting metals of Group IV are similar to those of boron and silicon, with a corresponding similarity between the deposition potentials of the high-melting metals of Group VI and carbon. Under these conditions the electrolysis can be carried out in the thermodynamic regime. The electrochemical synthesis of the carbides of Group VI metals and of the borides and silicides of Group VI metals is possible only in the kinetic regime, because in these systems the deposition potentials are markedly different.

A comparative study of the results obtained in studies of the elecrochemical reduction of the oxy-anions of high-melting metals and nonmetals in chloride, chloride, fluoride, and oxide melts having different acid–base properties has revealed three mechanisms for the formation of electrochemically active species:[2,3,73] the cationisation of an anion with formation of cationised species, the breakdown of an oxy-anion with formation of oxide–halide complexes, and the formation of dimeric complexes.

By constructing electrochemically active species of different structure and composition we can generate conditions enabling multielectron electrochemical processes to be realised. This approach allows us to control the rate of formation of these species in multielectron systems and the potential of the charge transfer reaction, to reconcile the potentials of different processes, and to achieve the HES of quasimetallic high-melting compounds.

Problems arising in the electrochemical synthesis of quasimetallic high-melting compounds are currently being studied by workers from various countries.[4,34,39,44,94]

The results of those workers, and those obtained by the present writers, on the electrochemical synthesis of quasimetallic high-melting compounds from various salt systems are discussed below. The compositions of the systems examined, the experimental conditions, and the compositions of the products in the HES of carbides, silicides, and borides, and also of double carbides, are shown in Table 4.

IV. High-temperature electrochemical synthesis of multicomponent high-melting compounds

1. Synthesis of molybdenum and tungsten carbide powders under an excess pressure of carbon dioxide

The potential application of the HES method can be extended by using carbon dioxide (whose concentration in the melt can be controlled by an excess pressure) as a source of carbon for the synthesis. This allows us to produce a buffer molten electrolyte based on low-melting alkali metal chlorides and having prescribed acid–base properties [cationised[74] $\{M_x^{2+}[M'O_4^{2-}]\}^{2x-2}$, dimeric[75,76] $M'_2O_7^{2-}$, fluoride oxide[77] $M'O_2F_4^{2-}$ (where M′ = Mo; W, M = Li^+, Ca^{2+}, Mg^{2+}, Al^{3+})], and to obtain a direct electrochemical synthesis of carbides in the presence of an excess pressure of carbon dioxide. The effects of the electrolyte composition, of the CO_2 pressure over the melt, of the temperature, of the cathodic current density, and of the design and materials of the electrodes on the phase composition and on the properties of the carbide powders thus obtained have now been established.[74,76] The reactions which provide the foundations of the HES and the special technological features of the process have been described.[74,78] We have developed a new design of electrolysis cell which can be used at 973–1073 K and under an excess pressure of CO_2 of up to 2×10^6 Pa. The specific surface of the powders was 6–10 $m^2\ g^{-1}$. The rate of deposition of WC in an NaCl–KCl–Na_3PO_4 electrolyte was 0.2–0.4 g $A^{-1}\ h^{-1}$ with a current yield of up to 56%; in a KCl–NaCl–NaF electrolyte the corresponding parameters were 0.35–0.52 g $A^{-1}\ h^{-1}$ and up to 75% respectively (see Table 4).[79]

2. Synthesis of highly dispersed powders of molybdenum and tungsten carbides from oxide melts

The low solubility of CO_2 in halide oxide melts allows us to work at low current densities (i_k) and to produce particles with diameters of 2–5 μm. Smaller particles (<2 μm) can be obtained in tungstate–molybdate–carbonate oxide melts by increasing i_k. The electrolytic reduction of the CO_3^{2-}, MoO_4^{2-}, and WO_4^{2-} ions in a melt of Na_2WO_4 takes place at low potentials.[75,79] This allows their simultaneous reduction, and therefore also the HES of the carbides. The specific surface of the powders is 10–20 $m^2\ g^{-1}$, the yield of product is 0.71 g $A^{-1}\ h^{-1}$, and the current yield is 93%–97%.

Graphite or vitreous carbon are used most effectively as anode material; nickel as cathode material. Highly dispersed powders often contain up to 5–7 mass% of free carbon and sorbed oxygen. Annealing the synthesised molybdenum and tungsten carbide powders in activated hydrogen almost completely eliminates the free carbon (from 7 to 0.1 mass%) and lowers the oxygen content by an order of magnitude (from 5 to 0.2–0.3 mass%).[80] The crystal lattice parameters of the monocarbide WC prepared in this way ($a = 2.906 \pm 0.003$; $c = 2.837 \pm 0.006$ Å) coincide with the accepted values.

3. Electrodeposition of molybdenum and tungsten carbide coatings from oxide and halide oxide melts

One advantage of HES over other methods of synthesis is its suitability for the production of coatings. The electrodeposition of Mo_2C coatings was achieved[75,79] from the purely oxide melt Na_2WO_4–Li_2MoO_4–Li_2CO_3. In this system the MoO_4^{2-} and CO_3^{2-} ions can be reduced simultaneously by electrolytic reduction. The experimental melts are stable, nontoxic, and nonhygroscopic, and do not require a protective atmosphere. Continuous oxides were obtained at 1073–1223 K and current densities between 10^2 and 10^3 A m^{-2}. The rate of deposition of the coating was 5–20 μm h^{-1}, the current yield of the product was up to 60%, its thickness was up to 50 μm (see Ref. 81).

The main shortcoming of oxide melts is the high concentration of tungsten and molybdenum. A eutectic NaCl–LiF melt was used in order to lower the concentration, and the deposition potentials of molybdenum, tungsten, and carbon were

determined for this medium.[82,83] The deposition potential of molybdenum from MoO_4^{2-} was 200 mV higher than the deposition of tungsten from WO_4^{2-}, and almost equal to the deposition potential of carbon from CO_3^{2-}. This accounts for the possibility of depositing coatings of Mo_2C and W_2C. The crystallisation of WC as a continuous coating could not be achieved. The rate of deposition of W_2C and Mo_2C was up to 10 μm h^{-1}, the current yield as a coating was up to 40%, the thickness up to 20 μm. The microhardness of Mo_2C was 1800–1900, that of W_2C ws 2900–3100 kg mm^{-2}.

An interesting study[84] of the effect of silver ions on the electrodeposition is relevant to the control of the structure of tungsten carbide coatings prepared from halide–oxide melts. It was established that the addition of 10^{-3} mol% of AgCl to a melt of the LiCl–KCl eutectic containing K_2CO_3 and K_2WO_4 produces [at $i_k = (2-50) \times 10^2$ A m^{-2}] hexagonal crystals of the carbides W_2C and WC instead of the needles and dendrites obtained in the absence of AgCl.

4. Synthesis of chromium, molybdenum, and tungsten silicides from halide–oxide melts

A thermodynamic analysis combined with voltammetric measurements showed that the HES of the silicides of Group VI metals can be achieved only in the kinetic regime, in which the more electropositive component (Cr_2O_3, Mo, W) is deposited first, and the other component (Si) is next deposited on its surface.[85–88] The diffuse reaction path leads to the formation of silicides of various compositions, up to the highest (MSi_2).

The $KCl-KF-K_2SiF_6-K_2CrO_4$ system has been used for the high-temperature electrochemical synthesis of chromium silicides. Depending on the composition and on the electrolysis parameters both individual phases (Cr_3Si and $CrSi_2$) and mixtures of these phases (with a small amount of free silicon) could be obtained.[85,89]

The electrochemical synthesis of molybdenum and tungsten silicides has been achieved in a molten chloride–cryolite mixture containing molybdate (or tungstate) and silica.[86,87] The HES is strongly influenced by the temperature and by the current density. Below 1123 K the reaction of the molybdenum (or tungsten) with the silicon does not go to completion, and at higher temperatures (>1223 K) the stability of the metallic salt deposit decreases. When $i_k < 5.6 \times 10^3$ A m^{-2} the product is contaminated by free metal, and when $i_k > 1.2 \times 10^3$ A m^{-2} a phase of the double silicide $(Al,Si)_2M$ appears (where M = Mo, W). The specific surface of the powders is 5–15 m^2 g^{-1}, the particle size is 0.5–2.0 μm, the rate of deposition of $MoSi_2$ is 0.2–0.3, that of WSi_2 is 0.3–0.45 g A^{-1} h^{-1}.

5. Synthesis of chromium, molybdenum, and tungsten borides from halide–oxide melts

The large difference between the electrodeposition potentials of chromium,[85] molybdenum,[86] and tungsten[87] from a chloride–cryolite melt containing sodium chromate (molybdate, tungstate) and the deposition potentials of the oxide fluoride complexes of boron[89] from the same systems, which can be as high as 0.7–0.8 V, suggests that the HES of the chromium, molybdenum, and tungsten borides can be carried out only in the kinetic regime. The electrochemical synthesis of chromium borides was achieved from a chloride–cryolite melt containing chromate and boron oxide.[89] Depending on the composition of the melt and on the electrolysis parameters both the individual phases (Cr_2B, CrB, CrB_4) and their mixtures could be obtained. The yield of the single-phase product CrB_4 was 0.14–0.21 g A^{-1} h^{-1}, the specific surface was 8–17 m^2 g^{-1}.

The electrochemical synthesis of molybdenum and tungsten borides was achieved from a molten chloride–cryolite mixture containing molybdenum (or tungstate) or molybdenum (or tungsten) oxide, and borax (or boric oxide).[90] The synthesis process was optimised by establishing the regimes leading to the production of the single-phase higher boride MB_4, which offers the most valuable physical and mechanical properties. At concentrations of B_2O_3 and $Na_2B_4O_7$ between 10 and 20 mass% complete boridation of the high-melting metal is observed, with formation of the MoB_4 and WB_4 phases. The yield of these products is 0.2–0.3 and 0.3–0.45 g A^{-1} h^{-1} respectively, and the specific surface of both powders is 5–15 m^2 g^{-1}.

6. Synthesis of titanium, zirconium, and hafnium borides from halide melts

The possible use of chloride and chloride–fluoride melts (containing not more than 10 mass% of fluoride) for the HES of titanium and zirconium borides has been studied.[91] It was found that the formation of MB_2 on the cathode (where M = Ti, Zr) is accompanied by a substantial energy effect [?overpotential. (Ed. of Translation)] of 0.32 for TiB_2 and 0.38 V for ZrB_2 (at 973 K). The potentials at which the synthesis takes place depend on the difference between the reduction potentials of the components, i.e. on the form of the electrically active species. In the BCl_3-TiCl_4, MBF_4-MTiF_6, $MBF_4-M_2TiF_6$, BCl_3-ZrCl_4, MBF_4-ZrCl_4, and $MBF_4-M_2ZrF_6$ systems (in a melt of KCl–NaCl) the difference between the deposition potentials of the high-melting metal and of boron is not more than 0.2 V. The HES conditions are chosen by varying the cation/anion composition of the electrolyte. By changing the electrolysis parameters we can obtain titanium and zirconium diboride powders having surface areas between 1×10^3 and 5×10^4 m^2 kg^{-1}, or continuous coatings up to 20 μm thick (see Table 4). The quality of the coatings is improved by carrying out the process in the refining regime with a MB_2 anode. The mechanism of the cathodic processes taking place during the HES of titanium diboride has been examined in detail.[92]

It was found[93] that the HES of hafnium diboride is possible only in the thermodynamic regime. In addition to the waves produced by the electrolytic reduction of the complexes of tervalent boron with quadrivalent hafnium, a wave at potentials more positive than the discharges of BF_4^- and HfF_6^{2-} by 0.1 and 0.35–0.4 V respectively was observed in a voltammetric study of the $NaCl-KCl-KBF_4-K_2HfF_6$ system. It was tentatively attributed to complex species: heteronuclear complexes produced by the interaction of the complexes of hafnium(IV) and boron(III). Coatings of hafnium diboride having a microhardness of 3200 ± 250 kg mm^{-2} were produced in this study.

7. Synthesis of the borides and silicides of vanadium, niobium, and tantalum from halide melts

It has been shown[94] that the borides of Group V metals can be prepared by HES from chloride–fluoride melts. Thermodynamic calculations led to the conclusion that the borides of the vanadium subgroup are characterised by a kinetic synthesis regime from chloride and fluoride melts. The conditions and regime for the synthesis of TaB_2 from chloride–fluoride melts and the potential regions for the deposition of tantalum, boron, and tantalum diboride have been determined[95] as a function of the activity of the fluoride ion in the melt. It was concluded from voltammetric measurements that conditions consistent with the thermodynamic synthesis regime can be achieved by varying the anion composition of the electrolyte (see Table 4).

The conditions and the regime of the synthesis of powdered Ta_5Si_3 from chloride–fluoride melts and the deposition potentials of Ta, Si, and Ta_5Si_3 have been determined[96] as a function of changes in the acid–base properties of the melt. It was concluded from voltammetric measurements that the thermodynamic synthesis regime applies in this case.

The electrodeposition of the borides of elements in the VA subgroup is described in a patent.[97] The method combines the following procedures: preparation of the borate melt, saturation of the melt with compounds of the elements from the VA subgroup by anodic dissolution of Fe–M alloy anodes (where M = V, Nb, Ta), and cathodic treatment of the articles to be coated. VB, NbB_2, and TaB_2 coatings were produced.

8. Electrochemical synthesis of the double silicides of molybdenum (or tungsten) and aluminium

When chloride–cryolite melts are electrolysed to deposit the disilicides of molybdenum and tungsten increasing the current density produces deposits of the double disilicides $M(Al, Si)_2$, where M = Mo, W.[98] If the chloride–cryolite melt contains more than 1.5 mass% of Na_2MO_4 the product contains molybdenum (or tungsten) disilicide and metallic molybdenum (or tungsten). If the concentration of Na_2MO_4 is less than 0.5 mass% some free silicon appears in the product, and in the concentration range $0.5 < [Na_2MO_4] < 1.5$ mass% silicon–aluminium alloys are formed. Depending on the current density the specific surface of the disilicide powders lies in the range 11.3–15.2 $m^2\ g^{-1}$ (see Table 4).

9. Synthesis of two-component intermetallic compounds based on molybdenum(tungsten) and cobalt(nickel)

Construction materials and coatings based on the high-coercivity wear and corrosion resistant W–Co, W–Ni, Mo–Co, and Mo–Ni alloys have recently stimulated wide interest. They are usually prepared by electrodeposition from aqueous solutions.[99] However, this method has several shortcomings: the concentration of nonmetals (O_2, N_2, H_2) in the final product is high, the rate of deposition is low ($i_k \leqslant 1 \times 10^3$ A m^{-2}), and alloys of constant composition cannot be obtained. The use of melts avoids these shortcomings.

Nickel and cobalt are much more noble (electropositive) than molybdenum and tungsten. Furthermore, to achieve the HES of intermetallic compounds based on molybdenum(tungsten) and cobalt we must find a method of bringing their deposition potentials closer together, and conditions compatible with their simultaneous discharge. This can be done by controlling the electrolytic reduction potential of the $[MO_4^{2-}]$ anions through acid–base interactions. We used the cationisation of the oxide complexes $\{M'_x[MoO_4^{2-}]\}^{2x-2}$ (where $M' = Ba^{2+}$, Ca^{2+}, Mg^{2+}), which are decomposed with formation of dimeric[75,76] and halide oxide complexes.[100] In the case of the Mg^{2+} cation it is possible to superpose the electrolytic reduction waves of Co^{2+} and $\{Mg_x[MoO_4^{2-}]\}^{2x-2}$ and to bring the deposition potentials of cobalt and tungsten to within 300 mV of each other (see Refs 100 and 102). Better results were obtained for the decomposition of $[MO_4^{2-}]$, in which the corresponding processes can be exactly superposed.[101,102]

These studies led to the choice of three systems for the synthesis of binary alloys based on molybdenum and two systems for tungsten alloys (see Table 4).

10. Synthesis of three-component hard alloy compositions

In powder metallurgy cobalt and nickel powders, which act as a binder component, are added to the charge when articles of molybdenum or tungsten carbide are made by hot pressing. This fact, and other unique properties of the ternary alloys, stimulated the search in the $WO_3–CO_2–CoCl_2$ system[102] for conditions which allow the simultaneous electrodeposition of carbon, tungsten(molybdenum), and cobalt(nickel), aimed at the HES of binary carbides. From the results of a study[103] of the electrolytic reduction of CO_2 dissolved in halide melts under an excess pressure systems for testing the possibility of bringing together the deposition waves of carbon from CO_2, of cobalt(nickel) from the $[MCl_4]^{2-}$ complex, and of molybdenum(tungsten) from various complex ionic forms were chosen. The simultaneous deposition of three components [carbon, molybdenum(tungsten), and cobalt(nickel)] was realised in systems with differences in discharge potential not greater than 200 mV. In the latter case the CO_2 acts not only as a source of carbon but also as an acidic additive which shifts the molybdenum(tungsten) deposition potential towards more positive values.

The compositions of the liquid electrolytes and the conditions for the synthesis are summarised in Table 4. In all the systems potentiostatic electrolysis is applied, at the potentials corresponding to the simultaneous deposition of the three components. A pure binary carbide was obtained only in one system. The yield of the single-phase product Co_3W_3C is 0.4–0.6 g $A^{-1}\ h^{-1}$, the particle size is 0.3–1.0 μm. Evidently the composition of the three-component alloy and its purity are determined by several factors: the ratio of the partial currents of the reacting components, the energetics of their interaction, and the possibility of parallel reactions between two components. The latter reactions are responsible for the presence of impurities of high-melting metal carbides.

Contents

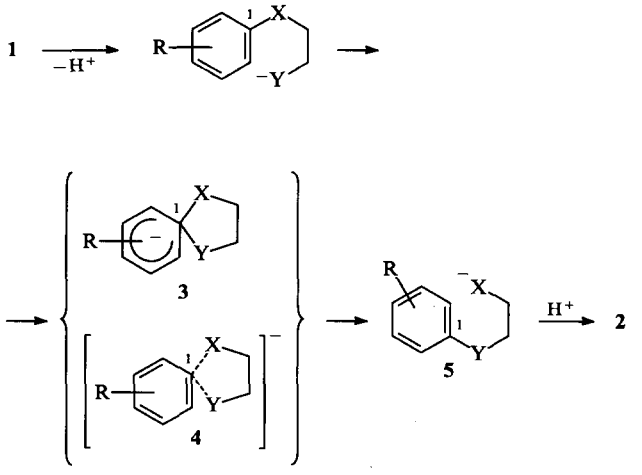
I. Introduction 133
II. Rearrangement of *o*-aminophenyl phenyl ethers 134
III. The Smiles rearrangement of aromatic polyfluoro-compounds 136

Abstract. A systematic account is given of the literature data on the Smiles rearrangement of *o*-aminophenyl phenyl ethers including data obtained by means of model studies on polyfluoro-derivatives. Attention is concentrated on the influence of the structure of *o*-aminophenyl phenyl ethers on their reactivity. The bibliography includes 51 references.

I. Introduction

The Smiles rearrangement plays an important role in the synthesis of condensed heterocyclic systems comprising activated aromatic halo-compounds and asymmetric bifunctional nucleophiles. In a general form, it can be represented by Scheme 1, which includes the inversion of the side chain in a type **1** structure.[1–3] An activated aromatic or heteroaromatic ring is the migrating residue, while the side chain may be part of the aromatic system.

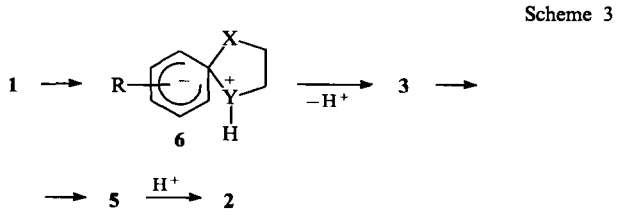
Scheme 1



1 **2**

Transformations of this kind were first investigated by Smiles and co-workers in 1931 in relation to *o*-hydroxy-derivatives of diaryl sulfones and sulfides.[4] Later the Smiles rearrangement was extended to a large number of aromatic derivatives with different combinations of groups X and YH and the most important factors affecting its rate were determined: activation of the migrating aromatic ring, mobility of the substituting group, nucleophilicity of the attacking centre, and acidity of the functional group YH.[1,2]

The Smiles rearrangement is usually carried out in a basic medium. The proposed reaction mechanism includes the YH ionisation stage and nucleophilic attack by the anion Y^- on the 1-position in the aromatic ring accompanied by the formation of an intermediate Meisenheimer spiro-complex **3** or the transition state **4** (Scheme 2).[1,2]



Scheme 2

The type **3** intermediates, including those with the functional groups X and Y linked by the *o*-phenylene fragment, were isolated or detected in solution by spectroscopic methods.[5–8] The Smiles rearrangement can occur as a reversible process,[1,2] which presupposes the irreversibility of the formation stages and of further reactions of the intermediate **3** and is most probable when the nucleophilicities of the centres X and Y are similar.[6]

Examples of the Smiles rearrangement which do not require the presence of bases and which occur without preliminary ionisation of the group YH are known. In such cases, the nucleophilic attack by the latter on the 1-position leads to the formation of a type **6** zwitterionic spiro-complex which is then converted into the intermediate **3** via deprotonation (Scheme 3).

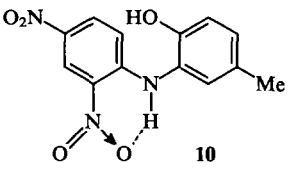
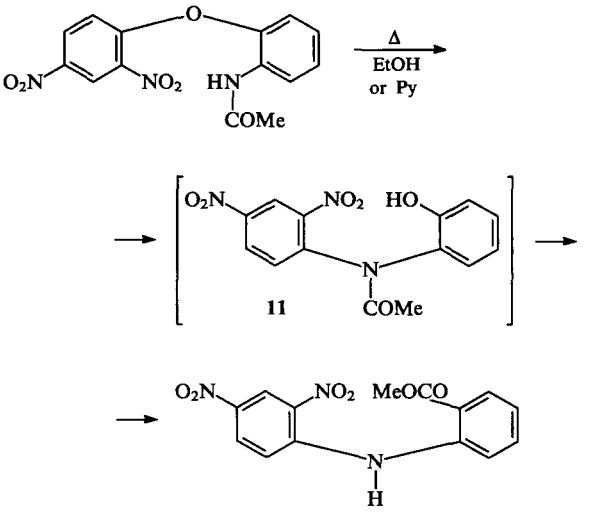
The rearrangement of *o*-aminophenyl phenyl ether to aryl(*o*-hydoxyaryl)amines, discovered and first investigated by Roberts and de Worms,[9] belongs to transformations of this kind. It has been demonstrated on numerous examples that this rearrangement plays a significant role in the synthesis of phenoxazines from aromatic polynitrohalo-compounds and *o*-aminophenols, preceding the final intramolecular cyclisation stage and determining the structure of the reaction products.[2,10,11] In the 1960s, a series of unexpected aspects of this reaction were discovered.[12,13] However, in a review[2] devoted to the Smiles rearrangement the data concerning the transformations of *o*-aminophenyl phenyl ethers were treated systematically to an inadequate extent. This factor as well as the results of our investigations in recent years, obtained by extending the Smiles rearrangements to aromatic polyfluoro-compounds,[14] led us to write the present review.

II. Rearrangement of *o*-aminophenyl phenyl ethers

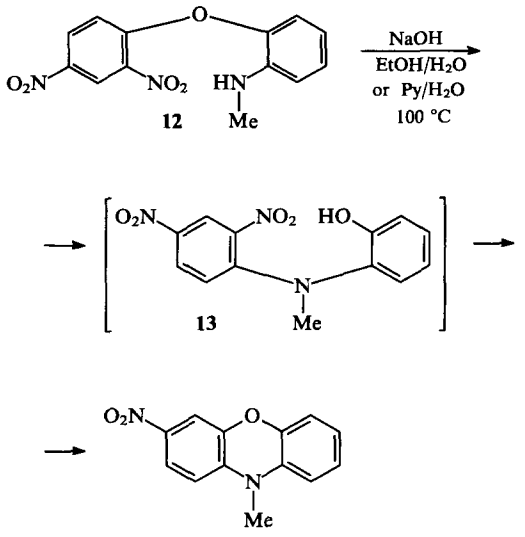


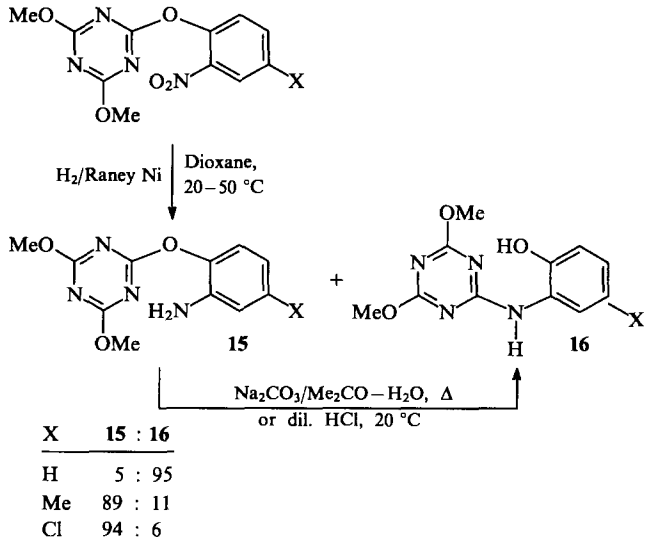
It was shown in 1934[9] that the interaction of 1-chloro-2,4-dinitrobenzene with 2-amino-*p*-cresol affords either the diphenylamine **7** or the diphenyl ether **8**, depending on the reaction conditions. On heating, compound **8** rearranges to the amine **7**. The reaction takes place in basic and hydroxyl-containing solvents (pyridine, aniline, alcohols, etc.) and is retarded in an alkaline [sic] medium. According to the authors,[9] the rearrangement of the ether **8** takes place without the preliminary ionisation of the amino-group, i.e. proceeds via Scheme 3.



It is assumed that aryl(*o*-hydroxyaryl)amines do not undergo the Smiles rearrangement.[1,2,15-19] The reversible formation of the spirocyclic complex **9** from *N*-methyl-*N*-picryl-2-aminophenol has been established by spectroscopic methods.[5,20] Presumably the absence of the Smiles rearrangement in the given instance is due to the relative ease of the dissociation of the C(1)–O bond with formation of a stable phenoxide anion.

The rearrangement of the ether **8** to the amine **7** is not accompanied by cyclisation and the formation of a phenoxazine. This feature, which has been explained by the formation of an intramolecular hydrogen bond stabilising the unreactive structure **10**,[18,21,22] made it possible to observe the Smiles rearrangement 'in a pure form' and helped to discover the influence of the nature of the substituents at the nitrogen atom and in the aromatic rings on the rate of the transformation.

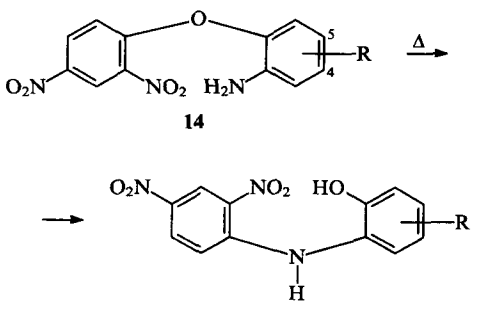




It has been shown that the higher the electron-accepting capacity of the acyl residue the greater the lowering of the rate of rearrangement caused by the *N*-acylation of *o*-aminophenyl ethers. Since the rearrangement of *o*-*N*-acyl-substituted diphenyl ethers takes place in a neutral medium, one may suggest that it takes place via Scheme 3.[9,23] The Smiles rearrangement is accompanied in this case by the migration of the acyl residue from the nitrogen atom to the oxygen atom, tentatively in accordance with a stepwise mechanism via the intermediate *o*-hydroxyamine **11**.[24]

The introduction of the electron-donating *N*-methyl group into the molecule of 2-aminophenyl 2,4-dinitrophenyl ether also lowers its capacity for the rearrangement. Thus compound **12** is stable under the conditions of the transformation of the NH_2 analogue and leads slowly to *N*-methyl-3-nitrophenoxazine only on heating in an alkaline solution.[25] The *para*-location of the nitro-group and of the heterocyclic nitrogen atom in the molecule of the phenoxazine formed indicate that the cyclisation stage is preceded by the rearrangement to the diphenylamine **13**. The latter is unstable under the reaction conditions because an intramolecular hydrogen bond, of the kind stabilising the NH_2 analogue, cannot be formed.[21,25]

Although the rearrangement of the *N*-methyl-substituted ether **12** requires an alkaline medium, its occurrence via Scheme 3 is most likely. The activating effect of alkali is apparently manifested in the stage involving the conversion of the zwitterionic type **6** spiro-complex into the intermediate **3**. The reaction mechanism involving the deprotonation of the spirocyclic complex as the rate-limiting stage had been established earlier as a result of a kinetic study of the rearrangement of 2-aminophenyl 2,4-dinitrophenyl sulfide[26] and of a series of similar processes.[8,27,28]

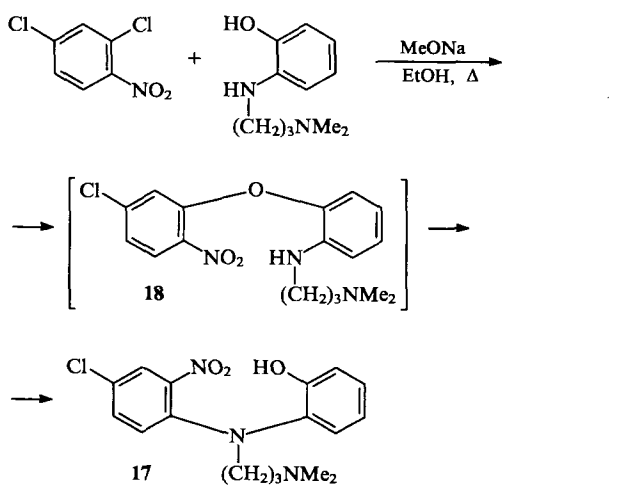


X	15 : 16
H	5 : 95
Me	89 : 11
Cl	94 : 6

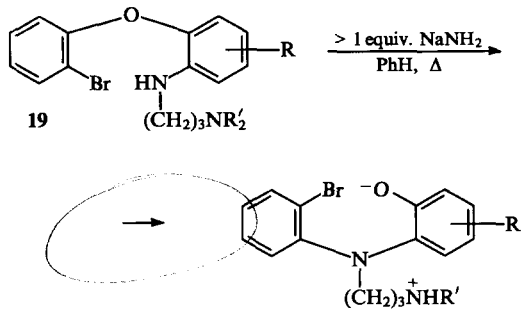
The influence of substituents in the ring carrying the amino-group on the rearrangement of *o*-aminophenyl phenyl ethers is fairly complex and not unambiguous. When Scheme 3 operates, the rearrangement should be facilitated by substituents increasing the basicity of the attacking amino-group or stabilising the phenoxide anion formed. The study of the rearrangement of type **14** ethers showed that the highest rate of transformation is attained for R = H; the introduction of a substituent of any kind into the *para*- or *meta*-position relative to the amino-group slows down the reaction, the greatest effect being manifested in the case of 5-methyl-substituted compounds (Table 1).[29,30]

Table 1. The durations of the rearrangement of the diphenyl ethers **14** in the 4:1 acetic acid–pyridine mixture at 50 °C.

R	*t*/min	R	*t*/min	R	*t*/min
4-H	5	4-Cl	60	5-H	5
4-Me	7	4-Br	30	5-Me	90
4-OMe	13	4-I	15	5-I	7
4-NH_2	50				

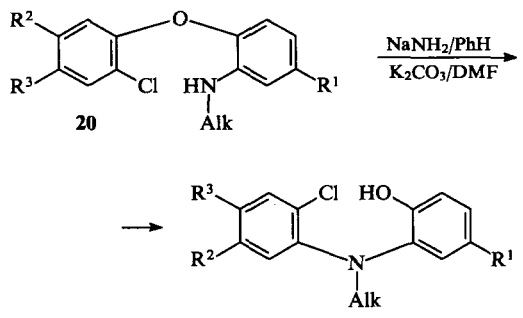


The direct dependence of the rate of rearrangement on the sum of the Hammett constants $(-\sigma_m + \sigma_p)$ of the substituent X has been discovered similarly for *o*-aminophenoxytriazines **15**, which are partly converted into the amines **16** during their synthesis by the reduction of the corresponding nitro-compounds: H(0) > Me (−0.101) > Cl (−0.146).[31]



On this basis, the activation of the migrating aryl residue was recognised as the most important factor determining the possibility of the occurrence of the Smiles rearrangement.[1,2] The rearrangements of *o*-aminophenyl phenyl ethers were investigated mainly in relation to 2,4-dinitro-derivatives.[9,23,25] We are not aware of any attempts to achieve them for mononitro-analogues.

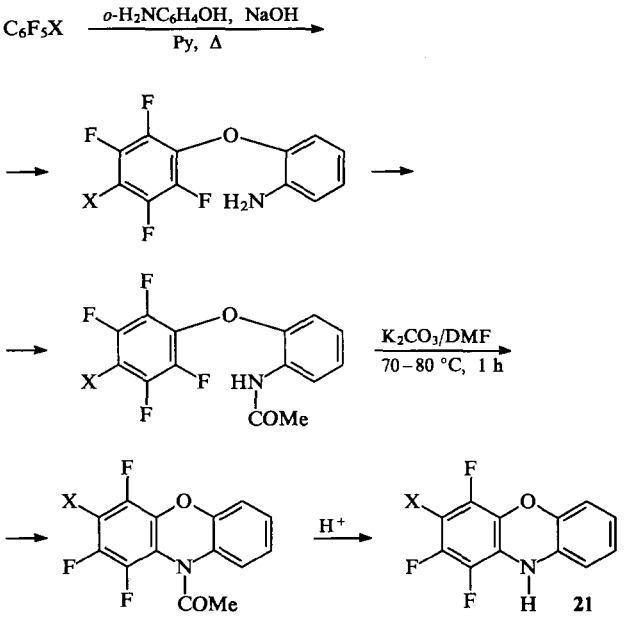
Data on the synthesis and reactions of the picryl ether of 2-amino-*p*-cresol, presented by Roberts and de Worms,[9] have been quite justifiably questioned by Drozd and coworkers.[20] As already mentioned above, the possibility of the occurrence of the Smiles rearrangement as a result of migration of an activated heterocyclic residue has been demonstrated in a number of studies.[31–33] Thus prolonged maintenance of the ether **15** (X = H) in acetone in the presence of sodium carbonate leads to its complete transformation into the amine **16**. A characteristic feature of the rearrangement in this case is the fact that it is catalysed not only by a base but also by an acid.[31] The catalytic effect of the acid is apparently associated with the enhancement of the electron-accepting capacity of the migrating ring by the protonation of the heterocyclic nitrogen atom.[34] The replacement of the methoxy-groups in compound **15** by the more electron-donating diethyl amino-groups suppresses the rearrangement.[31] However, the need for a high degree of activation of the migrating ring for the occurrence of the Smiles rearrangement of *o*-aminophenyl phenyl ethers was soon questioned.



In 1961, Bonvicino et al.[22] suggested that the reaction involving the formation of aryl(*o*-hydroxyaryl)amino **17** from *o*-*N*-(3-dimethylaminopropyl)phenol and 2,4-dichloro-1-nitrobenzene involves the rearrangement of the intermediate ether **18**.

In conformity with this hypothesis, they carried out the rearrangement of the ether **19** by refluxing it in benzene in the presence of an excess of sodium amide.[12]

This is the first example of the Smiles rearrangement with a halogen atom as the activating group. According to the authors,[12] it is determined by the higher nucleophilicity of the N-anion formed from the *N*-alkylamino-group under the reaction conditions. Indeed, 2-amino-5-chlorophenyl 2-bromophenyl ether, which gives rise to a somewhat less nucleophilic N-anion, does not change on prolonged refluxing with sodium amide in xylene.[22] However, it was shown later that type **20** ethers, which also do not contain strong electron-accepting groups in the molecule, do undergo the rearrangement on refluxing in dimethylformamide (DMF) in the presence of potassium carbonate, i.e. under conditions which in all probability do not ensure the formation of N-anions.[13,35] Examples of the nonactivated Smiles rearrangement in the presence of a base have been described also for other classes of compounds, but have not so far been explained convincingly.[2,13,36,37]



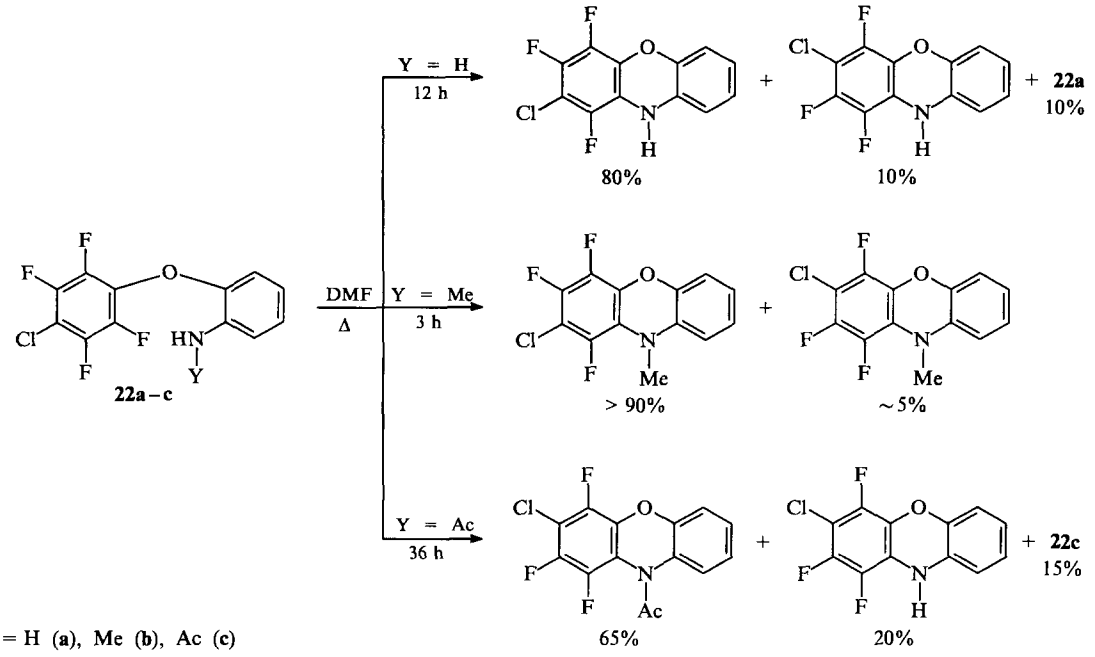
R^1, R^2, R^3 = H or Cl

Alk = CH_2Ph, $(CH_2)_3NMe_2$

On the whole, systematic studies by Roberts and also subsequent investigations quoted in the present review make it possible to outline the limits of the applicability of the Smiles rearrangement among *o*-aminophenyl phenyl ethers and to establish certain characteristics of the influence of structural factors on this process. However, the mechanism and elementary stages of the rearrangement remain unelucidated. There have also been no kinetic studies. This is partly due to the fact that in most cases the rearrangement of *o*-aminophenyl phenyl ethers is accompanied by side reactions, in the first place intramolecular nucleophilic cyclisation to phenoxazine derivatives.[2,10] There are not many examples of its observation 'in a pure form'. In our view, the problem of the synthesis of systems with a specified structure and the difficulty of analysing the reaction mixtures and of the determination of the structures of the product formed are also complicating factors. Polyfluoro-substituted *o*-aminophenyl phenyl ethers of the type 4-$XC_6F_4OC_6H_4NHY$-2', which can be readily synthesised from the simplest polyfluorobenzenes and *o*-aminophenol, are convenient objects from this point of view.[38-40] These ethers contain a fluorinated aromatic ring, the electron-accepting properties of which can be readily varied by altering the substituent X. The possibility of employing ^{19}F NMR spectroscopy for the analysis of the reaction mixtures and the identification of the products is a great advantage of the fluoro-compounds.

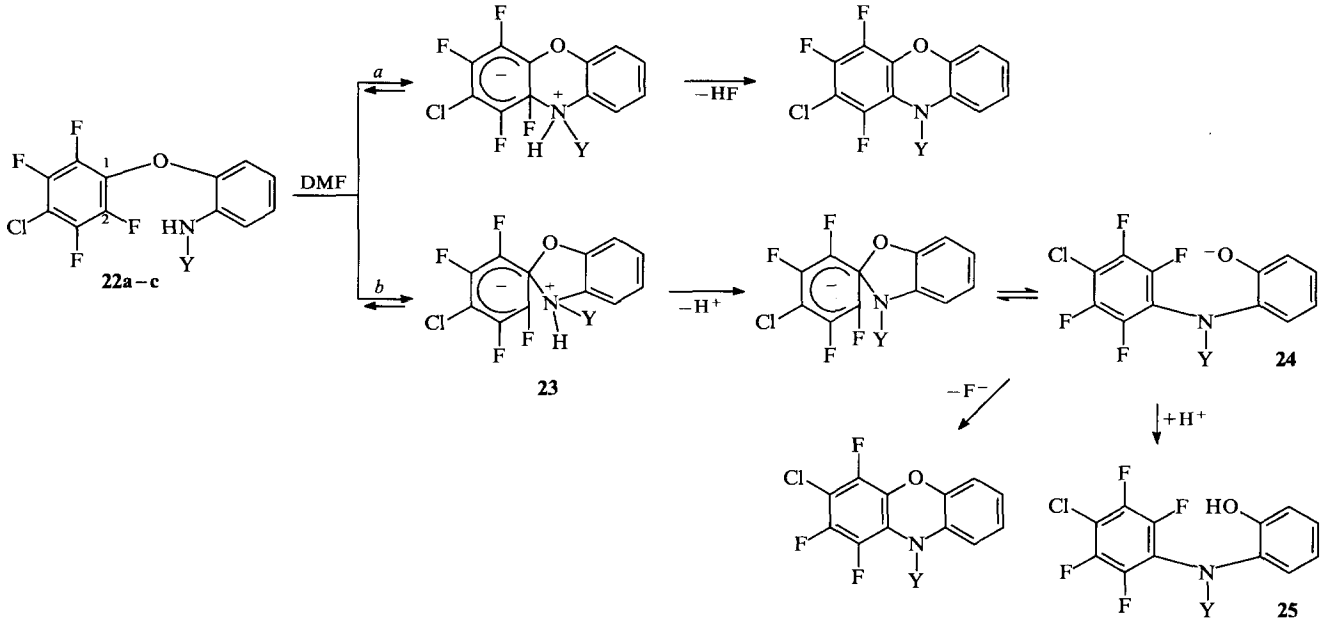
III. The Smiles rearrangement of aromatic polyfluoro-compounds

The Smiles rearrangement of aromatic polyfluoro-compounds was first observed by the present authors in the synthesis of polyfluorinated derivatives of phenoxazine from the compounds C_6F_5X and *o*-aminophenol.[41] It was shown with the aid of ^{19}F NMR spectroscopy that the molecule of the phenoxazine **21** (X = H or Cl) contains the OAr group and the substituent X in the *meta*-positions relative to one another. The change in the relative positions in the intramolecular cyclisation stage suggested that the formation of the phenoxazine system is preceded by the Smiles rearrangement.



X = F, H, Cl

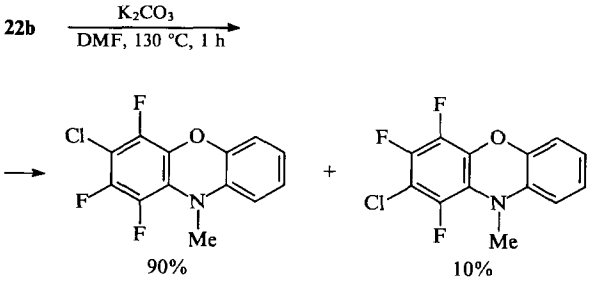
The transformations of polyfluorinated *o*-aminophenyl phenyl ethers have been investigated in detail in relation to compounds **22a-c** containing a chlorine atom in the fluorinated part of the molecule and the NHY group (Y = H, Me, Ac) in the nonfluorinated part.[14,42] It was shown that their refluxing in DMF leads to cyclisation to phenoxazines as a result of intramolecular nucleophilic substitution of the *ortho*-fluorine atom. The *N*-alkyl-substituted ether **22b** reacts faster, while the *N*-acetyl derivative **22c** reacts significantly more slowly than compound **22a**, which contains the NH_2 group (Scheme 4).



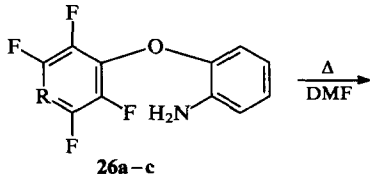
The structure of the phenoxazines formed indicates two reaction paths (Scheme 5): nucleophilic cyclisation as a result of the attack by the nitrogen atom on the 2-position with subsequent elimination of the fluoride ion (path *a*) and cyclisation with preceding Smiles rearrangement (path *b*). The second path is preferred because it involves the attack by the nucleophile on the most electrophilic C(1) carbon atom in the *para*-position relative to the chlorine atom, which agrees with the rules governing the directing effect in aromatic polyfluoro-compounds.[43,44]

The reaction path is determined by the nature of the group NHY. In the case of the ether **22c**, the molecule of which contains the comparatively weakly nucleophilic acetamido-group, the reaction proceeds wholly via path *b*. The diphenyl ethers **22a, b** are cyclised predominantly as a result of the

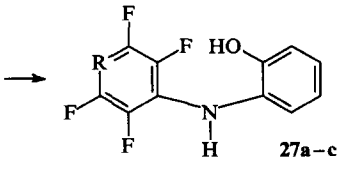
Scheme 4



Scheme 5



substitution of the fluorine atom in the 2-position in the fluorinated ring without the Smiles rearrangement. Such a change in the reaction path in the case of compounds containing more nucleophilic reaction centres (NH_2 and MeNH groups) is caused, in our view, by the greater difficulty in the second stage of process *b*, namely the deprotonation of the spiro-complex **23**. An essential condition for the occurrence of path *a* is the reversibility of the stage involving the formation of this complex.



As already mentioned in the preceding section, examples of the Smiles rearrangement with deprotonation of the spiro-complex as the rate-limiting stage have been described in the literature. It has been shown that such processes are susceptible to general base catalysis.[26–28] Accordingly, the introduction of potassium carbonate into the reaction of the ether **22b** drives the process predominantly via path *b*.

The only argument in support of the occurrence of the Smiles rearrangement in the case of the ethers **22a–c** is the structure of the phenoxazine derivatives formed from them. The corresponding aryl(*o*-hydroxyaryl)amines **25**—the rearrangement products—were not detected in the reaction mixtures. Presumably the introduction into the *para*-position of the fluorinated aromatic ring of the diphenyl ether molecule of an additional electron-accepting group, increasing the electrophilicity of the reaction centre 1 compared with the centre 2, makes it possible to reduce the reaction temperature and to stop the process at the rearrangement stage. Indeed, heating in DMF of type **26** ethers, containing a powerful electron acceptor in the *para*-position relative to the oxygen atom, led to the formation of the isomeric aryl(*o*-hydroxyaryl)amine **27**. Analysis of the ^{19}F NMR spectra of the reaction mixtures showed that the rearrangement is the only type of reaction.[45,46]

26a–c

27a–c

R = C—NO_2, C—CF_3, N

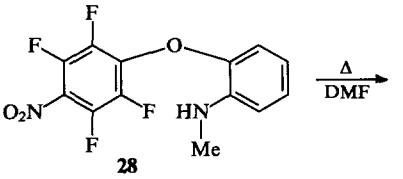
This made it possible to measure the rate of reaction of the ethers **26** when they are kept in DMF in the temperature range 60–120 °C and to estimate in this way their relative capacities for the Smiles rearrangement. The reaction rate constants were calculated from the first-order equation

$$k = \frac{1}{t}\ln\left(\frac{c_0}{c}\right) = \frac{1}{t}\ln\left(1 + \frac{H_a}{H_e}\right),$$

where t is the time, H_a is the integral intensity at the signals due to the F(3) and F(5) atoms [or F(2) and F(6)] in the ^{19}F NMR spectrum of the amine **27**, and H_e is the integral intensity of the signal due to the F(6) and F(5) atoms [or F(2) and F(6)] in the ^{19}F NMR spectrum of the ether **26** (Table 2).

Table 2. The rate constants for the rearrangement of the *o*-aminoaryl aryl ethers 4-$RC_6F_4OC_6H_4NH_2$-2′ **26a–c** in DMF.

Compound **26** (R)	Temperature/°C	Reaction rate constant $10^4 k/s^{-1}$
26a (C–NO_2)	60	2.17
	70	3.93
	80	7.59
	90	12.20
26b (C–CF_3)	90	0.12
	100	0.21
	110	0.53
	120	1.03
26c (N)	70	0.82
	80	1.66
	90	3.34
	100	7.21



The activating effect of the group R in the rearrangement of the ether **26** increases in the sequence (the relative rate constants at 90 °C are indicated in brackets) C–CF_3(1) < N(27) < C–NO_2(100) and corresponds to the influence of these groups on the rate of the nucleophilic substitution of the fluorine atom by an amino-group in aromatic polyfluoro-compounds.[47,48]

Roberts and coworkers[9,29] noted the activating effect of water on the rearrangement of *o*-aminophenyl phenyl ethers in aprotic solvents. At the same time, it is known that the addition of water to polar aprotic solvents can reduce the rate of the Smiles rearrangement.[28] Kinetic measurements on the rearrangement of the ethers **26** in DMF containing 20% of water showed that its influence on the rate of reaction is determined by the nature of the substituent R (Table 3). A catalytic effect has been observed for compounds **26a, c**. As in the case of 2-amino-4-methylphenyl 2,4-dinitrophenyl ether,[9] it may be due to the formation of hydrogen bonds with a substituent and the consequent enhancement of its electron-accepting properties. In conformity with this hypothesis, the rate of rearrangement of the ether **26b**, containing the CF_3 group in the molecule, is somewhat lower in aqueous DMF than in dry DMF.[46]

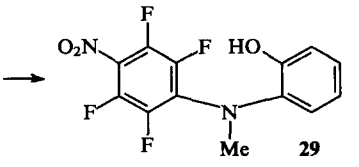


Table 3. The rate constants for the rearrangement of the *o*-aminoaryl aryl ethers 4-$RC_6F_4OC_6H_4NH_2$-2′ **26a–c** in the 80:20 DMF–H_2O mixture.

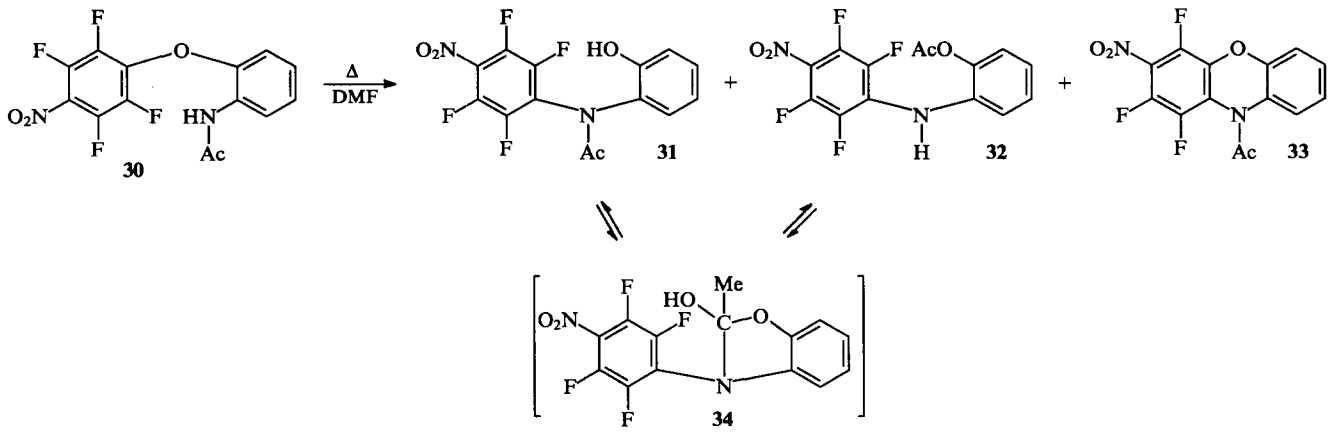
Compound **26** (R)	Temperature/°C	$10^4 k/s^{-1}$	$\frac{k_{DMF\cdot H_2O}}{k_{DMF}}$
26a (C–NO_2)	60	11.8	5.4
26b (C–CF_3)	100	0.15	0.7
26c (N)	70	1.01	1.2

The influence of *N*-substituents on the rearrangement of polyfluoro-substituted *o*-aminophenyl phenyl ethers has been investigated in relation to the derivatives of the ether **26a**.[14,42,48] The rate of rearrangement of the *N*-methyl-substituted ether **28**, which is unambiguously transformed into the isomeric amine **29** on heating in DMF, was measured by a procedure similar to that described for compound **26**.



28

29

A mixture of three compounds (compounds **31–33**) has been obtained from the acetamido-substituted diphenyl ether **30**. The formation of the amine **31** indicates the occurrence of the Smiles rearrangement. The presence of compound **32** in the reaction mixture is evidence that the rearrangement is accompanied by the migration of the acetyl group from the nitrogen atom to the oxygen atom.[49,50] A similar rearrangement had been observed earlier for nonfluorinated compounds,[9,24,25] but, in contrast to its dinitro-analogue **11**, the amine **31** was not only detected in the reaction mixture but was also isolated in a pure form. The dissolution of any of the isomeric compounds **31** and **32** in DMF leads to the rapid (during the dissolution and measurement of the ^{19}F NMR spectra) formation of a **31**:**32** = 3:1 equilibrium

Scheme 6

mixture. The data of Pavlova and Rachinskii[51] suggest that the migration of the acetyl group from the N atom to the O atom, observed under these conditions, takes place via the cyclic structure **34** (Scheme 6).

The fact that heating of the diarylamine **31** in DMF under the conditions of the transformation of the ether **30** does not lead to the phenoxazine **33** is very interesting. The presence of the latter in the reaction mixture obtained from the ether **30** is in all probability caused by the cyclisation of the intermediate type **24** phenoxide anion (see Scheme 5).

The Smiles rearrangement precedes the formation of compounds **32** and **33**. This makes it possible to estimate its rate by studying the kinetics of the consumption of the initial ether **30**. The rate of its transformation was determined from the time variation of the integral intensities of the signals due to the fluorine atoms in the ^{19}F NMR spectrum. The rate constant was calculated from the first-order equation

$$k = \frac{1}{t}\ln\left(\frac{c_0}{c}\right) = \frac{1}{t}\ln\left(\frac{H_0}{H}\right),$$

where t is the time, H_0 the initial integral intensity of the signals due to the F(3) and F(5) atoms [or F(2) and F(6)] in the ^{19}F NMR spectrum of the initial ether **30**, and H is the integral intensity of the signals due to the same atoms in the ^{19}F NMR spectrum at time t. The rate constants found for the rearrangement of compounds **28** and **30** and the ether **26a** at 90 °C are presented in Table 4.[14]

Table 4. The rate constants for the rearrangement of the diaryl ethers 4-$NO_2C_6F_4OC_6H_4NHY$-2′ in DMF at 90 °C.[14]

Compound	NHY group	Reaction rate constant, $10^4 k/s^{-1}$
26a	NH_2	12.2
28	NHMe	7.40
30	NHAc	1.32

Thus both the *N*-methyl-substituted ether **28** and the *N*-acetyl derivative **30** rearrange in DMF more slowly than compound **26a** containing a free amino-group in the molecule. The observed effect of *N*-substitution may be interpreted within the framework of the mechanism based on Scheme 4 and agrees with the hypothesis, put forward above, that variation of the substituent alters the rate-limiting stage in the Smiles rearrangement. Whereas the rate-limiting stage for the acetamido-compound **30** in a neutral medium involves in all probability the formation of a type **23** zwitterionic complex, the rate of the process for compound **28**, containing the more nucleophilic *N*-methylamino-group, may be determined by deprotonation[28] and in both cases the introduction of a base into the reaction sphere should have an activating effect. Indeed the transformation of the ethers **28** and **30** in the presence of potassium carbonate takes place below room temperature. The rearrangement of the ether **26a** is apparently of an intermediate type.

Thus the use of model aromatic polyfluoro-systems combined with ^{19}F NMR spectroscopy made it possible to expand greatly the possibilities for the study of the Smiles rearrangement of *o*-aminophenyl phenyl ethers and to obtain primary kinetic data concerning the influence of the nature of the reactants on the rate of reaction. Further development of studies on these lines may not only make a significant contribution to investigations of the Smiles rearrangement, but will undoubtedly promote the practical employment of the reactions of aromatic polyfluoro-compounds with bifunctional nucleophiles in the synthesis of a wide variety of fluoro-substituted heteroaromatic systems.

S-Cationoid reagents in organic synthesis

I V Koval'

Contents

I. Introduction	141
II. Cationoid sulfenium reagents	141
III. Sulfonium reagents	143
IV. Sulfoxonium (oxosulfonium) reagents	161

Abstract. The review is devoted to the methods of preparation, properties, and applications in organic synthesis of compounds of divalent, tetravalent, and hexavalent sulfur which may bear a positive charge on the sulfur atom, such as sulfenium, sulfonium, and sulfoxonium (oxosulfonium) reagents. The bibliography includes 178 references.

I. Introduction

During the last 10 – 15 years, the development of the chemistry of organic compounds of sulfur has been characterised by the extensive application of S-cationoid reagents, which play the extremely important role of active intermediates in many synthetic reactions, such as, for example, the selective oxidation of alcohols, the transfer of various functional groups, the introduction of a carbon – carbon double bond, the generation of radical-cations, ylides, etc. Such intermediates play an extremely important role in biological methylation processes occurring in living organisms[1,2] and also in processes involving the cleavage of peptides at the methionine units.

The majority of the S-cationoid reagents are unstable under the usual conditions, so that they are generated and employed as a rule in situ during the chemical reaction. Of the S-cationoid intermediates known at the present time, sulfonium salts have been the most thoroughly investigated. Convenient preparative methods of synthesis of the latter have been developed, their physicochemical properties have been investigated comprehensively, and their synthetic applications have been discovered. Some of the sulfonium salts, for example dimethylbromosulfonium bromide, dimethylchlorosulfonium chloride, dimethyl(*N*-succinyl)sulfonium chloride, etc., have entered the reference literature on preparative organic chemistry as important reagents for organic synthesis.

The interest manifested in sulfonium salts induced at the relevant time the appearance of a series of review publications,[1-3] which fully reflected the state of the chemistry of sulfonium salts during that period, but by now many new S-cationoid reagents have appeared and will be considered in the present review (the literature up to 1993 inclusive is considered).

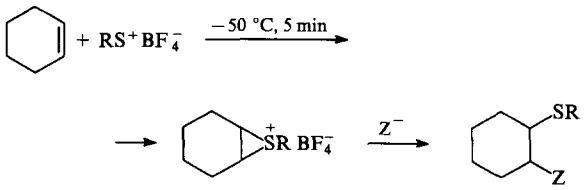
II. Cationoid sulfenium reagents

The cationoid sulfenium reagents include complexes having the general formula RS^+Y^-, in which the sulfenium cation RS^+ (R = Alk, Ar) is stabilised by an anionoid species Y^- of the type BF_4^-,[4-9] $SbCl_6^-$,[10] ClO_4^-,[11-13] etc.

$$RSX + MY \longrightarrow RS^+Y^- + MX$$

R = Me, Ph; X = Cl, Br; M = Ag, Li;

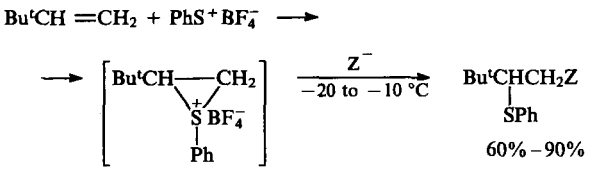


Y = BF_4, ClO_4, $SbCl_6$.

According to Cappozzi et al.,[14] the problem of the structure of these complexes still remains unsolved. In connection with the relatively low stability of cationoid sulfenium reagents, they are generated in situ in inert organic solvents (methylene chloride, nitromethane, dichloroethane) at low temperatures (−50 to −20 °C). Their synthesis is based on an exchange reaction.

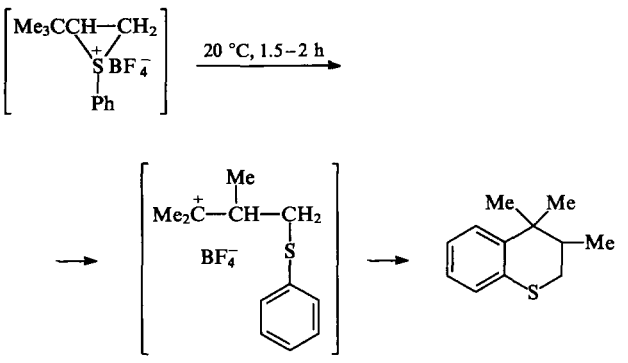
The resulting solutions of cationoid sulfenium reagents are relatively stable in the temperature range indicated and are used in the synthesis of polyfunctional sulfides. These syntheses are based on the electrophilic addition of cationoid sulfenium reagents to alkenes and the subsequent interaction of the intermediate episulfonium cations with nucleophiles introduced into the reaction medium in the last stage.[4,5]

The use of cationoid sulfenium reagents in reactions with alkenes makes it possible to carry out the electrophilic addition in two stages, the stages involving the addition of the electrophile RS^+ and the nucleophile Z^- being separated in time and independent of one another (Scheme 1).



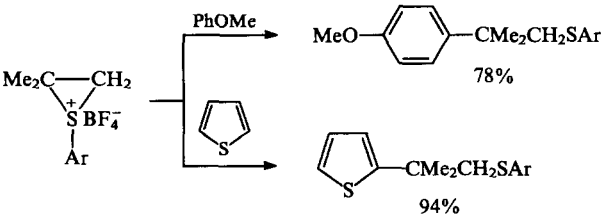
Scheme 1

R = Me, Ph; Z = OH, MeO, Cl, Br, OAc, $(EtCO_2)_2CH$, AcNH.

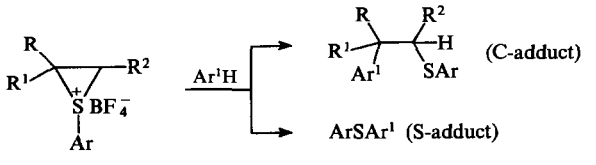


It is noteworthy that, in the addition of cationoid sulfenium reagents to alkenes with a branched structure, it is possible to direct the addition reaction towards the formation of products with a rearranged skeleton. For example, the episulfonium ion formed in the reaction of *tert*-butylethene with the complex

$PhS^+BF_4^-$ reacts at −20 to −10 °C with nucleophiles, affording polyfunctional sulfides in 60%–90% yields.[4]

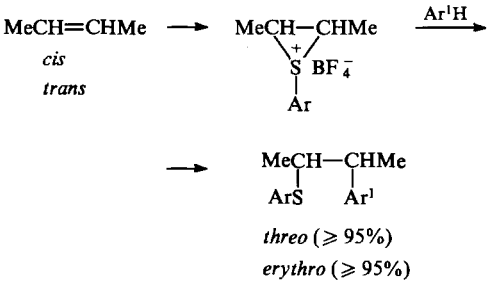


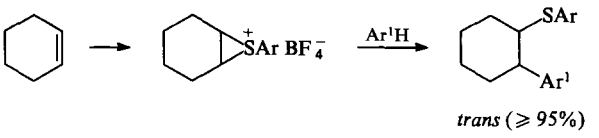
Z = OH, OMe, $MeCO_2$, H, $(EtCO_2)_2CH$, NEt_2.



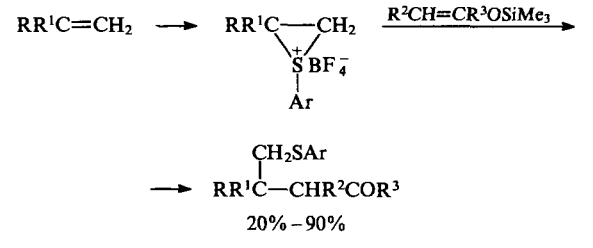
However, if the solution of the episulfonium complex obtained at −20 °C is maintained at 20 °C for 1.5–2 h, the main reaction product is 3,4,4-trimethylthiochroman regardless of the nature of the nucleophile Z,[4] which is due to the rearrangement of the episulfonium complex at the higher temperature to an intermediate carbonium ion, which in fact participates in the alkylation reaction.

It has been shown[9,15] that the stable *S*-arylepisulfonium complexes are capable of reacting not only with active nucleophiles but also with aromatic π-donors, which greatly expanded the limits of the applicability of the cationoid sulfenyl reagents in the synthesis of polyfunctional sulfides. For example, the interaction of episulfonium complexes with certain aromatic and heterocyclic compounds takes place in the absence of catalysts under mild conditions (−20 to 0 °C) in accordance with the general mechanism of the Friedel–Crafts reaction and leads to the formation of aryl(heteroaryl)-substituted sulfides.[15]



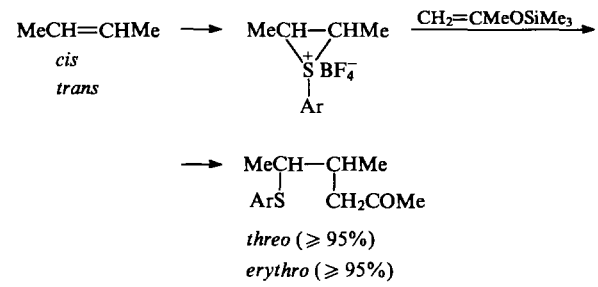


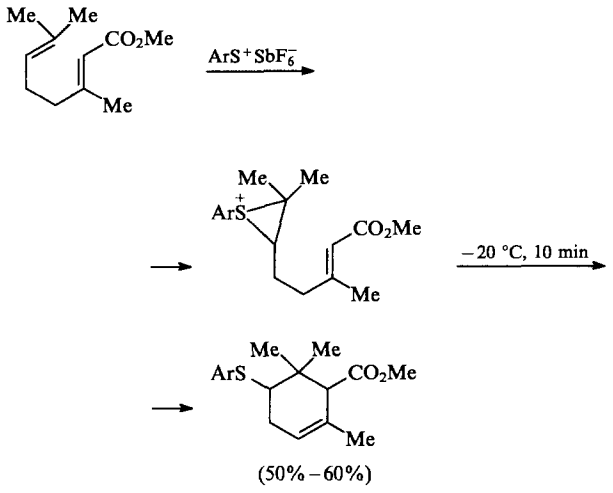
However, one should note that the reactions of the episulfonium complexes with aromatic compounds do not take place unambiguously, especially in the case of nonactivated aromatic compounds. This is due to the ambident nature of the episulfonium cation, which may react with the aromatic π-donor with participation of both a carbon atom (to form C-adducts) and the sulfur atom (to form S-adducts).[15]



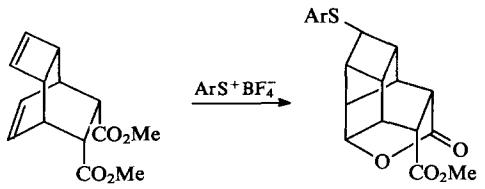
R, R^1, R^2 = H, Alk.

This disadvantage may be eliminated to some extent by varying the nature of the substituent at the sulfur atom. Thus in the reaction of the *S*-mesitylepisulfonium complex with aromatic compounds, the yield of the S-adduct does not exceed 5%–10%.[9] In the interaction of asymmetric episulfonium complexes with aromatic compounds, adducts of the Markovnikov type are formed exclusively, while in the case of the episulfonium complexes obtained from *cis*- or *trans*-but-2-ene and cyclohexene the stereochemistry of the products corresponds to the stereospecific anti-opening of the episulfonium ring by the aromatic π-donor, which indicates, according to Ibragimov and coworkers,[15,16] that the reaction proceeds via the intermediate formation of a bridged carbenium ion and not an open-chain β-arylthiocarbenium ion.

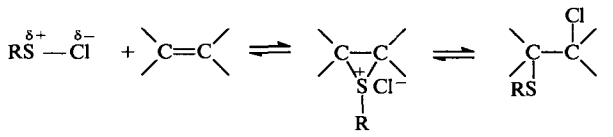




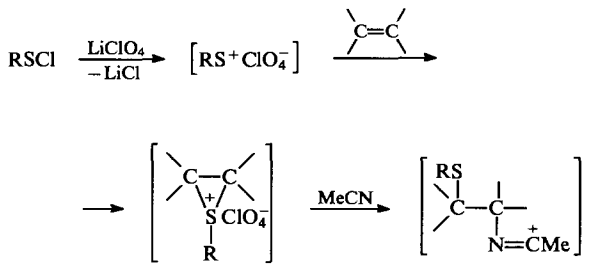
The trimethylsilyl ethers of enols proved to be active π-donors in reactions with episulfonium complexes. It has been shown[9,16] that the episulfonium complexes interact with such ethers even at −30 °C (1–2 h), affording γ-carbonyl-substituted sulfides, the structure of which corresponds to the Markovnikov and *trans*-stereospecific opening of the episulfonium ring by the nucleophile.

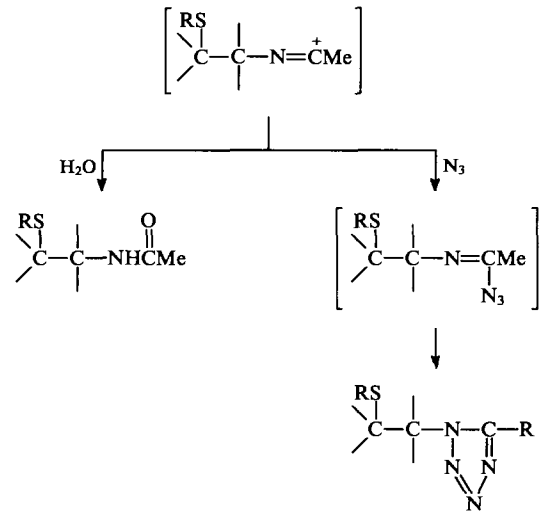


R = Me, Ph, H; R^1 = H, Me; R^2 = H; R^3 = Ph; R^2+R^3 = $-(CH_2)_4-$.



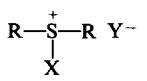
In the interaction of cationoid sulfenium reagents with dienes, the intermediate episulfonium cation may react with the π-electron system of the second double bond, giving rise to cyclic products.[9]





It is known[1] that the addition of sulfenyl chlorides to alkenes proceeds in accordance with the Ad_E2 mechanism, in which the cationic intermediate is the episulfonium cation—a weak electrophile which does not react with weak nucleophiles.

The method of the coupled addition of sulfenyl chloride to alkenes in the presence of a strong electrophile, for example lithium perchlorate, developed by Zefirov and coworkers,[11–13] is therefore of special interest. In this case, the sulfenyl chloride reacts even with acetonitrile, which is a weak nucleophile.



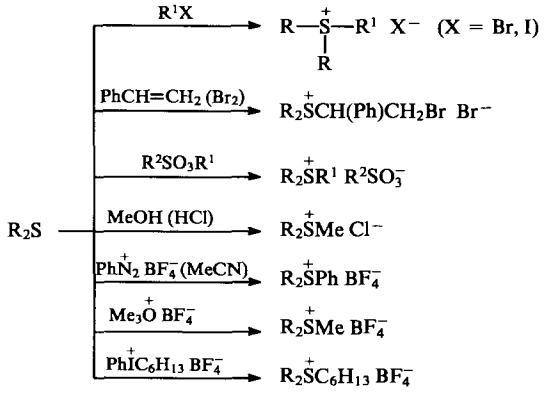
The immonium ion formed under these conditions is converted into the final products on treatment with various reagents.

R = Ph, 4-MeC_6H_4, 4-ClC_6H_4, 2-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$.

III. Sulfonium reagents

A characteristic feature of divalent sulfur compounds, for example sulfides, is their ability to react with electrophiles, which is due to the presence of a free electron pair at the sulfur atom by virtue of which the atom can participate in the formation of a third covalent bond. The positive charge arising at the sulfur atom is as a rule stabilised by the negative charge of the anion. The compounds formed under these conditions have the general name of sulfonium salts and are divided into several types depending on the nature of the groups surrounding the sulfonium centre: trialkyl(aryl)sulfonium, halosulfonium, aminosulfonium, alkoxysulfonium, aryloxysulfonium, acyloxysulfonium, alkyl(aryl)thiosulfonium salts, etc.

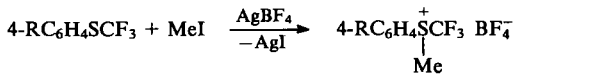
R = Alk, Ar; Y = Cl, Br, BF_4, ClO_4 etc.;



X = Alk, Ar, Cl, Br, I, F, OAc, NR'_2, OR', SR' (R' = Alk, Ar).

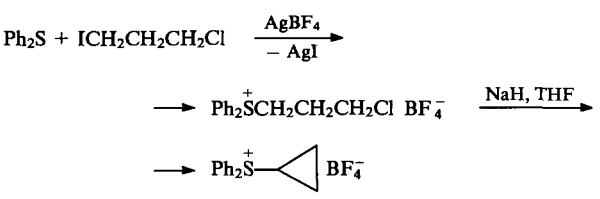
1. Trialkyl(aryl)sulfonium salts

a. Methods of synthesis of trialkyl(aryl)sulfonium salts



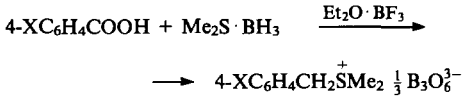
Preparation from sulfides. The alkylation (arylation) of sulfides by aryl halides,[12,17–19] alkenes,[2,20] sulfonic acid esters,[21,22] alcohols,[23] and diazonium,[2] oxonium,[2] and iodonium[24] salts is very frequently used to obtain trialkyl(aryl)sulfonium salts (Scheme 2).

Scheme 2



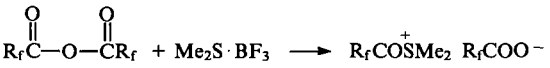
Dialkyl sulfides react with alkyl halides relatively easily, whereas diarylsulfides, as well as sulfides containing strongly electron-accepting groups at the sulfur atom, are alkylated by alkyl halides only in the presence of catalysts ($FeCl_3$, $AgBF_4$, etc.). For example, despite the reduced nucleophilicity of the sulfur atom in aryl trifluoromethyl sulfides, the latter were methylated by methyl iodide in methylene chloride in the presence of $AgBF_4$ (Scheme 3).[25,26]

Scheme 3

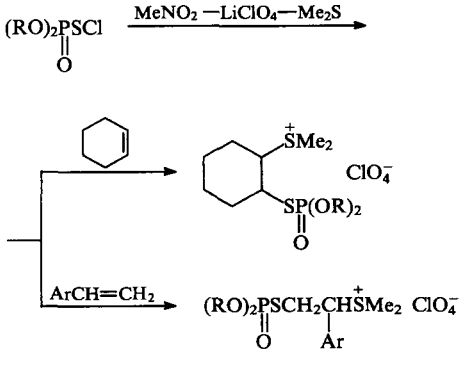


R = H, Me, Cl, NO_2.

The same catalyst has been used in the synthesis of cyclopropyldiphenylsulfonium tetrafluoroborate.[27,28]

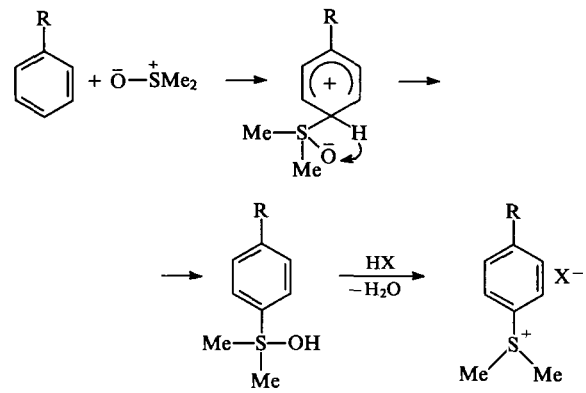


In the synthesis of trialkyl(aryl)sulfonium salts, the complexes of sulfides with BH_3 and BF_3 as well as various systems based on sulfides are used instead of the sulfides themselves. The reduction of aromatic carboxylic acids by the borane–dimethyl sulfide complex has been described.[29] The reduction products then react with dimethyl sulfide in the presence of boron trifluoride etherate to form the corresponding sulfonium salts.

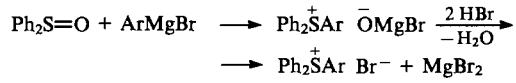


X = MeO, HO, H_2N.

The complex between Me_2S and BF_3 reacts relatively easily with the anhydrides of perfluorocarboxylic acids to form the corresponding sulfonium salts.[30]



It has been shown[31] that the addition of dialkoxyphosphonylsulfenyl chlorides to ethene hydrocarbons in the presence of the $MeNO_2$–$LiClO_4$–Me_2S system leads to sulfonium salts containing dialkoxythiophosphonyl groups.



R = Me, Pr^i; Ar = Ph, 4-$MeOC_6H_4$.

Preparation from sulfoxides. By virtue of the presence of the electron-deficient sulfur atom, dialkyl sulfoxides react as electrophiles with an aromatic ring activated by electron-donating groups (OH, OR, etc.), forming dialkylarylsulfonium salts.[1] The reaction is catalysed by a strong inorganic acid (HCl, H_2SO_4, etc.).

R = OH, OR; X = Cl, HSO_4.

Triarylsulfonium salts are formed in the reaction of diphenyl sulfoxides with arylmagnesium bromides.[1,2]

It has been noted[32] that, in the interaction of dimethyl sulfoxides with 5-R-6-methyl-2,4-diphenyl-3-azapyrylium perchlorate in acetic anhydride, the product is a sulfonium salt, which is converted on heating in alcohol into the salt $PhCH_2NHC(Ph)=C(R)COCH_2S^+Me_2\ ClO_4^-$.

b. Applications of trialkyl(aryl)sulfonium salts in organic synthesis.

Generation of sulfonium radical-cations. One of the characteristic features of trialkyl(aryl)sulfonium salts is their photolytic instability. On irradiation with UV light at a certain wavelength, they are cleaved, affording a mixture of products. The primary step in the photolytic process is the homolysis of one of the three C–S bonds with formation of sulfonium radical-cations, which give rise to secondary photolysis products on interaction with the solvent or solutes. For example, on pulsed laser irradiation, the photolytic cleavage of triarylsulfonium salts begins with the homolysis of the Ar–S bond.[33]

The diarylsulfonium radical-cations formed in this process are initiators of the polymerisation of alkenes.[33]

On irradiation of the sulfonium salt $(4\text{-}Bu^tOCOOC_6H_4)_3S^+.CF_3SO_3^-$ with light at wavelengths of 254 and 266 nm in acetonitrile or dimethylformamide (DMF), the sulfonium radical-cation $(4\text{-}Bu^tOCOOC_6H_4)_2S^{\cdot+}$ and trifluoromethanesulfonic acid are formed as the primary reaction products. Their further reactions lead to the sulfide $(4\text{-}HOC_6H_4)_2S$ and the sulfonium ions $(4\text{-}Bu^tOCOOC_6H_4)_2S^+(C_6H_4OH\text{-}4)$, $(4\text{-}HOC_6H_4)_3S^+$, and $(4\text{-}HOC_6H_4)_2S^+(C_6H_4OOCOBu^t\text{-}4)$.[34]

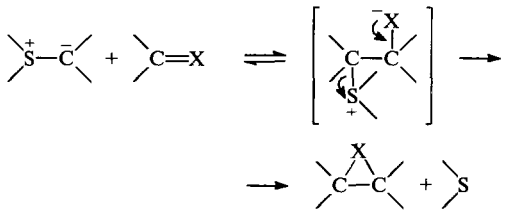
The photolysis of the isomeric sulfonium salts $RMeS^+PhSbF_6^-$ (R = 1-, 2-, 9-$C_{14}H_9$), which proceeds on UV irradiation at wavelengths in the range from 260 to 400 nm, has been described.[35] The primary step in the photolysis is the homolysis of the Me–S bond accompanied by the formation of the sulfonium radical-cation $PhRS^{\cdot+}$, the interaction of which with the solvent leads to acid products.

Generation of sulfonium ylides. The deprotonation of trialkylsulfonium salts by a base B is one of the commonest methods for the generation of sulfonium ylides.[36]

$$Me_3S^+ + B \rightleftharpoons Me_2\overset{+}{S}-\bar{C}H_2 + BH^+$$

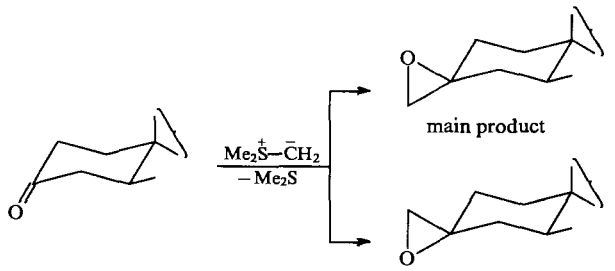
The mobility of the proton in the alkyl group of the sulfonium salt depends on many factors and in the first place on its acidity, the nature of the solvent, and also on the presence of other substances in the solution. Various combinations of bases and solvents, such as aqueous solutions of NaOH or KOH in the presence of tetraalkylammonium halides,[36,37] KOH in dimethyl sulfoxide (DMSO),[28,30] sodium hydride in tetrahydrofuran (THF)[28] or in DMSO,[36] *tert*-butyllithium in THF,[38] potassium *tert*-butoxide in THF,[2,28] and sodium dimethyl sulfoxide in DMSO or THF [36,39] are used to increase the mobility. In the presence of strongly electron-accepting groups in the α-position in the alkylsulfonium salt, the ylide may be formed even on treatment with organic bases, such as, for example, 1,5-diazabicyclo[5.4.0]undec-5-ene.[40]

In the preparation of an ylide from triarylsulfonium salts, one aryl group is replaced by an alkyl group (for example, the butyl group) with its subsequent deprotonation.[36]



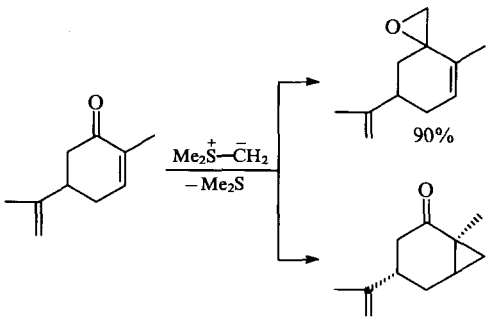
$$Ph_3S^+BF_4^- + BuLi \xrightarrow[-PhLi]{THF} Ph_2\overset{+}{S}Bu\ BF_4^- \longrightarrow Ph_2\overset{+}{S}-\bar{C}HPr$$

Sulfonium ylides are also obtained by adding nucleophiles to vinylsulfonium salts.[2]

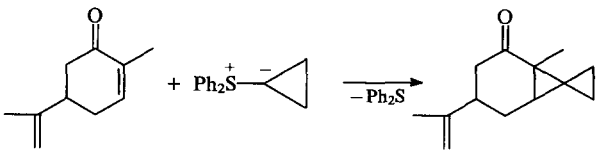


$$R_2\overset{+}{S}-CH=CR^1_2 + \bar{N}u \rightleftharpoons R_2\overset{+}{S}-\underset{\displaystyle Nu}{\bar{C}H}CR^1_2$$

When R = Me and R^1 = H, the methylation of the nucleophile via an S_N2 reaction competes with the addition reaction.

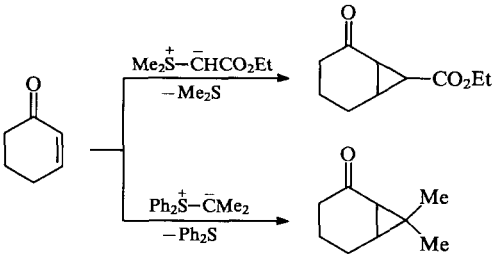


The high nucleophilicity of the carbon atom in the ylide group and also the tendency of the sulfonium centre to be converted into the readily eliminated sulfide group, are responsible for the principal application of sulfonium ylides in organic synthesis, namely the transfer of alkylidene groups to an electrophilic double bond via the intermediate formation of a betaine, which cyclises via direct substitution at the carbon atom.[2,41]

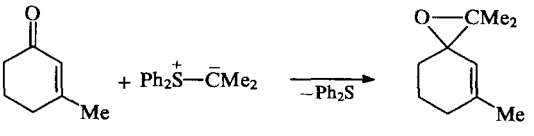


Depending on the structure of the ylide and the alkene, their addition to one another may lead to the formation of diastereoisomeric or structurally isomeric betaines. The cyclisation of such betaines gives various combinations of products. For example, the interaction of dimethylsulfonium methylide with cholestan-3-one leads to two isomeric products, with the isomer having an axial disposition of the epoxide substituent predominating.[2]

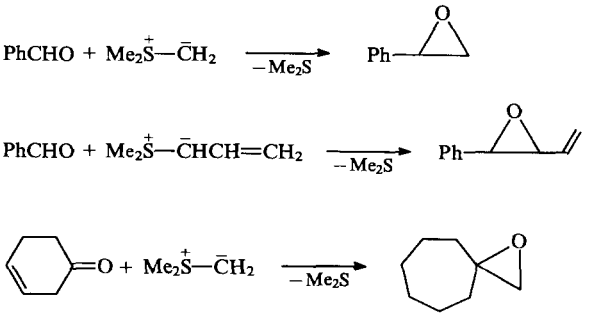
The addition of dimethylsulfonium methylide to carvone leads to two different products, with the epoxide predominating.[2]



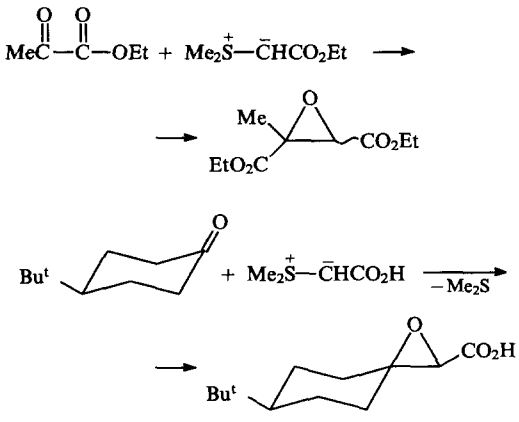
On the other hand, the addition of the diphenylsulfonium cyclopropylide to carvone takes place at the C=C bond with formation of one product.



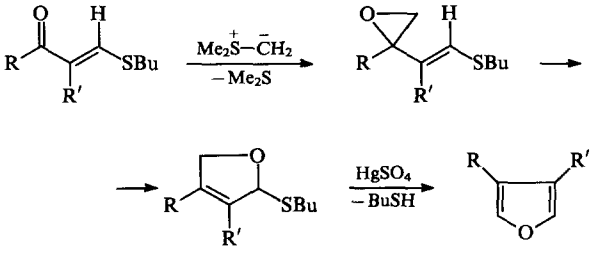
The addition of dimethylsulfonium ethoxycarbonylmethylide and diphenylsulfonium dimethylmethylide to cyclohexen-2-one also takes place at the C=C bond[2] (Scheme 4).



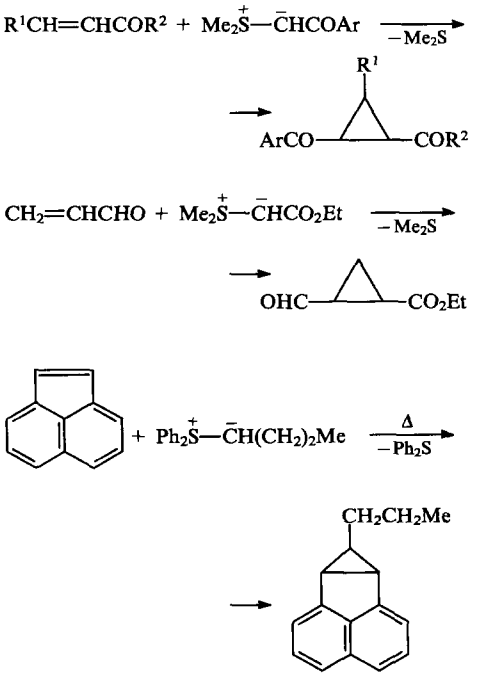
Scheme 4



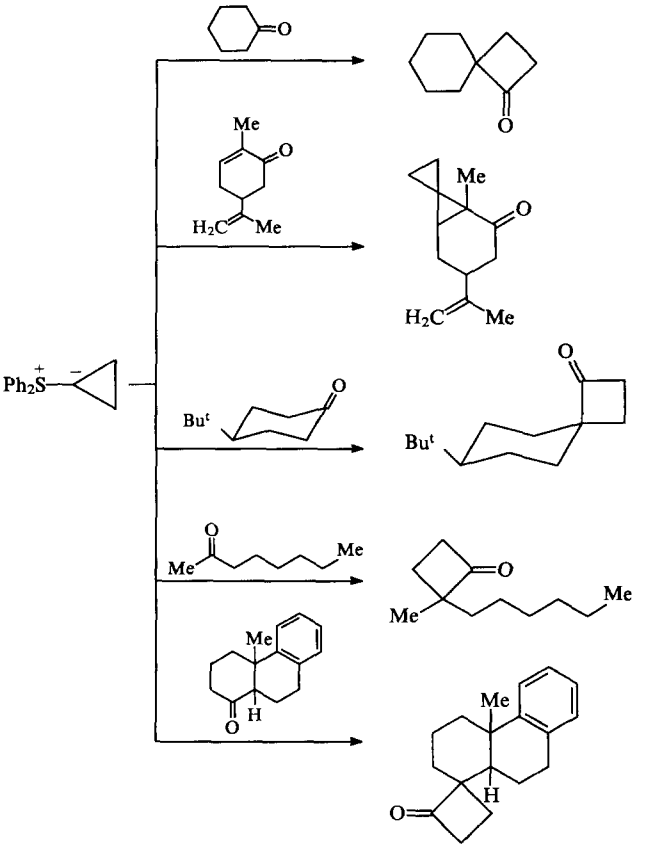
The introduction of an alkyl group in the 3-position in cyclohex-2-enone alters the mode of addition.[2]



As a result of the diversity and ready availability of aldehydes and ketones, their condensation with sulfur ylides has become the most important synthetic method for the preparation of oxiranes with a wide variety of structures.[2,36,42,43]

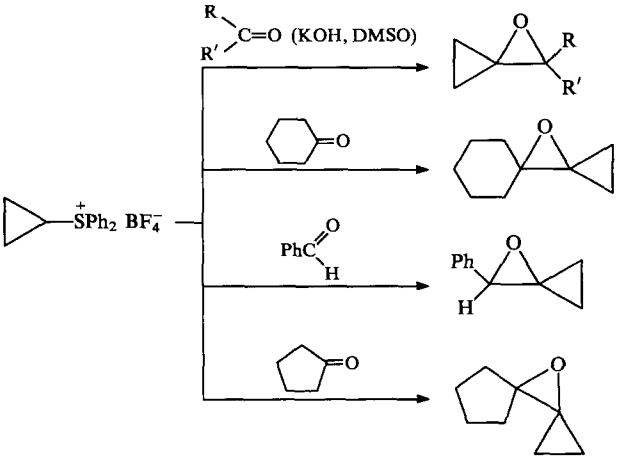


In the presence of a mobile hydrogen atom in the substrate molecule, the oxirane ring formed may be opened with subsequent formation of a five-membered ring, which is used in the synthesis of furans from dimethylsulfonium methylide and unsaturated ketones.[28]

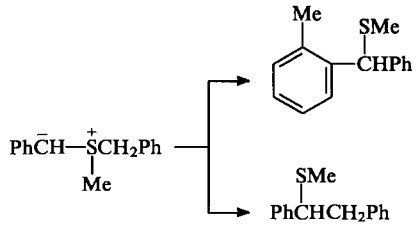


The availability of unsaturated compounds with a wide variety of structures makes it possible to employ the ylides for the synthesis of cyclopropanes (Scheme 5).

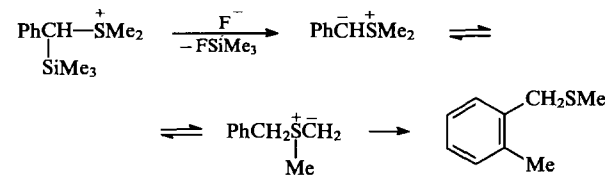
Scheme 5



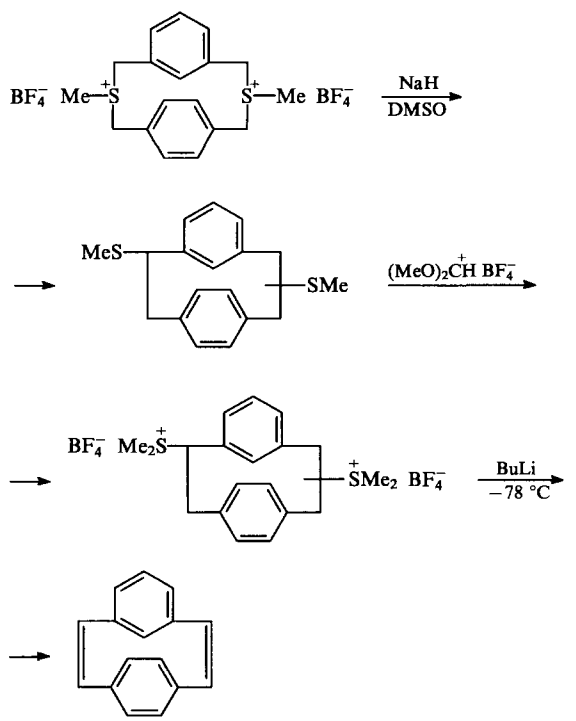
It has been suggested[44] that the biosynthesis of the cyclopropane ring in many natural products proceeds via the copper-catalysed transfer of the methylene group from the sulfonium methylide formed from *S*-adenosylmethionine.



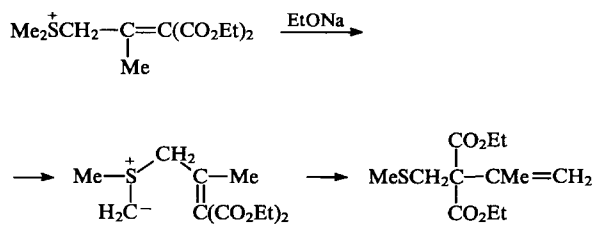
Diphenylsulfonium cyclopropylide, formed when cyclopropyldiphenylsulfonium tetrafluoroborate is treated with sodium dimethyl sulfoxide in THF, is widely used in the transfer of the cyclopropylidene group in preparative organic chemistry.[28] The interaction of this reagent with aldehydes and ketones and also with α,β-unsaturated ketones affords spirocycloalkanones and cyclic ketones.[27,28,44,45]



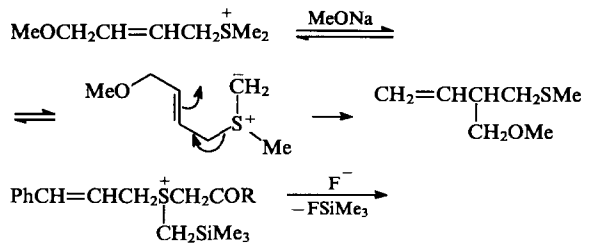
Oxaspiropentanes are intermediates in some of these reactions. They have been isolated by treating the carbonyl compounds with cyclopropyldiphenylsulfonium tetrafluoroborate.[46,47]

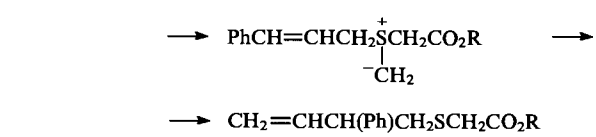


The tendency of sulfonium ylides to undergo rearrangements is frequently employed in the syntheses of various sulfides. For example, in the presence of strong bases, benzylsulfonium ylides undergo the [2,3]-sigmatropic rearrangement and also 1,2-shift rearrangements with formation of the corresponding sulfides.[2,15,48,49]

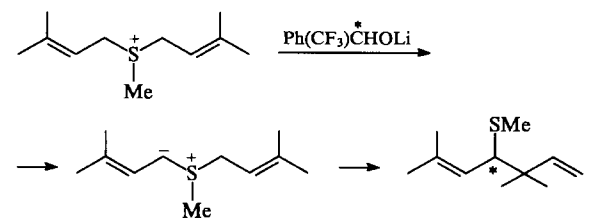


The [2,3]-sigmatropic rearrangement of the benzylsulfonium ylide, formed as a result of the desilylation of a α-trimethylsilylbenzylsulfonium salt by the fluoride anion, has been described.[50]

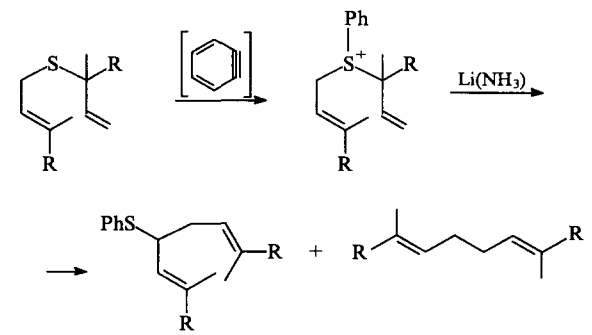




The 1,2-shift rearrangement of benzylsulfonium ylides constitutes the basis of the synthesis of cyclophanes.[36,51]

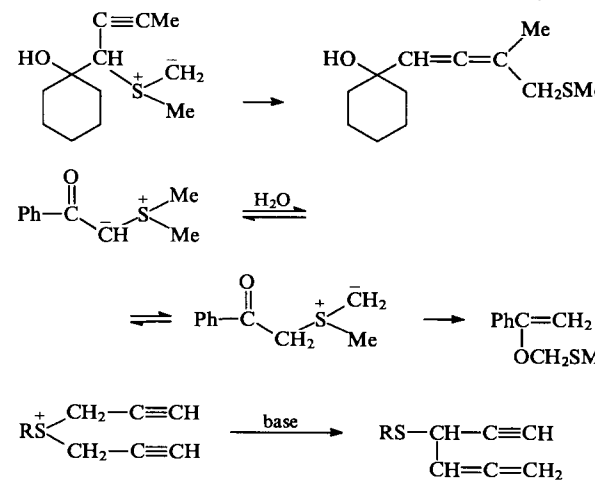


The [2,3]-sigmatropic rearrangements of allylsulfonium ylides, which take place on heating or on treatment with basic reagents, are used in the syntheses of but-3-enyl sulfides.[52-54]

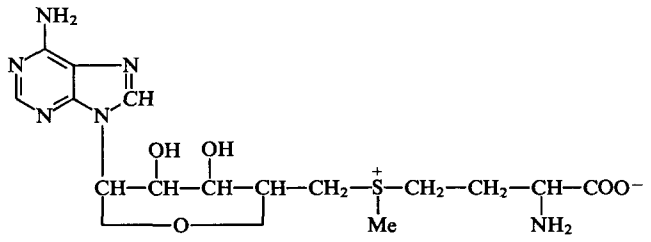


Thus the [2,3]-sigmatropic rearrangement of the sulfonium ylide generated from *S*-methyl-*S*,*S*-di(α,α-dimethylallyl)-sulfonium tetrafluoroborate in the presence of an optically active base led to an optically active sulfide.[54]

The synthesis of squalene has been achieved with the aid of the [2,3]-sigmatropic rearrangement of the corresponding allylsulfonium ylide (Scheme 6).[2]



Scheme 6



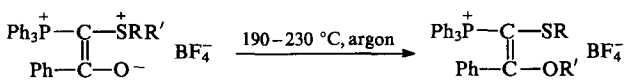
R = $Me_2C{=}CHCH_2CH_2C(Me){=}CHCH_2CH_2$.

Ylides and sulfonium salts containing triple bonds and heteroatoms can also participate in similar rearrangements (Scheme 7).[36,55]

Scheme 7

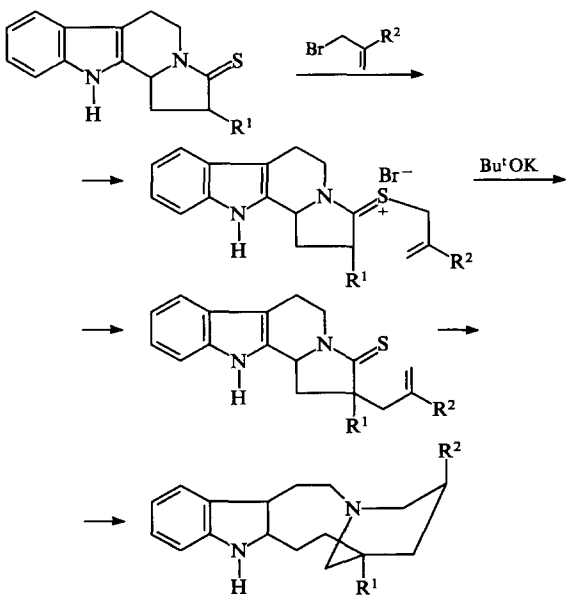
The transfer of alkyl and acyl groups. The high lability of the C–S bond in sulfonium salts makes possible their use as alkyl group transfer reagents, which has found application in biological methylation reactions[56] and in the biomimetic transalkylation of alkenes.[57] It has been suggested[1] that methylation in living organisms takes place with participation of the adenosylsulfonium salt of methionine.

The transfer of an alkyl groups to the sulfur atom of a thiolate anion[56,58,59] or sulfides[17,24,60] is used in the syntheses of asymmetric sulfides.



$$4\text{-}ClC_6H_4\overset{+}{S}(Me)\text{-}C_6H_4OMe\text{-}4\ SbF_6^- + 4\text{-}NO_2C_6H_4SNa \longrightarrow 4\text{-}NO_2C_6H_4SMe + 4\text{-}ClC_6H_4SC_6H_4OMe\text{-}4$$

$$Me_2\overset{+}{S}C_6H_{13}\ BF_4^- + Me_2S \longrightarrow MeSC_6H_{13} + Me_3\overset{+}{S}\ BF_4^-$$



$$Me_2S + Me_2CHBr \longrightarrow Me_2\overset{+}{S}\text{—}CHMe_2\ Br^- \xrightarrow{Me_2S} Me_2CHSMe + Me_3\overset{+}{S}\ Br^-$$

$$Me_2S + Me_3SiCH_2\overset{+}{S}Me_2\ I^- \longrightarrow Me_3SiCH_2SMe + Me_3\overset{+}{S}\ I^-$$

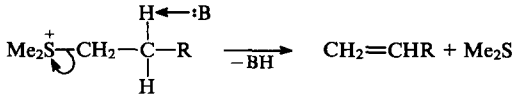
An example of the intramolecular transfer of an alkyl group from the sulfonium centre to an oxygen atom is provided by the isomerisation of dialkylsulfonium salts containing the triphenylphosphonium group, which takes place at 190–230 °C under an argon atmosphere.[61] This leads to the preferential formation of the (*E*)-isomer of the corresponding α,β-disubstituted styryltriphenylphosphonium tetrafluoroborate.

The Claisen thio-rearrangement of sulfonium salts, used in the syntheses of certain alkaloids, is also of the type involving the intramolecular transfer of an alkylallyl group.[54]

It has been noted[62] that sulfonium salts containing a nitro-group at a carbon atom adjoining the sulfonium centre are capable of being cleaved also in the presence of electrophiles. The cleavage then takes place at the S–C(NO_2) bond with transfer of the nitroalkyl fragment to the electrophilic part of the reagent.

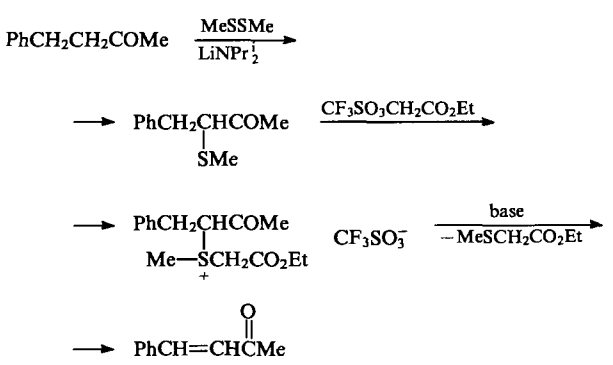
$$R_2\overset{+}{S}\text{—}C(NO_2)_2Z\ A^- + \bar{Y}\text{—}\bar{X} \longrightarrow YC(NO_2)_2Z + R_2S\overset{+}{X}\ A^-$$

Y—X = Cl–Cl, Cl–N(COR)$_2$, Cl–SO_2Cl, Cl–RS.



Z = COR, H.

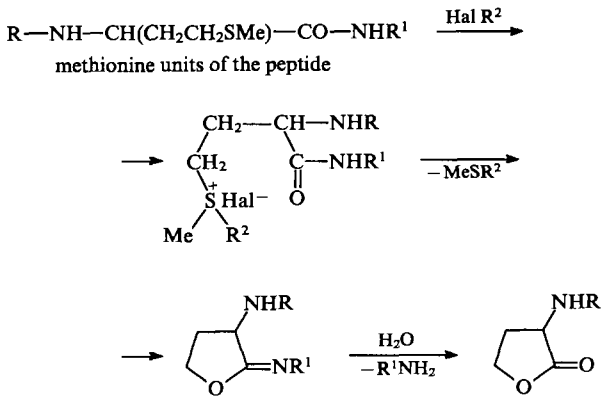
It has been shown[63–65] that the dimethylacylsulfonium salts $RCOS^+Me_2BF_4^-$ (R = Me, Bu^t, CF_3) act as acylating agents in reactions with alkenes, dienes, and ethynes, which is used in the synthesis of α,β-unsaturated ketones.



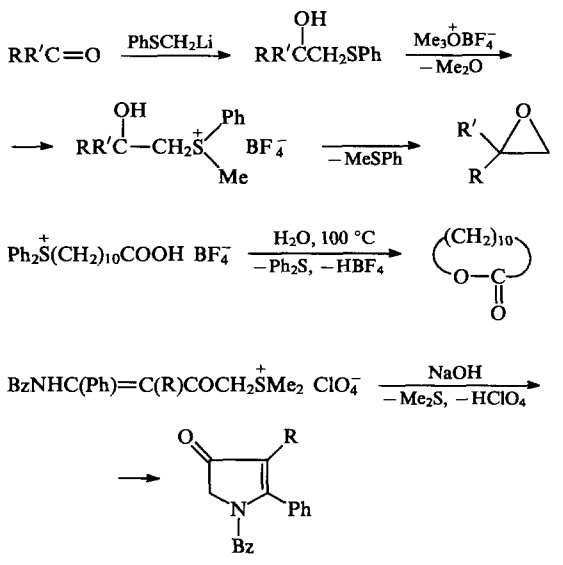
$$RCO\overset{+}{S}Me_2\ BF_4^- + CH_2{=}CHR' \xrightarrow[-HBF_4]{} RCOCH{=}CHR' + Me_2S$$

R = Me, Bu^t; R′ = Ph, CH_2=CMe.

Elimination of the sulfonium group. The sulfonium centre activates the β-hydrogen atoms in alkyl groups; the sulfonium group can also be the leaving nucleophile in elimination reactions. These factors have in fact determined the use of sulfonium salt in the syntheses of unsaturated compounds.[66]

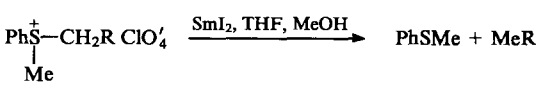


The conversion of a sulfide functional group into a sulfonium group and the elimination of the latter are used as a method for the introduction of a carbon–carbon double bond, for example in the conversion of saturated ketones into α,β-unsaturated ketones.[66–68]



One of the methods for protecting the carboxyl group involves its conversion into an alkylthiomethyl ester group $-CO_2CH_2SR$, which is resistant to the action of weak alkalis and reductants. This is frequently employed in peptide and phosphatide syntheses.[66] In order to remove the alkylthiomethyl group, it is initially converted into a sulfonium group by treatment with methyl iodide and is then cleaved with a weak solution of alkali.

The intramolecular displacement of the sulfonium group by other nucleophilic groups with formation of cyclic products has come to be widely employed in organic synthesis. For example, a method has been developed for the specific cleavage of peptides in the methionine units, involving the intramolecular displacement of the sulfonium group by the oxygen atom of a neighbouring amide group.[66]



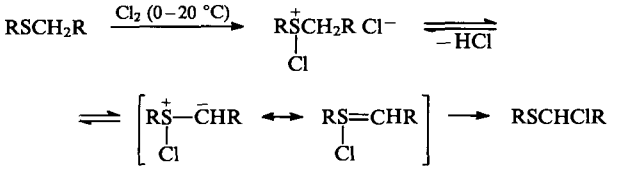
$HalR^2$ = BrCN, ICH_2CONH_2.

The intramolecular displacement of the sulfonium group is also used in the synthesis of oxiranes,[2] lactones,[68] and other heterocyclic compounds.[69]

The reduction of the sulfonium group by samarium diiodide in THF at 20 °C in the presence of 2 equiv. of methanol leads to the formation of the corresponding hydrocarbons and sulfides in quantitative yields.[70]

R = CN, 4-BrC_6H_4CO.

2. Halosulfonium salts

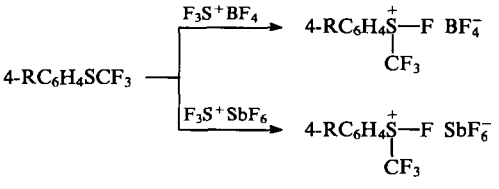


a. Methods for the generation of halosulfonium salts

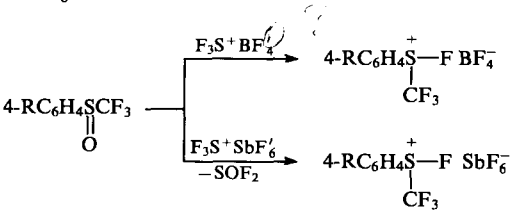
Generation from sulfides. The interaction of sulfides with the halogens is one of the commonest methods for the generation of halosulfonium salts. The reaction is carried out at low temperatures (−50 to −25 °C) in anhydrous inert solvents (CCl_4, CH_2Cl_2, $CHCl_3$, etc.).[28,71,72]

X = Cl, Br

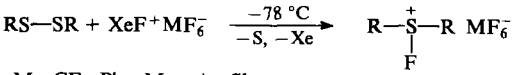
The solutions of the halosulfonium salts obtained may be stored in the dark without access of moisture for several weeks. At higher temperatures (0–20 °C), the halogenation of alkyl sulfides by the halogens leads to the formation of α-haloalkyl sulfides,[2,73] halosulfonium salts being formed as intermediates in this process.



Apart from the halogens, *tert*-butyl hypochlorite,[74–78] sulfuryl chloride,[79] and sulfonic acid *N*-chloroamides[76,80,81] are also used as halogenating agents.



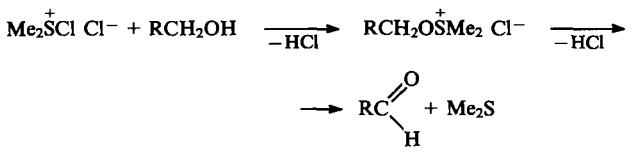
Z = BuO, SO_2Cl, $ArSO_2NH$.



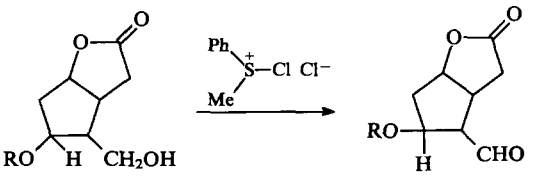
When aryl trifluoromethyl sulfides are treated with the complexes $F_3S^+BF_4^-$ and $F_3S^+SbF_6^-$, arylfluoro(trifluoromethyl)sulfonium salts are formed.[82]

Generation from sulfoxides. Arylfluoro(trifluoromethyl)-sulfonium salts are also formed when aryl trifluoromethyl sulfoxides are treated with the complexes $F_3S^+BF_4^-$ and $F_3S^+SbF_6^-$.[82]

Generation from disulfides. It has been noted[83] that, when disulfides interact with the complexes $FXe^+MF_6^-$ (M = As, Sb), the S–S and C–S bonds are cleaved with formation of fluorosulfonium salts.



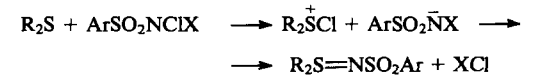
R = Me, CF_3, Ph; M = As, Sb.



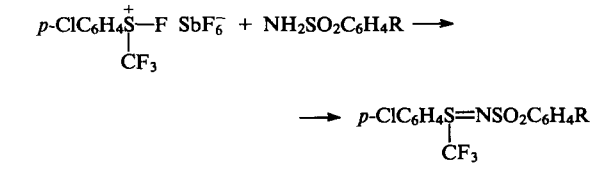
The interaction of the complex $FXe^+SbF_6^-$ with hydrogen sulfide at −78 °C leads to the formation of the fluorosulfonium salt $H_2S^+FSbF_6^-$.[83]

b. The use of halosulfonium salts in organic synthesis

Oxidation of alcohols. Chlorodimethylsulfonium chloride is widely used in organic synthesis as a mild oxidant which oxidises primary and secondary alcohols to carbonyl compounds.[28]



Chloro(methyl)phenylsulfonium chloride is used as a mild oxidant for the conversion of hydroxylactones into aldehydrolactones.[28]



R = 4-PhC_6H_4CO.

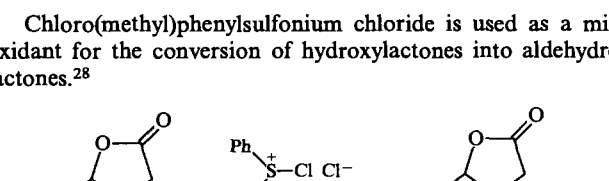
Preparation of alkyl bromides. Bromodimethylsulfonium bromide is widely used for the replacement of the OH group in an alcohol by bromine.[28] For this purpose, the sulfonium salt is treated with an excess of the alcohol for 4–5 h at 80 °C. The reaction takes place with inversion of the configuration.

Synthesis of sulfimides (sulfilimines). *N*-Arenesulfonylsulfimides[80,81,84–89] are obtained by the reaction of sulfimides with sulfonic acid *N*-chloroamides via the intermediate formation of the chlorosulfonium cation R_2S^+Cl and the sulfonamide anion $ArSO_2N^-X$ (X = H, Cl).

Arylfluoro(trifluoromethyl)sulfonium salts give rise relatively easily to *N*-arenesulfimides on interaction with sulfonic acid amides.[26,90]

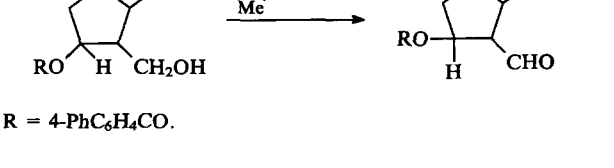
R = H, 4-Me.

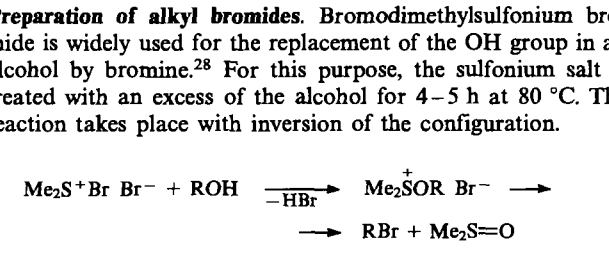
3. Aminosulfonium salts



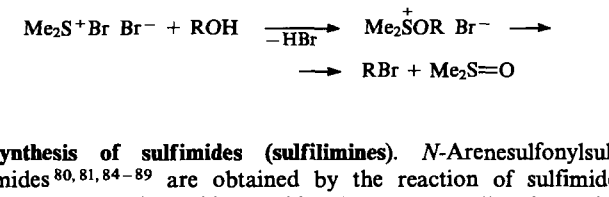
a. Methods for the generation of aminosulfonium salts

Generation from sulfides. Several variants of the generation of aminosulfonium salts from sulfides have been developed. According to one of them, the sulfides are converted into sulfonium salts by treatment with halogenating agents. The interaction of the sulfonium salts with amines leads to aminosulfonium salts.[80,91–98]

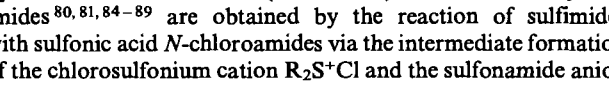




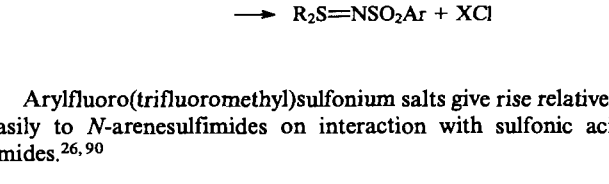
Z = Cl, Bu^{t}O, SO_2Cl, etc.



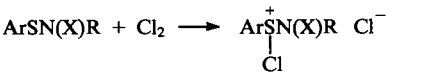
Another method is based on the reaction of sulfides with *N*-halo-compounds such as *N*-chloramine,[99] *N*-bromoacetamide,[100] *N*-chlorourethane,[100,101] *N*-chloramidines,[102] *N*-chloroguanidines,[102] *N*-chlorourea and its derivatives,[103,104] *N*-chlorosuccinimide,[28] *N*-chlorobenzotriazine,[105] and iminosulfonic acid *N*-chloroamides.[106]



X = Cl, Br; Z = H, MeCO, EtOCO, PhC(=NH)–, $NH_2NHC(=O)$–, $NH_2C(=O)$–, NH_2–CH(OMe)–.

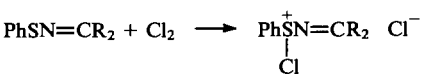


One of the modifications of these two variants for the generation of aminosulfonium salts involves the halogenation of sulfides in the presence of amines by halogenating agents such as *N*-chlorosuccinimide[107,108] and *tert*-butyl hypochlorite.[109]



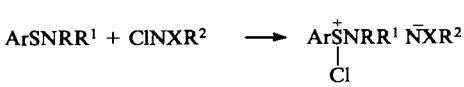
The third method for the generation of aminosulfonium salts from sulfides involves the interaction of the latter with certain derivatives of hydroxylamine, for example with hydroxyaminosulfonic acid,[80] *N*-arenesulfonyl-*O*-(*p*-nitrobenzenesulfonyl)-hydroxylamine,[80] *N*-ethoxycarbonyl-*O*-(*p*-nitrobenzenesulfonyl)hydroxylamine.[80] *O*-mesitylenesulfonylhydroxylamine,[110] and (+)-*O*-(α-bromocamphorsulfonyl)hydroxylamine.[111]

R = Alk; X = H, $ArSO_2$, EtOCO;



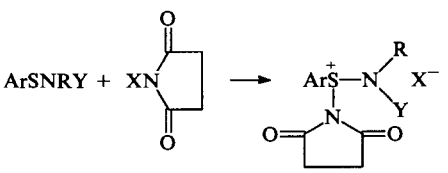
Y = HSO_3, 2,4,6-$Me_3C_6H_2SO_2$, 4-$NO_2C_6H_4SO_2$.

Generation from sulfenamides. The formation of aminosulfonium salts as intermediates in the reactions of sulfenamides with chlorine,[112–116] *N*-chloro- and *N*-dichloro-amides,[117–119] *N*-halosuccinimides,[120,121] *N*-chlorobenzotriazine,[122] and other halogenating agents has been noted.

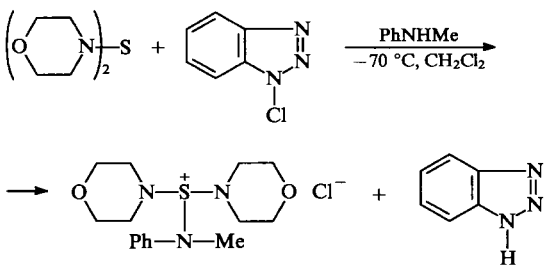


Ar = Ph, 4-MeC_6H_4, 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$;

R = Bu^t, $PhSO_2$; X = H, Na.

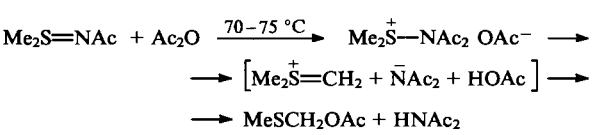


R = Ph, CF_3.



R = H, Alk; R^1 = Alk, Ar, $ArSO_2$;

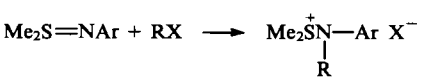
X = H, Cl; R^2 = ArCO, $ArSO_2$.



Ar = Ph, 2-$NO_2C_6H_4$;

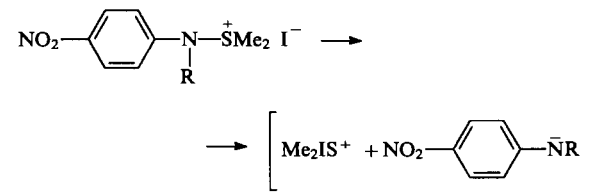
R = Me, $PhSO_2$; Y = Me, Na; X = Cl, Br.

Generation from sulfimides. On heating in acetic anhydride, *N*-acyl-*S*,*S*-dimethylsulfimides enter into the Pummerer reaction, which proceeds via an intermediate stage involving the generation of aminosulfonium salts.[123]



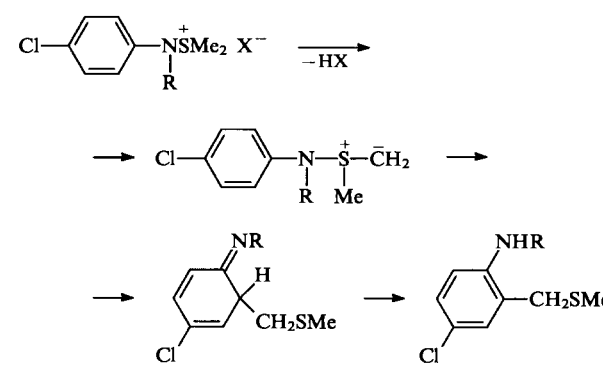
N-Acetyl-*S*,*S*-dimethylsulfimide is converted into an aminosulfonium salt on interaction with gaseous hydrogen chloride.[124]

Sulfimides unsubstituted at the nitrogen atom give rise to aminosulfonium salts on interaction with strong inorganic acids, for example with sulfuric acid.[125]



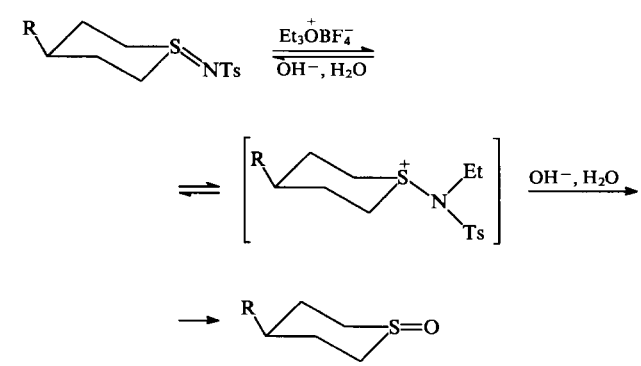
Unstable aminosulfonium salts have been obtained by the interaction of *N*-arenesulfilimides with alkylating or acylating agents.[80,81,126]

R = Me, X = Cl; R = EtOCO, X = Cl;



R = MeCO, X = MeOCO; Ar = *p*-$NO_2C_6H_4$, *p*-ClC_6H_4.

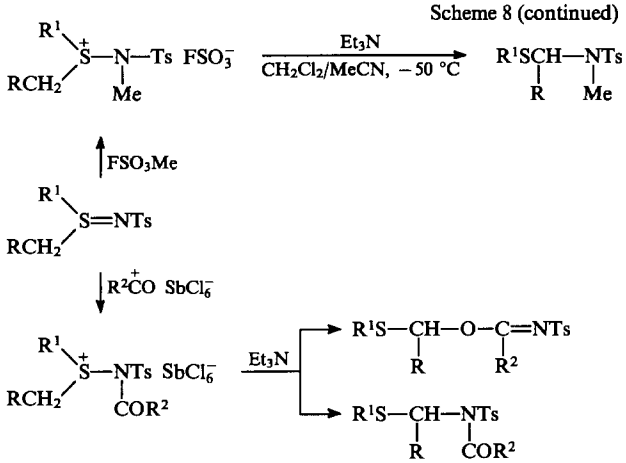
Further reactions of these salts are determined by the nature of the substituents in the benzene ring of the aryl group and by the basicity of X^-. In the case of strongly electron-accepting substituents (for example, NO_2) and highly basic X^-, X^- attacks the positively charged sulfur atom with subsequent dissociation of the S–N bond.



In the case of weakly electron-accepting or electron-donating substituents, the anion X^- abstracts a proton from the MeS group, giving rise to an intermediate ylide. The ylide then undergoes an intramolecular sigmatropic rearrangement, which leads to unstable cyclohexadiene derivatives and these are converted into the more stable benzene derivatives.

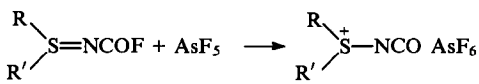
The replacement of one methyl group at the sulfur atom by the ethyl or propyl group does not alter the mode of abstraction of a proton — it is abstracted from the Me group as before, while on replacement of the methyl group by the benzyl group it is abstracted only from the latter, which is correlated with the decrease in acidity in the sequence $PhCH_2S$ > MeS > $AlkCH_2S$.

N-Arenesulfonylsulfimides give rise to aminosulfonium salts only on interaction with highly active acylating and alkylating agents such as oxonium salts,[80,81] methyl fluorosulfonate,[127] and complexes of carboxylic acid chlorides with $SbCl_5$.[127] The aminosulfonium salts formed in this case are relatively stable and undergo further reactions only on treatment with inorganic and organic bases (Scheme 8).



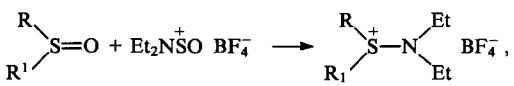
Scheme 8

R = Bu^t.



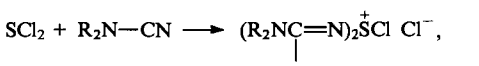
(continued over)

Scheme 8 (continued)



R = H, R^1 = R^2 = Me; R = H, R^1 = Me, R^2 = Et;
R = Ph, R^1 = Et, R^2 = Me;
R = H, R^1 = Me, R^2 = Ph; R = H, R^1 = Et, R^2 = Me.

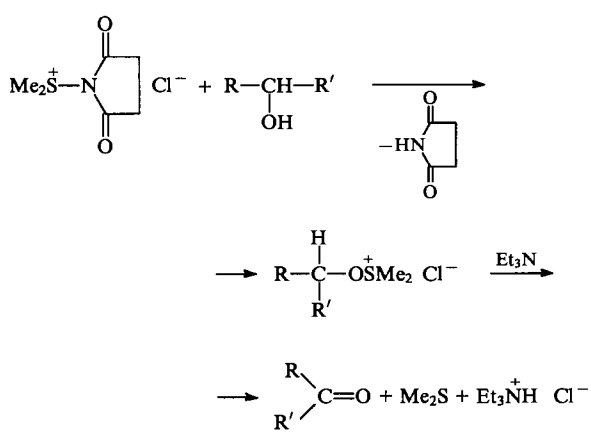
It has been shown [128] that the reaction of fluorocarbonylsulfimide with arsenic pentafluoride proceeds with abstraction of a fluoride anion and the formation of an aminosulfonium salt.



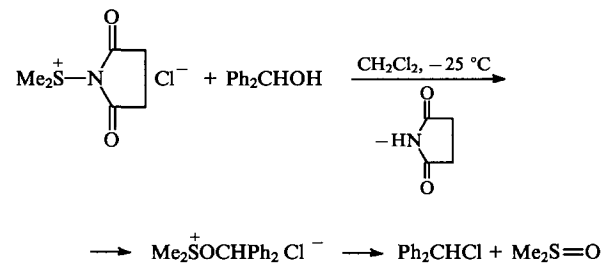
R = F; R′ = CF_3, NMe_2; R = CF_3; R′ = NMe_2.

Other generation methods. Among other methods, mention should be made of the interaction of sulfoxides with *N*-sulfinyldialkylimmonium salts [129]

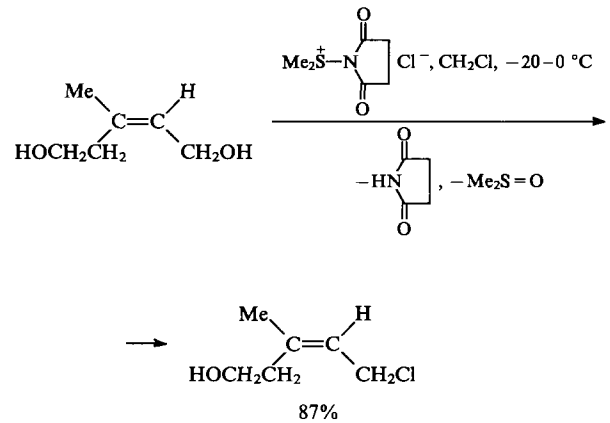
the reaction of sulfur dichloride with dialkylcyanamide [130]



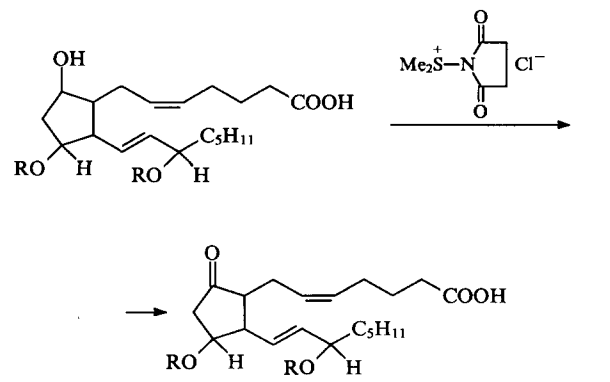
and the interaction of disulfides with carboxylic acid *N*-chloroamides; [131]



b. The use of aminosulfonium salts in organic synthesis

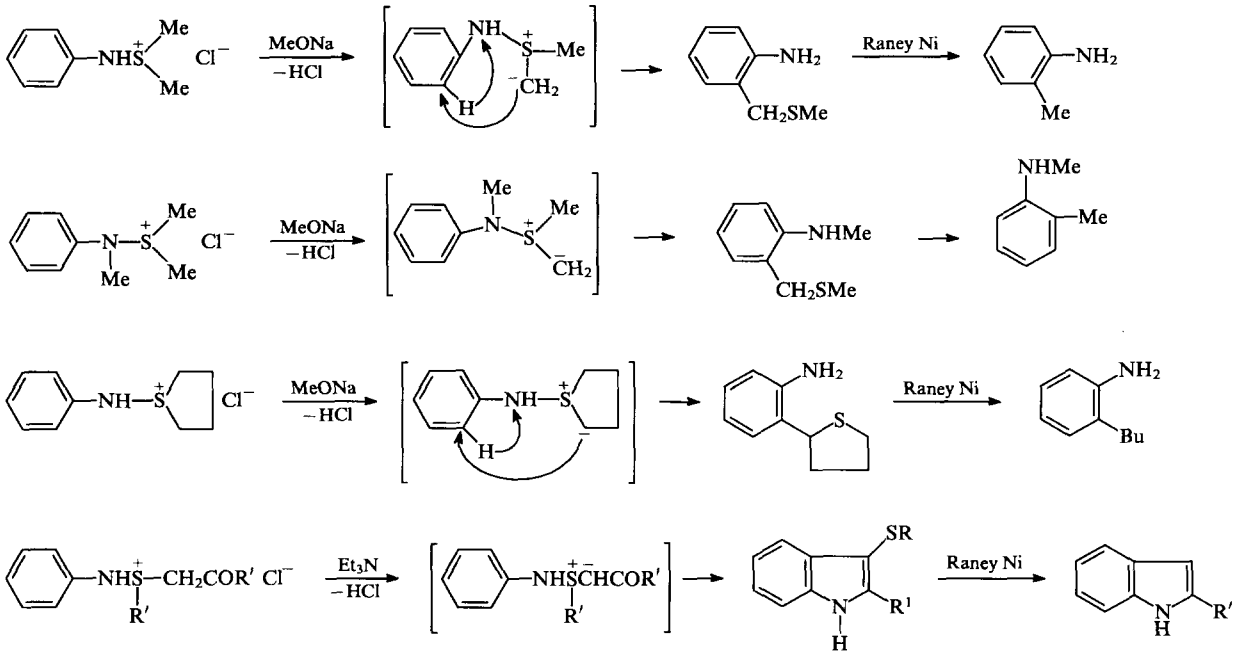


Dimethyl-*N*-succinylsulfonium chloride (the Corey–Kim reagent) has found extensive application in organic synthesis as a mild oxidant for alcohols,[28] which is superior in this respect to chlorodimethylsulfonium chloride.

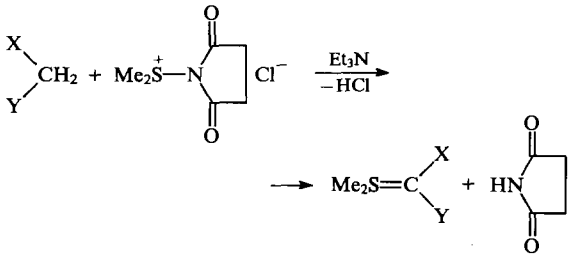


As an oxidant, the Corey–Kim reagent exhibits a high selectivity. For example, in contrast to primary and secondary aliphatic alcohols, allyl and benzyl alcohols are not oxidised by this reagent but are converted into the corresponding chlorides. In the case of diphenylmethanol, the yield of diphenylmethyl chloride reaches 95% in this reaction.[28]

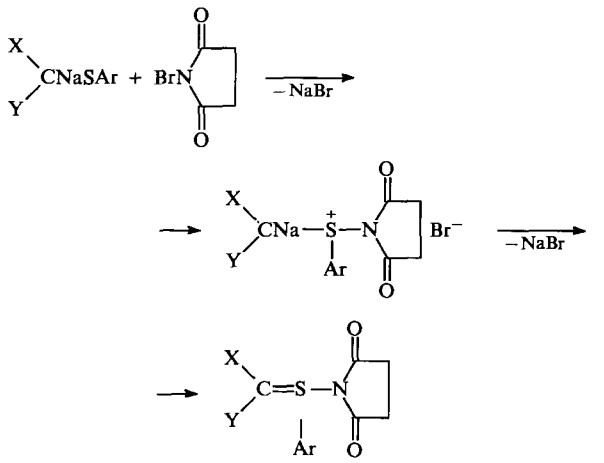
Under the same conditions, cyclohex-1-en-3-ol is converted into 3-chlorocyclohexene in a yield exceeding 95%. The conversion of (*Z*)-3-methylpent-2-ene-1,5-diol into the allyl monochloride in 87% yield can also serve as a clear example of the selectivity of the Corey–Kim reagent.[28]



The Corey–Kim reagent is also used in an improved synthesis of prostaglandins for the conversion of a hydroxy-group into a keto-group in a yield exceeding 90%.[28]



Generation of sulfur ylides. In the presence of bases, dialkylaminosulfonium salts may undergo C-deprotonation with formation of aminosulfonium ylides, which is also used in organic synthesis. For example, the conversion of dialkylaminosulfonium salts into aminosulfonium ylides with subsequent rearrangement of the latter is employed in the orthoalkylation or anilines [132] and in the synthesis of indoles (Scheme 9).[133]



Scheme 9

It is worth noting that, in the case of aminosulfonium salts containing a hydrogen atom at the nitrogen atom, the formation of sulfur ylides may be accompanied by a side reaction — the formation of sulfimides. The rearrangement of aminosulfonium salts in the presence of bases, which results in the formation of sulfides,[134] also proceeds via a sulfonium ylide generation stage. The formation of sulfur ylides has also likewise been observed in the interaction of Corey–Kim reagents with CH acids in the presence of triethylamine.[135]

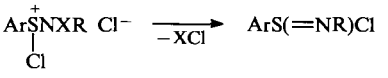
X = Br, Ac, CN;
Y = Br, Ac, CO_2Et, CO_2Me, Ph.

X = MeCO, Y = EtOCO, Ar = 2-$NO_2C_6H_4$;

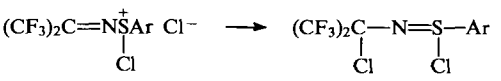
X = $PhSO_2$, Y = Ph, Ar = 4-$NO_2C_6H_4$.

It has been suggested[136] that the interaction of sodium salts of arylthio-CH acids with *N*-bromosuccinimide, which results in the formation of stable *S*-aryl-*S*-succinimidosulfonium methylides, proceeds via a stage involving the formation of aminosulfonium salts.

Synthesis of sulfimides. The N-deprotonation of aminosulfonium salts containing a hydrogen atom at the nitrogen atom is one of the commonest methods of synthesis of sulfimides.[80,81] Both organic and inorganic bases (Et_3N, NaOH, etc.) are used as the deprotonating agents.

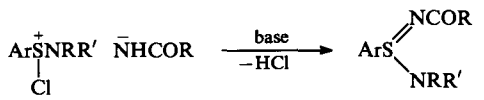


R = Alk, Ar, Het, X = Cl, Br; Z = H, MeCO, EtOCO, etc.

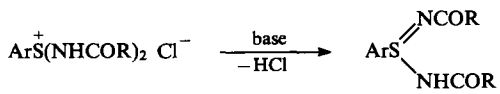


R = Alk, Ar; X = H, $ArSO_2$, EtOCO;

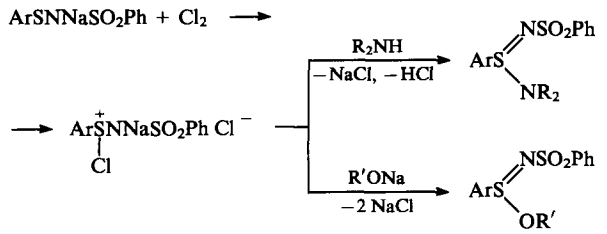
Y = HSO_3, 4-$NO_2C_6H_4SO_2$, 2,4,6-$Me_3C_6H_2SO_2$.



Synthesis of derivatives of iminosulfinic acids. The aminosulfonium salts formed on chlorination of *N*-substituted sulfenamides[112] or their sodium salts[113] are readily converted into iminosulfinic acid chlorides as a result of the elimination of HCl or NaCl.



R = Bu^t, $PhSO_2$, ArCO; X = Na, H.



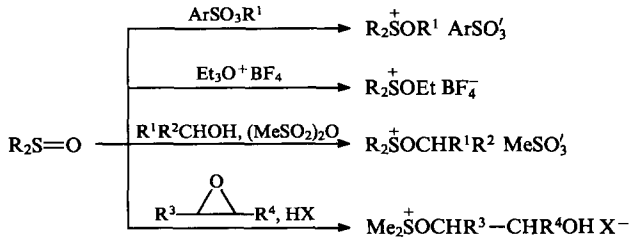
The dehydrochlorination of the aminosulfonium salts formed on interaction of *N*-chloroamides with sulfenamides[119] and disulfides[131] leads to the amides of iminosulfinic acids.

R = H, Alk; R′ = Alk, Ar, RCO

One cannot rule out the possibility that the chlorination of the sodium salts of *N*-arenesulfonylarenesulfenamides in the presence of various nucleophiles, which results in the formation of the amides[137] and esters[138,139] of iminosulfinic acids, also proceeds via a stage involving the formation of aminosulfonium salts.

Ar = 2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$;

R = Et, Bu, C_5H_{11}; R′ = Me, Et, Pr, Bu^i, Bu^n

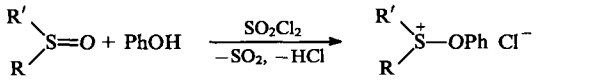


4. Alkoxy-, aryloxy-, and acyloxy-sulfonium salts

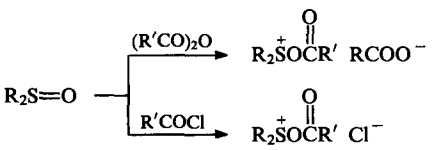
a. Methods for the generation of alkoxy-, aryloxy-, and acyloxy-sulfonium salts

Generation from sulfoxides. The commonest method for the generation of alkoxysulfonium salts involves the interaction of sulfoxides with alkyl halides.[1,2]

The alkyl esters of sulfonic acids,[28] triethyloxonium tetrafluoroborate,[2] alcohols (in the presence of the anhydride of methanesulfonic acid),[2] and epoxides (in the presence of strong acids)[2] are used as other alkylating agents.[2]



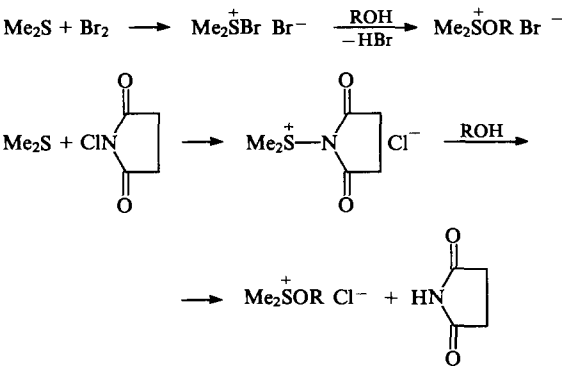
R = Alk, R^1 = Alk, Ar = 4-MeC_6H_4, 4-$NO_2C_6H_4$;



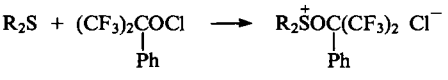
R^2 = Alk; R^3 = H, Alk, Ph; R^4 = H, Alk;

X = 2,4,6-$(NO_2)_3C_6H_2SO_3$.

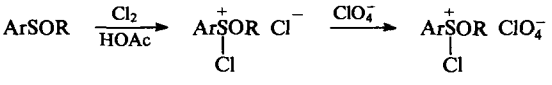
The synthesis of a phenoxysulfonium salt by the reaction of sulfoxides with phenol in the presence of sulfuryl chloride has been described.[140]



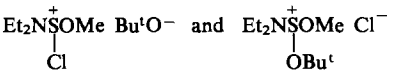
The interaction of the sulfoxides with carboxylic acid anhydrides[2,141,142] of halides[28] leads to the formation of acyloxysulfonium salts.



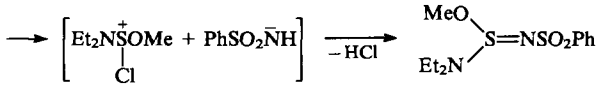
R = Me, Ph, CH_2=CH, etc.; R′ = Me, CF_3.



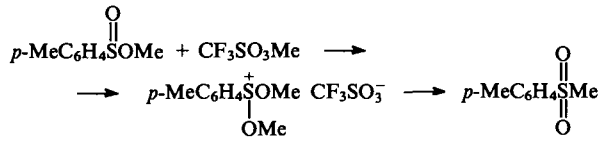
Generation from sulfides. Two alternative methods for the generation of alkoxysulfonium salts from sulfides have been developed. In the first method, the sulfide is converted into halo- or amino-sulfonium salts, which are subsequently treated with alcohols.[28]



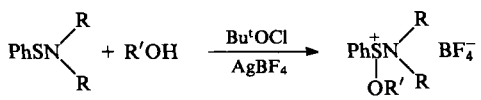
The second method involves the interaction of sulfides with alkyl hypochlorites.[105]



Generation from sulfenic and sulfinic acid esters. Alkoxysulfonium salts are formed on interaction of the alkyl esters of sulfenic acids with chlorine in acetic acid.[2]



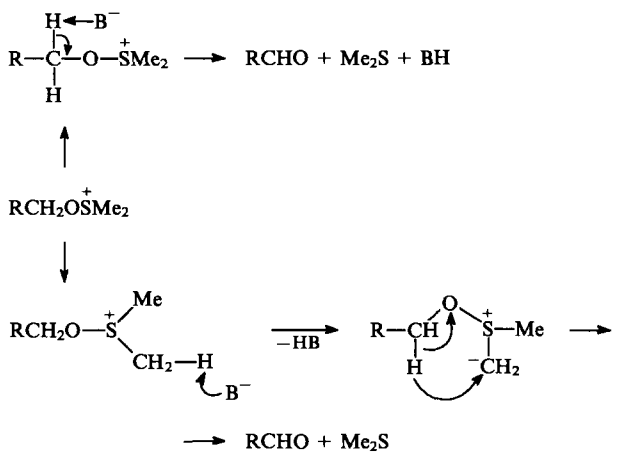
It has been noted[143,144] that the oxidation of *O*-methyl-*N*,*N*-dimethylaminosulfenates by *tert*-butyl hypochlorite to aminosulfinates proceeds via a stage involving the formation of alkoxysulfonium salts.



Evidently the oxidative imination of these compounds by the sodium derivatives of sulfonic acid chloramides[145] also proceeds via a stage in which alkoxysulfonium salts are generated.

The formation of a dimethoxysulfonium salt in the alkylation of methyl toluene-*p*-sulfinate by methyl trifluoromethanesulfonate has been postulated.[146]

Generation from sulfenamides. It has been shown[147] that *N,N*-dialkylarenesulfenamides react with *tert*-butyl hypochlorite in the presence of alcohols and $AgBF_4$ to form alkoxyaryldialkylaminosulfonium salts.

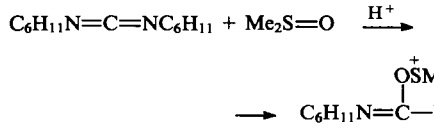


R = Me, $(CH_2)_5$, $(CH_2)_2O(CH_2)_2$; R′ = Me, Et, Pr^i, iso-C_6H_{11}.

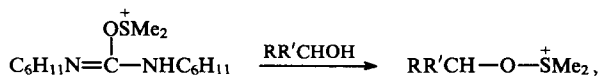
b. Applications of alkoxysulfonium salts in organic synthesis

Synthesis of carbonyl compounds. On treatment with bases, alkoxysulfonium salts are cleaved, affording carbonyl compounds in relatively high yields.

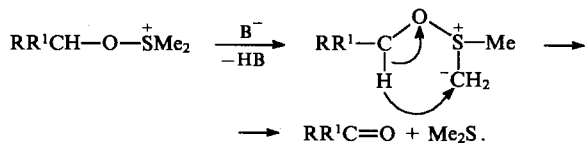
The cleavage can proceed in two ways.



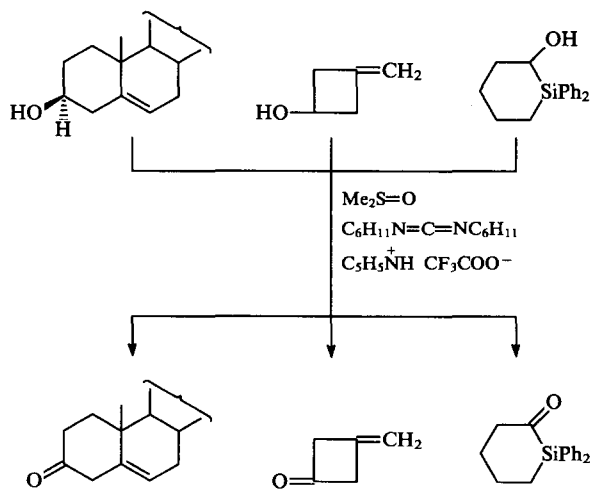
A whole series of convenient methods for the conversion of primary and secondary alcohols and also alkyl halides and tosylates into carbonyl compounds have been developed on the basis of this reaction. As a rule, alkoxysulfonium salts based on DMSO are used in these methods, which is evidently associated with their greatest availability. The advantage of these methods of synthesis of carbonyl compounds consist not only in the high yields of the target products but also in the fact that the oxidation of the aldehyde group to a carboxy-group is ruled out and other readily oxidised fragments, such as C=C and C–S–C, are not affected.



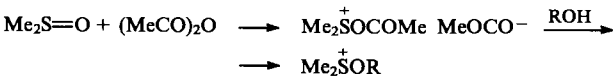
Depending on the method of generation of alkoxysulfonium salts, all these methods can be divided into several groups. The first group includes methods in which the alkoxysulfonium salt is formed as a result of the interaction of an alcohol with the alkoxysulfonium salt generated by the interaction of DMSO with the electrophilic species E^+ present in the reaction medium.[2]



Here it is essential that the electrophilic species should react with DMSO faster than with the alcohol and that the OE group should be readily eliminated. Dicyclohexylcarbodiimide (DCC) combined with proton sources, for example pyridinium fluoroacetate, acetic anhydride, trifluoroacetic anhydride, and methanesulfonic acid anhydride is most often employed as the electrophile. When the last two compounds are used, the alcohol is introduced into the reaction medium after the reaction of dimethyl sulfoxide with the electrophile. The oxidation of the alcohol by the DMSO–DCC system includes three stages: the activation of DMSO by the electrophile with formation of a primary alkoxysulfonium salt:

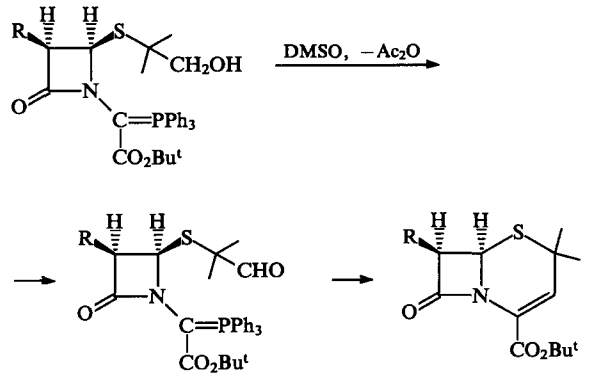


the interaction of the alkoxysulfonium salt with the alcohol to form a secondary alkoxysulfonium salt:



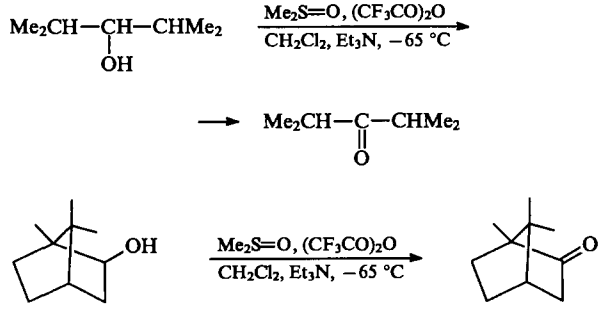
the decomposition of the secondary alkoxysulfonium salt:

Cholesterol, 3-methylenecyclobutanol, and 1,1-diphenylsilacyclohexan-2-ol have been oxidised to the corresponding ketones by means of the DMSO–DCC system.[2]



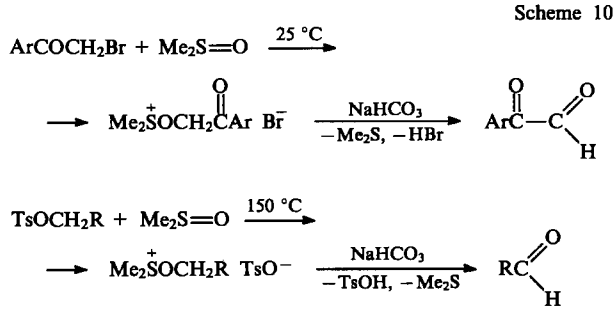
The acylsulfonium salt formed in the DMSO–$(MeCO)_2O$ system is converted into an alkoxysulfonium salt as a result of its interaction with the alcohol.[2]

This system is also used in the oxidation of hydrocarbons, sterically hindered alcohols, and also alcohols with readily oxidisible functional groups such as the sulfide and phosphorus-containing groups. For example, the conversion of a phosphorane, containing the β-lactam group, into a bicyclic



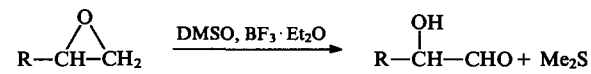
product takes place as a result of the Wittig reaction with participation of the aldehyde group formed on oxidation of an alcoholic group by the DMSO–$(MeCO)_2O$ system without change in the phosphorane and sulfide functional groups.

R = $NHC(O)CH_2Ph$.



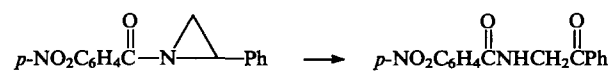
The formation of side products – acetates and methylthiomethyl ethers – must be regarded as a disadvantage of this system.

Among other methods, mention should be made of the use of the DMSO–methanesulfonic acid anhydride system in DMF for the oxidation of testosterone to androst-4-ene-2,17-dione and of the DMSO–trifluoroacetic anhydride system in CH_2Cl_2.[148] The latter method has been used in the oxidation of sterically hindered alcohols. For example, in the presence of this system 2,4-dimethylpentan-3-ol and isoborneol are converted into diisopropyl ketone and camphor in 86% and 93% yields respectively.[149]

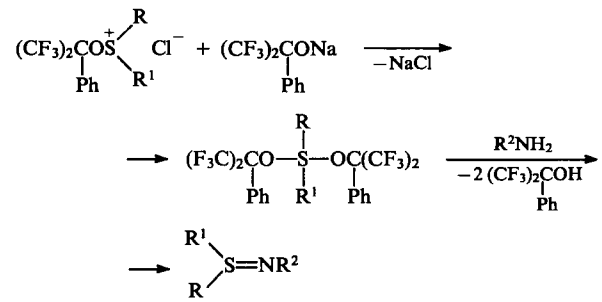


Methods in which the alkoxysulfonium salts are generated by the interaction of DMSO with halo-derivatives or tosylates in the presence of $NaHCO_3$ or collidine, which not only decompose the intermediate alkoxysulfonium salt but also neutralise the acid side products, are included in the second group of methods of synthesis of carbonyl compounds from alkoxysulfonium salts (Scheme 10).[2]

Scheme 10

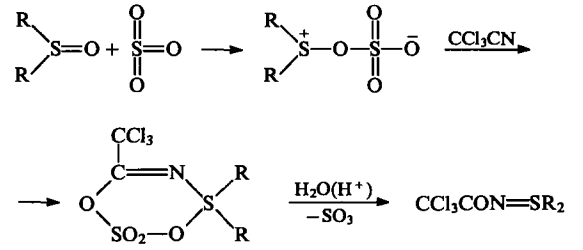


These methods are especially suitable in the case of halo-derivatives and tosylates, which tend to undergo S_N2 substitution reactions (α-halogenated esters and acids, phenacyl and benzyl halides, primary alkyl iodides, sulfonates). However, one should note that, when secondary halo-derivatives and tosylates are employed, the yields of the carbonyl compounds are low owing to the competing elimination reactions.

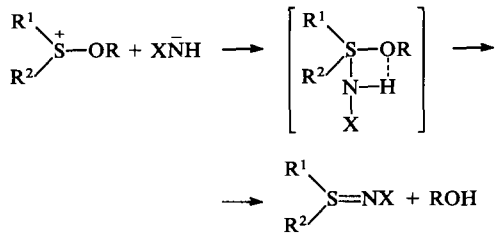


The third group comprises methods in which the intermediate alkoxysulfonium salts are the products of the interaction of DMSO with three-membered heterocyclic compounds in the presence of acid catalysts. For example, the interaction of DMSO with epoxides in the presence of $BF_3.Et_2O$ leads to the formation of α-hydroxyaldehydes.

On heating in DMSO at 115–120 °C, the ring in *N*-acylaziridines is opened with conversion into *N*-substituted amides.

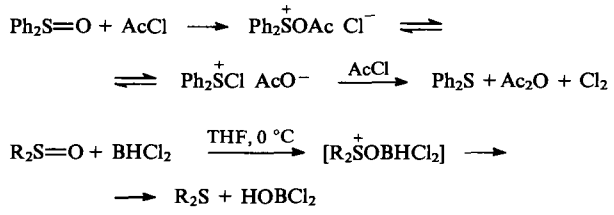


Synthesis of sulfimides. Several methods have been developed for the preparation of sulfimides from alkoxysulfonium salts. One of them involves the conversion of alkoxysulfonium salts by alkoxides into sulfuranes, which give rise to sulfimides on interaction with amines.[105]

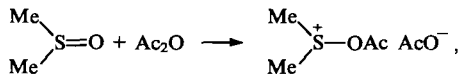


Another method is based on the interaction of alkoxysulfonium salts, generated from sulfoxides and active electrophiles E^+, with N-nucleophiles.[80,81]

The activating electrophiles employed are P_2O_5, $(CF_3CO)_2O$, SO_3, H_2SO_4, and BF_3.[80,81] Amines and amides of sulfonic and carboxylic acids are employed as the N-nucleophiles. The sulfonium salts formed in the reactions of sulfoxides with SO_3 also react with nitriles to form sulfimides.[149] The proposed reaction mechanism involves the attack by the electron-deficient carbon atom of the nitrile group on one of the oxygen atoms of the sulfonium salt, which occurs only in the case of nitriles containing strongly electron-accepting groups.

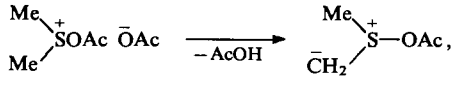


The synthesis of sulfimides by the reactions of the sodium derivatives of the amides and sulfonic and carboxylic acids with alkoxysulfonium salts has been described.[150] According to the authors, the reaction is stereospecific and proceeds with retention of configuration of the sulfur atom, which is due to the formation of an intermediate four-membered cyclic compound stabilised by an intramolecular hydrogen bond.

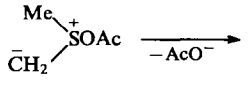


R = Me–C6H4–CHMe2, R^1 = 2-$MeOC_6H_4$, R^2 = Ph

X = $ArSO_2$, CH_2ClCO, $CHCl_2CO$, CF_3CO



Synthesis of sulfides. Several methods have been developed for the synthesis of sulfides from sulfoxides involving an intermediate stage in which alkoxy- or acyloxy-sulfonium salts are generated. One of them amounts to the reduction of sulfoxides by an excess of acetyl chloride[151] and by dichloroborane.[152]

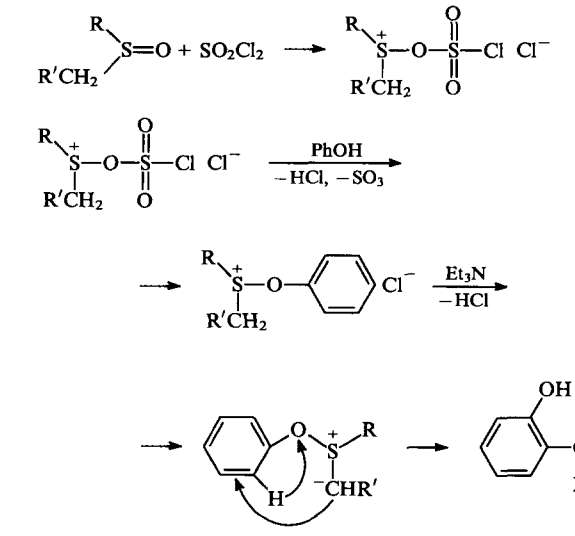


However, the method has not found extensive application, since more effective and convenient procedures have been developed for the reduction of sulfoxides and sulfides. Reactions leading to the formation of sulfides differing in structure from those employed for the synthesis of the sulfoxides are frequently used. One of them is based on the Pummerer rearrangement, which takes place when sulfoxides are heated in acetic anhydride.[2,153] The mechanism of this rearrangement includes the following stages:
the formation of an acyloxysulfonium salt:

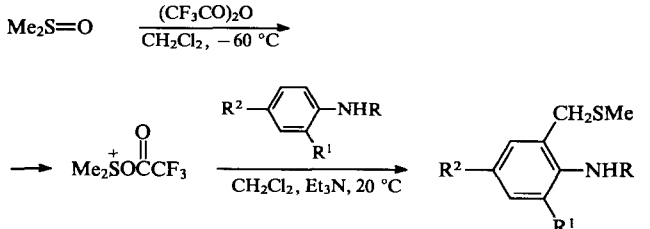
the conversion of the acyloxysulfonium salt into an ylide:

the formation of a sulfonium cation:

the interaction of the sulfonium cation with the acetate anion:



The presence of alkoxide anions in the reaction mixture leads to the formation of a methylthiomethyl ether or an alkoxymethyl methyl sulfide, which makes it possible to explain the formation of this compound as a side product in the oxidation of alcohols by the DMSO–$(MeCO)_2O$ system.

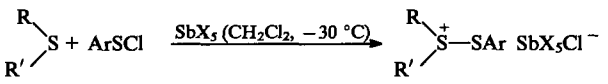


The regioselectivity of the Pummerer rearrangement, observed for asymmetric sulfoxides, can be predicted on the basis of the comparison of the relative acidities of the two α-protons in the acyloxysulfonium salt. Bearing in mind the ease of the conversion of sulfides into sulfoxides, the Pummerer rearrangement is a very important method for the conversion of one set of sulfides into another.

Other methods for the conversion of sulfoxides into sulfides are based on the intramolecular rearrangement of aryloxysulfonium salts proceeding via an ylide generation stage.[140] The final result of such 2,3-sigmatropic rearrangement is the introduction of an alkylthiomethylene group into the *ortho*-position in phenols.

An alkylthiomethylene group is introduced similarly into the *ortho*-position in aromatic amines.[141]

R = H, Me, Ph; R^1 = H, MeO; R^2 = H, Me, MeO

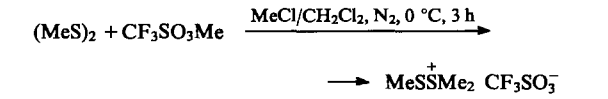


5. Alkyl(aryl)thiosulfonium and [dialkyl(aryl)]alkyl(aryl)-thiosulfonium salts

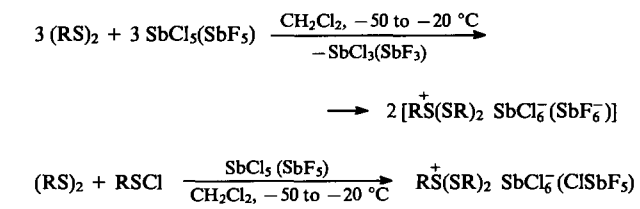
a. Methods of generation

Generation from sulfides. Dialkyl sulfides and certain diaryl sulfides react relatively easily with arenesulfenyl chlorides in the presence of silver perchlorate[154] or Lewis acids,[155] forming (dialkyl)arylthiosulfonium salts.

Ar = Ph, 4-MeC_6H_4



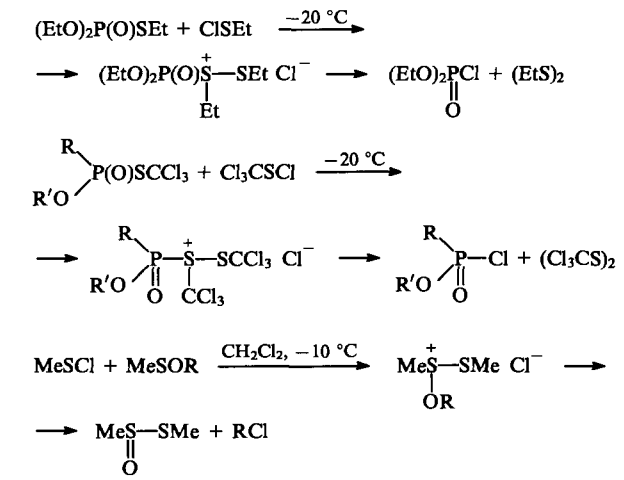
R = R′ = Me, Ph; R = Me, R′ = 4-ClC_6H_4; X = Cl, F



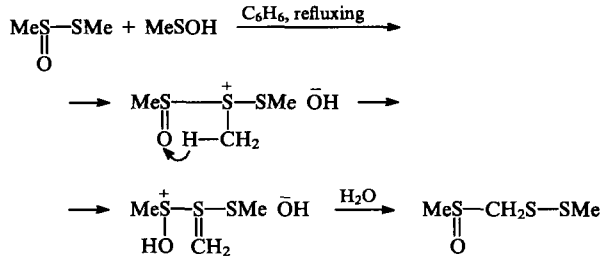
Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4, 2,4,6-$Me_3C_6H_2$, 4-$CF_3C_6H_4$.

Some of these salts are relatively stable and can be isolated in a crystalline state and analysed by ^1H and ^{13}C NMR spectroscopy.[155]

Generation from disulfides. (Dialkyl)alkylthiosulfonium salts have also been obtained by the interaction of dialkyl disulfides with methyl trifluoromethanesulfonate.[156]

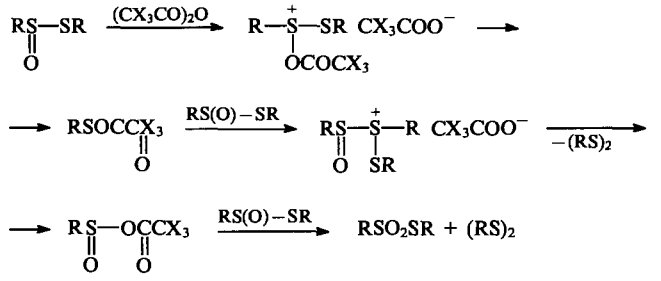


The interaction of dialkyl disulfides[157,158] and diaryl disulfides[159–161] with Lewis acids ($SbCl_5$, SbF_5) or with sulfenyl chlorides leads to the formation of [dialkyl(aryl)]alkyl(aryl)-thiosulfonium salts.



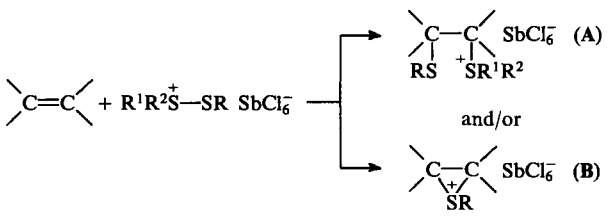
R = Me, Ph, 4-ClC_6H_4, 4-MeC_6H_4, 2,4,6-$Me_3C_6H_2$.

The salt solutions obtained can be stored without change for several hours at −50 to −20 °C. The formation of intermediates of analogous structure in the disproportionation of disulfides in an acid medium has been postulated.[162]

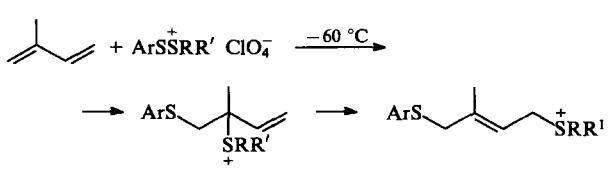


Other methods of generation. The formation of alkylthiosulfonium intermediates has been observed in the reactions of alkanesulfenyl chlorides with phosphorothiolates[163] and sulfenates.[2]

It has been suggested[164] that the sulfenic acids formed in the thermal dissociation of thiolosulfinates in the absence of trapping agents may react with the thiolosulfinates to form sulfinylthiosulfonium intermediates, which are converted into alkane-α-sulfinyl disulfides as a result of the Pummerer rearrangement.



The probable mechanism of the rearrangement of thiolosulfinates on treatment with the anhydrides of trichloro- and trifluoro-acetic acids, described in the literature,[165] also involves the generation of thiosulfonium intermediates.

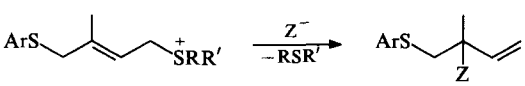


R = Me, $PhCH_2$; X = Cl, F.

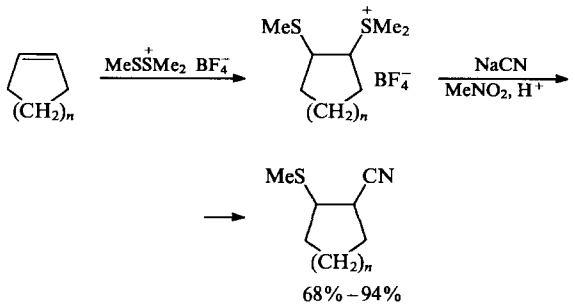
b. The applications of alkyl(aryl)thiosulfonium and [dialkyl(aryl)]-alkylthiosulfonium salts in organic synthesis

It has been noted[155,157,158,166] that alkyl(aryl)thiosulfonium salts are effective agents for transferring the RS^+ groups to the double bond in Ad_E reactions with alkenes such as cyclohexene, 1-methylcyclohexene, tetramethylethene, cyclooctene, styrene, isoprene, etc. These reactions take place relatively easily even at −10 to −30 °C and lead to the formation β-alkyl(aryl)-thiosulfonium salts **A**[155,157,158,166] and/or *S*-alkyl(aryl)episulfonium salts **B**.[155–158]

According to Kal'yan et al.,[155] the interaction of alkenes with the salts RR′S^+–SAr $SbCl_6^-$ (R = R′ = Me; Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4, 2,4,6-$Me_3C_6H_2$, 4-$CF_3C_6H_4$, C_6F_5) and RR′S^+SAr $SbCl_6^-$ [R + R′ = $-(CH_2)_4-$, Ar = 4-ClC_6H_4, 2,4,6-$Me_3C_6H_2$] proceeds most unambiguously. In the reactions of these salts with cyclohexene, styrene, and isoprene, the formation of only β-arylthioalkylsulfonium salts A, readily isolated in the form of substances fairly stable in the solid state, has been observed. According to ^1H NMR data, the salts obtained under these conditions from isoprene have the structure of 1,4-adducts formed as a result of the rearrangement of the 1,2-adducts.

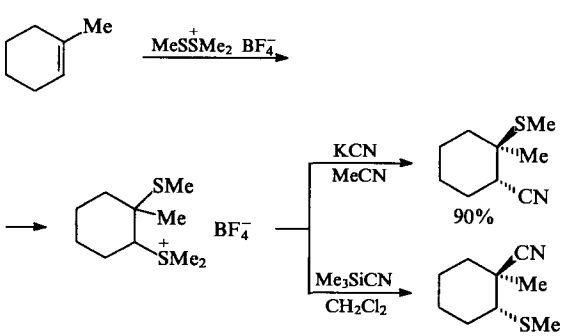


The formation of the episulfonium salt **B** has been observed in the reaction of ($RR'S^+-SC_6H_4Me$-4) $SbCl_6^-$ (R = Me, R′ = C_6H_4Cl-4) with cyclohexene, but, when the methyl group in the *S*-aryl fragment of the initial salt is replaced by CF_3 or Cl, a 1 : 1 mixture of the salts **A** and **B** is obtained. This enabled the authors[155] to postulate the primary formation of the episulfonium salt **B**, the interaction of which with the sulfide present in the reaction mixture leads to the salt **A**. The reactivity of the episulfonium salt **B** is then determined by the nature of the substituents in the *S*-aryl fragment. In terms of their reactivity in relation to nucleophiles, certain salts **A** are close to the episulfonium salt **B**. Thus the reactions of these salts with the acetate anion lead to the corresponding acetoxy-adducts.

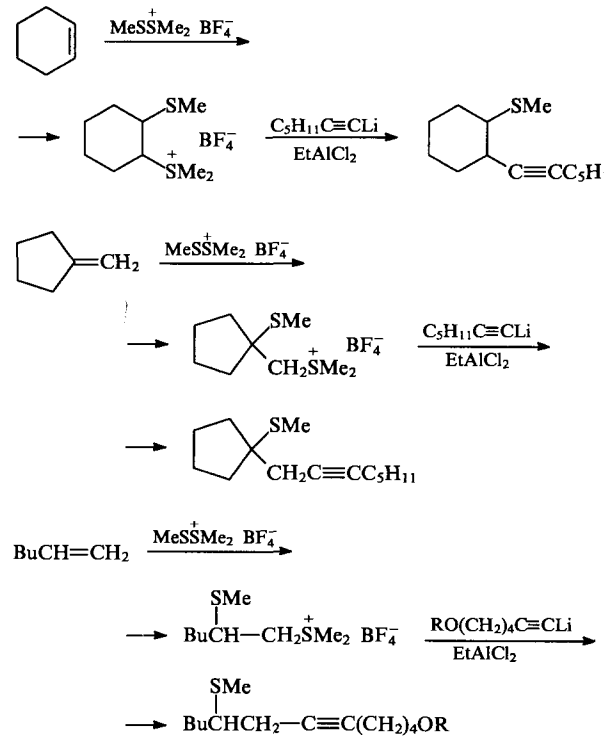


R = Me, Ph; R′ = Ph, 4-ClC_6H_4.

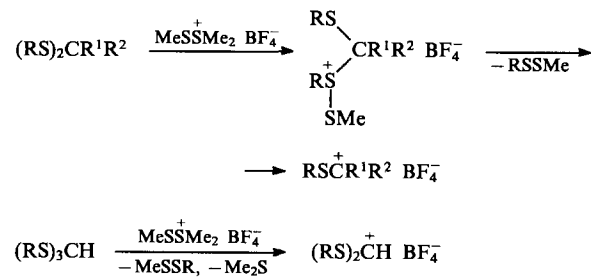
Salts of type **A** based on isoprene react in an unusual manner with the acetate anion and other nucleophiles. In this case, the reaction proceeds exclusively in accordance with an S_N2 mechanism with formation of β-acetoxysulfides.



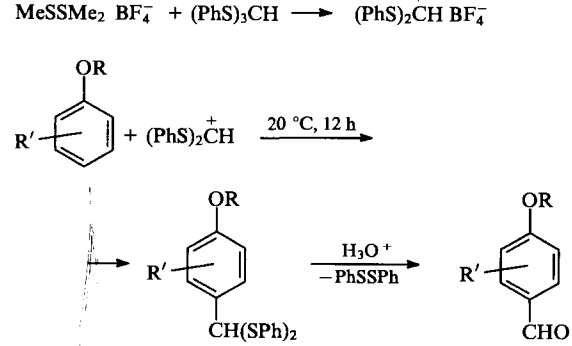
It has been noted[9] that β-alkyl(aryl)thiosubstituted salts **A** are effective electrophiles for the transfer of the β-alkyl(aryl)thioalkyl group in reactions with anionic C-nucleophiles. For example, it has been shown that the adducts of different alkenes with $MeS\overset{+}{S}Me_2$ BF_4^- react fairly readily with the cyanide ion, which has made it possible to develop a general method for the cyanosulfenylation of alkenes under mild conditions.



68%–94%

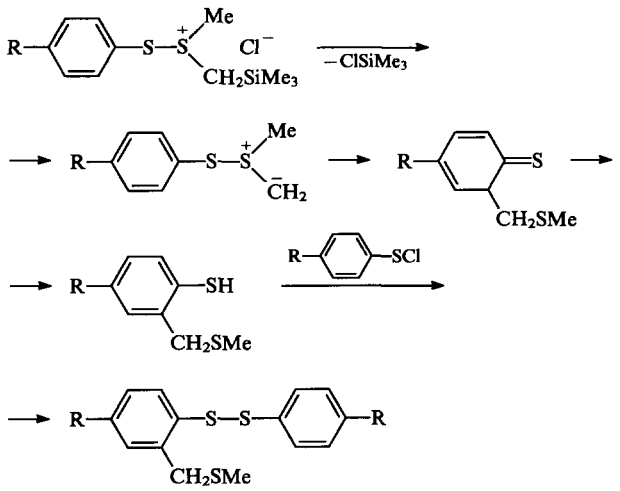


When the reaction conditions are altered, both regioisomers may be obtained.

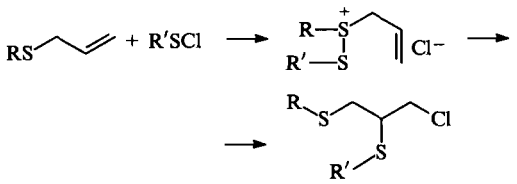


Complexes of acetylides with organoaluminium compounds are also used as the C-nucleophiles.[9]

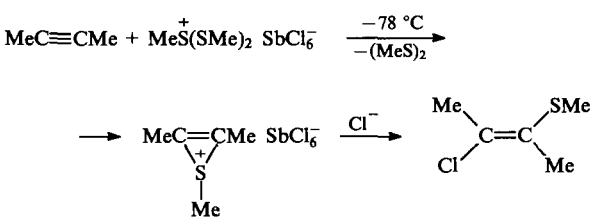
One of the very important aspects of the use of alkyl(aryl)-thiosulfonium salts in organic synthesis is the generation of α-thio-substituted[167] and α,α-dithio-substituted[168] carbonium ion intermediates.



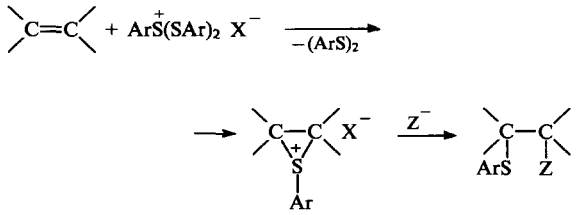
In a regioselective method[169] for the formylation of phenols and naphthols, a α,α-diphenylthio-substituted carbonium ion is generated with the aid of the salt $MeSS^+Me_2$ BF_4^-.



The rearrangements of alkyl(aryl)thiosulfonium salts are frequently employed to synthesise various sulfur-containing compounds. For example,[170] the spontaneous 2,3-sigmatropic rearrangement of the salts $RR'S^+SAr$ Cl^- (R = Me; R′ = CH_2SiMe_3; Ar = Ph; 4-MeC_6H_4, 4-ClC_6H_4), formed in the

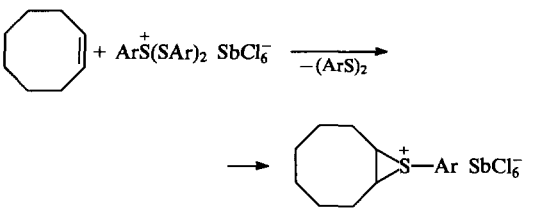


reactions of arenesulfenyl chlorides with methylthiomethyl(trimethyl)silane, has been described.[170] The authors suggest[170] that the rearrangement proceeds via an ylide formation stage.



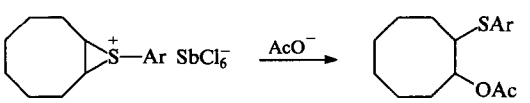
An interesting case of a degenerate 2.3-sigmatropic rearrangement has been observed in the interaction of sulfenyl chloride with allyl sulfides.[54,171]

[Dialkyl(aryl)]alkyl(aryl)thiosulfonium salts are also effective agents for the transfer of the RS^+ group in Ad_E reactions with unsaturated hydrocarbons. The interaction of such salts with ethyne hydrocarbons leads to the formation of thiirenium salts, the reactions of which with nucleophiles involve ring opening and the formation of unsaturated sulfides.[172]



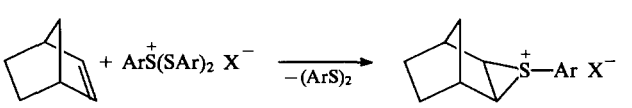
(Diaryl)arylthiosulfonium salts react rapidly with alkenes even at −60 °C, affording the corresponding *S*-arylepisulfonium salts, which are converted into β-substituted aryl sulfides on treatment with nucleophiles.[159–161]

Ar = Ph, 4-ClC_6H_4, 4-MeC_6H_4, 2,4,6-$Me_3C_6H_2$.



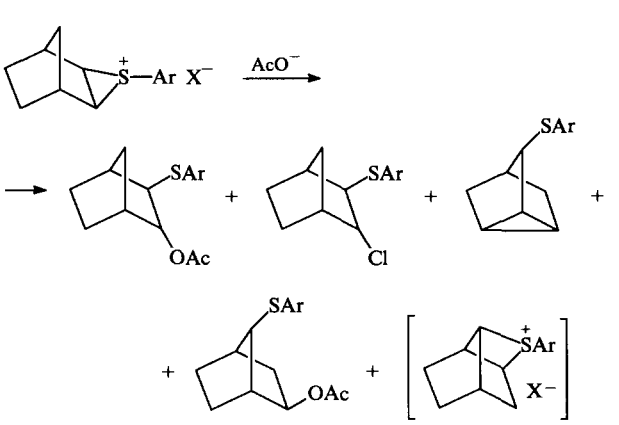
X = $SbCl_6$, SbF_5Cl, Z = OAc.

The reaction of (diaryl)arylthiosulfonium salts with cyclooctene has been studied in greatest detail. In this case, the authors[161] were able to isolate *S*-arylcyclooctenoepisulfonium hexachloroantimonates in a crystalline state in 100% yield.



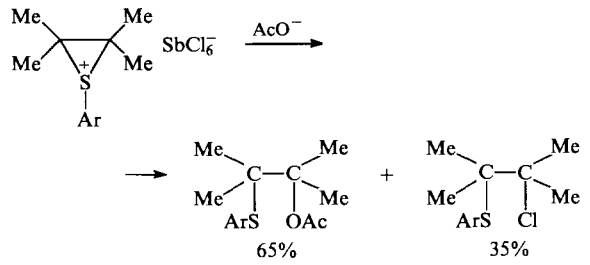
Ar = Ph, 4-ClC_6H_4, 4-MeC_6H_4, 2,4,6-$Me_3C_6H_2$.

The reactions of these salts with the acetate anion lead to the formation of 2-acetoxycyclooctyl aryl sulfides.



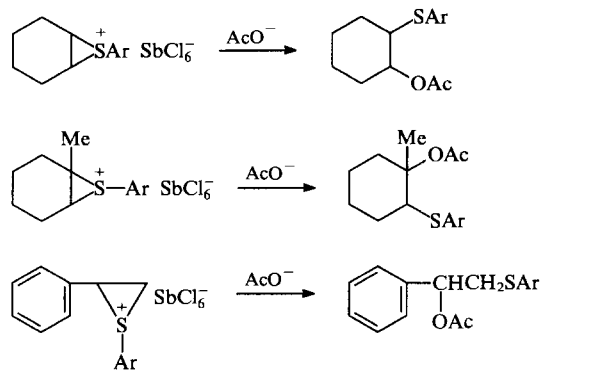
The corresponding *S*-arylnorbornylideneepisulfonium salts have also been isolated in the solid state and characterised.[161]

X = $SbCl_6$; Ar = 4-ClC_6H_4, 4-MeC_6H_4, 2,4,6-$Me_3C_6H_2$.

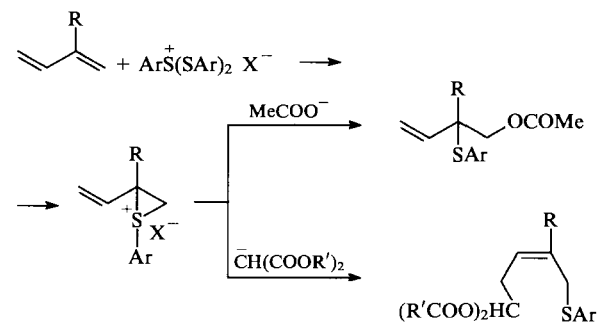


X = SbF_6; Ar = 4-ClC_6H_4, 2,4,6-$Me_3C_6H_2$.

The interaction of these salts with the acetate anion results in the formation of a mixture of several products, which, according to the authors,[161] is due to their instability in solution.

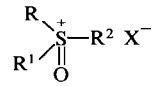


The composition and structure of the final products of this reaction are influenced significantly also by the nature of the initial episulfonium salt. For example, the reaction of the *S*-methylnorbornylideneepisulfonium salt with the acetate anion leads to the formation of only one product—2-acetoxy-3-methylthionorbornane in 95% yield.[161]



In the reaction of the $ArS^+(SAr)_2$ (Ar = 2,4,6-$Me_3C_6H_2$) salt with tetramethylethene, the authors[161] were able to isolate the episulfonium salt in the crystalline state in 89% yield. The interaction of this salt with the acetate anion leads to the formation of a mixture of two products—2-acetoxy-3-mesitylthio-2,3-dimethylbutane and 2-chloro-3-mesitylthio-2,3-dimethylbutane.

The episulfonium salts formed in the reactions of cyclohexene, 1-methylcyclohexene, and styrene with $ArS^+(SAr)_2\ SbCl_6^-$ (Ar = 2,4,6-$Me_3C_6H_2$) are unstable and it was not possible to isolate them in the crystalline state. Their presence was demonstrated by their reactions with the acetate anion, which resulted in the formation of the corresponding β-acetoxysulfides.

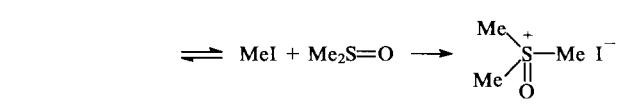


The interaction of (diaryl)arylthiosulfonium salts with butadiene and isoprene[173] afforded the corresponding *S*-aryl-episulfonium salts, which were isolated in a free state. They are hygroscopic crystalline substances stable at temperatures below 0 °C. The reactions of these salts with the acetate anion lead to 1,2-acetoxyarylthio-adducts (yield up to 90%), whilst their interaction with sodiomalonic ester proceeds via a different mechanism and the formation of 1,4-adducts (yield up to 60%).

R = H, Me; R′ = Me, Et; X = BF_4, SbF_6, $SbCl_6$;
Ar = Ph, 4-ClC_6H_4, 4-MeC_6H_4, 2,4,6-$Me_3C_6H_2$, 4-$CF_3C_6H_4$, C_6F_5.

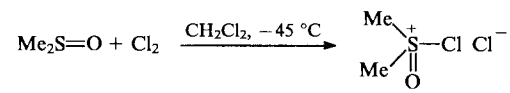
IV. Sulfoxonium (oxosulfonium) reagents

Oxosulfonium salts having the general formula



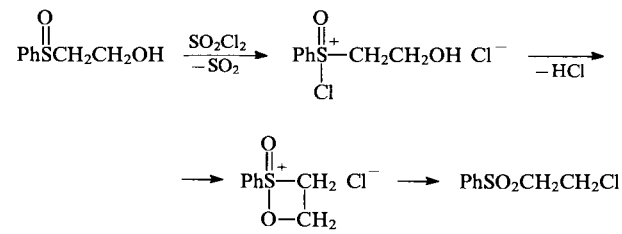
R = Alk, Ar; R^1 = Alk, Ar; R^2 = Alk, Ar, $NAlk_2$;
X = Cl, Br, I, BF_4, etc.;

as well as some of their derivatives are the principal members of the class of oxosulfonium reagents.



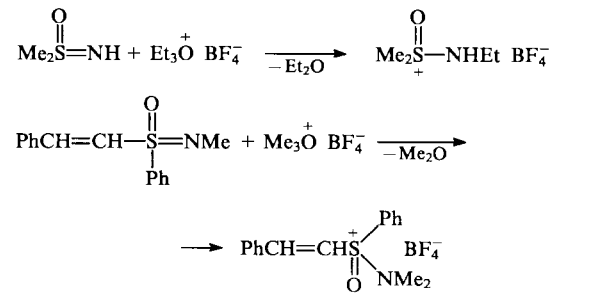
1. Methods for the generation of oxosulfonium salts

a. Generation from sulfoxides



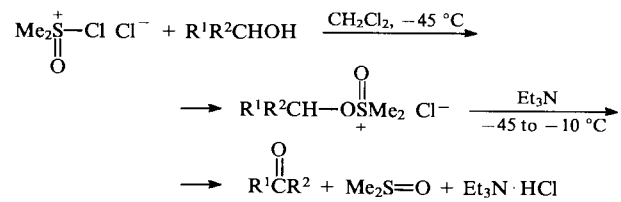
The reaction of dimethyl sulfoxide with methyl iodide results in the formation of dimethylmethoxysulfonium iodide, which is slowly converted into the thermodynamically more stable trimethyloxosulfonium iodide.[2]

Optically active oxosulfonium salts are obtained from optically active sulfoxides by their interaction with the MeI–HgI_2 system.[173] Dimethyl sulfoxide reacts with chlorine in methylene chloride at −45 °C, forming a relatively unstable chlorodimethyloxosulfonium salt.[174]



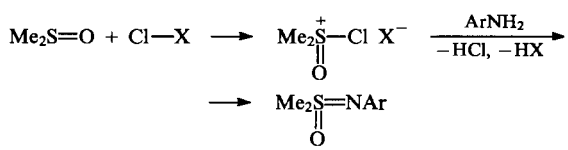
Chlorooxosulfonium salts are also obtained at an intermediate stage in the oxidative chlorination of β-hydroxysulfoxides.[175]

b. Generation from sulfoximides



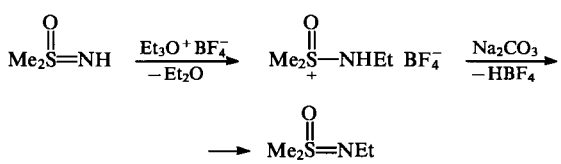
Sulfoximides which are unsubstituted or substituted at the nitrogen atom react relatively easily with trialkyloxonium salts to form oxosulfonium salts.[2]

2. Applications of oxosulfonium salts in organic synthesis



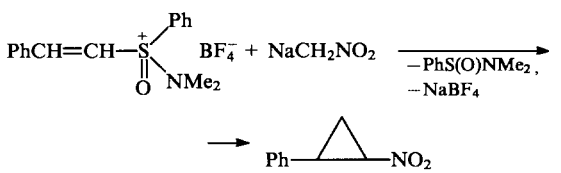
a. Oxidation of alcohols

Chlorodimethyloxosulfonium salts, formed as a result of the chlorination of dimethyl sulfoxide by chlorine, are used to oxidise primary and secondary alcohols to carbonyl compounds.[176]



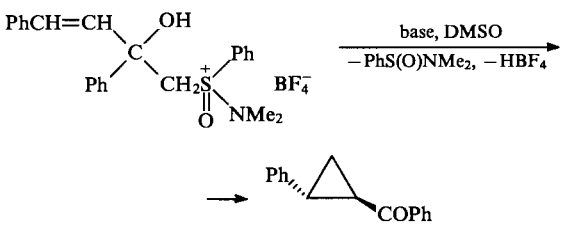
b. Synthesis of sulfoximides

The interaction of chlorooxosulfonium salts with aromatic amine entails the replacement of the chlorine atom at the sulfur atom by the imido-group with formation of sulfoximides.[91]



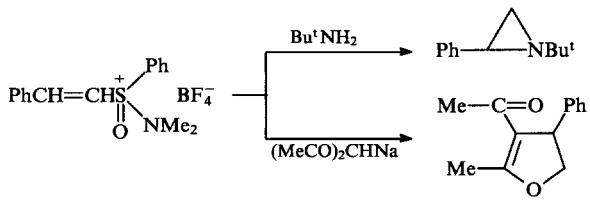
X = Cl, Bu^{t}O.

Sulfoximides are also formed when dialkylaminooxosulfonium salts are treated with bases, which, bearing in mind the ability of unsubstituted sulfoximides to be alkylated by trialkyloxonium salts, may be used to convert unsubstituted sulfoximides into *N*-substituted ones.

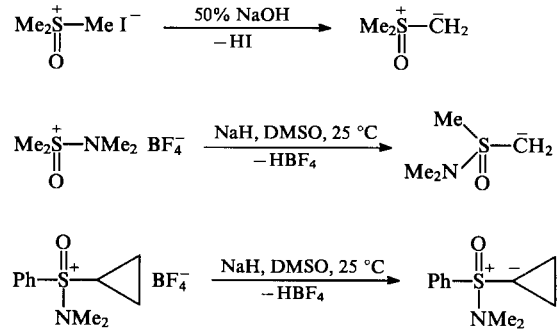


c. Synthesis of cyclopropanes

The interaction of substituted vinyloxosulfonium salts with C-nucleophiles, for example with sodionitromethane, results in the formation of cyclopropanes.[2]

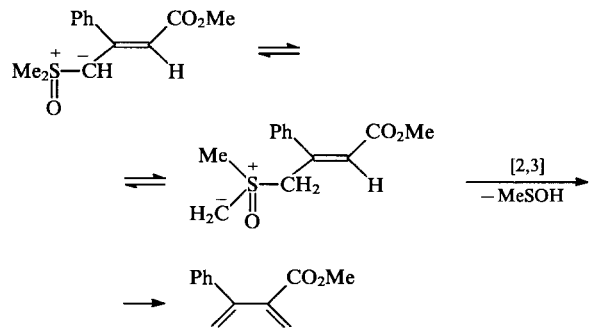


The intramolecular cyclisation of oxosulfonium salts containing an activated double bond also leads to cyclopropanes.[177] It has been suggested that in this case an oxonsulfonium ylide is generated with subsequent transfer of the methylene group to the C=C bond.

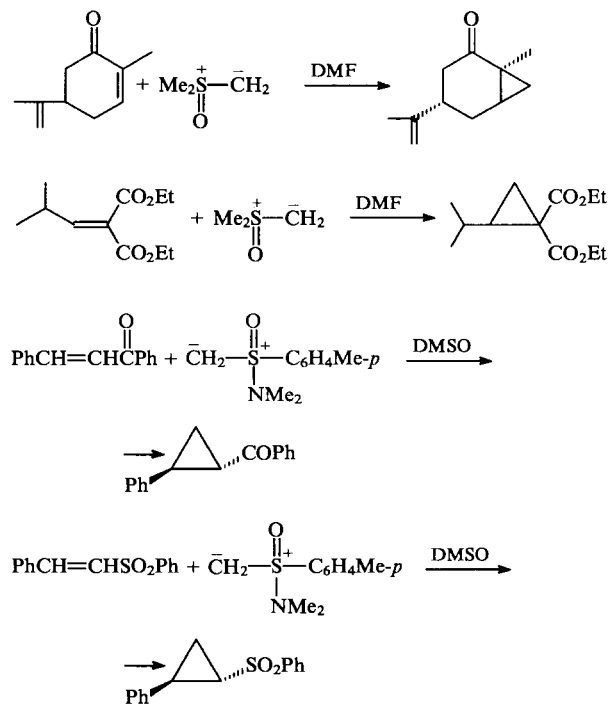


d. Synthesis of heterocyclic compounds

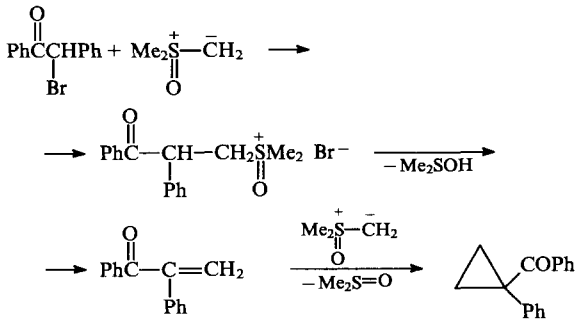
On interaction with primary amines, substituted vinyloxosulfonium salts afford aziridines, whilst their interaction with the sodium salt of acetylacetone leads to dihydrofuran derivatives.[178]



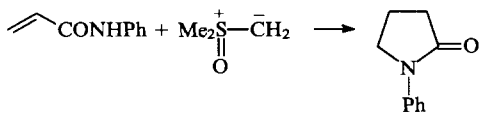
e. Generation of oxosulfonium ylides



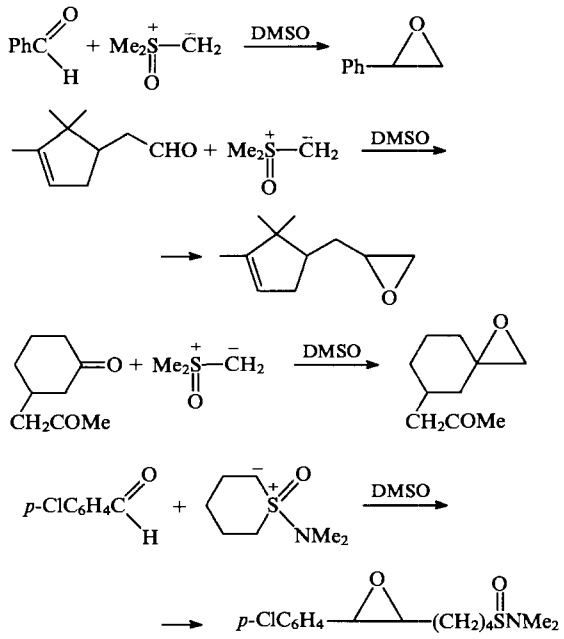
Treatment of dialkyloxosulfonium salts with deprotonating agents leads to the formation of oxosulfonium ylides,[36] which are more stable than dialkylsulfonium ylides.



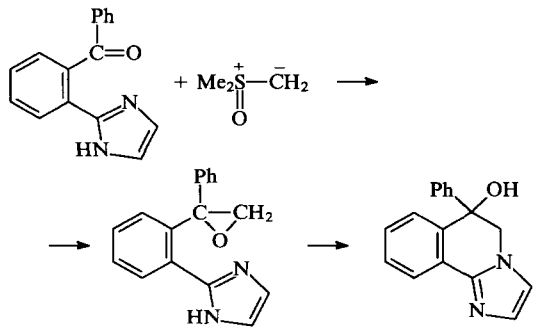
Together with oxosulfonium salts, oxosulfonium ylides have found extensive application in the synthesis of dienes, cycloalkanes, epoxy-compounds, spiro-compounds, and other products of fine organic synthesis. For example, the thermal rearrangement of certain alkenyloxosulfonium ylides is used in the synthesis of dienes.[2]



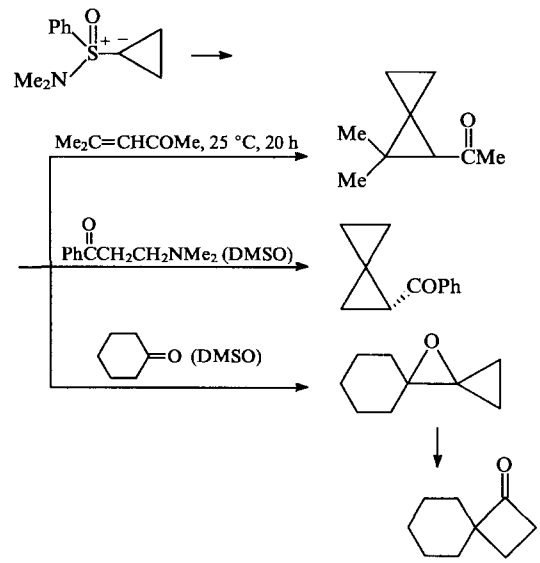
Oxosulfonium ylides are selective agents for the transfer of the methylene group to the electrophilic double bond. As a rule, these reactions lead to the formation of cyclopropanes. In the case of α,β-unsaturated carbonyl compounds, the methylene group adds not to the carbonyl group but to the C=C bond.



In the interaction of oxosulfonium ylides with α-bromoketones or esters, cyclopropanes are formed as a result of a sequence of alkylation, elimination, and methylene group transfer reactions.



The transfer of the methylene group to the double bond in *N*-substituted amides of α,β-unsaturated carboxylic acids is accompanied by a prototropic shift and subsequent cyclisation with formation of γ-lactams.[2]



The addition of the methylene group to the C=O bond in aldehydes and ketones has found extensive application in the synthesis of epoxy-compounds with a wide variety of structures.[36]

In those cases where the epoxide molecule contains other reaction centres as well as the oxygen atom, there is a possibility of structural isomerisation.

The transfer of the cyclopropylidene group to the C=C and C=O bonds with the aid of cyclopropyloxosulfonium ylides is to a large extent analogous to the effect of diphenylsulfonium cyclopropylide (see above) and is used in the synthesis of spiro-compounds.[28]

* * *

It is seen from the present review that the application of S-cationoid reagents in fine organic synthesis has become very common during the last 10–15 years. It is based on the ability of such reagents to participate in the transfer of thiyl, methylene, and other functional groups and also on their involvement in the generation of radical-cations and ylides, in the selective oxidation of alcohols, and in other very important processes. This property is used widely in the syntheses of sulfides, cyclopropanes, epoxides, carbonyl compounds, spiro-compounds, sulfimides, sulfoximides, derivatives of iminosulfinic acids, and other important products of fine organic synthesis with functional group substituents.

Abstract. The structure of the intermediate surface compounds in heterogeneous catalytic oxidation reactions involving molecular oxygen and sulfur is discussed. The degrees of reliability of the role of various proposed structures in catalysis are evaluated. The reaction mechanisms derived from information on the surface complexes are presented. The bibliography includes 141 references.

I. Introduction

In our previous review[1,2] we have discussed the intermediate surface compounds observed during spectroscopic surface studies under the conditions of various heterogeneous catalytic reactions. The present review, which concludes the series, deals with oxidation reactions involving oxygen and sulfur. These reactions differ from those previously considered[1,2] by strongly involving atoms from the catalyst lattice.

The problem of the intermediate form of both the oxygen and the substance to be oxidised, and of the mechanism of their activation, invariably arises in studies of the mechanism of oxidation reactions.

Oxygen can be incorporated in an oxide lattice, or convert a metal into an oxide. In these cases the lattice can be treated as an intermediate form. The ionic forms O_2^-, O^{2-}, and O^- were observed by EPR and Raman spectroscopy during the reduction of the O_2 molecule to the regular lattice of O^{2-}. They were treated as compounds taking part in the catalytic reaction.

II. Oxidation of carbon monoxide

The simplest oxidation reaction is the oxidation of CO. Its mechanism has been studied by many workers both on metals and on nonmetals. In particular, detailed studies have been made of the oxidation of CO on the faces of single crystals of the metals Pt, Pd, Ir, Ru, and Rh.[3]

On Pd(111) this reaction has been studied at low pressures (1.5 Torr) by absorption-reflection IR spectroscopy combined with kinetic measurements.[4] The rate of the reaction depended on the coverage of the surface by carbon monoxide.

The adsorption of CO and O_2 was also studied by low-energy electron diffraction (LEED), electron energy loss spectroscopy (EELS), and X-ray photoelectron spectroscopy (XPES). It is widely thought that at temperatures close to or below that of the catalytic reaction CO is adsorbed as bridging or linear carbonyls. Oxygen is adsorbed in a molecular or an atomic form. The mechanism of their interaction can include the following steps:

$$CO \rightleftharpoons CO_{ads},$$

$$O_2 \longrightarrow 2\,O_{ads},$$

$$O_{ads} + CO_{ads} \longrightarrow CO_2,$$

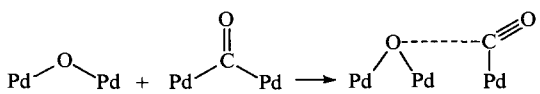
$$O_{ads} + CO \longrightarrow CO_2,$$

$$O_2 + 2\,CO_{ads} \longrightarrow 2\,CO_2.$$

The last of these reactions can be ignored, because the formation of CO_2 is not observed on a surface saturated with CO and exposed to gaseous oxygen. The interaction of CO with O_{ads} can take place with CO either in the gas phase (the Eley–Rideal mechanism) or in the adsorption layer (the Langmuir–Hinshelwood mechanism).

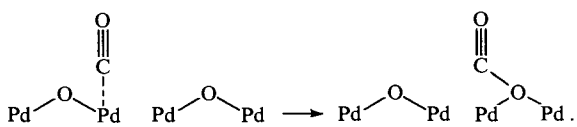
In the various mechanisms for the interaction of CO with C_{ads} it is assumed that the reaction takes place between neighbouring O_{ads} and CO_{ads} species, between more distant species (when the reaction is made possible by surface diffusion), or on the boundary of surface islets consisting of O_{ads} and CO_{ads}.

It is not self-evident that the effects observed at very low pressures can occur also at the higher pressures more commonly used in catalysis. It has been suggested[3] that since the pressure ratio



$$r = k\frac{P_{O_2}}{P_{CO}},$$

occurs in the rate equation for the reaction the rate should be independent of the total pressure, and therefore all the features of the reaction should be the same at low and at high pressures.



The same forms of adsorbed CO and oxygen were observed in a study by IR spectroscopy of the oxidation of CO on Pd at steady state.[5]

Bridging and linear forms of adsorbed CO, located both on terraces and on steps, were observed[6] on a Pt(335) surface by IR absorption–reflection spectroscopy. The carbon monoxide on the steps was oxidised substantially faster than the carbon monoxide on the terraces.

The oxidation of CO on Pd supported on a layer of SiO_2 deposited on a Mo(110) crystal face was studied by absorption–reflection IR spectroscopy and by temperature programmed desorption (TPD) over a wide range of pressure (10^{-9}–10^{15} Torr) and temperature (70–700 °C).[7] At low pressures the CO and the oxygen were adsorbed separately, probably as islets. In order to induce the reaction a CO molecule must diffuse into an islet of O_{ads}, surmounting the opposing barrier as a result of the exothermic reaction

At high pressures and relatively low temperatures a shift in the CO frequencies was observed in the stationary state, and attributed[7] to the simultaneous adsorption of CO and O on the same atom of Pd (O–Pd–CO), or to the formation of the weakly adsorbed precursor

The transition state is reminiscent of the CO_2 molecule. We know[8] that the vibrational excitation of the CO_2 molecule is strongest when the molecule is formed in a layer strongly covered with oxygen before being desorbed. Under certain conditions this can give rise to a 'pressure gap': a large difference between the effects observed at high and at low pressures.

A study of the EELS spectra during the oxidation of CO on Rh(111) showed[9] that the Rh–O–CO_2 complex, stabilised by OH groups, is formed on oxidised rhodium (i.e. in an excess of O_2). Carbon dioxide adsorbed on a clean Rh–O surface is desorbed at a temperature 100 K lower than from a Rh–OH surface.[9] It was concluded that the decomposition of the carbonate species could be rate-limiting.

Many studies of the oxidation mechanism of CO were carried out on supported metals,[10–21] because in these systems the specific surface of the catalyst is much greater and the intensity of the IR bands is correspondingly high.

According to Cant and Donaldson[10] the CO absorption band at 2075 cm^{-1} is unchanged during the interaction of CO with O_2 on Pt/SiO_2 at 40–50 °C. The kinetic order of the reaction (first order) with respect to the coverage of the surface with CO molecules (θ_{CO}) is attributed[10] to the location of the reaction at the boundary between CO_{ads} and O_{ads} islets.

A study of the IR spectra in the transition regime during the oxidation of CO on a 9.1% Pt/SiO_2 catalyst at 100–160 °C detected[11] a transition from the Eley–Rideal to the Langmuir–Hinshelwood mechanism as the adsorption of CO increased. However, unambiguous spectroscopic studies (i.e. studies of the kinetics of the intensity changes of the IR bands of the adsorbed species) were not attempted.

A study in which the rate of the reaction on Pt/SiO_2 was compared with the kinetics of the change in the Fourier transform IR (FTIR) spectra has been reported.[12] At 300 °C, when the rate of the reaction was high, the coverage θ_{CO} was less than 1% (i.e. below the sensitivity limit of the apparatus). Linearly bound CO was observed under conditions of low catalyst activity.

Simultaneous measurements of the band intensities in the FTIR spectra with one-second resolution and of the rate of the reaction in the transition regime were carried out[13] on Pt/Al_2O_3 at 140 °C. Self-oscillations were observed, with four linear forms of adsorbed CO and one bridging form. The linear CO–Pt form (2073 cm^{-1}) responds most rapidly to a change in composition of the gas phase. The yield of CO_2 is most accurately correlated with the intensity of the absorption band of the linear form (2092 cm^{-1}), which corresponds to the adsorption of CO on a Pt atom adjacent to a Pt–O bond. The following mechanism has been proposed for the oxidation mechanism of CO on Pt:

$$O_2 + 2\,Pt_n \overset{(1)}{\rightleftharpoons} 2\,Pt_nO,$$

$$O_2 + 2\,Pt \xrightarrow{(2)} 2\,PtO,$$

$$CO + Pt_nO^* \xrightarrow{(3)} CO^*Pt_nO^*,$$

$$CO^*Pt_nO^* \xrightarrow{(4)} Pt_n + CO_2,$$

$$CO + Pt \overset{(5)}{\rightleftharpoons} PtCO^*,$$

$$CO + 2\,Pt \overset{(6)}{\rightleftharpoons} Pt_2CO^*,$$

$$CO + PtO \overset{(7)}{\rightleftharpoons} PtOCO^*,$$

$$PtOCO^* \xrightarrow{(8)} Pt + CO_2,$$

$$PtCO^* + Pt_nO \xrightarrow{(9)} CO^*Pt_{n+1}O^*,$$

$$CO^*Pt_{n+1}O^* \xrightarrow{(10)} Pt_{n+1} + CO_2,$$

$n > 2$, surface compounds are shown by an asterisk.

Reactive oxygen is formed with the participation of at least two Pt atoms. The monoxide is easily formed, but when adsorbed on PtO it is inactive in this reaction. The reaction between O* and CO* can take place if the O* diffuses to a CO* centre or if gaseous CO interacts with PtO*. The reaction is possible also at the boundaries of the CO islets, where the linearly adsorbed CO can react, though this species has no activity when located within the islet.[14]

Also the oxidation of CO on Pt/SiO_2 and Pd/SiO_2 at 80–320 °C has been studied by FTIR spectroscopy with one-second resolution, and the kinetics of the reaction were studied with a quadrupole mass spectrometer.[15] It was found that the dissociation of O_2 is probably the rate-limiting step, and the adsorption of CO is a fast process. All three forms of CO react with O_2 at the same rate. The model proposed for the reaction assumes the presence of CO islets with very reactive boundaries.

In a study of the reaction of CO with O_2 on Ru/SiO_2, Rh/SiO_2, and Pd/SiO_2 it was found that the linear and the bridging forms of CO react faster than the dicarbonyl forms.[16] On Pt supported on graphite the bridging forms of CO have a greater reactivity than the linear forms (Pt–C≡O).[17] Conversely, it was reported[20] that on Pd–Rh/SiO_2 the linear forms of CO are more active than the bridging forms. According to Anderson[18] on Pt–Rh/Al_2O_3 only the linear forms adsorbed on the Pt can contribute to the reaction. The $Rh(CO)_2$ forms are not active in this reaction.

Six forms of surface carbonyl were detected on Rh supported on SiO_2, Al_2O_3, or La_2O_3: Rh–CO, Rh_2–CO, Rh^+–CO, $ORh^+(CO)_2$, ORh^+CO, and $Rh^+(CO)_2$.[19] The following reaction mechanism was proposed:

$$Rh^0 + CO \xrightarrow{(1)} Rh^0CO,$$

$$Rh^0 + \tfrac{1}{2}O_2 \xrightarrow{(2)} Rh^+O_l \rightleftharpoons Rh^+O_s \rightleftharpoons Rh^0O_s,$$

$$Rh^+O_s + Rh^0CO \xrightarrow{(3)} CO_2,$$

$$Rh^+O_s + CO \xrightarrow{(4)} O_sRh^+CO \xrightleftharpoons{CO} O_sRh^+(CO)_2,$$

$$Rh^+ + O_2 \xrightarrow{(5)} Rh^{n+}O_s \xrightarrow{CO} Rh^+ + CO_2,$$

$$O_sRh^+(CO)_2 \xrightarrow{(6)} Rh^0CO + CO_2,$$

$$O_sRh^+CO \xrightarrow{(6a)} Rh^0 + CO_2.$$

Here O_s is oxygen on the surface, and O_l is oxygen in the lattice.

The breakdown of the complexes with formation of CO_2 takes place at high temperatures. When transition metal oxides are added to the supported metals the lattice oxygen also contributes to the oxidation of CO. On $Pd-CeO_x/Al_2O_3$ the kinetics of the oxidation of CO have been studied by EPR.[21,22] It was found that the low-temperature (100–150 °C) reaction takes place only on catalysts which contain the reactive $O_2^- - Ce^{4+}$ ion. The kinetics of the change in concentration of the O_2^- ion at 100 °C correspond to the kinetics of the oxidation of the CO. In the high-temperature region (> 200 °C) the O_2^- form is not observed. As reported,[21] in this case the lattice oxygen $O^{\delta-}$ takes part in the reaction.

In a study by FTIR spectroscopy of the oxidation of CO on Au supported on Co_3O_4, α-Fe_2O_3, or TiO_2 carboxylate and CO_3^{2-} groups were seen on the catalyst surface, and the last names disappeared during the reaction.[23] Nevertheless a mechanism which ascribed the formation of CO_2 to the decomposition of carboxylates was proposed.

The oxidation of CO at 20 °C on Ag/Y_2O_3 and Cu/Y_2O_3 has been studied by EPR.[24] At low concentrations of Cu and Ag the reaction followed the mechanism

$$e \longrightarrow \square_O^- \xrightarrow{2\,CO} (CO)_2^- \xrightarrow[-CO_2]{O_2} O_2^- \xrightarrow[-CO_2]{2\,CO} CO_2^- \longrightarrow CO_2 + \square_O + e,$$

$$CO + 2\,O_2^- \longrightarrow CO_3^{2-} + \square_O,$$

$$e + Ag^{2+}(Cu^{2+}) \longrightarrow Ag^+(Cu^+).$$

$\square_O$ is an oxygen vacancy.

At high concentrations of Ag or Cu the reaction follows a different path:

$$Ag^+(Cu^+) + CO + 2\,O^- \longrightarrow Ag^{2+}(Cu^{2+}) + CO_3^- + 2e + \square_O,$$

$$CO_3^- \longrightarrow O^- + CO_2,$$

$$e + Ag^{2+}(Cu^{2+}) \longrightarrow Ag^+(Cu^+),$$

$$Ag^+(Cu^+) + CO \longrightarrow Ag^+(Cu^+)–CO,$$

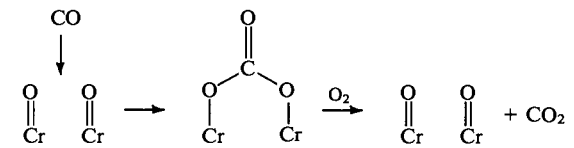
$$\tfrac{1}{2}O_2 + 2e + \square_O \longrightarrow O^{2-}.$$

The participation of conduction electrons and of lattice oxygen is stipulated also for the oxidation of CO on oxides. The oxidation of CO on ZnO after exposure to light was studied[25] by EPR between −50 and +80 °C, and the following reactions were observed:

$$Zn–O^- + CO \longrightarrow Zn–CO_2^-,$$

$$Zn–CO_2^- \longrightarrow Zn–CO_2 + e,$$

$$Zn–CO_2^- + O_2 \longrightarrow Zn–CO_2 + O_2^-,$$



$$Zn–\square–Zn + 2e \longrightarrow Zn–O–Zn + Zn_i^0,$$

$$Zn–\square–Zn + \tfrac{1}{2}O_2 \longrightarrow Zn–O–Zn,$$

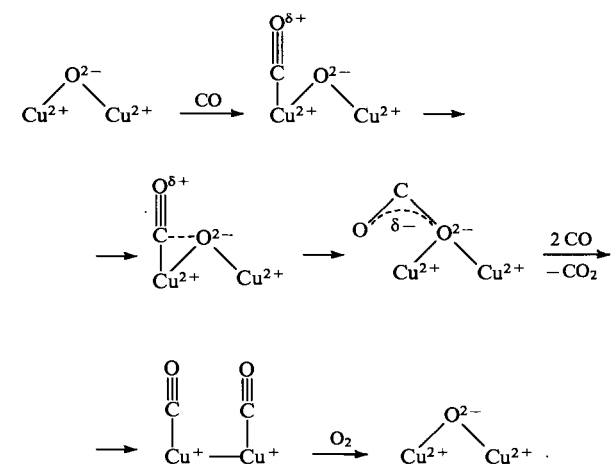
Zn_i^0 is an interstitial zinc atom.

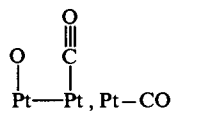
According to data on the potentiometric monitoring of the state of an MnO_x surface[26] a metastable state of the oxide is produced under the condition of CO oxidation at 138–310 °C. The oxygen does not fill the anion vacancies on the surface but takes part in the catalytic reaction.

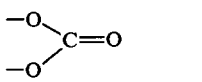
The mechanism of the oxidation of CO on Cr_2O_3,[27,28] ZnO,[29] and CuO,[30,31] was studied by IR spectroscopy (but not in situ). On Cr_2O_3 surface carbonates of type **1** are formed after the admission of a CO + O_2 mixture at low temperatures. At 150 °C their rate of decomposition with formation of CO_2 is quite high. In a flow of CO + O_2 the rate of decomposition of the carbonates is two orders of magnitude higher in the absence of O_2. In both cases the rate of decomposition of the carbonates is close to the rate of formation of CO_2. The following associative mechanism has been proposed[27,28] for the reaction:

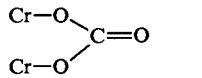
1

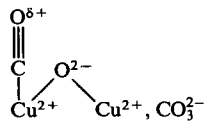
Above 300 °C almost no carbonate groups are formed on the Cr_2O_3 surface. At this temperature the increase in the reactivity of the lattice oxygen produces a transition from an associative to a dissociative mechanism. The oxidation of CO can also take place without the participation of molecular oxygen from the gas phase. The acceleration of the decomposition of carbonates in the presence of O_2 has been observed also on ZnO.[29] According to EPR data the O_2^- ion radical contributes to this decomposition (oxidation). On the surface of CuO both carbonyl and carbonate compounds can exist.[30,31] The Cu^{2+}–CO carbonyl complexes are formed only at subzero temperatures. They are then oxidised according to the scheme:











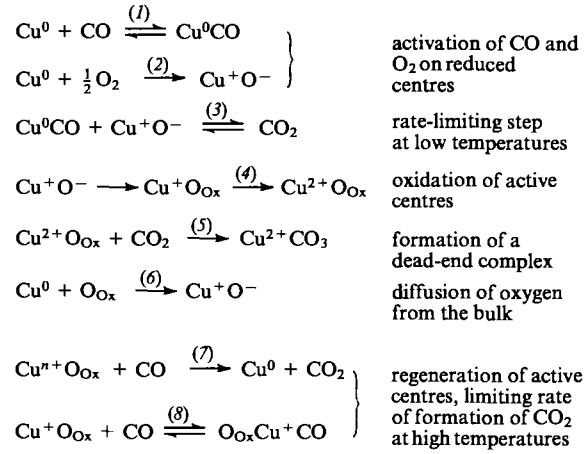


Table 1. Intermediate compounds in the oxidation of CO.

Catalyst	Intermediate complex	Reliability[a]	Ref.
Pt, Pd, Rh, Ir	M–CO, M_2CO, M–O	M	5,6
Pd/SiO_2-MoO_3	Pd–O–Pd–CO, Pd_2CO, 	H	7

[a] Here and elsewhere the symbol H denotes a high level of reliability, M a medium level, and L a low level.

In the presence of O_2 the surface carbonates are decomposed, possibly by a displacement mechanism (associative substitution). The overall rate of formation of CO_2 by the dissociation of all the carbonates is close to the observed rate of oxidation of CO on CuO. In spite of statements to the contrary,[30] a study by FTIR spectroscopy failed to detect surface carbonates under the conditions of the oxidation of CO on CuO.[32] It was suggested that the surface carbonates are formed by the readsorption of CO_2, i.e. they are dead-end forms. The following reaction mechanism was proposed:

A similar conclusion (that the carbonates are dead-end compounds) was reached in a study[33] of the oxidation of CO on a $CoO-Co_3O_4$ catalyst.

The intermediate compounds observed in the oxidation of CO are listed in Table 1. Thus, it has been shown fairly reliably that surface carbonyls and atomic oxygen take part in the oxidation of CO on both metals and oxides. Apparently the carbonates are dead-end compounds. At low temperatures we can observe the formation of associative complexes, in which O_{ads} and CO_{ads} are bound to the same or to neighbouring metal atoms on the surface.

III. Oxidation of ammonia

The oxidation of ammonia to NO and H_2O takes place on the platinum metals at high temperatures (800–1000 °C), when the reaction follows mainly a heterogeneous–homogeneous mechanism. Spectroscopic studies were carried out at lower temperatures. Under these conditions the reaction products include nitrogen and the nitrogen oxides N_2O and NO. On massive platinum the oxidation of ammonia was studied by emission IR spectroscopy,[34] which detected the formation of NH_2 species. The complex $Ag(NH_3)_x(NO)_y$ was observed on a silver surface, and NO_{ads} on an iron surface. On catalysts having a high activation energy for NH_3 a complex corresponding to the initial stages of the reaction is formed (in the case of Pt, the NH_2 entity). On the other hand if the catalyst has a low activation energy the species adsorbed on its surface participate in the later stages, closer to the stages which take the reaction to completion (in the case of Fe this is the adsorbed NO molecule). The formation of HNO, which apparently dissociates into OH and N_{ads}, has been observed[35] by EELS and thermal desorption methods during the oxidation of ammonia on Pt(111).

After carrying out the $NH_3 + O_2$ reaction on an MgO–CoO catalyst spectral bands corresponding to the NO_2^- and NO_3^- groups were observed[36] in the IR spectra measured at room temperature. The following mechanism for the formation of these groups was proposed:

$$Co^{2+}O^{2-} + NH_3 \longrightarrow NH_2^- Co^{2+}OH^-,$$

$$Co^{2+} + O_2 \rightleftharpoons Co^{3+}O_2^- \text{ (from EPR data)},$$

$$2\,NH_2^- + 3\,Co^{3+}O_2^- + 2\,O^{2-} \longrightarrow$$

$$\longrightarrow 2\,NO_2^- + 4\,OH^- + 3\,Co^{2+},$$

$$NH_2^- + 2\,Co^{3+}O_2^- + O^{2-} \longrightarrow$$

$$\longrightarrow NO_3^- + 2\,OH^- + 2\,Co^{2+}.$$

The following reactions are also possible:

$$2\,NH_3 + 3\,Co^{3+}O_2^- + 4\,O^{2-} \longrightarrow \longrightarrow 2\,NO_2^- + 6\,OH^- + 3\,Co^{2+},$$

$$2\,NH_3 + 4\,Co^{3+}O_2^- + 4\,O^{2-} \longrightarrow \longrightarrow 2\,NO_3^- + 6\,OH^- + 4\,Co^{2+}.$$

The formation of NO^- also cannot be excluded, but the NO^- bands in the IR spectrum are obscured by those of NO_2^- and NO_3^-.

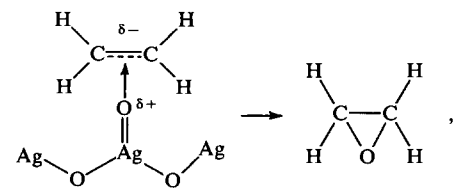
An IR spectroscopic study[37] of the interaction of NH_3 with O_2 on MgO detected the NH_2^- complex on the surface. The $Si-NH_2$ and $Fe-NH_2$ complexes formed during the oxidation of ammonia on Fe_2O_3/SiO_2 have been described.[38] In the oxidation of NH_3 under the influence of NO on NaY zeolite Naito and Tamaru[39] observed the double complex $Ag(NH_3)_x(NO)_y$, which decomposes into N_2 and H_2O. It was shown[40-42] that the surface ammonium ion is an intermediate in the oxidation of ammonia by nitrogen oxides on V_2O_5 catalysts. We note that the information on the surface compounds given in the latter reports was obtained under conditions far removed from those of a practical catalytic reaction. Therefore it is doubtful whether or not the specified complexes have any relevance to actual reactions. The only exception is a group of papers[43-45] in which the role of the surface complexes is determined on the basis of simultaneous measurements of the reaction rate and of the rate of conversion of the surface compounds.

Table 2. Intermediate compounds in the oxidation of ammonia.

Catalyst	Intermediate complex	Reliability	Ref.
Pt	NH_2	M	34
Ag	$Ag(NH_3)_x(NO)_y$	M	34
Fe	NO_{ads}	M	34
Pt(111)	HNO	L	35
CoO–MgO	NO_2^-, NO_3^-	L	36
MoO_3	NH_4^+	H	43
ZnO	N_2O(ads)	H	44
Fe_2O_3	OH, NH_3(ads), NH_4^+, NH_2	M	45
Fe_2O_3/SiO_2	$FeNH_2$	L	38
V_2O_5	NH_4^+	L	40–42

Exposing MoO_3 to an $NH_3 + O_2$ mixture at 25–400 °C produces NH_4^+ ions on the surface.[43] A study of this catalytic reaction by the response method provide a quantitative proof that the ammonia is an intermediate compound. In the case of ZnO (see Ref. 44) N_2O(ads) is formed on the surface, and on α-Fe_2O_3 the OH group is formed (see Ref. 45) with coordinately bound ammonia, NH_4^+, and the NH_2 group. The following self-consistent chain of conversions of these complexes can be suggested:

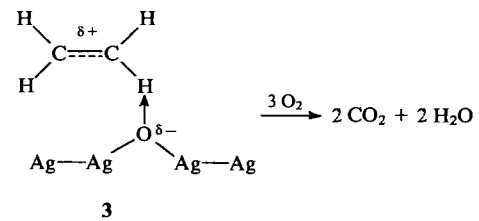
$$NH_3 \longrightarrow NH_4^+ \longrightarrow NH_2\,(ads) \longrightarrow \longrightarrow N_2O(ads) \longrightarrow N_2 + NO.$$



As in the case of metals the activation energy for the overall reaction (oxidation of NH_3) is lower for the catalysts on which intermediates formed in stages close to the final stage of the reaction are adsorbed.[43] Data on the intermediate compounds taking part in the oxidation of NH_3 are summarised in Table 2.

IV. Partial oxidation of olefins

The oxidation of hydrocarbons takes place by two main paths: to compounds containing oxygen (partial oxidation) and to CO_2 and H_2O (extensive oxidation). We shall first examine a partial oxidation reaction in which the main skeleton of the molecule is not broken down, and one or two oxygen atoms are added to the molecule with formation of compounds containing oxygen.

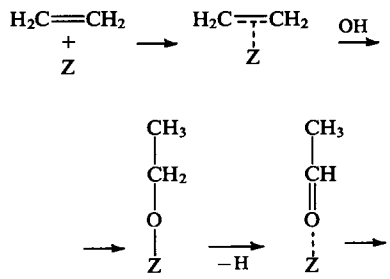


The simplest olefin (ethylene) gives ethylene oxide (C_2H_4O) after partial oxidation. Both weakly and strongly bound acetaldehyde, and also silver acetate, have been detected[46] on an Ag/α-Al_2O_3 catalyst by diffuse reflectance FTIR spectroscopy combined with kinetic measurements in the transitional regime under conditions conducive to the oxidation of C_2H_4 to C_2H_4O. An analogous study on an Ag/γ-Al_2O_3 catalyst revealed adsorbed ethylene,[47] carbonates, and Ag–CO, which are probable precursors of the extensive oxidation products.[48]

New possibilities in the study of intermediate compounds were offered by the development of the TAP (temporal analysis of products) reactor, in which the product directly desorbed from the surface can be analysed by using special attachments, thus avoiding the problem of readsorption. This development also allowed the use of millisecond (and even microsecond) measurement times, well beyond the limits of the characteristic catalysis times (10^{-2}–10^2 s) (see Gleaves et al.[49]). The application of the TAP reactor to the study of the oxidation mechanism of ethylene on powdered Ag showed[50] that the deep and the partial oxidation reactions of ethylene involve the same surface complexes of ethylene but different forms of oxygen. Carbon monoxide is formed more rapidly than ethylene oxide, mainly because of the interaction with the more weakly bound surface oxygen. Ethylene oxide is formed from both the atomic oxygen on the surface and the subsurface oxygen, which keeps the silver in an intermediate charge state Ag^{n+} (probably Ag^{3+}). Svoboda et al.[50] confirmed a scheme[51] according to which 'electrophilic' oxygen $O^{\delta+}$ forms the complex **2**, which is a precursor of ethylene oxide,

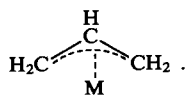
2

whereas 'nucleophilic' oxygen $O^{\delta-}$ gives the complex **3**, which is an intermediate in the deep oxidation reaction:



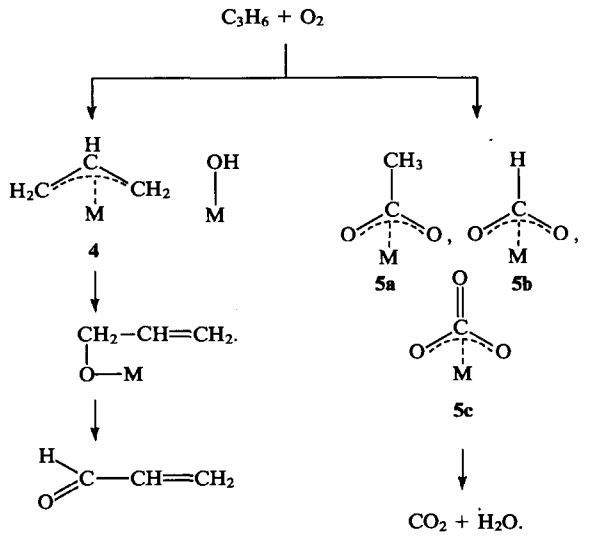
3

This mechanism is further confirmed by an analysis of the Raman spectra obtained in situ during the oxidation of ethylene on Ag(111) and Ag(110). Under the catalysis conditions three Ag–O vibration bands were observed, corresponding to $Ag-O_{ads}$, the –Ag–O–Ag– subsurface group, and dissolved oxygen. The subsurface oxygen disappears as ethylene oxide is formed.



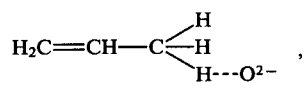
In the oxidation of ethylene to acetaldehyde on MoO_3/TiO_2 the complex π-$C_2H_4^+$ and adsorbed acetaldehyde have been observed, as well as a weak enolic complex.[52] It is assumed that

the reaction takes place with the participation of an OH surface group by a hydration–dehydrogenation mechanism:



Under the conditions of the oxidation of C_3H_6 on Ag/SiO_2 a bidentate carbonate and polymeric surface formations were observed on the surface. An analysis of the in situ FTIR spectra also revealed the presence of adsorbed acrolein.[53]

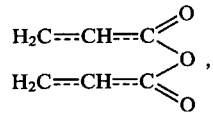
The oxidation of propylene to acrolein on oxide catalysts takes place through the intermediate formation of a π-allyl complex. Many isotopic studies have established the indistinguishability of the C(1) and C(3) carbon atoms in the propylene molecule, and of the hydrogen atoms attached to them.[54] This is evidence for the symmetry of the complex:



4

The precursor of the π-allyl complex is a π-olefin complex. The adsorption centres for the olefin in the form of π-complexes on the oxides can be not only the metal ions but also surface acidic centres of the Brønsted type.[55] π-Allyl complexes **4** were detected spectroscopically on $Bi_2O_3-MoO_3$,[55] Cu_2O, and Ga molybdates.[56] On the other hand the carbonate–carboxylate complexes **5a–5c** are most often observed on the deep oxidation catalysts. This suggested the following general scheme for the oxidative transformations of C_3H_6:

On ZnO acrolein is not formed, and diallyl is obtained ($CH_2=CH-CH_2-CH_2-CH=CH_2$).[57] According to IR spectral studies in this case the π-allyl is converted into σ-allyl $[CH_2=CH-CH_2]^-$, which is probably anionic. Subsequent transformations give the dimer C_6H_{10}. On Bi–Mo oxide propene oxidation catalysts the π-allyl complex was observed under the conditions of the reaction.[58] The kinetics of the processes leading to its formation and decomposition were measured by in situ IR spectroscopy. Increasing the activity of the catalyst (by increasing its molybdenum content) lowers the activation energy for the consumption of π-allyl. We note that the number of cases in which the presence of π-allyl complexes on the surface has been truly established is small, and that the catalysts on which the observations were made were not good catalysts for the oxidation of propene to acrolein. Evidently the formation of the π-allyl complex (the initial rupture of a C–H bond) is the rate-limiting step of the reaction, after which the complex rapidly undergoes further transformations. Satisfactory spectroscopic studies of this process have not yet been reported. In the oxidation of C_3H_6 to acrolein on $USb_{4.6}O_{13.2}$ bands due to adsorbed acrolein were observed[59] in the IR spectra. It was concluded from isotopic data that the π-allyl complex takes part in the reaction.

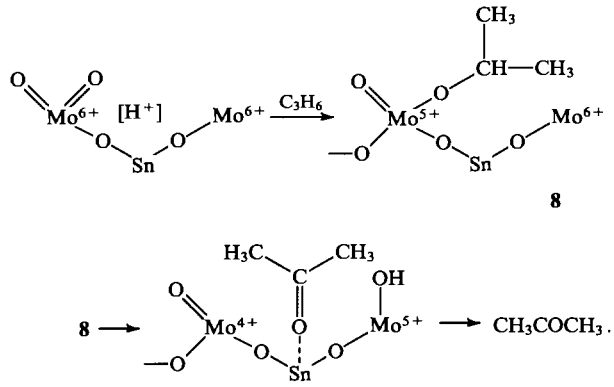


Weakly bound adsorbed forms of propene observed on Ti–Sb–O[60] and Fe–Sb–O catalysts,[61]

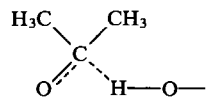
6

could be the precursors of acrolein. The process does not necessarily require activation of the double bond.[60,61] The acrolein can be formed immediately after the breaking of the C–H bond coordinated to O^{2-} in the complex **6** (see also Ref. 62). The participation of weakly bound forms of adsorbed propene in the oxidation to acrolein on $Bi_2O_3-MoO_3$ was detected during experiments with the TAP reactor.[63] Two forms of adsorbed oxygen were also observed: one contributes to the partial oxidation, the other does not contribute directly but exchanges readily with the oxygen from the gas phase.

A study by FTIR spectroscopy of the partial oxidation of propene and isobutene to acrolein on the industrial Co(Mg)–Mo–Bi–Fe oxide catalyst showed that under the conditions of the reaction 1% of the surface is occupied by the compound **7** of the acrylic anhydride type:

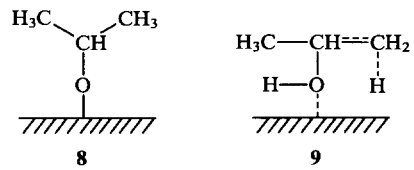


7

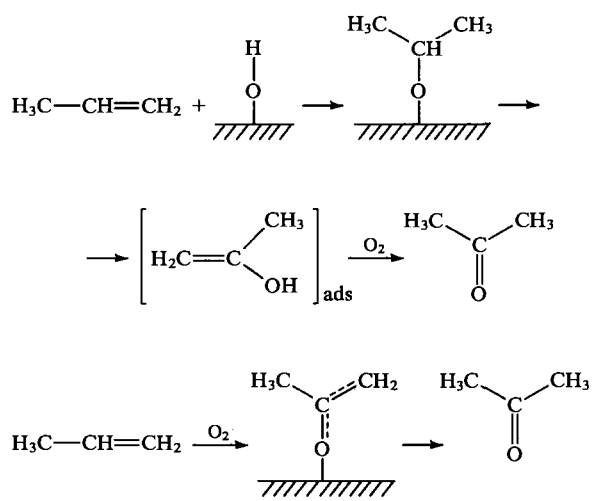


which is converted into an unsaturated aldehyde by reacting with a proton-donor reagent (i.e. with another olefin molecule, for example C_3H_6 or iso-C_4H_8).[64,65] This allows the associative substitution mechanism to take place.

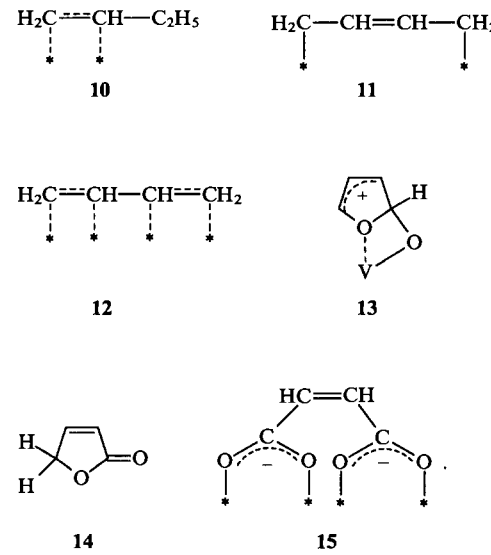
The first stages of the oxidative ammonolysis of propylene with formation of acrylonitrile ($CH_2=CHCN$) are apparently similar to the first stages of the oxidation of propene to acrolein (through π-olefin and π-allyl complexes).[66] However, it was found that the rate of oxidative ammonolysis is always higher than the rate of oxidation of olefins to unsaturated aldehydes. Obviously, the ammonia gives intermediate forms which intercept (for example) the hydrogen from olefins. Bands due to NH_4^+ and to coordinatively bound ammonia have been observed in the IR spectra obtained after the oxidative ammonolysis of propene on a Co–Mo–Bi–Fe oxide catalyst.[67]



On oxide catalysts containing V and Mo propene can undergo partial oxidation to acetone but not to acrolein. A spectral study[68–71] of this reaction detected the surface isopropylates **8**. As reported,[68] the oxidative transformations of olefins on Sn–Mo–O catalysts take place by the scheme



Here the rate-limiting step is the dehydrogenation of the surface isopropylates **8**, and the intermediate complex is



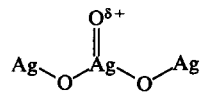
However, the reliability of these results is doubtful because the IR spectra were not measured under the conditions of the catalysis. An in situ study by IR spectroscopy on the Sn–Mo–O and Sn–V–O catalysts revealed the presence of two surface complexes:[71]

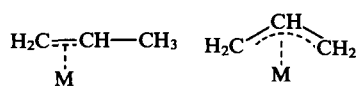
The intensity of the bands of the complex **8** on Sn–V–O increases with temperature up to 120 °C, and then decreases (while the yield of acetone increases). It was concluded that the complex **8** is an intermediate. On Sn–Mo–O the enol complex **9** contributes to the formation of some of the acetone. The following mechanism was proposed for the reaction:

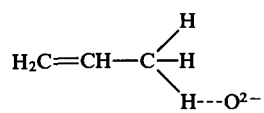
In the oxidation of but-1-ene on $V_2O_5-P_2O_5/Al_2O_3$ at 100–150 °C (i.e. below the stationary reaction temperature) adsorbed 1-C_4H_8 (two π-complexes), 1,3-C_4H_6, furan, maleic anhydride, and 2,5-H-furanone were detected by IR spectroscopy.[72] Butadiene forms complexes of two types: the π-complexes **10** and **12** (interaction at the C=C bond) and the σ-complex **11** (1,4-addition). Furan is adsorbed at the C(2) atom (complex **13**), and 2,5-H-furanone forms the complex **14**. Maleic anhydride is chemisorbed as the stable complex **15**, but physisorbed maleic anhydride is also formed

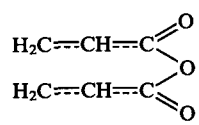
The asterisks denote surface atoms.

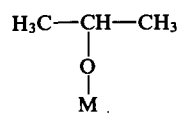
Among the complexes which have been observed only 2,5-H-furanone (**14**) is active under the catalysis conditions.[72] Bands from π-allyl and adsorbed butadiene were observed[73] in the IR spectra during the oxidative dehydrogenation of butenes on the ferrites $MgFe_2O_4$, $CoFe_2O_4$, and $CuFe_2O_4$. The breaking of the C–H bond and the formation of the π-allyl are probably the rate-limiting step. The formates, carboxylates, and carbonates formed during the adsorption are intermediates in the deep oxidation reaction.

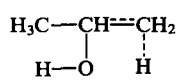


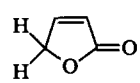


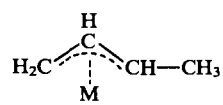








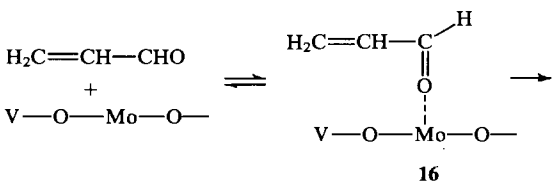




The oxidation of C_3H_6 and 1-C_4H_8 on γ-Bi_2MoO_6 was studied in the TAP reactor.[74] The reaction takes place by an oxidation–reduction mechanism. In spite of widely held views to the contrary there is no fast exchange of oxygen between the catalyst and $^{18}O_2$ from the gas phase. Therefore there can be no fast reversible chemisorption of O_2 with formation of O, O^-, or O_2^-. It is pointed out[74] that two types of centre are present on the surface: M and M′ (different oxygen vacancies). The M centres can be reoxidised by oxygen, and they can then reoxidise the M′ centres. The M′ centres are created by reduction and they cannot be directly reoxidised by oxygen. In the oxidation of C_3H_6 and iso-C_4H_8 no difference is found between the types of centre. Evidently these results can be explained in terms of our two- or three-phase catalyst model,[75] according to which the activation of olefins takes place on some centres, the activation of oxygen on others, and the diffusion of oxygen involves a third phase.

The intermediate oxygen forms produced in the oxidation of C_3H_6 on V_2O_5/SiO_2 were studied by EPR.[76] The products of the interaction of C_3H_6 with O_2^- and those of the oxidation of C_3H_6 in the stationary regime are identical, but the concentration of O_2^- under the reaction conditions is two orders of magnitude lower than the level required to achieve a stationary rate.

Table 3 summarises the data on the intermediate compounds which take part in the partial oxidation of olefins.



In conclusion we note that many published papers have dealt with the mechanism of the partial oxidation of olefins, and many surface forms have been observed, but so far there have been very few reports containing all the necessary spectral and kinetic data, and the existence of most of the suggested intermediates is hypothetical.

Table 3. Intermediate compounds in the partial oxidation of olefins.

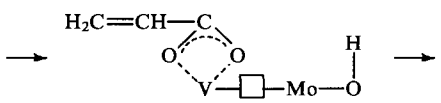
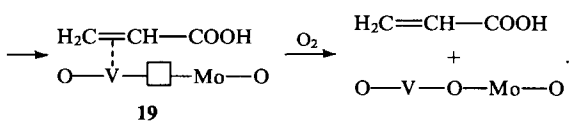
V. Oxidation of aldehydes to unsaturated acids



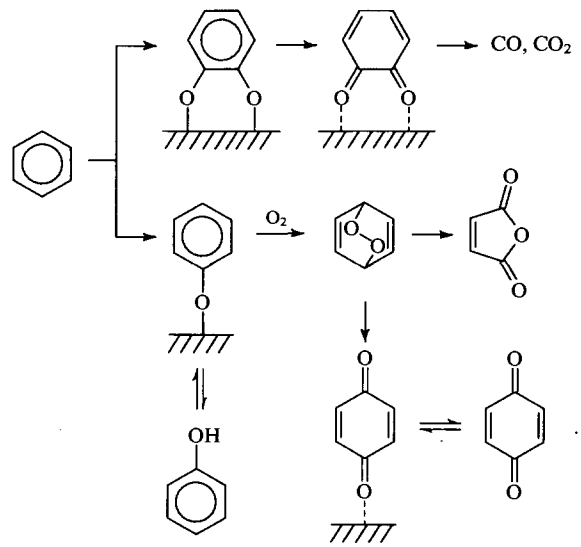
Unsaturated acids can be prepared by the further oxidation of unsaturated aldehydes produced from olefins. The reaction takes place on V–Mo oxide catalysts, including V–Mo–O heteropolycompounds and heteropolyacids. The oxidation of acrolein to acrylic acid was studied by in situ IR spectroscopy on VMo_3O_{11}[77] and on V–Mo–O/SiO_2.[78] Several complexes containing C=C bonds (complex **16**) and also COO^- (complexes **17** and **18**) and C=O (molecular adsorption of CH_2=CHCOOH, complex **19**) were seen. The rate constants for the transformations of these complexes were measured. The following reaction mechanism was proposed:



16

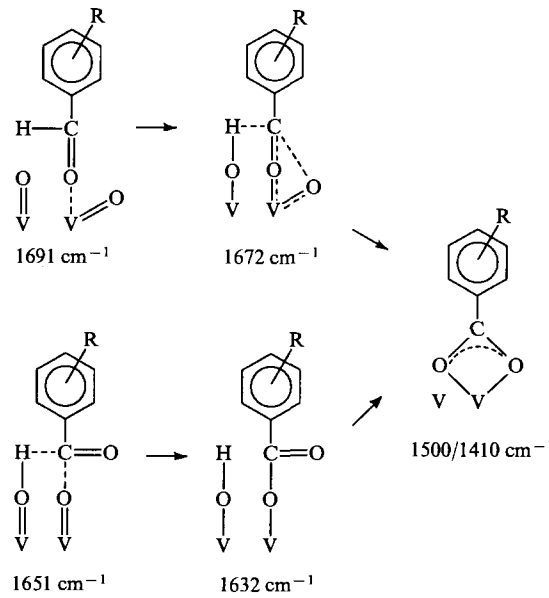
17

18



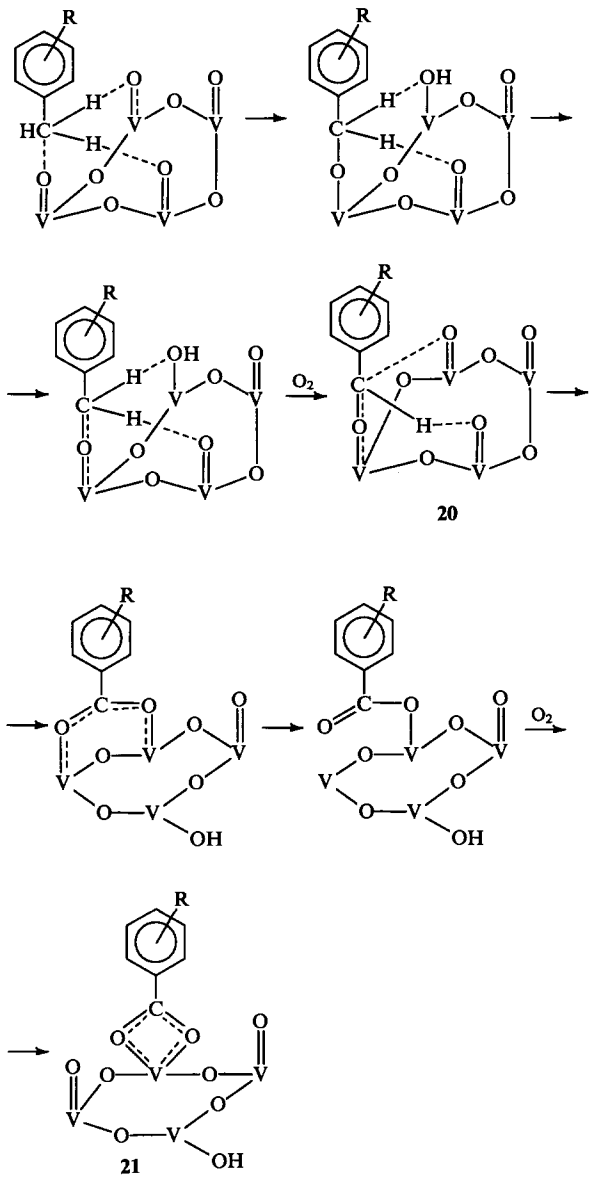
19

The rate-limiting step is the conversion of the complex **17** (which is not observed in practice) into the complex **18**. The catalyst should contain Mo^{6+} (or W^{6+}) ions for the σ-bonding of the acrolein, and V^{4+} (Mo^{4+} and Ti^{4+}) ions of the weakly basic or amphoteric type for the formation of salt-like acrylates. However, the degree of correspondence between the kinetics of the change in intensity of the IR lines and the kinetic curves describing the formation of acrylic acid is not stated. The reliability of the observed intermediate complexes can be classified as high (H).



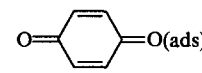
VI. Partial oxidation of aromatic hydrocarbons

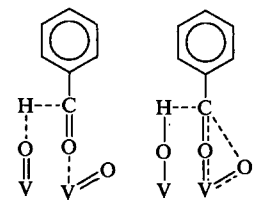
Aromatic hydrocarbons undergo partial oxidation on the same catalysts as olefins. The surface compounds formed by the interaction of benzene with oxygen at 280 °C on a V_2O_5/TiO_2 catalyst have been studied by FTIR spectroscopy.[79] Adsorbed quinone, phenol, maleic anhydride, and carboxylates were detected on the surface. The following mechanism was proposed:



The IR spectra of the resulting surface compounds were recorded[80] at room temperature after the partial oxidation of toluene and *o*-xylene on V_2O_5/TiO_2. The $C_6H_5-CH_2-V$ and $C_6H_4(CH_3)CH_2-V$ complexes which were observed led to the conclusion that the first step of the reaction is the breaking of the C–H bond in the methyl group. In these complexes the aromatic ring is positioned parallel to the surface.

In situ FTIR spectra were obtained[81] during the selective oxidation of toluene to benzaldehyde and of *o*-xylene to α-toluyl aldehyde on V_2O_5/TiO_2. Complexes of aldehydes, carboxylates, and benzoates were observed on the surface.





The following mechanism has been proposed for the oxidative transformations of toluene (or xylene) on the surface: it assumes that an aldehyde can be formed by the decomposition of the complex **20** without oxidation, and an acid by the decomposition of the complex **21**.

The oxidative ammonolysis of toluene on V–Sb–Bi–O/Al_2O_3 was studied by thermal desorption and IR spectroscopy.[82] NH_4^+ ions and ammonia coordinately bound to Lewis-acid centres were detected. Heating the system to 200 °C to 300 °C produced also NH_2. The adsorption of toluene leads to the formation of π-complexes and benzoate structures, and in the reaction with NH_3 benzamide and benzimide structures were also noted. The concentration of benzoate (unlike that of benzimines) is not correlated with the yield of the reaction products (nitriles). Adsorbed ammonia poisons the deep oxidation centres and thus prevents the formation of benzoates. The mechanism of the partial oxidation of benzene and phenol in the presence of N_2O has been studied on the Fe–ZSM-5 catalyst.[83] Bands of adsorbed phenol were seen in the diffuse reflectance IR spectra. Active oxygen O_{ads}, which has a very low bond energy, is formed during the decomposition of N_2O.

Table 4 shows the intermediate compounds which contribute to the partial oxidation of aromatic compounds.

Table 4. Intermediate compounds in the partial oxidation reactions of aromatic compounds.

Reaction, catalyst	Intermediate complex	Reliability	Ref.
Oxidation of benzene to oxygen compounds on $V_2O_5-TiO_2$	$M-OC_6H_5$, $M-OC_6H_4OH$, 	L	79
Oxidation of toluene to toluic aldehyde and of *o*-xylene to benzaldehyde on $V_2O_5-TiO_2$	$C_6H_5CH_2-V$, $C_6H_4(CH_3)CH_2-V$ 	L M	80 81

Oxidation of benzene to phenol by N_2O on Fe–ZSM-5	O(ads), C_6H_5OH(ads)	M	83

VII. Partial oxidation of alkanes

Very detailed studies of the oxidation of methane with formation of C_2H_4, C_2H_6, CH_3OH, and CH_2O have recently been reported. Attempts to obtain the in situ spectra of surface compounds under the conditions of the partial oxidation of methane were unsuccessful.[84] This is evidently due to the fact that at high temperatures the reaction proceeds by a heterogeneous–homogeneous mechanism, and the lifetime of the intermediate species on the surface is very short. Under the conditions of its oxidative condensation (700–900 °C) methane interacts with the surface oxygen O_s, forming methyl radicals and OH groups on the surface.

$$CH_4 + O_s \longrightarrow CH_3^{\cdot} + OH_s,$$

$$2\,OH_s \longrightarrow H_2O + O_s.$$

The methyl radicals recombine in the gas phase, and are thus converted into ethane and (further) into ethylene.

$$2\,CH_3^{\cdot} \longrightarrow C_2H_6,$$

$$C_2H_6 + O_s \longrightarrow C_2H_4 + H_2O.$$

The interaction of methane with films of oxide catalysts under the conditions of adsorption at 300–500 °C and under the conditions of CH_4 oxidation was studied *in situ* by the new and very sensitive surface electromagnetic waves method.[85,86] Bands from OH and OCH_3 groups were detected in the IR range at 900–1100 °C. They are obviously associated with the compounds formed during the extensive oxidation of methane to CO_2 and H_2O.

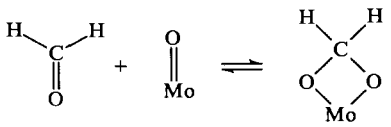
$$CH_4 + O_s \longrightarrow CH_3 + OH_s,$$

$$CH_3 + O_s \longrightarrow OCH_3,$$

$$OCH_3 + O_2 \xrightarrow[-H_2O]{} \underset{\underset{O}{\|}}{\overset{O}{\|}}{>}CH \longrightarrow CO_2$$

Bands ascribed to OCH_3 and carbonate complexes were observed also in the FTIR spectra recorded after the oxidative condensation of methane into C_2 hydrocarbons on MgO.[87] These complexes take part in the extensive oxidation processes on the surface. Similar processes were observed by XPES during studies of the oxidation of CH_4 on NaOH/CaO and NaOH/(BaO, CaO).[88] It was found that methane interacts with surface carbonate (CO_3^{2-}) at 500–750 °C, forming a surface compound which rapidly disappears when the methane is pumped off. Possible intermediate complexes include the CH_3O and C=O groups, which are further oxidised to CO_2.

A study of the mechanism of oxidative condensation by combining the TAP reactor[89] with isotopic methods[90] showed that the methane taking part in the reaction is effectively not adsorbed on MgO and BaO/MgO surfaces. Apparently it reacts by the collision mechanism



$$CH_4 + O_s \longrightarrow CH_3^{\cdot} + OH_s,$$

and initiates further oxidative processes in the gas phase.[84] On the other hand heterolytically adsorbed methane is involved in the $CH_4 + CD_4$ isotope exchange.[90] It forms complexes of the $CH_3-Mn^{n+}O^{2-}H^+$ type on the basic centres, which differ from the O^- centres involved in the homolytic breakdown of the CH_4 molecule.

The surface forms of oxygen created during the oxidative condensation of methane on BaO/MgO were studied by in situ Raman spectroscopy.[91,92] The peroxide groupings (O_2^{2-}) observed in this way at 844 cm^{-1} are stable in the presence of O_2, and at 740 °C they react with CH_4 over a period of several minutes. By using a TAP reactor it was shown that the lifetime of the adsorbed oxygen which reacts with methane on BaO/MgO is greater than 20 s. This species could also be the peroxide group. However, a longer-lived form of surface oxygen (O_s) is involved in the oxidative condensation of methane on MgO.

The oxidation of methane to formaldehyde takes place most selectively on catalysts which contain molybdenum, vanadium, or silicon oxides. A study by in situ laser-Raman spectroscopy of the partial oxidation of methane to formaldehyde on MoO_3 monocrystals led to the conclusion[93] that in this reaction the intermediate oxygen compounds are the Mo=O groups on a (100) MoO_3 face, whereas the Mo–O–Mo groups are involved in the extensive oxidation. A dispersed heteropolyacid is formed on the surface of the Mo–Si–O catalyst.[94] According to XPES and Raman spectroscopy Mo=O groups are formed as well under the catalysis conditions.

A study of the isotope exchange of O_2 under the conditions of the oxidation of methane to formaldehyde on MoO_3/SiO_2 showed[95] that not only the MoO_3 but also the SiO_2 contributes to the exchange. A very fast exchange between CH_2O and the oxygen of the catalyst was also noted: it was ascribed to the equilibrium

According to data obtained in a TAP reactor[96] a surface oxygen species with a lifetime between 5 and 60 s is responsible for the oxidation of CH_4 to CH_2O on V_2O_5/SiO_2. Compounds containing oxygen and related to the oxidative condensation or to the oxidation of methane to formaldehyde were not detected under the catalysis conditions. Intermediate compounds such as the $^{\cdot}CH_3$ and $CH_3O_2^{\cdot}$ radicals migrating from the surface into the gas phase[84,91] will not be considered here.

Dissociative forms of carbon on the surface of metals [C(ads), CH_x(ads)] are apparently intermediates in the oxidation of methane by oxygen[97] or by carbon dioxide[98] with formation of synthesis gas (CO + H_2). The vapour phase conversion of methane on Ni/NaY at 300 °C has also been studied by in situ IR spectroscopy.[99] Formate was found on the surface after the reaction. The following reaction mechanism was proposed:

$$H_2O + S \rightleftharpoons H_2O-S,$$

$$CH_4 + M \rightleftharpoons MC + 2H_2,$$

$$MC + H_2O-S \rightleftharpoons HCO-M + \tfrac{1}{2}H_2 + S,$$

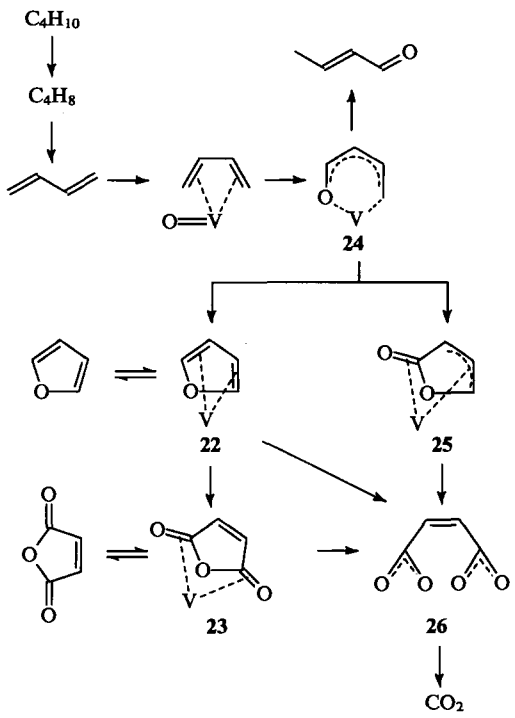
$$HCO-M + H_2O-S \rightleftharpoons HCOO-M + H_2 + S,$$

$$HCOO-M \longrightarrow CO_2 + \tfrac{1}{2}H_2 + M.$$

The last step is rate-limiting.

In the oxidation of ethane on Pd/Al_2O_3 and Pd/SiO_2 in situ IR spectra obtained at 200–600 °C revealed acetate and carbonyl complexes acting as intermediates in the extensive oxidation reaction.[100] The oxidative dehydrogenation of ethane to ethylene apparently takes place by a heterogeneous–homogeneous mechanism.[101]

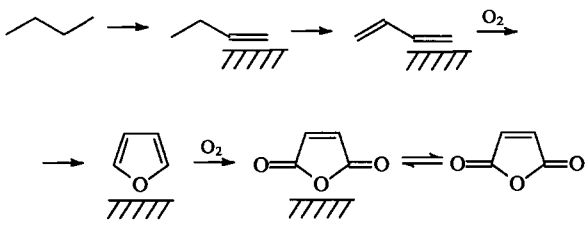
The oxidation of CH_4, C_2H_6, and C_2H_4 on Co_3O_4 and on Pd/TiO_2 has been studied.[102] The interaction of CH_4 with Co_3O_4 produces surface OH groups, carbonates of two types, and (apparently) Co–CH_2–Co groups. The formation of CH_3CHO and acetate adsorbed on the TiO_2 carrier has been observed in the reaction of C_2H_4 with O_2 on Pd/TiO_2. The ethane is first dehydrogenated to ethylene by an oxidation–reduction reaction, involving the $Pd^{2+}-O_2^{2-}$ ion pair, and then the C_2H_4 is rapidly oxidised to CH_3CHO, which undergoes decarbonylation with formation of Pd–CH_3 + CO. The Pd–CH_3 complex is formed also by the reaction between CH_4 and the $Pd^{2+}-O_2^{2-}$ pair. This is followed by the reactions



$$CH_3 \xrightarrow{O_2} CH_2 + H(OH) \xrightarrow{O_2} CH_2O \xrightarrow{O_2} CO + H_2O.$$

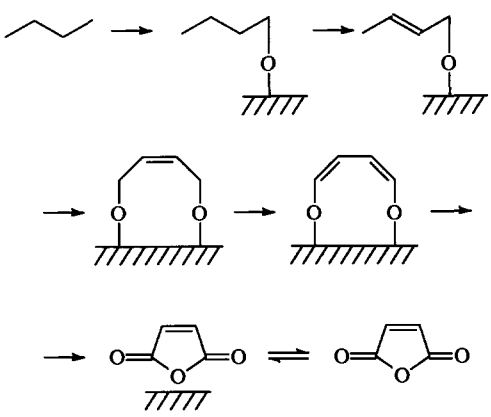
The final result is deep oxidation of the CH_4.

Many studies have been devoted to the partial oxidation of butane to maleic anhydride and other oxygen compounds on V–Ti and V–P oxide catalysts. The mechanism of the oxidation of butane on TiO_2 and $V_2O_5-TiO_2$ has been examined[103,104] by studying the FTIR spectra of C_4H_6, furan, and maleic anhydride on the catalysts in the presence and in the absence of O_2. The sequence of transformations on $V_2O_5-TiO_2$ shown in Scheme 1 was proposed. At room temperature the complex **22** (adsorbed furan) is first formed. At higher temperatures a strong band assigned to the complex **24** appears in the IR spectra. At 200 °C its intensity decreases, and an absorption band corresponding to the complex **26** appears. As a result of the interaction with oxygen the intensity of the band assigned to the complex **24** increases again. The absorption band which characterises the complex **24** disappears at 250–300 °C, and absorption bands due to the complexes **23** and **25** are produced. Maleic anhydride is formed only in the presence of oxygen: in the absence of oxygen the maleates **26** are obtained. Evidently, these decompose by associative interaction with O_2. On TiO_2 only the π complex of C_4H_8 (or C_4H_6) with Ti^{3+} is formed reversibly. On a V–P–O catalyst maleic anhydride is formed even in the absence of O_2, and maleates are not observed. Obviously, in this case the oxygen in the bulk of the catalyst has a higher mobility. The V–O–Ti bridging forms, which are more nucleophilic than V–O–P, may



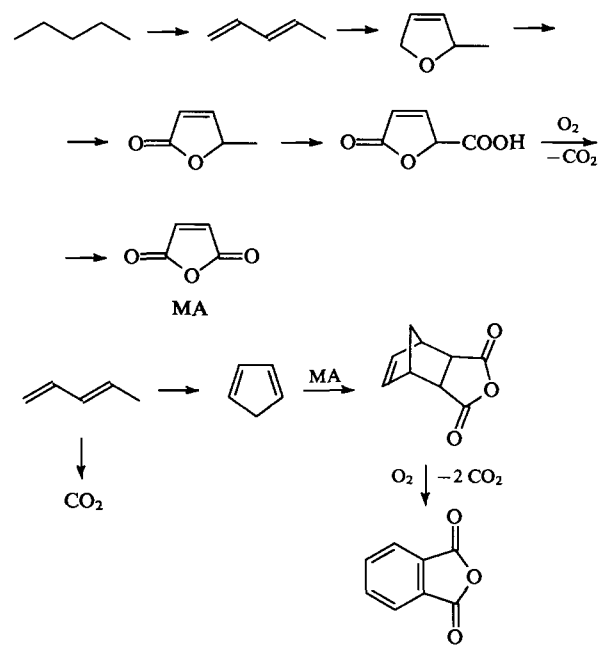
also contribute to the formation of the maleates. This leads to nonselective catalysis.

Scheme 1



Two possible paths for the conversion of butane into maleic anhydride on a vanadium–phosphorus oxide catalyst have been considered:[105]

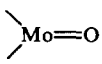
(a) the olefin path

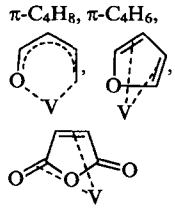


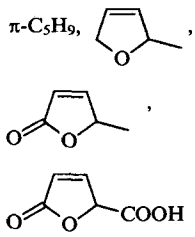
(b) the alkoxide path

The olefin path (a) has been called[105] the equilibrium path, because all the contributing intermediates are in adsorption equilibrium with the gas phase. The alkoxide path (b) is a nonequilibrium process: all the intermediates (except the last) remain on the surface, and only maleic anhydride is desorbed into the gas phase. However, the formation of the surface complexes listed above was not confirmed spectroscopically, and their structure was determined only from indirect data obtained by ^{31}P NMR and EPR methods.

The difference between the mechanisms of the partial oxidation of butane and butene (see Section IV) also suggests that the alkoxide path is preferable to the olefin path. It is assumed[106] that the oxidation of C_4H_{10} on $(VO)_2P_2O_7$ is characterised by a strong adsorption of the intermediate substances, which suppresses their desorption into the gas phase and limits their surface mobility. Under these conditions the number of free centres is also limited, leading to the geometric isolation of the active intermediates and thus suppressing the oxidation to CO and CO_2. On $(VO)_2P_2O_7$ the oxidation mechanism of butane and pentane to maleic anhydride was studied by in situ FTIR spectroscopy, and by using a TAP reactor.[106–108] Exposing the catalyst to a mixture of C_5H_{12} and O_2 produced a large number of IR spectroscopic bands for which only a tentative assignment was given.[106] The IR spectra of the sample vacuum treated at 400 °C after the adsorption of C_5H_{12} contained absorption bands from weakly adsorbed olefins, and after the adsorption of a $C_5H_{12} + O_2$ mixture they contained the bands from adsorbed anhydride. The intensity of the absorption band from the anhydride increases with time, and bands associated with more highly oxidised substances are produced. By using a TAP reactor it was shown that at 427 °C pentane is converted into furan (reaction time 0.2 s), which reacts further to give maleic anhydride (0.3 s) and phthalic anhydride (0.5 s). On the basis of these observations the following reaction scheme was proposed:







The formation of methylmaleic anhydride in the initial stages of the reaction, which confirms the proposed scheme, was observed. All the substances specified in this scheme are on the surface in an adsorbed state. A competition then takes place between the addition of atomic oxygen, which leads to the formation of maleic anhydride, and the elimination of an H atom, with formation of phthalic anhydride. To form phthalic anhydride we also require the presence on the surface of another adsorbed molecule of an unsaturated C_5 hydrocarbon. By using the TAP reactor in a study of the oxidation mechanism of butane on $(VO)_2P_2O_7$ (see Ref. 108) it was shown that this catalyst has a unique ability to retain absorbed oxygen and to transmit it effectively to a hydrocarbon. We observe the conversion of $(VO)_2P_2O_7$ into amorphous $VOPO_4$,

$$^{18}O_2 + 2\,(VO)_2P_2O_7 \rightleftharpoons 4\,VOPO_4,$$

which involves the transfer of four oxygen atoms in a single step.

Table 5. Intermediate compounds in the partial oxidation of alkanes.

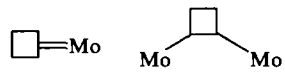
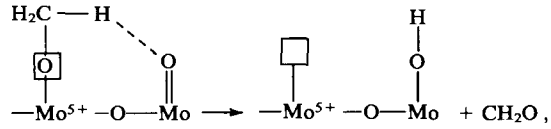
Vapour conversion of methane on Ni/NaY	$HCOO^-$	L	99
Oxidation of ethane on Pd/TiO_2	CH_3CO-Ti, CH_3CHO(ads), C_2H_4(ads),	L	102
Oxidation of butane to maleic anhydride on V_2O_5/TiO_2	π-C_4H_8, π-C_4H_6, 	M	103, 104
Oxidation of pentane to maleic anhydride on $(VO)_2P_2O_7$	π-C_5H_9, 	H	106–108

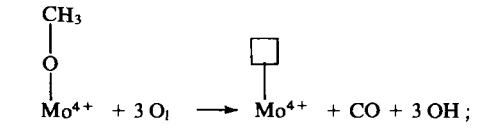


Data on the intermediate compounds which contribute to the partial oxidation of alkanes are shown in Table 5.

The oxidation reactions of alkanes can be classified into two groups: high-temperature reactions (500–600 °C, gas-phase conversion of methane and other alkanes, oxidation of alkanes to synthesis gas, and possibly also extensive oxidation), which take place by a complete dissociation mechanism with formation of H_{ads}, O_{ads}, and C_{ads}, and low-temperature reactions (oxidative dehydrogenation with formation of oxygen compounds), involving various large surface complexes. Among all the partial oxidation processes the oxidation of butane to maleic anhydride has been studied in most detail. In this stage the formation of intermediate complexes has been established with a high level of reliability.

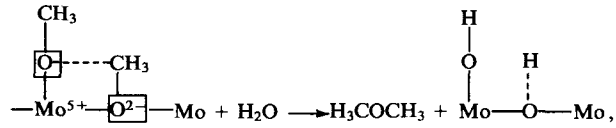


VIII. Oxidation of alcohols

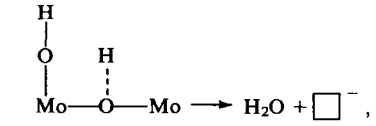


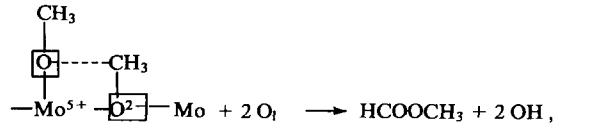
The mechanism of the oxidation of alcohols has been studied on various oxides: MoO_3,[109,110] Cr_2O_3,[111,112] TiO_2,[112] and ZnO.[113] Alkoxides, formates, and other forms resembling the complexes observed in the dehydrogenation of alcohols (see Ref. 1) were found on the surface.

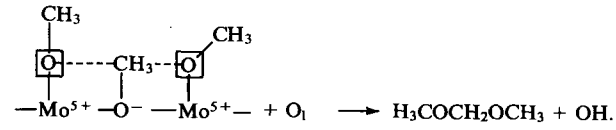
The oxidation of methanol on MoO_3 at 170–440 °C was studied by in situ FTIR spectroscopy in the transition regime.[109,110] According to these data the CH_3OH is adsorbed on vacancies of two types:



The products CH_2O and CO are formed on vacancies of the first type:







O_l is lattice oxygen.

On the vacancies of the second type the following reactions take place:

In the stationary state the MoO_3 surface is slightly reduced, and the rate-limiting step is provided by reoxidation, i.e. the filling of vacancies with oxygen.

On Cr_2O_3 the reaction was studied by in situ FTIR spectroscopy; the kinetics of the formation of the products H_2O, CO_2, and CH_2O were monitored at the same time.[112]

However, the quantity of adsorbed substances was not compared with the composition of products in the gas phase. The mechanism of the reaction is

$$CH_3OH + O^{2-} \longrightarrow CH_3O^- + OH^-,$$

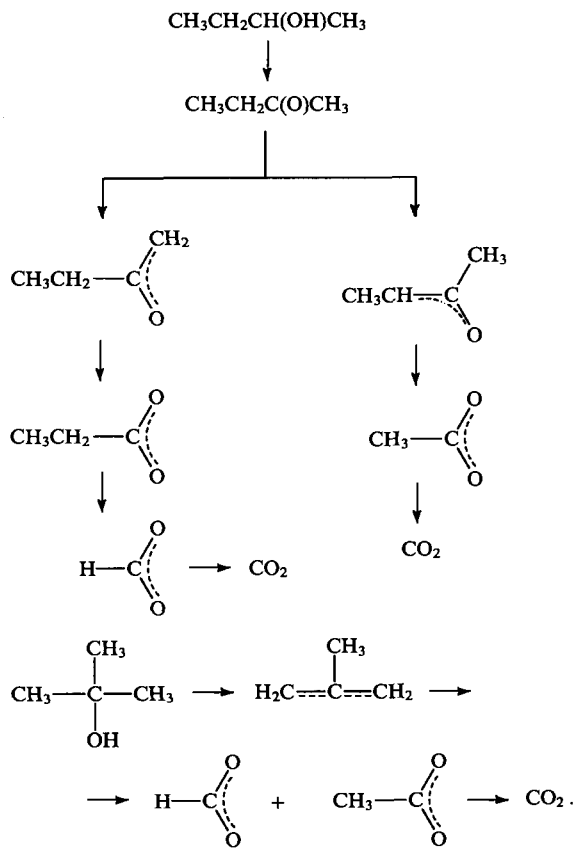
$$CH_3OH + OH^- \longrightarrow CH_3O^- + H_2O,$$

$$CH_3O^- + O^{2-} \longrightarrow CH_2O + OH^- + 2e,$$

$$CH_2O + 2O^{2-} \longrightarrow HCOO^- + OH^- + 2e,$$

$$2HCOO^- \longrightarrow H_2 + 2CO_2 + 2e,$$

$$HCOO^- + OH^- \longrightarrow H_2O + CO + O^{2-},$$



$$O_2 + 4e \longrightarrow 2O^{2-},$$

$$2OH^- \longrightarrow H_2O + O^{2-}.$$

Thus the oxidation of methanol on Cr_2O_3 takes place by the series of reactions [111]

$$CH_3O \longrightarrow CH_3O(ads) \longrightarrow HCOO(ads) \longrightarrow CO, CO_2.$$

After the oxidation of *sec*-butanol and *tert*-butanol on ZnO at 80–150 °C formates and carboxylates were detected by IR spectroscopy.[113] The same bands were found in the IR spectra after the oxidation of butan-2-one. It follows that the first step in the reaction is the conversion of butan-2-ol into butan-2-one. This is followed by the reactions

An interesting study (by in situ EXAFS spectroscopy in conjunction with UV-VIS and IR spectroscopy) of the oxidation of ethanol to acetaldehyde on dimeric Mo complexes supported on SiO_2 has been reported.[114] The EXAFS spectra were measured at 70 °C (or in some cases at −195 °C). The cooling time from the reaction temperature (150 °C) was relatively long (up to 1 h). The following oxidation–reduction mechanism was proposed on the basis of these results:

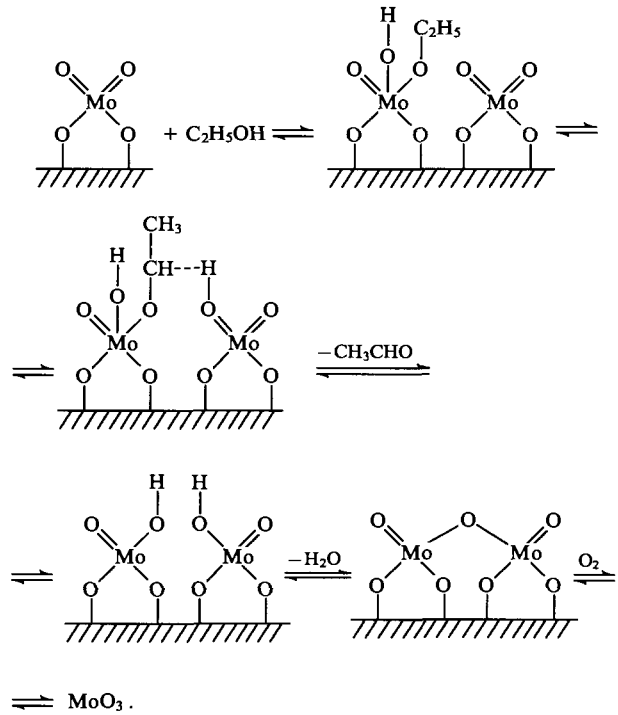


Table 6. Intermediate compounds in the oxidation of alcohols.

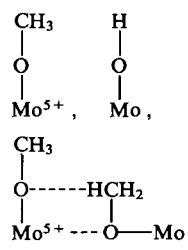
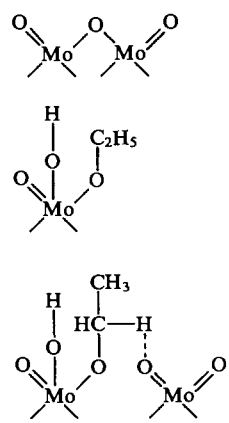
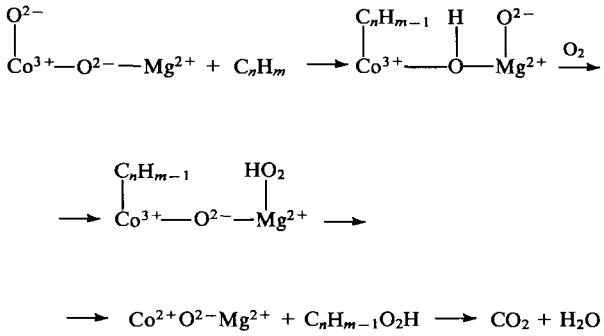




Reaction, catalyst	Intermediate complex	Reliability	Ref.
Oxidation of methanol on MoO_3		H	109, 110
Oxidation of methanol on Cr_2O_3	CH_3O^-, OH^-, $HCOO^-$	M	111, 112
Oxidation of *sec*-butanol and *tert*-butanol on ZnO	$HCOO^-$, $RCOO^-$, $R^{\cdot}$	L	113
Oxidation of ethanol to acetaldehyde on Mo/SiO_2		L	114

Table 6 gives a summary of the data on the intermediate compounds which take part in the oxidation of alcohols.

The formation of alkoxides and carbides during the oxidation of alcohols on oxide surfaces can be taken to be established to a relatively high degree of reliability. However, their influence on the kinetics of the reaction is still uncertain.



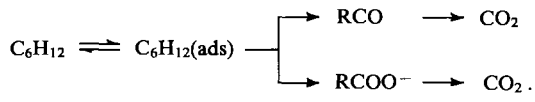
IX. Extensive oxidation of organic compounds

We have already discussed several processes which contribute to the oxidation of organic compounds and ultimately lead to the formation of CO and CO_2. It is generally thought that extensive oxidation takes place through surface carboxylates and carbonates. The formation of carboxylate structures of the $HCOO^-$ type (in some cases destructively oxidised as a C–C bond) by the interaction between hydrocarbons and surface oxygen was first reported by Kuznetsov et al.[115] However, real kinetic data on the contribution of these forms to the catalysis are still scarce.

The oxidation of CH_4, C_2H_6, and C_2H_4 on CeO_2 at 20–400 °C was studied by in situ EPR and FTIR spectroscopy methods.[116] At 200 °C the surface contains $HCOO^-$, which is converted into carbonate at 300 °C. The initiation of extensive oxidation is independent of the oxygen pressure, but it is affected by the pretreatment of the CeO_2 catalyst. The O_2^- ion is inert up to 300 °C: evidently, the O_2^{2-} ion reacts with hydrocarbons in this temperature range. In the IR spectra obtained under the conditions of oxidation of C_2H_4 and C_3H_6 at 100–300 °C on $Bi_2O_3-MoO_3$ bands from strongly bound complexes leading to the deep oxidation products were observed[48] in addition to the bands corresponding to π-allyl. On Ag/Al_2O_3 and Tl_2O_3/Al_2O_3 the precursors of the deep oxidation products were found to be surface carbonates.[48]

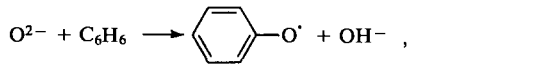
In the oxidation of ethane on Pd/Al_2O_3 absorption bands due to adsorbed acetates and acetaldehyde were seen in the IR spectra.[117] On Pd/SiO_2 or on pure Al_2O_3 these surface compounds are not formed: their formation requires the presence of both Pd and Al_2O_3. Probably the compounds are formed on the Pd and then migrate to the Al_2O_3 by the spillover mechanism. Under these conditions ethane is not adsorbed.

Acetates, formates, and benzoates were observed in the oxidation of C_3H_6 and $C_6H_5CH_3$ on 5% CoO–MgO.[118] The formation of O_2^- was also noted. According to these workers[118] the reaction may follow the scheme



$$\longrightarrow Co^{2+}O^{2-}Mg^{2+} + C_nH_{m-1}O_2H \longrightarrow CO_2 + H_2O\,.$$

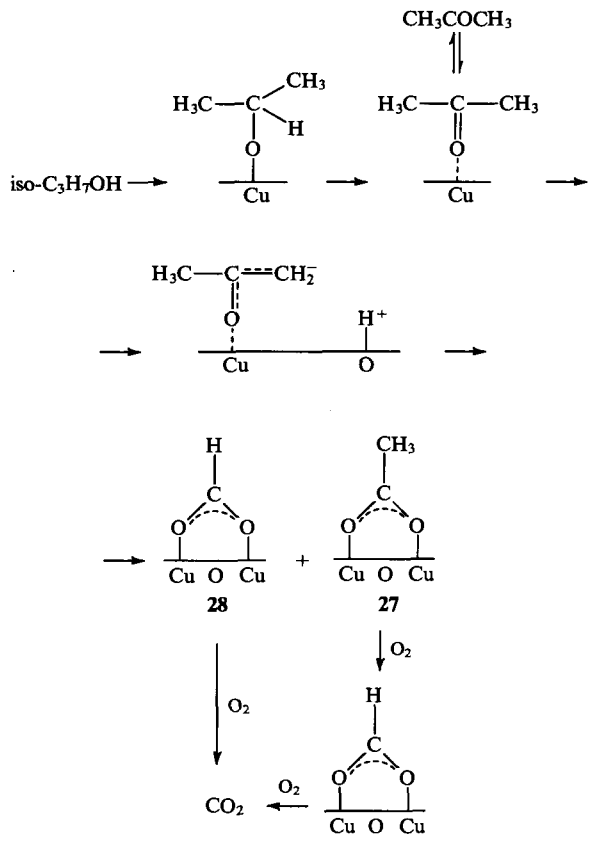
The hydroperoxide $C_nH_{m-1}O_2R$ (for example, All–OOH) can decompose into $CH_3CHO + H_2CO$ and then be oxidised to carboxylates and finally to CO_2. We note that a similar mechanism was proposed earlier[119] for the oxidation of C_3H_6 on CoO–MgO. The oxidation of isobutene on V_2O_5/TiO_2 was studied by FTIR spectroscopy.[120] At low V_2O_5 concentrations dimerisation takes place, and at high concentrations the isobutene undergoes extensive oxidation. In the former case π-complexes of iso-C_4H_8 are observed on the surface, in the latter we find alkoxides and carboxylates. As reported,[120] acid centres of the Brønsted type and the lattice oxygen give rise to the extensive oxidation.



In the oxidation of butene on Mg–Fe–O and Zn–Fe–O[121] the strongly adsorbed C_4H_8 σ-complex is retained on the surface up to 500 °C, but in the presence of O_2 it is retained only up to 200 °C, i.e. up to the temperature at which CO_2 appears in the gas phase. It is suggested that the σ-complex interacts with O_2 to give the $HCOO^-$ form, which is an intermediate in the extensive oxidation reaction of C_4H_8 to CO_2. On $MgO-Al_2O_3$, $ZnO-Al_2O_3$, and Al_2O_3 the σ-complex is not oxidised to $HCOO^-$, and these catalysts do not show any activity in the extensive oxidation process. The interaction of a series of hydrocarbons (C_3H_6, C_4H_6, and C_6H_6) with oxides was studied by FTIR spectroscopy.[122] On SiO_2 only physisorbed molecules were observed. On γ-Al_2O_3 at 300 °C bicarbonates and acetates were formed from C_3H_6, whereas on γ-Fe_2O_3 carbonates were formed at room temperature, and at 150 °C formates and acetates were formed from C_3H_6, carboxylates from C_4H_6, and an oxidised product from C_6H_6. On TiO_2 bicarbonate was observed at room temperature, and at 150 °C acetone, aldol (from C_3H_6), and carboxylates (from C_4H_6) were observed. These substances may be the precursors of the extensive oxidation products.

The kinetics of the extensive oxidation of cyclohexane on NaX and KY zeolites were studied in our laboratory[123–126] in conjunction with in situ measurements of the IR spectra. The reaction can follow two paths:

The rate of the catalytic reaction is proportional to the overall concentration of the two complexes, but the carbonyl complexes decompose faster than the carboxylates (acetates and formates). Thermal desorption data confirm that the carbonyl complexes decompose at temperatures 50–100 K lower than the carboxylates, and therefore transformations through the carbonyl compounds are the main reaction path of the extensive oxidation. Self-oscillations were observed[123,125] in the oxidation of cyclohexane on KY zeolite, and oscillatory changes synchronous with those of the reaction rate were noted in the intensity of the IR bands from adsorbed carbonyl compounds. It was assumed that the carbonyl group is bound to a peroxide group.



The oxidation of benzene (and also of toluene and *o*-xylene) was studied on supported vanadium oxide catalysts by the EPR method.[127] The reaction

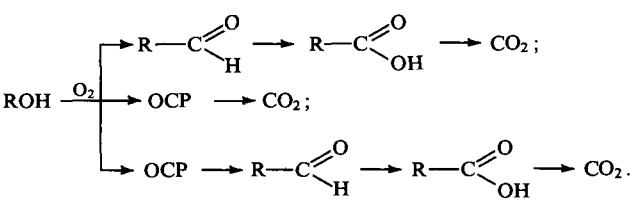
leads to the formation of free-radical products which are ultimately oxidised to CO_2.

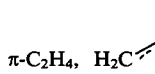
The mechanisms of the oxidation of alcohols on oxides have already been discussed above. Here we shall only deal briefly with some studies specially aimed at the mechanism of the extensive oxidation of alcohols. According to spectroscopic data,[128] in the oxidation of isopropanol on CuO at 20–80 °C the resulting isopropylates interact with oxygen from the gas phase. The lattice oxygen reacts in a similar way only at 120–150 °C. The formation of CO_2 is accompanied by the disappearance of the carboxylates. The kinetics of the disappearance of the carboxylates during the treatment of the surface in the iso-$C_3H_7OH + O_2$ reaction mixture at 100–200 °C were studied by in situ IR spectroscopy.

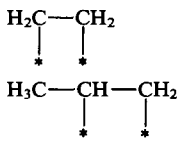
Under these conditions the concentration of isopropylates decreases, but that of formates goes through a maximum:

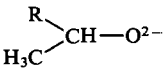
Under stationary conditions the concentration of formates on the surface is constant, and the time needed to establish the steady state is shorter than the time needed for the chromatographic analysis. Thus we have two extensive oxidation regimes: in the low-temperature regime the reaction proceeds through weakly bonded forms (type **27**) and through more strongly bonded forms (type **28**).

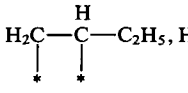
The oxidation of ethanol, n-propanol, isopropanol, n-butanol, isobutanol, and *tert*-butanol on Sn–Mo–O at 125–200 °C was studied by in situ IR spectroscopy. When the alcohol was removed from the reaction mixture the intensity of the IR bands corresponding to alcoholates and alcohols bound to the surface by a hydrogen bond and to aldehydes and acids rapidly fell to zero. The other bands remained in the IR spectrum for a much longer time. These bands are mostly due to condensation products containing carbonate and anhydride fragments. In the oxidation of butyric anhydride the same compounds are formed as in the oxidation of n-butanol, but the oxidation of the acids does not give oxidative condensation products (OCP). Under stationary conditions (in contrast to the initial period) absorption bands due to adsorbed alcohols and alcoholates are not observed. The following formal scheme has been proposed[129] for the reaction:

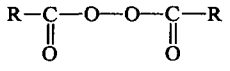


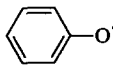


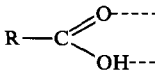












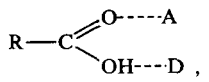


Table 7. Intermediate compounds in the deep oxidation reactions of organic compounds.

Reaction, catalyst	Intermediate complex	Reliability	Ref.
Oxidation of CH_4, C_2H_6, C_2H_4 on CeO_2	$HCOO^-$, CO_3^{2-}, O_2^{2-}	M	126
Extensive oxidation of C_2H_4, C_3H_6 on $Bi_2O_3-MoO_3$	π-C_2H_4, 	L	48
Extensive oxidation of C_2H_4, C_3H_6 on Ag/Al_2O_3, Tl_2O_3/Al_2O_3		L	48
Oxidation of ethane on Pd/Al_2O_3	CH_3COO^-, CH_3CHO(ads)	M	117
Oxidation of C_3H_6, $C_6H_5CH_3$ on $CoO-MgO$	CH_3COO^-, $HCOO^-$, $C_6H_5COO^-$, O_2^-	L	118
Extensive oxidation of iso-C_4H_8 on V_2O_5/TiO_2		M	120
Oxidation of C_4H_8 on Mg–Fe–O, Zn–Fe–O		L	121
Oxidation of C_3H_6, C_4H_8, C_6H_6 on oxides	$HCOO^-$, CH_3COO^-, $RCOO^-$, CO_3^{2-}, HCO_3^-	M	122
Oxidation of cyclohexane on NaX, KY zeolites	RCO, $RCOO^-$ 	H	123–126
Oxidation of benzene on V/SiO_2, MgO, ZrO_2	O_2^-, 	M	127
Oxidation of i-C_3H_7OH on CuO	$C_3H_7O^-$, CH_3COO^-, $RCOO^-$, CO_3^{2-}, HCO_3^-	M	128
Oxidation of alcohols on Sn–Mo–O	Oxidative condensation products	M	129
Oxidation of HCOOH and CH_3COOH on Pt/Al_2O_3		L	130
Oxidation of $H_2C=CHCHO$ and CH_3CH_2CHO on Cu_2O	$RCOO^-$, $RCH=CHO^-$, C_xH_y, C_x	L	131

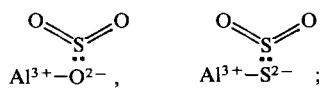
The oxidation of the acids HCOOH and CH_3COOH on Pt/Al_2O_3 also was studied by IR spectroscopy.[130] At low temperatures the complexes

were detected (where A is an electron acceptor and D is an electron donor).

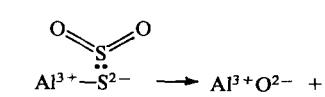
These complexes interact with O_2 at 200–300 °C. Strongly bound acetates and formates do not react with O_2. In the HCOOH complex the C–H bond is broken during the interaction with O_2, and in the CH_3COOH complex the C–C bond is broken.

X-Ray photoelectron spectroscopy and thermal desorption methods were used to study the extensive oxidation of acrolein and propionaldehyde on a $Cu_2O(100)$ surface.[131] The products of this reaction are CO, CO_2, and H_2O. Enolate and carboxylate complexes are observed on the surface, but the latter (in general) do not take part in extensive oxidation, and only a small fraction of the products is formed from the enolate. It is suggested[131] that the main extensive oxidation path includes the deoxygenation of the adsorbate, the dehydration of C_xH_y, and the final burning of the surface carbon by oxygen from the lattice.

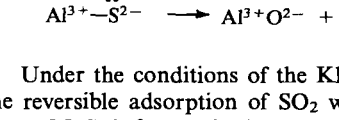
A list of data on the intermediate compounds which contribute to the extensive oxidation is given in Table 7.



Though surface carbonates and carboxylates are very often observed in the extensive oxidation of organic compounds these complexes do not provide the main path for the formation of CO_2. At low temperatures a different path can be established, involving intermediates which are difficult to identify because of their short lifetimes. They are probably free-radical or peroxidic products. The extensive oxidation takes place by a free-radical mechanism (and in some cases by a heterogeneous–homogeneous mechanism). At high temperatures a complete decomposition of the organic molecule with oxidation of C_{ads} to CO_2 and of H_{ads} to H_2O is more probable.



X. Reactions involving sulfur



The Klaus reaction $H_2S + SO_2 \rightarrow S_2 + H_2O$ takes place on several oxide catalysts. After the interaction of $H_2S + SO_2$ on Al_2O_3 the IR and UV spectra of the surface compounds were recorded at 20–400 °C.[132] The SH and OH groups are stable up to 150 °C.

$$H_2S + O^{2-}(surf) \longrightarrow H_2O + S^{2-}(surf)$$

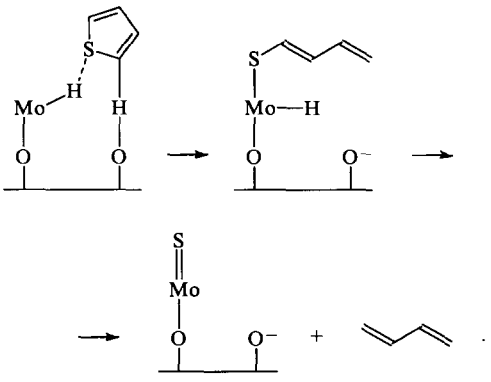
At higher temperatures we find the S^{2-} form, which is stable up to 300–400 °C, with bands at 220–260 nm in the UV spectrum. The interaction of $Al^{3+}S^{2-}$ and $Al^{3+}O^{2-}$ with SO_2 at 150 °C produces sulfite–sulfate complexes:

Under the conditions of the Klaus reaction on Sn–Mo–O the reversible adsorption of SO_2 was observed by IR spectroscopy. MoS_2 is formed in the presence of H_2S. If SO_2 is adsorbed first, followed by H_2S, the absorption bands due to adsorbed SO_2 are weakened and the bands at 800–1000 cm^{-1} become stronger. This is because of the formation of S_2 molecules, with the possibility of reoxidation of the catalyst with formation of the Mo=O bond.[133] The IR and UV spectra of the adsorbed substances were recorded also after carrying out the Klaus reaction on the NaX zeolite.[134] The changes in the intensity of the bands were ascribed to the reactions

$$SO_2 + OH^- \longrightarrow HSO_3^-,$$

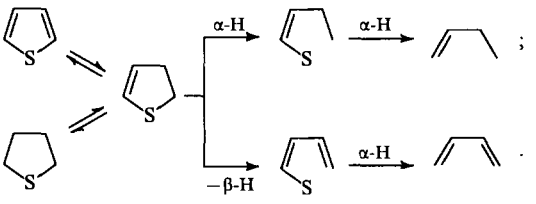
$$H_2S \longrightarrow HS^- + H^+,$$

$$2\,HSO_3^- + H_2S \longrightarrow S_2O_4^{2-} + S + 2\,H_2O,$$



$$2\,HSO_3^- + 2\,HS^- \longrightarrow S_2O_4^{2-} + S_2^{2-} + 2\,H_2O,$$

$$S_2^{2-} + 2\,SO_2 \longrightarrow S_2O_4^{2-} + 2\,S,$$

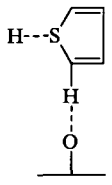


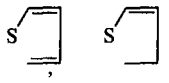
$$SO_2 + H_2O \longrightarrow HSO_3^- + H^+.$$

Polymers of the S_8 type, which behave both as products and as intermediates, were also observed. The same products were found when the oxidiser SO_2 was replaced by oxygen.

The hydrogenation and the hydrodesulfurisation of thiophene on a 10% MoO_3/Al_2O_3 catalyst were studied by IR spectroscopy.[135,136] Thiophene weakly adsorbed on the OH groups was observed, together with carboxylates and thiocarboxylates. These may be the intermediate compounds. Thiophane is not an intermediate compound, and therefore we may assume that breaking of the C–S bond precedes the hydrogenation:

According to thermal desorption data[137,138] the key intermediate in the hydrogenation of thiophene on $Co–Mo–O/Al_2O_3$ is dihydrothiophene, which (depending on the hydrogen pressure and on the temperature) can be converted into thiophene, thiophane, and the reaction products. Butene can be formed from the dihydrothiophene intermediate by the two-stage hydrogenation of the α-carbon with simultaneous breaking of the C–S bonds, whereas β-elimination in the first stage and α-hydrogenation in the second stage give butadiene:





It may be assumed that the hydrogenation–dehydrogenation reactions take place on centres of one type, and the hydrodesulfurisation reactions on centres of another type. The main weakness of the published work[135–138] is the failure to allow for the contribution to the reaction from the sulfur atoms of the sulfide catalyst. It was shown[139] that under the conditions of the reaction on MoS_2/Al_2O_3 a strong exchange of sulfur takes place between H_2S and MoS_2.

The reaction of methanol with H_2S on Al_2O_3 and WO_3/Al_2O_3 was studied by NMR.[140] It follows from the analysis of the NMR spectra taken after the reaction that CH_3O and CH_2S groups are present on the surface. It is suggested that CH_3SH is formed by the interaction of the CH_3O and HS surface groups, and $(CH_3)_2S$ by the interaction of CH_3O and CH_3SH.

The data on the intermediate compounds in reactions involving sulfur are summarised in Table 8.

Table 8. Intermediate compounds in reactions involving sulfur.

XI. Conclusion

In our previous reviews[1,2] an attempt was made to describe the results of studies of the surface complexes formed in heterogeneous catalysis carried out during the past 15 years using modern experimental methods. Our aim was to cover the largest possible number of investigations, but because of the rapid developments in this field of catalysis the task was not easy. Some general conclusions can be drawn from the data which have been assembled.

(1) In spite of our critical assessments of the reliability of the contributions made by various intermediate states there is little doubt that in the great majority of cases the confidence level is not high. The most convincing evidence that an observed surface compound is an intermediate in the reaction is the coincidence of the rates of transformation of the surface complex and of formation of the product. Only few studies adopting this approach have been reported, mainly because of the great experimental difficulties. The most serious of these difficulties is the need for simultaneous measurements of the spectroscopic and the catalytic characteristics of the system. Another difficulty is the need for quantitative spectroscopic measurements. This requires a knowledge of the extinction coefficients or of the scattering coefficients in the surface complexes, and information of this type is scarce. However, we should stress the fact that this approach is being strongly developed at the Institute of Chemical Physics of the Russian Academy of Sciences.

(2) Both the spectroscopic and the kinetic measurements of the consumption of reactants and of the accumulation of products in the gas phase usually have an unacceptably low time resolution. In order to create a complete picture of the mechanism we require faster measurements, at least in the millisecond range (i.e. at the lower limit of the time constants in catalysis). This calls for the development of new methods of measurement. One of the most promising of the new methods is the use of the TAP reactor.

(3) Many different surface compounds are formed when a given reaction is carried out on different catalysts. Even in the case of similar catalytic systems different workers report different surface complexes. This is usually attributed to differences in the reaction mechanism. However, another possible explanation[141] suggests that for a given mechanism the relative rates of the different stages may be different on different catalysts. As a result we may observe different surface complexes on different catalysts. Of course, in order to test this explanation we require detailed information on the intermediate compounds formed in a given reaction on different catalysts.

(4) By analogy with empirical dependences such as the Polanyi–Semenov rule, which describes the relationship between the energy of a bond and the activation energy of the reaction, it has been possible to establish general dependences relating the activation energy of a reaction to the decomposition energy of the intermediate complexes. In some cases, when the structure of the intermediates on the surface is close to the structure of the final products, we observe a lowering of the activation energy. However, data of this type are still too few to provide unambiguous conclusions.

(5) Often spectroscopic studies detect surface compounds which are formed on an active part of the catalyst but then migrate towards an inactive part. A characteristic of these compounds is their lack of sensitivity (or low sensitivity) towards changes in the reaction parameters (temperature, pressure, composition of the components). Typical of this behaviour is the accumulation of surface compounds on a carrier, on one of the phases of a mixed catalyst, or on one of the faces of a simple catalyst by the spillover mechanism. The accumulated surface compound can 'feed' the main reaction when the process conditions are changed. In complex multistage reactions this accumulation can produce the transport of molecules from some active centres towards others, spatially separated from the former.

(6) The data presented in our review show that the mechanisms proposed for heterogeneous catalytic reactions, though plausible, are largely conjectural. Obviously, this state of affairs is due to the almost total absence of reliable information on the intermediate compounds. Therefore we may finally conclude that further progress in our understanding of heterogeneous catalysis calls for a systematic study of intermediates.

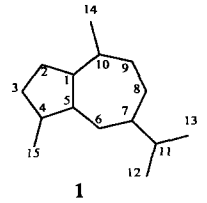
Approaches to the total synthesis of sesquiterpenoids of the guaiane series

B T Zhuzbaev, S M Adekenov, V V Veselovskii



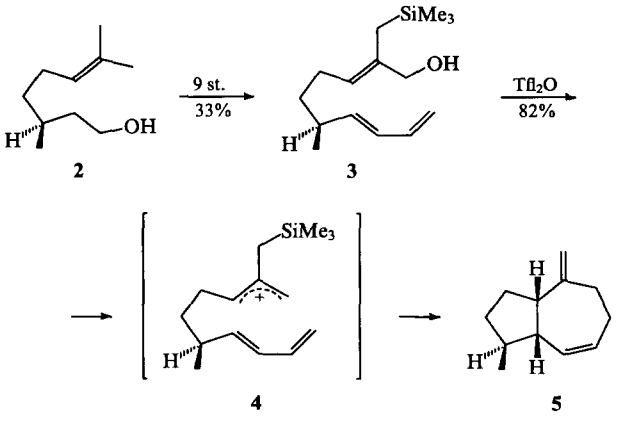
Contents

I. Introduction	187
II. Synthesis of guaiane sesquiterpenoids by the skeletal isomerisation of mono-, bi-, and tri-cyclic precursors	188
III. Pentacondensation of cycloheptane derivatives	194
IV. Heptacondensation of cyclopentane derivatives	197

Abstract. The approaches to the synthesis of guaiane sesquiterpenoids are considered. Attention is concentrated on the most general methods for the construction of their hydroazulene carbon skeleton. The bibliography includes 91 references.

I. Introduction

The guaiane series sesquiterpenoids **1**, which are widely distributed in nature,[1–4] are interesting objects to chemists engaged in synthesis. The development of research into their synthesis has also been stimulated by the discovery of many-sided biological activity in numerous representatives of compounds of this class.[4–6]



1

The present review includes data obtained on the synthesis of guaiane sesquiterpenoids (GS) mainly during the last 10–15 years as well as earlier studies which have not been adequately described in review articles[7–12] and a monograph.[13] Virtually all the known methods of synthesis of GS can be divided into three groups: (1) skeletal isomerisation of mono-, bi-, and tri-cyclic precursors; (2) pentacondensation of derivatives of cycloheptane; (3) the construction of the hydroazulene skeleton from suitably functionalised cyclopentanes. Two novel methods, based on the intramolecular cationoid [4 + 3]- and [3 + 2]-cycloadditions, remain outside the limits of this classification.

According to the first of these,[14,15] the hydroazulene **5** is formed from the intermediate **4**, generated from the allyl alcohol **3**—a product of the nine-stage (9 st.) transformation of (*S*)-citronellol **2**. In view of the high stereoselectivity of the formation of the hydroazulene **5**, the use of this procedure may prove exceptionally effective for the construction of the molecules of *cis*-joined GS.[15]

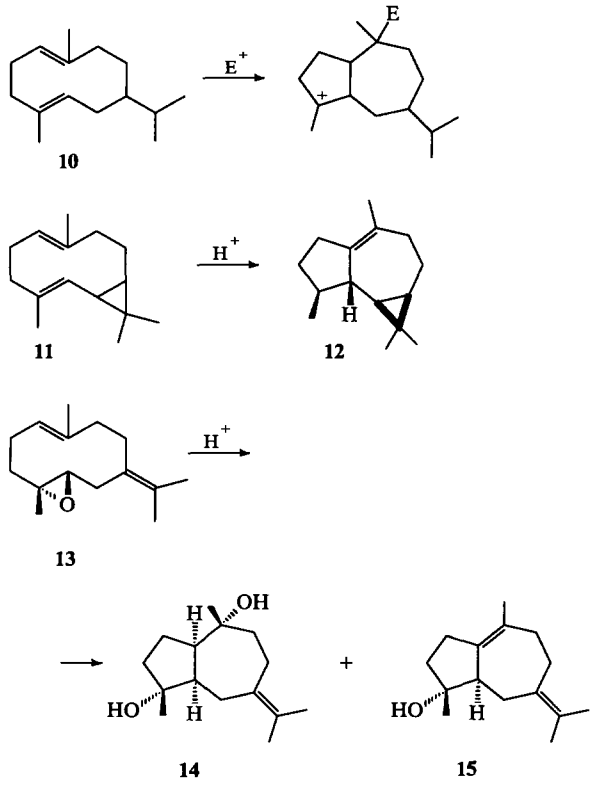
2 **3** **4** **5**

Tfl = trifluoromethanesulfonyl.

In the second method, the key stage of the synthesis of (±)-β-bulnesene **9**[16,17] is the stereospecific conversion of the dihydropyranone **6** into the *trans*-joined hydroazulone **8**, probably via the pyrylium intermediate **7**.

6 **7** **8** **9**

DBN = 1,5-diazabicyclo[4.3.0]non-5-ene.

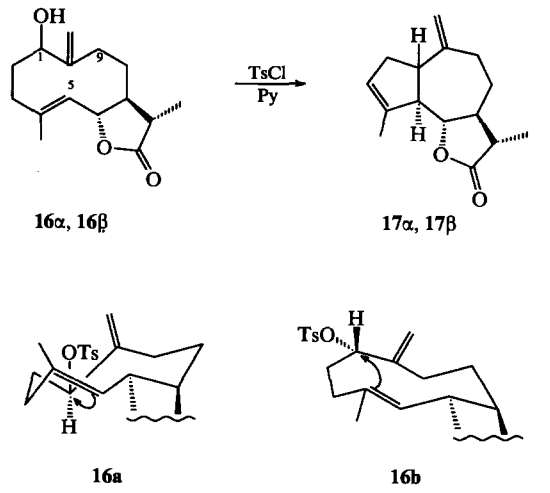


II. Synthesis of guaiane sesquiterpenoids by the skeletal isomerisation of mono-, bi-, and tri-cyclic precursors

This approach is used at present fairly widely. It proved particularly effective in the partial synthesis of guaianolides from germacrane and eudesmane sesquiterpene lactones.

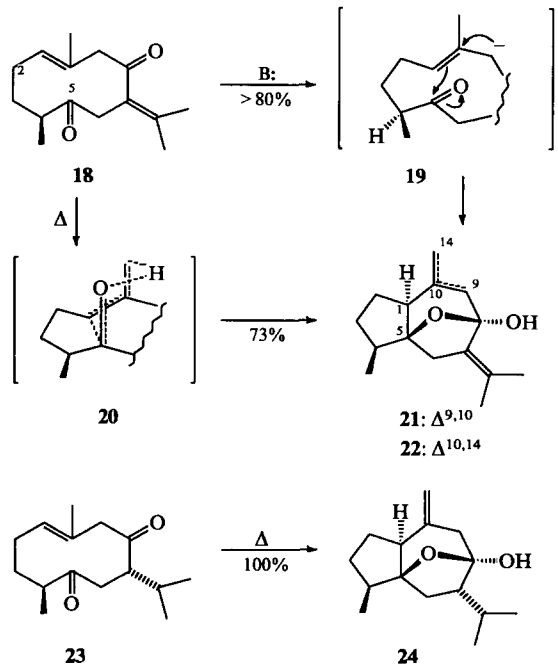
1. Transformation of cyclodecane derivatives resembling biogenesis

According to Hendrickson,[18] the key stage in the biogenesis of GS is the anti-Markovnikov electrophilic cyclisation(EC) of their germacrane precursors of type **10** (Scheme 1).



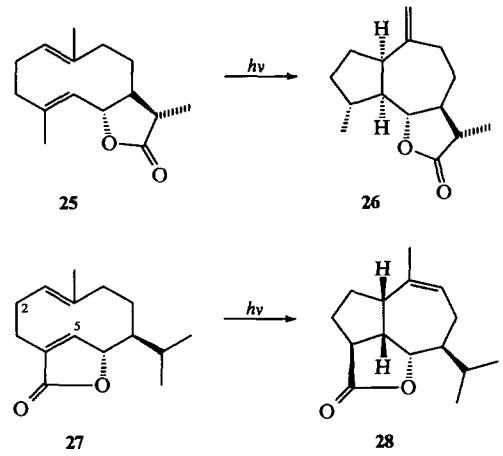
Scheme 1

This hypothesis stimulated a vigorous search for equivalent models. The result of such search has led to the development of a large number of biogenesis-like schemes for the synthesis of GS.[12,19] One of the early examples of the use of this approach is based on the acid-initiated conversion of bicyclogermacradiene **11** into a mixture of tricyclic products with a significant predominance of guaiane **12**.[20] Another example of the anti-Markovnikov electrocyclisation in the series of germacranes is the transformation of the epoxide **13** into a mixture of the diol **14** and the alcohol **15**.[21]



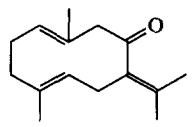
Analysis of the stereochemical results of such transformations permits the conclusion that the biomimetic reaction, proceeding via a concerted mechanism, is subject to conformational control.[12] This is confirmed, for example, by the results of the solvolytic electrocyclisation of gallicin **16β**[22] and of its C(1)-epimer **16α**,[23] which proceeds readily under the conditions of the tosylation of the secondary alcohols indicated (Scheme 2). The product of the cyclisation of gallicin **16β** is then the *cis*-joined guaianolide **17α**, the stereospecificity of the formation of which is evidently due to the preferred conformation **16a** of the initial allyl alcohol (and of its tosylate) with the equatorial orientation of the leaving group and with the disposition of the C(1), C(4), and C(5) centres in close proximity in space. The solvolysis of the epimer **16α**, leading to *trans*-**17β**, is treated taking into account the fact that the conformer **16b** is preferred.

Scheme 2



Rigid stereochemical control is also characteristic of the thermal or base-catalysed cyclisation of $\Delta^{1,10}$-5-ketogermacranes — the probable biogenetic precursors of the *trans*-joined 5-hydroxyguaianes.[12,24,25] Thus, on treatment with K_2CO_3 in methanol or with basic Al_2O_3 in benzene, the dehydrocurdione **18** is smoothly converted into the curcumenol **21**, evidently via a stage involving the formation of the allyl carbanion **19** (Scheme 3).[24] Its regioisomer **22** has been obtained in a high yield from the dehydrocurdione **18** under the conditions of the thermal reaction proceeding in accordance with a mechanism of the ene type via the probable transition state **20**. The thermolysis of the curdione **23** leads similarly to the curcumol **24** also without epimerisation of the centre adjoining the carbonyl group.[25]

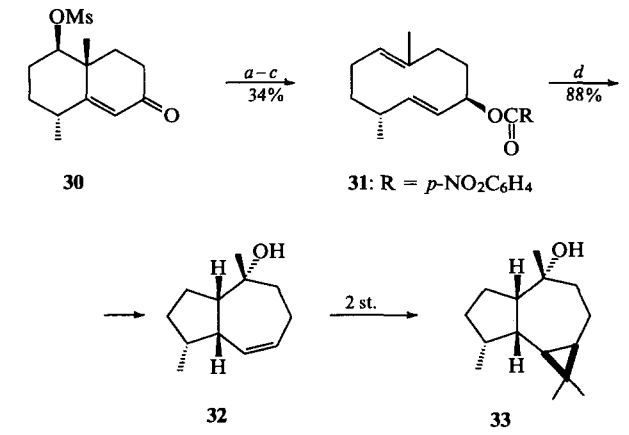
Scheme 3



Individual examples of the stereospecific photocyclisation of compounds of the germacrane series to GS have been described. In particular, it has been shown that the sole product of the photolysis of dihydrocostunolide **25** is the *cis*-joined guaianolide **26**.[26] The irradiation of the germacranolide **27** leads similarly to the tricyclic lactone **28** (Scheme 4).[27]

Scheme 4

There are at present no reliable methods for the oxidative transformation of the functionalised germacrane skeleton into the guaiane skeleton. In a study recently undertaken for this purpose,[28] it has been shown that treatment of the germacratrienone **29**



29

with a solution of $Pb(OAc)_4$ in acetic acid results in the formation of a complex mixture of substances containing predominantly unsaturated *cis*-guaiane ketoacetates.

It is noteworthy that the syntheses of GS considered above, based on the transformation of germacranes which are difficult to obtain, are hardly of preparative value. The approach, developed by Marshall,[29] by virtue of which the type **31** cyclodecadienes, which are related to germacranes, become obtainable from decalin derivatives **30**, is of definite interest. For example, the Grob fragmentation of the methanesulfonate **30**, initiated by a strong base, readily affords the trisnorderivative of germacrane, the solvolysis of which in the form of the nitrobenzoate **31** leads stereospecifically to the hydroazulenol **32**, which is subsequently converted into (±)-globulol **33**.[30]

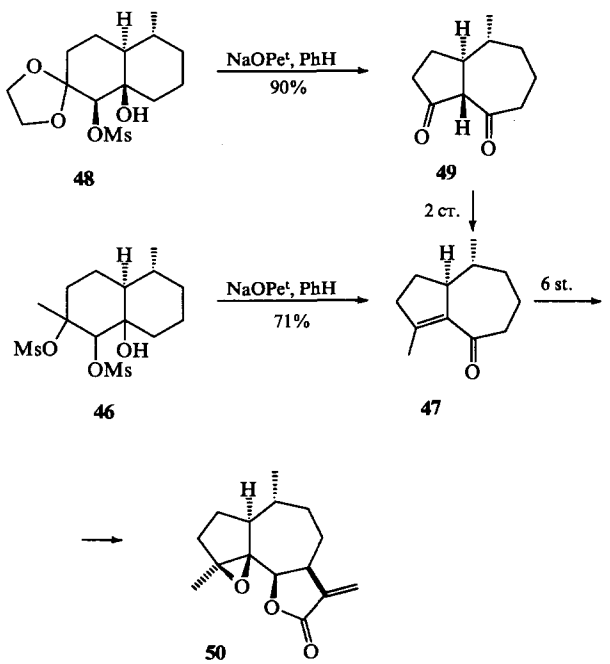
(*a*) BH_3; (*b*) NaOMe–MeOH; (*c*) p-$NO_2C_6H_4COCl$; (*d*) $NaHCO_3$, H_2O–$C_4H_8O_2$.

2. Skeletal rearrangements of derivatives of bicycloalkenes

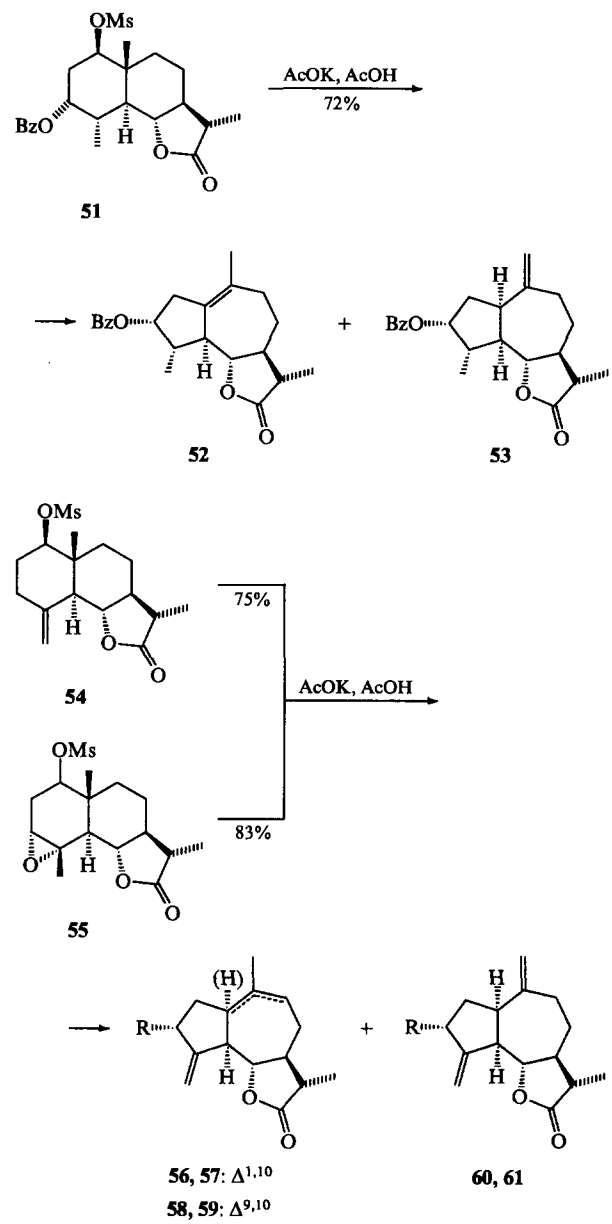
The skeletal rearrangements of bicycloalkenes as a method for the construction of GS molecules has been studied mainly in relation to decalin derivatives, among which sesquiterpenes of the eudesmane series occupy an important place. One of the first examples of the application of this approach is the photoisomerisation of α-santonin **34** and some of its C(8)-derivatives to the corresponding type **35** guaianolides observed by Barton.[31,32] The latter are used subsequently in the partial synthesis of many natural products.[33] The stereospecific nature of the rearrangement, noted also for the photolysis of cross-conjugated tetrahydronaphthalenes related to compound **34**,[34–38] makes it possible to regard this procedure as a reliable means of obtaining the hydroazulene precursors of GS and some of their natural representatives. For example, the guaianolide **36** has been synthesised in this way from α-santonin **34**.[39] Data are available concerning the use of a series of derivatives of α-santonin **34** for the synthesis of (−)-estafiatin.[40]

Scheme 6



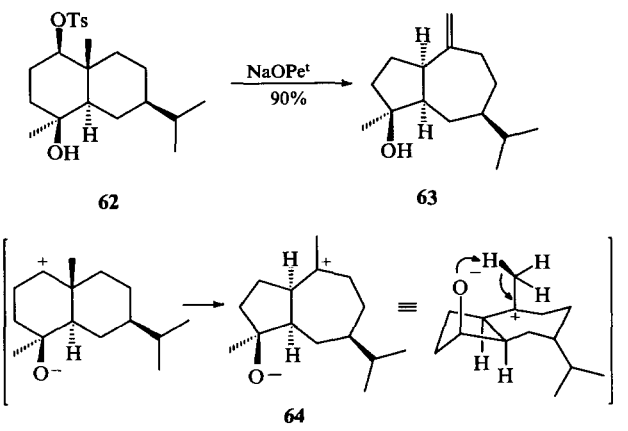
The methodology described above proved effective also in the syntheses of the bulnesenes **40** and **42** (Scheme 6), the key stage of which is the photolysis of the α- and β-dienones **38**, leading to the epimeric guaianes **39** and **41** respectively.[41,42] [The α- and β-dienones are obtained in their turn from (+)-dihydrocarvone **37** by Robinson's method.]

The dihydro-analogues of guaianes **39** and **41**, synthesised by the same procedure from the enones **43**, have been used in the synthesis of the corresponding stereoisomeric aldehydes **44** and **45** with the *trans*-joined hydroazulene skeleton.[43]



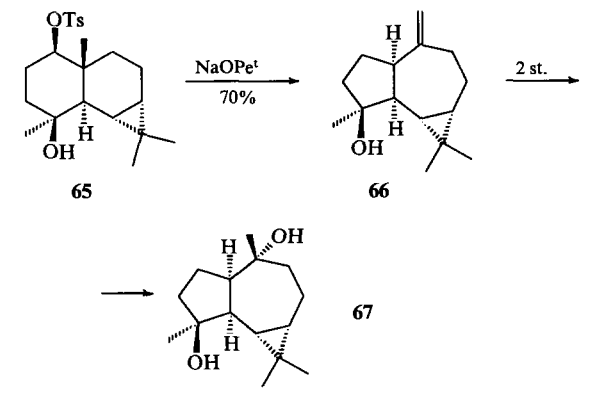
An alternative procedure, ensuring the stereospecific formation of the hydroazulene precursors of GS from perhydronaphthalenes, uses the solvolytic rearrangement of suitably functionalised derivatives. For example, a scheme for the total synthesis of the guaianolide **50** is based on a pinacol type rearrangement of the sum of the diastereoisomeric methanesulfonates **46**, leading to the hydroazulenone **47**. The latter can also be obtained from the diketone **49** — the product of the solvolysis of the methanesulfonate **48**.[44,45]

Pe^t = *tert*-pentyl (Translator).



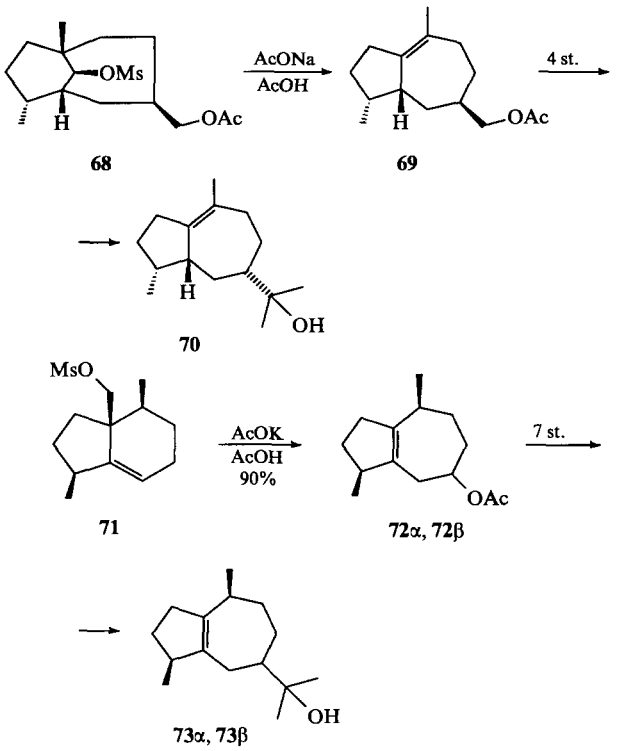
The synthesis of diverse representatives of guaianolides from α-santonin **34** similarly involves the use of the skeletal isomerisation of the α-santonin derivatives **51**, **54**, and **55**.[46-50] It was found that the solvolysis of these methanesulfonates by potassium acetate in acetic acid leads to mixtures of the corresponding regioisomeric hydroazulenes *endo*-**52**, **56**–**59**, and *exo*-**53**, **60**, **61** in comparable proportions (Scheme 7).

Scheme 7

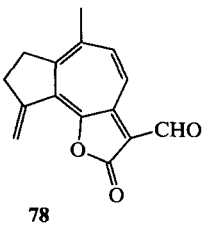


The observation by de Groot and coworkers[51-53] that the *tert*-pentyloxide-initiated skeletal rearrangement of type **62** tosylates leads to a virtually quantitative yield of *exo*-methylene products, in particular to (±)-epi-nardol **63** (Scheme 8), is of special interest in this connection.

Scheme 8



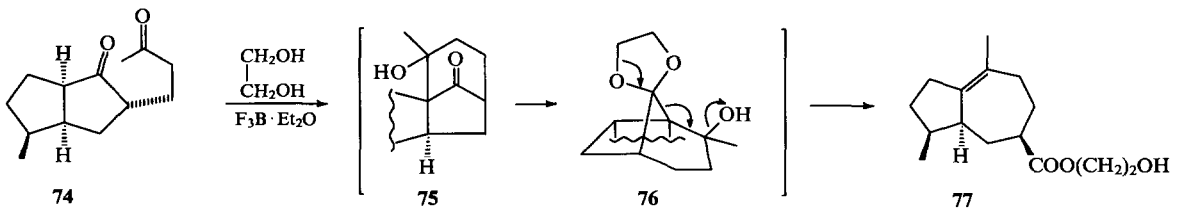
The significant increase in the regioselectivity of the reaction in this case can be accounted for by the presence in compound **62** of an axial hydroxy-group at the C(4) atom, its deprotonation and the involvement of the resulting alkoxide ion in the intramolecular elimination of a proton from the carbonium ion **64**, which leads to the alkene **63**.



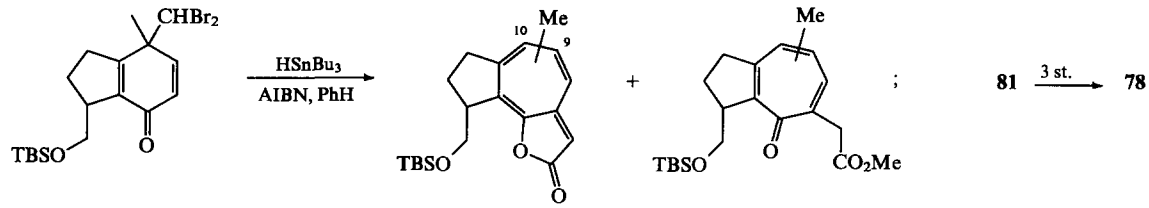
The isomerisation of the tricyclic tosylate **65** [53] leads similarly to the exclusive formation of the guaiane **66** — the key compound in the total synthesis of the natural diol **67**.

Thus the skeletal isomerisation of decalins is used fairly widely in the synthesis of hydroazulenoids. The use for this purpose of the skeletal rearrangement of other bicycloalkanes is so far restricted to only isolated examples (see also Heathcock and coworkers [8,9]). For example, the solvolysis of the bicyclic methanesulfonate **68** leads to smooth formation of the hydroazulenoid **69** from which (±)-bulnesol **70** was subsequently obtained. [54] In the scheme for the total synthesis of the guaiol **73β** and its epimer **73α**, the solvolytic isomerisation of the bicyclo[4.3.0]nonane derivative **71** to a mixture of the epimeric acetates **72** was employed as the key stage. [55]

Another novel method of synthesis of bulnesol **70** is based on the ability, observed by Sakai and coworkers, [56] of type **74** δ-diketones to undergo a rearrangement with ring expansion leading to cycloheptane derivatives under the conditions of the $F_3B.OEt_2$-initiated formation of an ethylene ketal. This reaction of the diketone **74** evidently includes the formation of the intermediate aldol **75** and the ethylene ketal of the β-hydroxyketone **76** and the cleavage of the latter to the hydroazulene **77** on treatment with a Lewis acid (Scheme 9).



Mention must also be made of the recently developed scheme for the synthesis of the guaiane phytoalexin lettucenin A **78**, [57] in which use is made of the known ability of the type **79** dibromomethylcyclohexadienones to be converted into substituted tropones on treatment with $HSnBu_3$ (in the presence of a source of radicals).



In the case of the hexadienones **79**, this reaction leads to a mixture of products **80–83** (Scheme 10) with compound **81** predominating. The latter was converted into the guaianolide **78** in three simple stages.

Thus the use of the skeletal isomerisation of bicycloalkanes is a fairly universal strategy applicable to the synthesis of a wide variety of representatives of GS.

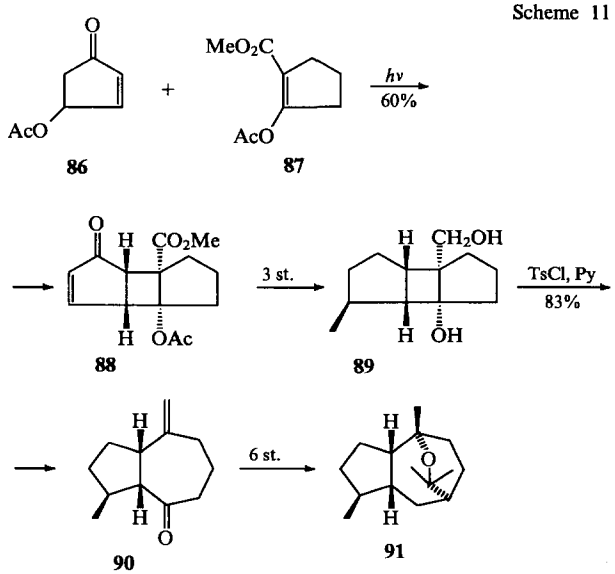
TBS = Bu^tMe_2Si.

3. Skeletal isomerisation of tricyclodecanes

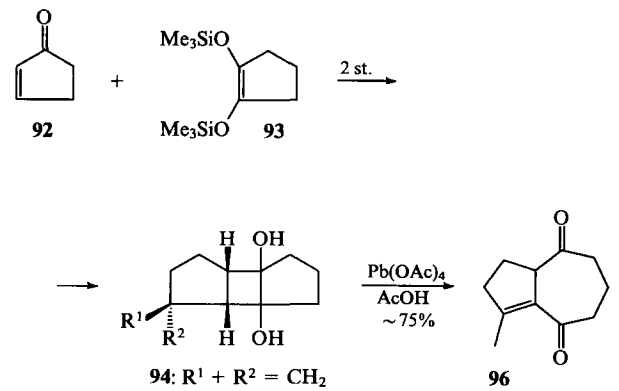
The skeletal isomerisation of functionalised tricyclodecanes, involving the degradation of their cyclobutane fragment, serves as an effective method of synthesis of GS. The likely usefulness of this approach was first demonstrated by de Mayo and co-workers [58] in relation to the two-stage synthesis of the diketone **85** involving the retroaldo type of cleavage of the photoadduct of cyclopentene and cyclopentadione enol acetate.



84 85

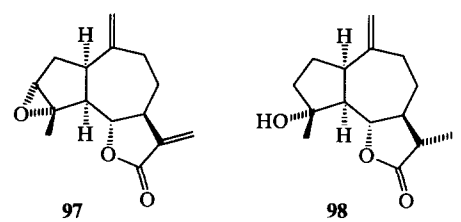
An evident advantage of this approach is the availability of compounds of type **84**, which have been synthesised by the [2 + 2]-cycloaddition of simple initial materials.

Thus the photochemical [2 + 2]-cycloaddition of substituted cyclopentenes **86** and **87**, leading predominantly to the cyclic adduct **88**, has been used in the total synthesis of (±)-5-epikessane **91** [59] in order to construct the carbon skeleton of the key tricyclodecane **89**. Next the enone **88** was converted in three stages, including the Michael methylation which proved stereospecific in this instance, into the diol **89**. The latter was smoothly cleaved under the conditions of the solvolysis into the hydroazulenone **90** — the precursor of (±)-5-epikessane **91** (Scheme 11).



Scheme 11

86 87 88 89 90 91

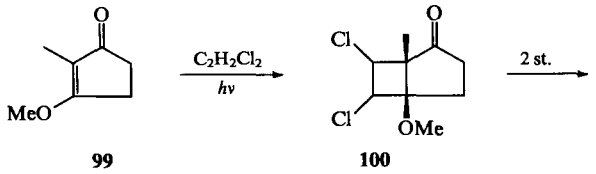


The tricyclic diol **94** and the triol **95** were obtained similarly from the cyclopentene derivatives **92** and **93**. The oxidative degradation of the diol and triol, accompanied in the case of the triol **95** by the degradation of the tertiary alcohol, affords smoothly the diketone **96** (Scheme 12).

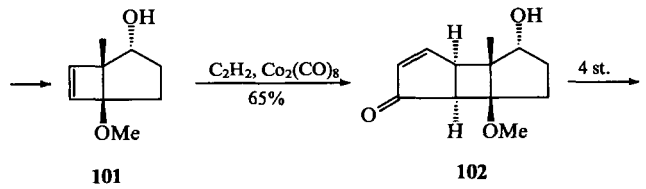
Scheme 12

92 93 94: $R^1 + R^2 = CH_2$ 95: R^1 = Me; R^2 = OH 96

The diketone was then used in the synthesis of (±)-estafiatin **97** and (±)-compressanolide **98**. [60-62]

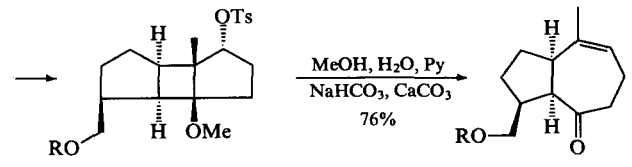


97 98



An alternative method of synthesis of the type **84** tricyclodecane compound has been used successfully in the synthesis of a GS precursor — the hydroazulenone **104**. [63] Thus the key stage in the synthesis of the hydroazulenone **104** is the formation of the tricyclic enone **102** under the conditions of the Pauson–Khand reaction of ethyne with the bicycloheptene **101**, which is formed in its turn from the photoadduct **100** of the methoxycyclopentenone **99** and *trans*-1,2-dichloroethene.

Yet another variation of this approach is the use of intramolecular [2 + 2]-cycloaddition in order to construct tricyclic precursors of hydroazulenoids. It was first demonstrated by Pattenden and coworkers [64] in relation to the photolysis of the enol acetate **105**.



The effectiveness of this scheme in the synthesis of the hydroazulene **108** proved, however, to be low in view of the low regioselectivity of the photocyclisation of the enol acetate **105**, leading to a mixture of the isomeric tricycloalkanes **106** and **107** in proportions of approximately 3:2, and only the minor component **107** gives rise to the target diketone **108** on retroaldol cleavage.

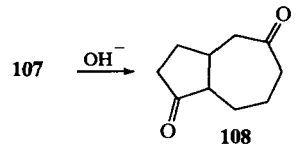
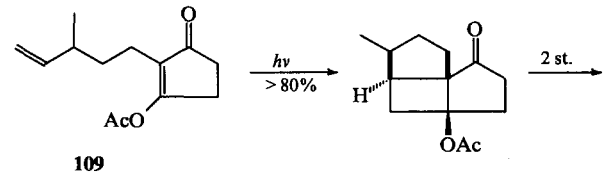
103 104



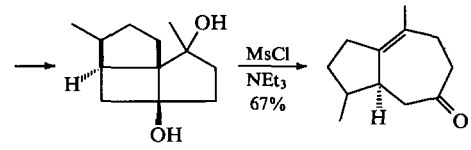
R = $SiPh_2Bu^t$.

105

106 107

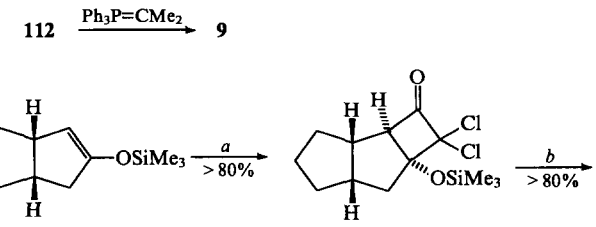


108



The photochemical [2 + 2]-cycloaddition of the enol acetate **109** takes place regiospecifically and leads to the sum of the epimeric tricyclodecanes **110** in a yield exceeding 80%.[65] The latter are then converted into the diols **111**, which are smoothly converted under the conditions of the solvolysis into a mixture of the epimeric hydroazulenones **112** in proportions of approximately 3:1. The conversion of the ketones **112** into the corresponding alkenes afforded the epimeric (±)-β-bulnesenes **9**.

An interesting development of this methodology arose in a recent study by Korean chemists,[66] who synthesised a series of hydroazulenones (compounds **116**, **120**, and **124**) from the readily available silyl vinyl ethers **113**, **117**, and **121**. The thermal [2 + 2]-cycloaddition of the latter to the dichloroketene generated in situ leads regio- and stereo-specifically to the tricyclic dichloro-derivatives **114**, **118**, and **122**. The reduction of the latter with Bu^n_3SnH in the presence of azobisisobutyronitrile (AIBN) leads to the tricyclodecanes **115**, **119**, and **123**, which are cleaved almost quantitatively under the conditions of mild desilylation by F^-, affording the diketones **116**, **120**, and **124** respectively.



Thus an attractive feature of this approach is the possibility of its use from readily available starting materials, the choice of the key tricyclic structure ensuring the necessary functionalisation of the hydroazulene precursor of GS formed on its isomerisation.

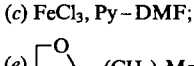
III. Pentacondensation of cycloheptane derivatives



The strategy in the synthesis of GS based on the construction of their hydroazulene skeleton by the pentacondensation of cycloheptane derivatives was first employed as late as 1982.[67] Its subsequent development arose from effective methods being devised for the synthesis of suitably functionalised cycloheptane precursors. Thus Heathcock et al.[67] synthesised the cycloheptenone **127** from the cyclohexenone, which was converted, via the silyl vinyl ether **125** stage, into the bicyclic compound **126**. The latter underwent skeletal isomerisation to the cycloheptenone **127** (Scheme 13). The CuI-catalysed Michael coupling of the enone **127** and the Grignard reagent **128** takes place stereoselectively and leads to a mixture of the isomeric ethylene ketals **129** (*trans*:*cis* ≈ 4:1). Under the conditions of mild hydrolysis and as a result of the accompanying intramolecular crotonic condensation, the latter are smoothly converted into the epimeric hydroazulenes **130** in the same proportions.

Scheme 13

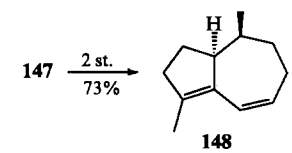
(*c*) $FeCl_3$, Py–DMF; (*d*) NaOAc, MeOH;

(*e*)  (**128**), CuI, THF; (*f*) 5% HCl, EtOH.

This methodology may acquire special interest in connection with the recent studies by Brocksom et al.,[68] who used the industrially available (+)-menthene **131** in order to synthesise the bicycloheptane **132**. The oxidation of the regioisomeric alcohols **133** and **134**, formed on skeletal rearrangement of compound **132** catalysed by Ag^+ ions, affords smoothly the chiral cycloheptenone **135** as the sole product.

In a recently published study,[69] the cycloheptenones **142** and **143**, related to the ethylene ketals **129**, were obtained by isomerisation under solvolytic conditions of the bicyclo[3.2.0]-heptane derivatives **140** and **141** respectively (Scheme 14).

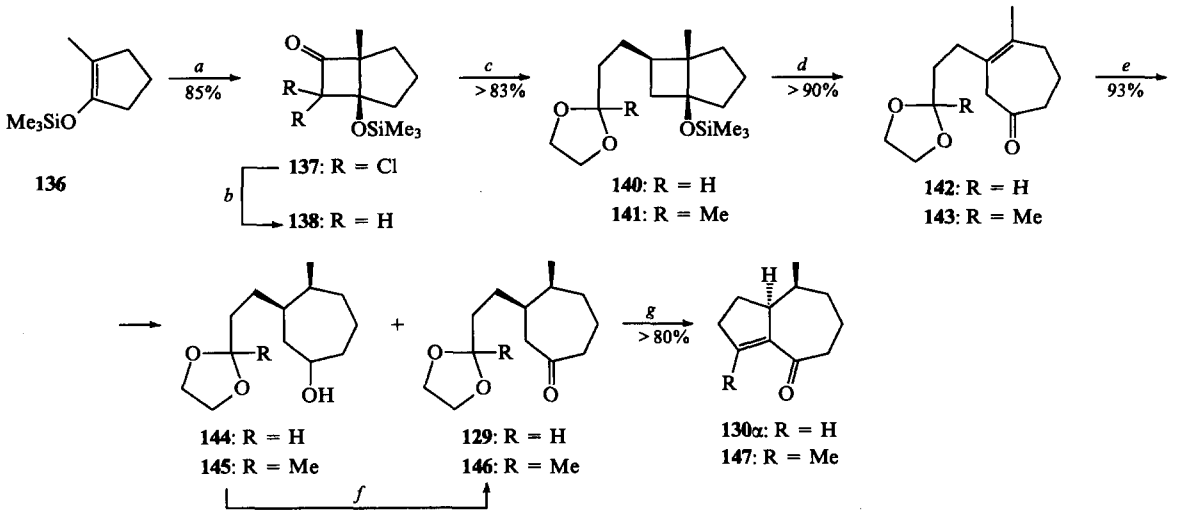


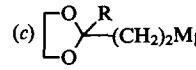
The latter proved to be obtainable by means of the thermal [2 + 2]-cycloaddition of dichloroketene to the silyl vinyl ether **136**.[70] The dehalogenation of the resulting bicycloheptanone **137** by Bu^n_3SnH in the presence of AIBN and the coupling of the resulting ketone **138** with the corresponding organomagnesium reagents **128** and **139** leads to compound **140** and **141**. The hydrogenation of the alkenes **142** and **143** over a rhodium catalyst, accompanied by the partial reduction of the ketones **129**

(*a*) $CHBr_3$, $C_{16}H_{34}Me_3N^+Br^-$; (*b*) $AgNO_3$, Me_2CO-H_2O (9:1);

(*c*) $C_5H_5N^+H\,ClCrO_3^-$, CH_2Cl_2.

and **146** to the alcohols **144** and **145**, and then cyclisation of the latter led ultimately to the hydroazulenone **130α** described above and the azulenone **147** — the key compound in the synthesis of (±)-clavukerin A **148**.





Mori and coworkers[71] developed a novel scheme for the total synthesis of the guaiane **159**. Compound **152**, a cycloheptene precursor of compound **149**, was obtained in 14% yield from alkylglutaric acid **149** via the intermediate bisdiazodiketone **151**, which cyclises to the enedione **152** in the presence of copper acetylacetonate (Scheme 15). The product of the hydrogenation of compound **152** — the cycloheptanedione **153** — was then converted into the monoketal **154**, the regio- and stereo-selective alkylation of which by the bromo-derivative **155** and subsequent ozonolysis of the resulting alkene **156** led ultimately to the diketone **157**. On treatment with a base, the latter cyclises smoothly to the hydroazulenone **158**, the eight-stage transformation of which afforded the target product (±)-**159**.

The γ-diketone **167**, structurally related to the diketone **157** and employed recently[72] in the total synthesis of (±)-gnididione **168**, was synthesised from methylglutaric acid anhydride **160** (Scheme 16). The ketodiester **162** was obtained by coupling compound **160** with the dilithium derivative **161**. It was subsequently converted into the hydrazone **163**, which underwent smoothly the Dieckmann condensation with formation of the bicyclic compound **164**. The alkylation by the bromo-derivative **166** of the ketone **165**, obtained from compound **164**, required the use of a double excess of the deprotonating agent and afforded the required diketone **167** as the sole product, which exists in the enolic form.

Yet another aspect of the approach under consideration, the development of which appears especially attractive, involves the use of the industrially available 2,4,6-cycloheptatrienone (tropone) as the starting material for the synthesis of GS. This methodology was first applied by Rigby and coworkers[73–75] in the total syntheses of (±)-estafiatin **97**, (±)-dehydrocostus-lactone **169**, and (±)-grosshemin **170**, which are discussed in detail in two reviews.[11,13]

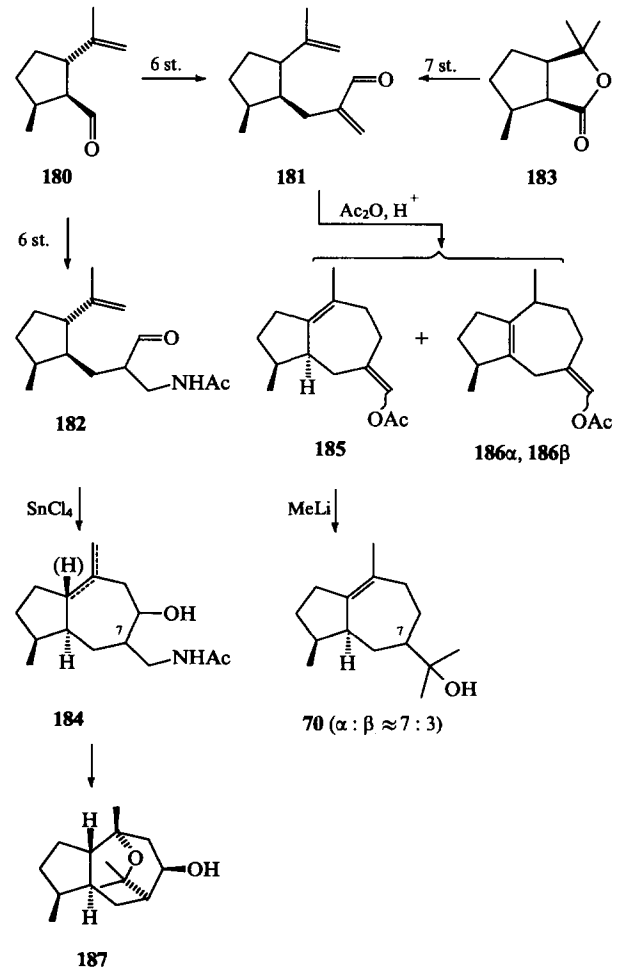
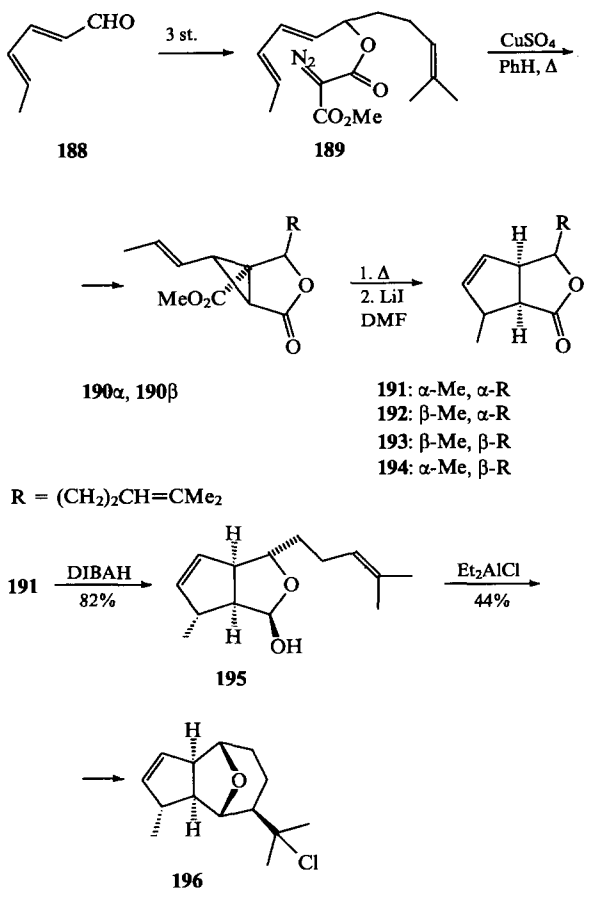
The principal stages of the syntheses of these compounds are presented in Scheme 17. Thus the hydroazulene precursor of the guaianolides **97** and **169** — the epoxide **172** — was obtained as a result of the $F_3B.OEt_2$-catalysed cyclisation of the aldehyde **171**.[73] The known ability of tropone to interact with organometallic reagents via the 1,8-addition mechanism is used in its turn to synthesise the aldehyde **171**. The tricyclic compound **174**, which is of key importance in the synthesis of grosshemin **170**, was obtained similarly. It is a product of the $Cu/CuSO_4$-catalysed cyclisation of the diazoketone **173**.[74]

Scheme 17

Yet another synthetic scheme, based on the 11-stage transformation of tropone into (±)-cyclocolorenone **179**,[76] involves the condensation of the silyl ether **175** with the cationoid complex **176**. The resulting diastereoisomeric adducts **177** were converted into a mixture of epimeric γ-diketones **178** (*cis*: *trans* ≈ 8:1) by successive demetallation and hydration in the presence of Hg^{2+}. The dominant component, compound *cis*-**178**, was isolated chromatographically and was smoothly cyclised to the target product **179** by treatment with a base.



Thus examples of the application of this strategy in the synthesis of GS considered in this section demonstrate the possibility of its successful use to obtain diverse natural products from readily available starting materials.



IV. Heptacondensation of cyclopentane derivatives

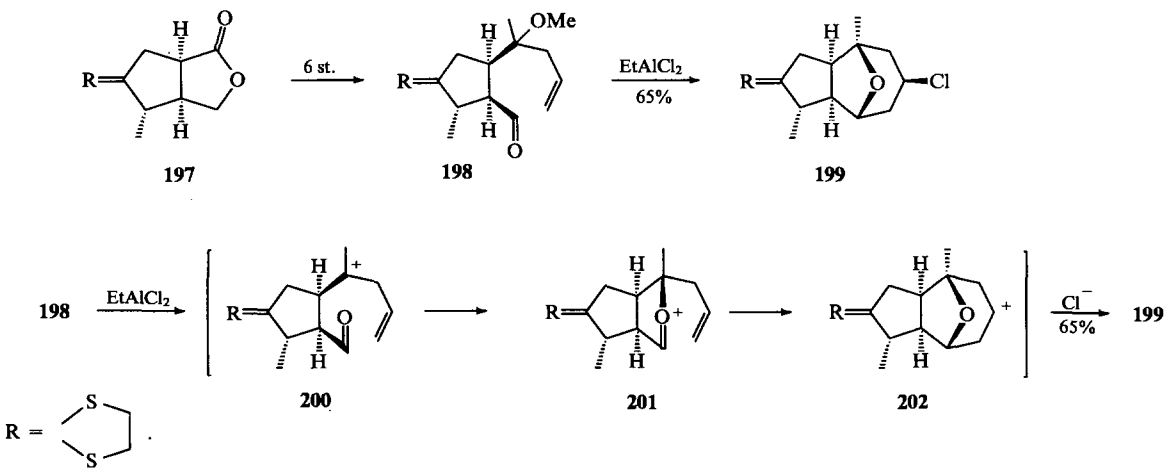
In contrast to the approach described in the previous section, the present one involves the construction of the hydroazulene skeleton of the GS by the closure to a seven-membered ring of the side chains of suitably functionalised cyclopentane precursors. For example, Andersen and coworkers, who were the first to apply this strategy in the total synthesis of certain natural guaianes,[77–79] used the unsaturated aldehydes **182** and *trans*- and *cis*-**181** as the cyclopentane precursors. The aldehydes **182** and *trans*-**181** were synthesised from the product **180** of the photocyclisation of citral, while compound *cis*-**181** was obtained from the lactone **183**. The principal results of these investigations, which have been analysed in a review,[9] are illustrated by Scheme 18.

Scheme 18

Scheme 19

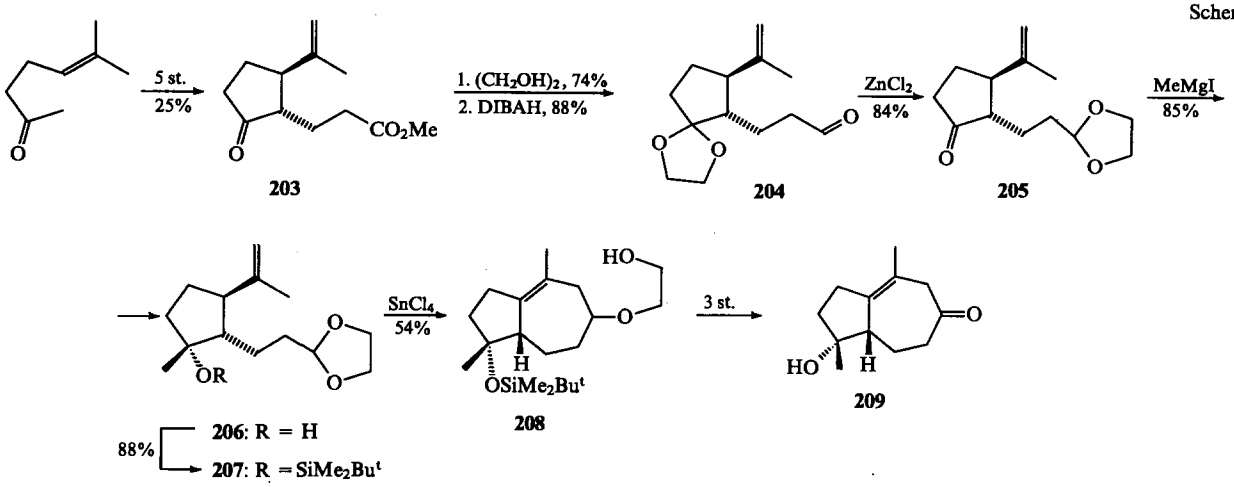
In particular, the regioselectivity of the electrocyclisation of the unsaturated aldehyde *trans*-**181** proved to be low, which significantly reduced the overall effectiveness of the synthesis of (±)-bulnesols **70**. The latter were obtained as a result of the further transformation of the hydroazulene precursor **185**, which predominates in the **185**:**186**α ≈ 2:1 mixture.[77] The unsaturated aldehyde *cis*-**181** is cyclised similarly, affording the sum of the regioisomers **185** and **186**β (~3:1).[78] The intramolecular version of the Prins reaction also leads to a mixture of the regio- and stereo-isomeric hydroazulenoids **184** in the case of the aldehyde **182**. *exo*-Methylene 7α-epimers, employed subsequently in the synthesis of (±)-kessanol **187**, were isolated chromatographically and their overall yield was ~40%.[79]

In order to develop further this methodology, Hudlicky et al.[80] investigated the possibility of obtaining the guaiane structures from the bicyclic hemiacetal **195** synthesised from a suitably substituted diazoketone **189** (Scheme 19). The diazoketone **189**, prepared from sorbaldehyde **188**, cyclises smoothly in the presence of Cu^{2+} ions with formation of the epimeric cyclopropanolides **190** (α:β ≈ 2:1), which can be readily separated chromatographically. Each of them undergoes subsequent thermolysis and demethoxycarbonylation, which results in the formation of **191**:**192** ≈ 2:1 and **193**:**194** ≈ 3:1 mixtures of the stereoisomeric cyclopentanolides. The possibility of using lactones of this type as the precursors of GS has been demonstrated in relation to the lactone **191**, which was isolated chromatographically in a pure state. It was reduced by diisobutylaluminium hydride (DIBAH) to the hemiacetal **195**, which cyclises stereospecifically to the hydroazulenoid **195** on treatment with Et_2AlCl.



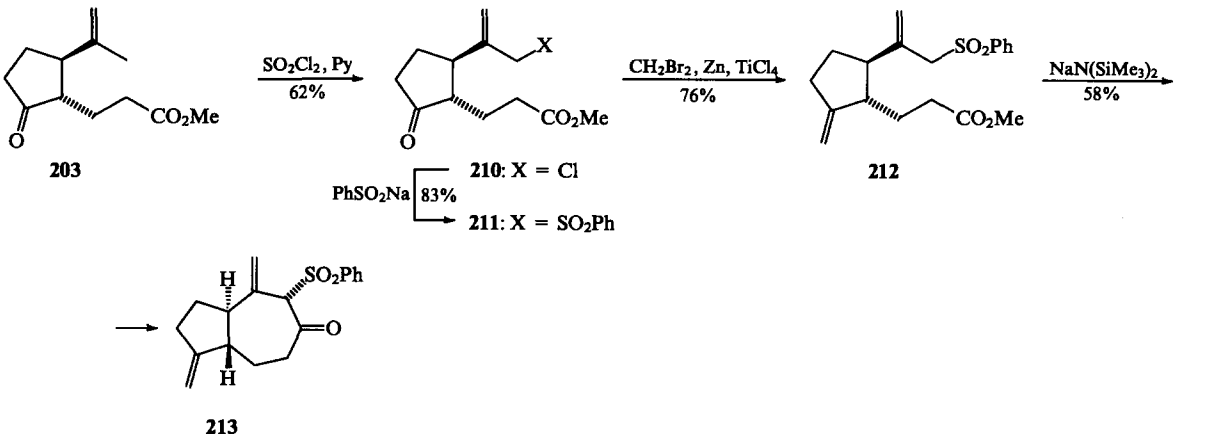
The intramolecular Prins reaction of the unsaturated aldehyde **198**, obtained from the chiral cyclopentanolide **197**,[81] was recently used similarly[82] in the enantioselective synthesis of the hydroazulenoid **199**, homochiral with respect to grosshemin **170** (Scheme 20). The formation of the enantiomerically pure hydroazulenoid **199** as the only product of the cyclisation of the mixture of the diastereoisomers of compound **198** can be explained by their initial cleavage on treatment with $EtAlCl_2$ and by the stabilisation of the cation **200**, arising as a result of such cleavage, in the form of the oxonium ion **201**. The electrophilic attack by the latter on the multiple bond in the side chain of the same molecule and the interaction of the resulting carbonium ion **202** with the excess $EtAlCl_2$ lead ultimately to the chloro-derivative **199** in ~65% yield.

Two variants of the heptacondensation of substituted cyclopentanes have been achieved using the *trans*-ketoester **203**, obtainable from methylheptenone, as the monocyclic precursor of the GS.[83] Thus the cyclopentanone **203** was initially converted into the ethylene ketal, the reduction of which by DIBAH affords smoothly the aldehyde **204** (Scheme 21).[84]

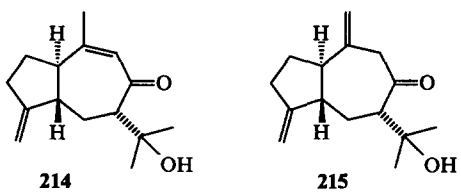


The attempt to cyclise the latter under the conditions of the Lewis acid-catalysed Prins reaction unexpectedly led to the product of intramolecular transketalisation — the ketone **205**, which was subsequently converted into the silyl ether **207** in two stages, including the reaction with MeMgI, which proved to be highly stereoselective. Treatment of the silyl ether with $SnCl_4$ leads to the bicyclic product **208**, the conversion of which into the hydroazulenone **209** is carried out in three stages.

A shorter route to the formation of guaiane structures from the ketoester **203** proved possible[85,86] via the Dieckmann intramolecular cyclisation of the sulfonecarboxylate **212** (Scheme 22). The latter was obtained from the ketoester **203** in three stages via the chloroderivative **210** and the sulfone **212**. Treatment of the sulfonecarboxylate **212** with sodium *N*,*N*'-bistrimethylsilylamide in benzene leads stereospecifically to the hydroazulenone

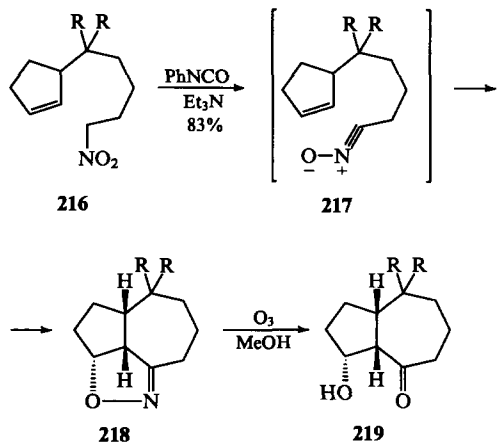


Scheme 20



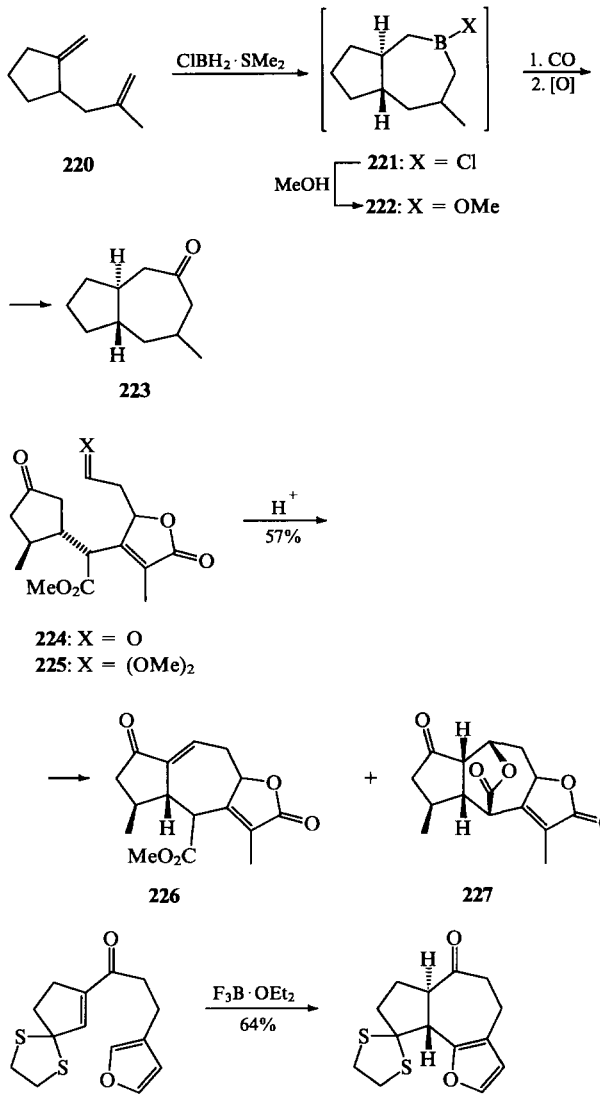
Scheme 21

Scheme 22



213, which was used further in the synthesis of the ketoalcohols 214 and 215 having the guaiane skeleton.

Among other known methods for the heptacondensation of substituted cyclopentanes, a novel procedure, employed in the synthesis of the hydroazulenone **219** and involving the intramolecular [3 + 2]-cycloaddition of the nitrile oxide **217** generated in situ from the nitroalkene **216**, may be of definite interest for the synthesis of the hydroazulene precursors of GS.[87]

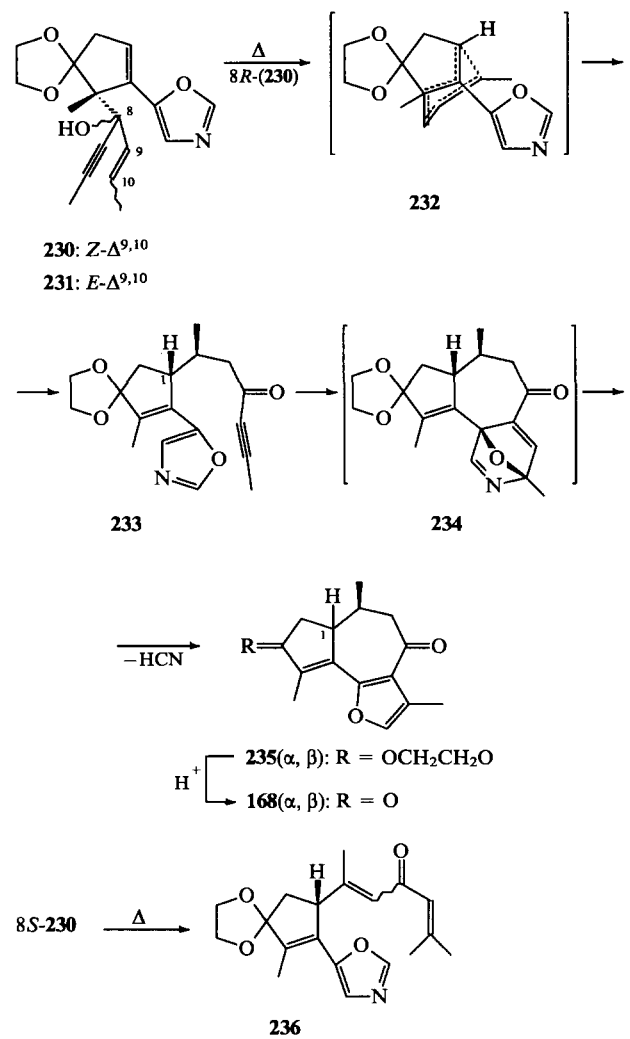


Yet another variant of a nontraditional attainment of the same aim has been recently demonstrated by Stevenson and Bryson.[88] The hydroboration of the diene **220** by $ClBH_2.SMe_2$ leads to the smooth formation of the boracyclane **221**, the conversion of which into the hydroazulenone **223** has been achieved by means of standard carbonylation.

The scheme for the total synthesis of guaianolides proposed by Winterfeldt and coworkers,[89] in which the stage involving the cleavage of the acetal **225** to the aldehyde **224** by CF_3COOH is accompanied by the formation of the diastereoisomeric enones **226** and an insignificant amount of the transesterification product **227**, is based on the intramolecular crotonic type condensation of the ketoaldehyde **224**.

R = CO_2Me

It is noteworthy that the heptacondensation of substituted cyclopentanones, carrying in the side chain a lactone ring already formed or its synthetic equivalent, is regarded nowadays[89–91] as a promising approach to the construction of the tricyclic skeleton of guaianolides and related furanoterpenoids. One of the variants of the application of this strategy consists, for example, in the electrocyclisation of the cyclopentane derivative **228**, terminated by a furan substituent, which affords the furanohydroazulenone **229** as the only product.[90]



220 223 226 227 228 229

The recently published study[91] on the total synthesis of (±)-gnididione **168**, the key stage of which is the intramolecular [4 + 2]-cycloaddition of the oxazole **233** — the product of the oxy-Cope rearrangement of the tertiary alcohol **230**, is of interest in this connection (Scheme 23). It was found that the formation of the chair-shaped transition state **232**, leading to the secohydroazulenoid **233**, is favoured by the (*R*)-configuration of the C(8) centre of the carbinol **230**. In the case of the thermolysis of the (*S*)-carbinol **230**, the preferential formation of the dienone **236** is observed. The dienone arises as a result of the involvement of the ethyne fragment of the molecule of compound **230** in the rearrangement. Under more severe conditions, the transformation of the carbinol **230** is not limited to the formation of the oxazole **233**, which is converted as a result of the thermal [4 + 2]-cycloaddition into the unstable cyclic adduct **234**, cleaved subsequently to give the target furanoterpenoid in the form of its ethylene ketal **235β**. It is noteworthy that the relative configuration of the substituents at the C(1) atom of the ketal **235** is controlled by the (*Z*)-geometry of the butenyl residue of the initial alcohol **230**. It was found that, when the carbinol **231** with a transoid $\Delta^{9,10}$ bond is used, the above sequence of reactions makes it possible to obtain the C(1)-epimer of gnididione **168β** — the hydroazulenoid **168α**.

* * *

Scheme 23

In conclusion one should note that the search for the specific syntheses of sesquiisoprenoids of the guaiane series makes a significant contribution to the development of the fundamental and methodological aspects of modern organic chemistry. In addition, further studies in this field are of current interest, because they make it possible to discover reliable sources of these terpenoids, which are difficult to obtain from natural raw materials, as well as their analogues, including compounds which are of definite interest for medicine and agriculture.

V.	Other methods for the direct synthesis of coordination compounds	216
VI.	Conclusion	217

Abstract. Data on the direct synthesis of coordination compounds from zerovalent metals and organic ligands are surveyed and described systematically. The preparation of metal complexes in the gas and liquid phases is considered. It is shown that the direct syntheses are single-stage processes and make it possible to obtain all types of coordination compounds — molecular and π-complexes, metal chelates, and dinuclear and polynuclear structures. Problems of competitive reactions in the course of the direct synthesis of complexes of ambident ligand systems are discussed. The bibliography includes 289 references.

I. Introduction

A wide variety of methods are used nowadays to synthesise coordination compounds.[1-5] Metal complexes are obtained mainly by the direct interaction of the components (the ligands and a source of the complex-forming metal),[1-7] as a result of ligand[6-8] and metal[6] exchange, and under the conditions of template synthesis,[7-10] which includes also the method of nascent reagents.† In the reactions listed above, the source of the metal is either its salts or carbonyls.‡ At the same time, it has long been known that coordination compounds may be obtained as a result of direct synthesis from zerovalent metals. The possibility of employing compact metals for the synthesis of coordination compounds was first demonstrated by Gerdes[11] and Chugaev,[12] who obtained metal complexes during electrolysis. Methods for the synthesis of complex compounds under the conditions of gas-phase reactions,[13-15] oxidative dissolution of zerovalent metals in nonaqueous media,[16,17] and in the solid phase[18,19] were developed subsequently. These methods became the basis of a new field in synthetic chemistry — the direct synthesis of coordination compounds and organometallic compounds from zerovalent metals. Particular aspects of this problem have been described in a series of reviews.[13-17,20-25] and monographs.[4,26-28] However, on the whole the direct synthesis of metal complexes has not been dealt with in the review and monograph publications on coordination chemistry.[2-5]

The aim of the authors of the present review was therefore to survey the current data on the direct synthesis of coordination compounds from zerovalent metals and organic ligands. Attention was concentrated on the types of ligand systems and the complexes formed during these reactions.

In describing the data, we adhered to the classification of coordination compounds put forward in a previous review.[29] According to this classification, metal complexes are divided into molecular complexes, chelate complexes, π-complexes and polynuclear structures. Such a classification does not conflict with the subdivision of the complexes employed in modern coordination chemistry (see, for example, Kostromina et al.[5]).

In describing the problems of the direct synthesis of coordination compounds from zerovalent metals and organic ligands, we decided to employ individual postulates and references from earlier reviews[13-15] and monographs.[26]

† The formation of ligands under the conditions of formation of a complex from the components on a metal matrix.

‡ The modification of the complexes is widely carried out in the template syntheses.[7-10]

II. Gas-phase synthesis

1. Methods, conditions, apparatus, and reagents

Coordination compounds are obtained in the gas phase in a vacuum apparatus via the direct interaction of the vapour-phase atomic metals and ligands.[14,15,20,21,26,30-36] However, these reactions are restricted by the stability of the complexes in a high-temperature medium: they are frequently accompanied by the decomposition of the coordination compounds and reactions of the ligand systems (see, for example, Domrachev and Zinov'ev's review[15]). For this reason, greatest effectiveness is attained in gas-phase synthesis when metal and ligand vapours are condensed at low temperatures (cryosynthesis).[13-15,25,26,30,31] The range of working temperatures is usually from 10 to 273 K although in isolated instances both high (295 – 325 K)[37-39] and low (~4 K)[40] temperatures have been used.

Cryosynthetic reactions have been considered in reviews[25,41] and in a monograph.[42] It has been emphasised[41] that cryosynthesis involving gaseous metals is an irreversible process, since extremely high supersaturations of the vapour phase with respect to the metal are employed in it. The metal vapour obtained at high temperatures (2000–2500 K) is transported in vacuo as a stream of atoms which react at low temperatures with the condensed ligand phase.

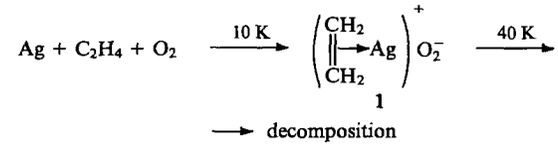
The mechanism of the co-condensation of atomic metals with ligand systems has been considered in relation to the direct synthesis and decomposition of dibenzenechromium.[15] It was shown that the reactions occurring with formation of dibenzenechromium from gaseous chromium and solid, liquid, or gaseous benzene at 77, 298, and 1000 K respectively are thermodynamically allowed. The elementary steps in the synthesis–decomposition reactions of diarene complexes have been considered in two publications.[43,44]

The apparatus for the direct synthesis of metal complexes in the gas phase is on the whole simple in design, since it comprises the usual high vaccum systems.[15,45,46] Different versions of the apparatus differ as regards different solutions of the problem of the evaporation of the metal and of the supply of the ligand to the reaction chamber.

The technology of the vaporisation of metals has been developed quite satisfactorily. This process is achieved mainly by four methods:[15] (1) from a resistively heated evaporator; (2) as a result of the induction heating of the container with the metal; (3) by electron bombardment; (4) by exposing the metal specimen to a laser beam. The advantages and disadvantages of each of the above methods of preparation of metal vapours and the procedures for the supply of ligands to the reaction chamber and for the isolation of the coordination compounds formed in the direct syntheses have been considered.[15] The vaporisation methods indicated make it possible to obtain virtually all the metals of the Periodic System,[13–15,26] including refractory metals (chromium, molybdenum, and tungsten),[14,15,30,31,34,47–50] in the vapour phase.

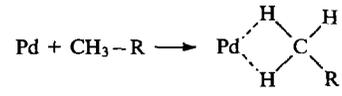
Organic systems, mainly unsaturated, aromatic, and heteroaromatic compounds and their derivatives, are used as the ligands in the gas-phase synthesis. Taking into account the maximum possible number of electrons which a ligand of the unsaturated hydrocarbon type can give up to the metal, it is useful to differentiate among such ligands monoalkenes,[14,15,26,37–40] dialkenes,[14,15,26,30,51–54] and cyclic dienes[13–15,26,51,55–57] and trienes.[57] Ethyne and its derivatives are also used as ligand systems.[14,15,20,26,37,53,54] Aromatic hydrocarbons, especially benzene and its derivatives,[14,15,47–49,58–62] as well as heteroaromatic ligand systems such as thiophene[26] and pyridine[15,17,26,30,63] are most widely used among the ligands for the gas-phase synthesis of coordination compounds.

Apart from the compounds listed above, oxygen-containing organic derivatives are used as ligands—ethers,[26] ketones (especially acetone),[53,64] β-diketones,[15,35,36] organic acids,[15] and their anhydrides[15] and chlorides.[14]



Two types of reactions occurring in the gas phase with formation of metal complexes have been differentiated[15]—reactions involving the addition of metal atoms and reactions involving the insertion of metal atoms in a C–X bond (X = H or a halogen).[15] The first embrace a wide range of the ligands listed above and comprise reactions leading mainly to the formation of π-complexes. Reactions of the second type are accompanied by the formation of organometallic compounds with metal–carbon σ-bonds.[15,25,26,31,32,65]

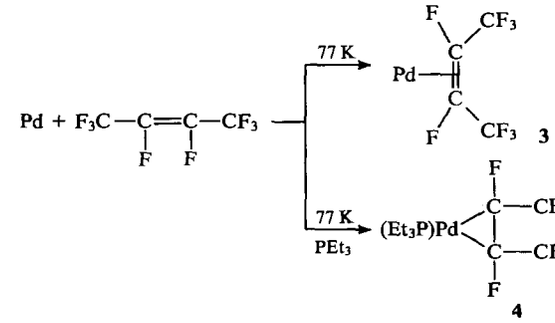
2. Coordination compounds



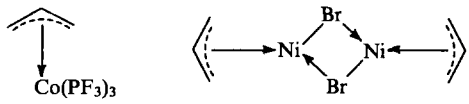
a. Gas-phase synthesis of π-complexes

The metal complex compounds obtained by gas-phase synthesis comprise mainly two types: π-complexes and metal chelates.

The simplest π-complexes have been synthesised by the reaction of metal vapours with alkenes (monoalkenes). The co-condensation of silver and ethene vapours in the presence of oxygen at 10 K leads to an unstable ethenesilver complex **1**, which decomposes on heating to 40 K.[26]

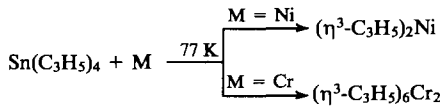


The ethene complexes of copper (argon, 295 and 325 K, pressure 50–600 Torr),[37] nickel (helium),[40] and palladium (helium, 300 ± 5 K, 0.5–0.8 Torr)[38] have been described. The kinetics of the gas-phase reactions of neutral transition metal atoms with alkenes have been investigated in relation to interactions of yttrium, molybdenum, zirconium, and niobium with ethene, propene, butene, and isobutene.[39] The effective rate constants for the above reactions have been found (helium, 300 K, 0.5–0.8 Torr) and it has been shown that under these conditions yttrium, zirconium, and niobium react rapidly with the above alkenes, while molybdenum reacts slowly.[39] Kinetic data indicating the interaction of monoalkenes with 3*d* and 4*d* metals have been published.[38,40,53] Thus the syntheses of scandium, titanium, vanadium, and nickel complexes of alkenes have been reported.[38] The same communications give the effective rate constants for the interaction of nickel and palladium with ethene, propene, and but-1-ene at a pressure of 0.5–0.8 Torr in helium. The formation of stable adducts of palladium with alkanes, to which the structure of the donor–acceptor π-complexes **2** has been attributed, is especially emphasised. These complexes do not fit within the framework of the ideas concerning the usual π-complexes.



2

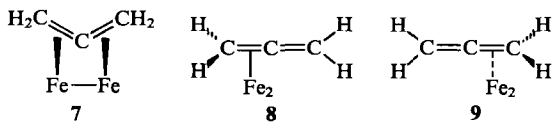
The interaction of ethene with iron results in the formation of 1 : 1 adducts,[53] while its interaction with copper affords 1 : 2 adduces.[37] The copper complex has been characterised thermodynamically. It is noteworthy that there are no X-ray diffraction data in the literature for the metal complexes with alkenes obtained by gas-phase synthesis. Therefore the ideas developed by Caroll et al.[39] and the schematic donor–acceptor model of the metal–alkene bond put forward by them are useful for the understanding of the mode of coordination of the metal in the alkene complexes. The σ-interaction makes a significant contribution to this bond. The interactions, not only with alkenes but also with their halo-derivatives, lead to π-complexes. Thus a reaction in which the coordination compound **3** is formed from perfluorobutene has been described in a monograph.[26] The same process in the presence of triethylphosphine leads to the σ-complex **4**.[14,15] However, the structures of complexes **3** and **4** cannot be regarded as rigorously demonstrated.



Gas-phase reactions of alkenes and haloalkenes with metals, accompanied by the formation of π-allyl complexes, are known. In particular, the interaction (at 77 K) of propene with atomic cobalt in the presence of phosphorus trifluoride results in the formation of the π-allyl complex **5**.[26,30] The reaction of bromopropene with atomic nickel at 77 and 298 K leads to the bisallyl derivative **6**.[26]

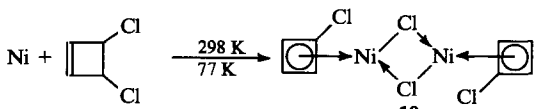
5 **6**

Organometallic compounds can serve as sources of the allyl ligand, which is indicated by the formation reactions of the π-allyl complexes of nickel and chromium.[15,26]

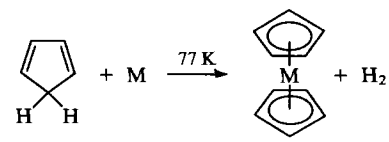


Acyclic diene hydrocarbons form in the gas phase a series of π-complexes in which the unsaturated ligands function predominantly as η^4-donor molecules.[14,15,17,26,30,51-53,66] The main bulk of these complexes have been synthesised from buta-1,3-diene, for which five types of coordination compounds have been differentiated. These have the compositions with metal : diene ratios of 1 : 1, 1 : 2, and 1 : 3 and also metal : diene : another ligand (L) = 1 : 1 : L_n and 1 : 2 : L_n, where L = CO, PF_3, or PR_3. According to Mitchell and Hackett's data,[53] the 1 : 1 complexes are formed in the reaction of buta-1,3-diene with iron at room temperature and a pressure of 100 Torr, while the 1 : 1 : L_n complexes are produced in the reaction of the above diene and trimethyl phosphite.[15] For cobalt and iron, there is a possibility of the formation of 1 : 2 coordination compounds.[15,26] The commonest type of the 1 : 2 : L_n complexes includes those of iron,[14,15,51] cobalt,[15,66] chromium,[14,67] and ruthenium.[52] In particular, ruthenium forms the stable adducts $Ru(\eta^4\text{-}C_4H_6)_2L$, where L = PF_3, CO, and Bu^tNC.[52] The 1 : 3 complexes (M = Mo, W)[15,66] have been characterised by X-ray diffraction. These data indicate equal distances between the molybdenum and tungsten atoms and all the carbon atoms of the butadiene ligand.

The photochemical cryosynthesis of iron complexes with allene in solid argon (10 K) takes place in an unusual manner.[54] The formation of dinuclear iron π-complexes in this process has been detected by Fourier IR spectroscopy.[54]



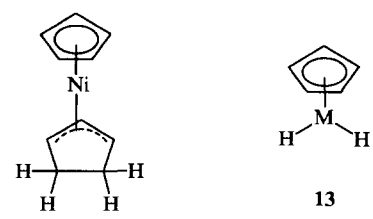
A structure described by formulae **7**–**9** has been proposed for these π-complexes.



7 **8** **9**

The complexes of cycloalkenes occupy an important place among the coordination compounds synthesised in the gas phase from atomic metals.[14,15,26,50,55,57] The cyclobutadiene complexes are represented by compound **10**, which has been obtained as a result of the following reaction:[26]

10

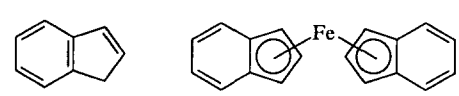


The greatest number of η^5-coordinated complexes having the general formula **11** have been synthesised from cyclopentadiene and its substituted derivatives.[14,15,20,50,55,57,68] During the reaction, the hydrogen atoms are substituted by the metal and the ligand system is aromatised.

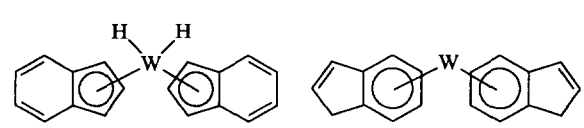
11

M = Co, Fe, Cr, Mo, W.

When atomic nickel is introduced into the process under consideration, the cyclopentadienyl ligand rings undergo intramolecular dehydrogenation-hydrogenation, the product of which is complex **12**.

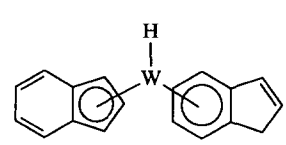


12 **13**



M = Cr, Mo, W.

When cyclopentadiene interacts with atomic chromium, molybdenum, or tungsten, the monocyclopentadienylmetal hydride complexes **13** are formed.[14]



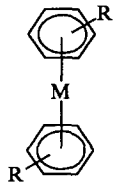
The reactions of indene **14** with iron and tungsten lead to complexes **15**–**18**, a characteristic feature of which is unusual bond isomerism due to the involvement of the cyclopentadienyl and benzene rings in coordination.[26]

14 **15**

16 **17**

18

This interesting phenomenon has been considered in relation to a limited number of systems and its causes are still not clear.



Mixed-ligand carbonylcyclopentadienyl $[C_5H_5M(CO)_2]$, cyclopentadienylpentamethylcyclopentadienyl $(C_5H_5MC_5Me_5)$, and cyclopentadienylethyne $[C_5H_5M(C_2H_2)_2]$ complexes of rhodium and iridium are known.[56]

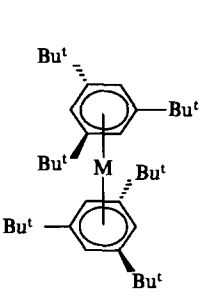
The π-complexes of cyclohexa-1,3-diene (CHD) and cycloocta-1,3- and 1,5-dienes (COD) have been obtained by gas-phase synthesis with participation of atomic metals.[15,26,57] The complexes formed in these reactions have the compositions MLL'_n, ML_2, ML_2L', where L = diene, L' = H, CO, PF_3, PR_3, $Ph_2PCH_2CH_2PPh_2$, or BuNC, and M = Fe, Cr, or Mn.

The complex $Mn(\eta^4\text{-}1,3\text{-}CHD)_2CO$ has been obtained by condensing atomic manganese with cyclohexa-1,3-diene at 77 K and subsequent heating of the condensate to 293 K.[57] Its structure was demonstrated by X-ray diffraction and is therefore not open to doubt.[57] The manganese complexes of cycloocta-1,3-diene $Mn(\eta^5\text{-}C_8H_{11})(CO)_3$ and $Mn(\eta^3\text{-}C_8H_{13})(CO)_4$, in which the ligand system has undergone dehydrogenation-hydrogenation, have been synthesised under the same conditions.[57] The cocondensation reactions of cycloocta-1,3-diene and cycloocta-1,5-diene with metals have been considered in detail in a review[15] and in a monograph.[26] (New publications concerning ligands of this type have not appeared.) Among the results quoted in the above review,[15] the fact that cycloocta-1,3-diene isomerises, on formation of a complex with chromium, to the 1,5-diene ligand system is of greatest interest. X-Ray diffraction showed that the structure of the complex $C_8H_{11}Cr(PF_3)_3H$ is the same as that of (η^4-cyclooctadienyl)hydridotris(trifluorophosphine)chromium.

There are relatively few data on the gas-phase synthesis of π-complexes of cyclotrienes. However, there are no obstacles to such synthesis being achieved: the complexes $[Mn(\eta^4\text{-}C_7H_8)_2CO]$ and $[Mn(\eta^5\text{-}C_7H_9)(CO)_3]$ have been obtained (cryosynthesis at 77 K) from cycloheptatriene (C_7H_8), although the yield was low (5%–8%).[57]

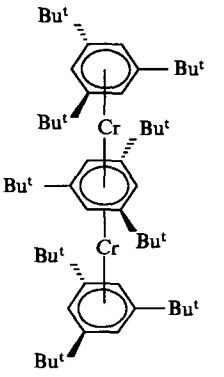
The use of the aromatic benzene system (formally the hexatriene) system, benzene homologues, and substituted benzene derivatives as the ligands has led to extensive possibilities for the gas-phase synthesis of various arene π-complexes. At the present time, arene π-complexes, the structure of which is described predominantly by formula **19**, have been obtained under the conditions of gas-phase synthesis with virtually all transition metals and a wide variety of aromatic η^6-ligand systems.

19



Early publications on the gas-phase synthesis, properties, and structures of type **19** complexes have been surveyed in reviews[13–15,30,47] and in a monograph.[26] Special mention should be made of communication ref. 48 in which 38 diarene sandwich complexes of type **19** (R = F, Cl, CF_3, Alk, OAlk, $NAlk_2$, COOAlk), obtained by the co-condensation of the metal and the ligands at 77 K and a pressure of 5×10^{-4} Torr, have been described. The complexes have been characterised by ^{13}C NMR spectroscopy and their comparative thermal stabilities have been estimated.

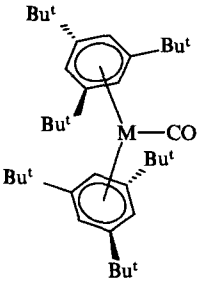
A large number of diarenechromium complexes, including those containing fragments coordinatively active in relation to the metal indicated (the phosphorus atom and the C≡C and C≡N bonds) as well as polynuclear aromatic compounds, have been described in a review.[47]



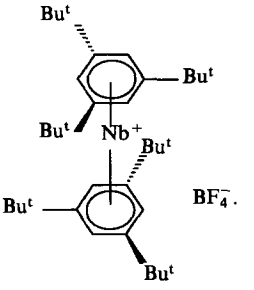
A series of π-complexes containing substituents such as ferrocenyl (yield 1%),[69] PrCO (4%), CH_2Ph (48%), and CH_2CH_2OH (5%) [70] have been obtained.

When the vapours of atomic yttrium, titanium, hafnium, niobium, chromium, molybdenum, and tungsten were heated with 1,3,5-tri-*tert*-butylbenzene, the diarene complexes $M[\eta^6\text{-}C_6H_3Bu^t_3]_2$ **20** were obtained.[59–61] The reactions take place at 77 K and the product yields are 20% (M = W), 30% (M = Cr, Mo), and 40% (M = Y, Ti, Zr, Hf).

In the case of chromium, the triple-decker complex **21** $Cr_2[\eta^6\text{-}C_6H_3Bu^t_3]_2[\mu\text{-}\eta^6 : \eta^6\text{-}C_6H_3Bu^t_3]$ is formed together with the diarene compounds **20** (yield 2%).[61] Reactions of zirconium and hafnium in the presence of carbon monoxide lead to the



20



21

stable 18-electron zirconium adduct **22** and the analogous relatively unstable hafnium complex. The reaction of complex **20** (M = Nb) with $AgBF_4$ in toluene is accompanied by the formation of a tetrafluoroborate complex containing the stable 16-electron cation **23**.

22 (M = Zr, Hf)

23

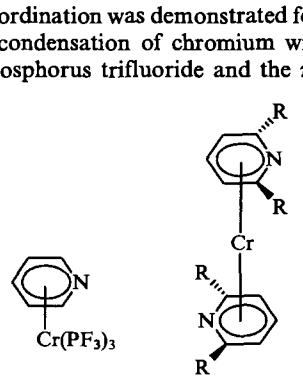
The structures of complexes **20**–**23** have been demonstrated by mass spectrometry and ^1H NMR spectroscopy.[61] The yttrium complex **20** is interesting because it is paramagnetic ($\mu_{ef} = 1.74\ \mu_B$ at room temperature) and gives rise to clear-cut EPR signals in methylcyclohexane solution at 77 K; $g_{\|} = 2.085$ (doublet), $g_{\perp} = 2.005$, and $A = 3.0$ mT for ^{89}Y. X-Ray diffraction studies showed that the complex contains parallel benzene rings and is the first representative of η^6-coordination compounds of zero-valent yttrium.[60]

The chromium complex **19** with a dialkylamino-substituent (R = NMe_2) has been known for more than 20 years[15,48] and its structure has been demonstrated by X-ray diffraction.[71] However, the analogous complex with aniline could not be obtained for a long time. The complex **19** [R = $N(SiMe_3)_2$] has been obtained recently[49] by the co-condensation of chromium with bis(trimethylsilyl)aminobenzene at 77 K. After treatment with tetrabutylammonium fluoride trihydrate in tetrahydrofuran (THF) at 298 K, it affords the dianilinechromium complex **19** (R = NH_2). The reaction described proceeds in accordance with the following scheme:

$$Cr + 2\,PhN(SiMe_3)_2 \xrightarrow[\text{co-condensation}]{77\ K} \longrightarrow \mathbf{19}\,[R = N(SiMe_3)_2] \xrightarrow{Bu_4NF \cdot 3H_2O} \mathbf{19}\,(R = NH_2).$$

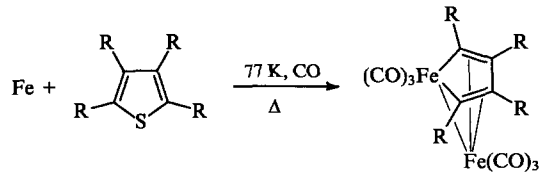
Complex **19** (R = NH_2) with $T_m = 501$ K has been characterised by elemental analysis, ^1H and ^{13}C NMR, and mass spectrometry and its reduction potential and Brønsted basicity have been investigated. It is striking that, in the interaction of di(π-aniline)chromium and its π-*N*,*N*-dimethylaniline analogue with HBF_4 in ether, the nitrogen atoms are protonated.

Diarenemetal π-complexes which had not been introduced previously into the reactions of the type considered, in particular those of titanium, have been synthesised.[49,72] Thus complex **19** (M = Ti, R = Et) has been obtained in ~100% yield by the reaction with ethylbenzene at 77 K in vacuo.[72] The study of the properties of η^6-naphthalenechromium complexes showed that a series of coordination compounds having the general formula (η^6-arene)CrL_3, where arene = $C_{10}H_8$, $C_{10}H_7Me$, or $C_{10}H_6Me_2$ and L = CO, PMe_3, $P(OMe)_3$, or PF_3, have been obtained, in addition to di(η^6-naphthalene)chromium(0), on co-condensation of the metal and naphthalene or its methyl derivatives (L) at 193 K. The complexes have been characterised by ^1H NMR. It is emphasised that atomic chromium interacts with 1,4-dimethylnaphthalene stereospecifically, forming predominantly (up to 95%) the isomer in which the metal is bound to the unsubstituted aromatic ring.



Numerous studies have been devoted to the stabilities, physicochemical properties, and structures of the diarene complexes obtained by gas-phase synthesis (see, for example, Refs 13–15, 26, 30, 49, and 71). The synthesis and decomposition of the diarene complexes have been considered in two investigations.[74,75] The possibility of employing the additivity method to calculate the ΔH for the vapours of the diarene complexes has been demonstrated.[76] Electronic[77,78] and fluorescence[79] spectra of the molybdenum complexes have been obtained and interpreted. The oxidation–reduction properties of the diarene derivatives of zerovalent metals have been investigated.[80]

Apart from the diarene compounds of types **19**, **20**, **22**, and **23**, the monoarene complexes **24** and the cyclopentadienylarene complex **25** have been obtained by gas-phase synthesis.[14,15]



24 (L = PF_3) **25**

Complexes of heteroaromatic systems, obtained by gas-phase synthesis, are represented by the π-complexes of pyridine and its *C*-methyl substituted derivatives. The possibility of the involvement of the heteroaromatic π-system of the pyridine ring in coordination was demonstrated for the first time in relation to the cocondensation of chromium with pyridine in the presence of phosphorus trifluoride and the π-complex **26** was obtained.[30]

The low-temperature interaction of atomic chromium and 2,6-dimethylpyridine led to the sandwich π-complex bis(2,6-dimethylpyridine)chromium **27** (R = Me).[63] Its structure was demonstrated by X-ray diffraction.[81] When trimethylsilylpyridine derivatives were used in the same synthesis, it was possible to obtain di(η^6-pyridine)chromium **27** (R = H).[82] We emphasise that none of the di(η^6-pyridine)metal complexes can be obtained in the usual way.[83,84]

It has been shown in a review[85] that thiophene does not react with zerovalent metals, but a reaction accompanied by the desulfurisation of the heterocycle is known.[26]

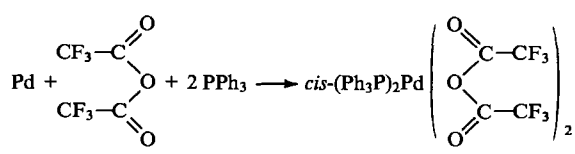
This finding indicates a radical rearrangement of the thiophene system during the complex formation reaction. It must be taken into account in the further studies of the gas-phase syntheses of metal complexes with participation of heteroaromatic systems, the π-donor activity of which is not open to doubt.[85–87]

It has been shown in a review[15] that the gas-phase synthesis with participation of zerovalent metals and alkynes leads mainly to the trimerisation of the ligand systems with formation of benzene and its substituted derivatives. This is also confirmed by the data compiled in a monograph.[26] At the same time, a reaction indicating the formation of metal complexes with alkynes is presented in the same communication.

$$Fe + Me_3Si-C\equiv C-SiMe_3 \xrightarrow{77\ K} Fe(Me_3Si-C\equiv C-SiMe_3)$$

The possibility of obtaining the metal complexes of alkynes in atomic syntheses has been confirmed also in subsequent publications.[20,37,53,54,88] When nickel,[88] iron,[53] and copper[37,88] are co-condensed with ethyne at 10 K, the complexes $M(\pi\text{-}C_2H_2)_n$, where $n = 1, 2$, are formed. It is striking that the iron complex with methylethyne having the same composition has been obtained in the reaction of allene with iron at 10 K (argon, irradiation with visible light).[54] The reaction takes place in accordance with the following scheme:

$$Fe + H_2C{=}C{=}CH_2 \xrightarrow{h\nu} Fe(HC\equiv C-CH_3).$$



The last compound is converted into the σ-complexes $H-Fe-C\equiv C-CH_3$ and $H_3C-Fe-C\equiv CH$ on irradiation with UV light.[54]

It was shown above that the mixed-ligand complex $C_5H_5Mn(HC\equiv CH)_2$ is formed on interaction of ethyne, cyclopentadiene, and manganese under the conditions of cryosynthesis.[56]

The complexes obtained in gas-phase syntheses from atomic metals and oxygen-containing ligands are represented by a relatively small number of examples. Aromatic alcohols, ethers, ketones, and acids behave as the usual η^6-arene ligands, forming substituted di(η^6-arene)metal complexes of type **19** (R = CH_2CH_2OH,[70] OAlk,[14,15] COAlk,[70] or COOAlk,[15] where Alk = Me or Pr). Alcohols form metal alkoxides in the gas-phase synthesis. Stable complexes giving rise to colloidal systems in nonaqueous solutions with a particle size of ~8 nm have been obtained from acetone and atomic palladium. It has been suggested[64] that the following reaction involving the addition of the metal to the ketone takes place:

$$n\,Pd + x\,Me-\overset{\overset{O}{\|}}{C}-Me \xrightarrow{77\ K} Pd_n\left(Me-\overset{\overset{O}{\|}}{C}-Me\right)_x.$$

However, the structures of the reaction products formed have not been studied in detail. An addition reaction also takes place between palladium and trifluoroacetic acid anhydride in the presence of triphenylphosphine.[15]

At the same time, it is known[14] that the interaction of carboxylic acid chlorides with atomic palladium in the gas phase leads to insertion products of the metal in the C–Hal bond.

An example of such a reaction is presented below:

$$Pd + RCOCl \longrightarrow RCOPdCl$$

$R = CF_3$, C_3F_7.

The data presented in this section indicate the extensive possibilities of gas-phase synthesis in the preparation of diverse metal π-complexes.

b. Gas-phase synthesis of metal chelates

The metal chelates synthesised in the gas phase belong mainly to a single class of complexes — transition and nontransition metal β-diketonates. This is due to the high stability of β-diketones and β-diketonates under the conditions of the gas-phase synthesis.[15,36]

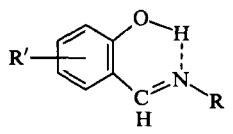
The gas-phase syntheses of metal acetylacetonates having the general formulae $M(acac)_2$ (M = Mn, Fe, Ni, Pd, Cu, Zn, Sn) and $M(acac)_3$ (M = Cr, Fe, Dy, Ho, Er) were described in early communications (see, for example, Domrachev and Zinov'ev[15]). The yields of the complexes obtained by the co-condensation of the vapours of acetylacetone and the atomic metals indicated varied in the range from 10% to 32% under the conditions of cryosynthesis. However, it was later possible to obtain (see, for example, Mazurenko and coworkers[36]) a series of β-diketonates at temperatures in the range 363 – 543 K (M = Co, Ni, Cu, Cr, Fe, Ti, Hf, Zr) in nearly quantitative yields (90% – 100%). It was emphasised[36] that the direct synthesis is the most promising method for the industrial preparation of β-diketonates. The productivity of the apparatus for the synthesis of the complexes increases sharply when the ligands are employed in the form of aerosols, which makes it possible to introduce appreciable amounts of β-diketones into the reaction zone with the simultaneous regulation of their concentration. Among other studies on these lines, mention should be made of the cryosynthesis of coordination compounds containing radionuclides, in particular ^{63}Ni acetylacetonate.[89]

The possibility of using the gas-synthesis for the preparation of various metal chelates is of interest.[90]

Analysis of the data presented in this section indicates extensive possibilities of the gas-phase synthesis for the preparation of π-complexes with alkene and aromatic ligands. At the same time, examples of the employment of heteroaromatic and chelating ligands in such syntheses are extremely limited and so far do not permit conclusions concerning the prospects for the preparation of metal complexes of heterocycles and inner-complex compounds in gas-phase reactions.

III. Liquid-phase synthesis

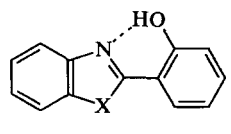
The syntheses of coordination compounds from zerovalent metals in the liquid phase comprise reactions of three types — direct interaction of the zerovalent metals and ligands, oxidative dissolution of compact metals in nonaqueous media, and electrosynthesis. Such reactions lead to the formation of predominantly molecular adducts and inner complexes as well as individual π-complexes and polynuclear clusters.



1. Synthesis of complexes by the direct interaction of zerovalent metals and ligands

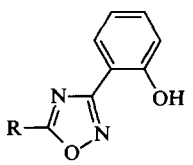
In contrast to the gas-phase syntheses, this method of direct interaction of metals with ligands does not require special apparatus — the reactions take place under the usual conditions.

The method is used widely for the synthesis of individual types of π-complexes and metal chelates, although it is also possible to obtain other types of coordination compounds. As stated in a review,[17] the method of direct interaction of metals and ligands has been used successfully for the preparation of π-allylpalladium complexes (reaction between bromopropene and palladium at 353 K under a nitrogen atmosphere), the praseodymium complex of cycloocta-1,5-diene (in THF), and cyclopentadienyl derivatives of europium and ytterbium (in liquid ammonia).



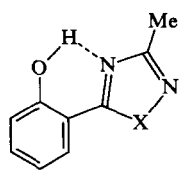
The formation of inner complexes in the syntheses under consideration is difficult mainly due to the chemical inertness of the *d* and *f* metals behaving as complex-forming agents in reactions involving the substitution of hydrogen atoms in the chelating ligands.[3] However, it has been possible to isolate metal chelates in satisfactory yields for individual ligand systems and zerovalent metals. Thus the interaction of acetylacetone with a series of *d* metals (Ti, Mn, Cr, Fe, Co, Ni, Cu, Mo, and Pd) has been investigated and it has been shown that iron forms bis- and tris-acetylacetonates, whereas the remaining metals are passive under an inert atmosphere.

Ligands containing the OH group in the *ortho*-position relative to the C=N group interact extremely effectively with zerovalent metals. Such ligands include salicylaldoxime **28** (R = OH),[17,91] salicylidene-*o*-aminophenol **28** (R = C_6H_4OH-*o*),[92] 2-*o*-hydroxyphenylbenzazoles **29**,[93] 3-hydroxyphenyl-5-R-1,2,4-oxadiazoles **30** (R = Me, Ph, $PhCH_2$),[92,94] 3-*o*-hydroxyphenyl-1,2,4-triazoles **31** (X = NH, NPh), and 3,5-di(*o*-hydroxyphenyl)-oxadiazole **32**.[95]



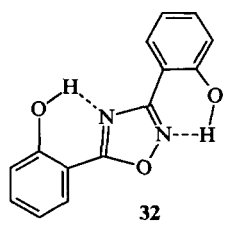
28

R = OH, C_6H_4OH-*o*, Py; R′ = H, OMe



29

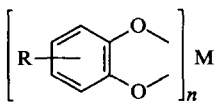
X = NH, NR′, O, S



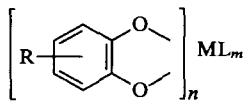
30

R = Me, Ph, CH=CH$_2$

31

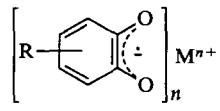


X = NH, NPh

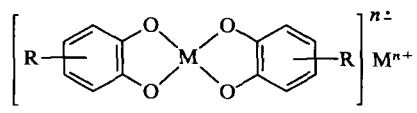


32

The solvents employed in these syntheses were ether, phenol, phenetole, acetylacetone, and dimethylformamide (DMF). The yields of the complexes vary in the range 80% – 100%. The complexes described have the compositions ML_2 [**28**(R = OH) – **31**] and ML [**28**(R = C_6H_4OH-*o*) and **32**] depending on the basicity of the ligands (LH or LH_2). The complexes ML are interesting because they have a dimeric structure (for the ligand **28**) or an oligomeric structure (for the ligand **32**) and are representatives of polynuclear compounds.[29,96,97] The polymeric nature of the complexes from the ligand **32** has been confirmed by magnetochemical[98] and EPR spectroscopic measurements: they indicate the presence in the copper(II) and cobalt(II) complexes considered of exchange-linked ions forming part of the composition of the polymeric coordination structure of the type $LH(ML)_nLH$ ($n = 1, 2, \ldots, \infty$).[95] In the copper complexes investigated, there is an exchange interaction of the antiferromagnetic type with an exchange integral $J \approx -100$ cm^{-1}, whereas in the cobalt coordination polymers ferromagnetic exchange is observed with $J \approx 20 - 30$ cm^{-1}.[95]



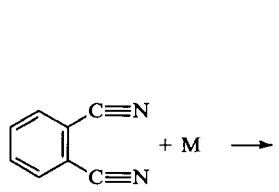
o-Quinones are extremely reactive ligands,[17,99-112] especially those containing *tert*-butyl substituents. Complexes of *o*-benzoquinones, *o*-semiquinones, and catechols of this kind have been obtained. They are radical in nature and play an important role in coordination chemistry.[106-108] In nonaqueous solvents (hexane, dimethoxyethane, toluene, THF, and chloroform), mainly the formation of complexes of types **33**–**36** (R = 3,5- or 3,6-Bu^t_2) has been observed by EPR.



33

34

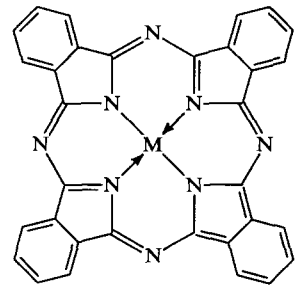
35



36

The formation of radical *o*-semiquinolates of type **33** has been detected for thallium,[109] indium,[102] zinc,[100,103,110] cadmium,[100,103,110] magnesium,[103] barium,[103] aluminium,[100] gallium,[105] and tin.[99] The adducts **34** are characteristic of copper and silver (L = PPh_3, $m = 2$, $n = 1$)[17] and also of indium (L = phen, m, $n = 1$).[102] Data on the radical-anion salts of types **35** and **36** have been presented in a review[17] and other publications.[99,110] Metal complexes of catechols can be obtained also from tetrahalo-*o*-quinones, for example $Sn(X_4C_6O_2)_2$ (X = Cl, Br).[102]

The data of Ozarowski et al.[103] and Adams et al.[105] are of greatest interest for the study of the properties and structures of type **33** complexes. Magnesium, barium, zinc, and cadmium complexes of 3,5-di-*tert*-butyl-1,2-*o*-benzoquinone (L) and their adducts with pyridine, 2,2′-bipyridyl, and *N,N,N′,N′*-tetramethylethylenediamine(L′), having the compositions ML_2 and $ML_2 \cdot nL'$ ($n = 1, 2$), were isolated preparatively and characterised in the first of these studies. Complexes **33** and their adducts with L′ have been obtained by the reaction of the above zerovalent metals and ligands in toluene; detailed EPR spectroscopic studies confirmed their biradical nature and made it possible to establish the conformations of the biradical ligands. The study of Adams et al.[105] was devoted to the triradical gallium complex of 3,5-di-*tert*-butyl-1,2-*o*-benzoquinone **33** ($n = 3$). This compound was obtained by heating gallium and the ligand in boiling toluene (under an argon atmosphere) and was characterised by X-ray diffraction. The complex has the form of a three-blade propeller with the gallium atom in the centre: the length of the C–C bond between the chelating oxygen atoms is 1.439(12) Å, which indicates the semiquinone nature of the ligands. It is striking that the above value differs little from the length of the same bond (1.433 Å) in the chromium analogue, the structure of which had been characterised previously.[112] The gallium complex **33** ($n = 3$) exhibits ferromagnetic properties; its magnetic moment is 2.95 μ_B at 320 K and 3.58 μ_B at 9 K; it then again decreases and is 3.26 μ_B at 2 K.



Thus direct evidence for the formation of radical complexes in the reactions of zerovalent metals with *o*-diquinones was obtained in the studies quoted above, methods were developed for the synthesis of these coordination compounds, and the characteristics of their structure and their physicochemical properties were established.

In a number of instances, the interaction of zerovalent metals with the ligand is accompanied by a template reaction, which yields macrocyclic chelates. The template reaction involving the direct synthesis of the macrocyclic phthalocyanine complexes **38** from zerovalent metals and *o*-phthalodinitrile (1,2-dicyanobenzene) **37**, which has long been known, has now become a classical reaction.[9,10,17,113,114]

37

M = Fe, Co, Ni, Cu, Zn, Cd, Sn.

38

The phthalocyanine complexes **38** are formed in high-boiling solvents — α-methyl- and α-chloro-naphthalene, *o*-dichloronitro- and trichloro-benzene, and quinoline. Apart from the ligand **37**, *o*-cyanobenzamide, phthalimide, and diiminoisoindoline have been introduced into this reaction.[17,113]

In conclusion of this section, we may note that molecular complexes are formed on direct interaction of metals and ligands.[17] Such complexes have been obtained, for example, between alcohols and carboxylic acids, on the one hand, and bases (pyridine, bipyridyl, and phenanthroline), on the other.[115-117]

2. Synthesis of complexes on oxidative dissolution of metals

In contrast to the direct synthesis methods considered above, the oxidative dissolution of metals in the liquid phase, accompanied by the formation of coordination compounds, proceeds in the presence of oxidants.[14,16,17,118-153] The simplest mechanism of this reaction may be as follows:[16]

$$M^0 + Ox \xrightarrow[-ne]{mL} L_mM^{n+} + Red + P,$$

where M is the metal, Ox the oxidant, L the complex-forming agent (ligand), Red the reduced form of the oxidant, and P the products of the interaction of the components of the medium.

The halogens were used as the oxidants in the old investigations (see the literature in the review of Gernovskii et al.[17] and also Kurskov[130]). Later, hydrogen halides[17,126,129,132,138,148-150] and halohydrocarbons[118-120,124-127,131,133,137,148,150] began to be employed widely. This change is not fortuitous — the synthesis of coordination compounds with the aid of hydrogen halides and especially halohydrocarbons takes place in donor–acceptor nonaqueous solvents under mild conditions without the use of corrosive media and special apparatus. Apart from the oxidants investigated, the sulfates, perchlorates, bromates, and chromates of certain metals,[17] mercury chloride,[4] and nontraditional oxidants[4,128] — nitrosonium (NO^+X^-), arenediazonium ($ArN_2^+X^-$), and triphenylcarbenium ($Ph_3C^+X^-$, X = BF_4, ClO_4, PF_6) salts — began to be used in individual syntheses.

Ammonium salts are extremely effective reagents in the synthesis of coordination compounds by the oxidative dissolution of metals.[153-171] A simple and readily applicable method of synthesis of metal complexes based on the following reaction has been developed:[153,156,166,169]

$$M^0 + m\,NH_4X + n\,L + \tfrac{1}{2}p\,O_2 \longrightarrow MX_mL_n + m\,NH_3 + p\,H_2O.$$

We may note that metal oxides also enter readily into this reaction.[153,168,169,172-176]

Cobalt,[16,17,119,120,130,155,156,158] nickel,[16,17,120,160,161,164] iron,[16,17,118,120,130,134,145] zinc,[153,159,166,169] and copper[16,17,118,121,123,127,134,135,137,141,142,146,153,159,166,169] are most frequently employed in liquid-phase syntheses. Many studies have been devoted to the dissolution of platinum group metals and the formation in these syntheses of palladium,[16,17,124,129,131,133,134,136,143] platinum,[129,131,133,134] and rhodium[129,131] complexes. Much attention has been devoted to the preparation of gold[132,134,138,148,150] and silver[138,139] complexes in oxidising donor–acceptor media. The preparation of titanium,[119] chromium,[125,134] manganese,[119] cadmium,[163] niobium,[126] tantalum,[126] and europium[128] complexes has been described in individual publications. It has been suggested[117] that lanthanide (Ln) complexes may be formed in the $Ln-PBu_3-CCl_4$ system, but their synthesis has not been described.

Solvents which in the majority of cases are also ligands are represented mainly by compounds with N and O donor atoms such as acetonitrile (AN),[16,17,118,128,129,146] benzonitrile (BN),[130] aliphatic amines (AM),[130,164,166,167,169] pyridine (Py),[16,17,133,178] dimethyl sulfoxide (DMSO),[16,17,118,120,130,138,139,143,146,148–150] dimethylformamide (DMF),[16,17,118,119,124,126,137,146,155,164] formamide (FA), monomethylformamide (MFA), dimethylacetamide (DMA),[121,123,141,145] alcohols,[157,160] and propylene carbonate (PC).[142] Apart from the compounds listed above, azoles,[137] 2,2′-bipyridyl (Bipy),[16,17,121,123,130,142] 1,10-phenanthroline (Phen),[123,131] and adenine[137] function as N donors and urea,[125] pyridine *N*-oxide,[120,133,178] triphenylphosphine oxide,[120,178] dimethylglyoxime,[130,179] and β-diketones[130,151,152,179] function as O donors. Triphenylphosphine has been used as a ligand with a phosphorus donor atom.[130]

The complexes obtained as a result of the oxidative dissolution of zerovalent metals include all types of complexes,[17] but their proportions are very different.

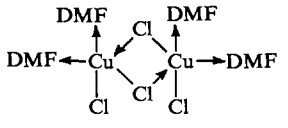
A single example of a π-complex, obtained by the oxidative dissolution of zerovalent copper in the $1,5\text{-COD}-DMF-CCl_4$ system, is known. In the complex $[Cu(COD)Cl]_2$ synthesised, copper is stabilised in the lowest oxidation state (+1) by the soft cyclooctadiene ligand system, which is confirmed by the diamagnetism of the complex considered.[16,179] This result agrees with the familiar postulate that, within the framework of the principle of hard and soft acids and bases (HSAB), soft bases (ligands) stabilise the lowest oxidation states of the complex-forming agents.[180]

There have also been only a few dinuclear and polynuclear complexes synthesised in oxidative systems.[16,17,118,123,141,171,181]

The main bulk of the complexes obtained by the method considered are molecular complexes and metal chelates.

a. Synthesis of molecular complexes

In conformity with the approach proposed in the review of Lavrent'ev and Khidekel',[16] it is possible to differentiate two types of compounds among molecular complexes — neutral and ionic. The former include, for example, adducts having the general formula MX_mL_n, where M = Co,[16,178] Cr,[125] Ni,[16,178] Fe,[118,178] Cu,[16,118,137,146,178] Pd,[131,133,146] Pt,[131] Rh,[131] Zn,[159,166,169] Cd,[163] Au,[132,148,150] Ag,[138] MoO_2,[16] WO_2,[16] and Eu,[128] L = DMSO,[16,17,118,146,148–150] DMF,[16,17,118,137,146] DMA,[16] AN,[16,17,118,128,146] Py,[133,177] Py–O,[133,178] and Ph_3PO,[177] X = Cl, Br, NCS, and BF_4, and *m*, *n* = 1–3. Coordination compounds of the second type are represented by complexes of the following metals: iron complexes[16,17,118] — *cis,trans*-$[Fe^{III}(DMF)_nCl_2].[Fe^{III}Cl_4]$, (*n* = 3, 4), *cis*-$[Fe^{III}(DMSO)_4Cl_2]Cl$, *cis*-$[Fe^{III}(DMSO)_4Cl_2][FeCl_4]$, $[Fe^{III}(DMSO)_5Cl][FeCl_4]_2$, $[Fe^{III}.(DMSO)_5Cl][Fe_2Cl_6O]$, $[Fe^{II}(AN)_6][Fe^{III}Cl_4]_2$, and $[Fe^{II}.(BN)_6][Fe^{III}Cl_4]_2$; copper complexes[146] — $[Cu^{I}(AN)_4]BF_4$, $[Cu^{I}(Me_3S)_3]I_4$, $[Cu^{II}(DMSO)_5](BF_4)_2$, $[Cu^{II}(DMSO)_4(AN)_2].(BF_4)_2$, $[Cu^{II}(DMSO)_4DMF\cdot AN](BF_4)_2$, and $[Cu^{II}(DMSO)_4.AN\cdot H_2O](BF_4)_2$; cobalt complex[16] — $[Co^{II}(DMSO)_6][Co^{II}Cl_4]$; chromium complex[125] — $[NH_2Me_2][CrCl_6]Cl$; palladium complexes — $[NH_4]_2[PdCl_4]$,[129] $[NH_2Me_2]_2[PdBr_4]$,[124] $[NH_2Bz_2]_2.[PdBr_4]$,[124] $[NHMe_3]_2[PdBr_4]$,[133] $[Me_3NOH]_2[PdBr_4]$,[133] $[(PyO)_2H]_2[Pd_2Cl_6]$,[133] and $[PdL_2Br_2][PdBr_4]$ (where L = Ph_3BuP);[131] platinum complexes[129] — $[NH_2Me_2]_2[PtCl_6]$ and $[PtLBr_2][PtBr_4]$; rhodium complexes — $[NH_2Me_2]_4.[RhCl_6]Cl$,[129] $[PyH][RhPy_2Br_4]$, $[Ph_3BuP][Rh(CO)_5Br_4]$,[131] and $[Ph_3BuP][Rh(CO)Br_4(EtOH)]$;[131] titanium complex[126] — $[NH_2Me_2]_4[TiOF_4][TiF_6]\cdot HF\cdot H_2O$; zirconium complex[126] — $[NH_2Me_2]_2[ZrOF_4]\cdot 2HF$; niobium complex[126] — $[NH_2Me_2]_2.[NbOF_5][NH_2Me_2F]\cdot 4HF$; tantalum complex — $[NH_2Me_2].[TaOF_5][NH_2Me_2]\cdot HF$; gold complexes[148,150] — $[Me_3S].[AuBr_4]$, $[Me_3S][AuBr_4(Me_2S)]\cdot H_2O$, $[Me_3SO][AuBr_4]\cdot H_2O$, $[Me_2BuSO][AuBr_4]\cdot H_2O$, $[Me_3S]_2[Au_2Br_8]\cdot 2DMSO\cdot H_2O$, and $[Me_3S][Au_2Br_7(Me_2S)]\cdot 3H_2O$; silver complex[139] — $[Me_2S^{+}CH_2.COR][AgX_2]^{-}$.

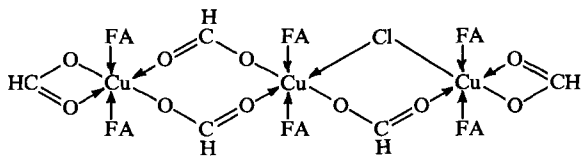


The structures of the dimethyl sulfoxide complexes indicated above have been investigated by X-ray diffraction (see the references in the paper of Lavrentiev et al.[118]).

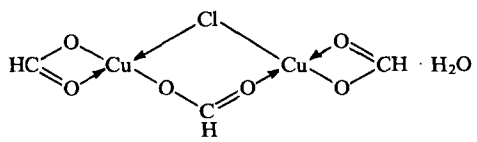
The above complexes are interesting not only because of their unusual composition but also because in some of them the complex-forming agents are in different oxidation states (for example, in the iron complexes). Another characteristic feature of the complexes obtained in donor–acceptor oxidative systems is the stabilisation in them of uncharacteristic oxidation states of the metals. Thus, together with the usual oxidation states of the metals, in particular +1 and +2 for copper, diamagnetic § Cu(+3) complexes are formed in the $Cu-DMSO-CCl_4-TU$ system (TU = tetramethylthiuram disulfide) according to Shirshova et al.[142]

It is believed[143] that the use of the same system in the case of palladium leads to intermediate univalent palladium complexes. Oxidation of zerovalent gold by hydrogen chloride or bromide in DMSO led to the isolation of univalent and trivalent gold complexes — $[(Me_2S)AuBr]$ and $[(Me_2S)AuBr_3]$.[132,148,150] We emphasise that trivalent copper and gold complexes as well as univalent palladium complexes are encountered comparatively rarely.

It has been emphasised in a review[16] that the complexes considered can contain as ligands both the components of the reaction mixture (solvents, additional ligand systems) and the products of the reactions of these components. This postulate was clearly confirmed when amides[16,118,123,141,179] and sulfoxides[132,144,148–150] were employed as the ligands. Diverse complexes are formed in M^0–amide–Ox systems, the nature of which is determined by the nature of the amide ligand, the metal, and the oxidant. It has been shown in the above review[16] (see the references therein) that complexes with transformed ligand fragments — $[(Me_2NCH)_2CH].[Fe^{III}(DMF)_6][Fe^{III}Cl_4]_4$ and $[MeNH_3]_4[Fe^{II}Cl_6]\cdot H_2O$ — have been isolated from the $DMF-Fe-CCl_4$ system and characterised. The reaction proceeds with dissociation of the bonds in the DMF molecule: N–CH_3, NC–O, and N–CHO.



Amides behave similarly in the oxidative system containing copper and CCl_4: apart from the isolation and structural characterisation of complex **39** with the unchanged DMF ligand, complexes with a significantly modified ligand system are formed.



39

§ However, diamagnetism does not constitute incontrovertible proof of the oxidation state of copper, since there are quite a few paramagnetic compounds among trivalent copper complexes.[3] The Cu^{3+} ion has the d^8 electronic configuration, like Ni^{2+}.

For example, formamide (FA) gives rise to three types of complexes in the same system:[141] $[Cu(HCOO)_2(FA)_2]$, $[Cu_3Cl.(HCOO)_5(FA)_6]$, and $[Cu_2Cl(HCOO)_3].H_2O$, while methylformamide[141] gives rise to the tetrameric cluster $[(MeNH_3).Cu(HCOO)_3]_4$. The complex $[Cu(HCOO)_2(FA)_2]$ has also been obtained by dissolving copper in formamide in the presence of atmospheric oxygen and α,α′-bipyridyl.[123] On the basis of X-ray diffraction data, a polymeric structure was attributed to it and it was demonstrated that it belongs to the class of network carboxylates. The copper atom, which occupies the centre of inversion, coordinates the oxygen atoms of two formamide molecules and four formate groups. The coordination polyhedron is a tetragonal bipyramid. In the formate group and in the formamide molecule, the bond lengths are close to the standard values. In the tetrameric compound $[(MeNH_3)Cu(HCOO)_3]_4$, the individual formatocuprate anionic fragments are linked by NH...O hydrogen bonds to the methylammonium cations.[141] The N...O distance is 2.81 Å. The structures of the complexes $[Cu_3Cl(HCOO)_5(FA)_6]$ and $[Cu_2Cl(HCOO)_3]\cdot H_2O$ can be represented by formulae **40** and **41** respectively.

40

41

The formation of copper formate complexes in the Cu–FA(or MFA)–CCl_4 systems has been accounted for by the hydrolysis of formamide and methylformamide under the copper oxidation conditions in the presence of CCl_4.[141]

Analysis of the data presented shows that the compositions of the complexes formed on oxidation of zerovalent copper in the CCl_4–amide system are determined mainly by the nature of the amide ligand: complexes of the type $[Cu_nCl_{2n}(DMF)_m]$ are formed in the case of DMF, whereas FA and MFA hydrolyse and the products of their hydrolysis behave as ligands. Furthermore, the compositions and structures of the complexes formed in the Cu^0–CCl_4–DMF system are influenced by the component ratios:[179] the complex $[CuCl_2(DMF)_2]_2$ was isolated for $[CCl_4]=[DMF] \gg [Cu^0]$, whereas in the case where $[CCl_4] \approx [DMF] \approx [Cu^0]$ the complexes $[Cu_3Cl_6(DMF)_2]$ and $[Cu_4OCl_6(DMF)_6]$ were isolated.

In the DMA–Fe–CCl_4 system, dimethylacetamide gives rise[145] to the complex $[Fe^{II}Fe^{III}_2Cl_8(DMA)_6]$ with an unaltered ligand system. X-Ray diffraction showed that the iron atoms in the crystals of this complex are in typical octahedral and tetrahedral environments in proportions of 1:2. DMA is coordinated via the oxygen atoms. This mode of coordination of the ligand considered follows also from IR spectroscopic data: an appreciable decrease [in the frequency?] of the stretching vibrations of the carbonyl group in the complex (~1600 cm^{-1}) is observed compared with the analogous absorption of free DMA (1655 cm^{-1}). Dimethylformamide undergoes even more prolonged changes in the DMF–Pd–$PhCH_2Br$,[16] DMF–Pt–HCl,[129] and DMF–Rh–HCl[129] systems. Ionic ammonium halide complexes were isolated in all cases—$[Me_2N(PhCH_2)_2][PdBr_4]$, $[H_2NMe_2]_2[PtCl_6]$, and $[H_2NMe_2]_4[RhCl_6]Cl$ respectively. The structures of the complexes described have been demonstrated[129] by X-ray diffraction for the platinum complex and by X-ray diffraction, magnetic susceptibility, and electronic and photoelectron spectroscopic methods for the rhodium complex.

Like DMF, dimethyl sulfoxide forms complexes containing as the ligand system a DMSO molecule[16,17,118,130] and the products of the reaction of this ligand and the oxidant.[132,138,139,143,148–150] As stated above,[16,17,118,130] molecular adducts of DMSO have been obtained in the DMSO–M^0–CCl_4 systems, where M = Fe or Co. In the case of Pd, Au, and Ag, the sulfoxide molecule is deoxygenated and sulfide complexes are formed. The oxidation of palladium in the presence of DMSO and HBr involves the formation of the complex $(Me_2S)PdBr_2$;[16] when CI_4 is used as the oxidant, the complex PdI(MeS).H_2O is obtained.[143] The oxidation of zerovalent gold in the DMSO–RX system (R = H, Bu; X = Cl, Br) is accompanied by the formation of a series of the dimethyl sulfide complexes examined above.[132,148,150] One of the processes occurring in this case is described by the scheme[132]

$$Au^0 + Me_2SO + HBr \xrightarrow[293\ K,\ 72\ h]{} \underset{A}{[(Me_2S)AuBr]} + [(Me_2S)AuBr_3](solution) \xrightarrow{H_2O} \underset{B}{[(Me_2S)AuBr_3]}.$$

The structures of complexes **A** and **B** have been established by X-ray diffraction. It was shown that the crystals of complex **A** contain intermolecular Au...Au chain contacts and intermolecular Au...Br contacts, which build up the square-planar coordination of the gold atoms to a distorted bipyramidal coordination. At the same time, a complex with an unaltered ligand system has been obtained in the DMSO–Au^0–BuBr system—the butyldimethyloxosulfonium salt $[Me_2SO(Bu)].[AuBr_4]$.[148,150] Together with a deoxygenated molecule of the sulfur-containing ligand, the mixed compound $\{[Me_3S]_2[Au_2Br_8].2DMSO\cdot H_2O\}$ contains also DMSO.[148,150]

Silver forms in the same systems the trimethylsulfonium salts $[Me_3S]AgBr_2$ and $[Me_3S]Ag_2X_3$, where X = Br or I.[138] When ketones were added to the reaction mixture, the ionic complexes $[R_2\overset{+}{S}-CH_2COR][AgX_2^-]$ (R = Me, Ph) were synthesised. These are carbonyl-containing sulfonium salts of silver halides. It has been suggested[139] that the above complexes are formed as a result of the condensation of DMSO with the ketones in an acid medium in the presence of silver halides in accordance with the scheme

$$Me_2SO + R'-CH_2COR \xrightarrow[-R'OH]{HAgX_2} [Me_2S^+-CH_2COR][AgX_2^-].$$

The condensation occurred when silver was dissolved in a DMSO–HBr mixture at 333 K for 3 h or after being allowed to stand for two days with subsequent addition of ketones (acetone or acetophenone). Similar complexes, containing iodine as the ligand X, have been obtained in the reaction of $Me_2S.I_2$ with acetone to which AgI and a mixture of hydriodic acid and alcohol had been added or on dissolution of the complex $[Me_3S]Ag_2I_3$ in a DMSO–HI mixture on heating with addition of an alcoholic solution of acetone.[138] The structure of the carbonyl-containing complexes has been demonstrated by X-ray diffraction.

The isostructural compounds with X = Br or I and R = Me contain a chain of the tetrahedral anions $[AgX_4]^-$, in which small differences are observed between the Ag–X bond lengths together with appreciable angular distortions (up to 20°). The structure of the analogous complex with R = Ph and X = Br is made up of the tetrahedral anions $[AgBr_4]^-$ joined together via the common edges of the tetrahedra to give an infinite chain.[139] The proposed mechanisms of the interaction of sulfoxides with

zerovalent transition metals in donor–acceptor media are based on the literature data concerning the chemistry of sulfoxides and the results of studies on the oxidation processes considered.[148–150]

An attempt has been made to describe the mechanism of the oxidative dissolution of metals.[16,17,140,146] It was initially suggested (see the bibliography in the relevant reviews[16,17]) that these processes proceed via the intermediate formation of reactive complexes between the oxidant and the solvent, which possess an enhanced ability to bind the electrons of the metal, facilitating thereby its oxidation. The mechanism of such a process has been tentatively represented as follows:

$$S + A \rightleftharpoons S\cdot A \rightleftharpoons [S^{\delta+}\cdot A^{\delta-}] + M^0 \rightleftharpoons$$
$$\rightleftharpoons M^0[S^{\delta+}\cdot A^{\delta-}] \rightleftharpoons M^+[S\cdot A^-] \rightleftharpoons M^+ + [SA^-] \rightleftharpoons \ldots$$

where S is the solvent and A the oxidant (electron acceptor). The role of the metals and oxygen in the oxidation processes considered has been discussed.[16,17] However, the evidence for the above mechanism is so far inadequate.

The concept of donor–acceptor electron-transport systems (DAETS) is therefore more attractive.[140,146] According to these ideas, dipolar onium compounds, simulating the intermediate products of the DAETS interaction, are formed in oxidising media. The interaction of onium compounds of the type $[Me_2Et\overset{+}{S}=O][BF_4^-]$, $[Me_2N\overset{+}{C}H-OEt][BF_4^-]$, and $[Me_3\overset{+}{S}=O]I^-$ with metallic copper has been investigated to demonstrate the oxidation of metals in nonaqueous media with formation of DAETS.[146] This led to the isolation of a series of complexes containing the metal in the +1 oxidation state—$[Cu^I(AN)_4]\cdot[BF_4]$, $Cu^I[Me_3S^+]_3I_4$, and Cu^IPy—and in the +2 oxidation state—$[Cu^{II}(DMSO)_5][BF_4]_2$, $[Cu^{II}(DMSO)_4(AN)_2][BF_4]_2$, $[Cu^{II}(DMSO)_4\cdot AN\cdot H_2O][BF_4]_2$, and $[Cu^{II}(DMSO)_2\cdot AN\cdot DMF][BF_4]_2$. Mixed-ligand complexes containing DMSO, DMFA, and AN molecules simultaneously have been obtained from a solution of the $[Me_2Et\overset{+}{S}=O][BF_4^-]$–$Cu^0$DMSO DAETS system to which a mixture of DMFA and AN had been added. It is striking that some of the above complexes can be obtained also under the usual conditions involving the oxidative dissolution of copper. The structure of the complex $[Cu^I(AN)_4][BF_4]$ has been established by X-ray diffraction.

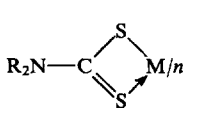
The complexes containing DMSO as a ligand are interesting because, as suggested by Epel'baum et al.[146] on the basis of IR spectroscopic data, three types of bonding of the DMSO molecule to divalent copper occur in them—via the oxygen and sulfur atoms and with participation of both donor centres. Since the commonest bonding between Cu^{II} and DMSO involves the coordination of the metal to an oxygen atom,[180] the above results[146] require additional evidence, in particular X-ray diffraction studies of the structures of divalent copper complexes of DMSO.

b. Synthesis of metal chelates

The inner complexes obtained in oxidative donor–acceptor systems in the presence of chelating ligand systems are represented by transition metal acetylacetonates,[16,130,151,179] carboxylates,[152] dimethylglyoximates,[142,143] 8-hydroxyquinolinates,[16,179] and dithiocarbamates.[142,143] The acetylacetonates $Co(acac)_2$ and $Fe(acac)_3$ are formed in the acacH–DMSO–BN oxidative system (where BN = benzonitrile) under a nitrogen atmosphere.[130] Atmospheric oxygen accelerates not only the dissolution of cobalt but also the formation of $Co(acac)_3$. The same complex has been isolated in the presence of triethylamine, which is not coordinated to the metal of the acetylacetonate considered. On the other hand, N donors such as pyridine and α,α′-bipyridyl (L) form with the acetylacetonate the adducts $M(acac)_2\cdot nL$, where M = Co or Fe and $n = 1, 2$. The complex $Cu(acac)_2$, obtained in an oxidative system incorporating a hydrogen halide, has been described.[16,179] The oxidative dissolution of yttrium in systems containing acetylacetone as the main component as well as acetone, ether, dioxane, acetonitrile, pyridine, α,α′-bipyridyl, DMSO, DMF, 2-pyrrolidinone, and acetic acid (AcOH) has been investigated recently.[151] Complexes having the same composition $Y(acac)_3\cdot 2H_2O$ have been isolated from Y–acac–Me_2CO (ether, dioxane, acetonitrile) mixtures. The complexes $Y(acac)_3\cdot H_2O\cdot Py$, $Y(acac)_3\cdot H_2O\cdot\frac{1}{2}Bipy$, $Y(acac)_3\cdot H_2O\cdot DMSO$, $Y(acac)_3\cdot\frac{5}{3}H_2O\cdot\frac{1}{3}DMF$, $Y(acac)_3\cdot\frac{5}{3}H_2O\cdot\frac{1}{3}PC$, and $Y(OAc)_3\cdot 2H_2O$ are formed in the acac–Py (α,α′-Bipy, DMSO, DMFA, PC, and AcOH) systems respectively.

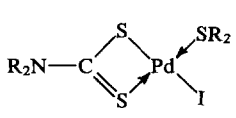
Direct dissolution of zerovalent bismuth and antimony in the presence of an oxidant has been used to obtain the carboxylates of the above metals.[152] The reaction proceeds in accordance with the scheme

$$2M + 6HL + 3[O] \longrightarrow 2ML_3 + 3H_2O.$$



Bismuth formate and acetate (in the presence of atmospheric oxygen or H_2O_2 as oxidants) and antimony acetate and trifluoroacetate (in the presence of nitric acid, acetyl peroxide, or acyl nitrates) have been obtained in this way.

Coordination compounds are readily synthesised in oxidative metal donor–acceptor systems when dimethylglyoxime is used as the ligand.[16,17,130,179,182] Dimethylglyoxime is a classical chelating ligand.[3,12] Inner complexes of the type ML_2, where LH = dimethylglyoxime (DGl) have been obtained from it. However, the use of the method involving the oxidative dissolution of metals makes it possible to obtain not only the complexes ML_2, but also $MX_n(LH)_m$ and $MX_{n-p}(LH)_mL_p$. In addition, the mixed-ligand complexes $MX_n(LH)_m\cdot p$Solv, where Solv = DMSO or DMF, are known. A complex of the first type is formed in the Ni^0–LH–AN–CCl_4 system.[179] Coordination compounds of the second type are represented by the complexes [CuCl.LH] obtained in the Cu^0–LH–EtOH–CCl_4 system;[17,179] compounds of the third type comprise the complexes $[CoX_2(LH)L]$, where X = Cl, Br, or I.[130,179,182] Their formulae have been expressed in the form $H[CoX_2L_2]$. One of the complexes of this type described (X = Cl) is diamagnetic,[179] which indicates that it contains cobalt in the +3 oxidation state.



Solvated complexes include a series of compounds, for example $[CuCl_2(LH)_2DMSO]$[179] and $[NiCl_2(LH)_2]_n\cdot DMF$.[17,130] The preparation of complexes with a fully preserved ligand system (LH) is of fundamental importance for the coordination chemistry of chelating ligands incorporating an acid EH group, to which much attention has been devoted recently.[7,183]

Copper[142] and palladium[143] dimethyldithiocarbamates have been synthesised in oxidative systems containing FA, DMF, and DMSO or PC, CI_4, and tetramethylthiuram (or its cation). A series of copper complexes containing apparently both copper(II) and copper(III)—$[CuI(Me_2NCS_2)_2]CHI_3$, $[Cu_2I(Me_2NCS_2)]$, $[Cu_2I_4(Me_2NCS_2)_3]$, $Cu_2SCN(Me_2NCS_2)_2\cdot H_2O$, $[Me_2NH_2]\cdot[CuCO_3(Me_2NCS_2)]\cdot Cu_2S$, and $[Cu_3I_2(Me_2NCS_2)_5]$—and palladium complexes—$PdI[Me_2NCS_2]$, $Pd[Me_2NCS_2][Me_2S]$, and $Pd_3I_3[Me_2NCS_2]_3[Me_2S]$—have been obtained.

The presence of the dimethyldithiocarbamate fragment in the complexes considered has been demonstrated by IR spectroscopy and, in the case of the coordination compounds **42** (M = Cu^{2+}, $n = 2$)¶ and **43**, by X-ray diffraction.[142,143]

42

43

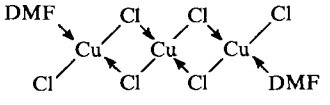
R = Me, Et.

¶ Complex **42** has been obtained on slow sublimation of the compound $[Cu_3I_2(Me_2NCS_2)_5]$ at 473–493 K.

The data presented in this section indicate the possibility, in principle, of synthesising inner complexes by the oxidative dissolution of metals in donor–acceptor media. However, few chelating ligand systems are known for this type of the direct synthesis of metal complexes.[3,6,7,9,10,182]

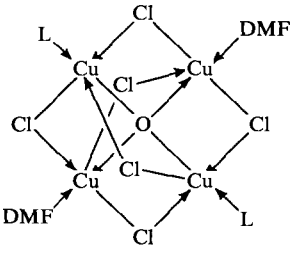
c. Synthesis of dinuclear and polynuclear complexes

The polynuclear complexes synthesised as a result of the oxidative dissolution of zerovalent metals in donor–acceptor systems are of undoubted interest from the standpoint of the chemistry of dimetallic and polymetallic coordination compounds.[29,97,184–186] The dinuclear and trinuclear copper compounds **39–41** as well as ionic iron, palladium, gold, and silver compounds containing several metal atoms in the molecule may be assigned to complexes of this type.



The advantage of direct synthesis is the possibility of the specific preparation of complexes with different contents of metal atoms. Thus, by varying the component ratios in the Cu^0–DMF–CCl_4 system, di-, tri-, and tetra-nuclear cluster structures have been obtained.[181] The reactions are described by the following scheme:

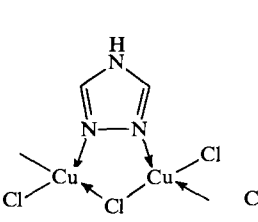
$$Cu^0 + DMFA + CCl_4 \xrightarrow{[DMFA]\approx[CCl_4]\gg[Cu]} [Cu_2Cl_2(DMFA)_4]_4 \quad \mathbf{39}$$



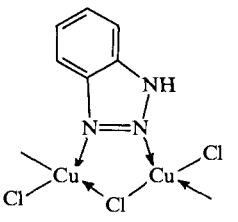
$$Cu^0 + DMFA + CCl_4 \xrightarrow{[DMFA]\approx[CCl_4]\approx[Cu]} [Cu_3Cl_6(DMFA)_2] \quad \mathbf{44}$$

$$Cu^0 + DMFA + CCl_4 \xrightarrow{[Cu]\ll[DMFA]\ll[CCl_4]} [Cu_4OCl_6(DMFA)_2] \quad \mathbf{45}$$

The structures of complexes **39**, **44**, and **45** have been demonstrated by X-ray diffraction.[118,181]

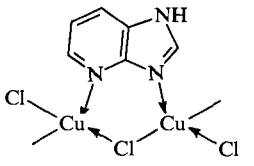


44



45, L = DMF,[181] Me_2NH[171]

Clusters with the same metal core and a structure similar to that of complex **45** have been described.[171] Their general formula is $Cu_4OCl_6 \cdot n(CH_3)_2NH \cdot m$Solv, where $n=4$, $m=0-2$, and Solv = MeOH or DMSO.



The bimetallic compounds **46–48** with two copper atoms are formed in the Cu^0–DMF–L system, where L represents nitrogen-containing heterocycles: 1,2,4-triazole, benzotriazole, and adenine.[137] We emphasise that the authors[137] attributed an erroneous formula to complex **48**, having included in the coordination the nitrogen atom of the NH-pyrrole fragment, which is known[29,187–190] to lack donor properties almost completely.

47

48

However there is no doubt about the bridging function of the triazole ligand in complexes **46** and **47**: this mode of coordination of triazoles and their derivatives has been unambiguously demonstrated by X-ray diffraction (see the bibliography in the review of Garnovskii et al.[190])

In conclusion we may point out that the physicochemical properties and the structures of the coordination compounds described here have been relatively little investigated. This remark applies particularly to the fact that the magnetic properties of dinuclear and polynuclear complexes, many of which (for example, complexes **39–41**, **44**, and **45**) are of undoubted interest as magnetic-exchange clusters, have been scarcely studied at all.

IV. Electrosynthesis of coordination compounds

Electrosynthesis is not only the oldest[11,12] but also one of the easiest preparative methods of synthesis of coordination compounds.[4,17,22–24,27,191–194] Electrosyntheses are carried out using dissolving anodes or cathodes, reactions involving the former type of electrodes being particularly widely used. The essential feature of the electrosyntheses of complexes are described by the simple scheme[22]

$$M^+ + L + e^- \longrightarrow [M...L].$$

If the ligands LH with an acid EH group (E = NR, O, S, Se) participate in the process, the following reactions take place:[17]

$$M \xrightarrow[-ne]{} M^{n+},$$

$$LH \longrightarrow L^- + H^+,$$

$$M^{n+} + nL^- \longrightarrow ML_n.$$

In the last case, the mechanism presupposes the anodic dissolution of the metal with subsequent complex formation.[4,24]

Anode: $nL^- + M \longrightarrow ML_n + ne$,

Cathode: $nHL + ne \longrightarrow nL^- + \frac{1}{2}nH_2$.

Thus the electrochemical reactions do not require the use of oxidants or reductants. This makes them definitely attractive.[4] Other important advantages of the electrosynthesis of coordination compounds over the usual synthetic methods consist in the possibility of regulating them, in the preparation of compounds otherwise difficult to synthesise, and in carrying out the processes under mild conditions with high yields.[17,27] Alcohols, THF,

DMF, DMSO, acetonitrile, pyridine, propylene carbonate, sulfolane, diglyme, and hexamethylphosphoramide (HMDA) are most widely used as solvents in electrosyntheses. All types of coordination compounds can be obtained with the aid of electrosynthesis, but the method is most widely applied at the present time in the synthesis of molecular and inner complexes.

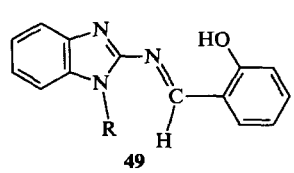
a. Electrosynthesis of molecular complexes

The molecular complexes obtained by electrosynthesis are represented by diverse adducts of organic N, P, and O donors with metal halides (pseudohalides) and organometallic halides.[4,23,24,27,195-199] The former have the general formula $MX_n \cdot pL$ and the latter have the formula $R_mMX_{n-m} \cdot pL$, where M are Group I (Cu, Ag, Au),[27,197] Group II (Zn, Cd),[23,27,199] Group III (Ga, In),[23,27] Group IV (Sn, Pb, Ti, Zr, Hf),[23,24,195] Group V (V),[23] Group VI (Cr),[23,196] Group VII (Mn),[24] and Group VIII (Co, Ni, Pd)[23,27,198] metals, L = acetonitrile, pyridine, bipyridyl, *o*-phenanthroline, ethylenediamine (En), imidazole, PR_3, $R_2PCH_2CH_2PR_2$,[23,27] DMSO, dioxane, or urea,[23,27] R = alkyl or aryl, X = OH,[199] halogen,[23,27] CN,[23] NCO,[197] or ClO_4,[197,198] and m, n, $p = 1-3$.

Under the conditions of electrosynthesis with anodic dissolution of cadmium in acetonitrile solution containing *N*-(hydroxyethyl)salicylideneimine and phenanthroline, the adduct $Cd(OH)_2 \cdot (Phen)_2$ was obtained[199] instead of the azomethine chelate.[200] The structure of this molecular complex was demonstrated by X-ray diffraction: it was an octahedral structure with the CdN_4O_2 coordination unit.[199] Ionic complexes of the cationic[4,23,24,195,197,198] and anionic[23,24,195,196] type can be assigned to the same type of coordination compounds. The cationic complexes are represented by a fairly wide range of compounds[23,27] synthesised by the anodic dissolution of metals in organic solvents containing strong inorganic acids — HBF_4 or $HClO_4$. Ammonium salts of perchloric acid also serve as a source of perchlorate anions (see, for example, McAuliffe and coworkers[197,198]).

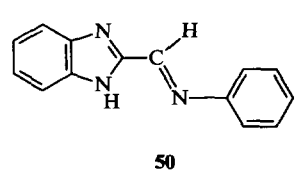
A series of cationic complexes with the general formula $[ML_n][BF_4]_m$, where L = acetonitrile or DMSO, $n = 4$, 6, and $m = 2$, 3, have been obtained by the electrolytic dissolution of metals (Zn, Cd, In, Ti, V, Cr, Co, Ni, Fe) in acetonitrile or DMSO solution in the presence of HBF_4.[23,27] The electrochemical dissolution of the copper anode in acetonitrile in the presence of 2,2′-bipyridyl, 2(1*H*)-pyridone, and tetramethylammonium perchlorate leads to isocyanatobis(2,2′-bipyridyl)copper(II) perchlorate $[Cu(C_{10}H_8N_2)_2(NCO)]ClO_4$. According to X-ray diffraction data,[197] the cation of the complex considered is a square pyramid with the isocyanate group at the apex. The latter is coordinated to copper via the nitrogen atom, which is of interest for the consideration of the ambident binding of pseudohalide ions.[180,201] Electrosynthesis with a cobalt anode under the same conditions in the presence of 1,10-phenanthroline promotes the formation of the complex $[Co(CO_3)(Phen)_2] \cdot ClO_4$.[198] According to X-ray diffraction data, the cation of this complex has an octahedral structure as a result of the bidentate binding of the phenanthroline ligand (N,N-coordination) and the carbonate ion (O,O)-coordination.[198]

Among the anionic complexes, compounds of the type $[Et_4N]_m[MBr_4]$, formed during electrosynthesis with participation of zerovalent metals, bromine, and tetraethylammonium bromide in solution in a benzene–methanol mixture, have been described.[23,24] The metals employed were Au, Cd, In, Sn, Ti, Hf, Th, Co, Ni, and Fe. The adducts of metal thiolates with N, P, and S donor ligands may be assigned to molecular complexes.[202-205] Thus electrolysis at a copper anode in acetonitrile solution with Et_4NCl as the supporting electrolyte in the presence of *o*-methylthiophenol and 1,10-phenanthroline leads to the formation of the complex $[Cu(SC_6H_4Me\text{-}o)(Phen)]_2 \cdot AN$, the structure of which has been demonstrated by X-ray diffraction.[203] Under the conditions of galvanostatic electrolysis in acetone or acetonitrile, a series of complexes having the general formula $M(SR)_2L_2$, where M = Co or Ni, R = Ph, 2,3,5,6-F_4C_6H, 3-MeC_6H_4, or 2-$C_{10}H_7$, and L = *o*-Phen or Bipy have been obtained.[204] Magnetochemical measurements {μ_{ef} = 2.70 μ_B for the complex $[Co(SPh)_2(Phen)_2]$ and μ_{ef} = 3.30 μ_B for the nickel analogue} and the compositions of the complexes indicate an octahedral configuration. The occurrence of the latter has been unambiguously demonstrated by X-ray diffraction for the cation of the complex $[Co^{III}(SPh)_2(Phen)_2]ClO_4$.[204] Adducts having the general formula $CuSR \cdot nL$, where R = Ph, *o*-, *m*-, or *p*-MeC_6H_4, or 2,3,5,6-F_4C_6H, L = $Me_2NCH_2CH_2NMe_2$, PhNCS, Bu^tNCS, or PPh_3, and $n = 0.5$, 1.5, 2, have been synthesised[205] by the electrochemical dissolution of copper in acetonitrile solutions of the thiols and the ligands (L).



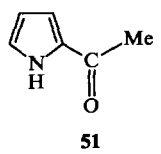
b. Electrosynthesis of π-complexes

Compilations of data on the electrochemical synthesis of transition metal π-complexes have been published.[4,22,24,27] They cover the electrosyntheses of metal complexes of cycloalkenes [for example, the copper complex of cyclooctadiene $Cu(COD)_2ClO_4$,[27] the nickel derivative of cyclooctatetraene Ni(COT),[22] and the bis(η^5-cyclopentadienyl) metal derivatives of type **11** (M = Fe, Mn, Ni,[4,22,27])]. Ferrocene **11** (M = Fe) was first obtained electrochemically by the dissolution of an iron anode in a dimethylformamide solution of cyclopentadienylthallium.[4] The analogous manganese and nickel complexes have been synthesised by the electrolysis of the lithium, sodium, or cadmium salts of cyclopentadiene in solution in THF.[4] However, it was subsequently demonstrated that the metallocene complexes can be obtained directly from cyclopentadiene and its derivatives.[206,207] The electrosynthesis of the type **11** and **15** metallocene complexes from CH acids having the general formula RH, where R = cyclo-C_5H_5, MeC_5H_4, 2,4-$Me_2C_5H_3$, C_5Me_5, indenyl, or fluorenyl, is therefore of special interest.[207] It has been shown that the π-complexes R_2M [207] (R = C_5H_5 or 2,4-$Me_2C_5H_3$ and M = Fe, Ni, Co, or Zn; R = MeC_5H_4 or fluorenyl and M = Fe or Ni; R = indenyl and M = Fe) may be obtained by electrolysis at soluble anodes (M = Fe, Co, Ni, Cu, Zn) and a platinum cathode in solutions in acetonitrile (AN – $MeOCH_2CH_2OMe$ and AN – THF with Bu_4NBr as the supporting electrolyte). In addition, the cyclopentadienyl π-complexes $(C_5H_5)CuPPh_3$, $[Co(C_5H_5)_2]Br$, $[Co(C_5H_5)_2(CoCl_4)]$, and $[Co(C_5H_5)_2(CoBF_4)]$ have been synthesised.

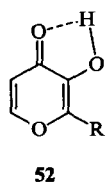


The above examples of electrosynthesis indicate the limited applicability of this method in the preparation of metal π-complexes and this situation has persisted to this day.

c. Electrosynthesis of metal chelates



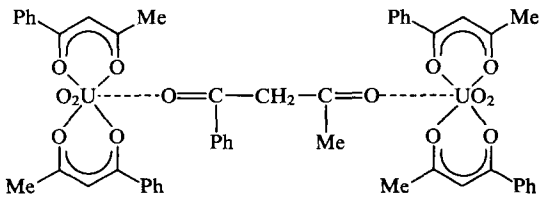
Only individual chelating ligands have been used in the electrosynthesis of inner complexes until quite recently: dimethylglyoxime,[4,12,17,27] β-diketones,[17,23,27] Schiff bases **49** and **50**,[4,17,24,27] azoles,[4,17,27] *o*-hydroxyphenylazoles and benzazoles **29**,[17,27] 2-acetylpyrrole **51**,[23] and 3-hydroxy-4-pyrone **52**.[23]



49

50

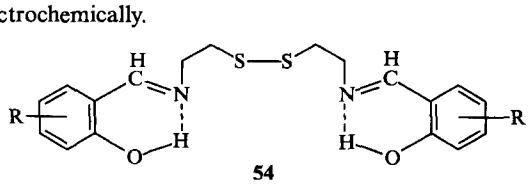
51



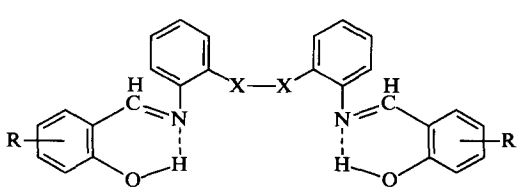
52

Electrosyntheses of inner complexes comprising metallocycles with different numbers of members [ring atoms] and with different ligand environments (N, O, S) have now been achieved.

Among chelates with a six-membered metallocycle, mention should be made of the complexes of β-diketones [36,195,209-211] and azomethines [200,212-223] which have been obtained electrochemically. Thus the electrosynthesis of cadmium,[209] thorium,[195] and dysprosium [210] β-diketonates has been described. The structure of the adduct $Cd(acac)_2$.Phen has been demonstrated by X-ray diffraction.[209] Systematic studies[36] have shown that β-diketonates having the compositions ML_2 (M = Ni), ML_3 (M = Al, In, Co, Fe, Ti, Zr), ML_4 (M = Zr, Hf), ML_2·Solv (M = Ni, Fe), ML_3Cl (M = Ti, Zr), $TiL_2(OMe)_2$, and ZrL_3OMe are formed in satisfactory yields from a wide variety of β-diketones and their fluoro-derivatives under the conditions of electrosynthesis. These chelates have been synthesised from liquid β-diketones or their 15%-20% solutions in methanol, ethanol, acetonitrile, and DMF with LiCl, LiBr, NH_4Cl, or Bu_4NBF_4 as the supporting electrolytes.

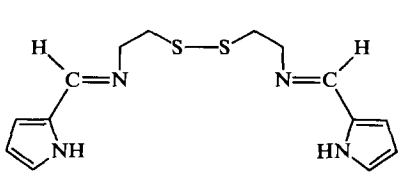


The electrochemical oxidation of uranium leads to chelates of the type UL_4 and UO_2L_2 (LH = β-diketone).[211] Apart from these complexes, the compound $UO_2L_2(HL)_{0.5}$ was isolated and the structure **53** was attributed to it. It was justified by IR spectroscopic data,[211] but in our view this requires more rigorous evidence.

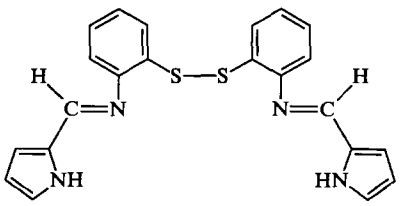


53

The inner complexes of Schiff bases have been obtained by electrosynthesis in an acetonitrile solution of the ligands using a platinum electrode (cathode) and an anode consisting of the complex-forming metal.

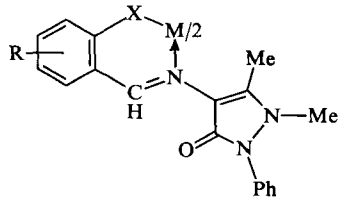


Together with the complexes containing alkyl or aryl substituents at the nitrogen atom of the azomethine group (R = Pr^i, Bu, *p*-MeC_6H_4, *p*-ClC_6H_4, *p*-$O_2NC_6H_4$),[200] a large number of *o*-hydroxyazomethines containing the coordinatively active fragments **28** (R = 2-Py,[212,214] CH_2CH_2Py-2,[213,215] $CH_2CH_2NMe_2$ [213]), **54**,[217] **55** (X = S,[218,220,223] Se [222]), **56**,[216] and **57** [216] at the above nitrogen atom have been synthesised electrochemically.

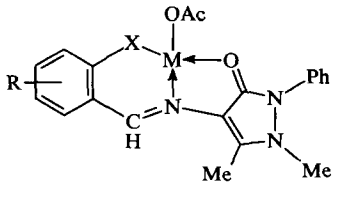


54

55 (X = S, Se)



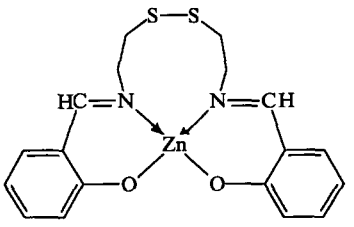
56



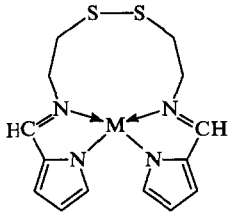
57

Analysis of X-ray diffraction data shows[214] that the nitrogen atom of the pyridine ring in the copper complex of the ligand **28** (R = 2-Py-3-Me, R′ = 5-OMe) is not involved in the coordination, i.e. this formally tridentate ligand system behaves as a bidentate system and the metallocycles MN_2O_2 involving the phenolic oxygen and the azomethine nitrogen are formed in the complexes described. This situation is characteristic of the copper complex obtained from the ligand **28** [R = CH_2CH_2Py, R′ = 4,6-$(OMe)_2$]. The complex has a square-planar structure with a non-coordinated nitrogen atom of the pyridine ring.[213] At the same time, X-ray diffraction data indicate the involvement in the coordination of the pyridine ring in the nickel complex of *N*-(2-pyridylethyl)salicylideneamine **28** (R = CH_2CH_2Py), which leads to the NiN_4O_2 octahedron.[215] The results described are of undoubted value for the understanding of the problem of competitive coordination in a series of formally tridentate ligand systems — different ways of binding the latter depending on the electronic configuration of the metals and the structure of the complexes formed by them.[7,208,224-226]

Azomethines containing an antipyrine fragment at the nitrogen atom can be assigned to the same class of ambident ligand systems.[219] Inner complexes of type **58** (X = O) having the composition ML_2 have been obtained from them by the electrochemical method.[219] Both the involvement[227] and the lack of such involvement of the oxygen atom of the carbonyl group[219,227] in coordination, apart from the phenolic oxygen and the azomethine nitrogen, have been postulated in such inner complexes. In this case, the electrochemical method has the advantage that, when it is employed, complexes **58** with the composition ML_2 alone are formed, whereas under the usual conditions involving the use of the metal acetates coordination compounds of two types were isolated: ML_2 (compounds **58**) and MLAcO (compounds **59**).[227]



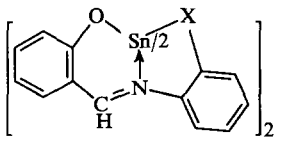
58



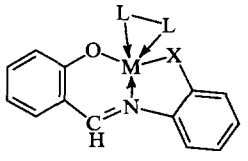
59

The formally hexadentate ligand systems **54**-**57** behave in an unusual manner under the conditions of electrosynthesis. The disulfide structure of the ligand **54** remains unaltered in the complex formation reaction.[217] The structure **60** has been proposed for the complex. The coordination polyhedron is a tetrahedron formed with participation of the phenolic oxygen atoms and azomethine nitrogen atoms.[217]

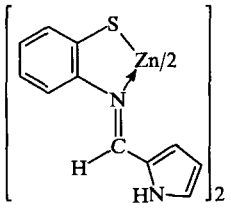
The complexes ML **61**, obtained from the ligands **56** and **57**, evidently have a similar structure without the involvement of sulfur atoms in the coordination.[216] In the remaining cases, the dissociation of the X–X (X = S, Se) bonds and the formation of a complex with a comparatively rarely encountered N,X- or N,O,X-ligand environment are observed under the conditions of electrolysis.[7,208]



60

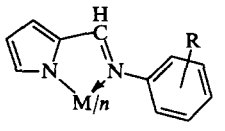


61 (M = Ni, Cu, Zn, Cd)

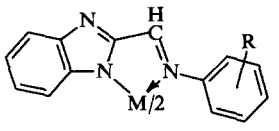


It has been demonstrated by X-ray diffraction that two types of complexes are formed from compound **55**—complexes **62** (X = S,[218] Se[222]) and **63** (M = Zn, L–L = 2,2′-Bipy;[220] M = Co, L–L = *o*-Phen[223]).

62

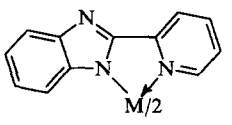


63



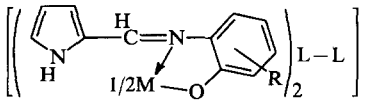
64

The dissociation of the disulfide bond in the ligand **57** (LH_2) results in the formation of the complex $Zn(LH)_2$ **64**, which is, according to X-ray diffraction data, a complex of pyrrolemethylidene-*o*-aminothiophenol, in which the pyrrole fragments are not involved in coordination.[216] The results described expand the possibilities for the synthesis of coordination compounds containing in the coordination units the N and S(Se) donor atoms, in which considerable interest has been shown recently.[7,208,224–227] In this connection, we may note that complexes of type **64**, containing the five-membered coordination units MN_2X_2 (X = S, Se), have been synthesised fairly long ago using metal salts or were obtained by template synthesis.[7,208]



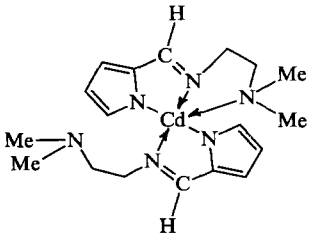
Coordination compounds of another type (compounds **65**–**67**) with the five-membered metallocycle MN_4 have been obtained by electrolysis from azomethines derived from the aldehydes of five-membered nitrogen heterocycles—pyrrole-2-aldehyde[228–237] (complex **65**), benzimidazole-2-aldehyde[4,24] (complex **66**), and 2-(2′-pyridyl)benzimidazole[4,24,27] (complex **67**).

65

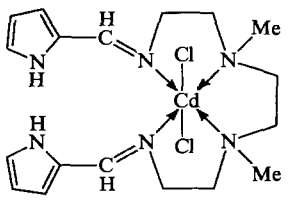


66

67



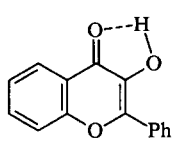
Complexes **65** are classical,[7,208,238–240] but the application of electrosynthesis not only made it possible to expand the range of such compounds but also helped to refine their structures and to elucidate questions concerning the competitive reactions of azole ligand systems with zerovalent metals. X-Ray diffraction data for the pyrrolealdiminates **65**, obtained under the conditions of electrosynthesis (solution in acetonitrile), indicate that the copper complex **65** ($M = Cu^{2+}$, R = *p*-Me, $n = 2$) contains the tetrahedrally distorted metallocycle CuN_4,[229] while the trivalent cobalt chelate **65** ($M = Co^{3+}$, R = *o*-Me, $n = 3$) is an octahedron with the CoN_6 coordination unit.[229] X-Ray diffraction data has shown that an analogous ligand environment MN_6 is characteristic of the adducts of the nickel chelate **65** (M = Ni, R = H, $n = 2$) and the cadmium chelate **65** (M = Cd, R = 2-OMe, $n = 2$) with bipyridyl.[231] Competitive coordination and the formation of three types of structures are characteristic of the ambident ligand systems of the pyrrolealdimine type: with participation of the iminophenol fragment (complex **68**),[232,235,237] with participation of all the nitrogen donor atoms (complex **69**),[233] and with participation of the iminoamine group (complex **70**).[236]



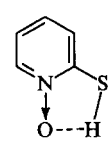
68

R = H, 4-Me, 5-Me, 5-Cl, 3,5-Me_2;

M = Co, Ni, Zn; L–L = acetonitrile, Bipy, *o*-Phen



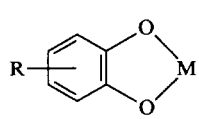
69

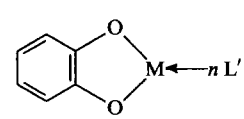


70

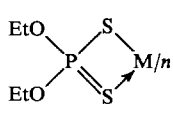
We emphasise that the pyrrole fragment in complexes **68** and **70** is not involved in coordination. This may be associated with the electrosynthesis being carried out in solution in acetonitrile and with the presence in the reaction medium of powerful chelating N-donors such as 2,2′-bipyridyl, 1,10-phenanthroline, or a macrocyclic fragment. A definite confirmation of this hypothesis is provided by the finding that, when the electrochemical synthesis is carried out with participation of ligands of the azole series having a lower NH acidity than pyrrole in an alcoholic medium,[241] the *N*-metal-substituted complexes **66** and **67** are formed.[4,24,27,242] A characteristic feature is that *N*-metal substitution is observed in the electrochemical synthesis in methanol (ethanol) and for the azoles themselves.[27,242]

Among other metal chelates with a five-membered metallocycle, one may mention complexes synthesised electrochemically from bidentate oxygen-containing donor ligands **52** (R = Me)[243] and **71**,[244] as well as pyridine-2-thiol *N*-oxide **72**.[245] The presence of five-membered metallocycles of type MO_4 and MO_2S_2 in these complexes has been demonstrated by X-ray diffraction.[243-245]

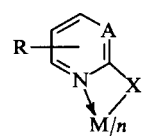




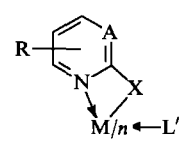
71



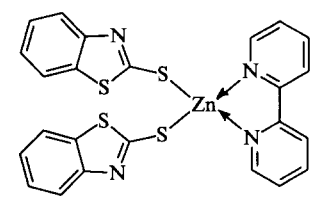
72



The electrochemically synthesised inner complexes with four-membered chelate units are represented by complexes of catechols (complexes **73**)[246-248] and their adducts with N- and O-bases (complexes **74**),[246-248] dialkylthiocarbamates (complexes **42**),[249] dialkyl phosphorodithioates (complexes **75**).[249] 2-pyridinol [complex **76** (X = O, A = CH)],[250-252] pyridine-2-thiol [complex **76** (X = S, A = CH)], pyrimidine-2-thiol [complex **76** (X = S, A = N)],[255-258] and their molecular adducts with azines and bisazines (complexes **77**).[256-258]



73 (R = H, cyclo-C_4H_4, 3,4,5,6-Br_4) **74**

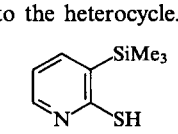


75 **76** **77**

A = CH, N; X = O, S

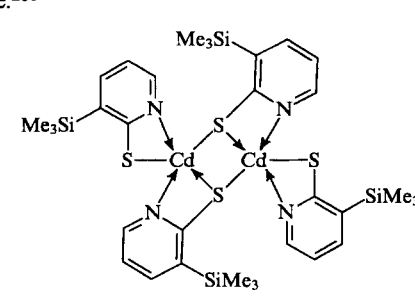
Complexes **73** and **74**, having the compositions ML and ML·*n*L′ respectively (M = Zn,[246] Cd,[246] Sn;[247] LH_2 = catechols; L′ = Bipy, Phen, Py, DMSO; *n* = 1, 2), have been obtained in acetone with the above metals as the anode. In the case of the indium anode, the complex [In(LH)], in which only one of the two phenolic hydrogen atoms of 1,2-dihydroxybenzene is substituted by the metal, is formed under the same conditions.[248] The electrosyntheses of the complexes of dialkyldithiocarbamates [complexes **42** (R = Me, Et)] and diethyl phosphorodithioates (complexes **75**) have been carried in solution in acetonitrile with silver, zinc, cadmium, indium, thallium, cobalt, nickel and iron anodes.[249] When 1,10-phenanthroline (L′) was added to the reaction mixture, the adducts ML_n·Phen (M = Ga, V, Mn, Co, Fe) were obtained. The complexes were characterised by elemental analysis, the results of which indicated[249] the formation of the inner complexes ML_2 **42** and **75** (*n* = 2), ML **42** (M = Ag, Tl; *n* = 1) and **75** (M = Cu, Tl, Ga; *n* = 1), and ML_3 **42** (M = Fe, In, Tl; *n* = 3) and **75** (M = Co; *n* = 3). The ^{31}P NMR spectra of compound **75** were also obtained. Metal chelates of divalent iron, copper,[250] zinc and cadmium,[251] and cobalt and nickel[252] have been obtained from 2-pyridinone under the conditions of electrosynthesis and isolated. In our view, the results of magnetochemical measurements for complexes **76** and **77** (X = O, A = CH) are of greatest interest. In particular, the values of μ_{ef} for the copper complexes $[CuL_2]\cdot 3H_2O$ and $[CuL_2\cdot Phen]\cdot 3H_2O$ are 1.5 and 2.4 μ_B respectively[250] and may be associated with exchange interactions of the antiferromagnetic and ferromagnetic types.[98]

The heteroarene-2-one and heteroarene-2-thione ligands are known to form several types of complexes.[253,255,256,258,259] X-Ray diffraction data have shown that structures in which the MN_2S_2 metallocycle is a fragment are characteristic of the adducts of pyridine-2-thiol [complexes **77** (A = CH, X = S: M = Ni,[253] L′ = Bipy, R = H, *n* = 2; M = Zn,[254] L′ = Phen, R = H, *n* = 2)] and pyrimidine-2-thiol [complexes **77** (A = N, X = S: M = Ni,[255] L′ = Bipy, R = H, *n* = 2; M = Cd,[256] L′ = Phen, R = H, *n* = 2; M = Zn,[257] L′ = Py, R = 4,6-Me_2, *n* = 2; M = Ni, Cd,[258] L′=Bipy, Phen, *n* = 1)]. The metallocycle is formed via the endocyclic nitrogen atom of the pyridine type and the thiol sulfur atom. The adduct-forming ligand (L′) lead to octahedral (Bipy, Phen)[253-256,258] or trigonal bipyramidal (Py)[257] configurations. On the basis of magnetochemical data, an octahedral structure has been attributed to the adduct of the nickel complex of benzothiazole-2-thione with 2,2′-bipyridyl (μ_{ef} = 3.4 μ_B) and 1,10-phenantholine (μ_{ef} = 2.9 μ_B).[259] However, the magnetic criterion can hardly be used for an unambiguous choice between octahedral and a tetrahedral coordination. The occurrence of the latter for the adducts of benzothiazole-2-thiolates is entirely probable when account is taken of the results of X-ray diffraction studies on the tetrahedral complex **78**.[259]



78

The structure of compound **78** is interesting also because it does not involve the formation of a four-membered metallocycle of type MN_2S_2 characteristic of all the complexes of 2-azinols and azine-2-thiols described above.



b. Electrosynthesis of bimetallic and polymetallic complexes

The few existing examples of the electrosynthesis of polymetallic complexes show that this method is promising.

A cadmium complex CdL_2 has been obtained under the conditions of the electrolysis (acetonitrile, Et_4NClO_4) of pyridine-2-thiol **79** with a trimethylsilyl substituent attached to the heterocycle.[260]

79

80

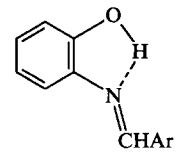
According to X-ray diffraction data and in contrast to the inner complexes **76–78**, this compound has the dimeric structure $[CdL_2]_2$ **80**, in which the cadmium atoms involved in a trigonal bipyramidal coordination are linked by sulfide bridges.[260] One cannot rule out the possibility that the nickel and zinc complexes of pyridine-2-thiol **79** have similar structures.[260] The tetranuclear complex $[Cu_4(\mu\text{-}C_5H_{11}S)_4(Ph_2PCH_2PPh_2)_2]$ has been synthesised by the reaction of copper with pentyl sulfide and bis-(diphenylphosphino)methane under the conditions of electrolysis (acetonitrile, Et_4NClO_4).[261] According to X-ray diffraction data, a new type of eight-membered cyclic structure Cu_4S_4, in which the copper atoms are linked by sulfide bridges, is formed in this complex.[261]

Complexes $[Et_3NH]^+[M_4(SPh)_{10}]^-$ with the tetranuclear anions, where M = Zn or Cd, have been obtained by direct electrochemical synthesis with participation of zinc (or cadmium), thiophenol, and triethylamine in acetonitrile with Et_4NClO_4 as the supporting electrolyte.[262] A bicyclic structure with terminal coordination of zinc and with the bridging SPh fragments is produced in the anion with M = Zn.[262] X-Ray diffraction studies have shown that the electrochemical synthesis makes it possible to create two types of hexanuclear cluster structures on the basis of 4,6-dimethylpyrimidine-2-thione: for Cu_6L_6, an octahedral cluster with six Cu atoms, each of which is trigonally coordinated to one N atom and two S atoms of three different ligands,[263] and for Cd_6L_6 a cyclic system with six cadmium atoms linked by sulfide bridges.[258] Since the electrosyntheses of both clusters considered were carried out under the same conditions (acetonitrile, Et_4NClO_4), one may postulate that the decisive factor in the creation of the structures indicated is the ability of the complex forming species (Cu^+, Cd^{2+}) to form different polyhedra.

The possibility of obtaining clusters from the complexes synthesised electrochemically is of undoubted interest. Thus the octanuclear cluster $[Cu_8(SC_5H_{11})_4(S_2CSC_5H_{11})_{11}]$ has been synthesised from the univalent copper complex of pentyl sulfide obtained under the conditions of electrosynthesis in acetonitrile using a copper anode[203] and carbon disulfide.[264] The interaction of the electrochemically synthesised adduct of the cadmium complex of pyrimidine-2-thione with 1,10-phenanthroline [complex **77** (M = Cd, A = N, L′ = Phen, R = H, n = 2)] and divalent copper hexafluoroacetylacetonate (F_6acac) in acetonitrile leads to the tetraheteronuclear complex $[Cu_2(Phen).(\mu^3\text{-}L)_2Cd_2(F_6acac)_2]\cdot 2AN$,[265] where L = the trianion of 1,3,5-tris(trifluoromethyl)cyclohexane-1,3,5-triol.

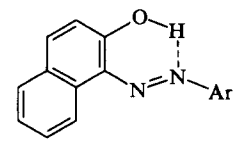
V. Other methods for the direct synthesis of coordination compounds

Special mention should be made of the synthesis of complexes from zerovalent metals in a melt[10,17,113] and under the conditions of boundary friction of the metals (tribochemical reactions).[17–19,266–279] These methods were segregated in a separate section because syntheses in the melt and tribochemical reactions may be regarded as solid-phase processes accompanied by transition to the liquid phase or (and this cannot be ruled out) may be regarded as processes occurring in a plasma.



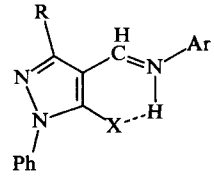
Virtually all the complexes obtained by these methods are inner complexes. Copper, nickel, cobalt, and zinc react exceptionally vigorously with fused salicylidene-*o*-aminophenol **28** (R = C_6H_4OH-*o*, R′ = H), *o*-hydroxyphenyl-1,2,4-oxadiazoles **30**, and 8-hydroxyquinoline.[17] The yields of the inner complexes in these syntheses are fairly high (up to 60%–70%). Benzoylacetone and acetoxime react with copper in the fused state, but the reactions are slow and afford low yields of the metal chelates. Macrocyclic complexes, for example metal-phthalocyanines **38**, have been synthesised in a melt of a mixture of solid reagents (the metal, *o*-phthalodinitrile or phthalimide, as well as certain other derivatives).[10]

The tribochemical method of synthesis of coordination compounds is based on the preparation of inner complexes under the conditions of boundary friction in a reactor which is a modification of the end-face friction machine.[17–19] The friction couple is made from the complex-forming metal (M^1 = specimen) and its alloy (M^2 = counterbody). The tribochemical reactions are described as follows:[19]

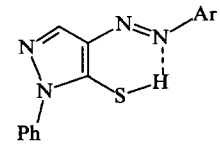


$$M^1 + n\,LH \xrightarrow[\text{friction}]{M^1/M^2} M^1L_n + \tfrac{1}{2}nH_2\,.$$

A scheme has been proposed for the formation of complexes under the conditions of boundary friction via chemisorption processes in which an electron is transferred from the metal atom to the ligand and the adsorbed molecules are rearranged in conformity with the geometry of the complex.[17–19] Another important factor governing the successful tribosynthesis of coordination compounds is the appearance in the region of the friction contact of zones with local temperatures in excess of 1273 K. This leads to the formation of a triboplasma in the microvolumes in which the complex formation reactions take place.[19,267]

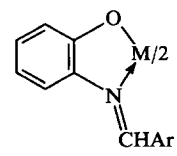


Ideas concerning tribocoordination and the influence of external conditions on the latter have been developed in a number of studies.[19,272,274,277–279] It has been established that a necessary condition for tribocoordination is the presence of acid HX groups (X = NR, O, S) in the molecules of the organic compounds used as ligands.[19] By virtue of their presence, the tribosynthesis of inner complexes has been achieved with participation of salicylideneaniline and its derivatives **28**,[17–19,267,273,276] arylidene-*o*-aminophenols **81**,[17–19] arylazonaphthols **82**,[17–19,266] azomethines **83**,[17–19] and azo-derivatives of the pyrazole series **84**.[17–19]

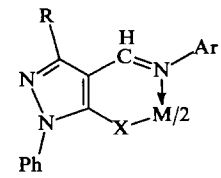


81

82



83 (X = S, Se)



84

Among the complexes obtained from the ligand systems **81–84**, the arylidene-*o*-aminophenoxides **85**, which are formed readily under the conditions of tribosynthesis, require special consideration.[17–19] Under the usual conditions, they are obtained from metal salts with fairly considerable difficulty owing to the hydrolysis of the azomethine linkage.[7,280]

85

86

The successful tribosynthesis of the metal chelates **86** from the ligands **83**, in which a constant interest has been shown in connection with the detailed characteristics of their

stereochemistry and stereodynamics, may be noted.[7,208,281] Inner complexes of other classes of ligand systems have also been obtained under the conditions of boundary friction. Thus the tribosyntheses of metal β-diketonate chelates, in particular the complexes of 3,3,3-trifluoro-1-thienoylacetone, have been described.[270,275]

The tribochemical method has definite advantages, since it makes it possible to obtain complexes over a wide temperature range in polar and nonpolar media. At the same time, the low yields of the final products (see, for example, Kuzharov et al.[18]) are its significant disadvantage. Because of this, the prospects for the application of the tribochemical method in modern synthetic coordination chemistry are obscure.

Definite advances have been made using ultrasound for the synthesis of complexes from zerovalent metals.[282–284] The inner complexes of 3*d* transition metals with salicylideneanilines of type **28** have been obtained with the aid of ultrasound.[282–284] However, much work still remains to be done on the improvement of this type of activation of zerovalent metals before a preparative method of synthesis of coordination compounds can be created on its basis.

VI. Conclusion

In assessing the data presented in the present review from the standpoint of modern coordination chemistry,[3–5,7,29,281] the following features must be emphasised.

First, the direct synthesis from zerovalent metals makes it possible to obtain all types of coordination compounds. In this connection, the gas-phase reactions are carried out mainly in order to obtain π-complexes, while the liquid-phase synthesis is designed predominantly for the preparation of molecular adducts and metal chelates.

Second, diverse organic ligand systems, forming molecular complexes, π-complexes, metal chelates, and clusters may participate in the direct synthesis. This factor permits the specific synthesis of complexes with a specified geometry and a specified location of their coordinate bond (see, for example, Refs 153, 169, 216, 229–238, 253–258, and 263).

Third, under the conditions of the direct synthesis of coordination compounds, it is possible to employ the metals of virtually all the Groups of the Periodic System and to regulate the oxidation states of the complex-forming metals by selecting the ligands. The preparation by this method of gold, silver, and lanthanide complexes is especially promising. Definite progress in regulating the oxidation states of the metals may be attained by means of a correct selection of ligand systems taking into account the principle of hard and soft acids and bases,[180,285,286] namely low oxidation states of the metals should be stabilised by soft bases (P, As, S, and Se donors), while high oxidation states should be stabilised by hard bases (N and O donors).

Fourth, despite the wide-scale employment of direct synthesis for the preparation of metal complexes, individual methods require improvement in order to bring them up to preparative application (gas-phase synthesis and tribosynthesis). For the application of certain methods, it is desirable to expand the range of ligand systems: chelating ligands in the gas-phase synthesis and compounds forming π-complexes and cluster structures in the liquid-phase synthesis.

Extensive possibilities for the study of the products of the direct synthesis arise from the use of ion-cyclotron resonance.[287,288]

All the features described above demonstrate the likely usefulness of the direct synthesis of metal complexes and give rise to the hope for the extensive employment of this method in coordination chemistry. This is also indicated by a review[289] devoted to the electrosynthesis of coordination compounds.

This review has been written with the financial support of the Russian Fundamental Research Fund (project 94-03-09731).

Abstract. The physicochemical foundations of known fluid supercritical extraction processes and of essentially new transcritical extraction processes in liquid–liquid systems, and in ultramicroheterogeneous systems with a subtransitional dispersed phase in micellar and liquid-crystalline transitions, are discussed via a unified approach based on conclusions of the modern fluctuation theory of phase transitions. It is shown that regions of enhanced selectivity of the phase redistribution exist on the path to the critical point both under supercritical and under subcritical conditions, and that a subcritical selectivity maximum is possible only if the system contains a region in which the classical theory of critical phenomena is applicable. In the selective extraction into both the subcritical and the supercritical phases a weak, universal (physical) selectivity may be accompanied and complemented by stronger specific chemical effects leading to selective complex formation. It is shown that the chemical reaction in the homogeneous phase can be treated as a first-order phase transition close to a second-order phase transition, and accordingly we observe a universal physical superextraction into this phase. The bibliography includes 79 references.

I. Introduction

Distillation and extraction processes depend on changes in the state of a fluid (gaseous or liquid) heterogeneous system along the equilibrium curve on a phase diagram caused by macrointeractions in the system. Distillation and extraction processes are usually carried out far from the critical point (CP). In two-phase systems the equilibrium curve terminates at the CP, where the difference between the coexisting phases disappears and the concepts of extraction and separation become meaningless (Fig. 1*a*). However, the response of the system to external influences is a maximum at the CP. Near the CP many other unique features of the critical state of matter become apparent due to the anomalous development of fluctuations and to the tendency of their correlation radius to increase towards infinity. Another important property of these systems is the loss of individuality of substances as the critical conditions are approached. The character of these properties is determined by the extent to which critical conditions are approached rather than by the individual character of the substances or even by the type of phase equilibrium. The conjunction of these two features produces uniquely favourable conditions for the realisation of various pathways for extraction, separation, and concentration processes using critical phases, thus creating methods of treatment which use no reagents and therefore emit no waste products.

The aim of this review is to examine by a unified approach the physicochemical foundations of the exploitation of the unique properties of the transcritical state of matter in extraction, separation, and concentration processes. The approach is based

on one of the most important conclusions of the modern theory of critical phenomena and of phase transitions: the existence of a unique and universal driving force[1,2] for the critical phenomena and phase transitions of the second kind.†

An alternative starting point is the postulate first put forward in Landau's classical theory of a continuous and monotonic replacement of one type of phase transition by another.[1] On the path towards the critical phase (or a 'pure' phase transition of the second kind) a phase transition of the first kind becomes increasingly 'weak', and increasingly sensitive to the effect of fluctuations on the character of the transition, i.e. it develops steadily increasing second-order properties.

A third (and very important) consideration is the hypothesis that transcritical and pre-transition phenomena in complex real multicomponent systems can be treated from the standpoint of the modern theory of critical phenomena, developed for the simplest model systems. In the first instance this refers particularly to a specific property of the transcritical state of matter: and enhanced solvent power of the transcritical phases, whose thermodynamic basis and molecular nature are most conveniently examined by considering the simplest two-component binary systems, i.e. critical solutions at infinite dilution. The concept of 'weak' phase transitions of the first kind and the postulate of universality in the properties of substances in the critical region allow the results of an analysis of the enhanced solvent power of critical phases to be applied to a wide range of real transcritical systems whose criticality (or degree of second-order nature) reveals itself not in a 'pure' form but in a form complicated by marked indications of first-order behaviour. A special case of this behaviour is the enhanced solvent power of systems containing an ultramicroheterogeneous dispersed phase.

The properties of the transcritical state can be exploited in extraction, separation, and concentration processes in various ways. In particular, extraction into critical phases from solid surfaces and extraction into critical phases through a noncritical interface have been used in liquid–gas systems. Supercritical fluid extraction processes near the gas–liquid critical point are known. Similar processes have been forecast for liquid–liquid systems. The use in extraction, separation, and concentration processes of the redistribution between phases in the subcritical region through the subcritical interface (Fig. 1*b*) and of the changes in the type of the phase transition under these conditions is new in principle. Processes of this type are known mostly in three-phase systems near the critical homogenisation point of two of the phases. In these processes an increased selectivity, determined by both universal physical effects and specific chemical effects, is observed when the system approaches the critical point, but in the subcritical rather than the supercritical region (in contrast to fluid supercritical extraction). The possibility of similar processes in ultramicroheterogeneous systems has been predicted.

These paths to transcritical superextraction all approach critical conditions, and therefore they can be analysed in terms of a unified concept leading to the prediction of several new phenomena.

II. Enhanced solvent power of critical phases

1. Thermodynamic causes

The thermodynamic causes of the increase in the solvent power as the system approaches the critical point (or a 'pure' phase transition of the second kind) are conveniently discussed in terms of a very simple binary system in which the solvent is a gas. In this case when a pure substance is dissolved in the gas under isothermal conditions (as a function of the gas pressure P) the solubility of the second component (N_2) varies according to the equation

$$\left(\frac{\partial N_2}{\partial P}\right)_{T,s} = \frac{v_2^0 - \left[v - (1-N_2)\dfrac{(\partial P/\partial N_2)_{T,v}}{(\partial P/\partial v)_{T,N_2}}\right]}{(\partial \mu_2/\partial N_2)_{T,P}}, \qquad (1)$$

where μ_2 is the chemical potential of the dissolved substance, v is the molar volume of the solution, and v_2^0 is the molar volume of the pure dissolved substance. The subscript s denotes differentiation along the coexistence curve. Eqn (1) follows from the generalised Gibbs–Duhem equation;[3] it has also been obtained[4] in terms of the quantitative theory of the solvent power of supercritical fluids. This equation describes the increase in the solvent power of a supercritical phase in terms of classical thermodynamics, resulting from the fall to zero of the derivatives $(\partial P/\partial v)_{T,N_2}$ and $(\partial \mu_2/\partial N_2)_{T,P}$ at the critical point. The role of the former of these derivatives is the more marked. Its tendency to zero on the path towards the critical point of the pure solvent depends on the chosen path, and therefore the thermodynamic properties of these solutions (and in particular the partial molar volumes) also depend on the path.[3,5] We note that all these authors[3–5] treat the approach to zero of $(\partial P/\partial v)_{T,N_2}$ near the critical point of the pure solvent under conditions of infinite dilution. Unless these conditions are stipulated the derivative $(\partial P/\partial v)_{T,N_2}$ is nonzero even on the gas–solute critical curve.[3–5] However, according to the modern fluctuation theory of the common nature of all critical phenomena (including phase transitions of the second kind[2]) and of the increased compressibility under all critical conditions[6] the derivative $(\partial P/\partial v)_{T,N_2}$ should decrease even if it does not vanish. This results in a growth of the solvent power of all critical phases. The problem lies in identifying the experimental conditions needed to observe this behaviour (the increased solvent power) experimentally, and the degree of approach towards the critical conditions. These arguments justify the assumption that Eqn (1) is universally applicable.

Let us examine the thermodynamic equations which describe the dependence of the partial molar volumes of the solvent ($\bar{v}_1$) and of the solute ($\bar{v}_2$) on N_1 and N_2 for the simplest two-component system:[7]

$$\bar{v}_1 = v + N_2\frac{(\partial P/\partial N_2)_{T,v}}{(\partial P/\partial v)_{T,N_2}}, \qquad (2)$$

$$\bar{v}_2 = v - N_1\frac{(\partial P/\partial N_2)_{T,v}}{(\partial P/\partial v)_{T,N_2}}. \qquad (3)$$

As it tends towards zero the derivative $(\partial P/\partial v)_{T,N_2}$ is always negative (in keeping with the classical thermodynamic stability conditions). Even more relevant to our problem is the nontrivial question of the sign of the derivative $(\partial P/\partial N_2)_{T,v}$. Under relevant conditions of divergence of the partial molar volumes this sign is assumed[2–5] to be arbitrary, though it has been stated[4] (without any evidence) that 'in practice' the derivative $(\partial P/\partial N_2)_{T,v}$ is positive. Allowing for Eqns (2) and (3) and for the negative sign of $(\partial P/\partial v)_{T,N_2}$, we may conclude that under conditions of divergent $\bar{v}_1$ and $\bar{v}_2$ (v being always finite) the sign of $(\partial P/\partial N_2)_{T,v}$ always agrees with that of the partial molar volume of the solute and is opposite to the sign of the partial molar volume of the solvent. This leads us to the universal thermodynamic conclusion that in keeping with the singularity of the partial molar volume of the solvent and irrespectively of its sign, the molar volume of the solution on the path towards the critical point always decreases. Thus, for negative values of $\bar{v}_1$ this decrease follows from the definition of a partial molar quantity, and for positive values of $\bar{v}_1$ it is produced by the negative value of $\bar{v}_2$ [of course, $(\partial P/\partial N_2)_{T,v} = -(\partial P/\partial N_1)_{T,v}$]. This important property of the molar volume of the solution of the path towards the critical point (i.e. towards the point for a 'pure' phase transition of the

† We shall treat the redistribution between phases as a phase transition of the second kind.

second kind) allows the general thermodynamic reason for the enhanced extraction of a substance into a critical phase to be identified in a specific case.

We note that in the modern theory of phase transitions both phase transitions of the second kind and 'weak' phase transitions of the first kind but close to the second kind are treated as critical phenomena.[2]

If the path to the critical point is examined under isobaric conditions an equation analogous to Eqn(1) can easily be obtained from the same generalised form of the Gibbs–Duhem equation:

$$\left(\frac{\partial N_2}{\partial T}\right)_{P,s} = \frac{-S_2^\circ + \left[S - (1-N_2)\dfrac{(\partial T/\partial N_2)_{P,T}}{(\partial T/\partial S)_{P,N_2}}\right]}{(\partial \mu_2/\partial N_2)_{P,T}} \qquad (4)$$

where S is the entropy of the solution, and S_2° is the molar entropy of the pure solute. This equation was first obtained in the author's laboratory.[8] The derivative $(\partial T/\partial S)_{P,N_2}$ in Eqn (4) plays the same role as $(\partial P/\partial v)_{T,N_2}$ in Eqn (1). Its decrease is the thermodynamic reason for the singularity in the partial molar entropy which enhances the solvent power of the critical phase as the critical point is approached. Equations similar to (2) and (3) can easily be obtained for the entropy, showing that the thermodynamic cause of the enhanced extraction into the critical phases under isobaric conditions is the increase in the molar entropy of the solution on the path towards the critical point. This increase is itself caused by the singularity in the partial molar entropy of the solvent, and is observed irrespectively of the sign of this singularity.

The general condition for a maximum in the isothermal dependence of the solubility on pressure in binary systems takes the form[7]

$$N_1^l(\bar{v}_1 - \bar{v}_1^l) + N_2(\bar{v}_2 - \bar{v}_2^l) = 0, \qquad (5)$$

where the subscripts denote the components and the superscripts denote the phase; the upper bar denotes a partial molar quantity. The presence of extrema on the composition dependence of the partial molar quantities predetermines the presence of extrema on the coexistence curve of the two equilibrium phases, i.e. on the solubility curve.[7] An analogous equation can be obtained for isobaric conditions.

By generalising the dependences described by Eqns (1), (4), and (5) we can establish not only that the solvent power of any critical phase is enhanced but also that the number of solubility maxima in the system is equal to the number of critical points.[8] In the special case of the solubility of an individual substance in a gas the solubility maximum is associated with the presence of a lower critical point in the gas–gas equilibrium, and if an upper critical point is also possible in the gas–gas equilibrium the solvent power of the gas phase should have a second maximum.[7]

2. Increase in the solvent power in 'weak' phase transitions of the first kind

The monotonic nature of the change in the type of the phase transition creates a very large class of so-called 'weak' phase transitions of the first kind, or phase transition of the first kind close to phase transitions of the second kind. The concept of weak phase transitions of the first kind and the widespread occurrence of transitions of this type in practical solutions have stimulated many attempts to find and to characterise various universal dependences in these solutions. The most important of these is the anomalously high response of a substance in the critical state to macroscopic and even to microscopic perturbations.[2] The stipulation of weak phase transitions of the first kind (close to transitions of the second kind) justifies the assumption of a universal enhancement of the solvent power in all cases of more or less clearly displayed second-order properties, i.e. λ-anomalies in the second derivatives of the thermodynamic potential with corresponding S-shaped changes in the first derivatives of the thermodynamic potential (enthalpy, volume, and entropy). The nature of the most important dependences can be determined from the results of studies of critical solutions at infinite dilution.[3]

Several uniquely anomalous dependences, apparently incompatible with classical thermodynamics,[3] have been observed in these solutions and explained in terms of the classical phenomenological theory.[5] The universality postulate suggests that in dilute critical solutions the most clearly marked effects are characteristic of the critical state as a whole, and that these effects should be observed to a greater or lesser extent in all practical critical phases during 'weak' phase transitions of the first kind. Indeed, at the critical point of the pure solvent

$$(\partial P/\partial v)_T = (\partial^2 P/\partial v^2)_T = 0,$$

whence it follows that

$$(\partial V/\partial P)_T = (\partial^2 V/\partial P^2)_T = \infty.$$

The anomalously high compressibility, observed not only in critical solutions at infinite dilution but also in solutions with 'weak' phase transitions of the first kind close to transitions of the second kind, should increase the solvent power. The universality of the anomalous properties of critical solutions at infinite dilution was first postulated in a general form by the writer,[9] and subsequently received independent confirmations.

3. Increased solvent power of ultramicroheterogeneous systems

The enhanced solvent power of systems containing an ultramicroheterogeneous dispersed phase, which increases with the dispersion as a result of changes in the type of the dispersed phase–medium phase transition from the first to the second kind, is of special interest.[10,11] A change in the type of phase transition on the surface of the dispersed phase as the system moves towards the critical point is phenomenologically consistent with Landau's assertion that the curve describing phase transitions of the first kind cannot terminate at a single point and must gradually be converted into a curve for phase transitions of the second kind, so that the two curves have a common tangent.[1] The effect is clearly illustrated in Fig. 2, which shows the dependence of the surface tension on both surfaces of the intermediate phase in a three-phase water–amphiphile–oil system upon the degree of enrichment of the intermediate phase by the components of the lower (water–salt) and the upper (oil) phase. Obviously, in the solubilisation within the droplet of the microemulsion by 'mechanical capture', without any allowance for the change in the type of phase transition and for the effect of this change on the interfacial redistribution, the size and nature of the solubilised volume should be strongly dependent on the type of microemulsion (the inverted microemulsion solubilises the aqueous phase, the normal solubilises the organic phase). This is indeed observed in practice: for surface tensions of 10^{-1}–10^{-2} dyne cm^{-1}, that is corresponding to microemulsion particles in which the intermediate amphiphilic phase is enriched with the components of the water-salt and the organic phase.[12] However, further lowering the surface tension (which corresponds to a decrease in the size of the microemulsion particles[12]), with a gradual transition from an amphiphilic to a micellar microemulsion phase (i.e. at surface tension values in the range 10^{-3}–10^{-5} dyne cm^{-1}), we can see not only an enrichment of the intermediate phase with the components of both the upper and the lower phase but also a decrease in the distance between the curves (see Fig. 2). Thus we observe an increase in the solvent power of the amphiphilic phase even in lyophilic ultramicroheterogeneous systems, with the approach of the 'weak' phase transition of the first kind to a 'pure' phase transition of the second kind. In this case the increase in the degree of criticality of the system is due to the increase in the fluctuations in the surface of the particles (micelles) with decrease in particle size. A thermodynamic driving force for the increased extraction into the micellar phase is provided by anomalies in the compressibility and in the change in the partial molar volumes.

Under isobaric-isothermal conditions the entropy of the ultramicroheterogeneous system increases with the degree of dispersion.[10,11] Allowing for these effects and for the primarily entropic nature of the subcritical redistribution of the components between the phases[13] we may assume that in multicomponent systems under isobaric–isothermal conditions the special properties of the partial molar entropies of the solute in the transcritical phases are the thermodynamic reason for the presence of maxima in the solubility.[10,11]

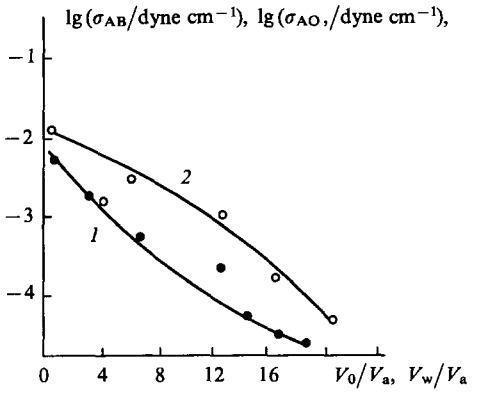

Figure 2. Plots of the surface tension σ in a three-phase system at the interfaces of an intermediate amphiphilic microemulsion-micellar phase with an upper (organic, *1*) and a lower (aqueous salt, *2*) phase against the bulk enrichment of the intermediate phase by the components of the upper (V_w/V_a) and the lower phase (V_0/V_a).[11]

We note that, as shown in Fig. 2, the solvent power of ultramicroheterogeneous systems varies only in the case of lyophilic ultramicroheterogeneous systems. Lyophobic ultramicroheterogeneous systems are thermodynamically unstable, they can be broken down by microscopic perturbations, and their enhanced solvent power can be observed only under conditions specially chosen to stabilise the degree of dispersion, for example by evolving hydrogen at a cathode, by cavitation produced by ultrasonic treatment of the liquids, or by forming Manegold spherical foams (gas emulsions) stabilised by surface-active substances. In all these cases we are dealing with the stabilisation of the gas–liquid interface in a dispersed system at the disappearance boundary of this surface, i.e. at the maximum spread of its fluctuations on the path from a colloidal dispersion to a true solution of a gas in a liquid. In most cases these phenomena have not been discussed from the point of view of changes in the nature of the phase transformation with increasing dispersion, but they can be easily incorporated into the concepts now being developed.

4. Molecular nature of the enhanced solvent power of critical phases

It is important to note that the enhanced solvent power of any critical phase is due to the special properties of partial molar quantities, as can easily be seen by examining the thermodynamics of the simplest binary transcritical systems. The left-hand sides of Eqns (1) and (4) exist only because of the singularity of the partial molar quantities. The signal of the partial molar quantities can be either positive or negative for both the solvent and the solute. The only universal feature is the nature of the decrease (in the critical region) of the molar volume of the solution as a result of the increased compressibility and of the anomalies in the partial molar volume. It has been shown[14] (in the case of critical dilute solution) that the compressibilty extrema correspond to the extrema of the partial molar quantities (Fig. 3). Under the same conditions maxima corresponding to clusters are observed in the solution: these are formations containing up to 10^2 molecules and having a local

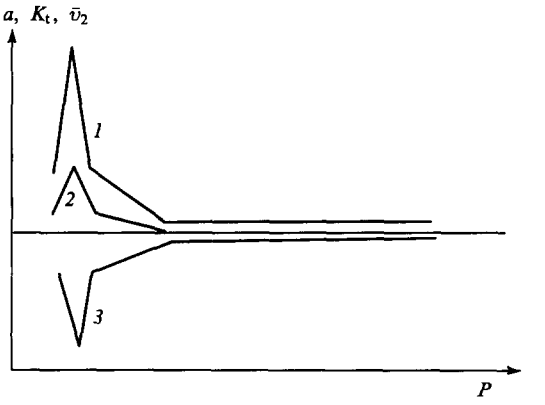

Figure 3. Plots of the size of the clusters (*1*), of the compressibility (*2*), and of the partial molar volumes (*3*) in the CBr_4-CO_2 system at infinite dilution.[14]

density higher than the average for the solution. Until recently the physical nature of the sign of the divergence of the partial molar quantities was not clear, but recent studies using molecular dynamics have thrown some light on the problem. According to Pelsche and Debenedetti[15] the anomaly in the partial molar volumes of a dissolved substance $\bar{v}_2$ is always (irrespectively of its sign) a universal phenomenon, accompanied by an increase in the size of the cluster (a shell surrounding the molecules of solute, with correlated fluctuations of the order parameter). Under these conditions infinitely dilute solutions of a Xe-like Lennard-Jones fluid in a Ne-like Lennard-Jones supercritical fluid show enhanced solvent–solute interactions near the critical point of the solvent, whereas in a 'symmetrical' system (an infinitely dilute solution of a Ne-like Lennard-Jones fluid in a Xe-like Lennard-Jones supercritical fluid) the shells surrounding the solute molecules are depleted of solvent. The stronger solvent–solute interactions correspond to an increased concentration of solvent in the cluster and to a negative divergence of $\bar{v}_2$ (tending to $-\infty$). On the other hand lowering the solvent content of the cluster corresponding to a positive divergence of $\bar{v}_2$ (tending to $+\infty$). In either case the local density of the cluster exceeds the average density of the solvent.

The same universality of the enhanced solvent power of the supercritical phases is observed in the extraction in liquid–liquid systems. Anomalies in the compressibility have been found even in solutions of liquid metals in the supercritical region (Fig. 4).

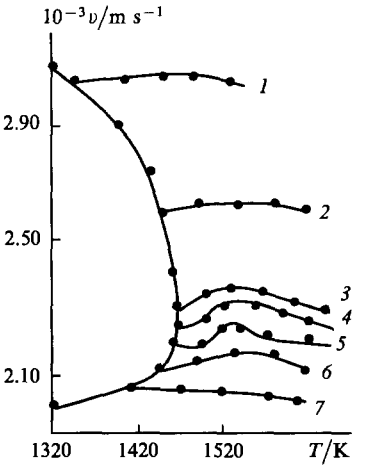

Figure 4. Compressibility anomalies in the critical region of the homogeneous phase-separating Cu–Te system. Plots of the velocity of ultrasound for alloys with an initial concentration of Te of 5 (*1*), 10 (*2*), 16 (*3*), 17.5 (*4*), 18 (*5*), 20 (*6*), and 29 at.% (*7*) (from data by Glazov et al.[16])

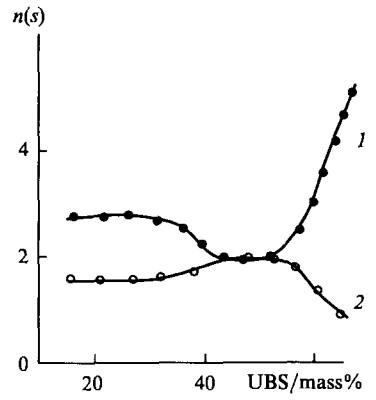

Figure 5. Dependence of the hydration number (*1*) and the solvation number (*2*) of the micelle-forming component uranyl benzenesulfonate (UBS) in the organic phase of the tributyl phosphate–water–UBS system on the concentration of UBS.[18]

The concept of universality in the extraction into micellar and liquid-crystalline phases due to the abundance in these phases of 'weak' transitions of the first kind with a 'diffuse' concentration[17] has provided explanations for several results previously treated as 'anomalous'.[10,11] The molecular nature of the enhanced solvent power of critical phases has been confirmed by a study by NMR of micellar extraction systems.[18] According to these results a region of universality is found in a tributyl phosphate (TBP)–water–uranyl benzenesulfonate (UBS) micellar solution in which the hydration and the solvation number in the hydration–solvation shell of the micelle-forming component become identical (Fig. 5). This means that the solvation shell of the micelle-forming component (in our case uranyl benzenesulfonate) contains both water and the hydrophobic solvent, i.e. that we have a region of universality. These experimental data confirm the validity of the concept of universality in the enhanced solvent power of the micellar phases and in the physical superextraction into these phases. The phenomenon has been called[18] reversible hydration. It confirms the concept of universality on a microscopic scale and contradicts the traditional explanation of solubilisation in the nucleus of a micelle in terms of 'mechanical' trapping of the conjugated phase. The observed solubilisation of both hydrophilic and hydrophobic substances is usually explained by the bicontinuous structures model proposed by Winsor,[19] according to which both normal and reversed-phase micelles are present in the micellar solution.

The concept of universality in the enhanced solvent power of ultramicroheterogeneous systems, produced by the fluctuational nature of the particle surfaces, is consistent with the well-known compression of knots of macromolecules produced by cross-linking within the knots.[20] Enhanced absorption of impurities in highly dispersed aerosols is also known. Evidently this effect becomes more marked as the degree of dispersion and therefore also the role of fluctuations are increased (as in the case of ultramicroheterogeneous liquid–liquid systems). This interpretation follows from the postulated universality of critical phenomena, and agrees well with the higher acidities observed in fog (up to pH 1.6) than in rain.[21] The assumption of fluctuations in critical phenomena allows us to predict other effects due to the development of fluctuations as the size of ultramicroheterogeneous particles is decreased: for example, a maximum in the absorption of CO_2 and SO_2 impurities during the condensation of superheated steam.[8]

5. Dependence of the solvent power of critical phases on the path to the critical state

A thermodynamic paradox, attributed to the 'nonclassicality' of critical phenomena, has been pointed out.[22] The effect of this paradox is that the thermodynamic state at the critical point is not uniquely defined by the conjugation of the available thermodynamic characteristics. This property of binary systems leads to several theoretical anomalies. As reported,[22] these anomalies are not experimentally accessible in liquid–gas systems, but it is thought that they could be observed near the liquid–liquid critical point in the case of two-component systems. We suggest that the ambiguity in the definition of the critical state by a conjunction of thermodynamic characteristics should produce a dependence of the properties of the critical phase on the path by which the critical point is approached.[8]

These dependences have been observed only in very dilute critical solutions. There are no reports of similar effects in concentrated solutions. One method of observing a dependence of the solvent properties of critical phases on the path by which these phases are produced is to study periodic colloid structures, whose composition and structure are known to depend on the method of preparation.[8]

Additional evidence for a dependence of the solvent power of a critical phase on its method of preparation is provided by the fluctuation theory of critical phenomena, according to which the partial derivatives of the concentration with respect to the chemical potential depend both on the degree of approach to the critical point and on the chosen path. In both cases we find a change in the critical index μ (see Anisimov's monograph[2]). Thus, if the critical point is approached by varying the concentration (φ) rather than the temperature the critical index for the surface tension, usually 1.26, takes the value

$$\frac{\mu}{\beta} \approx 3.9 \quad \text{and} \quad \sigma - \sigma_c \sim (\varphi - \varphi_c)^{\mu,\beta},$$

where β is also a critical index.

On the other hand if a concentration region to which the classical approximation applies exists at large distances from the critical point the deviation from the normal value at the critical point becomes less marked:[8,23]

$$\sigma - \sigma_c \sim (\varphi - \varphi_c)^3 \ln[(\varphi - \varphi_c)^{-1}].$$

This behaviour theoretically confirms the dependence of the solvent power of critical phases on the path by which the critical state is approached, since (as reported[10,24]) the σ values near the critical point are related to the solvent power of the critical phase and therefore also to the redistribution between phases. This allows the prediction of additional methods of exploiting the properties of the transcritical state of matter in extraction, separation, and concentration processes.

III. Pathways of transcritical superextraction

1. Superextraction through a noncritical interface

The simplest method of purification and deactivation of various solid surfaces is to use the universal solvent power of the critical phases. These extraction processes can be carried out both by using the macroscopic critical phase, corresponding to the end point of the equilibrium curve, and by relying on microscopic ultramicroheterogeneous lyophilic and lyophobic transcritical systems having a colloidal level of dispersion. Extraction is achieved by introducing into the system (in addition to the critical phase) another, noncritical interface which allows not only the removal but also the separation of the components to be extracted (see Fig. 1*b*). When the macroscopic critical phase is used this path is associated with the development of fluctuations in the volume between the two macroscopic subcritical phases which unite into a single critical phase under critical conditions.

A slightly different path to transcritical superextraction through a noncritical interface is also available: the creation of a critical extracting phase through microscopic critical phenomena in micellar ultramicroheterogeneous systems, in which we can observe the fluctuational erosion of the surface of the microscopic particles, ultimately leading to the fluctuational erosion of the interface between the dispersed phase and the dispersed medium. As in the case of extraction with ultramicroheterogeneous subcritical phases the processes of transcritical superextraction into ultramicroheterogeneous systems through a noncritical interface are usually not treated as subcritical. However, processes of this type are well known in membrane extraction processes in various types of emulsion, in which the formation of nanodispersions plays a controlling role.[25] Nanodispersions are formed with a change in the type of the phase transition on the surface of ultramicroheterogeneous particles, and as a result they not only stabilise a large number of emulsions but they also act as an extractant, able to control even the direction of the extraction process (in particular, they can lower the selectivity of the membrane extraction process in a multiple emulsion).

2. Fluid supercritical extraction processes

Fluid supercritical extraction processes[26] are among the most widely used methods of extraction through a noncritical interface into critical phases. Their main advantage is the ease of control through gradual changes in the gradient of the parameters of state and the physical nature of the extraction (which makes the process totally reversible). In supercritical fluid extraction from solutions the desired components can be isolated in a pure state. Control of the process (for example, the replacement of extraction by re-extraction) is carried out by gradually lowering the pressure, thus lowering the density of the fluid phase (upon which both the capacity and the selectivity of the fluid phase are strongly dependent).

Fluid supercritical extraction processes are used in the extraction, separation, and concentration of organic and of inorganic substances, in the purification of effluent waters, in the regeneration of adsorbents and catalysts, in the removal of toxic substances from soils, etc.[26] Because of the possibility of reagent-free re-extraction these processes offer a promising approach to the development of ecologically clean methods of separating and concentrating substances.[26] The most commonly used extractants are CO_2, ethane, and ethylene i.e. gases with a critical temperature close to 20 °C.[26-28] Other transcritical solvents have been suggested: for example, transcritical water vapour (classified[29] as a 'supersolvent').

Another feature of the fluid supercritical extraction process should be mentioned: in addition to having an anomalously high sensitivity to small changes in the parameters of state these processes are also anomalously sensitive to the presence of a third component (co-solvent) and to the chemical interaction (always quite weak) between the substance to be extracted and this component.[26-28] To produce an acceptable approximation to the experimental data in the physicochemical interpretation of the co-solvent effects in supercritical fluids we must allow for both the physical and the chemical components of the thermodynamic potential.[30] The addition of a co-solvent which interacts with the substance to be extracted can greatly increase the universal physical selectivity of the process as a result of the contribution from the specific chemical selectivity of the additive. If the active co-solvent is an alcohol (which is easily separated from the products) the complete reversibility of the process is retained since only the parameters of state (temperature and pressure) are varied. This feature is important from the point of view of developing technologies free from waste products. The use of fluid supercritical extraction in the technology of inorganic materials[31] (for example, for the separation of mixtures of liquid metals using inert gases as extractants) presents no theoretical difficulties. This would avoid the possibility of chemical decomposition of the extractant in work with very concentrated toxic or radioactive substances.

The extraction of inorganic salts (lanthanides and actinides) can be enhanced by modifying the extractant (CO_2) by additions of methanol with a selective complexing agent. Thus, in the fluid supercritical extraction of lanthanides and actinides from soils, the addition of co-extractants to the fluid superextractant has been suggested: these are compounds able to complex metal salts (dithiocarbamates, fluorinated β-diketones, tributyl phosphate).‡ It was found that tervalent lanthanides (La^{3+}, Eu^{3+}, Lu^{3+}), and also Th^{4+} and UO_2^{2+}, can be efficiently extracted from solid materials by using CO_2 modified by methanol and containing fluorinated β-diketones at 60 °C and 150 bar. It was also found that the addition of small amounts of water to the solid samples greatly increases the effectiveness of the extraction. A strong positive synergism is observed when tributyl phosphate is added together with β-diketones in the fluid supercritical extraction of lanthanides and actinides with CO_2 without modification by methanol. It is important to note that no synergism with tributyl phosphate is observed when the β-diketones do not contain fluorine substituents. Thus, chemical selective complex formation processes play a key role in the universal physical fluid superextraction, as in normal liquid–liquid processes. We note a serious shortcoming of these processes from the standpoint of their application to the extraction and concentration of radioactive substances: the need to work at relatively high pressures. In this context the application of superextraction processes near the critical conditions of liquid–liquid systems (which can be realised at atmospheric pressure) could be of interest.

3. Superextraction processes near the critical conditions for liquid–liquid systems

The possible realisation of supercritical extraction processes at atmospheric pressure near the critical conditions of liquid–liquid systems was theoretically substantiated,[32] and this was also predicted on the basis of the assumed universality of the properties of substances in the critical state.[33,34] More recently a maximum in the solvent power of a binary phase-separating liquid–liquid system near the critical consolute point was observed experimentally,[35] but none was found near the critical point of a ternary mixture.[32] It was shown[36] that the enhanced solvent power of liquid–liquid phases is associated with anomalous activity coefficients under critical conditions and is a universal property of critical phases. The universality is attributed to an increased compressibility. Because of the low compressibility of liquids near the critical phase separation point of a liquid–liquid system the concentration range of the subcritical conditions is very narrow, and therefore the practical possibilities of the method are problematic.[8]

Universal superextraction is more clearly seen in liquid–liquid systems in the case of phase transitions in micellar systems 'diffuse' in concentration, or in the case of abundant phase transitions close to the second kind, as in liquid–crystalline systems.[11,37] In these cases the extraction of substances by the critical liquid phases can reach enormous proportions (up to the complete homogenisation of the phases to be extracted). The increase in the homogenisation with increasing second-order properties of the micellar system (i.e. with decreasing micelle size) is illustrated in Fig. 2. A study of the extraction of uranyl benzenesulfonate by tributyl phosphate has shown[18] that the micellar–liquid-crystalline homogenisation of this system is physically reversible because of the reversibility of the hydration. As can be seen from Fig. 5 at high concentrations of uranyl benzenesulfonate the universality region (equality of the hydration and solvation numbers) disappears, the hydration

‡ See a recently published paper by C W Wai, Y Yen, and F Jean in *Pittsburg Conf. Anal. Chem. and Appl. Spectrosc., Chicago III, 27 Febr.–March 1994, Abstr.* (Chicago, 1994) p. 127

begins to predominate over the solvation, and the highly hydrated organic substance is no longer retained by the organic phase.

By combining the universal physical effects with specific chemical effects we can use the micellar extraction processes in separation and concentration experiments. Thus, the universality of the micellar extraction can be used for concentrating materials when the wanted component (aluminium) is held in the organic phase because of the formation of a complex between aluminium and the phenol–formaldehyde oligomer at the water re-extraction stage.[38] The formation of a complex with the phenol–formaldehyde oligomer in the same micellar extraction–re-extraction process allows gallium to be selectively concentrated and separated from aluminium.[39] Obviously the role of chemical reactions in processes of universal superextraction in liquid–liquid systems at atmospheric pressure is similar to the role of specific interactions with a co-solvent in the fluid supercritical extraction processes discussed above.

4. Universal superextraction processes through a subcritical interface

A new method of exploiting the special features of the transcritical state by using the redistribution of the components through a subcritical interface in the far subcritical region (see Fig. 1) is also of interest. These processes, so far observed only in phase-separating liquid–liquid systems, takes place when the system is moved away from the critical phase separation point, and are apparently unrelated to pretransition phenomena. However, for at least two reasons [the similarity in properties and composition of phases produced by the separation of one phase (usually the aqueous) and based on the same component (water)], these processes are related to the transcritical state of matter and they can be interpreted from this point of view. Detailed studies of three-phase extraction systems have been reported.[40–45] A new type of system, containing a third liquid phase similar in composition and properties to the equilibrium water phase, has been discovered. The third phase is found in ether(diisopropyl etc.)–aqueous hydrochloric acid systems containing metal chlorides both extractable and nonextractable by ether. It was shown[44] that the third phase is formed by the 'reversible extraction' of the ether into the aqueous phase by the hydrogen chloride in the form of the hydrated ether–HCl complex, which is poorly soluble in both water and ether. The second water phase formed under these conditions can extract all the components of the equilibrium water phase (without exception, but to different extents), including those which are poorly extractable or not extractable by ether. This accounts for the closeness of the system to the critical phase separation point.

5. Extraction in three-phase liquid systems near the critical homogenisation point of two of the phases

In this case the critical phase separation point for two subcritical phases is relatively far from the conditions of the experiment, which allows adequate selectivity in the extraction of the various components. For example, the distribution coefficients in the hydrochloric acid medium are greater than 200 for iron, 2–5 for tin and zinc, about 1 for cobalt, and less than 0.1 for nickel. The distribution and separation coefficients are markedly increased by the introduction of complex-formers. Thus, the formation of mixed metal–tin–chlorine complexes with hydrated ether allows the almost complete single-stage extraction of platinum, osmium, and iridium.[42,43] An analysis of these results[40–45] leads to the formulation of two principles of three-phase extraction equilibrium under subcritical conditions.

(1) The phase-forming component (poorly soluble in the phase-separating layer and insoluble or almost insoluble in the non-phase separating layer) becomes concentrated in the third phase, formed by the phase separation of one of the two liquid phases initially at equilibrium in the far subcritical region.

(2) The third liquid phase formed under the far subcritical conditions is an extractant for all the impurities of the separating phase.

The first principle explains the effects of forming a second aqueous phase and a second organic phase in extraction systems containing tributyl phosphate: the latter phase is well known as a concentrate of metal solvate ('red oil') in systems with uranyl nitrate and tributyl phosphate in a paraffin diluent. The extent of extraction of the components into the third phase through a subcritical interface in the far subcritical region is determined by universal physical effects and by highly selective chemical effects. It should be noted that the reported[40–45] enhancement of the extraction power and selectivity of the systems in the redistribution of the components between the phases is a consequence of the location of the system in the subcritical region. This property is independent of the presence in the system of a third (organic) phase, which plays no part in the separation processes.

A similar effect was noted in a study[46–48] of the increased extraction and separation in an extraction system consisting of two equilibrium aqueous phases one of which is strongly depleted of water by the addition of poly(ethylene glycol). In these systems the poly(ethylene glycol) acts not as an extractant but as a complex-former, which allows the formation of two aqueous phases having the same main component and similar compositions. The extraction is achieved by introducing complexing agents into the system. Supplementing the weak physical selectivity effects with clearly marked chemical effects produces results similar to those found in fluid supercritical extraction, but in this case the superextraction processes takes place in the subcritical rather than in the supercritical region.

6. Changes in the character of the phase transition during the redistribution between phases on the path to the critical point

According to Landau's views[1] on phase transitions of the first kind but close to the second, and to Fisher's postulate[49] of a continuous, purely entropic process leading to phase transitions in the critical state, we can formulate some conclusions on the type of changes in the nature of the phase transitions on the path to the critical point. If the redistribution between phases is treated as a phase transition of the first kind it should develop an increasing similarity to phase transitions of the second kind as the system approaches the critical point. The writer first proposed[13] (as a hypothesis) that the role of the entropy should increase along this path, and therefore in the equation

$$\Delta G = \Delta H - T\Delta S, \tag{6}$$

the enthalpic component (ΔH) of the change in the Gibbs free energy (ΔG) should tend to zero faster than the entropy component ($T\Delta S$). Therefore the plots of ΔH and $T\Delta S$ should converge into a single adiabatic curve. If this hypothesis is valid a region of adiabatic redistribution between phases should exist on the path to the critical point (as on the path to any phase transition of the second kind). In multicomponent two-phase systems this redistribution should show a maximum selectivity and a maximum sensitivity to small entropy differences between the redistributed components. In other words a region of adiabatic selectivity of the redistribution between phases should exist on the path to the critical point in multicomponent two-phase systems. The adiabaticity hypothesis was thermodynamically validated,[50] and the adiabaticity of weak phase transitions of the first kind was confirmed in terms of the classical theory of a two-phase flux near a liquid–gas critical point. By using a series expansion of the pressure near the critical point in powers of the difference between the time-dependent and the critical volume it was shown[51] that the equation for the phase equilibrium line coincides with the equation for the critical isentrope. This conclusion confirms the hypothesis of adiabaticity of the redistribution between phases, and it also explains the inconsistency between many experimental data and the adiabaticity hypothesis.

Thus, the specific heat λ-curves near the critical point are symmetrical because of the heat of the transition.[49] Critical solutions at infinite dilution are nonadiabatic.[3] This paradox can be resolved by noting that in a general derivation[51] the conclusion can be valid only if a region in which the classical theory of critical phenomena is applicable exists near the critical point. The classical theory of critical phenomena (region of low Ginzburg numbers) may be valid for conducting liquids[2] (solutions of electrolytes, liquid metals), and also for three-phase fluid systems[52] on the path to the tricritical point. Regions of subcritical adiabaticity of the redistribution between phases can exist only in these cases.[50]

The correctness of this conclusion is convincingly illustrated by considering the energetics of micelle formation. As we know, micelle formation is a weak phase transition of the first kind,[11] and therefore a decrease in the energy steps with temperature can be regarded as an increase in the criticality of the system. As can be seen from Fig. 6, as the criticality of the system is increased a tendency for the ΔG and $T\Delta S$ curves to merge into a single adiabatic curve is found only in electrolyte solutions. Thus the experimental data confirm the theoretical limitations to the possible existence of a subcritical adiabatic binodal.

7. Subcritical features of partial molar volumes and redistribution between phases

Proof of the existence of maxima in the subcritical selectivity follows from an analysis of the changes in the partial volumes on the path to the critical point. The relationship between extrema in the partial molar volume and in the solubility in critical phases was discussed above, including the simplest case of the solubility of a liquid in a gas.[7] For the far subcritical region it can be shown that because of the asymmetric location of the critical point relative to the coexistence curve we can expect extrema in the partial molar volume $\bar{v}$ and in the corresponding redistribution between phases.[50-55] As is shown in Fig. 7, in volume–composition coordinates the spinodal on the path to the critical point is tangential to a perpendicular to the composition axis at the point R. This point should correspond to an extremum in the partial molar volume $\bar{v}$. This statement becomes self-evident if in the condition for an extremum in the partial molar volume,

$$\left(\frac{\partial \bar{v}_2}{\partial x_2}\right) = 0,$$

$\bar{v}$ is replaced by the derivative of the chemical potential μ_2 with respect to pressure, and the order of the differentiation is changed,

$$\left(\frac{\partial \bar{v}_2}{\partial x_2}\right)_{P,T} = \left[\frac{\partial}{\partial P}\left(\frac{\partial \mu_2}{\partial x_2}\right)_{P,T}\right]_{x_2,T} = 0, \qquad (7)$$

(the subscript 2 denotes a dissolved substance). The condition (7) means that the $(\partial\mu_2/\partial x_2)_{P,T} = 0$ curves are independent of composition at the $\bar{v}$ extremum, i.e. they are tangential to a perpendicular to the composition axis. The spinodal $(\partial\mu_2/\partial x_2)_{P,T} = 0$ is a special case of these curves, and therefore it should also be tangential to the composition axis[50,55] at a point in the $\bar{v}$ extremum. This conclusion has a general thermodynamic significance: the extremum is due to the asymmetry in the position of the critical point on the binodal, and the asymmetry itself is a consequence of the failure of the critical points of the pure components to coincide. Furthermore, in liquid–liquid systems the critical points are usually located asymmetrically on

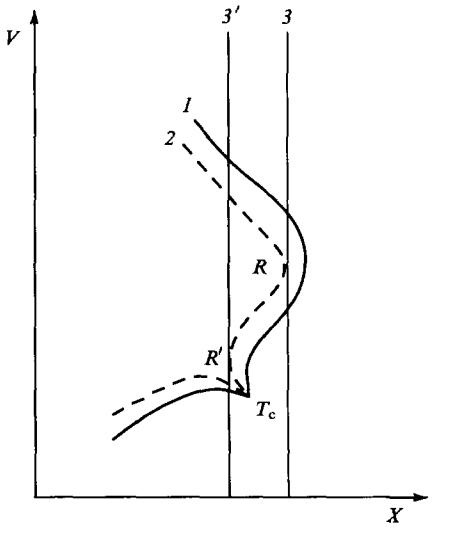

Figure 7. Asymmetry of the position of the critical point on the coexistence curve (*1*), making the spinodal (*2*) tangential to the perpendiculars to the composition axis in volume (V)–composition (X) coordinates at the extremal points R and R' in the far and the near subcritical region respectively (*3* and *3′* are the perpendiculars to the composition axes).[50]

the coexistence curve. The only exception is the rare case of a unit Hundt coefficient.[56] It is important to note that the solubility extrema are an individual characteristic of any binary system. Accordingly, in a multicomponent system the extremum points of the solvent power characterise the region of maximum selectivity in the solvent power of one phase with respect to the components of the other phase. This maximum is associated with the presence of extrema on the coexistence curve, and in general it can be located relatively far from the critical point, in the far subcritical region. However, the presence of extrema in the spinodal, at which the curve is tangential to a perpendicular to the composition axis in volume–composition coordinates (see Fig. 7), and its thermodynamic consequences regarding the distribution between phases, can be noted not only in the far but also in the near subcritical region, in which the theory predicts a singularity of the coexistence curve and of the associated spinodal.[57] The slope of the coexistence curve in the classical region near the critical point is one of the fundamental characteristics of any binary system.[58] The transition to universality (subcritical singularity) again confirms the validity of our proof of the presence of a maximum in the adiabatic selectivity of the subcritical redistribution between phases. The existence, under these conditions, of a region in which the spinodal is tangential to the perpendicular to the composition axis is a geometric necessity, as it is in the far critical region (see Fig. 7). Accordingly, in multicomponent two-phase systems two maxima in the subcritical selectivity should be found on the path to the critical point (in the far and in the near subcritical region respectively).[50]

8. Degree of generality of the predicted features of the transcritical selectivity of the redistribution between phases

According to Cahn[59] the bulk properties of the equilibrium phases in the subcritical region vary in the same sense as their surface properties. By developing and generalising this statement we may conclude that the regions of special features of the surface and of the bulk properties on the path towards the critical point are mutually related: in all cases the regions of changes in the wetting properties correspond to regions of adiabatic selectivity, and vice versa. In particular, in three-phase systems we should observe a maximum selectivity of the extraction into the wetting phase (for an adiabatic redistribution between phases) in the region of Cahn transitions from non-wetting to wetting of the α and β phases by the intermediate phase γ.

The general character of the predicted features is shown in Fig. 8. It can be seen that the curves describing the components of the thermodynamic potential for weak phase transitions of the first kind on the path to the critical path along the coexistence curve are in a symmetrical correspondence with the Nernst heat theorem.[60,61]

However, we should stress the fact that the generality of a subcritical adiabatic selectivity is limited to the case of classical subcritical fluids, i.e. to the existence (on the path to the critical point) of a region in which the classical theory of critical phenomena is applicable. The presence of two (rather than one) regions of subcritical adiabatic selectivity of the phase redistribution in multicomponent systems is also important. This assertion is also confirmed (in terms of the concepts considered here) by the experimentally observed sequence of Cahn transitions on the path to the critical point,[23] possibly related to the presence of several points of intersection of the ΔG and $T\Delta S$ curves in Fig. 8.

The regions of maximum separation (like the regions of the wetting transitions) can be far removed from the critical point along the coexistence curve. Thus, Cahn transitions have been observed several tens of degrees below the critical point.[23] By developing and generalising Cahn's views on the correspondence of surface and bulk properties, we may conclude that a well defined selectivity maximum with almost complete extraction of one of the components, and negligibly small extraction of the others, from the aqueous phase into propane has been observed in this region of Cahn transitions for the fluid extraction of various dyes in the presence of an aerosol of OT (sodium di-2-ethylhexylsulfosuccinate) at 25 °C, i.e. several tens of degrees from the critical point of propane (96.7 °C).[61] In this same region the homogenisation of the two-phase propane–OT aerosol–water system has been observed[62] under conditions which (like the selectivity conditions) depend strongly on the pressure. In this region we are dealing with physical superextraction, but since this superextraction takes place in a subcritical (rather than a critical) phase on the path to the critical point its universality is combined with universality of the maxima in the physical selectivity of the subcritical redistribution between phases whose existence has been predicted,[13] thermodynamically validated,[50] and experimentally demonstrated.[62]

The maximum in the selectivity of the phase redistribution through a subcritical interface into a transcritical region corresponds to the maximum in the selectivity of the extraction of the components of noncritical phases into a supercritical phase through a noncritical interface, i.e. under conditions of normal fluid supercritical extraction (Fig. 9). The existence of this maximum is illustrated in Fig. 9 for the fluid supercritical extraction of terpenes by carbon dioxide.[63] We note that in every case the selectivity maxima are located on the path to the critical path but not in its immediate vicinity. The presence of selective extraction in the region of the pretransition phenomena discussed in modern theories would be fundamentally incompatible with the modern theory of critical phenomena, one of whose main conclusions is the universality of the properties of matter

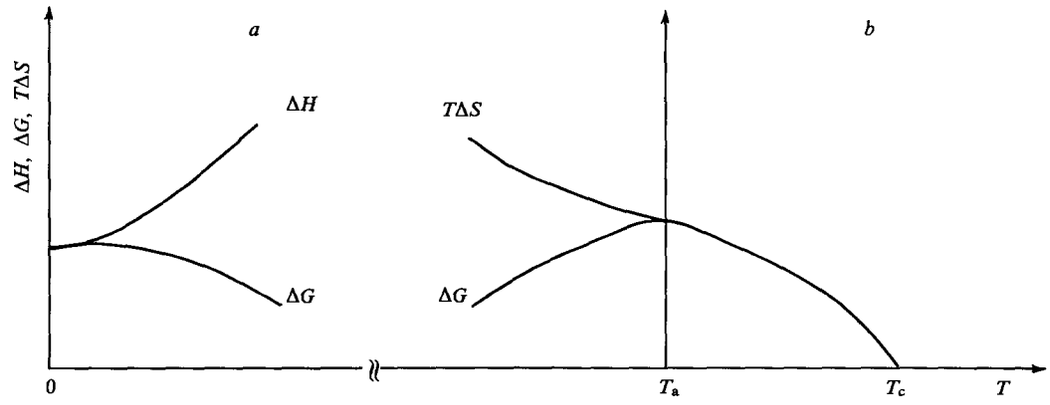

Figure 8. Symmetry of the Nernst heat theorem (*a*) and of the universal subcritical adiabaticity of the redistribution between phases in classical subcritical fluids (*b*). T_c is the critical temperature, T_a is the temperature of the transition to adiabaticity.

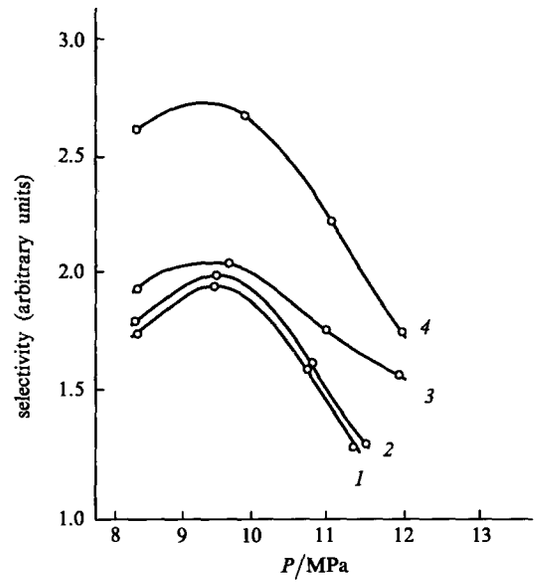

Figure 9. Selectivity in the supercritical region against pressure at different temperatures for the extraction of terpenes by CO_2 (see Ref. 63). (*1*) 40 °C, (*2*) 50 °C; (*3*) 60 °C, (*4*) 70 °C.

under these conditions. This conclusion has been confirmed experimentally[64] by showing that in equilibria between critical and ordinary phases dissolved substances are found in the phases in the same proportions. Another important conclusion is that in both regions of maximum transcritical selectivity (subcritical and supercritical) weak manifestations of universal physical selectivity can be enhanced by marked specific (chemical) effects due to selective complex formation. This is observed also in well known fluid supercritical extraction processes, and in recently described fluid subcritical superextraction processes.

IV. Possibility of subcritical selectivity in ultramicroheterogeneous systems

To conclude this phenomenological discussion of the features of transcritical superextraction we shall make one more observation concerning ultramicroheterogeneous subcritical systems. Wetting transitions accompanied by adiabatic and highly selective redistribution between phases should be found also in ultramicroheterogeneous liquid – liquid and liquid – gas systems on the path to a 'pure' phase transition of the second kind. Indeed, as long as the concept of an interface is meaningful in an ultramicroheterogeneous system it can be treated as a nominal 'wall' (C) with an equilibrium angle of contact, to which Young's law applies:

$$\sigma_{1,2}\cos\theta = \sigma_{1,3} - \sigma_{2,3}. \tag{8}$$

Following Cahn's approach[59] we shall assume that on the path to a 'pure' phase transition of the second kind the different between the interfacial energies $(\sigma_{1,3} - \sigma_{2,3})$ is determined mainly by the compositions of the equilibrium phases (J), and is dependent on temperature as is $(\varphi_2 - \varphi_1)$, i.e. in accordance with the universal scaling relation

$$(\varphi_2 - \varphi_1) \sim t^{\beta}, \tag{9}$$

where β is the critical index, equal to 0.33. On the path to a phase transition of the second kind, as on the path to the critical point, we can use the universal relationship

$$\sigma_{1,2} \sim t^{\mu}, \tag{10}$$

where μ is the critical index, equal to 1.26. From (8) – (10) we find

$$\cos\theta \sim t^{(\beta-\mu)}; \quad \beta - \mu = -0.93. \tag{11}$$

According to Eqn (11) the maximum wetting in a ternary two-phase ultramicroheterogeneous system should be observed at some distance from the phase transition of the second kind, i.e. on the path towards the phase transition, as in the wetting transitions on the path to the critical point in Cahn's original work.[59]

We can arrive at the same result by treating any third component as a nominal 'wall'. In this case on the path to a 'pure' phase transition of the second kind we find a maximum in the wetting of this component, and therefore also a maximum in the adsorption of its ultramicroheterogeneous particles. Since (at least, in three-component systems) the wetting phase is thermodynamically unstable (allowing for possible changes in the masses of the phases) it acts as the extracting phase. The combination of the maximum wetting and the maximum sorption points for various components defines the region of maximum selectivity.[50] Under these conditions the phase redistribution should be approximately adiabatic. In particular, this should be observed near adiabatic micelle formation transitions (see Fig. 6*b*).

V. Chemical reaction in the extractant phase and supercritical extraction into this phase

1. Chemical reaction and the critical phase

As reported,[3] in a critical solution in CO_2 at infinite dilution the apparent constant of the chemical dimerisation reaction ($2NO_2 = N_2O_4$) in the critical phase increases, and tends (if not to infinity) to a finite nonzero value. The thermodynamic dimerisation constant is expressed in terms of the chemical potentials, and therefore it cannot have singularities at the critical point (since the chemical potentials can have singularities only in their higher derivatives[2]).

A similar statement applies to the experimental data (discussed by Tveecrem et al.[65] and interpreted by this author[36]) on the dimerisation of nitrogen dioxide near the liquid – liquid critical point in the perfluorocyclohexane – carbon tetrachloride system. These data suggest the presence of singularities in the activity coefficients under critical conditions. It was shown that the data,[65] however interpreted, confirm the presence of superextraction in the liquid – liquid system near its critical phase separation point. On the other hand the apparent decrease in the rate constant of the chemical reaction under critical conditions is associated not only with anomalies in the activity coefficient but also with the tendency of the diffusion coefficients to vanish under critical conditions.[66]

Thus in micellar systems, in which criticality (fluctuation) conditions are found on the micelle surface rather than in the bulk of the phase, we observe an acceleration of chemical reactions ('micellar catalysis'[67,68]). But the problem of correlating chemical reactions and phase transitions has also other aspects. Thus, the polymerisation of sulfur in many organic solvents leads to the appearance of a new critical phase separation point.[69] Chemical reactions have a similar effect on phase transitions in H-bonded systems. Corrales and Wheeler[69] have examined theoretically other possible types of interaction between chemical reactions and phase transitions (not yet observed experimentally), in which the reaction acts as the driving force of the phase transition.

The possibility of stabilising (or, more strictly, metastabilising) the critical state by inducing a relatively slow chemical reaction in the homogeneous metastable critical phase has been pointed out.[70]

2. The chemical reaction as a weak phase transition of the first kind

The most interesting aspect of the interaction between chemical reactions and phase transitions of the second kind (or critical phenomena) is seen by treating the chemical reaction in the vicinity of the position of equilibrium (the equivalence point) as a

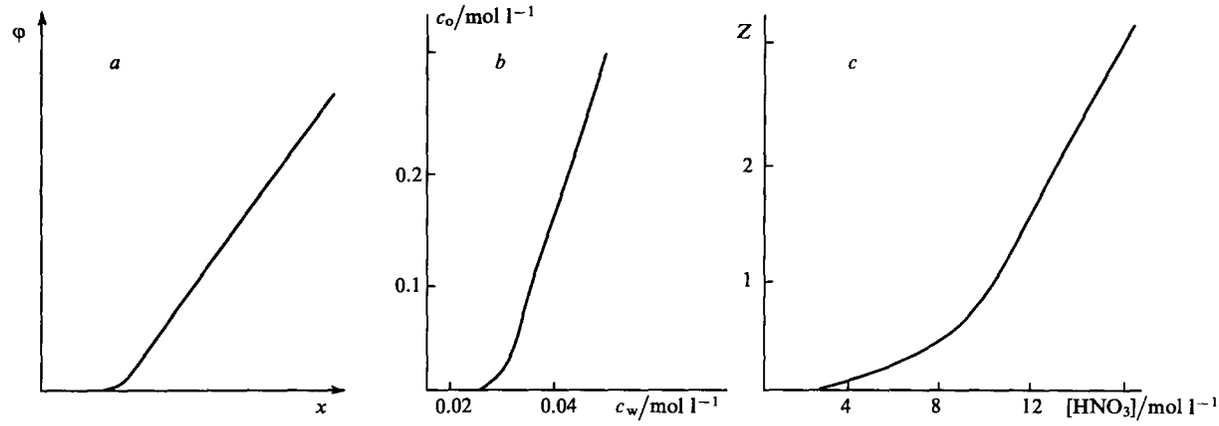

Figure 10. Plots of the concentration of monomers combined into micelles (φ) against the total concentration of monomers x (*a*); of the concentration of copper in the organic phase against its concentration in the aqueous phase in the micellar extraction by tetrachloromethane (*b*); of the concentration ratio of nitric acid and the tributyl phosphate solvate of uranyl nitrate in the organic phase (Z) against the concentration of nitric acid in the aqueous phase in the extraction of nitric acid into the tributyl phosphate solvate of uranyl nitrate (*c*). *a* and *b* from Ref. 11, *c* from Ref. 76.

weak phase transition of the first kind or as a special type of phase transition with marked second-order features. This problem has been examined theoretically[71,72] for the simplest one-dimensional model by studying reactions of the type

$$A \rightarrow X,$$

$$B+X \rightarrow Y+D,$$

$$2X+Y \rightarrow 3X_1,$$

$$X \rightarrow E.$$

It was assumed that the reactions take place near the equilibrium position. Features of transitions of the second kind were detected in the reactions by the reduced perturbation method.

By using Landau's theory it was shown[73] that a chemical reaction can be treated as a phase transition of the second kind even in regions far from equilibrium.

Published data on the superextraction by micellar liquid–crystalline alkylphenol phases at neutral pH values of all the components of conjugated phases are consistent with these theoretical considerations, according to which any manifestation of transitions of the second kind should lead to superextraction in the phase. These results were interpreted[10,11,17] as an indication of supercritical extraction at atmospheric pressure. It was also shown[74,75] that the extraction by metal solvates with tributyl phosphate and other organic extractants produces superstoichiometric supersaturation of the organic phase. The same workers[74,75] have treated the extraction of nitric acid by tributyl phosphate as a physical phenomenon. Rozen and Andrutskii[76] have pointed out the weakness of these conclusions[74,75] on the dimerisation of nitric acid in an organic phase. The formation in the organic phase of mono-, di-, tri-, and tetrasolvates of nitric acid was postulated in order to explain the observed phenomena. However, in this variant four empirical constants are needed to account for the almost linear extraction isotherm (without any indication of saturation) inferred[76] from the published data[74,75] for the dependence of the extraction of nitric acid into the tributyl phosphate solvate of uranyl nitrate on the concentration of nitric acid in the aqueous phase. But it has been shown[10] that similar isotherms without any indication of saturation are observed for micelle formation described as a phase transition of the second kind,[77] and also in the micellar extraction of copper dibutyl phosphate by tetrachloromethane.[10,18]

It can be seen from Fig. 10 that the special features of micelle formation, micellar extraction, and extraction by metal solvates are similar: the extraction into the organic phase shows no sign of saturation (i.e. of a horizontal asymptote for the isotherm). The micelle formation isotherm observed as a phase transition of the first kind which is close to the second kind has exactly the same shape. This experimental fact agrees well with the assertion[78] that many phenomena traditionally treated as chemical are in fact physical effects (in this case effects of universal physical superextraction at atmospheric pressure). The mechanism of this process is still unclear: is it due to a transition of the second kind or (as suggested[79]) is it an experimental observation of anisotropy in the solvates, caused by liquid-crystalline transitions? In any case it is clear that we are dealing with supercritical extraction at atmospheric pressure, but if this extraction is induced by second-order features of a chemical reaction the extractant can be any solvate or other chemical compound in the organic phase, and salts of any metal can be the extracted salts. On the other hand if the superextraction takes place because of the second-order properties of liquid-crystalline transitions only mesogen molecules can be the extractants.

Abstract. The theoretical and experimental studies devoted to the regularities of foam adsorption concentration and separation of substances occurring in the liquid phase in molecular, ionic, or micellar form are surveyed. The main characteristics of foam concentration and separation, their analytical dependences on the structural parameters of the foam, and their interdependences are analysed. Quantitative relationships for the characteristics of foam separation with due regard to the influence of foam destruction have been obtained. The dependences of the concentration coefficient on the expansion factor and dispersity of the foam and also on the capillary pressure in polyhedral (dry) foams prepared from solutions of individual surfactants and their mixtures are analysed. The reasons for concentration restrictions (upper and lower limits) of the foam concentration method are discussed. Examples of partial separation of surfactants in a foam and foam chromatography are considered. Brief information on equilibrium displacement and acceleration of chemical reactions in a foam is presented. The bibliography includes 77 references.

I. Introduction

Surface separation and concentration of substances comprise a group of related processes based on the regularities of adsorption and wetting. The longest used and best known among these processes is foam flotation. There exist several methods for the concentration of minerals based on flotation. According to one of these, mixtures of solid particles of various natures and degrees of dispersity are dispersed in an aqueous suspension by a gas. As this takes place, hydrophobic particles adhere to the rising bubbles, while hydrophilic particles remain in the bulk. Another method involves pumping of a suspension being separated onto a foam. This flotation process was called[1] foam separation. In the oil flotation process, drops of an emulsion to which ore particles adhere are used instead of gas bubbles. In the case of film flotation, the crushed ore is poured onto a constantly moving water surface; the easily wetted particles sink, while the poorly wettable ones remain at the surface and are then collected with the aid of a special device. A similar principle of flotation, but involving other properties of collecting agents, is also used for separation of drops of the organic phase from dilute emulsions, specifically, for the purification of waste water from oil impurities.

During the last two decades a large number of studies have been reported (see, for example, Refs. 2—6) on nonchromatographic methods of surface separation of dissolved substances (molecules and ions) and highly dispersed particles (colloids and other small particles), to which the regularities of normal flotation are inapplicable. Among these methods are isolation of ions, surfactants, proteins, dyes, and other organic compounds, colloidal particles, and microorganisms. Surfactants can be extracted from a solution or separated from each other (if in a mixture of surfactants) owing to different degrees of adsorption of components. In order to extract inactive components (in particular, ions), one should use collecting agents, which increase the ability of compounds to concentrate at the surface. The most frequently used collecting agents are diphilic compounds. Mechanisms of the action of these compounds are varied and depend on the type of species being extracted (ions, proteins, or colloidal particles). For example, ionogenic surfactants with high surface activities are typical collecting agents in the flotation of ions and molecules. As a result of ion exchange, the collecting agent attracts the substance being extracted (colligend) to the surface and forms an insoluble surface active compound with it (for example, iron ions can replace sodium ions in an anionic surfactant). This ion exchange reaction occurs most frequently in the bulk solution. In this case, the collecting agent acts as a precipitant that participates in the formation of a hydrophobised poorly soluble compound (sublate) in the bulk of the dispersive medium.

The processes of surface separation of dissolved compounds and particles of a colloidal degree of dispersion have been classified according to various criteria:[2–5] the substances being isolated (electrolyte ions, surfactants, organic compounds with high molecular weights, colloidal particles, microorganisms, etc.);[4] the type of particles in the composition of which the colligend is collected; the aggregative state of the phase in which the particles being flotated are collected; the type of interaction (binding) of the collecting agent with the compound being extracted, and according to other criteria.

Received 25 April 1993
Uspekhi Khimii **64** (3) 251–264 (1995); translated by Z P Bobkova

The methods of surface separation are named differently in various papers: in the case of extraction of surfactants they have been referred to as adsorption flotation,[2] foam flotation,[3] foam in fractionation, foam separation, or adsorption concentration,[5] and in the case of extraction of ions, the methods of ion flotation,[2] foam flotation of hydrophobic precipitates, etc. have been reported.

All these methods have many common features, but, at the same time, they are noticeably distinct. For example, in foam flotation of macroscopic particles (suspensions), separation is governed by wetting and adhesion and involves the step of the water–particle–gas three-phase contact; the concentration and separation of surfactants in a foam are determined by the adsorption ability, the rate of diffusion of the surfactant, and the properties of the foam (especially its stability). The principle of accumulation of substances at a surface and similarity of the equipment should be considered to be common features of these processes.

In the present review we shall restrict ourselves to the analysis of the foam method of concentration and separation of compounds that exist in solution as ions, molecules, or micelles (without formation of dispersions or precipitates). This method is based on the regularities of adsorption and the properties of a stable foam. The adsorption-bubble separation without foam formation, as well as flotation extraction and ion flotation with accumulation of a thin layer of the hydrophobic product at a surface, are outside the framework of our present review.

Depending on the purpose of foam separation, it will be referred to as adsorption foam concentration (separation of dissolved species from the solvent) or foam separation (in the case of partial or complete separation of dissolved species from one another).

II. Characteristic features of the adsorption concentration of surfactants in a highly expanded polyhedral foam and methods for determining its structural parameters

Concentration of surfactants in a foam occurs due to their adsorption on the bubbles of the gas, which is passed through a layer of the solution, followed by the separation of the foam from the solution. This process can be either batch or continuous. The surface separation is mostly achieved due to the single-stage distribution of compounds between the bulk phase and the surface layers of foam bubbles. Transformation of a gas dispersion into foam is accompanied by segregation of the excess liquid from the latter (syneresis of the foam), which brings the composition of the foam product closer to that of the adsorption layers, by the change of the spherical shape of bubbles into polyhedral, by a partial internal destruction of the foam (a decrease in the liquid–gas interface due to coalescence of bubbles and diffusional transfer of gas from small bubbles into larger ones), and by distribution of the foam column as a whole. Desorption of the surfactant from the vanishing surfaces results in an increase in its concentration within the Plateau–Gibbs† channels and in three-dimensional parts of the films. Syneresis of a foam results in additional adsorption of the surfactant at the surface of bubbles lying below, and where several surfactants are present, because the desorption-adsorption event is repeated many times, some redistribution of the surfactants with height and in an increase in the lifetime of the foam occurs.

The return of the liquid phase partially enriched in the surfactant into subsequent portions of the foam is called internal dephlegmation. Its contribution to variations of the effectiveness of the concentration and separation becomes substantial at low concentrations of surfactants [below the critical concentration for micelle formation (CCM)].

The adsorption concentration is normally carried out under the conditions of the gravity separation of the liquid from the foam.[2–4,6] The equipment used in these processes has been described in detail in a number of monographs.[2–4,6] A method for the adsorption concentration of surfactants under the conditions of accelerated and more complete drying of foams by creating a pressure differential in the liquid phase of a foam and the corresponding high capillary pressure in the Plateau–Gibbs channels in the course of the liquid separation, has been suggested in a series of papers.[7–10]

The use of polyhedral foams for the processes of adsorption concentration and separation increases the effectiveness of the latter. The relative simplicity of the geometry of the Plateau–Gibbs channels and films (compared with a nonpolyhedral foam) allows one to obtain quantitative dependence of various characteristics of the adsorption concentration on structural parameters of a foam (expansion factor, dispersity, size of the channels).

Below we present technological features of concentration and separation of surfactants carried out under the conditions of capillary drying of a foam and also some characteristics of 'dry' foams.

For preparation of a highly expanded dry foam by the capillary method, a foam is brought into contact with a porous plate, beneath which a reduced pressure P_0' is created (see Refs. 11 and 12). The pressure differential

$$\Delta P = P_0 - P_0',$$

(P_0' is the external pressure above the foam; usually, ambient pressure) should not exceed the capillary pressure in the pores of the filter

$$\Delta P_m = \frac{2\sigma \cos\theta}{r},$$

(where σ is the surface tension of the solution; θ the contact angle of wetting of the material of the filter; r the radius of a pore),‡ otherwise not only the liquid, but also the gas, would pass through the pores of the filter.

Under the action of the pressure differential in the liquid phase of the foam, the liquid quickly flows out until this differential is equilibrated by the capillary pressure in the foam. The porous partitions can be made of ceramics, metal ceramics, or glass, or be dense grids.

The increase in the expansion factor and in the capillary pressure in a dry foam is accompanied by the simultaneous decrease in the stability of the foam and increase in the time necessary for the equilibrium capillary pressure, corresponding to the pressure differential applied, to be established. Therefore, the optimum pressure differential, which will ensure the necessary expansion factor of the foam and a lifetime sufficient for its technological processing, should be selected experimentally.

The scheme of a laboratory unit for investigating the adsorption foam concentration in the continuous regime is presented in Fig. 1.

Separation column (*1*) is a vertical cylinder placed in a temperature-controlling jacket (*2*); in the bottom of the column there is a gas dispenser, viz. a removable glass filter (*3*), which allows gas dispensers of various porosities to be applied. In the lower section of the column there is also a cock (*4*), which serves for withdrawing samples of the solution subjected to separation. In the upper section of the column a number of holes are situated at various levels with respect to the solution surface (*5*–*7*) for the egress of the foam and for disposition of electrodes (*8*) and a capillary micromanometer (*9*), which measures pressure in the Plateau–Gibbs channels. The foam is dried with the aid of a cartridge filter (*10*), which is a metal frame covered with a

† Plateau borders in Western literature (Editor).

‡ If there are pores with different radii, the greatest one is meant.

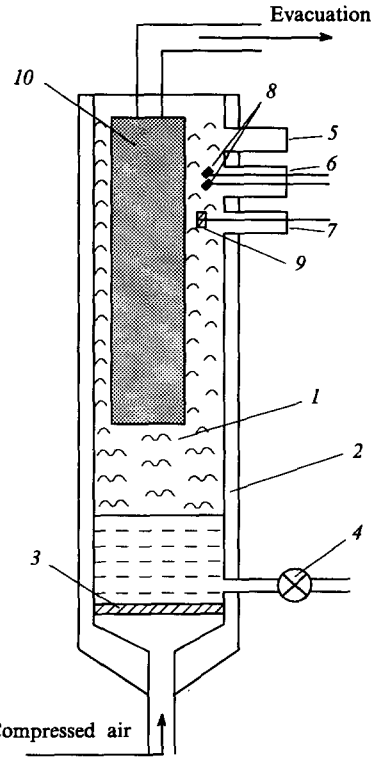

Figure 1. The scheme of a laboratory unit for adsorption concentration in 'dry' foams. (*1*) A separation column; (*2*) a temperature-controlling jacket; (*3*) a removable glass filter; (*4*) a cock for withdrawing samples of the liquid; (*5–7*) holes for the egress of the foam; (*8*) platinum electrodes; (*9*) a micromanometer; (*10*) a cartridge filter.

metallic grid having a mesh of 60 μm. A cylinder smaller in diameter than the column acts as the cartridge. It occupies 1/3 of the height of the column and is located 5–15 cm above the level of the liquid. A reduced pressure (ΔP_L = 1.0 – 2.0 kPa) of no more than the capillary pressure in the pores of the filter (grid) is produced within the cartridge. Under the action of the pressure differential, the liquid from the foam is drawn off into the cartridge. The liquid that finds its way into the cartridge is collected in a glass sampler, which makes it possible to determine the surfactant concentration and to evaluate the losses. Hereafter this liquid will be referred to as 'filtrate'.

It should also be noted that a dry polyhedral foam is very sensitive to external factors, including the rate of its movement and the diameter of vessels and tubes in which it moves. Special rheological studies§ have shown that intense destruction of a foam occurs at expansion factors of more than 300 even when the foam moves in the sliding mode (piston mode). For this reason, in the case of continuous drying of a moving foam the coefficient of the concentration of a surfactant is lower than in the case of a stationary foam in a batch-operating unit, the pressure in the Plateau–Gibbs channels being the same.[7,8]

A major part of the physicochemical characteristics of foam concentration correlates quantitatively with the expansion factor and dispersity of the foam. The expansion factor of a foam (n) characterises the volume proportion of liquid in the foam:

$$n = \frac{V_F}{V_{L,F}}, \tag{1}$$

where V_F is the volume of the foam and $V_{L,F}$ is the volume of liquid in it.

§ See, for example, P M Kruglyakov, T V Meshkova *Kolloidn. Zh.* **52** 487 (1990).

To determine the expansion factor, especially of dry foams, the conductometric method is most commonly used,[1,8,9] as

$$n = \frac{\kappa_F}{\kappa_L B}, \tag{2}$$

where κ_F and κ_L are the specific electric conductivities of the foam and the solution of a foam-forming agent respectively, B (= 1.5 to 3) is a coefficient depending on the distribution of the liquid between the channels and films.[13–15] For a polyhedral foam with a purely channel conduction mechanism, where the liquid in films may be neglected, $B = 3$, and for a foam with a film conduction mechanism, where the contribution of channels may be neglected, $B = 1.5$ (see Ref. 14).

Analysis of experimental data carried out by Lemlich[14] has shown that the coefficient B increases monotonically from 1.5 to 3 as the expansion factor increases from 4 to 200, and that the experimental data obtained for bubbling foams are well approximated by the relationship

$$B = 3 - 2.5\left(\frac{\kappa_F}{\kappa_L}\right)^{1/3} + 0.5\left(\frac{\kappa_F}{\kappa_L}\right). \tag{3}$$

Characteristics of foam concentration depend substantially on the dispersity of the foam,[2–6] for which a variety of methods exist for its determination, for example, microphotography, an optical method, a method based on the measurement of the gauge pressure after destruction of the foam, and others (for details, see Refs. 5, 16, and 7).

A method based on the simultaneous measurement of the local expansion factor and the pressure in the Plateau–Gibbs channels at the same level in a foam[18] is very convenient for kinetic studies of the variation of the dispersity in highly expanded foams. The expression used is

$$a = (0.46\sqrt{n} - 1.8)\frac{\sigma}{\Delta P_L}, \tag{4}$$

where a is the size of the edge of a polyhedron (from here on, a dodecahedron), n the expansion factor of the foam at a given instant τ, σ the surface tension of the foam-forming solution, and ΔP_L the gauge pressure measured by a micromanometer at time τ.

Relationship (4) is obtained by simultaneous solution of the equation that relates the expansion factor to the size of the edge of a polyhedral bubble and to the radius of curvature of the Plateau–Gibbs channels and the dependence of the capillary pressure on the surface tension of the solution and the gauge (reduced) pressure in the channels.[5] Eqn (4) is valid for a monodisperse foam. A real foam is a polydisperse system. The dispersity of such a system can be expressed quantitatively via average values for size, surface area, and volume of particles. These average values can be determined from the known function of size distribution of bubbles. Then the average linear (a_L), average surface (a_S), and average volume (a_V) magnitudes of the parameter a will be expressed by the relationships

$$a_L = \int_0^\infty F(a)a\,da, \tag{5}$$

$$a_S^2 = \int_0^\infty F(a)a^2 da, \tag{6}$$

$$a_V^3 = \int_0^\infty F(a)a^3 da, \tag{7}$$

where $F(a)$ is the size distribution function for bubbles.

From Eqns (5)–(7) the volume–surface averaged parameter a may be written as follows[19]

$$a_{VS} = \frac{a_V^3}{a_S^2} = (0.46\sqrt{n} f_a' - 1.8)\frac{\sigma}{\Delta P_L} , \quad (8)$$

where

$$f_a' = \frac{a_V^{3/2} a_L^{1/2}}{a_S^2} .$$

To calculate the coefficient f_a', taking into account polydispersity of the system, we used various functions suggested as distribution functions for foams.[5] It turned out that the resulting values of the parameter differ from each other by no more than 5%. For example, when the de Vries[20] function,

$$F(R) = \frac{6\alpha R}{(1+\alpha R^2)^4} \quad (9)$$

(α is the distribution parameter), or the γ-function,

$$F(R) = cR^{\alpha-1}\exp(-\lambda R) , \quad (10)$$

(α and λ are distribution parameters selected from normalisation conditions

$$\int_0^\infty F(R)\mathrm{d}R = 1) ,$$

was taken as the distribution function, the resulting values of the coefficient f_a' were 1.15 and 1.14 (at $\alpha = 2$ and 3, respectively) for the γ-function and 1.16 for the de Vries function.

In the discussion of experimental data throughout the subsequent sections of the review we have used the volume–surface averaging of the parameter a based on the de Vries distribution function.

III. Characteristics of the effectiveness of concentration, separation, and purification of solutions of surfactants

The process of foam separation of surfactants is used for solving various problems: the concentration of surfactants in a foam aimed at their extraction or at purification of the solution from the surface active impurities; complete or partial extraction of one of the components or fractionation of surfactants for the purpose of separating them from each other; displacement of a chemical equilibrium in the foam with respect to the initial solution, for example, to increase the degree of hydrolysis of a soap.

To evaluate the effectiveness of foam separation processes, various physicochemical characteristics are used, for example, the degree of extraction, concentration coefficients, selectivity coefficient, carry-over of the liquid, etc.[2, 21, 22]

Distribution of a surfactant between a foam and a solution is characterised by the coefficient (constant) of concentration (R^f). The small (R_{min}^f) and large (R_{max}^f) coefficients of concentration are distinguished:[2,4,5,26]

$$R_{min}^f = \frac{c_F}{c_{L,0}} , \quad (11a)$$

$$R_{max}^f = \frac{c_F}{c_{L,R}} , \quad (11b)$$

where c_F is the surfactant concentration in the foam including the substance of the adsorption layers; $c_{L,0}$ and $c_{L,R}$ are surfactant concentrations in the solution prior to and after the process. Equations connecting the coefficient of concentration to parameters of the foam structure (dispersity, expansion factor, and the radius of curvature of the Plateau–Gibbs channels) can be derived from the balance equations for the surfactant and the liquid phase, and data on the foam structure.

The total amount of a surfactant in a foam (G_F) is given by

$$G_F = G_L + G_S = V_{L,F}\, c_{L,F} + \Gamma_S , \quad (12)$$

where G_L is the amount of the surfactant in the liquid phase of the foam (channels and films) without considering adsorption layers, G_S is the amount of the surfactant in adsorption layers, $V_{L,F}$ the volume of the liquid phase of the foam, $c_{L,F}$ the concentration of the surfactant in the liquid phase of the foam, S the total interfacial area in the foam, and Γ the degree of adsorption.

The total concentration of the surfactant in the foam is

$$c_F = \frac{G_F}{V_{L,F}} = c_{L,F} + \frac{\Gamma S}{V_{L,F}} . \quad (13)$$

On the one hand, if one considers a unit volume of the foam containing υ bubbles of radius R, then the total interfacial area in this foam is $S = \upsilon 4\pi R^2$, and the volume of gas bubbles is

$$V_g = \upsilon\frac{4}{3}\pi R^3 .$$

On the other hand, $V_g = 1 - V_{L,F}$, therefore

$$\upsilon = \frac{3(1 - V_{L,F})}{4\pi R^3} .$$

Taking into account the number of bubbles, we have

$$\frac{S}{V_{L,F}} = \frac{3(1 - V_{L,F})}{RV_{L,F}} = \frac{3(n-1)}{R} . \quad (14)$$

From Eqn (11a) with allowance for (13) and (14) we obtain

$$R_{min}^f = \frac{c_{L,F}}{c_{L,0}} + \frac{3\Gamma(n-1)}{c_{L,0}R} . \quad (15)$$

Rubin and Gaden,[22] who assumed that $c_{L,F} = c_{L,0}$ and that the liquid volume in the foam can be neglected in relation to the total volume of the foam, derived a relationship for the concentration coefficient:

$$R_{min}^f = 1 + \frac{k\Gamma n}{Rc_{L,0}} , \quad (15a)$$

where k is a geometric coefficient for the shape of bubbles ($k = 3$ for a spherical foam and $k = 3.3$ for a polyhedral foam of the pentagonal dodecahedron type). However, the $V_{L,F}$ value for a spherical foam is substantial and amounts to 48% of the total foam volume for simple cubic packing and 26% for hexagonal close packing; the expansion factor varies at these packings from 2.01 to 3.85, which may introduce large errors into the calculations of the numerical value for R_{min}^f. In a polyhedral foam the volume of liquid may be neglected in comparison with the foam volume, but for determination of $R_{min}^f(n)$ more detailed information on the structure of the foam is required.

The ratio of the interfacial area to the volume of liquid in a foam can be expressed via unit cell parameters of the foam. If a pentagonal dodecahedron is taken as the unit cell, this ratio will be[5]

$$\frac{S}{V_{L,S}} = \frac{20.7a^2}{6\times 1.725\, a^2h + 10\times 0.16\, r^2a} = \frac{20.7a^2}{10.35\, a^2h + 1.6\, r^2a} , \quad (16)$$

where $20.7a^2$ is the area of the dodecahedron surface, 6 and 10 are the numbers of films and channels that belong to one polyhedron, $1.725a^2$ is the area of a dodecahedron face (a film), h the thickness of the film, $0.16r^2$ the cross-section area of a channel of curvature radius r.

From Eqn (11a) and relationships (13) and (16), formulae can be derived for calculating concentration coefficients at various distributions of liquid between the channels and the films.

For the film model of foam (where all the liquid is located in the films, $10.35a^2h \gg 1.16r^2a$) the concentration coefficient R^f_{min} is

$$R^f_{min} = \frac{c_{L,F}}{c_{L,0}} + \frac{2\Gamma}{hc_{L,0}} . \quad (17)$$

For the channel model of foam (where all the liquid is located in the channels, $10.35a^2h \ll 1.16r^2a$), with allowance for the fact that the foam expansion factor for this model is

$$n = \frac{7.66\,a^3}{1.6\,ar^2} = 4.8\frac{a^2}{r^2} ,$$

the concentration coefficient is given by

$$R^f_{min} = \frac{c_{L,F}}{c_{L,0}} + \frac{\Gamma n}{0.37\,c_{L,0}a} . \quad (18)$$

If the radius of curvature of the Plateau–Gibbs channels is expressed in terms of the capillary pressure $R = P_\sigma/\sigma$, then the equation for the concentration coefficient assumes the form

$$R^f_{min} = \frac{c_{L,F}}{c_{L,0}} + \frac{\Gamma a}{0.77\,c_{L,0}} \left(\frac{P_\sigma}{\sigma}\right)^2 . \quad (18a)$$

Relationship (18) indicates that when $\Gamma = \text{const}$ and $n = \text{const}$, the concentration coefficient is determined by the dispersity of the foam, and when $\Gamma = \text{const}$ and $a = \text{const}$, it is determined by the expansion factor of the foam and the capillary pressure.

The parameter a can be expressed in terms of the radius of a sphere whose volume is equivalent to that of the dodecahedron ($7.66a^3 = \frac{4}{3}\pi R^3$), that is

$$a = 0.816R.$$

By substituting this dependence into Eqn (18) we obtain

$$R^f_{min} = \frac{c_{L,F}}{c_{L,0}} + \frac{\Gamma n}{0.302\,c_{L,0}R} . \quad (18b)$$

The resulting expression is analogous to relationship (15a). In the absence of internal disruption when the surfactant concentration in the bulk parts of the foam $c_{L,F}$ is equal to its concentration in the solution from which the surfactant is extracted, the first term in Eqns (18) and (18b) is equal to unity.

When internal disruption occurs, i.e. diffusion of the gas between the bubbles and coalescence or destruction of the foam column, the liquid phase is enriched in the surfactant that is desorbed from the surfaces of vanishing films. The more intense the destruction process, the larger the quantity of the substance desorbed returning into the bulk of the foam. The increase in the concentration of the substance in the liquid phase of the foam occurring in the course of destruction is expressed by the dependence[23]

$$c_{L,F} = c_{L,0} + \int_{\varepsilon_\tau}^{\varepsilon_0} \Gamma n\,d\varepsilon . \quad (19)$$

where $c_{L,F}$ is the surfactant concentration in the liquid phase of the foam at a given instant, $c_{L,0}$ the initial surfactant concentration in the liquid phase of the foam, ε_τ and ε_0 are specific surface areas of the foam at time τ and at the initial instant, respectively, n the expansion factor of the foam corresponding to the given specific surface area at a given instant. Thus, if the destruction proceeded at a constant expansion factor and a constant adsorption, the increase in the substance concentration in the foam bulk ($\Delta c = -\Gamma n \Delta\varepsilon$) would correspond exactly to the diminution of the substance due to desorption from the surface layers.

In view of Eqn (19) expression (18) assumes the form

$$R_{min} = 1 + \frac{1}{c_{L,0}} \int_{\varepsilon_\tau}^{\varepsilon_0} \Gamma n\,d\varepsilon + \frac{\Gamma n_\tau}{0.37 c_{L,0} a_\tau} , \quad (20)$$

where n_τ is the expansion factor of the foam at time τ, a_τ the size of the edge of a polyhedron at time τ, n a variable expansion factor which varies from $n(\varepsilon_0)$ to $n(\varepsilon_\tau)$ in the course of concentration.

In the case where the foam is stable and the duration of the process is low, the concentration caused by the internal breakdown is not very great. For unstable foams and prolonged processes the concentration resulting from the internal disruption and destruction of the column is comparable with that occurring in the adsorption layers. In addition, if concentration is carried out with increase in the expansion factor in the course of gravity syneresis or by the method of the capillary drying of the foam, then the excess of the substance that accumulates in the bulk sections of the foam owing to its destruction would be removed with the liquid being drawn off from the foam and would result in a diminution of the effectiveness of the concentration processes.

When the concentration of a mixture of surfactants is carried out, the selectivity of foam separation is evaluated from the selectivity coefficients, which are generally represented by the ratios between the coefficients of concentration of the ith (R_i^f) and jth (R_j^f) components:[2,5]

$$K_{ij} = \frac{R_i^f}{R_j^f} . \quad (21)$$

It should be noted that the selectivity coefficient like the concentration coefficient is a relative value depending not only on the nature of substance but also on the initial concentration of the surfactant in the solution.[3, 24–26]

In order to evaluate the effectiveness of isolation of surfactants in the course of foam separation, especially in a foam being destroyed, it is expedient to introduce a parameter γ characterising the quantity of the substance extracted with the foam (G_F) per unit volume of the gas consumed (V_g):

$$\gamma = \frac{G_F}{V_g} . \quad (22)$$

If we assume that adsorption reaches a constant equilibrium value during foam concentration, the foam is not destroyed, and the whole bulk of the gas remains in the foam, then using Eqn (22) and taking into account the balance of the substance in the foam (12) we obtain the following dependence

$$\gamma = \frac{c_{L,F}V_{L,F} + \Gamma S}{V_g} = \frac{c_{L,F}}{n-1} + \Gamma\varepsilon \simeq \frac{c_{L,F}}{n} + \Gamma\varepsilon , \quad (23)$$

where $(n-1) \approx n$ for highly expanded foams.

It follows from Eqn (23) that with the expansion factor of the foam being constant the effectiveness of the extraction is mostly determined by the degree of its dispersity, since normally $c_{L,F}/n \ll \Gamma\varepsilon$.

The coefficient of the effectiveness of extraction is related to the concentration coefficient by the following relationship

$$\gamma = R^f_{min} \frac{c_{L,0}V_{L,F}}{V_g} = R^f_{min} \frac{c_{L,0}}{n} . \quad (24)$$

Thus, the greater R^f_{min}, the greater the coefficient of extraction effectiveness at $c_{L,F} = \text{const}$ and $n = \text{const}$. Eqn (24) also shows that when the extraction is carried out from solutions with different initial concentrations of surfactants (at $R = \text{const}$), to achieve equal effectivenesses of the process different amounts of the gas are required.

With allowance for the internal destruction [Eqn (19)] the dependence (23) assumes the form

$$\gamma = \frac{c_{L,0}}{n_\tau} + \frac{1}{n_\tau}\int_{\varepsilon_\tau}^{\varepsilon_0} \Gamma n \, d\varepsilon + \Gamma\varepsilon_\tau \ , \tag{25}$$

where n_τ is the expansion factor of the foam at time τ, and ε_τ the specific surface area of the foam at time τ.

Carry-over of a liquid with a foam during foam separation is reflected by the volume factor R_V [21,22] and the water flooding coefficient β_V.[28]

$$R_V = \frac{V_{L,F}}{V_{L,0} - V_{L,F}}, \tag{26a}$$

$$\beta = \frac{V_{L,F}}{V_{L,0}} \ , \tag{26b}$$

where $V_{L,F}$ is the volume of the liquid in the foam product and $V_{L,0}$ is the initial volume of the liquid at the beginning of separation.

The same parameters can be expressed in terms of the expansion factor of a foam

$$R_V = \frac{n_0}{n - n_0} \ , \tag{27a}$$

$$\beta = \frac{n_0}{n} \ , \tag{27b}$$

where n is the expansion factor of the foam as it leaves the separation column, n_0 the foam expansion factor on the assumption that the whole liquid has been converted into the foam.

The influences of various factors on the carry-over of liquid with the foam have been studied by many authors.[21,29–33] In particular, empirical equations relating the reciprocal of the expansion coefficient to the viscosity and density of the foam-forming solution, the diameter of foam bubbles, and the rate of its movement were obtained.[32,33]

In the general case, it is rather difficult to predict quantitatively the carry-over of a liquid with a foam. Analytical equations describing the distribution of liquid with height have been obtained only for a hydrostatically equilibriated foam.[34–36]

The distribution of liquid throughout the height of the column of a moving foam can be calculated only for the simplest (steady-state) regime.[36] This calculation is possible only for the channel variant of foam with stationary surfaces of the channels if the rate of the foam movement is lower than the rate of gravity syneresis in a spherical foam V ($V = 1$ cm s^{-1}).[36]

Some results on the distribution of liquid with height for a foam being continuously generated have also been obtained by numerical methods on a computer with the aid of various hydrodynamic models.[37–41]

The volume of liquid carried away with a foam is determined, on the one hand, by the rate at which the liquid is incorporated into the foam (which is proportional to the rate of bubbling of the gas) and, on the other hand, by the rate at which this liquid flows out of the foam (the rate of syneresis). In fact, when the consumption of the gas is low and the whole excess liquid has time to flow out from the foam, then a foam with an expansion factor close to the hydrostatically equilibriated distribution of liquid with height should be formed at the outlet from a foam generator. Conversely, when the consumption of the gas is high, the expansion factor should diminish and approach asymptotically that of a spherical foam.

In the medium region of gas consumption the expansion factor of the foam at the outlet from the foam generator depends substantially not only on the rate of bubbling but also on physicochemical properties of the solution of a foam-forming agent (viscosity, surface tension) and the structural parameters of the foam (dispersity). To analyse the experimental data obtained for this region one can use the equation of syneresis in a gravitation field[42] which contains two empirical constants, the value for one of which ($V'_{L,0}$) is known:

$$\Delta V'_L = V'_{L,0}\frac{\tau}{\tau + V_{L,0}/w_0} \ , \tag{28}$$

where V'_L is the volume of liquid that has flowed out of the foam by time τ (referred to unit cross-sectional area of the foam), $V'_{L,0}$ is the initial volume of liquid in the foam referred to unit surface area, and w_0 is the initial volumetric rate of syneresis.

The analytical dependence of w_0 on the structural parameters of a foam is unknown. Therefore, to carry out a semiquantitative estimation of the influence of the structural parameters of a foam and the properties of a foam-forming solution, one may use the equation for the flow rate of homogeneous polyhedral foam for the channel variant [36]

$$\begin{aligned} w_0 &= 3.6 \times 10^{-4}\frac{r^4}{\eta R^2}\left[\rho g - \left(\frac{\partial p}{\partial H}\right)_0\right] \\ &= 3.3 \times 10^{-3}\frac{R^2}{\eta n^2}\left[\rho g - \left(\frac{\partial p}{\partial H}\right)_0\right] \ , \end{aligned} \tag{29}$$

where 3.6×10^{-4} and 3.3×10^{-4} are hydrodynamic coefficients, R the average radius of a bubble, η the dynamic viscosity, r the radius of curvature of Plateau–Gibbs channels, ρ the density of the foam-forming solution, g the acceleration due to gravity, and $(\partial p/\partial H)$ the gradient of the capillary pressure with the height of the foam column at the beginning of syneresis.

It has been found [29,30] that at low specific gas consumptions (< 0.8 cm min^{-1}) a foam with a distribution of liquid hydrostatically equilibriated with height leaves the foam generator regardless of the type of surfactant. At high specific gas consumptions (> 20 cm min^{-1}) a foam with an expansion factor of 10–12 comes out of the foam generator. The authors did not manage to achieve further decrease in the expansion factor owing to the very high rates of syneresis in slightly expanded foams and the 'break-down' of the foam formation on further increase in the gas consumption.

When the rate of gas consumption falls within the limits $0.8 < W_g < 20$ cm min^{-1} the carry-over of a liquid with a foam depends considerably on the rate of syneresis. All the factors that decrease the rate of syneresis [diminution of bubble size and of the surface tension, increase in the surface and dynamic viscosities, and lowering of the foam column [see Eqn (29)] resulted in increase in the carry-over of the liquid with the foam. Conversely, all the factors increasing the rate of syneresis diminished the carry-over of the liquid with the foam.

A detailed study of Eqns (25a)–(25b) and identification of the relationship of characteristics of foam separation to structural parameters of the foam and to each other are possible on the basis of the material balance equations for the substance in the foam and in the solution, including those taking into account destruction of the foam.

The material balance for a substance involved in foam separation is given by the formula

$$G_0 = G_F + G_R \ , \tag{30}$$

where G_0 is the amount of the substance in the original solution, G_F is the amount of the substance in the foam, and G_R is the amount of the substance in the solution after the separation.

In view of Eqn (12) the material balance may be written as follows:

$$G_0 = G_L + G_S + G_R \ . \tag{31}$$

The total volume of the liquid involved in foam separation is given as:

$$V_{L,0} = V_{L,F} + V_{L,R} , \quad (32)$$

where $V_{L,0}$ is the volume of the solution subjected to foam separation, $V_{L,F}$ is the volume of the liquid phase in the foam, and $V_{L,R}$ is the residual volume of the solution after foam separation.

If we express the substance amounts by means of the corresponding concentrations and volumes, we obtain

$$c_{L,0}V_{L,0} = c_{L,F}V_{L,F} + \Gamma S + c_{L,R}V_{L,R} , \quad (33)$$

where $c_{L,0}$ is the surfactant concentration in the solution subjected to separation, $c_{L,F}$ the surfactant concentration in the liquid phase of the foam, $c_{L,R}$ the surfactant concentration in the solution after separation, and S the total interfacial area in the foam. All these parameters are values averaged through the whole period of foam separation.

If there is no internal disruption in the foam or destruction of the foam column, then $c_{L,F}$ varies from $c_{L,0}$ to $c_{L,n}$ in the course of separation. On the assumption that the specific interfacial area in the foam is constant and the concentration in the liquid phase of the foam is close to the initial value, Eqn (33) with account taken of Eqn (31) can be represented as follows:

$$c_{L,0}V_{L,0} = c_{L,0}V_{L,F} + \Gamma S + c_{L,R}(V_{L,0} - V_{L,F}) . \quad (34)$$

Taking into account that $n = V_F/V_{L,F}$, $S/V_F = \varepsilon$, and $c_{L,0} = c_{L,F}$, we obtain from Eqns (34) and (26b)

$$\frac{\Delta c}{\beta} = \Delta c + \Gamma \varepsilon n . \quad (35)$$

Here β is the water flooding coefficient

$$\beta = \frac{\Delta c}{\Delta c + \Gamma \varepsilon n}, \quad (36)$$

where $\Delta c = c_{L,0} - c_{L,n}$, ε and n are the specific surface area and the expansion factor of the foam (average values throughout the process).

The water flooding coefficient is related to the volume factor (R_V) by the relationship[27]

$$R_V = \frac{\beta}{1 - \beta} \quad (37)$$

The combination of Eqns (36) and (37) gives

$$R_V = \frac{\Delta c}{\Gamma \varepsilon n} . \quad (38)$$

For the process of foam separation in which the foam is dried through the action of a pressure differential in the Plateau–Gibbs channels Eqns (31), (32), and (34) assume the form

$$G_0 = G_L + G_S + G_D + G_R , \quad (39)$$

$$V_{L,0} = V_{L,F} + V_{L,D} + V_{L,R} , \quad (40)$$

$$c_{L,0}V_{L,0} = c_{L,F}V_{L,F} + \Gamma S + c_{L,D}V_{L,D} + c_{L,R}V_{L,0} - c_{L,R}V_{L,F} - c_{L,R}V_{L,D} . \quad (41)$$

The index D designates the corresponding values in the 'filtrate'. Considering that $c_{L,D} = c_{L,F}$, $S = V_F\varepsilon$, $n = V_F/V_{L,F}$, and $\beta = V_{L,F}/V_{L,0}$, we obtain from Eqn (41)

$$\beta_F = \frac{\Delta c_{max}}{(c_{L,F} - c_{L,R})(1 + \delta) + \Gamma \varepsilon n} \quad (42)$$

where $\Delta c_{max} = c_{L,0} - c_{L,R}$, β_F is the flooding coefficient of the foam that emerges from the column (irrespective of the liquid carried away with the 'filtrate'), $\delta = \beta_D/\beta_F$ is the constant of drying, and $\beta_D = V_{L,D}/V_{L,0}$ is the coefficient of carry-over of the liquid with the 'filtrate'.

As the process is carried out, the concentration of the substance in the liquid phase of the foam varies within the range $c_{L,R} \leqslant c_{L,F} \leqslant c_{L,0}$.

At the start, $c_{L,0} = c_{L,F} = c_{L,D}$, and the water flooding coefficient is given by

$$\beta_{F(0)} = \frac{\Delta c_{max}}{\Delta c_{max}(1 + \delta) + \Gamma \varepsilon_0 n_0} . \quad (43)$$

At the end of the process $c_{L,F} = c_{L,R}$, and

$$\beta_{F(R)} = \frac{\Delta c_{max}}{\Gamma \varepsilon_R n_R} . \quad (44)$$

The overall flooding coefficient of the foam, β_Σ, with allowance for the liquid extracted during drying ('filtrate'), is found from the equation

$$\beta_\Sigma = \beta_F + \beta_D = \frac{\Delta c_{max}}{(c_{L,F} - c_{L,R})(1 + \delta) + \Gamma \varepsilon n}(1 + \delta) . \quad (45)$$

From Eqn (34), taking into account (19), one can obtain the following expression for the foams destroyed during the foam separation:

$$c_{L,0}V_{L,0} = \left(c_{L,F} + \int_{\varepsilon_\tau}^{\varepsilon_0} \Gamma n \, d\varepsilon\right) V_{L,F} + \Gamma S_\tau + c_{L,R}V_{L,R} , \quad (46)$$

where S_τ is the surface area of bubbles in the foam at time τ.

From Eqn (36), the general expression for the carry-over of the liquid phase with a foam, which undergoes destruction, can be obtained from

$$\beta = \frac{\Delta c_{max}}{\Delta c_{max} + \int_{\varepsilon_\tau}^{\varepsilon_0} \Gamma n \, d\varepsilon + \Gamma \varepsilon_{min} n_\tau}, \quad (47)$$

where $\Delta c = c_{L,0} - c_{L,R}$, and ε_{min} is the specific surface area of the foam at the outlet from the column at time τ.

For the process of foam concentration involving capillary drying, an equation can be obtained which relates the water flooding coefficient to the structural parameters of the foam.[43]

The mass (α_m) and concentration (α_c) degrees of extraction are characteristics of the completeness of the extraction of a substance:

$$\alpha_m = 100 \frac{G_0 - G_R}{G_0}, \quad (48)$$

$$\alpha_c = 100 \frac{c_{L,0} - c_{L,R}}{c_{L,0}} \quad (49)$$

The equations of the material balance during the foam separation and dependence (48) make it possible to obtain an equation relating R^f_{min}, β to α

$$\alpha = 100\frac{G_0 - G_R}{G_0} = 100\frac{G_F}{G_0}$$

$$= 100\left(\frac{c_{L,F}V_{L,F} + \Gamma S}{c_{L,0}V_{L,0}}\right)$$

$$= 100\left(\frac{c_{L,F}}{c_{L,0}} + \frac{\Gamma S}{c_{L,0}V_{L,F}}\right)\frac{V_{L,F}}{V_{L,0}} = 100R^f_{min} \quad (50)$$

It can be seen from Eqn (50) that only two of the three characteristics of the adsorption concentration are independent. For example, at different concentration coefficients, the same degree of extraction can be achieved by the appropriate variation of the water flooding coefficient.

The effectiveness of the removal of impurities from a solution is characterised by the purification coefficient (factor)

$$o = \frac{c_{L,0}}{c_{L,R}} . \quad (51)$$

From the material balance equation, one can obtain an expression for the purification coefficient containing the structural characteristics of foam:[5]

$$o = \frac{c_{L,0}}{c_{L,R}} = 1 + \frac{\Gamma S}{c_{L,R} V_{L,R}} = 1 + \frac{2.7\,\Gamma n}{c_{L,R} a} . \quad (52)$$

Eqns (51) and (52) are of little use for determining the limiting values of the purification coefficient, since in the case of low surfactant concentrations the stability of the foam dramatically decreases, and the foam layer containing the adsorbed product has no time to separate from the solution.

For this reason determination of the minimum residual surfactant concentration necessary to obtain a stable foam provides more precise information on the purification coefficient. The minimum residual concentration is close to that for the formation of black spots (c_b) in microscopic foam films ($c_{L,0} = c_{St} = c_b$) in the circumstances where they are formed

$$o_{max} = \frac{c_{L,0}}{c_b} . \quad (53)$$

Some researchers, for example, Skvirskii et al[44] and Sontag and Strenge,[45] maintain that a stable foam is formed only when the concentrations of surfactants correspond to the limiting degrees of their adsorption (Γ_∞), while others, for example, Venstrem and Rebinder[46] and Ekserova and Sheludko[47], have noted that a stable foam can also be obtained when the surfactant concentrations are much lower than those necessary to reach Γ_∞. In fact, a dramatic increase in the lifetime of a foam is typical of the concentration regions corresponding to the formation of black spots in microscopic foam films.[5,48]

The formation of black spots in thermodynamically non-equilibrium films has a probability character.[49,50] It can be observed experimentally if the lifetime of a black spot is greater than the time resolution of the instrument. The probability of the detection can be calculated from experimental data as the ratio of the number of films in which black spots have been observed to the total number of films examined.

The probability (W_b) of observing black spots in an ordinary black film from a solution of sodium dodecyl sulfonate exists over a wide concentration range, 2.5×10^{-6} to 3.5×10^{-4} mol l^{-1}. It rises substantially in the initial section, up to a concentration of $\sim 10^{-5}$ mol l^{-1} when the degree of filling of the adsorption layer, Γ/Γ_∞, is 0.4. However, even when this probability is equal to unity, the complete saturation of the adsorption layer is not yet reached [$\Gamma/\Gamma_\infty = 1$ at $c = (5.0 \pm 0.2) \times 10^{-4}$ mol l^{-1}].

The increase in the probability of the formation of Newton black films for the same surfactants lies within a narrow range of surfactant concentrations (from 8×10^{-5} to 2×10^{-4} mol l^{-1}) that correspond to the saturated adsorption layer ($\Gamma/\Gamma_\infty = 1$ at $c = 1.1 \times 10^{4}$ mol l^{-1}). It is important to keep in mind this distinction between the concentration dependence of the probability of detecting black spots and the lifetime of the foam, while determining the minimum residual concentration of the surfactant.

A necessary and sufficient condition for the principal possibility of foam separation is that a substance is concentrated in the foam, i.e. $R^f_{min} > 1$.

Eqn (18) implies that in a polyhedral foam the condition $R^f_{min} > 1$ is satisfied when $\Gamma n/0.37a > c_{L,0}$, since $c_{L,F}/c_{L,0} \simeq 1$. This inequality determines both the lower and the upper limits of foam concentration, outside of which concentration is impossible ($R^f = 1$). However, the reasons why this relationship no longer holds are different. Thus, the upper limit of the applicability of the foam separation method is often attributed to the CCM,[4,51] since at this concentration σ = const, and $d\sigma/dc = 0$. However, in the region of concentrations not far exceeding the CCM, where $\sigma(c)$ = const, adsorption of a surfactant has a positive value, which is indicated by direct measurements of adsorption in this region. The calculation according to Eqn (18) shows that for typical micelle-forming surfactants ($\Gamma = 3 \times 10^{-10}$ mol cm^{-2}, $a = 10^{-2}$ cm) $R^f_{min} > 1$ already at $n > 40$. This expansion factor can be achieved both by using the method of drying with the aid of porous plates and by drying in a gravitational field at a low gas consumption in the separation column and with a high foam column. Thus, if the lifetime of a foam is sufficient for technological processing ($\tau = 10-15$ min), then its high expansion factor can be achieved and adsorption concentration of a substance can be carried out at $c_{L,0} >$ CCM.[22,52]

IV. Experimental studies on the concentration of individual surfactants and mixtures

The distribution of a substance being extracted between a liquid and a foam, which is characterised by the concentration coefficient, has been studied in foam separation processes under conditions both of gravity[2,22,23,43] and of accelerated syneresis.[7,10,43,52,53]

Under the conditions of gravity syneresis, R^f_{max} diminishes with decrease in the height of foam in the separation column (at a constant specific rate of gas delivery to the separation column) or with increase in the rate of bubbling at a constant height of the foam column.[43]

The concentration coefficient R^f_{min} increases with decrease in the size of bubbles only if n = const [Eqn (18)]. If the expansion factor changes simultaneously with dispersity (as is often the case under the conditions of gravity syneresis, since the decrease in the sizes of foam bubbles results in a decrease in the rate of syneresis and in the formation of a foam with a lower expansion factor at the outlet from the foam generator), then a decrease in the size of bubbles often leads to a decrease in R^f_{min}, rather than to its increase.[4,43]

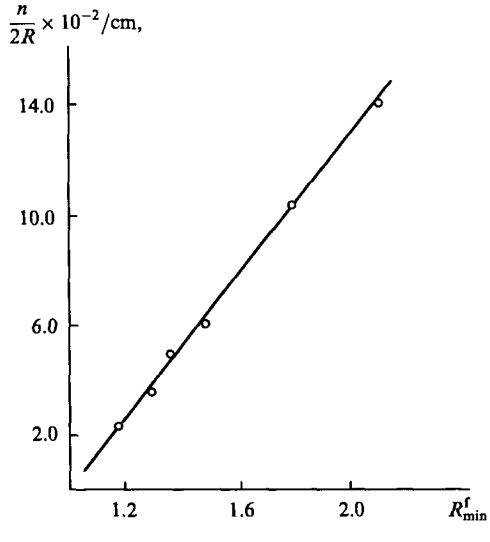

Figure 2. The dependence of the ratio $n/2R$ on the coefficient of concentration of sodium butyl diphenylsulfonate in a foam. The initial concentration of the surfactant in the solution was 2.4×10^{-3} mol l^{-1}.

A study of foam separation of sodium butyl diphenyl sulfonate in an ordinary slightly expanded foam has shown[22] that the concentration coefficient increases linearly with increase in the $n/2R$ value in conformity with relationship (15a) (Fig. 2).

An expansion factor of more than 100 is rarely achieved in standard separation columns, and therefore, under these conditions, the concentration coefficient is of the order of several tens or, occasionally, several hundreds.

Greater magnitudes of the concentration coefficient can be reached in dry foams.[5,7-10,52,53] Kruglyakov and Kuznetsova[7] have studied the influence of the capillary pressure, the expansion factor, and dispersity on R^f_{min}. The foam was prepared from solutions of sodium dodecyl benzenesulfonate (DDBSNa) and 20-oxyethylated nonylphenol (NP-20). The concentration coefficient R^f_{min} increased in direct proportion to the expansion factor (at $a = \text{const}$) and in inverse proportion to the parameter a (at $n = \text{const}$) (Fig. 3 *a*, *b*).

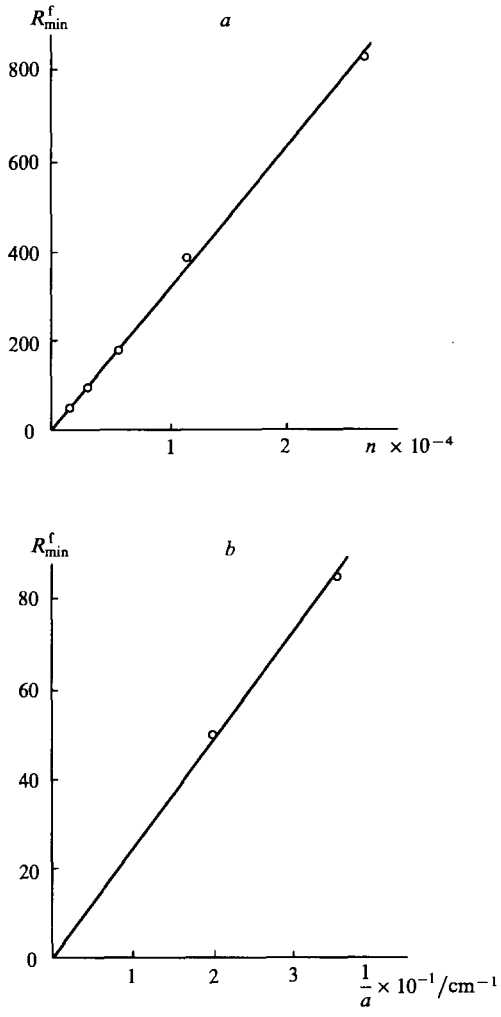

Figure 3. The dependence of the coefficient of concentration of a surfactant in a foam on the expansion factor (*a*) and dispersity (*b*) of the foam. (*a*) $a = \text{const}$; (*b*) $n = 1000$.

Interesting results have been obtained in a study of concentration of proteins in a dry foam.[53] Under the conditions of gravity syneresis a foam prepared from proteins has a low expansion factor ($n = 20-30$) and a concentration coefficient of 1.5–3. In the case of accelerated syneresis under the action of high pressure differentials, the foam expansion factor can be as high as 500 and the concentration coefficient is 50–70 (Fig. 4).

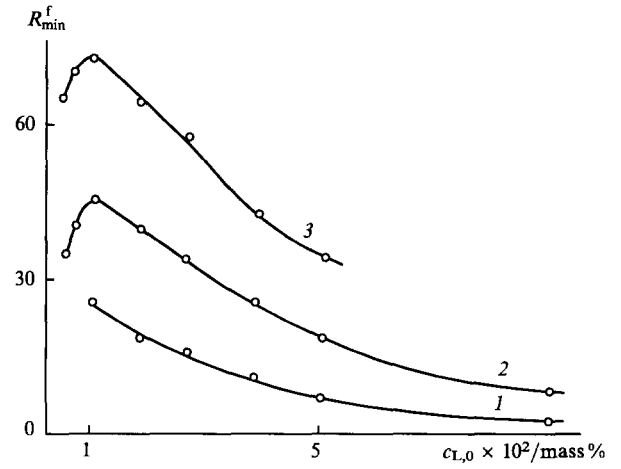

Figure 4. The dependence of the concentration coefficient for serum albumin on its initial concentration in a foam-forming system at various degrees of expansion of the foam. *n*: (*1*) 150; (*2*) 300; (*3*) 500.

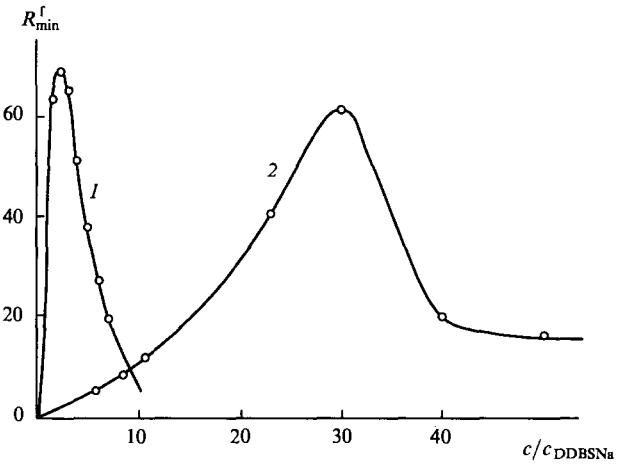

Figure 5. The dependence of the coefficient of concentration of saponin (*1*) and valeric acid (*2*) on component concentration ratios in mixtures with DDBSNa. The concentrations of the components in the mixtures are given in percent (*1*) and in mol l^{-1} (*2*).

If a surfactant is not a good foam-forming agent it cannot be concentrated in a dry foam; therefore a good foam-forming agent is introduced in the solution of such compound, and concentration of the resulting mixture is carried out. Valeric acid, saponin, and α-chymotrypsin were concentrated in such a manner (DDBSNa and DDSNa were used as foam-forming agents).[9] When concentration is carried out from a mixture, the dependence of R^f_{min} on the ratio between the components has an extreme character (Fig. 5).

The low-molecular-mass protein antibiotic nisin was successfully concentrated from a culture liquid in a highly expanded foam stabilised by the foam-forming agent Tween-80. In the absence of a special foam-forming agent no stable foam is produced from the culture liquid. By adding Tween-80 one can extract nisin; however, the concentration coefficient in a foam under the conditions of gravity syneresis does not exceed 4–5 (see Ref. 54). To increase the degree of concentration, a multistep process involving destruction of foam and subsequent foaming is required. When nisin is concentrated in a dry foam (dried with the aid of filtering partitions) the degree of concentration can be increased to $R^f_{min} = 350$.

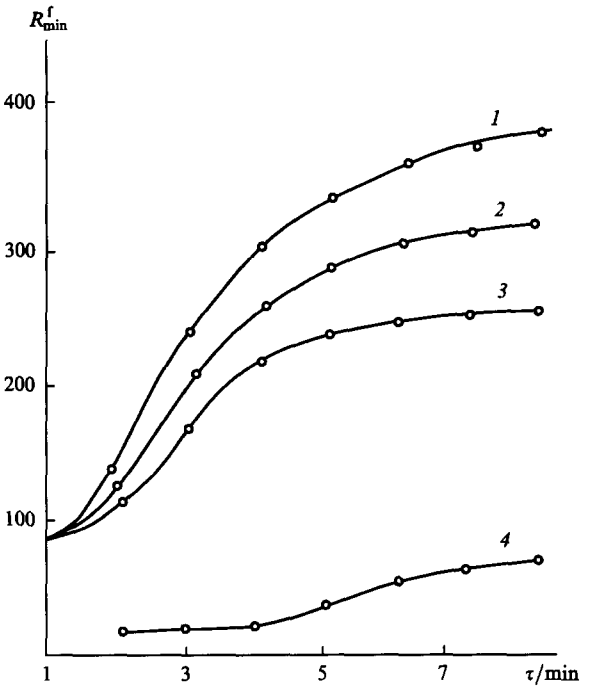

Figure 6. The time dependence of the concentration coefficient and its constituents for a foam prepared from a DDBSNa solution.
(*1*) $R_1^f = \Gamma n_\tau / 0.37\, c_{L,0}\, a_0$; (*2*) $R_2^f = R_3^f + R_4^f$;
(*3*) $R_3^f = \Gamma n_\tau / 0.37\, c_{L,0}\, a_\tau$; (*4*) $R_4^f = \int_{\varepsilon_\tau}^{\varepsilon_0} \Gamma n\, d\varepsilon \Big/ c_{L,0}$.

The influence of the internal disruption on the parameters of foam concentration has been experimentally studied by Khaskova and Kruglyakov.[27,43] They carried out quantitative evaluation of the effect of the internal disruption on the variation of the concentration and extraction coefficients for foams prepared from solutions of DDBSNa and sodium oleate (NaOL) having distinct destruction kinetics.[27,43] Fig. 6 shows the kinetic dependence of the concentration coefficient and its constituents for a foam prepared from a solution of DDBSNa [see Eqn (20)]. Curve *1* corresponds to the variation of R^f occurring as the foam is dried provided that there is no destruction in it. Curve *2* shows the variation of R^f with allowance for foam destruction. Curve *3* reflects the accumulation of the substance in adsorption layers provided $a = \text{const}$, and curve *4* shows the accumulation of the substance in the liquid phase of the foam owing to its internal disruption. The second term of Eqn (20) was calculated by graphical integration on the basis of the $n = f(\varepsilon)$ dependence. One can see that foam destruction results in a decrease in the concentration coefficient.

Similar results were obtained for a foam prepared from a solution of NaOL. In this case, the influence of foam destruction on the concentration coefficient was still more pronounced. The proportion of the quantity

$$\frac{1}{c_{L,0}} \int_{\varepsilon_\tau}^{\varepsilon_0} \Gamma n d\varepsilon$$

in foams prepared from NaOL solutions was $\sim 50\%$ of the theoretical R^f value (in the concentration without destruction). The coefficient of extraction effectiveness is affected by the foam destruction to an even greater degree: for a foam formed from a solution of DDBSNa it varies from 5.4×10^{-8} (at the beginning of the process) to 4.7×10^{-8} mol cm^{-3} (at the end), and for a foam obtained from a solution of NaOL, it varies from 10.8×10^{-8} to 3.89×10^{-8} mol cm^{-3} (see Refs 27, 43).

In the course of drying, some liquid is removed from the foam and, if the specific surface area of the foam considerably decreases, the liquid is substantially enriched in the substance being extracted. To determine the loss of a substance with the filtrate one can use the following characteristics

$$\alpha_{D,\tau} = \frac{G_D}{G_{F,\tau}}, \tag{54}$$

$$\alpha_{D,0} = \frac{G_D}{G_{F,0}}, \tag{55}$$

where G_D is the amount of the substance removed from the system with the filtrate, $G_{F,0}$ the initial amount of the substance in the foam, and $G_{F,\tau}$ the amount of the substance in the foam at time τ. The characteristics $\alpha_{D,\tau}$ and $\alpha_{D,0}$, similarly to R_V, R^f, and γ, can be expressed in terms of the foam structural parameters, adsorption, and concentration of the surfactant in the solution.[43] If $\alpha_{D,0} \ll 1$ and $\alpha_{D,\tau} \ll 1$, the losses during drying are small.

The losses with the filtrate have been determined under steady-state conditions: a foam with a known volume was prepared from a definite volume of liquid in a separate cell, this foam was then dried in the same cell by increasing the pressure to $\Delta P = 1.6$ kPa. Variations of the expansion coefficient, the pressure in the Plateau–Gibbs channels, and dispersity in the foam were monitored. In the filtrate produced by the drying process the concentration of the surfactant was determined and the losses of the substance to be extracted, which occurred during drying and destruction of the foam, were found from Eqn (54).

The $\alpha_{D,0}$ values for stable foams obtained from solutions of DDBSNa with 0.01 or 0.1 mol l^{-1} of NaCl added are 0.2 and 0.3, respectively. Foams produced from solutions of sodium oleate are destroyed under conditions of forced syneresis much more intensely, and in this case the losses with the filtrate reach $\alpha_{D,0} \simeq 0.6$. When $\alpha_{D,0} > 0.4-0.5$, the filtrate should be returned to the separation column in order to diminish losses of the substance extracted by foam separation.

A negative influence of foam destruction on the concentration and extraction coefficients has also been found[27,43] in the separation of foams with various stabilities carried out under the conditions of gravity syneresis: as a result of the internal disruption of a foam these coefficients decrease over a wide range of concentrations of the surfactant being extracted.

A positive influence of the internal disruption on the concentration coefficient (i.e. its increase) is observed only in the cases where a very small $c_{L,0}$ value lies in the range $c_b < c_{L,0} < c_{\Gamma,\infty}$ ($c_{\Gamma,\infty}$ corresponds to the saturated adsorption layer). This is caused by the fact that desorption from film surfaces during the foam destruction increases the surfactant concentration in the liquid phase of the foam, and, as a consequence, the degree of adsorption increases to the values that ensure formation of a small volume of a stable foam. It therefore becomes possible to separate the foam from the original solution with $R^f > 1$.

A positive influence of the internal destruction on the concentration coefficient due to the internal return of the solution (dephlegmation) has been found experimentally in foam separation processes carried out for solutions of DDBSNa and lysozyme at $c_b < c_{L,0} < c_{\Gamma,\infty}$.[43,55]

Studies on the identification of the upper and lower concentration limits of the applicability of the foam separation method have been reported.[43,52,55]

It was found experimentally that concentration from solutions of surfactants with a concentration $c_{L,0} = (2-3)$CCM is possible with $R^f_{min} = 6-9$ (for foams obtained from solutions of NaOL) or $R^f_{min} = 27-30$ (for foams obtained from solutions of DDBSNa).[43,52]

To evaluate the minimum residual concentration, a rather simple method can be used involving determination of the surfactant concentration above which a stable foam is formed under the conditions of steady-state operation of a separation

column (when the height of the foam column remains constant during the delivery of a gas).[55] The foam-forming ability is estimated based on the ratio V_F/V_g (where V_F is the greatest volume of foam obtained in a separation column over period τ in the steady-stade regime and V_g is the volume of the gas bubbled into the column over the same period), the parameter a and the rate of gas bubbling being constant during the course of the experiment. The experimental dependences $V_F/V_g = f(c)$, $\tau = f(c)$, and $\Delta N/N = f(c)$ (τ is the lifetime of the foam and foam films, $\Delta N/N$ the probability of the detection of black films) have similar characters for all surfactant types studied (DDSNa, DDBSNa, lysozyme). The minimum residual concentration is, as a rule, equal to the concentration at which black films arise with a probability of more than 50%. Moreover, if the $V_F/V_g = f(c)$, $\tau = f(c)$, and $\Delta N/N = f(c)$ curves vary by jumps, then the dependences of the concentration coefficient also vary by jumps. The variations described are characteristic of systems in which black spots (ordinary or Newton black films) arise in microscopic films at a definite concentration. If ordinary thin foam films are formed in a system (DDSNa and DDBSNa without an electrolyte, or lysozyme not at the isoelectric point), the lower threshold concentration cannot be distinguished unambiguously. In these systems, the minimum concentration is found from the particular conditions under which the process is conducted (the rate of gas bubbling, dispersity, the foam height in the column, etc) and has no clear-cut limit.

V. Separation of components of a mixture of surfactants in a foam

In the previous sections we have mostly considered the results of concentration of surfactants in a foam or purification of a solution from surfactants in binary systems. Our goal has been to increase the concentration coefficient or the degree of extraction of one of the components with the aid of the other, rather than to separate the components of the system from one another.

A partial or complete separation of two dissolved components can be carried out by the foam separation process. The separation occurs most easily when one of the components is surface inactive or has very low surface activity. For example, soaps and various synthetic surfactants can be readily separated (purified) from electrolytes; proteins can be separated from amino acids; and so on.

The separation of ions is most frequently carried out by ion flotation methods (without formation of a stable foam) involving ion exchange reactions, formation of nondissociated compounds, precipitation, coprecipitation, and other expedients.[2-4,6] The possibility of separating components without resort to ion flotation methods has been shown for the first time for mixtures of soap and dyes. Ostwald and coworkers[56-58] demonstrated the possibility of separating blue (triphenylmethane) and crimson-red (novococacine azo dye) dyes. With identical concentrations of these dyes in the initial solution (0.01 %), the concentration of the blue dye in the foam reached 0.22%, that for the red dye was 0.02 %. Their concentrations in the residual solution were 0.003 % and 0.01 %, respectively. A similar separation of bromothymol blue into a yellow dye (in the foam) and a blue dye (the residue), and also the separation of congorubin into a wine-red dye and a violet dye, respectively, were achieved in the experiments of Thiele.[59] Separation of other dyes has been considered by Skomorski.[60]

Other papers deal with the processes of partial separation of soap mixtures (sodium oleate and laurate), mixtures of salts of cholic and fatty acids, and a mixture of saponin, sodium oleate, and gelatin.[61-63]

A large number of examples of partial separations, including those of proteins, polymers, and other compounds, are presented in a book by Cassidy[64] and in other papers.[65,66] Analysis of these works shows that purification of sodium dodecylsulfonate from a dodecyl alcohol admixture is perhaps the only example of complete separation of one of the components of the mixture from the other (apart from inactive electrolytes) and that this separation in an ordinary foam is possible only when the concentration of the alcohol is low compared with that of sodium dodecylsulonfate.[64] The thermodynamic theory of the surface separation processes, based on the difference between the compositions of the surface layer and the bulk phases, has been outlined in a monograph.[4]

The fundamental relationship connecting the mole fraction of the i-th component of the system (N_i) to the change in the total number of moles (m) during the surface separation can be presented in the following way

$$\Delta N_i = (N_i^S - N_i)\frac{\Delta m}{m} . \qquad (56)$$

Here N_i^S is the mole fraction of the ith component in the surface layer.

If the dependence of N_i^S on the composition of the system is known, one can integrate Eqn (56) and follow the variation of the composition of a solution during foam separation in the concentration space (i.e. follow the course of the lines of surface separation). Experimental studies on the thermodynamic theory of surface separation (in particular on the course of lines of surface separation which show the manner in which the solution composition varies during foam separation) for ternary systems, the components of which do not interact chemically with one another, have been carried out in a number of studies.[4,67]

Surface separation theory implies that the effectiveness of the separation is determined mostly by the selectivity coefficients of the components.

The results of separation in a foam are strongly affected, apart from the adsorption ability, by the stability of the foam, which depends on the nature and concentrations of the components, since it takes a rather long time ($\sim 10-15$ min) for the adsorption equilibrium to be reached and for the excess liquid to separate without destruction of the foam column. The selectivity of foam separation for two or three surfactants from aqueous solutions has been considered in many papers (see, for example, Refs 3, 26, 68, 69). Shinoda and Mashio[68] studied the selectivity for several pairs of anionic surfactants differing in the length of the hydrocarbon radical and the nature of the polar group. It was shown, for example, that the selectivity coefficient for the DDBSNa/DDSNa pair in molecular solutions is 35–50, and for the DDBSNa/potassium undecylsulfonate pair is 180–200. In the case of micellar solutions, the coefficient of selectivity is substantially lower, for example, it amounted to 5–8 for the DDBSNa/TDSNa (TDSNa is sodium tetradecylsulfonate) and $C_{15}H_{31}COOK/C_{13}H_{27}COOK$ pairs; however, the difference in the carbon chain length in these pairs was also much smaller.

At low concentrations of surfactants the selectivity coefficient increased by a factor of 2.75 when one methylene group was added. The introduction of a benzene ring in the hydrocarbon chain was equivalent to the introduction of 3.5–4 methylene groups.

The selectivity of the isolation of inorganic ions in a foam[69] during their simultaneous adsorption with the cetylpyridinium chloride ion (0.75–1.0 mol l^{-1}) increased in the sequence $Cl^- < Br^- < I^- < SCN^-$. The adsorption increased in this sequence from 1.39×10^{-10} to 2.8×10^{-10} mol cm^{-2}. The use of recycling (dephlegmation), which changes the ratio between the components, allows the effectiveness of the separation to be increased, especially for pairs of substances whose surface activities are slightly different.[3]

Hargis and Rogers,[70] who studied foam separation of DDSNa/DDBSNa and DDSNa/BSNa mixtures (BSNa is sodium benzenesulfonate), have noted that the concentration coefficients of these surfactants remain constant over a wide concentration range regardless of the presence of the other component.

The partial separation of components occurring during movement of gas bubbles through a layer of a surfactant solution is regarded by some researchers as a modification of chromatography (see, for example, Refs 4, 64, and 66). One cannot achieve the complete separation of substances by this method because it involves only single-stage adsorption of the components of a mixture, and because of the low concentration coefficients in a foam in which syneresis occurs only under the action of gravity.

The effectiveness of the separation of components dramatically increases when dry foams, prepared under the action of the pressure differential in Plateau–Gibbs channels with the aid of porous plates, are used.[5,7,10,52,53] In this way a complete separation of proteins from deoxyribonucleic acid has been carried out.[10]

The possibility of chromatographic separation of surfactants in a foam has been reported.[71] To perform this process a foam with controlled size of Plateau–Gibbs channels was used. A solution of the mixture of surfactants to be separated (thymol blue dye, 5×10^{-4} mol l^{-1}, and DDBSNa, 1.5×10^{-3} mol l^{-1}) was passed through a layer of a foam prepared from a DDSNa solution with 0.4 mol l^{-1} of NaCl added. The foam was con-fined on both sides by porous partitions. The pressures on the outside of these partitions were dissimilar and lower than those on the inside by an amount not exceeding the capillary pressure in the partition pores. The solution of the mixture was delivered through that partition where the outside pressure was higher. Separation of the mixture was achieved owing to the multistage selective adsorption of the components at the surface of foam bubbles with the rate of the solution flow under the action of pressure differential ($\Delta P = 1.3$ kPa) being controlled.

In the mixture under study, DDBSNa and DDSNa are less active than the dye. As a consequence, DDBSNa appeared in the samples from the effluent, together with DDSNa, within 15 min, and within 30 min the effluent contained only DDBSNa. It was not until 40 min after the beginning of the process that traces of the dye appeared, i.e. one of the components (DDBSNa) was isolated by frontal analysis. It should be noted that foam chromatography, which has much in common with conventional liquid chromatography with a solid adsorbent, also has significant differences from it. The first of these is that it is impossible to obtain surfactant-free layers (sections) in foam chromatography. Other peculiarities are associated with the continuous decrease in the surface of the adsorbent (foam). The possibilities of foam chromatography have so far been poorly investigated.

Foam separation can also be used for shifting chemical equilibria or changing the rates of chemical reactions in a foam. If a reversible reaction, for example, the hydrolysis of a soap $NaR + H_2O = NaOH + HR$, can occur between dissolved compounds, the equilibrium in this reaction can be shifted in either direction depending on which component (NaR or HR) is more active. The change in the equilibrium constant in the surface layer compared with its magnitude in the bulk of the solution has been attributed to the concentration of the reactants in the surface layer (and the corresponding change in the activity) and change in the surface energy.[26]

The first quantitative experiments on moving an equilibrium in a foam have been carried out for soap solutions.[26] It was found that the foam, which underwent destruction, was acidic, whereas the remaining solution was alkaline, and the surface tension of this solution was twice as high as that of the liquid obtained from the foam. The hydrolysis is especially pronounced in dilute solutions. When the concentration of sodium oleate was 0.0002%, the ratio between the proportions of the acid and a base in the foam was 2.7, and it was only slightly dependent on the nature of the base. Similar results have been obtained for the foam prepared from a sodium laurate solution.[26]

Catalytic action of cationic surfactants (quaternary pyridinium chlorides) in the hydrolysis of 2,4-dinitrochlorobenzene and in the reaction with aniline in a foam has been observed.[74,75] For example, in the presence of quaternary pyridinium bases, the rate constant of the hydrolysis in a foam increased from 1.42×10^{-7} (without the surfactant) to 2.7×10^{-2} m^3 mol^{-1} s^{-1} (with surfactant), which is greater than in the case of catalysis in micelles (8.3×10^{-6} m^3 mol^{-1} s^{-1}). A similar acceleration of acid hydrolysis occurs also in the presence of anionic surfactants.[76,77]

In a series of papers[74–77] this catalytic action has been explained in the context of the mechanism of micellar catalysis and has been attributed to the concentration of reactants in adsorption layers of a foam, to a local change in the pH, and to the influence of orientation of reactant molecules in the adsorption layers and of the surface charge on the formation of the transition state (intermediate complex). The higher effectiveness of the film catalysis in a foam as compared with micellar catalysis has been accounted for by the structural features of the surface layers in a foam (the type of adsorption film) that facilitate attainment of transition states of reactions. However, the authors[74–77] undertook no special studies that would have unambiguously confirmed these assumptions.

To the best of our knowledge the influence of the foam structure and especially of the type of thin films (the ordinary and Newton black ones) on the rate of reactions has not been investigated.

VI. Conclusion

The drying of a foam by developing a pressure differential in the liquid phase with the aid of porous plates allows one to obtain high concentration coefficients for individual surfactants and their mixtures in the case where at least one of the compounds is a good foam-forming agent, and ensures chromatographic separation of substances in a foam.

The identification of the analytical relationships of characteristics of foam separation with the structural parameters of a foam and the properties of a surfactant makes it possible to optimise the process and to take into account the influence of foam destruction on various characteristics of surface concentration.

The internal disruption of a foam and the destruction of a foam column degrade the characteristics of the concentration. A positive influence of foam destruction (internal recycling) and, hence, of the external recycling and multistage separation on the concentration of individual surfactants, is manifested at low surfactant concentrations close to that for the formation of black spots in microscopic foam films.

Investigation of some reactions in a foam demonstrated a more pronounced catalytic action of surfactants in adsorption layers of a foam compared with their catalytic action in micelles.

Abstract. The review deals with the properties of solid and polymeric electrolytes incorporating (co)polymers or mixtures of polymers and copolymers doped with inorganic lithium salts. Such electrolytes are used for lithium chemical power sources. Attention is concentrated on the methods for the modification of the structure and composition of these systems by means of amorphous and network (co)polymers, additives promoting conversion into an amorphous form, crown-ethers, plasticisers, and ceramic powders, which increase the ionic conductivity of polymeric electrolytes. The methods for the preparation of thin films of polymeric electrolytes by plasma polymerisation and also procedures for the modification of the electrodes of lithium chemical power sources with polymeric electrolytes are considered.

Data on the ionic conductivities of the systems described are presented. The bibliography includes 129 references.

I. Introduction

Considerable efforts by specialists in the development and manufacture of chemical power sources (CPS) are nowadays directed to the creation of superminiaturised autonomous power sources. Studies in the last 10 years have shown that this problem can be solved with the aid of film-type polymeric electrolytes (PE). High specific characteristics are then attained (for example, a power capacity up to 200 W h kg^{-1} subject to a high degree of discharge) and satisfactory storage properties. The use of PE for the creation of rechargeable accumulators with a lithium anode is of special interest. The principal advantages of such accumulators are virtually total safety in use, the possibility of preparing CPS of any shape, the absence of liquid and gaseous components, a high resistance to mechanical influences, and a capacity for operation at high temperatures. Lithium accumulators with PE are employed most effectively in electric automobiles, in military and space technology, in microelectronics, in communication devices, and, especially, in combination with solar batteries.

According to the estimates of a number of investigators, lithium CPS with a polymeric electrolyte can replace in the future sulfuric acid-sodium batteries, accumulators based on systems of the Li/metal sulfide type, and even, partially, nickel–cadmium batteries.[1] Apart from their use in CPS, PE can be employed in sensor devices, condensers, and other solid state electrochemical devices.[2]

The principal task in the creation of solid PE involves nowadays the search for new compositions with a high ionic conductivity for ions of different species over a wide temperature range. The stability of the PE in air, their low cost, and the ease of their technological application are also very important. It is noteworthy that the possibility of constructing thin 0.5–100 μm films from electrolytes of the class considered and their elasticity constitute their major advantages compared with ceramic electrolytes. Furthermore, in terms of their transport properties, PE are only slightly inferior to liquid electrolytes.

Depending on the nature of the ionogenic centre, PE can be divided into two groups: (1) polymeric complexes — complexes of functional polymers with metal salts; (2) composite PE — compositions comprising film-forming polymers with low-molecular-mass solvents and electrolytic salts.

The polymeric complexes may be synthesised from polyesters, polynitriles, polyamides, polysulfones, and other functional polymers. By varying the structure of the polymer matrix and the composition of the complex, it is possible to obtain compounds with conductivities σ up to 10^{-2} S cm^{-1}. However, the variation of the properties under the conditions of constant current polarisation constitutes a significant disadvantage of this type of PE.

Composite PE may be obtained from a wide variety of polymers, solvents, and ionogenic salts. This makes it possible to regulate their properties over a wide range. The conductivity of the composite electrolytes is extremely sensitive to their composition and methods of preparation. After prolonged storage and also after polarisation with a direct current, an irreversible change in their structure takes place in many instances and leads to a significant decrease in conductivity. In order to obtain solid electrolytes, it is essential to have polymers with a high flexibility of the chain, a low cohesion

energy density, etc. The necessary and sufficient conditions for the employment of various polymers and matrices in polymeric electrolytes for CPS have been most fully considered in the review of Bruce and Vincent.[3]

In the present review, attention is concentrated on questions of the modification of solid polymeric electrolytes in order to increase their conductivity, of the influence of the purity of the PE components on the ionic conductivity and the electrical parameters of the CPS, and also of the chemical interaction in the lithium anode–polymeric electrolyte system.

II. The mechanism of ionic conduction in solid polymeric electrolytes

In composite PE, the driving force leading to the dissolution of the salt in the polymer arises from the oxygen, nitrogen, or sulfur atoms forming part of the composition of the polymer molecule and surrounding the lithium cations. The coordination groups in PE are the oxyalkanes $-CH_2-CH_2-O-$, azoalkanes $-CH_2-CH_2-NH-$, thioalkanes $-CH_2-CH_2-S-$, and the esters $-CH_2-CH_2-OCO-$. The following types of polymers are used for the preparation of the PE: linear homopolymers — poly(ethylene oxide) (PEO), poly(propylene oxide) (PPO), and polyethyleneimine (PEI), nonordered polymers–PEO/PPO; network polymers (with cross-links); cellular-branched copolymer blocks.

The organic polymers used for the preparation of the PE are usually insulators themselves. Their insignificant conductivity (of the order of $10^{-12}-10^{-10}$ S cm^{-1}) is due to the presence of impurities and is due to the diffusion of ions through the free volume of their macromolecules. Therefore fairly satisfactory ionic conductors can be obtained by dispersing various salts in the polymers at the molecular level. Among metal ions, those of lithium are the smallest and have the lowest activation energy and for this reason lithium salts are frequently employed to prepare electrically conducting compositions for different purposes. With increase in the size of the cation, there is an increase in the degree of binding of the salts to the macromolecules. An increase in the complexity of the structure of the cations lowers the degree of solvation of the low-molecular-mass ions by the macromolecules. The donor capacity (DN) of the solvents also influences the complex formation process. For example, in acetonitrile ($DN = 14.3$), the degree of association of polyesters with low-molecular-mass salts is higher than in methanol ($DN = 19.0$) solutions.[4–6]

The mechanism of the conduction in polymeric electrolytes, first proposed by Armand et al.,[7] presupposes ionic conduction in continuous conducting regions of the helical structure of the PEO and also the fact that it is effective predominantly in the amorphous phase of the PEO–salt system. Under these conditions, the ion migrates between the polymer chains by virtue of the segmental motions of the polymer matrix. It may be that such movement in the polymer is an important factor which determines the order of magnitude of the ionic conductivity in the solid state.

Bruce and Vincent[8] investigated ionic transport in polymeric electrolytes — amorphous PEO–$LiClO_4$ complexes — by an e.m.f. method for different compositions of the complexes. In this case, the steady-state current during polarisation by a permanent field was attained after several hours and was determined by the mobility of both Li^+ and ClO_4^- ions, while at a high salt concentration ion pairs are also mobile.[9] According to the data quoted by Gray,[10] at a fixed temperature the dependence of the conductivity on the perchlorate concentration is a complex function. At low concentrations, the conductivity σ diminishes rapidly with increase in the salt content. It then increases to a maximum, the position of which depends on the temperature, after which it again falls. The form of the observed dependences of σ on temperature and perchlorate concentration is caused, according to the authors, by charge transfer involving the Li^+ and ClO_4^- ions, the mobilities of which are influenced by the incomplete dissociation of the salt and by the formation of the cluster ions $Li(ClO_4)_2^-$ and $Li_2(ClO_4)^+$.

It has been shown by Brillouin and photon-correlation spectroscopy[11] that the cooperative movement of ~20 monomer units of the polymer is needed for ion transport. For $n > 4$, short-lived ion–polymer cross-links, restricting the mobility of the polymer segments, arise in the electrolyte. The density of the cross-links diminishes sharply with increase in temperature as a consequence of the formation of ion pairs, which exert a plasticising effect on the electrolyte.

In the study of the ionic association of the PPO–$LiClO_4$ complexes, the constancy of the number of dissociated ions under conditions when the monomer : salt ratio varies from 1000 to 30 was noted.[12] With increase in the salt concentration in PPO, the rate of formation of ion pairs also rises. The main contribution to the increase in the conductivity of the PE at low $LiClO_4$ concentrations comes from the increase in the number of dissociated ions and not from their mobility. The IR and polarised Raman spectra of the PPO–$LiCF_3SO_3$ complexes indicate the existence of three types of associated species: two differently coordinated ion pairs and a triple ion. It is claimed[13] that the free ions which had been believed previously to exist in these polymer–salt complexes are in fact cation–anion pairs in which the cation interacts weakly with the terminal CF_3 group of the anion.

The data of Arumugam et al.[14] on the diffusion coefficients of Li^+ and PF_6^- in the amorphous PEO–$LiPF_6$ electrolyte obtained using ^7Li and ^{31}P NMR with a pulsed field gradient over a wide range of temperatures (25–100 °C) and salt concentrations (up to 0.25 M) indicate different mechanisms of the transport of the cation and anion at a high salt concentration. A reduced sensitivity of the diffusion of the cation to the salt concentration and a deviation from the Nernst–Einstein relation have been observed. Cation jumps between ionic clusters and the diffusion of neutral ion pairs have been proposed as mechanisms to account for the results.

III. Modification of the polymeric electrolytes used in lithium chemical power sources

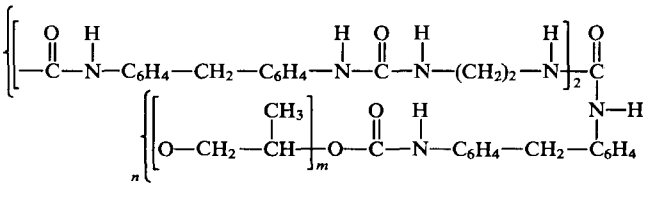
The main obstacle in the creation of low-temperature solid-state batteries with a polymeric electrolyte is the marked impairment of its ionic conductivity during storage caused by the crystallisation of the PE and a sharp increase in the size of its particles.[15] One of the ways of solving this problem is to base the electrolytes on complex polymeric compounds or to use these to modify the traditionally employed PE.

A survey of the experimental studies in recent years demonstrated that complexes of PEO with lithium salts are mainly employed as the solid PE, but their practical use in the manufacture of CPS is difficult, firstly, as a consequence of the tendency of PEO to crystallise, secondly, as a consequence of the hygroscopicity of the films based on it, and, thirdly, due to the small transport numbers of the cations.

Analysis of the literature data makes it possible to differentiate the following principal modification methods which increase the ionic conductivity of the polymeric electrolytes: the use of amorphous polymers and additives inducing conversion into an amorphous structure; the formation of a network system (cross-links); the introduction of crown-ethers, plasticisers, and ceramic powders. The application of such methods makes it possible to employ the PE in lithium CPS at normal temperatures.

The efforts of investigators engaged in the development of the PE have been directed mainly to the stabilisation of the state of the polymers containing amorphous sections or their preparation in the amorphous state. This is associated with the fact that the majority of polymeric electrolytes containing lithium salts have the maximum ionic conductivity when they exist in the amorphous state, which is the reason for the level of working

temperatures being approximately 100 °C. The possibility of creating electrolytes in a stable amorphous form, i.e. the preparation of polymers with a secondary structure having optimum electrochemical and mechanical properties, has therefore been discussed in recent years.[18,19] In particular, an amorphous single-state solid electrolyte with an improved ionic conductivity, the absence of crystallinity, and a satisfactory elasticity at 20 °C has been obtained by copolymerising ethylene oxide and other oxides of the type $-CH_2-CH(R)-O-$, where R = alkyl, alkenyl or alkynyl, containing between 1 and 12 carbon atoms, or $-CH_2-O-R'-R$, where R' is a polyether $-(CH_2-CH_2-O-)_p$ (p is an integer in the range from 0 to 10), or a cyclic ether containing more than three carbon atoms in the ring.[20] The oxides are selected from the group comprising tetrahydrofuran, dioxolane, and their derivatives. Short cross-links in the electrolyte are ensured by adding silicon, cadmium, boron, titanium, zinc, magnesium, or tin compounds. The polymeric electrolyte contains between 1.5 and 25 mass% of $LiClO_4$ or $LiCF_3SO_3$.



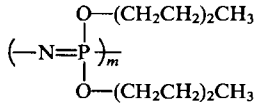
A PE with $LiClO_4$ has been obtained from an amorphous copolymer of ethylene and propylene oxides and allyl glycidyl ether (the content of the amorphous phase was 98%). Its maximum conductivity proved to be 75×10^{-5} S cm^{-1} at 25 °C for an electrolyte composition with a lithium : oxygen ratio of 0.05.[21]

In another study,[22] the polymer matrix was PEO, each monomer unit of the main chain of which contained the $-(CH_2-CH_2O)_x-R$ side chain, where $1 < x < 20$ and R is an alkyl group. The bond between the main and side chains in the polymer is formed via an ether group. The molecular mass (M) of the main polymer chain was $10^4-5 \times 10^6$, while that of the side chain was 50–2000. Such a solid PE has a high conductivity at 20 °C and may be used in lithium accumulators.

It proved possible to increase the conductivity of the PEO–$LiClO_4$ and PEO–$LiCF_3SO_3$ systems at low temperatures by adding low-molecular-mass polyethers $CH_3(OCH_2.CH_2)_nOCH_3$.[23–25] The materials obtained behave similarly to a solution of salts in the polymer of the dimethyl ether of ethylene glycol ($\sigma = 10^{-4}$ S cm^{-1} at 40 °C), but their mechanical properties turned out to be unsatisfactory.

The PE based on PEO may be modified by introducing various lithium salts of fluorinated monobasic salts. The complex of PEO with $LiCF_3SO_3$ has the highest conductivity among the complexes investigated ($\sigma \approx 4 \times 10^{-4}$ S cm^{-1} at 100 °C). An increase in the size of the anion in these salts leads to a decrease in σ. This has been attributed to a change in the interactions and mobilities of the ions. In the case of the $LiCF_3SO_3$ and NaI salts, there is a significant increase in the conductivity of the PEO-based PE and a decrease in the microviscosity.[26] It has been suggested that the observed effect is associated with the strong influence of the fraction of the amorphous 'elastomeric' phase and also with the inhomogeneity of the distribution of various cations and anions in different phases.

The PE can also be maintained in the amorphous state by creating segmented block copolymers in which the regularity of the chain is disturbed and hence crystallisation is hindered. A series of materials have been investigated[27,28] in which this principle holds, especially the system employed as the primary polymeric crystal, namely segmented polyether-polyurethane-urea, which has the structure $(A-B)_n$, where A is the solid segmented polyurethane-urea (~30 mass%) and B is a soft polyether segment.

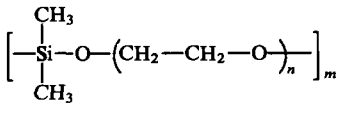


The polyurethane-urea segments tend to aggregate as a result of the formation of hydrogen bonds and of a two-phase microstructure, ensuring thereby that the electrolyte has excellent mechanical properties. Salts such as $LiClO_4$ dissolve selectively in the polyether. The relation between the morphologies, the dynamic-mechanical properties, and the ionic conductivities of the materials has been described.[28,29]

A similar matrix polymer — polyurethane-urea (PUU) — has been described.[30] 4,4-Dimethylbis(phenylene isocyanate)ethylenediamine and poly(ethylene glycol) ($M = 1000$) were used as the starting materials for its synthesis. The molecular mass of the soft (polyether) segment of the polymer is 1000, the mass fraction of the hard segment (polyurethane-urea) is 35, and the melting point of the polymer is 180 °C. A film formed from a complex of an alkali metal salt with PUU has a high ionic conductivity ($\sigma = 1 \times 10^{-5}$ S cm^{-1}) at 33 °C and a fairly high mechanical strength.

A method has been proposed for the preparation of the PE by the mechanical mixing in a solvent at room temperature of an acrylic poly(alkylene oxide) and a lithium salt with polyurethane (PU) or polyurethane-urea and subsequent heat treatment of the mixture.[31] The resulting solid electrolyte has $\sigma = 1.5 \times 10^{-5}$ S cm^{-1} and satisfactory mechanical properties. When the salt $LiClO_4$ is introduced into polyurethane, the ionic conductivity increases by three orders of magnitude: $\sigma_{max} = 10^{-4}$ S cm^{-1} at 20 °C is attained in PU : $LiClO_4$ = 8 : 1 mixtures.[32] In the presence of high contents of $LiClO_4$, the conductivity falls owing to the increase in viscosity. The difference between the conductivities of the PE based on PEO and PU is especially significant at temperatures below 80 °C, since a decrease in temperature entails a sharp (by a factor of ~10) decrease in the conductivity of PEO due to a structural rearrangement. Experiments in which lithium electrodes were employed established that the transport numbers of the lithium cations at 50–100 °C are 0.5–0.8. In order to prevent the impairment of the characteristics of batteries having PE as a result of prolonged storage, it has been suggested that a polymer having a urethane-like structure, in which the hydrogen atoms have been replaced by alkali or alkaline earth metal atoms, be used as the electrolyte.[33]

More flexible comb-branched systems may be obtained from polymers the main chain of which has a low glass point. These probably result in the formation of electrolytes with a maximum conductivity.[34] In order to synthesise such PE, a study has been made[35–37] of systems based on phosphazene and siloxane polymers. One of the most successful PE has been synthesised by substituting the chlorine atoms in poly(dichlorophosphazene) by alkyl groups as a result of treatment with the sodium salt of 2-(2-methoxyethoxy)ethanol in the presence of tetra-n-butylammonium bromide, which results in the formation of a compound having the formula



This polymer gives rise to single-phase amorphous electrolytes with different univalent, divalent, and trivalent salts.[35] The dependence of the ionic conductivity of the solid-phase polymeric complexes of an oligo(ethylene oxide) graft copolymer with polyphosphazene on temperature and concentration has been investigated.[38] The maximum value of σ ($\sigma_{max} = 10^{-4}$ S cm^{-1}) was observed for complexes of the copolymers with $LiClO_4$ at 25 °C and for a salt content of 15%. For the complexes of $LiClO_4$ (salt content 7.5%) with polyphosphazene modified by the grafting of oligo-oxyethylene with a degree of oligomerisation of 7, $\sigma = 3.5 \times 10^{-4}$ S cm^{-1}. For structurally involved complexes of a polycyclotriphosphazene with $LiClO_4$, the conductivity was $\sigma = 1.2 \times 10^{-4}$ S cm^{-1} (at 90 °C), the

maximum in σ shifting towards a higher salt concentration with increase in temperature.[39]

The main advances in the field of ionic polymeric conductors based on linear phosphazenes and polyacrylates containing PEO with different degrees of polarisation as substituents in the side chains have been considered in reviews.[40,41] It was shown that the complexes of the above polymers with the salts $LiCF_3SO_3$ and $AgCF_3SO_3$ exhibit an anomalously high conductivity with respect to the metal cations (up to 10^{-3} S cm^{-1}). These results agree well with the experimentally determined diffusion coefficients of the cations. A polymeric electrolyte, consisting of a mixture of the complex salt of poly[bis(methoxyethoxyethoxide)-phosphazole] (I) and PEO (II) and doped with $LiCF_3SO_3$ or $LiClO_4$ was cast from a I + II solution in acetonitrile and dried in vacuo at 100 °C.[42] For the ratio I : II = 1 : 1, the specific conductance of the electrolyte was 2×10^{-4} S cm^{-1} at 20 °C and 5×10^{-2} S cm^{-1} at 100 °C. A method of synthesis of oligoethyleneoxypolyphosphazene (OPP), containing allyl groups, has been proposed.[43] The method includes a stage in which hexachlorotriphosphonitrile is converted into dichlorophosphonitrile and the latter interacts with the corresponding alkoxides. During the synthesis, up to 5 mass% of $LiClO_4$ is introduced into the OPP, which ensures a fairly high conductivity of the PE with respect to lithium ions.

Polymers with a very low glass point have been obtained by the polycondensation of dichlorodimethylsilane with poly-(ethylene glycol).[44]

The high flexibility of the main chain and the absence of crystallinity (as a consequence of the irregularity of the chain) ensure a high conductivity of such polymers — much higher than the conductivity of poly[bis(methoxyethoxyethoxide)phosphazene].[35] The conductivity is comparable to that of the comb-branched siloxanes.[45] However, the practical employment of such systems is held back by the high sensitivity of siloxanes to hydrolysis.

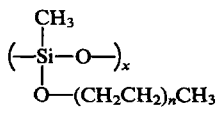
PE based on poly-*p*-phenylenevinylene (PPV) have also been proposed for the manufacture of accumulator batteries.[46] The films consist of a mixture of aqueous solutions of polymeric precursors of PPV (a water-soluble sulfonium salt) and a water-soluble polymer such as PEO, methylcellulose, or hydroxypropylcellulose in proportions of 1 : 1. PPV is obtained from the precursor salt form by heat treatment of it. The best results were obtained for mixtures of PPV and PEO doped with $LiClO_4$. Such mixtures are resistant to thermal degradation (up to 225 °C) and possess satisfactory mechanical properties.

Polymeric electrolytes with an amorphous structure are formed from a copolymer of acrylonitrile and sulfoalkyl methacrylate.[47] The conductivity of different salt forms of the PE then varies in the sequence lithium salt > sodium salts > potassium salts and increases with increasing oxygen : lithium ratio in the range 20 – 100. The new PE based on the copolymers with poly(vinyl alcohol), PVA, and polyacrylamide have a high thermal stability combined with a fairly high conductivity.[48]

One of the methods for retarding the transition of the polymer from the amorphous to the crystalline state involves the cross-linking of the polymer matrix, for example the cross-linking of PEO by exposure to γ-radiation or an electron beam.[49] In this case, one obtains PE with an improved conductivity with respect to lithium ions at a reduced temperature. The mechanisms of the radiolytic degradation and cross-linking of PEO in the solid state and in aqueous solutions have been investigated by the EPR method.[50] The decrease in crystallinity, the improvement in mechanical properties, and the increase in conductivity at 20 °C of the cross-linked polymeric materials indicate that γ-irradiation is a simple and effective method for the preparation of highly conducting and mechanically stable PE. However, the effect of the γ-irradiation of PE specimens based on PEO and lithium salts ($LiClO_4$ and $LiCF_3SO_3$) at 78 °C has not been confirmed.[51]

The cross-linking of a polymer composition consisting of PEO units with terminal C(O) – CH=CH – C_6H_4R (R = NO_2, Cl, OCH_3), C(O) – CH=CH – CH=CH – C_6H_5, C(O) – C(NC)= CH – C_6H_5, and C(O) – C(NC)=CH – CH=CH – C_6H_5 groups has been described.[52] The cross-linking takes place under the influence of accelerated electrons or UV irradiation. A thin-film PE (in a mixture with lithium salts) with a degree of cross-linking of 90% and an ionic conductivity of 1.7×10^{-4} S cm^{-1} at 20 °C was obtained.

Chemical methods for the cross-linking of the polymer matrix have been described in a series of studies. For example, film PE with satisfactory conductivity at 30 °C[53] as well as a strong and elastic PE with $\sigma = 6 \times 10^{-5}$ S cm^{-1} at 25 °C[54] have been obtained by mixing the product of the copolymerisation of polyglycerol with ethylene oxide or a mixture of ethylene and propylene oxides with a polyfunctional cross-linking agent (polyisocyanate) at 50 – 200 °C and a pressure of >10 kg cm^{-2}. The methods of preparation of PE based on lithium salts and poly(ethylene glycols) cross-linked by siloxane tetraisocyanate have been described.[55]



It has been suggested that a cross-linked copolymer of ethylene oxide and propylene oxide be used as the base of a polymeric electrolyte for a lithium accumulator.[56] In combination with a lithium salt, such a PE ensures a specific conductance of the lithium ions of the order of 10^{-5} S cm^{-1} at 25 °C. The product of the copolymerisation of the vinyl ether R – (O – CH_2 – CH_2)$_n$ – O – CH= CH_2 (R = Me or Et, n = 1 – 6) with the divinyl ether [CH_2=CH – (O – CH_2 – CH_2)$_n$ – O – CH=CH_2] (n = 1 – 6) is a cross-linked polyether with a glass point of 60 – 80 °C, which has been used as the matrix for the preparation of a solid PE.[57] The cross-linking of PEO-based resins by vinyl polymers has been described.[58] Before cross-linking, the (PEO-400)-maleate-isophthalate resins by styrene (St), vinylpyrrolidinone (VP), or vinylpyridine (VPD), $LiClO_4$ was added to the resins. For the ratio [PEO]/[Li^+] = 50, the conductivity of the PE obtained increases in the sequence VPD < VP < St. This sequence is correlated with the increase in the strength of binding of Li^+ on passing to more polar comonomers.

A polymeric electrolyte with stable characteristics,[59] capable of being used for a long time without a decrease in capacity, has been obtained from a polyether with cross-links of the urethane type. It contained the (O – CO – NR) (R = an inert group or an element in Group I of the Periodic System other than hydrogen) repeating unit. The electrolyte also contained an inorganic salt and an inert additive.

A polymeric electrolyte — a modified polyurethane network obtained from polydimethylsiloxane containing grafted PEO, cross-linked by an aliphatic diisocyanate, and incorporating 10% of $LiClO_4$ — has an ionic conductivity of 10^{-5} S cm^{-1} at 30 °C. It was used in solid-state electrochemical lithium batteries. Analysis of voltammetric data showed that, after the completion of the synthesis of the polyurethane network, the unreacted cross-linking agent may interfere with the diffusion of lithium ions at the electrode – electrolyte interface. The limiting currents were determined from the cathodic branches of the voltammogram. The internal resistance of the RuO_2/Li accumulator with a PE was determined from its discharge curves recorded at 60 and 80 °C. It proved to be 5 kΩ. After two discharge cycles with degrees of discharge of 95% and 73%, the adhesion of the PE film to RuO_2 and Li remained unchanged.

The morphology and physical properties of the electrolytes prepared from linear segmented polyurethanes based on PEG and alkali metal salts have been described in fair detail.[61] Systems based on siloxane polymers may be obtained by mixing in a common solvent lithium salts with an organopolysiloxane containing more than two COOH groups in the molecule.[62]

The conductivity of such a PE at 25 °C is 5.6×10^{-5} S cm^{-1}. Liquid comb-branched polymers of the type

may be additionally cross-linked by heating to 150 °C (in order to form rubber-like films).[45] The length of the side chain exerts only a slight influence in this case on the conductivities of the electrolytes. For a PE of this kind, containing $LiClO_4$ as the ionogenic additive, $\sigma = 1 \times 10^{-4}$ S cm^{-1} at 25 °C.

A number of authors patented liquid solidifying organosiloxane-oxyalkylene copolymers with acrylate functional groups into which $LiCF_3SO_3$ and azobisisobutyronitrile (AIBN) had been introduced. After solidifying at 85–90 °C for 30 min, elastic films 1 mm thick and with $\sigma = 1.6 \times 10^{-5}$ S cm^{-1} were obtained.

It is noteworthy that the assignment of a particular polymeric electrolyte in terms of the method of modification to the first or second group is arbitrary, since the appearance of cross-links between the macromolecules is a means of fixing the amorphous state.

One of the promising ways of modifying PE involves the introduction of crown-ether additives, which greatly increase the ionic conductivity.[64] Studies on the electrical and electrochemical properties of PE films consisting of PEO and the salts $LiCF_3SO_3$, $LiBF_4$, or $LiClO_4$, both containing and not containing 12-crown-4 (12Cr4), showed[65] that at a constant temperature σ for each salt depends on the concentration of the crown-ether, which is a maximum for the concentration ratio [12Cr4]:[Li] = 0.003.

The kinetics of the complex formation reactions between alkali metal cations and macrocyclic ligands — 12-crown-4, 18-crown-6, and 15-crown-5 — have been investigated.[66] Crown ethers of the 16-crown-5 group were also introduced into polyphosphazenes (PP) as side groups.[67,68] The temperature dependences of the conductivities of such PE, containing $LiClO_4$ or $NaClO_4$, have been investigated. The lg $\sigma - 1/T$ relation was linearised with the aid of the Vogel–Tammann–Fulcher relation. The highest value of σ was attained for PP–$NaClO_4$, which is associated with the higher degree of ionisation of the salt bound to the macromolecular part of the polyphosphazene. The introduction of 12-crown-4-ether both into the solid PE consisting of PEO and $LiBF_4$ and into a cathodic composition consisting of Li_xCoO_2, PEO, and $LiBF_4$ improves the ionic conductivity of the PE.[69] The electrolyte has a very low leakage current. The addition of a crown-ether improves the operation of the cell, lowers the dissociation peak and the resistance to charge transfer, and increases the current capacity and reversibility of the cell (this has been observed in the case of CoO_2 and TiS_2 cathodes).

Apart from crown-ethers, a bicyclic compound (cryptand), which also forms a complex with lithium ions, may be used as an additive.[70]

The addition of low-molecular-mass plasticisers such as ethylene and propylene carbonates to electrolytes based on PEO,[71,72] polyacrylonitrile (PAN) poly(tetraethylene glycol diacrylate), or polyvinylpyrrolidinone and also into hybrid films based on PMMA, polystyrene, PVC, PVA, PAN, and poly(vinylidene fluoride) in amounts up to 30 mol.% increased σ to 10^{-5}–10^{-3} S cm^{-1}.[74] The suitability of the hybrid films as PE in solid-state batteries is indicated by the stable potential of the Li/specimen/MnO_2 galvanic cell operating for more than 70 h without the decomposition of the electrolyte. The possibility of plasticising the PEO-based compositions by introducing poly(ethylene glycols) with different molecular masses has been investigated.[75,76] Such plasticisation increases σ by increasing the content of the amorphous phase in the electrolyte and simultaneously increasing the salt concentration in this phase.

The study of the conductivites of solid polyelectrolytic complexes of the alkali metal salts NaSCN, $NaCF_3SO_3$, and $LiCF_3SO_3$ with polymers based on methoxypoly(ethylene glycol methacrylate) $CH_2{=}C(CH_3)COO(CH_2CH_2O)_nCH_3$ [$n = 8$ (PMG-8) and $n = 22$ (PMG-22)] as a function of temperature and salt concentration showed[77] that the systems based on the copolymers of PMG-22 with polystyrene as well as systems plasticised by poly(propylene carbonates) have much higher values of σ than systems based on the homopolymers. Compositions based on a mixture of an alkyl acrylate (alkyl C_{1-8}) and/or alkoxyacrylate (alkoxy C_{2-5}) polymer with 5%–100% (relative to the mass of the acrylate polymer) of $LiClO_4$ or the lithium salt of a polymeric acid (polystyrenesulfonic acid, polyethenesulfonic acid) with a high conductivity, used as a thin-film electrolyte, have been described.[78] The organic solvent, with a high relative permittivity, serves as both the plasticiser and the solvent.

An interesting phenomenon — a sharp increase in the conductivity of the PE on mixing it with Al_2O_3 powder — has been observed by the authors of a series of investigations. Such PE were investigated by impedance spectroscopy, X-ray diffraction, and NMR. It was shown[79] that the conductivity of the polymeric PEO–NaI electrolyte increases on mixing with Al_2O_3, reaching a value in excess of 10^{-5} S cm^{-1} at room temperature.

An increase in conductivity and satisfactory mechanical properties are also manifested by the PE having the composition $(PEO)_8LiClO_4$ into which powdered β-Al_2O_3 with a small grain size (< 5 μm) have been introduced by mixing with a solution of PEO and $LiClO_4$ in acetonitrile.[80] The addition of Al_2O_3 [81] and of ceramic $LiAlO_2$ microspheres 1 μm in diameter[82] (up to a concentration of 10%–30%) has a positive effect on the mechanical properties and conductivities of solid PE. An increase in the conductivity by an order of magnitude is attained by introducing β-Al_2O_3, Li_2O–B_2O_3–SiO_2 ionic glasses, and ion-exchange resins in the lithium-form as fillers into PEO-based.[83,84] Since the ratio of the pre-exponential factor for the conduction and the activation energy satisfies the Mayer–Neldel rule for the entire range of filler concentrations, the authors concluded that the ion-conducting fillers do not participate in charge transfer through the solid electrolyte and that their presence leads merely to the composites being more amorphous.

IV. The influence of the purity of the components of the polymeric electrolyte on its electrochemical characteristics

It was noted above that the composition for the preparation of the PE consists as a rule of a polymeric binder, an ionogenic alkali metal salt, and the solvent. PEO is the polymer most often employed in PE and has been most thoroughly investigated, but it is extremely hygroscopic like many other polymers employed in the PE; the lithium salts are also hygroscopic. The stability of the properties of the PE films is largely determined by the purity of the components and their moisture content. Therefore all manipulations involving the PE component are as a rule carried out under a dry or inert atmosphere.

A high-molecular-mass highly pure PEO is obtained by anionic polymerisation. The mechanism of the absorption of water by polymers, including poly(ethylene oxide), and the influence of the polymer structure on this process have been described.[85] It was shown that the absorption of water depends greatly on the composition of the aqueous solution: it diminishes with increase in the salt concentration, and to a greater extent the higher the ionic charge. The interactions of PEO with water have been investigated by differential scanning calorimetry (DSC) and NMR spectroscopy.[86] The plasticised PEO was characterised by the ratio of the number of moles of D_2O to the number of moles of monomer units (R). The DSC results showed that an increase in R to 0.6 leads to a monotonic decrease in the melting point of

the PEO from 56 to 35.9 °C. For $R > 0.135$, another low-temperature fusion isotherm appears, which has been attributed to the decomposition of the eutectic mixture. It was observed that an increase in R leads, on the one hand, to a decrease in the melting point from 22.7 to 11.9 °C and, on the other, to a linear increase in the enthalpy of fusion. The absence of a low-temperature endotherm for lower R has been attributed to the small size of the pores through which D_2O diffuses. Analysis of the NMR line shape indicates the presence of a doublet for $R = 0.07$ and 0.096, which has been explained by the low rate of exchange (on the time scale of the NMR experiment) between the bound and free water.

Studies showed that the method of preparation of the PEO has actually no influence on the properties of the PEO–lithium salt polymeric electrolyte.[87] On the other hand, the purity of the solvent employed for the preparation of the composition (acetonitrile) is strongly reflected in the properties of the polymeric complexes formed. In 'dry' solvents, complexes with high melting points and high degrees of crystallinity are formed, whereas in 'moist' solvents the complexes produced have low melting points. Complexes with low melting points are suitable as electrolytes for use at 120 °C and above.

The dehydration of the PE films is necessary, since an insulating coating comprising lithium hydroxide is formed on the lithium anode when the latter comes into contact with moisture. In order to protect the lithium electrode against oxidation, Japanese investigators[88] introduced tin salts into the liquid electrolyte. Tin ions are substituted by metallic lithium and a thin coating of metallic tin, suppressing the formation of lithium hydroxide, is formed on the surface of the negative electrode.

The study of the influence of hydration and dehydration processes on the conductivity of films of a PEO-based solid electrolyte showed that the hydration of the PE having the initial composition $(PEO)_8NiBr_2$ results in the formation of at least two types of bound water:[89] weakly bound water, which is removed at temperatures of approximately 80 °C, and strongly bound water which can be removed only at 130–140 °C. It is suggested that the strongly bound water is present as the complex $(PEO)_8NiBr_2 \cdot 6H_2O$. The ionic conductivity depends greatly on the degree of hydration of the electrolyte, increasing by ~8–10 orders of magnitude during the moisture absorption process. A method for the preparation of anhydrous films comprising polymers (PEO, PPO) and salts (mercury and sodium perchlorates) from their hydrated forms has been described.[90]

Thus the electrochemical properties of polymeric electrolyte films can be easily reproduced, provided that the water content in the components and the solvent is strictly controlled and also when films in a dry, inert form are employed.

V. Preparation of thin films of polymeric electrolytes by plasma polymerisation

One of the most important problems in the development of solid polymeric electrolytes is that of the preparation of thin films with a high mechanical strength. Japanese investigators developed a technology for the preparation of thin polymeric films with ionic conductivity for lithium accumulators by plasma polymerisation.[91] Hybrid layers of the polymeric product, exhibiting ionic conductivity, are obtained in three consecutive stages: (1) plasma polymerisation (PM) of the monomer in a vacuum with a residual inert gas, (2) spraying of a lithium salt solution over the polymer layer (0.5 μm), and (3) plasma polymerisation of a fresh portion of the monomer. The characteristics of the solid PE which depend on the plasma parameters have been established.[91] A relative increase in the energy of the glow discharge leads to an increase in the number of cross-links in poly[tris(2-methoxyethoxyvinyl)-silane] and to a decrease in its conductivity. Ultrathin films (~1 μm) of a homogeneous PE have been obtained by the plasma polymerisation of methyl acrylate (MA) and tris(2-methoxy-ethoxyvinyl)silane (TMVS).[92] According to IR spectroscopic data, the structure of the polymer obtained is close to that of the MA–TMVS copolymer. A layer of LiI was sprayed on to the polymer layer and then a further polymer layer was deposited. The three-layer composite was maintained for 24 h in vacuo (10^{-3} Torr). On interaction with LiI, the ester group $COOCH_3$ is then converted into the carboxylate group. The conductivity of such PE at 20 °C is 10^{-8} S cm^{-1}, which is less than the value for the TMVS–$LiClO_4$ complex (10^{-6} S cm^{-1}).

A technology for the preparation of ultrathin solid-state lithium accumulators involving the use of a plasma-polymerised solid polymeric electrolyte has been described.[93] A layer of TiS_2 (~12 μm) was deposited on a borosilicate glass support by the vacuum spraying of $TiCl_4 + H_2S$ vapour; a layer of a solid PE (~1.5 μm) was then deposited on it by the plasma polymerisation of the 1:10 TMVS–Ar mixture in vacuo. A 3% methanol solution of $LiClO_4$ was sprayed onto the polymer film at 60 °C and then a further layer of the polymer and a layer of the lithium salt (~1.5 μm) were deposited. After being kept in vacuo at 80 °C, the resulting solid PE had a conductivity of 10^{-4}–10^{-3} S cm^{-1} at 20 °C. The accumulators operated at a current density of 100 mA m^{-2}.

The properties of such a thin three-layer PE film with a high conductivity, laid on a glass plate with gold deposited from a high-frequency plasma in a stream of gold and TMVS vapour, have been investigated.[94] It was noted that there are no alkene groups in the polymer film and the distribution of the ClO_4^- ions with respect to thickness is nearly homogeneous, which corresponds to a homogeneous distribution of lithium ions. Pin holes were not detected in the film by electron microscopy. For the films containing 7% of $LiClO_4$, the conductivities are respectively 4.4×10^{-5}, 4.5×10^{-6}, and 3×10^{-7} S cm^{-1} at 100, 50, and 10 °C.

Apart from the plasma-generated TMVS polymers, a solid polymeric electrolyte for chemical lithium batteries has been obtained from polyoctamethylcyclotetrasiloxane and $LiClO_4$ by plasma polymerisation under glow discharge conditions. The conductivity of such films, reaching 10^{-6} S cm^{-1}, is determined by the $LiClO_4$ content.[95] A solid-state lithium accumulator with a thin-film (10–15 μm) cathode comprising TiS_2 and a PE film obtained by the plasma polymerisation of octamethylcyclotetra-siloxane with subsequent grafting of the poly(propylene oxide)–$LiClO_4$ complex has also been described.[96,97] The structure of this plasma-generated polymer is similar to that of polydimethyl-siloxane. The ionic conductivity of the hybrid PE reaches 2.6×10^{-6} S cm^{-1} at 60 °C. For a current density of 8 μA cm^{-2} and room temperature, the discharge plateau for the first discharge of the accumulator corresponded to the 85% utilisation of the cathodic material. The chargeability of the accumulator was satisfactory, but its internal resistance was fairly high.

A CPS with an increased operating lifetime, capacity, and number of charge-discharge cycles has been patented.[98] In this CPS, the solid PE consists of a plasma-polymerised layer of an organic compound containing an alkali metal ion and an element with a higher electronegativity.

VI. Electrochemical stability of solid polymeric electrolytes

When polymeric electrolytes are employed in lithium accumulators, complex problems associated with the electrochemical stability of the electrolytes arise. However, the number of publications devoted to this problem is small.

Thus Armand noted[99] that the electrochemical stability of polyethers is comparable to that of aprotic solvents such as tetrahydrofuran and propylene carbonate. The kinetics of the electrochemical process occurring in the lithium cell and involving the PEO–$LiClO_4$ solid electrolyte are as a rule controlled by the diffusion of ions.[100] The study of the PE films based on phosphazenes with $LiCF_3SO_3$ showed that the limits of the electrochemical stability are determined by the

reduction of the lithium salt.[101] Molecular complexes of lithium salts with poly[bis(methoxyethoxyethoxide)phosphazene] (MEEP) and its analogues with a high ionic conductivity, but are unstable.[102,103] In order to increase the stability of the polymeric structure, the MEEP was cross-linked by poly(ethylene glycol) ($M = 1000$), since the cross-linked macromolecules are very stable. This made it possible to employ their complexes with $LiCF_3SO_3$ as ionic conductors up to 140 °C. Stable polymeric electrolytes for lithium CPS, in which the dimensions are satisfactorily maintained during operation and the conductivity is 6.7×10^{-5} S cm^{-1} at 25 °C, have been obtained from MEEP and PEO–[$LiN(CF_3SO_3)_2$].[104] Cyclic voltammograms indicate the stability of the PE at potentials up to 4.5 V relative to the Li^+/Li electrode. Their use in the Li/TiS_2 lithium cell ensures 200 charge-discharge cycles.

Preliminary data on their cyclic nature and stability have been obtained for PE based on Li/poly[*N*-3,6-dioxaheptylpyrrole] to which [poly(ethylene oxide)-styrene macromonomer]$_{20}$–$LiClO_4$ had been added.[105] The possibility of using such PE at room temperatures was demonstrated.

Films based on the complex $(PEO)_9LiCF_3SO_3$ were investigated in the temperature range 100–170 °C using voltammetry at a low scanning rate.[16] The reversible reduction of the electrolytes was observed over a wide range of external conditions and subject to the stipulation that a certain threshold potential was not exceeded. It was shown that the stability of the reduction of the PE is limited by the discharge of Li^+ and the stability of the oxidation is limited by the discharge of $CF_3SO_3^-$. At temperatures of about 140 °C, the region of the oxidative-reductive stability of the film exceeds 3.3 V. In the range 140–160 °C, the stability region diminishes by 1 V as a result of the oxidation of $CF_3SO_3^-$. The authors[16] note that, by virtue of their high electrochemical stability and effective mechanical properties, the PE films investigated may find an application in solid-state batteries.

In order to devise batteries of a similar type capable of working with satisfactory operating characteristics for a long time, it is necessary to suppress the crystallisation process in the PE, which is achieved by adding an elastomer (a butadiene–acrylonitrile copolymer) and a macromonomer based on styrene and PEO.[106] It has been shown by X-ray diffraction that, when the elastomer and the macromonomer are added, the PEO crystal cell remains monoclinic. In the course of 15 months, the diffraction patterns and the conductivities remained unaltered. The stabilisation of the conductivity was also achieved by the partial replacement of the PEO by oligo(ethylene oxide) (OEO) with terminal styrene groups keeping the ethylene oxide unit/Li^+ ratio unaltered.[107] Best results ($\sigma = 2 \times 10^{-4}$ S cm^{-1}) were obtained by employing $LiCF_3SO_3$ and by introducing from 20% to 50% of a low-molecular-mass oligo(ethylene oxide) with $M = 550$.

VII. Chemical interaction at the lithium anode – polymeric electrolyte interface

The electrochemical reactions at the electrode/polymeric electrolyte interface have been considered in a review.[108] It was shown that although an analogy with the reactions in a liquid electrolyte is in fact observed, the former reactions are more complex. Under open-circuit conditions, the formation and growth of a passivating film are observed at the lithium/polymeric electrolyte interface. The growth kinetics depend on the nature and composition of the electrolyte, which agrees well with data on the phase diagram of the PEO–electrolyte system.[109] It was established that the behaviour of the passivating film on polarisation of the lithium electrode cannot be described in terms of a simple model comprising a solid electrolytic or polymeric surface film, and a model comprising an ion-conducting film of a modified polymeric electrolyte with a high resistance was therefore proposed. The stability of the vacuum-sputtered lithium electrode in an ultrathin film electrochemical cell of the type Ni/PE/Li with PEO, PPO, and the oxyethylene–oxymethylene copolymer as the polymeric electrolyte was therefore investigated by impedance spectroscopy at room temperature.[110] The most intense reactions at the interface are observed in the case of PPO. This is due to the rapid reaction between lithium and the amorphous copolymer, which was demonstrated with the aid of cyclic voltammetry. Owing to the phenomenon of passivation, the Faraday efficiency depends to a large extent on the rate of scanning of the potential. Its decrease from 20 to 5 mV s^{-1} decreases the degree of reduction of lithium from 85% to 30%.[111]

The resistance at the lithium/PE interface was investigated in thin secondary CPS with a solid PE (PEO–$LiClO_4$).[112] It was shown that the discharge characteristics of the CPS are impaired during storage, which is apparently associated with the increase in the internal resistance of the polymeric electrolyte.

In order to improve the mutual adhesion and to reduce the ohmic resistance at the negative electrode/PE interface, it was suggested that an intermediate layer of the halide of the metal constituting the anode (Li, Na, K, Ag) be formed on the electrode surface. Such a layer exhibits cationic conductivity and plays the role of the solid electrolyte.[113] Small transitional resistances are established between this layer, on the one hand, and the metallic anode and the PE on the other.

Overall, the study of the processes at the lithium/PEO interface leads to the conclusion that the characteristics of the lithium accumulators with PE are limited not so much by the intrinsic ionic conductivity of the polymeric electrolyte as by the charge transfer to the interface.

VIII. Modification of the electrodes in lithium chemical power sources with a polymeric electrolyte

In selecting the PE for use in solid-state batteries, it is necessary to take into account not only their ionic conductivity and transport numbers but also their compatibility with the anodic and cathodic materials.

In assembling the primary cells based on PEO and lithium salts, metallic lithium or its alloy with aluminium are employed as the anode and MnO_2 [114] TiS_2, MoO_2, or V_6O_{13} [115,116] as the cathode. The composite cathode contains as a rule a metal oxide, carbon black, and a polymeric electrolyte. For example, the active mass of the positive electrode contained 45 vol.% of V_6O_{13}, 5 vol.% of acetylenic carbon black, and 50 vol.% of the PEO–$LiClO_4$ composition[32,116] or 75 mass% TiS_2, 10 mass% of graphite powder, and 15 mass% of PEO + NaI.[117]

The improvement of parameters of the cells such as the current density and the specific capacity is achieved by improving the technique for the preparation of the composite cathode.[118] In the first discharge cycle, 100% and 50% utilisations of the active material of the cathode are attained at current densities of 0.27 and 0.8 mA cm^{-2} respectively. The increase in the size of the cells from 1 to 100 cm does not impair their properties. A sol-gel technology for the preparation of positive electrodes has been described.[119]

Japanese investigators[120] proposed five compositions of the negative active substance: an alkali metal, an alkali metal alloy, an electrically conducting polymer, a complex of an alkali metal and an electrically conducting polymer, and a layered interstitial compound. The characteristics of thin-film rechargeable accumulators operating at 20 °C and employing solid polymerisation redox electrodes have been investigated.[121] The anodes were prepared from various substances: the product of the polymerisation of salt synthesised by the interaction of 2,5-dimercapto-1,3,4-thiadiazole with LiOH; carbon black; a mixture of poly(ethylene oxide) with a lithium salt. Such accumulators withstood 100 charge-discharge cycles without a significant impairment of the parameters.

The Bridgestone Corporation and Seiko Electronic Components Ltd (Japan) have jointly developed a series of rechargeable polymeric lithium power sources[122] having a capacity three times as great as that of the existing lithium accumulators and a 2–3 times greater potential compared with the nickel–cadmium batteries. In the new lithium accumulators, a Li–Al alloys, ensuring a high capacity, is employed as the negative electrode, and a conducting polymer is used as the positive electrode. The nominal potential of the accumulators is 3 V and the capacity is 2 mA h.

The development of lithium accumulators is hindered by the poor rechargeability of the negative electrode associated with the formation of lithium dendrites at a current density > 0.5 mA cm^{-2}.[123] It has therefore been suggested that a negative electrode consisting of interstitial lithium compounds be employed. It has been proposed that Wood's alloys (Pb–Sn–Cd–Bi), having low melting points and ensuring a high diffusion coefficient of lithium, be used as the material of such electrodes.

The reversibility of the lithium electrode, operating in conjunction with polymeric electrolytes $(PEO)_x \cdot LiCF_3SO_3$, where x is in the range $4 < x < 16$, has been investigated[124] by potentiometric and polarographic methods in the temperature range 100–170 °C. Satisfactory results were obtained.

A tendency has arisen in recent years to employ polymeric electrodes in chemical batteries with polymeric electrolytes. Thus an accumulator with a PE has been described.[125] Its negative electrode was made of an alkali metal (Li, Na, K) and a conducting polymer or a composite of a conducting polymer and an alkali metal, while the cathodic mass consisted of a composite of a conducting polymer and a polymeric electrolyte. The composite cathode for solid-state lithium accumulators may also consist of polypyrrole (PP),[126] into which between 0% and 50% of PEO of polybithiophene (PBT)[127] has been added. It was shown that the capacity of the PBT electrode in contact with the solid PE is lower than that of the substance in contact with a liquid electrolyte (propylene carbonate–$LiClO_4$), but increases with increase in temperature from 50 to 70 °C.

The possibility of creating thin-film polymer batteries with a high energy capacity from a complex of PEO and $LiClO_4$ has been described.[128] The use of TiS_2 or V_6O_{13} as the cathodes and of metallic lithium as the anode makes it possible to create batteries which ensure a current density of 0.5–1.0 mA cm^{-2} at 80–100 °C and can undergo up to 250 charge-discharge cycles.[129] The Faraday efficiency is 80%–90% and the specific energy capacity is not less than 100 Wh kg^{-1}. The replacement of $LiClO_4$ by $LiCF_3SO_3$ in the polymer complex impairs the characteristics of the cell (the efficiency is $< 15\%$) and requires an increase in the working temperature to 130 °C. The authors suggest that the new PE based on PEO make it possible to create CPS operating at room temperature and likely to be useful in transport systems.

The data presented indicate the undoubted growth of interest in the theoretical and practical studies on the creation of new solid polymeric electrolytes and the construction on their basis of CPS with a high energy capacity.

The synthesis, properties, and applications of *N*-acyl-α-aminoacids

A P Mikhalkin

Contents

I. Introduction 259
II. Methods for the acylation of aminoacids 259
III. Properties of acylaminoacids 263
IV. Practical applications 269

Abstract. The review gives a systematic account of, and surveys the literature data on, the methods of synthesis, the physical and colloidal properties, and applications of acyl derivatives of aminoacids. The bibliography includes 369 references.

I. Introduction

Aminoacid derivatives, in particular *N*-acyl-α-aminoacids, the molecules of which include the peptide and carboxy-groups (or the sulfo-group in the case of aminosulfonic acids) have aroused continuous interest because of their exceptionally broad spectrum of activity. The presence of the acyl fragment in the molecule imparts hydrophobic properties to these compounds and enables them to exhibit surface-active properties. Aminoacids and higher carboxylic acids (HCA) are used for the manufacture of *N*-acyl-α-aminoacids. The practical application of *N*-acyl-α-aminoacids in industry and in human vital activity merits special attention. They are biologically 'soft' and are readily decomposed by bacteria under natural conditions, which is very important in our era of progressive pollution of the environment by industrial and domestic waste.

The chemistry of aminoacids, including the practical aspects of the chemical synthesis of peptides from which acylaminoacids are obtained, is fairly widely represented in the literature.[1–11] However, there is at present only isolated information about the methods of synthesis of acylaminoacids suitable for industrial application, their properties, and their practical applications.[12–15] The large number of continuously appearing publications on this topic has necessitated a survey of the accumulated information.

This review gives a systematic account and discusses the methods of synthesis of *N*-acyl-α-aminoacids having the general structure $R^1C(O)NR^2[CH(R^3)CO]_nOH$ and the relation between their structure and their physicochemical properties and surface and biological activities.

Since the methods for the acylation of aminoacids by higher carboxylic acids have been described in fair detail in the literature, we shall deal in detail with certain data concerning the kinetics and general mechanisms of acylation by the Schotten–Baumann method and of the activated esters method, which are fairly widely used for the synthesis of the above compounds.

II. Methods for the acylation of aminoacids

Detailed analysis of the formation of the peptide linkage, carried out, for example, in the monograph of Gershkovich and Kibirev,[16] showed that as a rule the carboxy-group is initially activated in order to increase the electron density on the carbonyl carbon atom of the higher carboxylic acid and this is followed by nucleophilic attack, in the given instance by the amino-group of the aminoacid. Nowadays methods such as the carbodiimide, azide, mixed anhydride, activated esters, and carboxy-anhydride procedures are most widely used for the formation of the peptide linkage. However, these methods are not always effective in the development of a technology for the manufacture of acylaminoacids.

The ability of aminoacids to be acylated is in many respects determined by the nucleophilicity ($pK_a = 2.23 - 4.43$) of the amino groups,[1,7] steric factors, and the acylating capacity of the carboxylic acid derivatives RCOX, which is in its turn determined by the stability of the anion X^-. In terms of their reactivity, the principal types of acylating agents are equivalent to the acidity series (the stability of the anion X^-) and the series based on the rates of their hydrolysis and can be represented by the following sequence:

$$R^1COHal > (R^1CO)_2O \approx R^1COOR^2 > R^1CONR^2_2 > R^1COOH.$$

Hence it is seen that the most effective acylation of aminoacids requires the activation of the carboxy-group in carboxylic acids, for example up to the formation of acid chlorides, anhydrides, activated esters, etc. The overall mechanisms of reactions involving acylation by carboxylic acids and their various derivatives have been investigated quite adequately.[1–8, 16, 17]

The principal methods of synthesis of acylaminoacids suitable for practical application known at the present time are considered below.

1. Acylation by the Schotten–Baumann method

Acylation of aminoacids by HCA chlorides is one of the commonest methods of synthesis of acylaminoacids. It constitutes the basis of the industrial manufacture of a whole series of

products, for example 'medialans' which are derivatives of sarcosine.[18-20] There are various modifications of this method:

$$R^1COCl + H_2NCHR^2COOH \xrightarrow{NaOH} \longrightarrow R^1C(O)NHCHR^2COONa.$$

HCA chlorides with various structures are used as the acylating agents. The reaction is carried out in aqueous solutions, in aqueous organic mixtures containing 30%–50% of an inert water-soluble organic solvent, and in systems comprising two immiscible solvents, one of which is water. It is noteworthy that in the last case, for example in the water–toluene system, the yield of the target product is appreciably reduced.[15]

In the study of the kinetics of the acylation of α-aminoacids by benzoyl chloride in aqueous solutions, it has been shown[21] that the amino-group in the aminoacids investigated has a high reactivity, which is determined by the form in which the acid exists in solution. The forms having free amino-groups, $H_2NCHRCOO^-$ (A) and $H_2NCHRCOOH$ (B), are the most reactive, the activity of form A being higher. The rate of change of the concentration of benzoyl chloride, for example in the acylation of glycine in a water–dioxane mixture (298 K, $c_{H^+} = 1.17 \times 10^{-7}$ M), is described by the following equation when account is taken of its hydrolysis:

$$\frac{dc_b}{d\tau} = k_h c_b + \frac{kK_a}{c_{H^+}} c_b c ,$$

where k_h and k are the hydrolysis rate constant and the rate constant for the acylation of the α-aminoacid in form A by benzoyl chloride, K_a is the acid ionisation constant of the protonated amino-group of the aminoacid, c_b and c are the benzoyl chloride and aminoacid concentrations, and c_{H^+} is the concentration of hydrogen ions. Subject to the conditions $c \gg c_b$ and a constant pH of the reaction medium (the use of a buffer), the observed rate constant (k_o) for the given first-order reaction is calculated by the equation

$$k_o = k_h + \frac{kK_a}{c_{H^+}} c .$$

The constants, calculated by the least squares method (Table 1), show that under the experimental conditions the α-aminoacids do not catalyse the hydrolysis of benzoyl chloride; this is confirmed by the similar rate constants for the hydrolysis of the latter in reactions with various α-aminoacids. The reactivities of the amino-groups of α-aminoacids are analysed in terms of the quantity K_1, which includes the product of k and K_a. The reactivities of the amino-groups of the α-aminoacids investigated are approximately the same with the exception of L-proline and L-glutamine. The study of the hydrolysis kinetics of the chloride of lauric acid under conditions of aminoacid acylation has shown[22] that this reaction proceeds in the kinetic region with $E_a = 12.8 \pm 0.5$ kcal mol^{-1} at temperatures below 30 °C. The kinetic parameters for the acylation of a series of α-aminoacids by benzoyl chloride in aqueous solutions, obtained by Babaev et al.,[23] describe the experimental data satisfactorily (the error does not exceed 5%). However, there is no rigorous correlation between the reactivity of α-aminoacids and their structure.

The methods of synthesis of acylaminoacids via HCA chlorides proved to be effective not only for natural α-aminoacids but also for many others,[20,24] for example for α- and ε-aminohexanoic, α-aminobutyric, α-aminoisobutyric, and iminodiacetic acids as well as *N*-ethyl, *N*-propyl-, and *N*-butylglycine, *N*-methylalanine, and β-alanine.

In the acylation of sarcosine by HCA chlorides, it was found[25] that, in order to increase the quality of the product, it is necessary to maintain rigorously a series of technological process parameters (pH 10.5 ± 0.3, temperature below 30 °C, vigorous stirring during the addition of the acid chloride). In order to isolate the pure substances, the reaction mixture is extracted with ether, washed with water until neutral, dried over sodium sulfate, the solvent is distilled away, and the residue is recrystallised from hexane or petroleum ether.[24] It is recommended that acylsarcosine be neutralised by washing with hot water for 3 h at a temperature 10 °C below its melting point. More prolonged washing of the product under these conditions leads to the hydrolysis of the peptide linkage.

Table 1. The rate constants for the hydrolysis of benzoyl chloride (k_h) and the acylation of α-aminoacids (k_1 and k) and the acid dissociation constants (K) of α-aminoacids at 298 K and $c_{H^+} = 1.17 \times 10^{-7}$ mol litre^{-1}.[21]

α-Aminoacid (pK_a)[a]	$10^3 k_h$/s^{-1}	$k_1 = 10^7(kK_a)$/ s^{-1}	10^{-4} k/litre mol^{-1} s^{-1}

[a] The values of pK_a are quoted to within ±0.02.

Much attention has been devoted to questions of the purification of *N*-acyl-α-aminoacids. One of the effective ways of solving this problem involves the washing of the reaction mass with C_1–C_4 aliphatic alcohols with simultaneous reduction of pH and filtration of the precipitated deposit or the employment of an alcohol–water mixture in the acylation stage.[26,27] These procedures make it possible to obtain acylaminoacids with a purity of 98%–99%.[28] Further development of industrial methods of synthesis of acylaminoacids by the Schotten–Baumann method involves the optimisation of the process and the development of continuous technological production schemes.[29]

Together with the natural and synthetic aminoacids, hydrolysed proteins are an important raw material for the industrial production of acylaminoacids and oligopeptides.[1,18-20,25] The products of the cleavage of the waste from leather (in the tanning of leather) and food industries, products of plant origin (cereal fibrin), microorganism biomass, etc. are as a rule employed as the protein raw material. The protein is usually hydrolysed by boiling in an excess of concentrated hydrochloric acid or alkali.

The industrial manufacture of products based on hydrolysed proteins with the trade name 'Lamepons', and 'Meipons' have been organised using the chlorides of lauric, palmitic, stearic, and oleic acids, as well as mixtures of acids from coconut and tall oils, lipids, and phospholipids.[13,18,30] The industrial methods of synthesis of acylated hydrolysed proteins are based on the Schotten–Baumann reaction in accordance with the following scheme:

$$R^1COCl + H_2NCHR^2CO[NHCHR^3CO]_nNHCHR^4COOH \xrightarrow{NaOH} \longrightarrow R^1CONHCHR^2CO[NHCHR^3CO]_nNHCHR^4COONa,$$

where R^1 = alkylated HCA, and R^2, R^3, and R^4 are fragments present in the α-aminoacids of protein raw materials of different origin.

In practice, the reaction is usually carried out with the gradual addition of HCA chlorides and stirring. A constant pH (9.5) and temperature (20 ± 5 °C) are then maintained.[31,32]

A commercial product with the following composition (%) is obtained under these conditions: acyl derivatives (25.0), initial hydrolysed protein (3.5), HCA (6.0), NaCl (5.0), and water (60.5). The optimum process conditions, making it possible to attain the maximum conversion of HCA chlorides and to obtain a high quality target product in a high yield, have been determined in a number of studies.[29,33-37]

The acylation of aminoalkanesulfonic acids takes place similarly to the reactions with aminoacids. The best known of the industrially produced acylaminoalkanesulfonic acids are derivatives of methyltaurine with the commercial names 'Igepons', 'Metaupons', 'Hostapons', etc. The methods of synthesis of acylmethyltaurine (including the principal industrial method of its preparation) by the Schotten–Baumann reaction, have been described in fair detail in a monograph.[25]

In recent years, studies in this field have been directed to the synthesis of highly concentrated acyltaurines with an increased purity. For example, repeated heating (to 50–90 °C) of the reaction mass containing 30%–60% of moisture, up to 50% of acylmethyltaurine, and 6% of NaCl followed by cooling to 10–30 °C[38] makes it possible to eliminate up to 90% of water from it. Highly pure acyltaurines have been obtained in a high yield in the stoichiometric interaction of HCA chlorides with taurine in an aqueous alcoholic medium.[39] The product, free from the NaCl impurity, has been isolated on heating the reaction mass, from which the NaCl deposit was filtered off and the product was crystallised.[40] A continuous method of synthesis of acyltaurines involving the continuous introduction of measured amounts of HCA chlorides has been developed. The optimum parameters of the technological process (pH 9–10, T = 40–60 °C) make it possible to obtain a highly concentrated pure product with an impurity content < 3%.[29,41-44]

2. The anhydride method

Symmetrical organic acid anhydrides and mixed anhydrides of inorganic acids are used for the acylation of aminoacids. Despite the fact that they are all less reactive than HCA chlorides, their employment for the synthesis of acylaminoacids is fairly important. The amide linkage is formed in this case in accordance with the following scheme:

$$(R^1R^2CO)_2O + H_2NCHR^3COOH \longrightarrow$$
$$\longrightarrow R^1CONHCHR^3COOH + R^2COOH.$$

Symmetrical organic acid anhydrides are preferable to others because they make a wide variety of side reactions avoidable. However, it is not possible to avoid the formation of the corresponding acids from the anhydrides (in stoichiometric proportions). For this reason, mainly the anhydrides of lower carboxylic acids are used in this method. The employment of extremely reactive anhydrides of halogenated acids with electron-accepting substituents, for example trifluoroacetic acid anhydride, for the large-scale production of acylaminoacids is economically unsound.

Aminoacids are as a rule acetylated by acetic anhydride in water or in acetic acid. For glycine and racemic aminoacids,[45-47] the yield of the target product is 89%–92%. Acetylation by acetic anhydride in boiling glacial acetic acid afforded derivatives of DL-alanine,[48] DL-valine,[49] and 4-aminobutyric and 6-aminohexanoic acids.[50] *N*-Alkylaminoacids are acetylated similarly.[51,52] In order to improve the quality of the acetylaminoacids obtained, acetylation by acetic anhydride in ethyl acetate in the presence of the cation-exchange resin K in the H^+-form has been suggested.[53] Together with acetyl chloride, acetic anhydride is widely used for the preparation of acetyl derivatives of aminoalkanesulfonic acids.[54,55] A method for the acetylation of aminoalkanesulfonic acid in the solid phase has been proposed. It makes it possible to obtain extremely pure products in a high yield.[56] It has been demonstrated by liquid chromatography that the product is up to 97% pure and contains about 1.5% of the initial aminosulfonic acid.

A series of acyl derivatives have been obtained by acylating aspartic acid with the anhydrides of alkenyl(alkyl)succinic acids[57] and by acylating taurine with the anhydrides of propionic and butyric acids.[58] HCA (C_8–C_{22}) anhydrides have been used in a series of syntheses.[59]

Mixed HCA anhydrides with sulfuric and carbonic acids are included among effective acylating agents despite the fact that in this case there is a possibility of side reactions. When mixed anhydrides of HCA and sulfuric acid were used at −5 to 40 °C in a water–acetone mixture, acyl derivatives of alanine, lysine, glutamic acid, and peptides were obtained.[60] The products of the acylation of aminoacids by mixed anhydrides of HCA and alkylcarbonic acids [alkyl carbonates? (Translator)] are the corresponding alcohols and carbonic acid together with the acylaminoacids.[61]

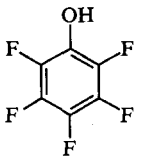
3. Method employing esters

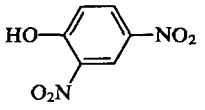
Despite the fact that only the activated esters method has found extensive application in the synthesis of peptides, in practice both HCA esters and their activated forms are used to synthesise acylaminoacids. As a rule activated esters are obtained from nitro-, chloro-, and fluoro-phenols. The acylation of aminoacids by HCA esters leads to the simultaneous formation of acylaminoacids and alcohols in accordance with the scheme:

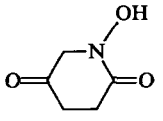
$$R^1COOR^2 + H_2NCHR^3COOH \longrightarrow$$
$$\longrightarrow R^1CONHCHR^3COOH + R^2OH.$$

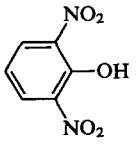
This reaction is usually catalysed by an equimolar amount of a strong base, for example sodium alkoxide, sodium and lithium tetrahydroaluminates, etc. When this method of acylation of aminoacids or their salts was used, the yield of the target product reached 90%–95%.[62] The yield of the product decreases appreciably in the presence of traces of moisture. Acyl derivatives of α-aminoacids,[63] oligopeptides,[64-66] hydrolysed proteins,[67] and methylpurine[68,69] have been obtained by this method.

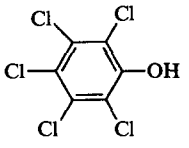
Nitrophenyl derivatives have been used to isolate α-aminoacids.[63,70,71] Pentafluorophenyl esters have been used successfully to acylate iminoacids despite the fact that *N*-alkyl substitution and branching at the α- and β-carbon atoms of the aminoacids interfere with the reaction.[72]

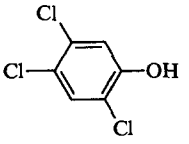


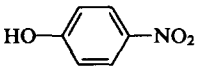


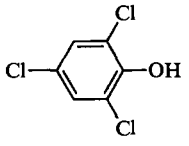






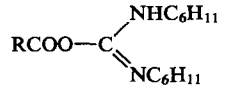






The reagents proposed nowadays for the activation of the carboxy-group and the subsequent formation of the peptide linkage by the activated esters method are as a rule stable during storage and exhibit a high reactivity, which in the case of substituted phenyl esters, for example, is determined by the acidity of their hydroxy-groups and by the type and position of the substituent and may differ by 2–3 orders of magnitude.[16] Pentafluorophenyl and nitrophenyl esters with a nitro-group which does not hinder the access of the amino-component to the electrophilic centre are the most reactive (Table 2, see over). A lower rate of acylation is characteristic of polychlorophenyl esters, which is due to the steric shielding of the electrophilic centre by the chlorine atoms in the *ortho*-positions.

4. Acylation by carboxylic acids



As a rule, aminoacids and their derivatives are not acylated by carboxylic acids at the usual temperatures. As stated above, the occurrence of such reactions under relatively mild conditions is possible only after the preliminary activation of the carboxy-group, for example by means of dicyclohexylcarbodiimide (DCHC).

$$R^1COOH + H_2NCHR^2COOH + C_6H_{11}N{=}C{=}NC_6H_{11} \longrightarrow$$
$$\longrightarrow R^1C(O)NHCHR^2COOH + C_6H_{11}NHC(O)NHC_6H_{11}.$$

Table 2. The rate constants (k) and the times (τ) required for 90% acylation by various activated esters.[16]

R^2	$10^2k/mol^{-1}\ s^{-1}$	τ/min
	40.4 ± 9	2.9
	18.4 ± 3	6.3
	5.4 ± 0.7	21
	1.73 ± 0.2	67
	1.72 ± 0.03	62
	0.3 ± 0.03	385
	0.1 ± 0.01	1088
	0.06 ± 0.002	1856

It has been suggested[73] that aminoacids are acylated in the presence of carbodiimides in accordance with a complex scheme involving the formation in the first stage of an adduct of the HCA and DCHC—*O*-acylurea.

This adduct, in which the carboxy-group is in an activated form, subsequently reacts with the aminoacid, forming an acylaminoacid. Acyl derivatives of glycine, alanine, leucine,[74] phenylalanine, lysine, methionine, glutamic acid,[75] and a number of other aminoacids[76] have been synthesised by this method in the presence of DCHC. It has been suggested that the acylation of HCA in an inert solvent with a calculated amount of carbonyldiimidazole be used to form the peptide linkage.[77] The imidazolide of the acid is formed as an intermediate in the reaction. It is subsequently transacylated to give the target products by reaction with the amino-group.

The synthesis of peptides, in particular of acylaminoacids, employing HCA as the acylating agent is favoured by the introduction into the reaction system of catalytic amounts of various phosphorus compounds: phosphorus chloride,[78] triphenyl phosphite,[79] the anhydrides of alkylphosphonic[80] and dialkylphosphinic[81] acids, derivatives of phenylphosphonic acid,[82] diethylphosphoryl cyanide,[83] diphenylphosphoryl azide,[84] and tetraethyl pyrophosphite.[1] Acylation by carboxylic acids in the presence of diethylphosphoryl cyanide is carried out in the presence of triethylamine.

$$R^1COOH + H_2NCHR^2COOH \xrightarrow[Et_3N]{NCP(O)(OEt)_2} R^1C(O)NHCHR^2COOH$$

The addition of tertiary amines promotes the formation of a carboxylate ion and the esterification reaction, increasing the yield of the target products. Acylaminoacids or peptides have been obtained in high yields (83%–94%) using carboxylic acids and diphenylphosphoryl azide.

$$R^1COOH + H_2NCHR^2COOH \xrightarrow[Et_3N]{N_3PO(OPh)_2} R^1C(O)NHCHR^2COOH$$

The effectiveness of the preliminary activation of the amino-group by tetraethyl pyrophosphite with formation of an amide has been demonstrated for the acylation of aminoacid esters with the aid of HCA.

$$R^1COOH + [(EtO)_2PNHCHR^2COOEt] \longrightarrow R^1C(O)NHCHR^2COOEt$$

The reaction with diethyl phosphorochloridite takes place in accordance with a similar mechanism.[1]

Despite the fact that the reactivity of carboxylic acids as acylating agents is extremely low without their preliminary activation, this method has found fairly extensive applications in practice in the development of technological processes. Acyl derivatives of glycine,[85] α-aminoacids, β-alanine, 6-aminohexanoic acid, and oligopeptides[86] have been obtained by this method. The reaction is carried out as a rule at 160–200 °C under an inert gas atmosphere. Depending on the type of the starting material, the yield of the target product can reach 40%–90% of the theoretical value. Under these conditions, acylaminoacids can be dehydrated with formation of oxazolones.

$$R^1C(O)NHCHR^2COOH \xrightarrow[-H_2O]{\Delta} R^1C\!=\!N\!-\!CHR^2 \;\; (O\!-\!C(O))$$

The method of synthesis of basic acylaminoacids, developed by the Ajinomoto Company,[87] involves the interaction of aminoacids with HCA at 100–250 °C in an organic solvent immiscible with water and forming an 'azeotrope with water' under the reaction conditions. The method of synthesis of acylaminoacids proposed by the Dynamit Nobel AG Company has effective technological parameters.[62] The experimental industrial technology for the production of acylaminoacids is based on the acylation of 6-aminohexanoic acid, obtained by the alkaline hydrolysis of ε-caprolactam,[88] and its amination and subsequent acylation by acrylic acid.[89,90] Acyl derivatives of peptides with valuable operating properties have been obtained by the reaction of HCA at 210–250 °C with oligopeptides obtained by

hydrolysing protein materials, in particular leather, bristle, hooves, animal hair, bird feathers, plant proteins, fish waste, and purified proteins such as collagen, casein, and elastin.[91]

Together with the traditional industrial methods for the synthesis of acyltaurides by the Schotten–Baumann acylation, a procedure involving the acylation of a methyltaurine salt by carboxylic acids has been proposed for commercial use.[92]

$$RCOOH + HN(CH_3)CH_2CH_2SO_3Na \xrightarrow[-H_2O]{\Delta} RC(O)N(CH_3)CH_2CH_2SO_3Na$$

A characteristic feature of this method is a higher content of the initial carboxylic acids in the reaction mass. The process is carried out at reduced pressure under inert gases. The corresponding acyl derivatives based on HCA have also been obtained for the sodium salts of *N*-cyclohexyltaurine,[93] *N*-2-hydroxypropyltaurine,[94,95] and methyltaurine.[96]

5. Other methods

Amides and carbon monoxide belong to the class of acylating agents which are rarely used in the synthesis of acylaminoacids but are potentially of practical value. The reaction of an amide with carbon monoxide and an aldehyde or a compound giving rise to an aldehyde takes place in the presence of a catalyst (Cat) in accordance with the scheme

$$R^1C(O)NH_2 + CO + R^2CHO \xrightarrow{Cat} R^1C(O)NHCHR^2COOH.$$

Group VIII transition metals (cobalt is the best) in the form of carbonyls, carboxylates, and various complexes have been proposed as catalysts.[97–100] The reaction is carried out at 50–150 °C, at a carbon monoxide partial pressure of 50–500 atm, in the presence of solvents, preferably alcohols, ethers, and ethyl acetate. The best results in the carbonylation reaction have been achieved with the aid of aliphatic aldehydes and primary amides.[99] As nucleophiles, amides add to the carbonyl group of aldehydes over a wide pH range and the initial product is usually an *N*-acylcarbinolamine $R^1C(O)NHCR^2R^3OH$.[17] When this reaction is carried out at an elevated temperature, the O → N rearrangement is facilitated. Under these conditions, ketones are as a rule less reactive.

A modified version of the above method, involving the replacement of the aldehyde by compounds containing double bonds, has been proposed.[101,102] The reaction is carried out in one stage, which increases its selectivity and rate. Ethers, ketones, and sulfoxides have been proposed as solvents. The highly nucleophilic amide anion, formed under these conditions on treatment with a strong base, undergoes Michael addition to the substituted alkene.

$$R^1C(O)NHR^2 \underset{}{\overset{OH^-}{\rightleftharpoons}} R^1C(O)\bar{N}R^2 \xrightarrow{R^3CH=CHCOOH} R^1C(O)NR^2CHR^3CH_2COOH$$

In practice, acylaminoacids are obtained under these conditions from alcohols and organic halo-derivatives.[103–105] The hydroformylation of an alcohol or halide in the presence of an amide and a catalyst (a Group VIII transition metal) is carried out at 50–200 °C and a pressure of 10–500 atm (a mixture of CO and H_2); the yield of the target product is up to 69%.

The method of synthesis of acylaminoacids by the reactions of oxiranes with amides, carbon monoxide, and hydrogen in the presence of cobalt-containing catalysts and promoting agents is of considerable interest.[106–109] Compounds containing Group I–V metals are employed as promoting agents. Among the diverse methods of synthesis of acyl aminoacids, the hydrogenation of an azlactone by *N*-acetylaminocinnamic acid in the presence of Raney nickel,[110] reactions of aliphatic nitriles with glyoxylic acid,[111] the interaction of an aminoacid salt with gaseous ketene,[112] and the acylation of the aminoacid by the succinimidine ester of the HCA[113] have been mentioned. In the last case, acyl derivatives of glycine, α- and β-alanines, and aspartic acid were obtained. The constant growth of the number of studies published on this topic shows that the methods are extremely promising.[114–118]

The processes based on the interaction of amides with chloro- and hydroxy-alkane sulfonates,[25] for example

$$R^1C(O)NHR^2 + HOCH_2CH_2SO_3Na \xrightarrow{\Delta} R^1C(O)NR^2CH_2CH_2SO_3Na + H_2$$

can also be included among the traditional methods of synthesis of acylaminoalkanesulfonic acids. Derivatives of aminomethanesulfonic[119,120] and aminoethanesulfonic[121–124] acids have been obtained in this way. For example, acylaminoethanesulfonates have been synthesised by the interaction of HCA, urea, and hydroxyethanesulfonates in the presence of an excess of the latter at 180–240 °C.[95,122] The process is distinguished by a high degree of conversion of the starting materials (92%–98%). HCA, amines, and hydroxyalkanesulfonates interact under virtually identical conditions.[125]

It has been suggested that, instead of amides, nitriles should be employed in the synthesis of acylaminoalkanesulfonates.[126–128] Acylaminoalkanesulfonic acids can also be obtained by aminating hydroxyethanesulfonates with subsequent acetylation[129,130] or activation of the aminoalcohols and the sulfonyl chlorination of the amidoalcohols obtained.[131]

One of the possible ways of obtaining acylaminoacids and their derivatives involves the interaction of lactams with HCA and their derivatives such as acid chlorides, anhydrides, esters, etc.[20] The acylation of lactams, for example of ε-caprolactam, by carboxylic acids is carried out at 240–250 °C and a pressure of 16 atm,[132] the target product being obtained with different degrees of oligomerisation of 6-aminohexanoic acid, depending on the ratio of the lactam and the acid taken for the reaction. The interaction of lactams with carboxylic acid esters leads to the formation of the corresponding acylaminoacids in fairly high yields (68%–71%).[133]

It follows from the foregoing that, for the industrial production of acylaminoacids, one may use (together with the acid chloride method, on the basis of which the technologies for the synthesis of virtually all the products of this kind have been developed by foreign companies) methods for their synthesis by the direct condensation of aminoacids with HCA, via carboxylic acid anhydrides, and by the reaction of amides, carbon monoxide, and an alkene (aldehydes, alcohols, and organic halides) are of considerable interest. The disadvantages of each of these procedures were noted above.

III. Properties of acylaminoacids

The properties of acylaminoacids are determined by the presence in the latter of peptide and carboxy-groups and by the conjugation of the lone pair of the nitrogen atom with the π-electrons of the carbonyl group, which leads to the manifestation by the peptide group of the properties of a double bond. The salts of these compounds in highly dilute aqueous solutions (below 10^{-3} M) tend to form micelles. Information about the properties of acylaminoacids has scarcely been treated systematically hitherto and is sometimes published in sources which are not readily available. The individual properties and constants of some of these compounds can be found in a number of communications.[11,14,15,24,25,68,134–140]

The solubility in water of *N*-acylaminoacids, forming colloidal solutions at low concentrations, is in many respects

Table 3. The dissociation constants (pK') and solubilities (P_s) of a series of aminoacids.[1]

Aminoacid	Chemical formula	pK'_1 (α-COOH)	pK'_2 (α-NH_3^+)	pH_i[a]	P_s/g[b]
Glycine	$CH_2(NH_2)COOH$	2.34	9.6	5.97	25.0
α-Alanine	$CH_3(NH_2)COOH$	2.34	9.69	6.00	16.6
Valine	$(CH_3)_2CHCH(NH_2)COOH$	2.32	9.62	5.96	8.8
Leucine	$(CH_3)_2CHCH_2CH(NH_2)COOH$	2.36	9.60	5.98	2.2
Sarcosine	CH_3NHCH_2COOH	2.23	10.01	6.12	
Aspartic acid	$HOOCCH_2CH(NH_2)COOH$	1.88[c]	9.60	2.77	0.5
Glutamic acid	$HOOC(CH_2)_2CH(NH_2)COOH$	2.19[d]	9.67	3.22	0.9
Lysine	$H_2N(CH_2)_4CH(NH_2)COOH$	2.18	8.95[e]	9.59	73.3
β-Alanine	$H_2N(CH_2)_2COOH$	3.60	10.19	6.90	16.6
γ-Aminobutyric acid	$H_2N(CH_2)_3COOH$	4.02	10.40	7.21	6.7
ε-Aminocaproic acid	$H_2N(CH_2)_5COOH$	4.43	10.75	7.60	

[a] pH at the isoelectric point. [b] Solubility in 100 g of water at 25 °C. [c] $pK''_1 = 3.65$. [d] $pK''_1 = 4.25$. [e] $pK''_2 = 10.53$.

Table 4. The solubilities of the sodium salts of certain *N*-acylated aminoacids (determined at the Krafft point).[140]

Aminoacid	Acyl group[a]				
	C_{10}	C_{12}	C_{14}	C_{16}	C_{18}
Glycine	(+) (40)	36 (65)	47 (93)	55 (−)	66 (−)
α-Alanine	(+) (154)	18 (666)	32 (523)	45 (301)	56 (−)
Valine	(+) (109)	(+) (372)	(+) (400)	8 (330)	36 (229)
Leucine	(+) (94)	(+) (299)	(+) (243)	(+) (236)	46 (−)

determined by the acid–base properties and structural characteristics of the initial aminoacids $R^1C(O)NR^2(CH_2)_nX$, such as the number and ratio of the polar groups (carboxy- and amino-groups), and the polar and nonpolar R^1 groups. The dissociation constants and solubilities of a number of aminoacids, the *N*-acyl derivatives of which are considered in the present review, are presented in Table 3. In the aminoacid series glycine–α-alanine–valine–leucine, the solubility in water decreases by an order of magnitude with increase in the size of the nonpolar R^1 group, i.e. with increase in their hydrophobicity. Thus, leucine, which contains the relatively large hydrophobic fragment Pr^iCH_2CH, can be extracted by hot n-butanol from its mixture with glycine. The solubilities of the basic α-aminoacids are much higher than those of the mono-carboxylic and acid α-aminoacids. Similar behaviour may also be traced for *N*-acyl derivatives of the same α-aminoacids (Table 4). The Krafft point for ionogenic surfactants characterises the lower temperature limit for the formation of micelles by the latter, because at lower temperatures the solubility of the surfactants is insufficient for the formation of micelles. The data in Table 4 show that the principal factors which determine the Krafft point are the size of the acyl group and the degree of branching of the aminoacid fragment.

The phase transitions from the solid to the liquid state (320–400 K) in acylaminoacids differing in the size of the acyl group have been investigated by IR spectroscopy.[141] It has been shown that, with increase in the number of methylene fragments and with the appearance of side chains in the aminoacid, ΔH_m and ΔS_m† both increase. Thus, for glycine and L-alanine derivatives the appearance of each additional CH_2 group entails an increase in ΔH_m and ΔS_m by 3–5 and 7 kJ mol^{-1} and by 8–10 and 18 J mol^{-1} K^{-1} respectively. Studies on solutions of acylaminoacid esters by spectroscopic methods have shown that they exist in the form of dimeric complexes[142] formed on associative interaction as a result of the formation of hydrogen bonds between the NH and ester CO groups.

† Enthalpy and entropy of fusion (Translator).

1. Spectroscopic properties

The UV spectra of acyl aminoacids are not of special interest to organic chemists because, like the UV spectra of the initial aminoacids and the HCA, they contain weak absorption bands in the region below 215 nm. The presence of a peptide group does not introduce a significant change into the UV spectra of acylaminoacids in this absorption region either.[143]

The IR spectra of acylaminoacids contain characteristic absorption bands of the functional groups C=O and OH (carboxyl), C=O and NH (amide bands I and II), and CH_3-, $-CH_2-$, and =CH– (the hydrocarbon skeleton). The range of the absorption frequencies of these compounds is determined by a number of factors (solvent, suspension medium, possibility of association, etc.) and for this reason Table 5 lists their average

Table 5. Characteristic vibration frequencies of the functional groups in the IR spectra of acylaminoacids.[14,15,144–146]

Functional group	Frequency/cm^{-1}	Type of vibrations
OH	3550–3000	stretching
NH	3460–3350	"
CH_3 and CH_2	2940–2870	"
C=O	1730–1710	"
C=O (amide I)	1685–1645	"
NH (amide II)	1550–1530	deformation

values. It is difficult to make reliable assignments in the high-frequency region of the IR spectra of acylaminoacids because the υ_{NH} and υ_{OH} bands of the corresponding groups in the free and associated states are as a rule observed simultaneously in this region.

^1H and ^{13}C NMR spectroscopy is one of the most important methods for the identification of acylaminoacids, which are polyfunctional compounds.

The ^1H NMR spectra of acylsarcosinate salts have been described in the literature. It has been shown that in aqueous solution acylsarcosinates exist as *cis*- and *trans*-isomers.[147] The presence of an intramolecular hydrogen bond between the amide carbonyl groups and the carboxyl in the *trans*-conformer has been established by NMR spectroscopy. On the basis of the spectra of certain acylaminoacids, general information has been obtained concerning the dependence of the chemical shifts of the amide protons on the dissociation constants of the carboxylic acid (the acylating agent)[148,149] and of the α-protons of the acylaminoacid on the nature of the solvent.[150] ^{13}C NMR spectroscopy has been more vigorously resorted to in recent years in order to investigate acylaminoacids containing long hydrocarbon groups. Thus Bouloussa and Dizabo[151] presented the ^{13}C NMR spectra of the palmitoyl derivatives of glycine, alanine, and glutamic acid, while Newmark and Hill[152] and Gunston[153] described a method for the assignment of the carbon atoms in the α-, β-, and γ-positions relative to the amide carbonyl group

Table 6. The chemical shifts of the signals in the ^1H NMR spectra (400 MHz) of the acylaminoacids $R^1C(O)NR^2(CH_2)_nX$.

Compound	$R^1C(O)-$	R^2	n	X	Solvent	Chemical shift/ppm (rel. to TMS)

[a] The same carbon atom. [b]The chemical shift of the CH_3 group is 37.2 ppm (J = 144 Hz). [c]Here the compound is $R^1C(O)[NR_2(CH_2)_n]_mX$ (m = 5). [d] The range of chemical shifts for individual compounds is quoted. [e]The chemical shift of the NCH_3 group is 36.5 ppm.

involving the use of deuterium exchange. NMR spectroscopy has made it possible to establish the nature of the associated species of acylaminoacids in aqueous systems and to show that the formation of their micelles is accompanied by an upfield displacement of the chemical shift for the hydrophilic part of the molecule as a result of conformational rearrangements around the C(O)–N and N–CH_2 bonds.[154]

Measurement of the ^1H and ^{13}C NMR spectra (400 and 20 mHz) for a series of acylaminoacids with long hydrocarbon groups, involving the use of spectrometers with superconducting magnets, which increased the chemical shift resolution, has made it possible to make a reliable assignment of the majority of the signals due to the functional groups of individual compounds and to identify them readily in technical products constituting multicomponent mixtures.[155–165] Typical chemical shifts for certain functional groups in the ^1H and ^{13}C NMR spectra of acylaminoacids are presented in Tables 6 and 7.

2. Chromatographic separation

Despite the fact that the separation of acylaminoacids by gas–liquid chromatography is extremely difficult owing to their relatively high molecular masses and extremely low volatility, the application of this method for the separation of acyl derivatives of, for example, glycine, alanine, α-aminohexanoic and α-aminoheptanoic acids, β-alanine, and the mixture of α-aminoacids produced by the hydrolysis of natural protein materials have been described in the literature.[166–172] High performance liquid chromatography has been very widely used to separate acylaminoacids (see for example, Refs 173–177). The order in which acylaminoacids are eluted is determined both by the nature of the aminoacids and by the structure of the acyl group.

3. Surface-active and bulk-phase properties

Like other anionic surfactants, acylaminoacids form micelles, by virtue of their diphilic structure, over a narrow temperature range exceeding the Krafft point, i.e. the temperature below which micelles are insoluble. The structures of the aminoacids differ from those of the traditional surfactants, for example HCA soaps, by the presence of the peptide groups, which impart to them a number of specific properties. In particular, they exhibit an increased resistance to acids and salts, a greater rigidity, lower pH values of their aqueous solutions, lower critical concentrations for micelle formation (CCM) and Krafft points, and a lower surface activity (G_m), but they have higher minimum surface tensions (σ_{min}).[25,140,178,179] Certain colloidal-chemical properties of acylaminoacids are presented in Table 8.

The available data show that the principal factors determining the Krafft points and CCM are the size of the acyl group and the degree of branching of the aminoacid fragment. The salts of acylaminoacids are less active at the liquid–gas interface than the corresponding HCA salts, where the nature of the formation of their micelles is largely determined by the enhancement of the hydrophobic properties of the molecule owing to the lateral branching at the C_α atom of the aminoacid fragment. This has been confirmed by the minimum surface tensions and the CCM. The CCM for acyl derivatives of α-aminoacids diminishes with increase in the hydrophobicity of the molecules in the following sequence; glycine > α-alanine > valine > leucine.[179–181] The hydrophobicity increases sharply for salts of acyl derivatives of lysine. On the other hand, the salts of acyl derivatives of aspartic acid (a dicarboxylic acid) are more hydrophilic. The contribution of aminoacid side chains to the relative hydrophobicity has been estimated from the CCM for the salts of the lauroyl derivatives of a series of α-aminoacids in a study of the formation of their micelles in various media[182,183] and the authors suggested that the CCM be used as a characteristic of a surfactant, reflecting its hydrophile-lypophile balance (HLB).

The formation of micelles by acylaminoacids is accompanied by a change in certain physical parameters of their molecules, for example by a displacement of the chemical shift of the nuclei of the nucleophilic fragment, which is a consequence of the conformational rearrangements about the C(O)–N and N–CH_2 bonds.[184] It is noteworthy that the mechanisms of micelle formation are very significantly influenced by the type and number of impurities. Thus it has been shown[185] that values of CCM_1–CCM_4 in the range 0.026%–0.12% have been found in a technical product—sodium oleoylmethyltaurinate containing NaCl and NaOH as the main impurities—from the points of inflexion in the isotherm and from the solubilisation of a dye. The different micellar structures, characterised by the four typical concentrations for micelle formation, correspond to spherical and non-spherical (cylindrical) micelles and their aggregates.

The influence of the structure of the acylaminoacid molecules on their surface and bulk-phase properties has been estimated quantitatively by calculation and by correlating the values of σ_{min} derived from experimental σ isotherms.[179] It was shown that this parameter increases steadily with increase in the size of the acyl group, obeying the familiar Duclos–Traube rule, and decreases with increase in the size of the carbon skeleton of the molecule of the initial aminoacid.

Adsorption in a layer with participation of the carboxy- and peptide-groups is characteristic of acylaminoacids. This increases the surface area per molecule in the monomeric layer of the surfactant and decreases its limiting adsorption.[198] It has been shown for acyl derivatives of glycine and alanine[199] that they form a condensed monolayer over the entire range of surface pressures at temperatures of 283.2–308.2 K. Under these conditions, an increase in the size of the side group of aminoacid entails an increase in the area of the monolayer.

4. Hydrophobicity

The hydrophobicity of the molecules of organic compounds is an important property which determines the effectiveness of their activity. In view of this, constant attention has been devoted to the development of methods for the quantitative estimation of hydrophobicity or the HLB. The hydrophobicity of molecules is determined by their structure (each functional group makes a definite contribution in accordance with the values of the fragment constants).[200] Thus the introduction of a hydrocarbon group into the molecule makes it more hydrophobic, whilst the presence in the molecule of a double or triple bond as well as the lone pairs of the oxygen and nitrogen atoms make the compound hydrophilic. Recently it has been suggested that, together with the traditional methods for the instrumental estimation of the HLB, one should employ reversed-phase high performance liquid chromatography.[177] The hydrophobicities of the dodecanoyl derivatives of 17 most important aminoacids have been estimated from their measured chromatographic capacity coefficients and the results have been correlated with calculated data. It was shown that the correlation coefficients for structurally similar acylaminoacids are extremely high (0.978–0.999).

It has been found that the hydrophobic parameters of acylaminoacids determine the colloidal-chemical properties of these compounds and their fungicidal activity. The correlation between the hydrophobic and colloidal parameters for the dodecanoyl derivatives of a series of α-aminoacids[181] is entirely satisfactory, particularly for the CCM and σ_{min}. The results of in vitro tests on acylaminoacids by a standard method in a medium with toxicants acting against agents inducing fungal diseases showed[201] that the fungicidal activity of these compounds is satisfactorily correlated with their hydrophobic parameters, particularly in the case of structurally similar derivatives of α-aminoacids.

Table 8. The melting points (T_m), the Krafft points, CCM, and σ_{min} for aqueous solutions of the sodium salts of the acyl derivatives of a series of aminoacids $R^1C(O)NR^2(CHX)_nY$.[13,20,25,140,156,178–197]

[a] The melting points T_m were taken from Refs 14, 15, 24, 25, 135, 139, 180, 187, 189, 191, and 193. [b] The following notation has been adopted: (+) — pure solutions at 0 °C; the numerals in brackets denote the concentrations of the Ca^{2+} ions in $CaCO_3$ (10^{-4} %).

IV. Practical applications

There are almost no literature data on the practical applications of acylaminoacids, especially on their use as biologically and surface-active substances. A need for such a survey has arisen as a result of the continuous growth in the number of publications devoted to the study of the properties of acylaminoacids and especially their practical applications. Acylaminoacids exhibit different physiological and biological activities and are employed widely in various investigations in biology and biochemistry.[202] The latter include the study of complex membrane proteins, the preparation of liposomal systems, the crystallisation and study of the structures of proteins, etc. The uses of acylaminoacids associated with human vital activity are presented below.

1. Physiologically active agents

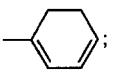
The search for new physiologically active agents among acylaminoacids embraces a wide range of compounds, for example acetylenic[203] and fluorine-containing[204–206] aminoacids, and phosphorus analogues of aminoacids.[207] The last exhibit an appreciable biological activity.[208]

Acylaminoacids, in particular derivatives of glycine, ornithine, and aspartic and glutamic acids have been detected in the organisms of certain warm-blooded animals and man.[1] This is due to the fact that they are the final products of the metabolism of proteins or are intermediates in the interconversions of aminoacids and proteins. It has been established experimentally that certain acyl derivatives are metabolised by the intestinal microflora under anaerobic conditions in vitro[209] and in animal tissues,[210] which leads to their deacylation.

The medical industry imposes very rigorous requirements on the chemical compounds employed. In this respect, acylaminoacids are favourable substances because their toxicity is extremely low. For example, LD_{50} = 5000 mg kg^{-1} (rats, administration via the stomach)[211] or 260–460 mg kg^{-1} (mice, intraabdominal administration)[212] for certain acylaminoacids. It was shown experimentally that acylaminoacids can be assimilated by the organism, since they are the starting materials for the synthesis of the organism's lipids and biologically active metabolites, for example arachidonic acid, the principal precursor of prostaglandins.[213]

Acetylcysteine, an active mucolytic agent which is indicated in the treatment of diseases of the respiratory organs, when there is a tendency toward lung haemorrhages, and in bronchial asthma, occupies an important place in the assortment of medicinal drugs.[214–216] Together with the mucolytic activity, acetylcysteine exhibits also an antibiotic activity.[217] The use of this preparation in the treatment of the diseases of the eye cornea[218] and for detoxication in cases of poisoning with methylmercury[219] in combination with haemodialysis has been described.

Effective preparations influencing the central nervous system have been discovered among acylaminoacids. These are derivatives of DL-aspartic[220] and 4-aminobutyric[221] acids, asparagine,[222] and the amides of acylaminoacids.[223] Their effect on the central blood circulation and the systemic arterial pressure, on the content of acetylcholine in various regions of the cerebral cortex, and on the functional disorders of the brain has been noted.



Acylaminoacids occupy a notable place among the rheumatological antiinflammatory and antiulcer preparations.[224–231] They are designed for the treatment of patients for whom the employment of traditional agents is contraindicated. Acylaminoacids do not as a rule induce undesirable side effects. A series of acylaminoacids are the active principles of antihypertonic[232–240] and therapeutic,[61,242] agents, inhibitors of enzymes with angiotensive activity,[235,243–246] and other preparations with many-sided activity.[247–252] The main principles of the selectivity and mechanisms of the action of medicinal drugs, including acylaminoacids, have been described in a monograph.[246] Thus certain acylaminoacids, for example benzoylglycine, are formed as metabolites when benzoic acid is eliminated from the kidneys. A series of benzoyl derivatives of aminoacids and oligopeptides have been used as anions in the study of a model of their transport through membranes.

Acylaminoacids with a complex structure which are the active principles of many medicinal drugs (ampicillin, oxacillin, carbenicillin, ceflorin, folic acid, levomycetin succinate, methotrexate, pantogam, picamilon, phenoxymethylpenicillin, cefazolin, cephalexin, and cephalothin) are included in a handbook.[253] These compounds are antibacterial, neotropic, and antitumour agents which are components of the Group B vitamin complex and participate in the carbohydrate and fat metabolism.

Table 9. Certain medicinal preparations based on *N*-acylaminoacids.

Compound	Chemical formula	Applications	Ref.
Acetylcysteine	$CH_3C(O)NHCHCOOH$ $\quad\quad\quad

Table 9 (continued)

Compound	Chemical formula	Applications	Ref.
Acylglutamine	$ABCC(O)NHCH(CH_2)_2CONH_2$ (R; $COOR^1$) A — Ph, cyclo-C_6H_{12}; B —  ; R — H, CH_3, C_6H_6; R^1 — H, M	Antiinflammatory agent and preparation for the treatment of diseases of the eye	225
6-(*N*-Acetyl)amino-hexanoic acid	$CH_3C(O)NH(CH_2)_5COOH$	Stimulation of the reparative processes in the healing of wounds and in the knitting of bones	248
Zn salt of 6-(*N*-acetyl)-aminohexanoic acid	$[CH_3C(O)NH(CH_2)_5COO]I_2Zn$	Therapeutic preparation with antiinflammatory and antirheumatic activities.	226
N-Acylaminoacids	$RC(O)NHCHCOOH$ (R^1) R — Alk (C_1-C_5); R^1 — $(CH_2)_4NH_2$, $-(CH_2)_3NHC(=NH)NH_2$	Antitumour and antiviral agent	249
Acylaminoacid derivatives	$RC(O)XC(O)NR^1CHR^2COOR^3$ R — Ar; R^1, R^2, R^3 — H, Alk (C_1-C_4); X — $-CH(SR^4)CHR^5-$; R^4, R^5 — H, Ac	Hypertonic preparations	232
Sulfur-containing acylaminoacids	$CH(2\text{-}HOC_6H_4)(CH)_2NC(O)ASR$ ($SCH_2CHCONHCHR^1COR^2$) R — H, Ac; R^1 — H, Alk, NH_2, COOH, H, S, RS; R^2 — OH, OAlk; A — $-(CH_2)_n-$, $n = 1-3$	Antihypertensive agents	233
N-(Thiopropanoyl)-aminoacids	$C(O)R^1CHCH_2SR$ ($NR^2CR^3R^4COOH$) R — Ac; R^1, R^2 — H, Alk; R^3, R^4 — Alk	Preparations with hypertonic activity	234
N-Acylaminoacid amides	$CH(YXR^2)(CH_2)_nSR^1$ ($CONR^3CHR^4COR^5$) R^1 — H, Bz, Ac; R^2 — H, Alk, Ac; R^3-R^5 — H, Alk, Ar; R^3, R^4 — $(CH_2)_m$, $m = 3, 4$; X — O, S; Y — (CHR)	Anticonvulsant and soporific agents and depressants of the central nervous system	223
N-(Mercaptoacyl)-aminoacids	$C(O)(CH_2)_nSH$ ($N(R)CHCOOH(R^1)$) R, R^1 — $(CH_2)_3$, $(CH_2)_4$, CH_2SCH_2; $n = 1-3$	Hypotensive preparation, in particular in the treatment of liver hypertonicity	236
N-(Carboxyacyl)-aminoacid derivatives	$C(O)CH_2XC(COR^3)R^1R^2$ ($N(COR^5)CH(CH_2)_m(CH_2)_nCHR^4$) R^1 — Alk, Ar; R^2 — H, Alk, Ar; R^3, R^5 — OH, OAlk, OAr, NH_2 R^4 — OAlk, SAlk; X — CHR, NR $n, m = 0-3$	Preparation for the treatment of hypertonicity	237
N-(Carboxyacyl)-aminoacids	$CHR^3(CH_2)_nC(O)R^4$ ($C(O)NR^2CHR^1COOH$) R^1 — H, Alk, Ph, HOC_6H_4, NH_2, HS; R^2, R^3 — H, Alk; n — 1, 2; R^4 — OAlk, OH	Inhibitors of the angiotensive transformation of enzymes	239

Acylaminoacids exhibit antimicrobial and antifungal activities and are used as disinfectants and antiseptic agents in toothpaste, tooth powders, and toilet requisites. These include acyl derivatives of glycine,[254] sarcosine,[13] arginine, histidine, lysine, diaminobutyric acid,[255] and their peptides.[256] The highest activity against Gram-negative bacteria among the homologous acyl derivatives has been discovered for caproylglycine[257] at the pH characteristic of the surface of the skin. Acyl derivatives of glutamic acid and glutamine have been proposed for the inhibition for the activity of bacteriophages[13,258] and are used in the preparation of antibiotics, enzymes, aminoacids, and nucleotides. The ability of acylsarcosinates to inhibit bacterial hexokinase and other acid forming enzymes, protecting thereby the tooth enamel, is widely used for commercial purposes in the manufacture of toothpaste.[20,259,260]

Table 9 presents a list of the medicinal preparations based on *N*-acylaminoacids.

2. Pesticides

Together with natural α-aminoacids and their alkyl derivatives, acylaminoacids exhibit a fairly broad spectrum of biological activity.[261]

Acylaminoacids manifest a fungicidal activity[254,262,263] and regulate the formation of ethene in plants, permitting an increase in the lifetime of cut flowers.[264] These products are effective as preparations against the tobacco mosaic virus and fungal and bacterial diseases of plants.[13,265–267] The stimulation of the growth of the central stem and of the flowering of carnations may be included among the advantages of the compounds indicated.[265–267] They are also capable of destroying the eggs of lice.[268–270] The highest biological activity has been noted for α-alanine derivatives.[261] The esters of acyl derivatives of alanine have found an application as herbicides against wild oats in spring and winter wheat, barley, rape, and pulses,[271–277] and as fungicides against phytophthorosis on tomatoes and potatoes,[278] peronosporosis on tobacco and hops, mildew on grape vine shoots, false mildew on onions,[279] root rot on beetroot, false mildew on potatoes,[280] and phytopathogenic fungi of the class of oomycetes.[281] Acylalanines act selectively on groups of peronosporaceous fungi.[279]

A large series of acylaminoacids with fungicidal activity have been synthesised from glycine, sarcosine, alanine, phenylalanine, valine, norvaline, leucine, proline, threonine, methionine, and α-aminobutyric acid.[13,265–267] Acylaminoacids are active against the diseases of rice (*Piricularia oryzae*)[12,282] and the radiating mildew on cucumbers and are used to combat *Bacterium oryzae, Diaporthe citri,* and *Spraerotheca fuliginca.*[283] Whilst exhibiting effective protecting properties in tests on plants in vivo, their toxicity to warm-blooded animals is low. They are nonphytotoxic and they accelerate the growth of plants. Studies on the mechanisms of the action of acylalanines on the fungal cell have shown that in most cases the synthesis of nucleic acid is retarded. The inhibition of the synthesis of RNA is the primary result of the attack by acylalanines, which has been confirmed by the retardation of the formation of RNA in a number of fungi.[279] The dodecanoyl derivatives of 15 α-aminoacids exhibit a fungicidal activity against fungi giving rise to fungal diseases: *Acterharia solani, Helmirtosporium sativum, Fusarium graminea-kum,* and *Fusarium nivali.*[201] The usual dose of the above preparations is 0.5–10 kg ha^{-1}.[284]

The benzoyl derivatives of alanine, valine, aspartic acid, and other acylaminoacids are effective herbicides.[13,285–287] These compounds proved to be effective in vivo against pathological fungi on plants, whilst they had no in vitro fungicidal activity.[288]

3. Cosmetic and hygienic preparations

The inclusion of acylaminoacids in cosmetic and hygienic preparations is due to their effective dermatological properties, biological compatibility, a low level of the irritant and allergenic activities on the skin, and the manifestation of specific types of biological activity. The use of acylaminoacids as polyfunctional surfactants in cosmetic and hygienic preparations has been described in a number of studies.[12,25,211,289,290]

The specific biological activity of acylaminoacids in cosmetic preparations is manifested by the regulation of the blood circulation in the skin. They are employed in moisturising creams for the treatment of dry skin[292] and for the retention of biologically active substances on the surface of the skin.[293] Acylaminoacids possess an antimicrobial activity against Gram-negative bacteria.[257] Acyl derivatives of a mixture of α-aminoacids have been proposed as a means of stimulating the growth of hair and promoting an increase in the content of soluble protein in the latter.[294] The preparation increases the diameter of growing hair by a factor of 2–3 and has a positive effect on the protein metabolism in the skin, increasing the content of soluble proteins by 25%–50%, which promotes a sharp decrease in defatting and irritant action. The biological activity was estimated from the total amount of soluble proteins (Bailey's method), hair being subjected under these conditions to trichlonometric monitoring by Khrunova's method.[295]

It has been demonstrated experimentally[296] that acyl derivatives of elastin are capable of penetrating deeper into the human skin epidermis compared with other agents, improving the tone and structure of the skin and eliminating fine wrinkles. The introduction of acylaminoacids combined with oligopeptides into a cream[297] has a moisturising and protecting effect on the hair and skin, limits the swellability of hair, reduces the level of irritant action in the presence of surfactants and alkalies, and makes it possible to restore damaged hair.

One of the principal requirements which must be met by modern cosmetics as regards skin care is the prevention of the premature ageing of the skin. For this purpose, deeper studies are necessary on the mechanisms of the ageing and moisturising of the skin and on the metabolic processes occurring in the latter. As a rule, acyl derivatives of hydrolysed protein,[298–300] glutamic acid,[301] and a number of other α-aminoacids[302,303] are included in such preparations in order to impart to them effective moisturising properties, to stimulate metabolic processes, and to maintain the normal water balance in the skin. As substances with a low primary toxicity and a weak side effect on the skin,[304] acylaminoacids have been proposed in recipes for decorative[305] and cleansing cosmetics.[306] They hinder the total removal of fat deposits during the washing of the skin and hair. This is important, since the secretions of the sebaceous glands have a protecting function while increased defatting of hair makes it dry and brittle and leads to the loss of its lustre and silky appearance.

Liquid detergents, shampoos, and gels occupy a leading place in the market of personal hygiene preparations. These preparations contain aminoacids and their derivatives, including acylaminoacids, as the most valuable additives.[13,307,308] In terms of a series of parameters such as the effectiveness of detergent action, degree of elution of aminoacids from the skin during washing, and the solubilisation of the defatting agent, acylaminoacids have a clear advantage over traditional surfactants such as HAC soaps, alkyl sulfates, and alkyl sulfonates.

A series of recipes for shampoos with a low irritant action and improved detergent and foam-forming properties, liquid and solid detergents, and gels incorporating acyl derivatives of β-alanine and acylglutamic acid have been developed.[309–326] Mild shampoos, which cause almost no irritation to the eyes and the skin on the head, for improving the state of hair have been created on the basis of acyl derivatives of hydrolysed proteins.[327–330] The introduction of the latter into recipes for shampoos eliminates the hardness and dullness of hair caused by the deposition of $CaCO_3$ from tap water.[331,332] Dermatologically mild detergents and shampoos with a wide variety of valuable properties from the consumer's point of view contain acyl derivatives of various α-aminoacids.[333–350]

When hair is washed, up to 50% of natural lipids are removed, as a result of which it becomes dry, loses its lustre, and

Table 10. Brief characteristics of certain recipes for cosmetic and hygienic preparations based on *N*-acylaminoacids.

Type of preparation	*N*-Acyl derivatives of aminoacids (mass %)	Consumption properties	Ref.
Shampoo	of glutamic acid		
	(1 – 10)	Preparations with a low irritant activity and improved detergent and foam-forming properties	309, 317, 318
	(20 – 25)	Transparent creamy detergents	310, 320
	or β-alanine		
	(0.5 – 10)	Preparations with improved detergent, foam-forming, and softening properties, which readily wash away fatty dirt, assist in feeding and strengthening hair, and do not irritate the skin and the mucous membranes around the eyes	325, 338
	(25 – 35)	In combination with acylsarcosinates, an effective preparation in the form of a transparent gel	326
	of hydrolysed proteins (3 – 30)	Dermatologically soft preparations for dry and sensitive skin, improving the state of hair, and possessing excellent foam-forming properties and increased stability during storage. These preparations exhibit a satisfactory affinity for the skin and hair, and improve the state of hair, rendering it pleasant to the touch, and preventing its entanglement during drying. They counteract the deposition on hair of water-insoluble salts, preventing the hardness and dullness of hair, and form on the damaged ends of hair a protective film which promotes softening and regenerative properties	327 – 332
	of sarcosine		
	(1 – 10)	Dermatologically soft preparations with high foam-forming and detergent capacities	336 – 338
	(30 – 50)	Transparent gel-like preparations, which do not irritate the skin and eyes	340
	of an aminoacid mixture (5 – 20)	Preparations with high foam-forming and detergent capacities. Therapeutic and healing agents with a low irritant activity containing biologically active additives, for example derivatives of α-pyridone	334, 335 333, 345
Cream	of oligopeptides (0.5 – 8)	Preparations improving the structure of the skin, influencing metabolic processes, promoting a better permeation through the corneous layer of the skin, and smoothing away fine wrinkles	296, 300
	of glutamic acid (0.1 – 12)	Effective preparations with biological activity for the care of ageing skin, improving its moisture-retaining capacity, and stimulating metabolic processes	301 – 303
Cream	of aminoacids (0.1 – 5)	Preparations promoting the restoration of damaged hair, increasing the affinity for the skin and softening and feeding the latter	297, 305
Preparations for hair care	of oligopeptides (0.1 – 3)	Effective preparations for the improvement of the state of hair by restoring its lipid balance, rendering it soft, improving its capacity for being set, and reducing the damage to hair after dyeing and the application of a chemical permanent wave	351, 356, 369
	of aminoacids (0.1 – 10)	Preparations softening leather and hair, imparting lustre to the latter and making it manageable, smooth, fluffy, and elastic. These preparations feed hair effectively, stimulate the occurrence of metabolic processes in it, exert an antistatic effect, improve the setting of hair, promote its growth, and prevent its falling out.	352, 354 – 359, 362 – 366
		The *N*-acylaminoacids in these preparations promote the retention of biologically active substances in hair and enhance blood circulation, thus preventing dandruff and loss of hair	291, 293

is difficult to set. The loss of lipids may be made good with the aid of cosmetics containing various plant extracts, natural lipids, and acyl derivatives of a series of α-aminoacids.[351] Cosmetics for skin and hair care in the form of lotions and sprays containing acyl derivatives of aminoacids and hydrolysed proteins soften hair,[352–362] strengthen it,[363,364] promote its growth,[365] feed it and stimulate metabolic processes in it,[366,367] improve its moisture retaining properties,[360,368] and reduce damage to hair and improve its structure.[369]

N-Acylaminoacids are a valuable cosmetic raw material for effective preparations with a broad spectrum of cosmetic and therapeutic and healing activities on skin and hair (Table 10).

Abstract. The review is devoted to methods for the modification of proteins by water-soluble diphilic block-copolymers of ethylene and propylene oxides and also to the properties of the resulting polymer–protein adducts. Two principal classes of such adducts are examined: conjugates obtained by forming covalent bonds between the protein and the polymer and noncovalent complexes. It is shown that the amphiphilic nature of the polymer chains gives rise to a series of new properties of the conjugates with the block-copolymers, such as the ability to be translocated into cells, the ability to solubilise insoluble biologically active compounds, the ability to serve as agents transporting the latter, and also the ability to interact with surfactants of different chemical nature. The bibliography includes 50 references.

I. Introduction

A vigorous development of a new aspect of protein engineering, involving the specific alteration of the properties of protein molecules as a result of their chemical modification by water-soluble polymers, began since the beginning of the 1970s. The conjugate obtained by means of such modification consists of two macromolecular fragments — the protein and polymer fragments — and combines the properties of each of them. Dextran,[1] poly-*N*-vinylpyrrolidinone,[2] and poly(ethylene oxide) (PEO)[3–5] are usually employed as the polymer fragments. Among the polymers listed above, PEO is most widely used. It is a nontoxic, nonimmunogenic synthetic polymer, which is available with a wide range of molecular masses.[6] The poly(ethylene oxide)– protein conjugates are characterised by weaker immunogenic and antigenic properties, an increased circulation period in the blood circulation system, and in many instances an increased stability.[7] These properties are to a large extent determined by the effect of the steric stabilisation of the protein globule resulting from the creation around the latter of a shell comprising attached polymer chains.

An important property of the PEO–protein conjugates is their ability to dissolve in organic solvents. This makes it possible to employ such conjugates as biocatalysts for peptide synthesis,[8] transesterification,[9] and amination of esters.[10]

The next stage in the construction of polymer–protein conjugates is the introduction of additional fragments (blocks) into the polymer chain in the stage involving the synthesis of polymeric reagents. This approach led to the formation of conjugates of proteins with block-copolymers of ethylene and propylene oxides, namely proxanols (Pro) and pluronics. These copolymers are nonionogenic surfactants in which the PEO and poly(propylene oxide) (PPO) blocks are respectively the hydrophilic and hydrophobic parts of the molecule.[11] Compared with the PEO–protein conjugates, the conjugates of proteins with the block-copolymers are characterised by a greater structural variety, manifested, firstly, by the possibility of attaching copolymers to different numbers, compositions, and arrangements of the blocks and, secondly, by the possibility of different arrangements of the polymer chains on the surface of the protein globule. The amphiphilic nature of the attached polymer chains gives rise to new properties of the conjugates, such as the ability to be transported into the cell,[12,13] the ability to solubilise effectively insoluble biologically active compounds,[14,15] the ability to serve as agents transporting the latter, as well as the ability to interact with surfactants of different chemical nature.[16] In the present review, we shall examine the methods of synthesis and characteristics of the protein–Pro conjugates as well as their physico-chemical and biological properties. Together with the traditional methods of synthesis of polymer–protein conjugates, effected via the covalent interaction of the polymer with the protein, new approaches to the synthesis of structures of this type, based on the formation of noncovalent complexes between the protein and Pro, will be considered.

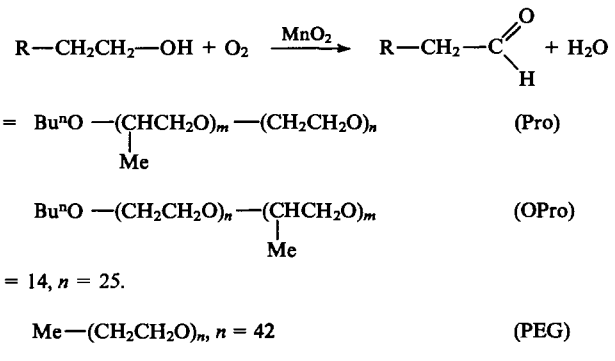
II. Synthesis, isolation, and characteristics of the conjugates

1. Synthesis of the conjugates



The conjugates of proteins with proxanols are synthesised by the reductive alkylation of the primary surface amino-groups of the protein by polymeric monoaldehydes,

where R is the polymer chain and E is the protein molecule.

Conjugates based on the following proteins have been obtained similarly: bovine serum albumin (BSA),[14] α-chymotrypsin (CT),[17] pyruvate kinase from the rabbit skeletal muscle, ricin from the castor bean, viscumin from the mistletoe,[18] the classical proteinase inhibitor of the Bauman–Birk type from the soya beans (BBI),[19] and cytrochrome *c*.[12] The conjugates based on CT and BBI have been obtained in the presence of reversible inhibitors of the active centres of enzymes. For example, in the synthesis of conjugates based on CT, we employed for this purpose *N*-benzoyl- or *N*-acetyl-L-tyrosine.[16] Sodium cyanohydroborate is a more convenient reducing agent for the preparation of the conjugates than sodium tetrahydroborate, which leads to the reduction of the disulfide bonds between polypeptide chains as a side reaction.

The monoaldehyde derivatives of PEO and Pro are obtained by oxidising the corresponding monofunctional polymers by atmospheric oxygen in solution in chloroform in the presence of manganese(IV) oxide as the catalyst.[20]

Evidently the only difference between the Pro and OPro (reversed proxanol) polymers consists in the position of the hydrophobic PPO block relative to the terminal aldehyde group. The use of these polymeric reagents makes it possible to synthesise conjugates with different sequences in the attachment of the polymeric blocks to the protein. The number of polymer chains in the conjugate may be regulated by varying the polymer/protein ratio in the reaction mixture.

The molecular models of the conjugates described in this review are presented in Fig. 1. Evidently the conjugates are star-shaped structures with a protein globule in the centre, the polymer chain being bound covalently to the globule. When polymeric reagents with a number-average molecular mass of 2000 are employed, the length of the polymer chains is 20.7 nm for PEO (Fig. 1, type *I*), and 21.6 nm for Pro and OPro (Fig. 1, types *II* and *III*), which is significantly greater than the diameter of the protein globule (for example, the average length of the two globule half-axes for CT is 2.5 nm). Such a structure suggests that the polymer chains provide a steric shield to the protein, diminishing its binding to macromolecular substrates, antibodies,

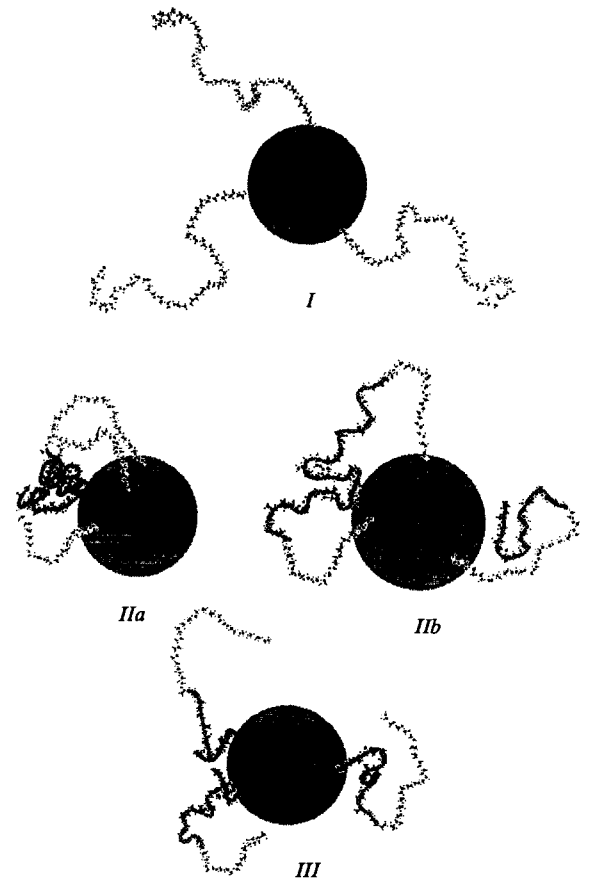


Figure 1. Molecular models of protein conjugates: (*I*) with PEO ($M = 2000$); (*IIa*) with Pro having a nonuniform distribution of polymer chains; (*IIb*) with Pro having a uniform distribution of polymer chains; (*III*) with OPro. The PPO blocks of the polymer chains of the proxanols are shown shaded; the radius of the protein globule is 25 Å (the average length of the two half-axes of the CT globule).[21]

and proteolytic enzymes. Evidently this effect of the polymer chains should depend on their number and on the nature of their distribution on the surface of the protein in the conjugate.

Since the polymer chains in the conjugates are attached only to a proportion of the surface amino-groups of the protein, a possibility arises of their different relative dispositions. Thus the polymer chains may be uniformly distributed on the surface of the protein (Fig. 1, *IIb*) or may be concentrated in one place with formation of domains (Fig. 1, *IIa*). Naturally, the formation of structures of a particular type is specified in the stage involving the synthesis of the conjugate. During the synthesis in aqueous buffer media, where proxanols manifest a capacity for self-association due to their diphilic nature,[22] conditions arise for their nonuniform distribution on the surface of the protein globule. The conjugates thus obtained may be regarded as a kind of intramolecular micelle, stabilised by the hydrophobic interaction between the polymer chains attached to the protein. On the other hand, when the conjugates are synthesised in aqueous organic media, where the hydrophobic interactions between the proxanol molecules are suppressed,[23] their more uniform distribution on the surface of the protein globule should be promoted. Taking these considerations into account, two series of conjugates were synthesised and will be designated below as nonuniform (nonun.) and uniform (un.). It is noteworthy that the concentrations of the organic solvent in the reaction mixture in the synthesis of the uniform conjugates were much lower than the threshold concentrations inducing the denaturation of the protein.[24]

In order to make sure that the above postulates are valid, it was necessary to estimate the differences between the distributions of the polymer chains on the surface of the protein globule in conjugates synthesised under different conditions. Use was made for this purpose of the ability of the polymer chains of poly(alkylene oxides) to interact with a bulky cyclic ligand — β-cyclodextrin (β-CD). We had shown earlier[25] that β-CD forms clathrate complexes with proxanols, the number of β-CD molecules 'threaded' onto the polymer chains being determined by the number of propylene oxide units entering into the composition of the proxanol. Naturally, the interactions of the polymer chains of the conjugates with this ligand depend on the nature of the distribution of the polymer chains on the protein surface. A uniform distribution of the polymer chains should not prevent the formation of complexes with β-CD, whereas for a nonuniform distribution the interactions are hindered for steric reasons. Indeed, it has been shown that only conjugates for which a uniform distribution of the polymer chains has been postulated (Fig. 1, *IIb*), form, like the free proxanols, crystalline clathrate complexes with β-CD which are insoluble in water. On the other hand, the conjugates with a tentatively nonuniform distribution of the chains do not form complexes with β-CD.[16] Thus it has been confirmed that the conjugates synthesised in an aqueous medium are characterised by a nonuniform (domain) type of distribution of the polymer chains, in contrast to the conjugates synthesised in an aqueous organic medium and characterised by a more uniform distribution. The differences between the structures of such conjugates are responsible also for a series of differences between their physicochemical properties and biological behaviour.

2. Purification of the conjugates

The purification of the conjugates based on proxanols in order to remove the excess polymeric reagent is a more difficult problem than in the case of the PEO – protein conjugates. This is due to the amphiphilic properties of the proxanols, which are capable of forming associated species with the polymer chains entering into the composition of the conjugate. Taking this into account, two purification methods have been proposed which make it possible to suppress the hydrophobic interactions between the polymeric reagent and the polymer chains of the conjugate: precipitation of the conjugate with acetone;[17] gel-permeation chromatography involving the use of the 1:4 ethanol – water mixture as the eluent.[12] Thin-layer chromatography has been used to demonstrate the absence of a free polymer impurity in the conjugate.

3. Characteristics of the conjugates

Tables 1 and 2 present the characteristics of the conjugates obtained: composition, degree of modification (average number of polymer molecules attached to one protein molecule), and the number of primary, i.e. unmodified, amino-groups in the protein component of the conjugate.

Table 1. Characteristics of the conjugates of α-chymotrypsin with poly(ethylene oxide) and proxanols.

Polymer	Type of conjugate[a]	Designation	Degree of modification (*n*)	CT content (mass%)[b]	No. of unsubstituted NH_2 groups (*m*)

[a] The method for the determination of the protein content in the conjugate.

The protein content in the conjugate was determined spectrophotometrically (λ = 280 nm) and also with the aid of the biuret reaction.[26] In all cases, the initial proteins were employed as the standard. It had been shown previously[3,4] that the presence of poly(alkylene oxide) does not affect the results of the assay of the protein by means of the biuret reaction. The composition was determined by the ^{13}C NMR method, which permits independent measurements of the contents of the protein and polymeric components. Such measurements have been carried out for two conjugates of BSA with Pro (Table 2). The regions where the signals of the protein and the polymer do not overlap were found from the spectra of the individual components in a preliminary experiment. For BSA, this is the 172–180 ppm region corresponding to the carbon atoms of the carboxy-groups, while for Pro this is the 70–77 ppm region corresponding to the carbon atoms of the methylene groups of the main chain. The integral intensities of selected analytical signals of the protein and the polymer were determined from the spectra of specially prepared solutions containing mixtures of the protein and Pro in specified mass proportions. The dependence of the integral intensities on the polymer/protein mass ratio for these solutions proved to be linear. The mass compositions of the polymer synthesised were determined from the integral intensities in their spectra by means of a calibration plot. It was found that the results obtained agree, within the limits of the error of the measurement, with data obtained by the spectrophotometric and chemical methods (Table 2). Subsequently we assumed that the use of only the spectrophotometric and (or) chemical methods which do not require large amounts of the test substance, was sufficient for the determination of the composition of the conjugate. In this case, the content of the polymer [m_{Po} (mass%)] in the conjugate was assumed to be

$$m_{Po} = 100 - m_{Pr}, \quad (1)$$

where m_{Pr} is the content of the protein (mol%). The degree of modification (n) was calculated from the composition of the conjugate as the average number of polymer molecules attached to one protein molecule:

$$n = \frac{m_{Po}/\bar{M}_{Po}}{m_{Pr}/M_{Pr}},$$

where $\bar{M}_{Po}$ is the number-average molecular mass of the polymer and M_{Pr} is the molecular mass of the protein.

In addition, the degree of modification was determined independently by titrating the residual unsubstituted primary amino-groups of the protein. For proteins where the total number of the primary surface amino-groups is known, the degree of modification n may be determined as the difference

$$n = r - m, \quad (2)$$

where r is the total number of surface NH_2 groups and m is the number of unsubstituted NH_2 groups.

It is noteworthy that the number of unsubstituted surface NH_2 groups in proteins is usually determined by titrating a solution of the protein with 2,4,6-trinitrobenzenesulfonic acid (TNBS).[27] However, in our case this procedure is inapplicable, since both the remaining unsubstituted NH_2 groups of the conjugates and the substituted, secondary amino-groups react with TNBS.[28] The number of surface amino-groups in the conjugates determined by the reaction with TNBS therefore remains the same as in the initial protein. In order to determine the number of residual unsubstituted amino-groups of the protein after conjugation, we resorted to Ruff's method[28] based on the interaction of the primary amino-groups with *o*-phthalic dialdehyde in the presence of mercaptosuccinic acid. The number of primary NH_2 groups was determined by this method in a series of CT conjugates. The degree of modification calculated by Eqn (2), taking into account the fact that the total number of primary amino-groups with CT is 15, proved to be close to the value calculated by Eqn (1) from the protein content in the conjugate.

A satisfactory agreement between the results obtained by the two methods confirms the fact that only the primary amino-groups of the protein are modified and that the other aminoacid residues are unaffected.

4. Catalytic properties of the conjugates

The catalytic properties of the CT-based conjugates are presented in Table 3, from which it is seen that:

1. The conjugates retain a high enzyme activity in relation to both substrates employed — the low-molecular-mass substrate [the ethyl ester of *N*-benzoyl-L-tyrosine (BTEE)] and the high-molecular-mass substrate (casein).

2. The kinetic constants of the hydrolysis of the low-molecular-mass substrate (BTEE) by the enzyme forming part of the composition of the conjugates changed only slightly compared with the native enzyme. Similar results were obtained also in the study of the hydrolysis of the high-molecular-mass substrate (casein). This is apparently associated with the fact that the active centre of α-chymotrypsin was protected in the conjugate synthesis stage by the inhibitor bound reversibly to it and so the polymer chains were unable to be bound in the immediate vicinity of the active centre of the enzyme.

3. A significant loss of enzyme activity was observed only after the attainment of high degrees of modification (11 and more attached polymer chains). A similar trend has been described by Chiu et al.[30] for conjugates based on CT and PEO. Evidently the decrease in activity in this case is not a consequence of the decrease in k_{cat} but occurs as a result of the decrease in the number of active centres in the conjugates [Table 3, $(Pro)_{11}$–CT(un.)].

5. Thermal inactivation of the conjugates

An important practical consequence of the modification of proteins by polymers is a change in the resistance of the protein globule to the effect of elevated temperatures.[31] The thermal stabilities of the conjugates between proteins and proxanols have

Table 3. The enzyme properties of the conjugates of α-chymotrypsin with poly(ethylene oxide) and proxanols.

Protein, conjugate	Activity in enzymic hydrolysis of casein (%)	Enzymic hydrolysis of BTEE			Content of active centres (%)
		activity (%)	k_{cat}/s^{-1}	10^5 K_m/mol litre^{-1}	
CT	100	100	31.2 ± 0.5	6.27 ± 0.94	80
$(Pro)_5$–CT(nonun.)	102	97	42.4 ± 2.8	13.0 ± 2.9	61
$(Pro)_3$–CT(un.)	103	115	–	–	80
$(Pro)_6$–CT(un.)	96	98	32.5 ± 1.2	6.18 ± 0.82	67
$(Pro)_{11}$–CT(un.)	50	57	37.0 ± 0.4	21.7 ± 3.5	40
$(PEO)_6$–CT	97	98	40.4 ± 0.8	9.3 ± 1.5	80
$(OPro)_3$–CT	98	100	–	–	80

been investigated by a method involving the kinetic study of the enzyme properties of the conjugates at the elevated temperature.[17] The corresponding kinetic curves (the time variations of the activity) are presented in Fig. 2. Evidently the rate of the thermal inactivation of CT diminishes significantly even after the addition of only three polymer chains (curves *2* and *3* in Fig. 2). With increase in the degree of modification of the conjugate, this effect becomes more pronounced (curves *4*–*6* in Fig. 2), i.e. the thermal stability of the conjugates increases in parallel with the increase in the degree of modification. The modification of the enzyme by PEO has the greatest stabilising effect (curve *6* in Fig. 2; the conjugate contains nine polymer chains), the specimen retains 80% of the initial activity after heating for 3 h at 45 °C.

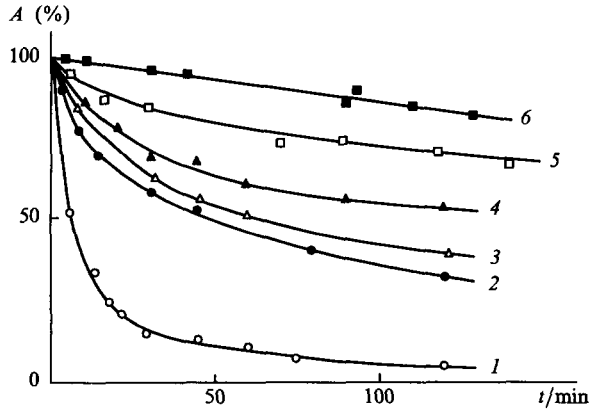

Figure 2. Kinetic curves for the thermal inactivation of CT and its conjugates with poly(alkylene oxides): (*1*) CT; (*2*) $(OPro)_3$–CT; (*3*) $(Pro)_3$–CT(nonun.); (*4*) $(Pro)_6$–CT(nonun.); (*5*) $(Pro)_5$–CT(un.); (*6*) $(PEO)_9$–CT. The thermal inactivation conditions here and in Figs 3 and 4 were as follows: 0.2 M tris.HCl, pH 8.0, 45 °C; the enzyme concentration in each specimen was 0.1 μM.

It was shown in a specially formulated experiment that simple addition of poly(alkylene oxides) to a solution of CT does not affect its thermal stability.

The difference between the shapes of the kinetic thermal inactivation curves for the CT–PEO conjugate (curve *6* in Fig. 2) and three conjugates with block-copolymers (curves *2*–*4*) is striking. In all cases, the curves were treated mathematically in terms of the variables of a first-order reaction. The kinetic data for the inactivation of the $(PEO)_9$–CT conjugate in terms of such variables can be described by a linear relation. The rate constant calculated from these data is $k = (2.3 \pm 0.1) \times 10^{-5}$ s^{-1}.

These relations for the remaining conjugates are represented by curves consisting of two or more regions with different shapes. The molecular causes of such heterogeneity in the case of native CT were discussed previously.[32] It is most likely that in the case of the conjugates this is also associated with their inhomogeneity as regards both structure and composition, which may be manifested both by a distribution with respect to the degrees of modification of different protein globules and by a nonuniform arrangement of the chains on the surface of an individual protein globule. Such inhomogeneity has a particularly notable effect on the properties of the $(OPro)_3$–CT(nonun.), $(Pro)_3$–CT(nonun.), and $(Pro)_6$–CT(nonun.) conjugates synthesised under conditions such that the polymeric reagents are in the micellar form, which promotes a nonuniform filling of the surface of the protein globule by the polymer (Fig. 1, *IIa*). On the other hand, the $(PEO)_9$–CT conjugate, containing polymer chains incapable of forming micellar structures,[33] should be characterised by a much more uniform distribution of the polymer chains. It may be that this is in fact one of the causes of the high thermal stability of the $(PEO)_9$–CT conjugate.

The thermal stability of the $(Pro)_5$–CT(un.) conjugate, synthesised under conditions which rule out the possibility of a micelle formation reaction between the molecules of the block-copolymers, approaches (curve *5* in Fig. 2) the thermal stability of the $(PEO)_9$–CT conjugate. This effect is particularly pronounced, since the degree of modification in the $(Pro)_5$–CT conjugate is smaller almost by a factor of two than in $(PEO)_9$–CT.

Thus the thermal stability of the conjugates increases in parallel with the increase in their content of polymer chains. For the same number of polymer chains, the thermal stability of conjugates with a uniform distribution of the chains is higher than that of the conjugates with a nonuniform distribution (curves *5* and *4* in Fig. 2). On the other hand, the stability of the conjugates in which the hydrophobic block is on the periphery is higher than that of the conjugates with the reverse order in the arrangement of the blocks. The results can be explained in terms of the ideas, being developed in the literature, according to which the modification of the protein surface by hydrophilic reagents should stabilise the protein molecule, since it makes it possible to shield the surface hydrophobic groups of the protein from unfavourable contact with water.[34,35] Indeed, as can be seen from Fig. 1 in the case of a nonuniform distribution of the polymer chains in the conjugate, a considerable proportion of the protein surface remains unprotected, whereas for a uniform distribution there is a greater possibility of the shielding of the protein globule. This in fact leads to an increase in the thermal stability of the conjugates with a uniform distribution of the chains compared with those having a nonuniform distribution.

6. Interaction of the conjugates with diphilic compounds

One of the remarkable properties of the conjugates of proteins with proxanols is their ability to interact with both synthetic and natural diphilic compounds.[17,36] The polymer chains then play the role of a reinforcing construction, organising around themselves assemblies of other diphilic compounds. In supramolecular structures of this kind, diphilic substances may have an indirect effect on the properties of the protein globule forming part of the composition of the conjugate. For example, we may quote the increase in the thermal stability of the conjugate following the introduction of the free proxanol (Fig. 3). This is apparently due to the binding of the polymer chains of the conjugate to the additionally introduced polymer with formation of a more compact polymer shell around the protein, which leads to the shielding of the hydrophobic domains on its surface.

Another picture is observed when β-CD, capable of forming clatrate complexes with proxanols, is introduced as a diphilic additive into the system. As shown previously, in the interaction with β-CD the polymer chains of the proxanols assume a more

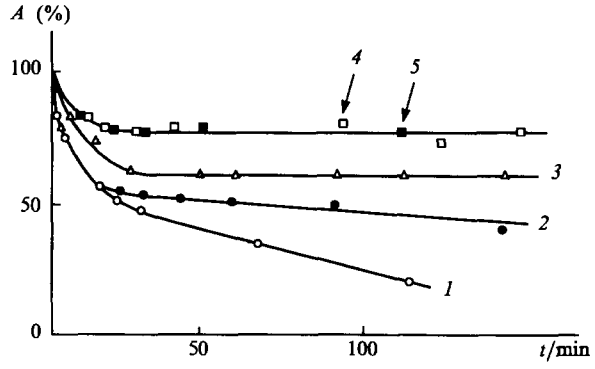

Figure 3. Kinetic curves for the thermal inactivation of the pure $(Pro)_4$–CT(un.) conjugate (curve *1*) and the conjugate with added Pro (curves *2*–*5*). Molar excess of Pro relative to the conjugate: (*2*) 50; (*3*) 100; (*4*) 500; (*5*) 750. For thermal inactivation conditions, see Fig. 2.

extended conformation.[37] Such chains are apparently no longer able to shield the hydrophobic sections of the protein and hence the thermal stability of the protein in the conjugate is somewhat reduced (Fig. 4), although it still remains higher than that of the native protein. It is noteworthy that β-CD affects only the thermal stability of the conjugates with a uniform distribution of the polymer chains on the protein surface (Fig. 1, *IIb*), but does not influence at all the thermal stability of the conjugates with a nonuniform distribution of the chains, with which it does not interact for the reasons stated previously.[16]

Thus the study of the thermal stability of the conjugates may constitute in many instances an extremely informative method, whereby complex formation reactions between the conjugates and diphilic substances may be discovered.

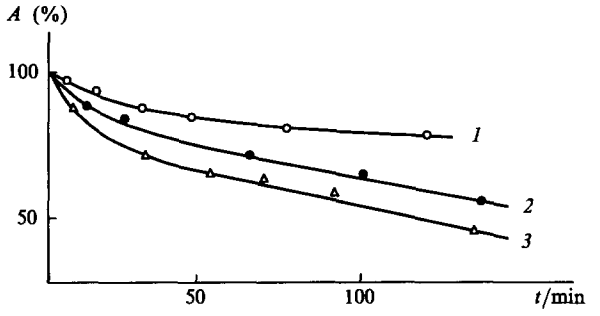

Figure 4. Kinetic curves for the thermal inactivation of the $(Pro)_3$–CT(un.) conjugate (curve *1*) and the same conjugate in the presence of β-CD (curve *2*) and egg lecithin (curve *3*) (Molar ratio conjugate : additive = 1 : 50). For thermal inactivation conditions, see Fig. 2.

III. Physicochemical properties of the conjugates

1. Differential scanning calorimetry

The data on the thermal stability of the conjugates obtained by the kinetic method have been supplemented by the results of the study of the thermal denaturation of the conjugates by differential scanning calorimetry (DSC). Fig. 5 presents heat absorption curves for aqueous solutions of CT and its conjugates. Evidently a significant alteration of the shape of the heat absorption peak is observed for the conjugates. Apart from the first maximum, located in the temperature range 47.6 – 49.6 °C as in the initial CT, a second maximum appears on the thermograms for the conjugates in the region of higher temperatures (54.5 – 55.5 °C), while for the $(OPro)_3$–CT and $(Pro)_7$–CT(un.) conjugates there is a shoulder in the same temperature range. Thus the appearance of an additional thermal transition is characteristic of all the conjugates. The most trivial explanation of this phenomenon is that the appearance of additional transitions is associated with the heterogeneity of the conjugates: the first maximum on the heat absorption curve corresponds to the fraction of the conjugate with a low degree of modification, while the second maximum corresponds to the fraction with a high degree of modification. However, this hypothesis conflicts with the DSC data for the conjugates with a higher degree of modification — $(Pro)_7$–CT(un.) (curve *6* in Fig. 5). As can be seen from the figure, there is only one maximum on the heat absorption curve for this conjugate (T_{max} = 51.2 °C) and there is a shoulder in the range 54.5 – 55.5 °C.

During the denaturation of the protein globule, the hydrophobic sections of the polypeptide chains are exposed to the solvent, becoming accessible to the hydrophobic units of the polymer chains entering into the composition of the conjugate. The appearance of a second maximum on the heat absorption curves for the conjugates is apparently due to the fusion of such a polymer – protein complex.

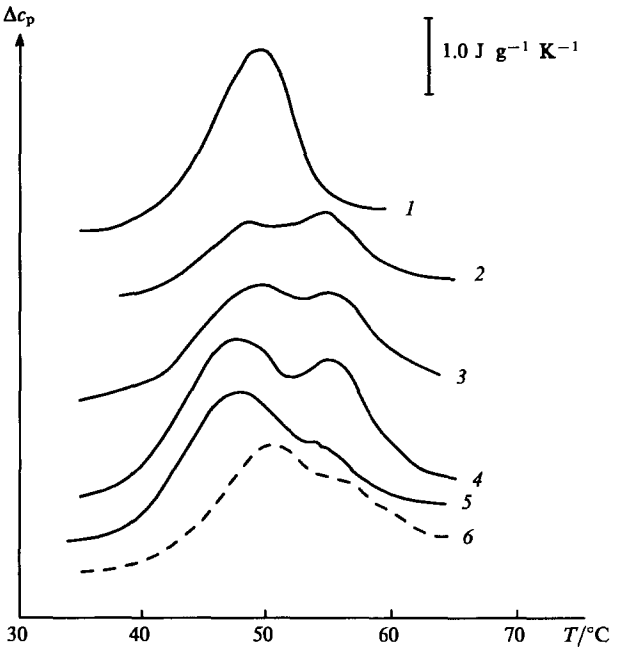

Figure 5. Heat absorption curves for CT (curve *1*) and its conjugates $(PEO)_3$–CT (curve *2*), $(Pro)_3$–CT(un.) (curve *3*), $(Pro)_3$–CT(nonun.) (curve *4*), $(OPro)_3$–CT (curve *5*), and $(Pro)_7$–CT(un.) (curve *6*). Buffer — 0.02 M sodium phosphate, pH 7.0; concentration of preparations 1 mg ml^{-1}; heating rate 1 K min^{-1} (c_p = heat capacity at constant pressure).

In order to demonstrate the validity of this hypothesis, additional studies were made. These confirmed the ability of proxanol to interact with CT at an elevated temperature. It was shown that:

1. During the scan heating from 20 to 60 °C (1 K per minute) of the solution of CT containing Pro (molar ratio 1 : 20), this protein does not aggregate.

2. Similar heating of a solution containing a mixture of CT and PEG leads to the aggregation of the enzyme similar to that occurring in the solution of CT under the same conditions.

3. The product of the interaction, obtained as a result of the heating of a mixture of CT with Pro to 60 °C and separated from the excess of the free proxanols, contains only 50% of the protein. According to ^1H NMR data, the remainder comprises the bound proxanol.

4. A peak whose maximum is close to the second maximum on the thermograms of the conjugate (T_{max} = 54.5 °C) is observed on the heat absorption curve for the solution containing a CT – Pro mixture.

The facts listed above show that the polymer – protein complex is formed at elevated temperatures. The complex has a fusion peak located in the same temperature range as the second maximum on the heat absorption curves for the conjugates.

Thus the DSC study of the conjugates showed that (a) the conjugates are thermally more stable than the initial protein, (b) that the thermal stability of the conjugates based on proxanol is comparable to that of the PEO – protein conjugates, and (c) that the appearance of the second maximum on the heat absorption curves for the conjugates is probably associated with the formation of intramolecular polymer – protein complexes.

2. Sedimentation of the conjugates

The hydrodynamic properties of the conjugates have been investigated by the high-speed sedimentation method. The sedimentation coefficients of the conjugates and the initial proteins are listed in Table 4, which shows that the modification of the proteins by polymers does not alter appreciably the sedimentation coefficient. This permits the conclusion that

Table 4. Sedimentation coefficients of proteins (s_{20}) and their conjugates with poly(ethylene oxide) and proxanols (T = 20 °C, 48 000 rev min^{-1}, 0.02 M phosphate buffer, pH 7.0).

	3	2.42 ± 0.15
	5	2.51 ± 0.16
	6	2.61 ± 0.21
	7	2.60 ± 0.18
$(Pro)_3$–CT(un.)	1	1.91 ± 0.13
	3	1.99 ± 0.15
	5	2.11 ± 0.08
	10	2.25 ± 0.13

solutions of the conjugates do not contain aggregates or products of intermolecular interaction in the experimental concentration range.

It might have been expected that, even in the absence of intermolecular interactions, the covalent attachment of polymer chains to the protein should have affected its sedimentation coefficient. The fact that significant changes in the sedimentation coefficients of the conjugates compared with those of the initial proteins were not observed apparently means that the increase in molecular mass in the modified protein is compensated by the flotation effect due to the polymer chain. It is noteworthy that the poly(alkylene oxides) used to modify the protein have a density close to that of water and they do not therefore undergo sedimentation in the ultracentrifuge.[38]

3. Hydrophobic chromatography

The hydrophobicity of the conjugates has been estimated with the aid of reversed-phase hydrophobic high-performance liquid chromatography (HPLC). Fig. 6 illustrates chromatograms of the native BBI and the $(Pro)_5$–BBI conjugate.[18] Evidently the retention volume of the conjugate is smaller than that of the native protein. This indicates its lower affinity for the hydrophobic carrier. The same trend has been observed also for the conjugates of CT with proxanol. At first sight, these results may appear surprising, since the modification by diphilic proxanols should impart an additional hydrophobicity to the protein. However, they can be accounted for by assuming that the hydrophobic blocks of the proxanol participate in intramolecular interaction with the hydrophobic region on the protein surface, whereas the hydrophilic blocks of the polymer occur mainly on the periphery of the conjugate.

4. Conformational models of the proxanol–protein conjugates

The entire set of data obtained with the aid of hydrophobic chromatography, sedimentation, and DSC indicate the existence of common features in the formation of the structures of the conjugates synthesised by the attachment of Pro to the protein.

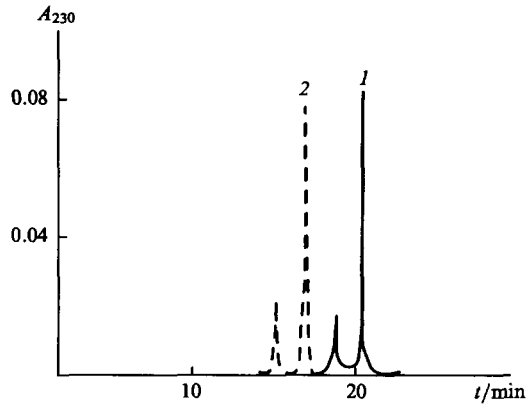

Figure 6. High performance liquid chromatography of native BBI (curve *1*) and of its conjugate $(Pro)_5$–BBI(nonun.) (curve *2*). The chromatography was carried out on a Zorbax C-8 column with 70% acetonitrile as the eluent; A_{230} = optical density at 230 nm.

These properties are manifested particularly strikingly for conjugates with a hydrophobic block on the periphery of the molecule (Fig. 1, structure *II*). The excess hydrophobicity introduced by the proxanols in such conjugates may be compensated either by the formation of intermolecular associated species or as a result of intramolecular interaction. Since associated species were not detected in dilute solutions of the conjugates, it is natural to postulate the formation of structures stabilised by intramolecular hydrophobic interactions. This hypothesis is confirmed by hydrophobic chromatographic data, indicating that the conjugates behave as substances which are more hydrophilic than the initial protein. Such structures are apparently constructed in the form of 'intramolecular micelles', in which the PPO blocks enter into the composition of the hydrophobic core, while the PEO blocks form part of the hydrophilic environment.

One can also postulate that the formation of such structures facilitates the complex formation reaction between the polymer chains of the proxanols and the protein occurring at elevated temperatures. It should be noted especially that the proposed structures have a definite conformational lability. This is manifested in the presence of hydrophobic or diphilic 'partners' such as lipids,[36] proxanol,[17] and cyclodextrins,[16] which are capable of interacting with the hydrophobic block of the polymer chains entering into the composition of the conjugates. There is probably in this case competition between the hydrophobic sections on the surface of the protein and the hydrophobic 'partners' for a chance to interact with the PPO block of the conjugate, as a result of which the 'intramolecular micelle' decomposes and mixed associated species or complexes are formed.

IV. Membranotropic properties of the conjugates

A fundamentally new property of the conjugates of proteins with proxanols is their ability to interact with biological membranes. Since the hydrophilic proteins forming part of their composition are not membranoactive, one can postulate that this property is due to the presence of the diphilic polymer chains of the proxanols. As shown previously, proxanols have the capacity to become incorporated in a biological membrane and to be translocated through it.[36]

In order to investigate the translocation of the conjugates through a biological membrane, use was made of the approach involving the study of the influence of these compounds on the rate of consumption of oxygen by liver mitochondria and the thymus lymphocytes.[12] It is known that the diphilic substances capable of being translocated through a cell membrane can

reach the NADH-dehydrogenase complex, located in the mitochondrion and responsible for cell respiration, and inhibit the NADH-dehydrogenase activity, which is manifested by a decrease in the rate of consumption of oxygen. When such experiments were carried out with the conjugates, it was found that some of them are capable of suppressing cell respiration of T-lymphocytes. This indicates their translocation to the cell. We investigated the dependence of the translocation of the conjugates on the nature of the attached chains and of their distribution relative to the protein globule.[13]

In order to elucidate the question of the influence of the nature of the arrangement of the hydrophilic and hydrophobic blocks in the proxanol chains in relation to the protein in the conjugate on its ability to suppress the respiration of T-lymphocytes, the effects of the type *II* and *III* conjugates based on CT and BSA were compared (Fig. 1): Fig. 7 shows that only type *II* conjugates, in which the hydrophobic block is on the periphery of the molecule, are able to suppress respiration in the lymphocytes. On the other hand, neither the PEO–protein conjugate, nor the conjugate with the hydrophilic block on the periphery of the molecule (type *III*), nor the initial CT affect respiration in the lymphocytes. The effectiveness of the influence of the type *II* conjugate on respiration is comparable to that of the pure proxanol. The concentrations which induce 50% suppression of the respiration were 9.8 ± 2.4 μg mol^{-1} for the proxanol and 30.0 ± 6.2 μg mol^{-1} for the conjugates (Table 5, A). Comparison of the corresponding concentrations of the free proxanol and the proxanol incorporated in the conjugates showed that they are similar (Table 5, B). Similar results were also obtained for the conjugates based on BSA and cytochrome *c*. This means that the capacity for translocation is determined by the polymer chains and depends little on the nature of the protein.

The conjugates of the three proteins investigated showed a similar effect also on respiration in isolated mitochondria (Table 5).

The dependence of the suppression of respiration on the number of polymer chains attached to the protein and needed to effect its translocation has been investigated in relation to the inhibiting effect of a number of CT conjugates with different contents of polymer chains. Fig. 8 shows that the suppression of cell respiration by the conjugates begins to be manifested to an appreciable extent in the presence of not less than three polymer chains per protein molecule.

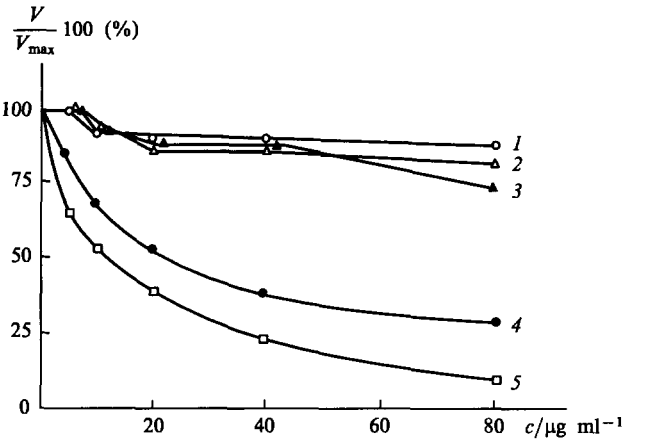

Figure 7. The influence of conjugates of proteins with various polymers on the rate of consumption of oxygen (V) by thymus lymphocytes: (*1*) initial CT; (*2*) $(PEO)_9$–CT; (*3*) $(OPro)_7$–CT; (*4*) $(Pro)_8$–BSA(nonun.); (*5*) $(Pro)_{10}$–CT(nonun.). The incubation medium for the lymphocytes contained (the concentrations are expressed as mM) NaCl (145), KCl (3.6), KH_2PO_4 (2), morpholinopropanesulfonic acid (8), and pyruvate (10); pH 7.4; T = 37 °C; the conjugates were added after oligomycin (0.2 μg ml^{-1}) and dinitrophenol (60 μM); in the control sample, the incubation medium was added instead of the conjugates to the lymphocytes; the concentration of lymphocytes in the cell was 10^8 cells in 1 ml.

Fig. 9 presents the results of a comparative study of the inhibiting effect of BSA-based conjugates, differing in the type of distribution of polymer chains on the surface of the protein globule, on the consumption of oxygen by T-lymphocytes. Evidently only the conjugates with a nonuniform distribution of chains cause a significant inhibition of respiration. CT conjugates with the corresponding structure exhibited the same effect.

As regards the mechanism of the action of conjugates on cell respiration, it is possible to examine several alternative versions: (1) the conjugates interact with the receptors located on the outer surface of the cell membrane and these receptors then transmit the signal to the cell; (2) the conjugates disrupt the cells; (3) the polymer chains are split off from the protein during the incubation of the conjugates with the lymphocytes and then

Table 5. The effectiveness of the suppression of the uncoupled respiration of lymphocytes and mitochondria by the Pro polymer and its conjugates with CT, cytochrome *c* (CYT), and BSA: $(Pro)_6$–CT(nonun.), $(Pro)_8$–CYT(nonun.), and $(Pro)_7$–BSA(nonun.).

Object of study	Pro	$(Pro)_6$–CT(nonun.)	$(Pro)_8$–CYT(nonun.)	$(Pro)_7$–BSA(nonun.)
	A. Concentration of Pro and the conjugates/μM (μg ml^{-1})			
Lymphocytes	4.9 ± 1.2 (9.8 ± 2.4)	0.66 ± 0.1 (30.6 ± 6.2)	1.1 ± 0.1 (33.0 ± 3.4)	0.75 ± 0.1 (61.0 ± 6.2)
Mitochondria	4.7 ± 1.2 (9.3 ± 2.4)	0.48 ± 0.06 (21.6 ± 4.7)	– –	– –
	B. Concentrations of free Pro and the Pro in the conjugates/μM			
Lymphocytes	4.9 ± 1.2	6.6 ± 1.9	3.3 ± 0.3	5.3 ± 0.5
Mitochondria	4.7 ± 1.2	4.8 ± 1.5	–	–

Remarks. The absorption of oxygen was recorded in the presence of 50–60 μM DNP, 4 mM glutamate, and 1 mM malate. The result was calculated as the arithmetical mean from 5–6 experiments. The table lists the concentrations of Pro and the conjugates inducing a 50% inhibition of the consumption of oxygen. The efficiencies of free Pro and the Pro in the conjugate are compared in Part B of the table.

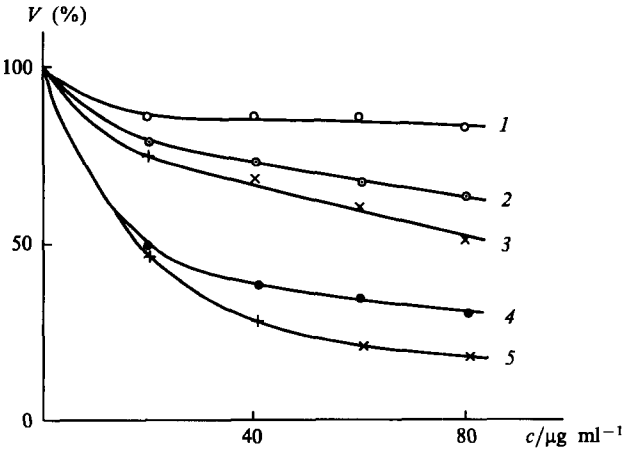

Figure 8. The influence of CT conjugates containing different numbers of Pro chains on the rate of consumption of oxygen by thymus lymphocytes: (*1*) $(Pro)_2$–CT(nonun.); (*2*) $(Pro)_3$–CT(nonun.); (*3*) $(Pro)_6$–CT(nonun.); (*4*) $(Pro)_{10}$–CT(nonun.); (*5*) $(Pro)_{15}$–CT(nonun.). For the experimental conditions, see Fig. 7.

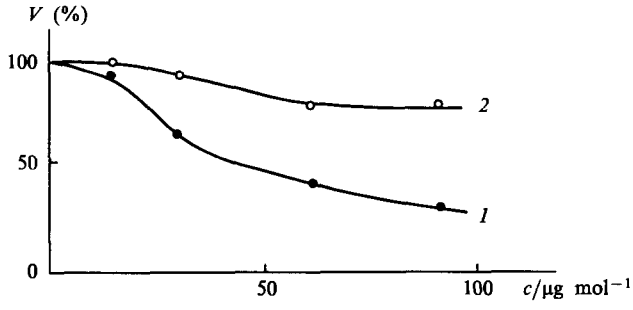

Figure 9. The influence of conjugates of BSA with a nonuniform (curve *1*) and uniform (curve *2*) arrangement of the Pro chains on the rate of consumption of oxygen by thymus lymphocytes: (*1*) $(Pro)_8$–BSA(nonun.); (*2*) $(Pro)_{15}$–BSA(un.). For the experimental conditions, see Fig. 7.

permeate through the cell membrane; (4) the conjugates permeate through the plasma membrane into the cell and reach the mitochondrial membranes.

The first hypothesis conflicts with the fact that the conjugates at virtually identical concentrations inhibit the separate respiration of both the cell as a whole and of an isolated mitochondrion. The substances capable of affecting the respiration of lymphocytes by interacting with the receptors on the outer surface of the plasma membranes, in particular with concanavalin A, increase the rate of their respiration only by 20% and do not affect the respiration of isolated mitochondria.[39]

It has been shown in special experiments that inhibition of the respiration of lymphocytes by proxanols and their conjugates is a reversible process and that it is fully restored after the cells have been washed. Consequently the inhibiting effects are not associated with the breakdown of the integrity of the plasma membranes of T-lymphocytes.

The separation of the polymer chains from the protein is also hardly likely to be the cause of the membrane activity of the conjugates. Indeed, on the basis of the idea that the $NH-CH_2$ bonds formed during the synthesis of the conjugate are hydrolytically stable and that their susceptibility to the action of hydrolytic enzymes is low, such separation appears fairly improbable. Nevertheless, in order to be able to reach the final conclusion that the polymer chains are not split off during the incubation of the conjugate with T-lymphocytes, an additional biological test of the ability of cells to cleave the conjugates has been carried out.[13] It confirmed with a high degree of reliability the absence of free proxanols in the supernatant after the separation of the cells. Thus one may conclude that the influence of the conjugates on the respiration of T-lymphocytes is the result of their permeation through the plasma membranes into the interior of the cells. Hydrophilic substances such as the proteins used to synthesise the conjugates are known to be incapable of permeating into the cells directly through the cell membranes. However, the same proteins acquire the capacity for translocation as a result of their being rendered hydrophobic by aliphatic acids.[40] The results permit the hypothesis that the modification of proteins by synthetic polymers (proxanols), capable of permeating through the cell membrane,[12] acts similarly to the addition of aliphatic acids. It must be emphasised that the necessary conditions for the translocation of such conjugates are the location of the hydrophobic blocks on the periphery of the conjugate molecule and also a nonuniform distribution of the polymer chains (Fig. 1, structure *IIa*). The type *IIb* and *III* conjugates of proteins with proxanols and the conjugates with PEO do not affect the respiration of cells. In certain cases, the PEO–protein conjugates may permeate into the cells via the endocytosis mechanism,[41] but the rate of this process is several orders of magnitude lower than that of the diffusion of the conjugate with membranotropic properties. Furthermore, endocytosis cannot occur in mitochondria.

Thus it has been shown that the covalent attachment of proxanols to hydrophilic proteins can serve as a method of imparting membranotropic properties to the latter.

V. Solubilising properties of the conjugates

1. The solubilisation of benzaflavin by conjugates of BSA with poly(alkylene oxides)

One of the important functions of serum albumins is their ability to transport nonpolar compounds of different chemical nature—aliphatic acids, hormones, and vitamins.[42] Bearing in mind the diphilic properties of proxanols described above, it might have been expected that their attachment to serum albumins would permit the creation of systems with an enhanced solubilising capacity in relation to water-insoluble biologically active substances. Such compounds include a dihydroriboflavin ester—5-acetyl-2′,3′,4′,5′-tetrabenzoyl-1,5-dihydroriboflavin [benzaflavin (BF)]. Dihydroriboflavin esters have a broad spectrum of biological activity and are of interest not only as long-acting vitamin B_2 preparations but also as medicinal drugs for metabolic therapy.[43]

The solubilisation of BF in aqueous solutions of BSA and its conjugates with poly(alkylene oxides) has been observed by UV spectroscopy at a wavelength of 306 nm, which corresponds to the BF absorption maximum. The extinction coefficients of the solubilised BF in a solution of pure BSA and of the $(PEO)_{14}$–BSA and $(Pro)_5$–BSA(nonun.) conjugates were determined from the dependence of the optical density on the concentration of the solubilised BF.

Protein, conjugate	BSA	$(PEO)_{14}$–BSA	$(Pro)_5$–BSA(nonun.)
10^{-3} ε/litre mol^{-1} cm^{-1}	4.9	4.7	3.5

The solubilisation limit (p), equal to the number of molecules of the solubilised substance per molecule of the solubilising agent, was determined by high-speed sedimentation in an analytical ultracentrifuge with an optical recording system. The use of the sedimentation method was based on the fact that the bound BF undergoes sedimentation together with the protein or the

conjugate.[13] The fact that the absorption by BF corresponds to a longer-wavelength part of the spectrum compared with BSA and the conjugates makes it possible to select a wavelength where only the bound ligand absorbs and its concentration can be determined.

In order to compare the solubilising capacities of BSA and the conjugates, a series of experiments were carried out in which the BF concentration was varied for a constant content of the protein or the conjugate. It is seen from the results that BSA has an appreciable solubilising capacity in relation to BF (Table 6). It was demonstrated by special experiments that proxanols do not solubilise BF. On the other hand, in all the systems containing the conjugates, the BF solubilisation limit proved to be higher than for BSA, the highest value corresponding to the $(Pro)_5$–BSA(nonun.) conjugate, in which the hydrophobic blocks are located on the periphery of the conjugate.

An increase in the number of polymer chains per protein molecule in the conjugate leads to a decrease in the solubilisation limit. This apparently occurs owing to the greater shielding of the regions responsible for the solubilisation of BF. Two procedures for the solubilisation of BF were used in the above investigation — by suspending BF and by introducing it into the above systems from an alcohol solution. The second procedure makes it possible to include a greater amount of BF, probably for kinetic reasons. The study by the nonelastic light scattering method of the system obtained by both procedures showed that, together with the particles whose size corresponded to the conjugate present in the system (less than 30 nm), larger particles with radii from 200 to 3000 nm (possibly BF aggregates) were observed when BF was introduced from an alcoholic solution. On solubilisation by the suspension method, only particles with radii less than 30 nm are formed.

In order to obtain systems with the optimum BF content, a study was made of the dependence of the solubilising capacities of BSA and the $(Pro)_5$–BSA(nonun.) conjugate on the pH of the medium (Fig. 10). The figure shows that the dependence is bell-shaped. The maximum solubilisation is observed in the pH range 7.6–9.0. Study of the dependence of the solubilisation limits on the phosphate buffer concentration (pH 6.2 and 7.2) showed that an increase in the buffer concentration impairs the solubilising

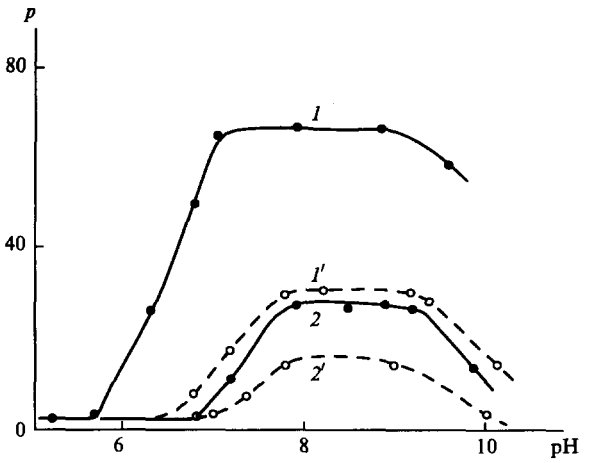

Figure 10. Dependence of the BF solubilisation limit on the pH of the medium: (*1*) visual method; (*2*) sedimentation method; BSA — dashed line; $(Pro)_5$–BSA(nonun.) conjugate — continuous lines.

capacities of both the protein and the conjugate. Thus, the attainment of the maximum solubilising effect requires the use of solutions in the pH range 7.6–9.0 at the lowest ionic strength.

Experiments in which the solubilisation of BF in solutions of BSA and the conjugates was investigated at an elevated temperature (40 °C) made it possible to observe an appreciable heterogeneity of such systems in contrast to the systems containing the pure solubilising agent (Table 6). A definite fraction of the substance undergoing sedimentation in such systems is characterised by a sedimentation coefficient exceeding by a factor of approximately two the corresponding sedimentation coefficients of the protein and the conjugates. It may be that the BF in such systems promotes the formation of 'bridges' between the protein molecules.

The results suggest that the BF molecules in the conjugates investigated are localised in the hydrophobic regions of the BSA

Table 6. The solubilising properties of BSA and its conjugates with poly(alkylene oxides) in relation to BF (0.02 M phosphate buffer, pH 7.2; the BF was introduced from alcoholic solution).

Solubilising agent	T/°C	p	s_{20}/Sv (solubilising agent)	s_{20}/Sv (complex with BF)	Fractions of different forms (%)
BSA	20	17	4.2	6.3	100
	40	17	6.7	11.0	47
				6.2	53
$(Pro)_5$–BSA(nonun.)	20	40	4.4	10.1	100
	40	40	6.8	14.2	21
				7.3	79

	40	19	6.6	13.2	47
				5.9	53
$(PEG)_{14}$–BSA	20	21	4.2	6.6	100
	40	21	6.5	10.5	49
				6.8	51
$(Pro)_{100}$–BSA[a]	20	18	2.9	6.2	100
	40	18	5.8	12.0	80
				6.6	20

[a] The solubilising agent was obtained from the conjugate $(Pro)_5$–BSA(nonun.) by adding free proxanol.

protein globule. This is also confirmed by the finding that the attachment of proxanol to other proteins, for example to class G immunoglobulins or to CT, which are unable to bind this ligand, has no effect on their solubilising properties.

2. The transfer of benzaflavin into mitochondria with the aid of BSA conjugates

The data presented in this Section presuppose the possibility of using the conjugates of proteins with poly(alkylene oxides) as agents transporting water-insoluble biologically active substances into the target cells. In order to test this hypothesis, a study was made of the transfer of benzaflavin into rat heart mitochondria.[15] This phenomenon was observed by studying the relation between the amount of BF bound by the mitochondria and the amount of BF present in solution in the solubilised form. The amount of BF bound by the mitochondria was determined from the difference between the total content of BF in solution and its content in the supernatant after incubation with the mitochondria. This quantity reaches a maximum after 1 min and remains constant on further incubation with the mitochondria.

It was observed that the BF solubilised by BSA and its conjugates with PEO and Pro is capable of being transported into the mitochondrial membranes. Quantitative data on the transfer of BF are presented by the binding isotherms in Fig. 11. In the BF concentration range investigated (up to 8×10^{-4} M), the dependences of the amount of bound BF on the concentration of free BF are linear:

$$\frac{[BF]_{bound}}{[MC]} = K[BF]_{free}, \quad (3)$$

where K is the proportionality coefficient, which depends on the nature of the solubilising agent, and [MC] is the concentration of the mitochondrial protein. The linearity of these relations showed that the experimental data correspond to the initial sections of the binding isotherms. It is important to emphasise that the experimental points obtained for different concentrations of the solubilising agent lie on the same isotherm characteristic of the given solubilising agent. Thus the proportionality coefficient in Eqn (3) is independent of the concentration of the solubilising agent.

It is of interest that BSA and its conjugate with PEO proved to have identical capacities to transport BF. Both solubilising agents may be characterised by the same proportionality coefficient $K = 0.31 \pm 0.01$ litre (g of mitochondrial protein)$^{-1}$. For the conjugate of BSA with proxanol, $K = 0.96 \pm 0.01$ litre (g of mito-chondrial protein)$^{-1}$. The higher capacity of the BSA–proxanol conjugate to transport BF can apparently be explained by the formation of a weaker complex between BF and this conjugate than the complex between BSA and its conjugate with PEO.

Thus the BSA–proxanol conjugates have definite advantages over other systems investigated as regards both their solubilising and transport capacities, which creates preconditions for their employment in the development of new medicinal preparations.

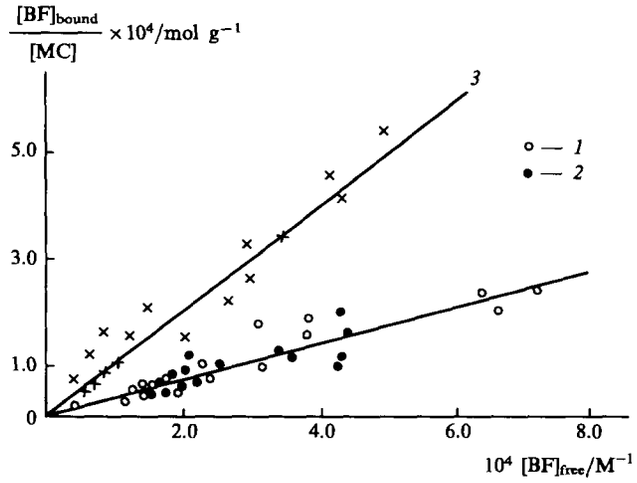

Figure 11. Dependence of the amount of bound BF [in moles per gram of the mitochondrial protein (MC)] on the concentration of free BF. Solubilising agent: (*1*) BSA; (*2*) $(PEO)_{14}$–BSA; (*3*) $(Pro)_5$–BSA(nonun.).

VI. Noncovalent complexes between α-chymotrypsin and the block-copolymer of ethylene and propylene oxides

The complex formation reactions between proteins and water-soluble proteins constitute one of the effective methods in protein engineering. Thus many synthetic linear polyelectrolytes form complexes with proteins.[44,45] Protein molecules are bound to polyions by electrostatic interaction, which may be accompanied by the formation of hydrogen bonds and hydrophobic contacts. In contrast to this, water-soluble polymers which contain no ionogenic group, for example PEO, do not form complexes with proteins.[46] When solutions of BSA or CT are mixed with solutions of proxanols at room temperature, complexes are not produced either.[21]

As mentioned above, we demonstrated in relation to CT that stable protein–proxanol complexes can nevertheless be obtained when their solutions are heated to temperatures corresponding to the onset of the thermal denaturation of the protein (this problem has been examined in greater detail elsewhere[46]).

The first results indicating the formation of mixed CT–Pro particles were obtained with the aid of a visual method for the observation of the turbidity of solutions of a protein and poly(alkylene oxide). The formation of such particles is also indicated by data obtained by the DSC method for aqueous solutions of CT, CT–PEG, and CT–Pro. Fig. 12 presents thermograms for the fusion of CT (curve *1*), CT in the presence of PEO (curve *2*), and CT in the presence of Pro (curve *3*). Evidently PEO does not affect the fusion of the protein globules: the fusion curves *1* and *2* virtually coincide (the heat of fusion is 1090 kJ mol^{-1} in the former case and 1080 kJ mol^{-1} in the latter). In contrast to this, in the presence of Pro, a shift of the fusion peak towards higher temperatures and an increase of its height (the heat of fusion is

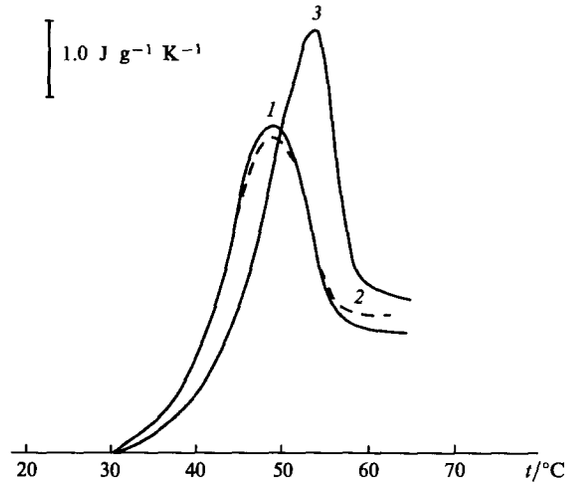

Figure 12. Heat absorption curves for CT (concentration 2 mg ml^{-1}, curve *1*), for a mixture of CT and PEO (2 mg mol^{-1} and 0.48 mg ml^{-1}, curve *2*), and for a mixture of CT and Pro (2 mg ml^{-1} and 0.48 mg ml^{-1}, curve *3*). Buffer—0.02 M sodium phosphate, pH 7.0; heating rate 1 K min^{-1}.

Table 7. Characteristics of the CT–Pro complexes (heating rate 1 K min^{-1}, initial temperature of the solution 20 °C, incubation time in the thermostat before the attainment of the upper limit in the heating process 5 min).

Complex	Preparation conditions		Content of polymer in complex/mol (mol of CT)$^{-1}$	Activity (% of initial protein)		Content of active centres (%)	10^5 K_m/M[a]	k_{cat}/s^{-1}
	upper limit in heating process/°C	CT:Pro molar ratio		before isolation	after isolation

[a]The kinetic constants were obtained by studying the enzymic hydrolysis of BTEE (pH 8.0; 25 °C). The errors were determined with a fiducial probability of 0.95.

[b]The complexes were cooled and isolated immediately after the attainment of the upper temperature limit of the heating process without subsequent incubation in a thermostat.

1250 kJ mol^{-1}) are observed. Hence it follows that during heating the CT and Pro are bound to one another in some way, giving rise to a new product, in which the protein component acquires a somewhat higher thermal stability. The thermally induced binding of CT and Pro is irreversible under the experimental conditions. After such solutions have been cooled, the mixed reaction product is preserved in them, which is indicated by the determinations of the protein content in the products isolated (Table 7) (the method of isolation of these products from the reaction mixture ensured the complete removal of the excess free polymer, which was checked by thin-layer chromatography.)

The question of the nature of the interactions between Pro and the protein is of fundamental importance. The hypothesis of the formation of a noncovalent complex is most natural. In order to determine the nature of the bonds between Pro and CT, we studied the dissociation of the complexes in the presence of urea by thin-layer chromatography (TLC). The method is based on the difference between the chromatographic mobilities of the dissociation products and the initial complex. The rate of dissociation of the complexes in aqueous solutions is low and the dissociation becomes appreciable only after 24 h. The process accelerates significantly in the presence of 8 M urea. These data show that the reaction products are noncovalent complexes between CT and Pro.

On the basis of ideas concerning the complex formation process, one may postulate that the composition of the complexes may be regulated in two ways: by varying the polymer/CT ratio at a fixed heating temperature and by varying the heating temperature for a fixed reactant ratio. Indeed, Table 7 shows that, for a fixed excess of Pro in the system, the number of polymer chains entering into the composition of the complex increases in parallel with the increase in the maximum heating temperature. For example, in the system with a 20-fold molar excess of Pro, the number of polymer chains entering into the composition of the complex increases from 5 to 11 when the upper temperature limit of the heating process rises from 44 to 60 °C. The same tendency towards an increase in the number of polymer chains in the complex is observed also with increase in the molar excess of the polymeric component for a fixed upper temperature limit of the heating process.

We may note that the protein fraction isolated from a mixture of CT and PEG after heating to 60 °C represents the pure protein, which indicates the absence of interaction between the components. This conclusion agrees well with the results of differential scanning calorimetry.

Fig. 13 presents the ^{1}H NMR spectra of pure CT and two of its complexes with Pro obtained by heating to 44 and 48 °C respectively. Evidently, with increase in the temperature of the formation of the complexes, the denaturation changes in the protein become more appreciable, although a complete breakdown of the native structure is not observed. On the other hand, the positions and width of the signals due to the polymeric component of the complex indicate a fairly high molecular mobility of the majority of the units of the polymer chains in the complex.

A notable feature of the complexes is that they retain enzyme properties. It was of interest to elucidate how the specific enzyme activity of the complexes depends on the conditions of their preparation and isolation. Table 7 presents data on the enzyme activity of the complexes directly after the completion of the heating process but before their isolation from the reaction mixture. They reflect the properties of the complexes closest to those at the instant of their formation. The enzyme activity of the complex was measured also after their isolation from the reaction mixture. Comparison of the activities of the complexes before and after their isolation shows that the activity of the isolated complexes was higher for all the systems investigated. It may be that this is associated with the fact that the molecules of the free Pro, present in excess, form micellar structures incorporating CT. As a result of this, the active centre of the enzyme becomes less accessible to the substrate. During the isolation of the complex from the solution, the micellar structures are disrupted, which leads to a greater accessibility of the enzyme active centre to the substrate. It is important to note that in certain cases an increase in the enzyme activity of the isolated complexes compared with the initial CT was actually observed. Similar superactivity phenomena had been observed earlier in a study of the enzymic hydrolysis of the ethyl ester of *N*-acetyl-L-tyrosine catalysed by CT in inverted micelles.[48–50]

It was therefore of interest to determine the kinetic constants for the hydrolysis of BTEE catalysed by the complexes and to compare them with the corresponding constants for the initial CT. The contents of the active centres in the complexes were determined simultaneously. The corresponding data are presented in Table 7. Evidently, with increase in the upper

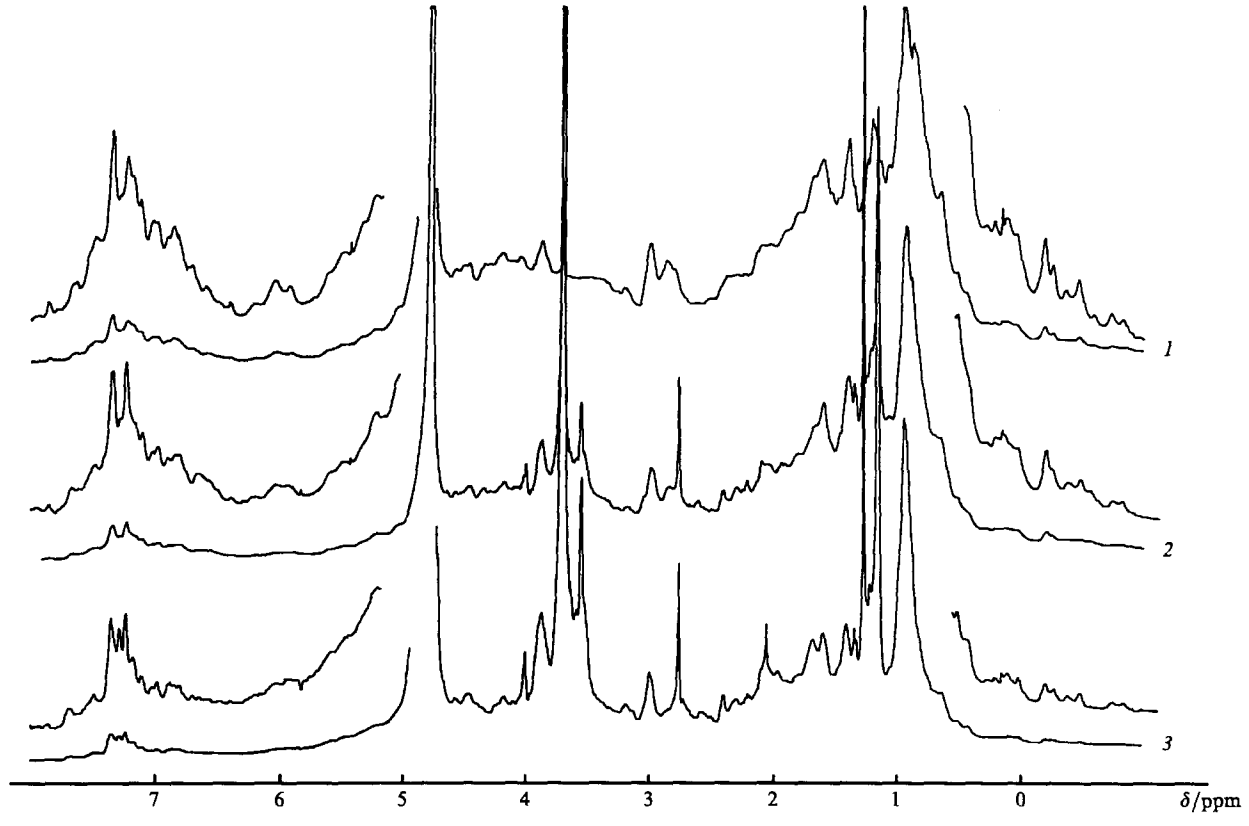

Figure 13. ^{1}H NMR spectra of solutions of CT (curve *1*), the CT–$(Pro)_5$ complex obtained by heating to 44 °C (curve *2*), and the CT–$(Pro)_7$ complex obtained by heating to 48 °C (curve *3*) in D_2O; concentration of protein in the specimen 2 mg ml^{-1}.

temperature limit in the heating of a mixture of CT and Pro and also in the incubation time for a fixed temperature limit in the heating process, the content of the active centres in the complex diminishes. The values of K_m increase steadily in the same sequence, which indicates a decrease in the affinity between the complex and the substrate. On the other hand, the increase in k_{cat} for the same series of catalysts indicates an increase in the catalytic effectiveness of the CT active centres entering into the composition of the complex.

On the basis of the overall results obtained, the mechanism of the formation of complexes between Pro and CT can be represented as follows. On heating, the protein globule uncoils, as a result of which the hydrophobic aminoacid residues appear on the surface of the protein. This is accompanied by the simultaneous dehydration of the hydrophobic Pro blocks, which promote the formation of compatible polymer–protein structures. During cooling and during the isolation of the complex from solution, sections of the hydrophobic Pro block are fixed near the protein globule via a multipoint interaction with the hydrophobic and polar groups located on the surface of the protein. The fact that the dissociation of the complex intensifies in the presence of a denaturing agent (urea) does not rule out the possibility that, together with the hydrophobic interactions, hydrogen bonds between Pro and the protein globule make a significant contribution to the stabilisation of the complex.

Thus the thermally induced interaction of Pro with CT leads to the formation of a new type of supermolecular structure—stable catalytically active complexes. The simplicity of the method of preparation of such structures and the retention of functional properties by the latter makes it possible to regard this procedure for the modification of proteins as one of promising methods in protein engineering.

VII. Conclusion

The methods developed for the preparation of conjugates of proteins and proxanols make it possible not only to vary within wide limits the structures and physicochemical properties of the products but also to simulate with their aid the biological functions of membranotropic proteins. The properties of the conjugates described above permit their use in enzyme therapy, in the creation of new therapeutic agents, and in the manufacture of biocatalysts for biotechnology soluble in organic media. Furthermore, these compounds may find applications in biochemical studies on water-insoluble biologically active compounds. The proposed alternative method for the modification of proteins by proxanols, based on the formation of nonvalence complexes between them, constitutes a new approach to the preparation of proteins modified by polymers. The set of covalent and noncovalent methods for the modification of proteins leads to extensive possibilities for the preparation of polymer–protein adducts with specified properties.

III.	Films, coatings, and layers	299
IV.	Structure and properties	301
V.	Conclusion	305

Abstract. Methods of preparing silicon nitride and silicon nitride materials as powders and as materials consolidated from the powders, and also as films and coatings, are reviewed. Information on the structure and on the physicochemical properties of silicon nitride materials is analysed and discussed. The bibliography includes 172 references.

I. Introduction

The synthesis of silicon nitride by heating elemental silicon in an atmosphere of nitrogen generated by the decomposition of potassium cyanide was first reported by Balmen in the middle of the last century.[1] Thus, though first synthesised about 150 years ago, silicon nitride (like silicon carbide) has played a leading role among all known refractory compounds (judging by the number of publications, seminars, conferences, etc.) only during the last two decades. The most 'productive' period was the autumn of 1993, when a symposium on silicon ceramics was held in Tokyo in September, the conference 'Silicon nitride 93' was held in Stuttgart in October, and a symposium on silicon ceramics as construction materials was held in Hawaii in November, in spite of the authoritative symposia held in December 1992 and in April 1993 respectively, in the USA, by the Materials Research Society and by the Ceramics Society, aimed at the scientific and the technological aspects of silicon nitride materials. This sustained interest is not fortuitous: it can be attributed to at least two factors. Firstly, to the remarkable properties of silicon nitride (high hardness, good tribological and elastic characteristics, low density, adequate mechanical and thermal stability, inertness towards many aggressive media, unique electrical properties, and readily available starting materials). Secondly, it is stimulated by the relative complexity of silicon nitride as the object of physicochemical research and technological development.

Whereas the first of these factors accounts for the wide range of possible applications of this compound (in structural, cutting tool, and tribotechnical materials, and also in materials with special physical and physicochemical properties), and therefore for the interest shown by specialists in different disciplines, the second factor explains the need for comprehensive investigations.

One of the most notable contributions was made in the 1950–1970s by Samsonov, who reported a comprehensive study of refractory compounds in general and silicon nitride in particular.[1,2] Monographs so far published on this topic are few,[3–5] and deal with aspects which are now obsolete: the more recent information is to be found in journals and in relatively obscure symposia.[6–9] The latest reviews[10–12] deal with specific aspects, and do not consider the overall problem. It should be noted that the chemical and physicochemical aspects are among the most important in the development of modern silicon nitride materials, and that their relevance is increasing continuously.

The aim of the present review is to discuss and generalise as fully as possible the most recent data on the synthesis and properties of silicon nitride in the form of powders and materials made from the powders, and also in the form of films.

II. Powders and their consolidation

1. Synthesis and thermal dissociation

Si_3N_4 powders can be prepared by many of the standard powder technology methods: direct synthesis in its numerous variants, carbothermic reduction, gas–phase synthesis and dissociation reactions, and mechanical comminution as an additional treatment. These methods are listed in Table 1 with some of their modifications.

The main methods of preparing Si_3N_4 powders used recently have relied on mechanosynthesis, now widely used in the preparation of powders of many refractory compounds and intermetallics.[13–15] It has been shown[16] that the use of ammonia during the milling of silicon is much more effective than the use of nitrogen. The hydrogen formed during the dissociation of ammonia reacts with oxygen impurities in the atmosphere and decreases the probability of forming oxynitride surface films, which suppress the nitridation of the silicon particles. Intensive milling of silicon in ammonia for 150 h, followed by vacuum treatment at 800 °C (τ = 8 h), produces α-Si_3N_4, but the product contains 14.22 at.% of oxygen, 1.28 at.% of iron, and 1.99 at.% of titanium. This result is undoubtedly encouraging, but it also makes clear the need for further optimisation of the regimes adopted in the preparation of Si_3N_4 by the mechanosynthesis method.

Table 1. Main methods of synthesis of silicon nitride powders and their variants.

Method	Main reactions	Main variants of the method
Direct synthesis of components	$3Si+2N_2 \rightarrow Si_3N_4$ $3Si+4NH_3 \rightarrow$ $\rightarrow Si_3N_4+6H_2$	Self-propagating high-temperature synthesis (SHS). Plasmachemical synthesis. Mechanosynthesis
Carbothermic reduction	$3SiO_2+6C+2N_2 \rightarrow$ $\rightarrow Si_3N_4+6CO$	–
Gas-phase synthesis	$3SiCl_4+16NH_3 \rightarrow$ $\rightarrow Si_3N_4+12NH_4Cl$ $3SiH_4+4NH_3 \rightarrow$ $\rightarrow Si_3N_4+12H_2$	Plasmachemical synthesis. Laser synthesis
Dissociation (pyrolysis)	$3Si(NH)_2 \rightarrow$ $\rightarrow Si_3N_4+2NH_3$ $(1/n)[SiR_2-NR]_n \rightarrow$ $\rightarrow Si_3N_4+RH+H_2$	Laser induced
Milling	–	–

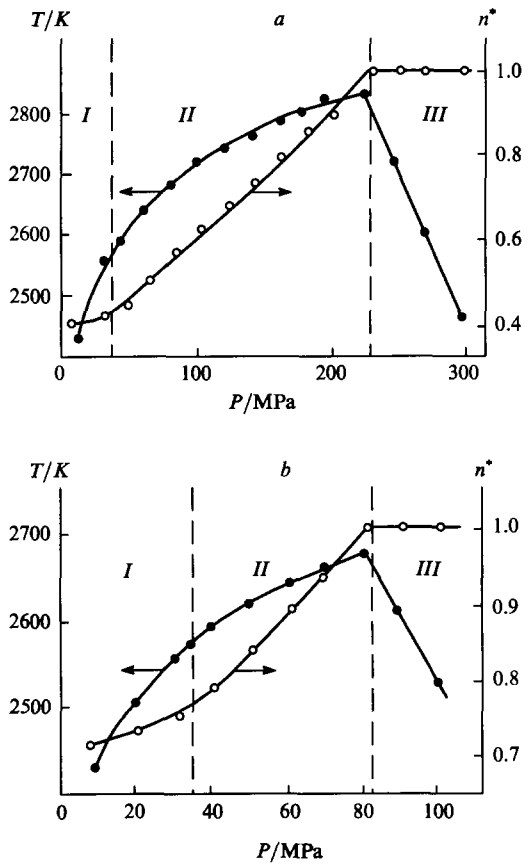

Figure 1. Effect of the nitrogen pressure on the adiabatic combustion temperature and on the extent of reaction of the silicon (n^*). (*a*) Si; (*b*) $Si:Si_3N_4 = 50:50$. Calculated for an assumed porosity of 65%. *I*–*III* see text.

The kinetics of the interaction of silicon with nitrogen are strongly influenced by the density of defects in the initial powders, as shown by X-ray structural analysis and by ESR and IR spectroscopy methods applied during the milling of silicon.[17] The mechanism of the reaction of silicon with nitrogen has been analysed in detail also by earlier workers,[4,10] and we shall not dwell upon it further here.

Detailed studies of the interaction of silicon with nitrogen during the self-propagating high-temperature synthesis (SHS) of the compound[18–21] have been reported. Fig. 1 shows the dependence on the nitrogen pressure of the calculated adiabatic combustion temperature of silicon and of the extent of reaction. The effect of diluting the initial silicon with silicon nitride, which lowers the nitrogen pressure and the combustion temperature, is also shown. Three regions of the reaction have been defined:[21] in the first (*I*) the rate of combustion is limited by the transport of nitrogen, in the second (*II*) the reaction is controlled by the high-temperature dissociation of the silicon nitride, and in the third region (*III*) rate limitation is provided by the reaction kinetics. In the latter region complete conversion of the silicon into the nitride is observed at the front of the combustion wave ($n^* = 1$).

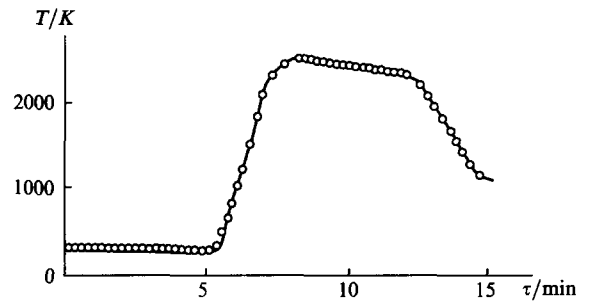

Figure 2. Typical thermogram for the combustion of a mixture of $Si:Si_3N_4 = 50:50$ in nitrogen at a pressure of 50 MPa (porosity 65%).[21]

On the whole these calculations are confirmed by experiment. Fig. 2 shows one of the thermograms obtained in the combustion of silicon (50 mass%) + Si_3N_4 (50 mass%) in nitrogen under a pressure of 50 MPa. The maximum combustion temperature recorded in these experiments (~2500 K) differs by approximately 100–150 K from the calculated values: in view of the approximate nature of the calculations this result can be accepted as fully satisfactory. However, at other temperatures the agreement between the experimental and the theoretical results was not so good.

One of the advantages of the silicon nitride powders prepared by the SHS method is their relatively low oxygen content (0.4%–0.6%).[22] This is due to the use of pure starting materials (semiconductor-grade silicon and thoroughly purified nitrogen). Commercial-grade powders prepared by the SHS method have a much higher content of impurities (for example, their oxygen content is between 1.5% and 2%). Some recent papers[23–25] describe their technological and other properties.

The favourable economic indicators of the SHS method have been discussed by Golubjatnikov et al.,[26] who calculated that for an annual production rate of 50 t by the SHS method the cost of 1 kg of Si_3N_4 powder would be ~US \$28, compared with ~US \$33.7 for material produced by the normal method. Characteristically, in both cases the main contribution to the cost comes from the economically inefficient milling operation.

The tempting idea of preparing silicon nitride powders by the self-propagating combustion of silane–ammonia mixtures without additions of oxygen has not so far been realised.[27] Only the synthesis of silicon oxynitride powders has been reported.

The carbothermic reduction of silicon oxide in a nitrogen atmosphere has long been of interest as a method of using widely available materials including waste products (for example rice husks[28]). However, the powders obtained by this method do not offer a high purity and require additional milling. Their purity can be improved by chemical purification (acid etching) of

the materials.[11] A detailed study of the mechanism of formation of Si_3N_4 under the conditions of carbothermic synthesis (T = 1400–1550 °C, p_N = 0.1–6 MPa) in relation to the properties of the carbon black and of the silicon has been carried out.[29] It was shown that at nitrogen pressures between 2 and 6 MPa the evaporation of the silicon monoxide and the formation of nonequilibrium phases can be largely suppressed, thus bringing the carbon and oxygen content of the reaction products under control. The special features of the carbothermic reduction of silica in nitrogen were discussed also by several contributors to the Stuttgart conference[9] in 1993. For example, it was reported that the well-known Dow Chemical Company (USA) had developed a technology for the carbothermic synthesis of Si_3N_4 which produced a powder of submicron particle size with a high content of the α-phase (>95%) and a relatively small content of oxygen (2%–2.5%) and of carbon (0.3%–0.5%).[30] The moderate cost and the useful technological characteristics of this powder were stressed.

Most of the work reported during the last few years relates to the gas-phase synthesis of silicon nitride, and is mainly aimed at the production of ultrafine powders (UFP) with a particle size of less than 100 nm (usually $d < 20$ nm).[15] The reactions between ammonia and the vapours of silicon tetrachloride or silane, or their derivatives, have been widely studied.[11,31–35] Work aimed at the preparation of carbide nitride powders should also be mentioned.[31,35]

Under appropriate conditions the gas-phase synthesis stimulates homogeneous nucleation, and thus allows silicon nitride to be prepared in the form of UFP. As has been pointed out,[11] the use of silicon tetrachloride or of silane as the starting materials involves some important considerations. On the one hand the low cost of $SiCl_4$ must be weighed against the need to take special steps to remove corrosive side products (NH_4Cl). On the other hand the less easily available silane, which also requires special precautions in handling, gives a better-quality product. Nevertheless silicon tetrachloride is widely used in the industrial production of silicon imide $Si(NH)_2$. This material decomposes at ~1000 °C with formation of amorphous Si_3N_4, which is then annealed to induce crystallisation at 1500 °C.[36]

The most significant results of the studies of gas-phase reactions include the recognition of the special features of the laser-assisted synthesis of silicon nitride as non-agglomerating UFP,[33] and also calculations of the thermodynamic equilibrium in the Si–H–Cl–N system in the temperature range 800 to 2600 K using SiH_4, $SiCl_4$, their many derivatives, and the imide.[37] The pyrolysis conditions in various media (argon, oxygen, nitrogen, helium) of crosslinked organosilicon polymers have also been analysed in detail.[38,39] The formation of various intermediates during these experiments was demonstrated by NMR and IR spectroscopy.

It should be noted that the use of organosilicon polymers of the polysilazane type $\{[SiR_2-NR]_n$ and $[SiR_2-SiR_2-N]_n\}$ as the precursors in the synthesis of UFP of silicon nitride and of its mixtures with silicon carbide is now being widely adopted.[40] Unfortunately, polymeric precursors of Si_3N_4 with the ideal atomic ratio Si : N : C = 3 : 4 : 0 cannot be prepared by the method used successfully for SiC. The traditional plasma methods of synthesising these products are still proving valuable.[31,32,41] Laser technology is used mainly on the laboratory scale. An increasing number of publications on the use of gas-phase reactions in thermal reactors of the flow type is now appearing. Thus, the thermal dissociation of hexamethyldisilazane $Me_3SiNHSiMe_3$ introduced in a stream of helium as the carrier gas (rate 8.55×10^{-3} mol min^{-1}, silazane concentration 16.5 mol%) has been described; some characteristics of the silicon nitride UFP thus obtained are listed in Table 2.[35]

The low density values (up to ~15% lower than in silicon nitride and carbide) and the acceptable agreement between the particle sizes calculated from measurements of the specific surface by the BET method and from transmission electron microscopy (TEM) data are noteworthy. However, the oxygen content of the powders was fairly high. The amorphous powders first obtained were then annealed. Annealing in an argon atmosphere caused crystallisation of cubic β-SiC ($T \approx$ 1300 °C), whereas α-Si_3N_4 was crystallised by an anneal at 1400 °C in a mixture of $NH_3 : H_2$ = 1 : 1.

The residence time of the precursor–gas mixture in a high-temperature reactor 25.4 mm in diameter and ~200 mm long was less than 0.1 s. The extent of conversion increased from 30% to 51% at temperatures between 1100 and 1400 °C. Approximately 2 g of the powder was deposited in 30 min on a rotating drum cooled in liquid nitrogen. It was noted that the preparation of nonagglomerating UFP required a low concentration of the precursor in the carrier gas (which minimises the probability of cluster coalescence in processes of short duration), a fast expansion of gas stream at the outlet from the high-temperature region into a low pressure of inert gas ($10^2 - 5 \times 10^3$ Pa), and rapid cooling of the particles. These assemblies also include special attachments for collecting the powder and for consolidating it in situ at high pressures with complete protection from the surrounding medium.

Studies of the milling of silicon nitride are still being reported.[42,43] Contamination of the product from the material of the milling balls and of the lining can be avoided by using piece parts made from silicon nitride, but milling is invariably accompanied by oxygen contamination. This effect is well illustrated by the milling of a powder of H1 grade (produced by H C Stark Co.) in a specially lined attrition mill (Table 3).[42]

Table 3. Some characteristics of a powder of H1 grade from the H C Stark company after milling for 4 h and 12 h.

Milling time/h	S/m^2 g^{-1}	d/nm	O (mass%)
0	8.4	220	0.9
4	20	95	2.1
12	30	60	3.0

T/°C	γ/g cm^{-3}	S/m^2 g^{-1}	Particle size d/nm		Composition		
			from BET data	from TEM data	x	y	z
1100	2.614	568	4	10	1.26	0.35	0.61
1200	2.737	555	4	10	1.35	0.40	0.47
1300	2.781	360	6	8	1.45	0.48	0.29
1400	2.783	272	8	6	1.51	0.49	0.28

Notes. γ is the pyknometric density; S is the specific surface.

The use of milled powders increases the density of sintered and hot-pressed samples.

To conclude this section we shall list the various forms of commercially produced silicon nitride: fibres, monocrystals, and SiAlON ceramics. The production and properties of Si_3N_4 fibres have been discussed in recent reviews.[11,44] Almost all the chemical methods listed in Table 1 are applicable to the production of fibres, but they require an additional organisation of the crystallisation processes in the liquid–vapour–crystal or vapour–crystal systems for the successful growth of fibres or of filamentary crystals (whiskers). For example, the formation of fibres by heating silicon imide with small addition of iron or of silicon oxide in an oxygen-free atmosphere at 1200–1500 °C or by high-temperature treatment of polycarbosilane in ammonia has been reported. It has also been pointed out[35] that monocrystalline nanofibres (30–40 nm diameter, length to diameter ratio > 500) can be produced in a very perfect structural state. It was suggested that the growth of these fibres takes place by the formation of liquid microdrops of silicon during the reduction and decomposition of the ultrafine SiC_xN_y powder, followed by dissolution and subsequent crystallisation of the nitride. The formation of single crystals of the α phase (up to 1 μm in diameter, several micrometres in length) was observed also in the synthesis of silicon nitride in the SHS regime at pressures of 10–180 MPa.[21]

Single crystals of α-Si_3N_4 (1–3 μm diameter, 6–10 mm in length) have been obtained[45] by the gas-phase method using the reaction $SiH_x + N_2 \rightarrow Si_3N_4$ with iron as a catalyst: they were used in studies of the physicomechanical properties of these crystals. Crystals of α-Si_3N_4 several millimetres long were produced[46] in a graphite crucible 300 mm in diameter at 1300 °C by the reaction of $HSiCl_3 + N_2 + H_2$ (pressure ~65 Pa). Crystals were isolated from the polycrystalline sample with a diamond cutting tool. It was pointed out that single crystals grown in the $\langle 10\bar{1}0 \rangle$ direction contained far fewer defects (cracks) than monocrystals with a [0001] orientation, though the latter were larger.

The term SiAlON usually refers to compounds formed in the $Si_3N_4-SiO_2-AlN-Al_2O_3$ system and having the general formula $Si_{3-x}Al_xON_{4-x}$. An authoritative review of the properties of these ceramics has recently been published,[47] and we shall not dwell upon them further.

2. Properties of the powders

The compositions and particle sizes of most of the industrial silicon nitride powders and of some samples now being developed are shown in Table 4. These data, collected by the present writer from various publications,[11,22–25,36,48–50] are on the whole consistent with the considerations discussed above on the advantages and disadvantages of the different methods of synthesis. According to Cambier et al.[50] in the late 1980s 18 companies in the USA, Japan, and Western Europe produced ~40 grades of Si_3N_4 powder, of which 35 were made by the direct synthesis method, 3 by the dissociation of the imide, and only one by the carbothermic and one by the gas-phase synthesis method.

An additional comment should be made concerning the specifications placed on the powders. Thus, the content of free silicon, which can be as high as 1%–2%, has to be specified.[25] High concentrations of free silicon are usually found in the powders prepared by nitridation of the silicon. In the prospectuses of the H C Stark Co. the quantity of free silicon in the H1, LC10, and LC12 grades is stated to be not more than 0.1 mass%. The content of metallic impurities is controlled in order to avoid the formation of vitreous phases, which seriously lower the high-temperature strength of silicon nitride materials at the grain boundaries. An associated requirement is the control of the oxygen content, but this effect is also influenced by the activation of the agglomeration process caused by the formation of a liquid phase, which we shall examine below. As was recently pointed out,[51] halogen impurities can also degrade the properties of the powders. In most of the commercial grades of silicon nitride the content of fluorine and chlorine is claimed to be 0.001–0.009 mass%.[36] The phase composition of the powders

has a marked influence on the microstructure of the sintered and hot-pressed materials. A predominance of the α-phase in the initial powders is thought to be the best composition.

Lastly, properties of UFP related to their agglomeration capacity have attracted special interest in recent development work on nanocrystalline materials.[15,35] The presence of agglomerates affects the formation in the structure of sintered materials of relatively large pores, which degrade the physicomechanical and other properties. More detailed formulations of the requirements on Si_3N_4 powders are continually being proposed, and therefore the data in Table 4 may have to be revised. We should also add that clear criteria for the agglomeration capacity of powders have not yet been formulated.

It follows from the above discussion that the chemical and the phase composition of silicon nitride powders possibly exert a dominant contribution to the final properties of the materials. Not surprisingly, therefore, the distribution of the components in the powders and the special properties of their surface layers continue to be studied in depth. We know that powder surfaces are usually enriched in oxygen; this effect is also seen[4] in Si_3N_4. The most successful recent studies of this type[48,51-57] used various methods of measurement: IR spectroscopy, X-ray photoelectron spectroscopy (XPES), Auger spectroscopy, and others. Szepvolgyi et al.[48] showed that no correlation existed between the overall chemical composition and the particle size of the powders (between 40 and 115 nm). The same workers observed an enrichment of the particle surface by carbon as well as by oxygen. The nitrogen was distributed more or less uniformly over the cross-section. The segregation of oxygen, fluorine, and carbon in the surface layer was observed also by other workers.[52,54-57]

Data on the oxygen content of the powders are of special interest. Possible sources of oxygen include the starting materials and substances specially added to facilitate the sintering process. The presence of oxygen can also be associated with special features of the preparation and pressing technology, and of the conditions under which the powders are stored and treated. In silicon nitride oxygen can be accommodated as so-called lattice oxygen (found in SiO_2 and in oxynitrides of variable composition, such as Si_2N_2O and complex SiAlON ceramics), and also in the composition of hydroxyl groups [$Si(OH)_x$ ($x > 2$)] with different degrees of hydration and of carbonate compounds. The presence of the last two forms was established by XPE spectroscopy.[54] The presence of oxygen in the adsorbed gases (CO, CO_2, water vapour) should also be noted. As reported,[48] the amount of oxygen in the surface layers is 2-20 times greater than in the bulk. According to chemical methods of analysis the oxygen content in the surface was 3-4 times greater than in the bulk.[57] According to calculations based on XPES data the N:Si ratio in the surface layers of powders supplied by the H C Stark company was 0.8-1.0, which differs markedly from the theoretical value of 1.63 but is almost indistinguishable from the value for the oxynitride Si_2N_2O.[58] The most uniform distribution of oxygen is found over the cross-section of carbothermic powders.[36,48]

The large segregations of carbon on the surface are also of interest: they can exceed the bulk content of carbon by a factor of several hundred.[48] The results of studies of the gas evolution during heating of the powders are of interest from this point of view.

The temperature and time dependences of the gas evolution from silicon nitride powders heated in high vacuum, prepared by the SHS method (with an oxygen content of 0.5%) are shown in Fig. 3. We note the dominant presence of carbon monoxide in the desorbed gases, whose evolution effectively ceases after 1.5 h annealing at 1000 °C. (The same treatment was applied to the Si_3N_4 powders to remove adsorbed and other gases before determining the dissociation pressure of the silicon nitride.) Gas evolution was studied also in other samples of Si_3N_4 powder (Table 5). As can be seen, the correlation between the total amount of adsorbed gases and the specific surface, though often observed, is not invariably followed. There is also no regularity in

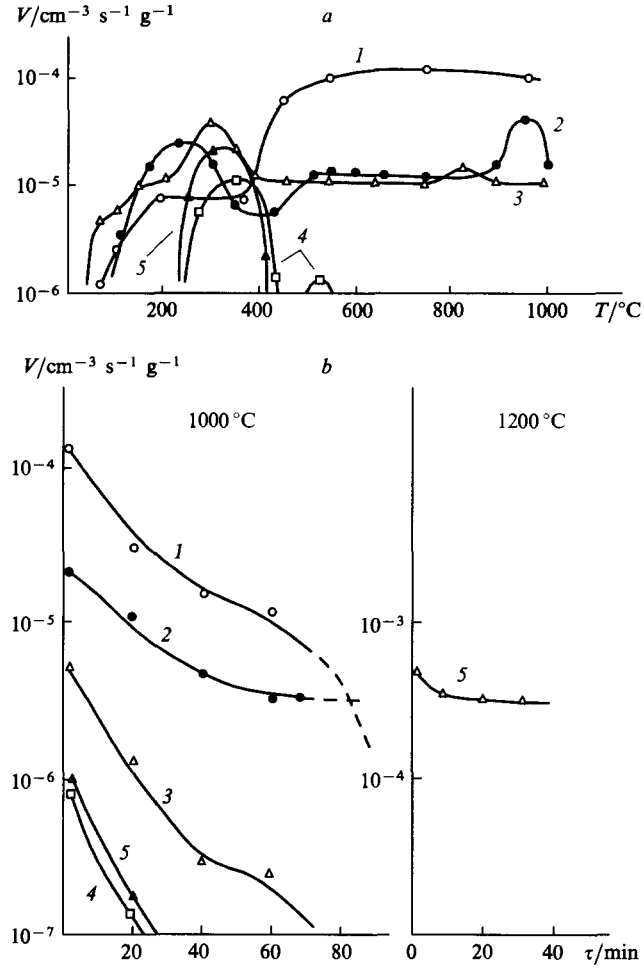

Figure 3. Temperature (*a*) and time dependence (*b*) of the rate of gas evolution during high-vacuum heating of a Si_3N_4 powder prepared by the SHS method.[59] (*1*) CO; (*2*) H_2; (*3*) N_2; (*4*) CO_2; (*5*) N_2.

the temperature at which the rate of gas evolution is a maximum. We know that silicon nitride undergoes hydrolysis when stored in insufficiently pure media. In powders heat treated in vacuum for 1 h at 1200 °C after brief exposure to the air a substantial decrease in the gas content was observed, the desorbed gases consisting mainly of CO.

Thus the results in Table 5 reflect not only the difference in grain size and in the general impurity level of the particles but also the difference between the storage conditions, which were markedly different in the powders listed in Table 4. The role of the storage conditions has been independently confirmed.[48] Whereas the overall level of impurity is determined mainly by the preparation technology, the distribution of the impurities over the cross-section of the particles is controlled by the conditions under which the powders are stored and subsequently handled.

It is important to note that in all the powders the predominant component of the desorbed gases is carbon monoxide (as was also observed, for example, in a study of the gas evolution from titanium nitride powders[63]). This effect can be correlated with the above mentioned segregation of carbon on the surface of the Si_3N_4 particles.[48,54,57] According to Vaivads et al.[54] the carbon can exist on the surface as carbonates and carboxyls.

Table 5 also shows that the temperature of the degassing heat treatment should be about 1000 °C for almost all the powders. However, it is not clear why the dominant species in the desorbed gas below 1000 °C is carbon monoxide, and not carbon dioxide, as could have been expected from the well known equilibrium of the Bell-Boudouard reaction.

[a] Q is the amount of gas evolved. [b] In the earlier work[60,61] (in contrast to Refs 59, 62, and 63), carbon monoxide and nitrogen were not distinguished in the mass spectroscopy determination of mass number 28. [c] This writer's results, obtained with the help of R A Lyutikov and V I Chukalin.

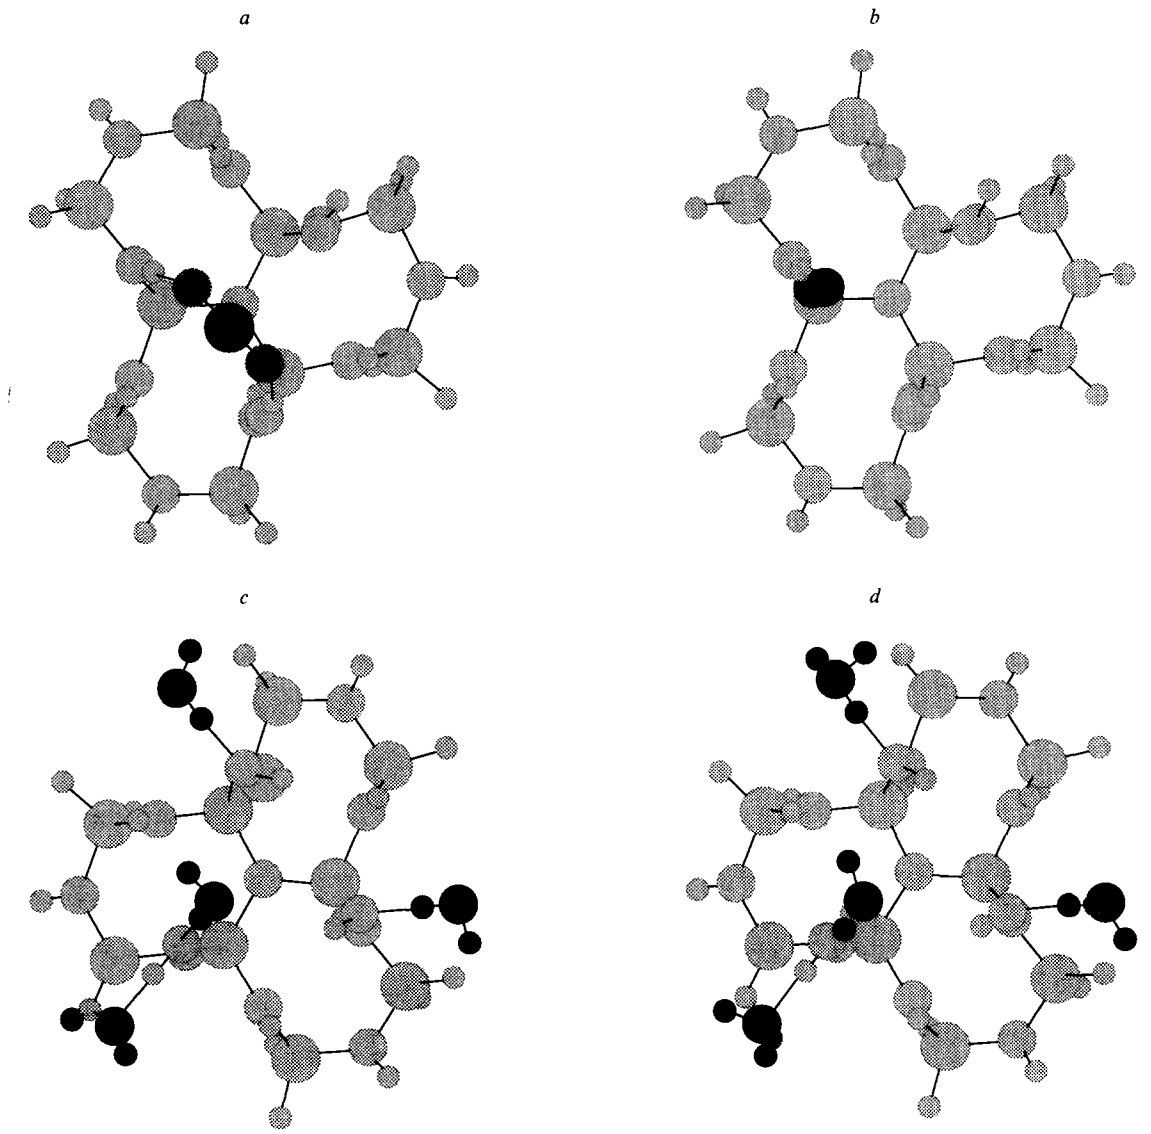

Figure 4. Schemes of the location (top view) of molecules of various adsorbates on the silicon nitride surface. (*a*) CO_2; (*b*) CO; (*c*) H_2O (4 molecules); (*d*) NH_3 (4 molecules). The adsorbate molecules are shown as filled circles. This figure was kindly supplied by N V Goncharova and E F Sheka.[66]

A complex picture of the structure of the surface layers of silicon nitride powders from different producers was observed in a study of these materials by the inelastic neutron scattering method.[64,65] An analysis of the spectra revealed the presence in the surface regions of the powders produced in a 'chlorine' plasma of adsorbed complexes of the NH_4Cl type, and also of NH_3 and HCl. In the case of powders produced by direct nitridation the presence of hydroxyl groups and water is suggested. Quantum-chemical calculations showed that silanol and silamine groups are the principal functional groups of the reaction centres on the surface.[66] Schemes of the proposed arrangement of CO_2, CO, H_2O, and NH_3 molecules on the silanol centres of the Si_3N_4 surface are shown in Fig. 4.

Other impurities also have been detected on the surface of Si_3N_4 and SiC particles: iron, aluminium, calcium, and sodium.[67] However, on the whole we must acknowledge the need for further systematic studies in this direction, using a range of modern methods and carefully standardised materials at all stages (preparation, storage, and applications of the powders).

We shall conclude our discussion of the powders by reexamining their relative costs. A figure of ~US $30 per 1 kg has been stated.[26] This was independently confirmed,[68] and a cost of $115 was quoted for 1 kg of UFP of Si_3N_4 ($d \approx 0.017$ μm) produced by laser synthesis. It was stressed that the main contribution (~96%) to the cost of the Si_3N_4 powders came from the cost of the silane. Thus the range $30–115 is typical of the cost of Si_3N_4 powders (including the UFP materials); for carbothermic powders it can be even lower than $30.

3. Consolidation

Consolidation processes (compaction, sintering, hot pressing, high-energy methods such as static or dynamic high pressures) are used to prepare silicon nitride materials having a prescribed density. In this context we must allow first of all for the covalent nature of the bonds in Si_3N_4, which accounts for the high brittleness, the high temperature of the brittle–ductile transition, and the low diffusional mobility of the material.

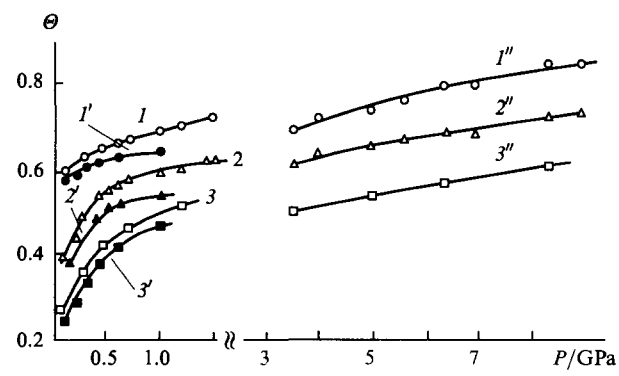

Figure 5. Pressure dependence of the relative density (Θ) in the compaction of Si_3N_4 samples of different granularity.[70] *1–3* compaction in the hydrostat; *1′–3′* compaction in standard dies; *1″–3″* compaction in high-pressure apparatus; *d*/μm: *1*, *1′*, *1″* 1; *2*, *2′*, *2″* 0.05; *3*, *3′*, *3″* 0.017.

Figs 5–7 show the results of a study of compaction over a wide range of pressure and temperature, and also of the sintering of Si_3N_4 powders.[61,69–73] As can be seen from Fig. 5, even at very high pressures (~9 GPa) samples with a relative density greater than 0.85 cannot be obtained at room temperature. The poor compressibility of Si_3N_4 is associated with a poor plasticity. In the case of UFP the limiting relative densities fall to 0.6–0.7 as a result of the negative effect of the interparticle friction. Only the use of combined high temperatures and pressures result in full densification, when the granularity effect of the powder is to a large extent suppressed (see Fig. 6). Sintering without the

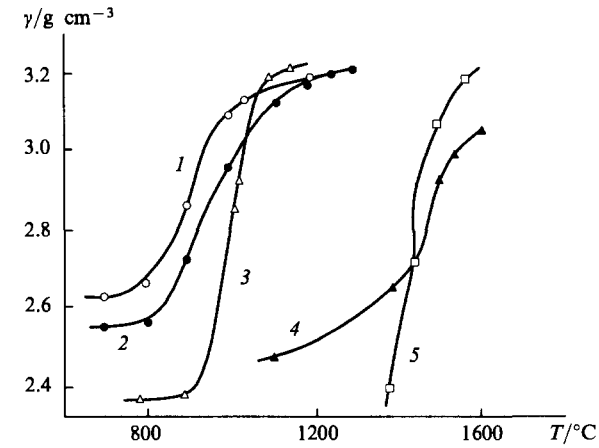

Figure 6. Effect of the compaction temperature and pressure on the density of Si_3N_4 powders of different granularity.[71–73] *d*/μm: (*1*) 1.1; (*2*) 0.75; (*3*) 0.05; (*4*) 0.45; (*5*) 0.08; *P*/GPa: (*1–3*) 8.5; (*4,5*) 3.

application of external pressure should produce a temperature of active densification greater than 0.85 T_m in silicon nitride as in other covalent solids (for example, boron and silicon) (see Fig. 7). This conclusion, previously formulated by me,[4,69,71] was recently confirmed by Kryl'.[74] It is interesting to note that whereas in powders of metals, alloys, intermetallics, and ionic compounds the transition to UFP is accompanied by a substantial lowering of the sintering temperature (see Fig. 7) in UFP with covalent bonds this effect is practically undetectable.

Because of the poor sintering properties of Si_3N_4 powders various oxides are added to them (Al_2O_3, MgO, Y_2O_3, singly or in combination) in order to form a liquid phase and thus to accelerate the sintering and hot pressing of the powders.[4] This artifice is used mainly in the hot isostatic pressing variant, which has been widely discussed (see, for example, Refs 69 and 75–79). The liquid phase is formed at high temperatures by the interaction between the added oxides and the films of silica and of oxynitrides present on the surface of the powder particles. The oxygen content of the initial powder plays a limiting role, and it is usually held at the 1%–2% level, though under these

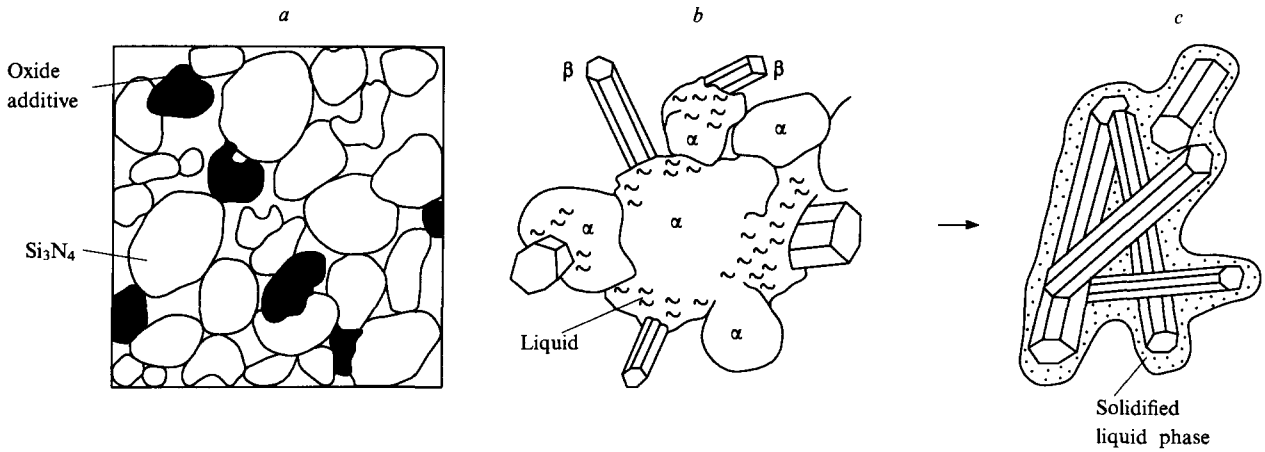

Figure 8. General scheme for the formation of a microstructure during the liquid-phase sintering of silicon nitride materials.[10] (*a*) initial powder; (*b*) α→β transformation; (*c*) microstructure of the densified sample.

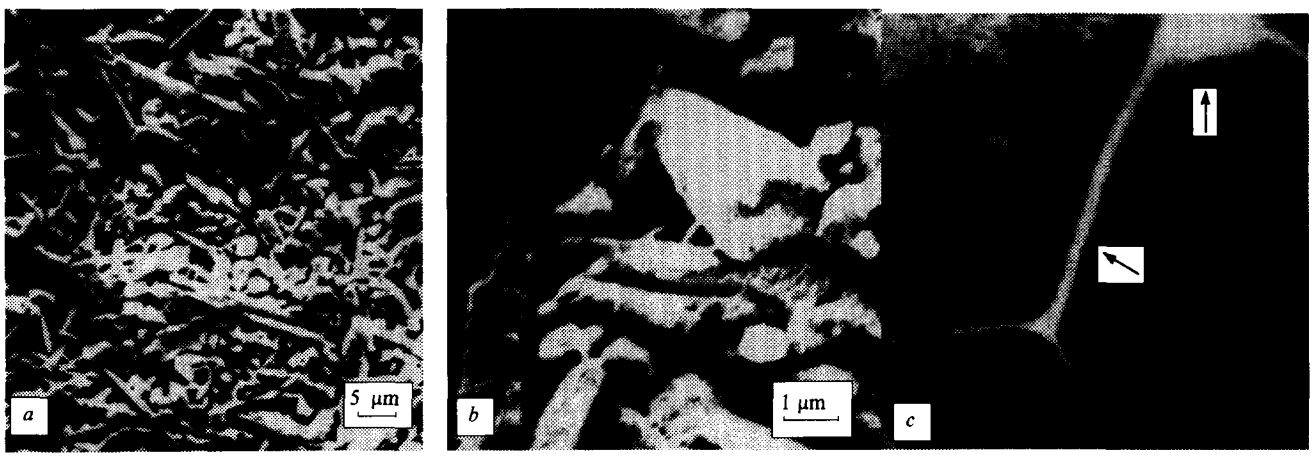

Figure 9. Microstructures of Si_3N_4 obtained in an optical (*a*), a scanning electron (*b*), and a transmission electron microscope (*c*).[10]

conditions the high-temperature strength and creep indices may undergo undesirable changes. Undoubtedly in this case the high-temperature consolidation is complicated by the dissociation of the silicon nitride. Consideration of the complex crystallographic processes associated with the crystallisation of the amorphous phases, the α→β transformation, and the crystallisation from the melts, and also for the normal shrinkage and recrystallisation during sintering and isostatic hot pressing, shows that the nature of the physicochemical mechanism of formation of the structure and properties of silicon nitride materials is far from being trivial.

The mechanism of the liquid-phase sintering and of the isostatic hot pressing has been analysed in many papers.[4,10,11,48,79–81] A general scheme of structure formation during liquid-phase sintering is shown in Fig. 8, while Fig. 9 shows real microstructures obtained by optical microscopy, scanning electron microscopy, and transmission electron microscopy.[10]

Suttor and Fischman[80] have quantified some features of the sintering mechanism. Fig. 10 shows the effect of temperature on the density and on the amount of β phase during the sintering of Si_3N_4 containing 10 mol% of (1:1) $Al_2O_3 + Y_2O_3$.[80] As can be seen from this figure, a significant change in density begins at 1400 °C (the temperature of the ternary eutectic in the $SiO_2-Al_2O_3-Y_2O_3$ system is 1350 °C). A relative density of 0.93 is reached at the temperature (T = 1650 °C), when the α→β transformation is only 23% complete. Microstructural studies of

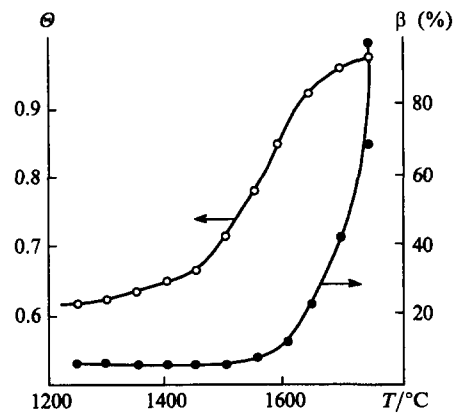

Figure 10. Effect of temperature on the relative density and on the content of β phase during the sintering of Si_3N_4 + 5% Al_2O_3 + 5% Y_2O_3 (see Ref. 80).

quenched samples showed that the characteristic columnar structure (elongated grains of the β phase, see Figs. 9*a* and 9*b*) is formed only during the closing stage of the sintering. Comparing the kinetic coefficients calculated from the experimental data with those of Kingery's theory of liquid-phase

sintering showed that under practical conditions a more complex mechanism must be postulated. NMR was used in a study[81] of the role of additives during sintering, which accounted for the distribution of the elements (^{29}Si, ^{27}Al, ^{25}Mg, ^{89}Y) in the different component phases.

The activating effect of additives of REE oxides (La_2O_3, CeO_2, and others) and of yttrium oxide drew attention to the possibility of finding an active influence on the formation of the so-called self-reinforced fibre structures and of increasing the strength and crack resistance parameters of the material at room temperature and above.[82-85] Thus, fracture toughness values K_{Ic} = 8–9 MPa $m^{1/2}$ have been obtained for the composition Si_3N_4 + 1% Al_2O_3 + 5% CeO_2, exceeding almost two-fold the normal values for silicon nitride materials.[82] The length of individual elongated grains in the structure of these compositions reached 40–50 μm. The bending strength (σ) at room temperature and at 1300 °C for the composition Si_3N_4 + 2% Al_2O_3 + 5% Y_2O_3, into which the additives were introduced by chemical mixing, was 1084 ± 49 and 722 ± 38 MPa respectively, which is also much higher than ordinary values. This effect is attributed to high-melting silicates, which are deposited at the grain boundaries in small quantities.[83] The following parameters have been reported[84] for hot-pressed Si_3N_4 + (8–10%) Y_2O_3 powders synthesised in a plasma: σ(20 °C) = 650–900 MPa, σ(1400 °C) = 550–780 MPa, K_{Ic} = 6–10 MPa $m^{1/2}$. Higher values were obtained for Si_3N_4 doped with oxides of the rare-earth metals: σ(~1500 °C) ≈ 800 MPa (see Takahashi et al.[85]).

Even from this brief survey it is clear that the concepts of grain boundary engineering are of great importance in the development of silicon nitride materials: this is a relatively new area in materials science,[86] which is only now beginning to be applied to silicon nitride. Some aspects of the recrystallisation of silicon nitride have been analysed in detail.[87,88] TEM was used[89] to examine the behaviour of the Si_3N_4 structure at high temperatures and pressures (T = 1300–2300 °C, p = 7.7 GPa). The development of plastic deformation with formation of a high density of dislocations and fragmentation of the larger grains was observed (at T = 1300–1500 °C), and also dynamic recrystallisation, produced both by the migration of grain boundaries and by the rotation of fragments (at T > 1500 °C). The formation of a microstructure is completed by collective recrystallisation, which proceeds rapidly at 2100–2300 °C.

Several studies of the crystallisation of amorphous Si_3N_4 have been published.[36,90-94] Fig. 11 shows the kinetic plots for the crystallisation of the α phase as equiaxial grains from an amorphous powder prepared by the ID method.[36] The calculated activation energy of the process was 890 kJ mol^{-1}. As can be seen from the figure, the crystallisation of Si_3N_4 is completed at 1440 °C. At higher temperatures we observe the formation of the α phase as needle-like grains, and carrying out the process under high nitrogen pressures (up to 100 MPa), at which gas-transport reactions are suppressed, shifts the temperature of the incipient formation of needle-like grains to the region of 1800–2000 °C.[91] Under high-pressure conditions the crystallisation of amorphous Si_3N_4 sets in at lower temperatures: ~800 °C at P = 5 GPa.[90] During sintering and hot pressing the amorphous powders are more inert than the crystalline powders: their active densification temperatures are shifted into even higher temperature ranges, but this effect is almost completely compensated by the use of activating oxide additives.[90,92] The crystallisation of a mixture of amorphous ultrafine powders of Si_3N_4 + SiC begins at 1500 °C and is completed at 1600–1700 °C, i.e. at higher temperatures than for the undoped silicon nitride.[94]

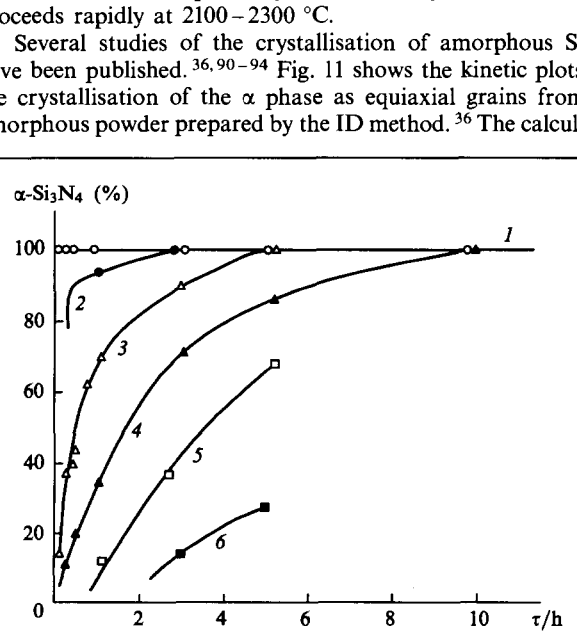

Figure 11. Kinetics of the crystallisation of α-Si_3N_4 from an amorphous powder prepared by the ID method.[36] T/°C: (*1*) 1440; (*2*) 1430; (*3*) 1420; (*4*) 1400; (*5*) 1385; (*6*) 1360.

Studies of the consolidation of Si_3N_4 by the shock compaction method have been reported.[95-97] It is claimed that samples with a relative density of 0.99 were obtained from powders of SN-E10 grade (see Table 3) at pressures of ~40 GPa and temperatures of ~1200 K; their hardness was H_V ~ 23 GPa, and their grain size (calculated from TEM data) was 50–60 nm.[97] The suggested densification mechanism includes plastic deformation and surface melting of the particles.

In conclusion we should note one of the earliest methods of consolidation of silicon nitride materials: reactive sintering. However, this method is rarely studied at present because it does not produce high-density articles. We shall only refer to one report[98] of the use in reactive sintering of fine silicon powders prepared by the laser treatment of silane, which markedly shortened the time of the process.

A relatively new method (infiltration by chemical deposition from the vapour phase, 'chemical vapour infiltration') has not yet found extensive application in the preparation of silicon nitride because of the presence of residual porosity in the final product and because of phase interactions. The use of this method to prepare composite materials of the graphite fibre–silicon nitride type has been reported.[99]

III. Films, coatings, and layers

Both chemical (CVD) and physical (PVD) methods of deposition from the gas phase are used, in different variants, to produce silicon nitride films, coatings, and layers. SiF_4 (or SiH_4, $SiCl_4$)–NH_3–H_2 mixtures are most commonly used. The thermodynamics and kinetics of the deposition of thin layers (up to ~1 μm) of Si_3N_4 have been discussed in monographs[3,5] from the standpoint of problems in microelectronics. Japanese workers[4,100] obtained coatings and layers of polycrystalline and of monocrystalline (as well as amorphous) Si_3N_4 up to 3–4.5 mm thick by deposition from $SiCl_4$–NH_3–H_2 mixtures onto graphite substrates at 1200–1500 °C. Fig. 12 shows the effect of the total gas pressure on the temperature limits of the deposition of the above forms of silicon nitride.

In recent years chemical deposition has been carried out mainly in a high-frequency plasma discharge: the main variants are called plasma assisted and plasma-enhanced CVD processes (PACVD and PECVD respectively). The effect of the power of the high-frequency (13.56 MHz) discharge on the thickness of the coating deposited from a SiF_4–NH_3–H_2 mixture has been studied.[101] The increase in thickness was substantial: at a power of 400 W the thickness increased by more than 50% and reached 700 μm. This result can be explained in terms of the increase in the electron temperature produced by the increased power of the plasma. A high electron temperature increases the rate of dissociation of the gas molecules characterised by a high bond energy, thus increasing the concentration of the corresponding free radicals. Since the bond energy of the SiF_4 molecule (~600 kJ mol^{-1}) is much higher than the bond

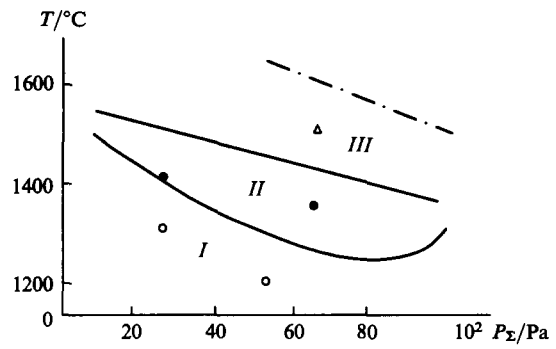

Figure 12. Regions of existence of amorphous (*I*), polycrystalline (*II*), and monocrystalline deposits (*III*) of Si_3N_4 (see Ref. 100). The points denote some specific regimes used to prepare amorphous or polycrystalline samples of size 10 × 40 × 1(3) mm and single crystals 2–3 mm long. The broken line shows the upper limit of the possible formation of deposits. P_Σ is the total pressure of the mixture of gases ($SiCl_4$ + NH_3 + H_2).

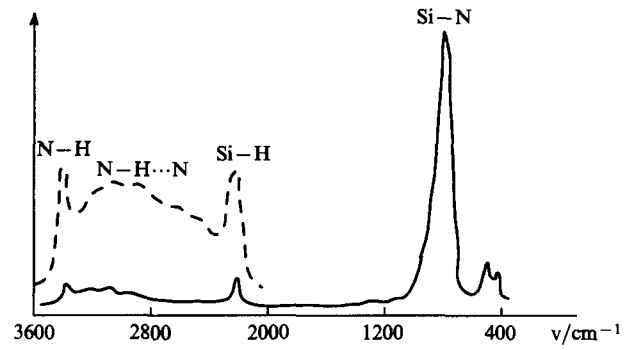

Figure 13. IR spectra of a film of Si_3N_4 0.8 μm thick prepared by PECVD at 293 K (see Ref. 105).

energy of NH_3 (~435 kJ mol^{-1}) it is assumed that the relative number of radicals containing silicon is higher in PECVD.

The optimisation of the regimes used in the deposition of Si_3N_4 films from SiH_4–NH_3–N_2–H_2 mixtures under PECVD conditions has been examined.[102,103] In particular, it was shown that when the power of the high-frequency discharge is increased the residual stresses in the films change sign and are converted from tensile (up to ~270 W) into compressive stresses (>270 W); hydrogen in the gas phase has a similar effect. Table 6 shows the results of an analysis of the composition of films prepared under different conditions.[103] The width of the forbidden gap (E_{gopt}), one of the most important characteristics of these films when used as isolating elements in semiconductor devices and in thin-film field effect transistors in liquid-crystal display systems, is also given in Table 6. As can be seen, the Si:N ratio, the concentration of hydrogen in the films, the presence of Si–Si bonds, and the E_{gopt} parameter show a complicated dependence on the power of the discharge and on the composition of the gas mixture. The use of stoichiometric nitride films, deposited under conditions of minimum residual compressive stress, is recommended.

Problems of hydrogen and other impurities in films of Si_3N_4 have a long history. Many different methods have been used to characterise the films: IR spectroscopy (in different variants), XPES, Auger spectroscopy, RBS, Raman spectroscopy, etc.[3,5,102–105] Fig. 13 shows the IR spectrum of a film of Si_3N_4 deposited from a SiH_4–NH_3–N_2 mixture at 293 K in the plasma of a high-frequency discharge (450 kHz).[105] The peaks at 825, 2215, 3000, and 3400 cm^{-1} correspond to the vibrations of the Si–N, Si–H, N–H...N, and N–H bonds. Traces of oxygen and carbon (~1 at.%) were detected in these films by Auger spectroscopy. IR and XPE spectroscopy methods were used to study the composition of SiN_xC_y coatings prepared by deposition from an $SiCl_4$–CCl_4–N_2–H_2 mixture at 1100–1700 °C onto a tungsten filament.[104] It was found that under these conditions (for example, at a deposition temperature of 1185 °C) the composition of the coatings corresponds to the formula $SiN_{0.8}C_{0.2}$, and that silicon carbide, silicon, and silicon nitride are undetectable.

The thermodynamics of the deposition of condensed phases in the Si–N–C–H system at temperatures up to 2800 K have been discussed by Varlamov et al.[106] It was shown that 'pure' silicon nitride (without codeposition of other condensed phases) is formed in the presence of an excess of nitrogen (N:Si>1.5) at relatively low temperatures ($T < 1100$ K). The regions of coexistence of different phases for C:Si = 4 and H:C = 225 are shown in Fig. 14. The thermodynamics of the formation of Si_3N_4 in the Si–N–Cl–H system have been analysed by Kruis et al.[37]

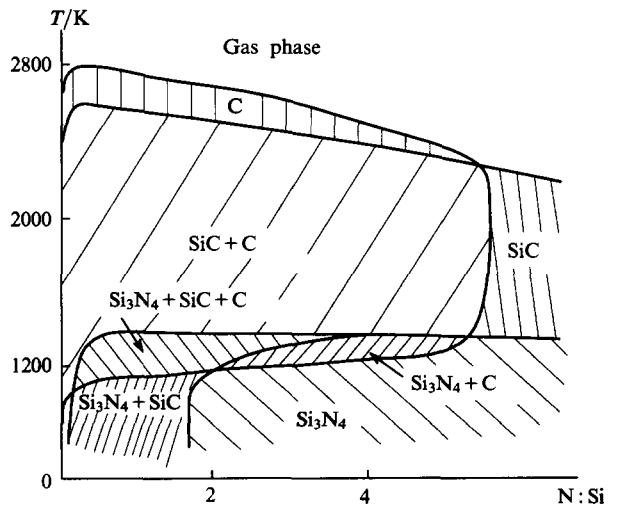

Figure 14. Regions of existence of condensed phases in the Si–N–C–H system with C:Si = 4 and H:C = 225 (total pressure 10^5 Pa).[106]

Table 6. Results of analyses of amorphous films of Si_3N_4 by Rutherford back scattering (RBS) and XPE spectroscopy methods.[103]

Deposition regime		E_{gopt}/eV	Si:N (from RBS data)	Concentration of components (XPES) (at.%)		
W/W	H_2:H_2+N_2 (%)			Si_3N_4	SiNH	Si–Si
100	100	4.1	0.98	76	13	11
400	100	5.6	0.78	76	15	9
300	50	5.3	0.90	85	5	10
300	0	5.3	0.75	90	0	10

Various PVD methods have also been actively applied to the preparation of silicon nitride films. They include a.c. and d.c. sputtering (in different variants), ion-beam deposition (including ion implantation), etc.[107-112] Si_3N_4 films prepared by d.c. sputtering have a columnar structure.[110] The effect of oxygen on the composition and properties of films prepared by r.f. sputtering was analysed by Volkov and Satunkina.[112] A new theory of ion-beam deposition (or ion beam assisted deposition, IBAD) identifies the effect of various technological factors on the composition and certain other properties of silicon nitride films prepared by evaporating silicon and bombarding the amorphous films with nitrogen ions.[109]

IV. Structure and properties

1. Crystal structure and nature of the bond

The crystal structure and the nature of the bond in silicon nitride have been discussed in detail by many workers (see, for example, Refs 3-5 and 10), and therefore we shall dwell on them only in the most general terms, mentioning some new results.

As we know, silicon forms only one chemical compound with nitrogen: Si_3N_4, which exists in two modifications (α and β). Silicon nitride crystallises in the trigonal (α) and the hexagonal crystal system (β). The crystals have identical structures of the Be_2SiO_4 type (phenacite). The main structural element in silicon nitride, as in many silicates, is the tetrahedron 'SiN_4'. A set of three of these tetrahedra share a common nitrogen atom, being arranged with angles of 120° between the tetrahedra. The structures of the α and β modification differ in the arrangement of the tetrahedra along the *c* axis, and therefore they contain different numbers of formula units in the unit cell. The structure of silicon nitride and its main parameters are shown in Fig. 15 and Table 7.

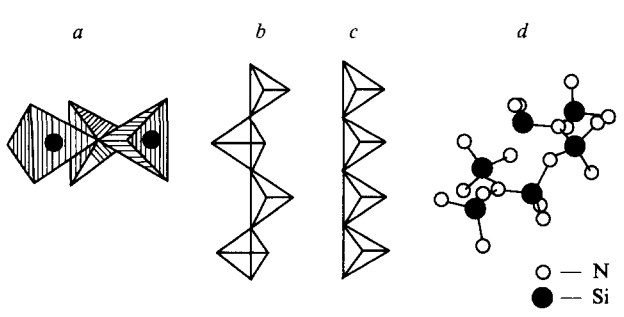

Figure 15. Structure of silicon nitride.[4] (*a*) group of three 'SiN_4' tetrahedra; (*b*) scheme of the arrangement of tetrahedra along the *c* axis in the α phase; (*c*) ditto in the β phase; (*d*) unit cell of β-Si_3N_4.

The special aspects and the mechanism of the α→β transformation have been widely discussed in the literature.[4,10,11,113] It was shown that only the α→β transition is possible: the reverse transition does not take place. This indicates a monotropic transition, and shows that the α→β transition can be classified as a transformation in the second coordination sphere, in which the mutual location of groups of atoms (tetrahedra) is changed but the structure within these groups stays unchanged. A calculation of the Madelung energy showed that above $T = 293$ K the β phase is more stable than the α, which again confirms the monotropic nature of the α→β transformation.[114]

The temperature and the detailed aspects of the α→β transition are still not entirely clear: we know, for example, that heating α-Si_3N_4 samples prepared by gas-phase deposition does not induce the transition at temperatures below 1800 °C.[4] It was pointed out[46] that hot isostatic pressing of the α single crystals at 1600 (P = 5 GPa) and at 2200 °C (P = 70 MPa) is also not accompanied by an α→β transformation. At the same time additions of oxides (MgO, Al_2O_3, Y_2O_3, and others) to activate the sintering and hot pressing processes (see Fig. 10) activate also this transformation as a result of liquid-phase crystallisation. An intensification of polymorphic transformations as a result of dissolution-deposition processes in the presence of a liquid phase is also characteristic of transitions of the rearrangement type in the second coordination sphere. Lastly, under high-pressure conditions (8.5 GPa) the α→β transformation begins at 800 °C and is completed at 1200 °C.[61,115] As was stated above, high pressures also lower the crystallisation temperature of amorphous silicon nitride.[90] However, on the whole we should stress the need for further studies in this area. The structure of amorphous films has been discussed in monographs.[3,5]

NMR is an effective method of localising various structural states and of producing a phase analysis of Si_3N_4, especially if the sample is rotated through the so-called magic angle.[81,116] Its main advantage over the traditional X-ray phase analysis (XPA) is the possibility of identifying not only the crystalline modification but also the amorphous phase, and of localising the position of the other elements (^{13}C, ^{15}N, ^{25}Mg, ^{27}Al, ^{89}Y, ^{189}La), as was stated above in the context of the sintering problem. Fig. 16 shows the forms of the ^{29}Si NMR spectral lines for the different modifications of silicon nitride.[116] As can be seen the NMR method offers information on both the α and the β modification, as well as the amorphous phase.

Though the covalent or covalent-ionic character of the bonds in silicon nitride has long been recognised, a clarification of the details of the electronic structure of this compound remains a topic for discussion.[117-121] Fig. 17 shows a general scheme of the transformation of the atomic orbitals of silicon and nitrogen during the transition to the electronic states of silicon nitride.[119] The conduction band is formed mainly from the 3*s* and 3*p* states of the silicon, and the *s* and *p* states of the nitrogen give rise to the valence band. Of course, this is a simplified picture of the electronic structure of silicon nitride, whose details are being determined by quantum-chemical calculations and by an experimental study of the emission and absorption spectra by various methods (XPES and others). The results of a calculation of the density of states in Si_3N_4 by the tight binding approximation and the corresponding spectroscopic data are shown in Fig. 18. The electronic structure of Si_3N_4 is controlled mainly by the local short-range order, and therefore the α and the β modification and the amorphous phase have almost identical pictures of the density of states. According to quantum-chemical calculations[119] the width of the optical gap is 5.3 eV, which is fairly close to the experimental results (see Table 6). The constitution and the electronic structure of the Si-H and N-H bonds and the defect states in amorphous silicon nitride films (α-SiN_x:H) have been

Table 7. Crystal structure and density parameters of Si_3N_4 (see Ref. 4).

Modification	Space group	Lattice parameters/nm			Length of Si-N bond/nm	Number of formula units in cell	X-ray density/g cm^{-3}

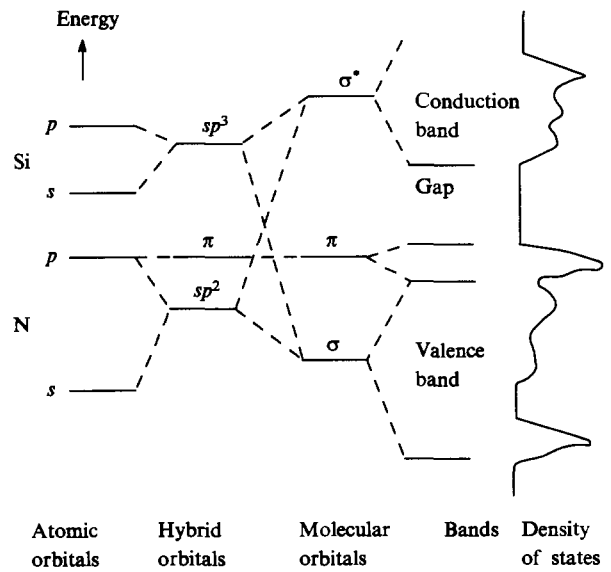

Figure 17. Scheme of the transformation of the atomic orbitals of nitrogen and silicon into the band structure of Si_3N_4 (see Ref. 119).

studied in depth.[119-121] The contribution of the ionic component to the bond energy of Si_3N_4 was estimated to be between 30% and 50%.[114,119]

Calculations of the band structure in β-Si_3N_4 and in the hypothetical compound β-C_3N_4 have been reported.[118] In silicon nitride the crystal structure parameters and the bulk elastic modulus based on these calculations were satisfactorily consistent with experimental data. A substantial amount of charge transfer towards the nitrogen atoms and a higher ionicity contribution were also observed in Si_3N_4 as compared with SiC and C_3N_4.

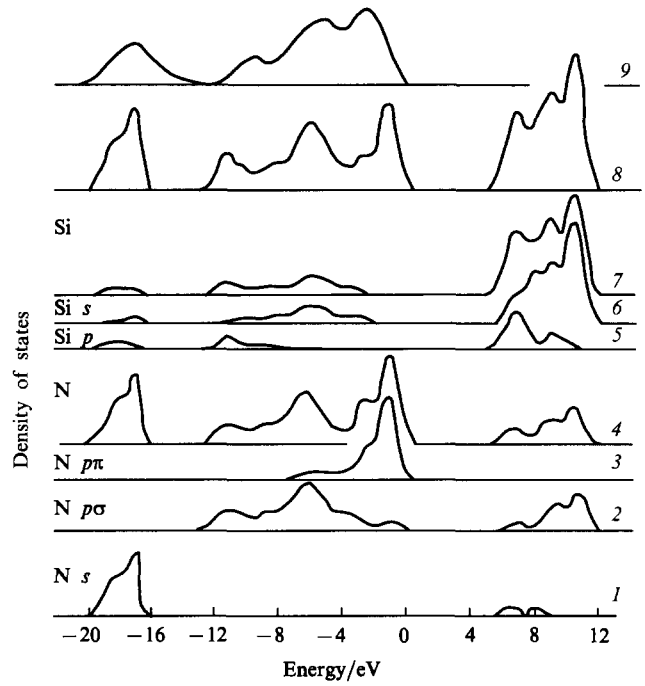

Figure 18. Calculated partial (*1*-*7*) and total (*8*) densities of states for β-Si_3N_4, and results obtained by the photoemission method (*9*) for amorphous films.[119]

2. Phase equilibria and physicochemical properties

The silicon-nitrogen phase diagram has been known for more than 30 years, and very few changes have been made during this period. Fig. 19 shows the diagram calculated for a pressure of 10^5 Pa.[122] Unfortunately, variants of this diagram for pressures above 10^5 Pa have not been produced. For a long time the melting point (T_m) of silicon nitride was given as ~1900 °C in standard handbooks, this being the temperature at which the dissociation pressure of the compound reaches ~10^5 Pa.

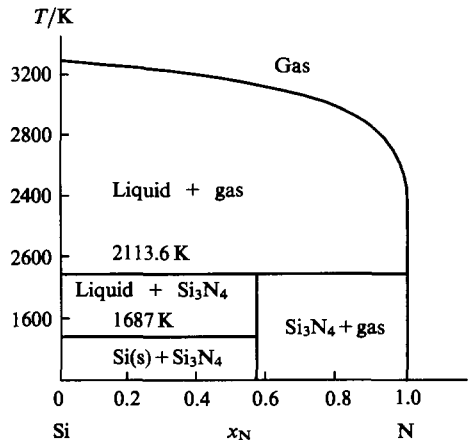

Figure 19. Silicon-nitrogen phase diagram calculated for a pressure of 10^5 Pa (see Ref. 122).

An attempt to determine the melting point was made by me earlier.[4,69,123,124] A value of $T_m \approx 2600$ °C was obtained by using the correlation between the melting point and the elastic modulus. An analysis of the diffusional mobility in silicon carbide and silicon nitride gave a similar value ($T_m \approx 2700$ °C). An analysis of data on the sintering of Si_3N_4 (see Fig. 7) suggested an intermediate value of T_m (2650 °C), which led to fully acceptable results.

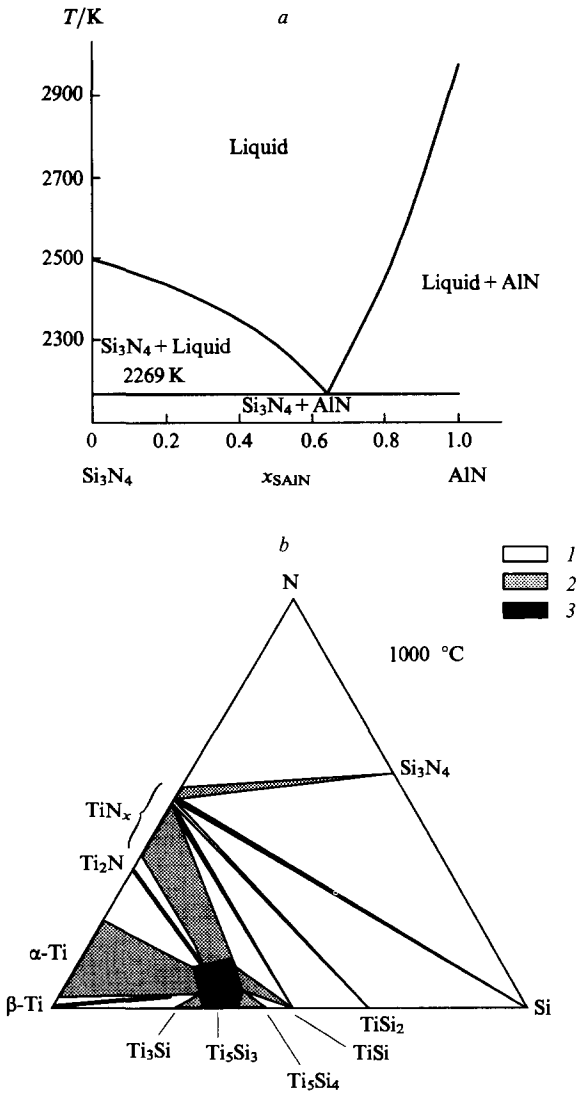

Figure 20. Calculated phase diagrams for Si_3N_4 + AlN (*a*) and Ti–N–Si (*b*).[122,133] Regions in the isothermal section: (*1*) three-phase; (*2*) two-phase; (*3*) region of existence of Ti_5Si_3.

Other workers adopted the following values of T_m in calculations of the phase diagram and of the isostatic hot pressing diagrams: ~2400 °C;[125,126] ~2330 °C;[122,127] 2564 °C.[78] It was pointed out[127] that the value $T_m \approx$ 2330 °C was calculated by comparing the properties of BeO and ZnO (see Weiss's thesis[128]). The entropy of melting of Si_3N_4 was given as 80.5 J K^{-1} mol^{-1}. An experimental determination of the melting point of Si_3N_4 under high nitrogen pressures showed that in the pressure region 120–198 MPa this parameter varies between ~2290 and ~2500 °C, and that the melting is incongruent.[129] Thus our estimates of T_m have been confirmed on the whole, but the need for further and more exact experimental determinations of the melting point has not disappeared.

Information on the phase diagrams of Si_3N_4 can be found in many publications (for example in Refs 4, 122, 125–128, 130–134). Computational methods are now widely applied, and have been used (for example) to construct the diagrams for Si–N–O (see Refs 126 and 130), Si–C–N–O (see Refs 130 and 131), Si–Al–N (see Refs 122 and 125), Si–M–O–N, where M = Al, Mg, Y, Ce, Ti (see Refs 130, 132, 133), and others. The regions of existence of the condensed phases in the Si–N–C–H system were shown above in Fig. 14.[106] In Fig. 20 we show as an example the Si_3N_4–AlN (see Ref. 122) and Ti–N–Si diagrams (see Ref. 133), calculated ignoring the gas phase (whose role, however, is substantial in the first of these systems). Experimental data on the polythermal sections of these and other diagrams for systems including Si_3N_4 are few.

Until recently data on the dissociation of silicon nitride were mostly inferred from results obtained at relatively low temperatures (up to 1500–1700 °C). In the writer's laboratory this temperature was increased to 2000 °C, and the samples included powders prepared by DS, GS, and SHS methods (see Table 4).[58,59,62,135] In Table 8 we show some of the results obtained in this way; Fig. 21 illustrates the temperature

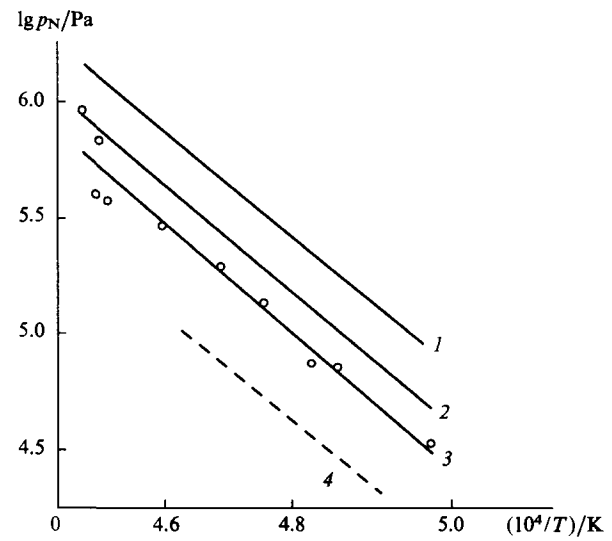

Figure 21. Temperature dependence of the dissociation pressure of silicon nitride. (*1*) GS powder (see Table 8); (*2*) DS powder; (*3*) SHS powder;[58,59] (*4*) from Ref. 136.

Table 8. Thermodynamic properties of silicon nitride.

dependence of the dissociation pressure of silicon nitride. The effect of the composition of the powders, and in particular of the oxygen content, on the dissociation pressure is evident. Some results published more than 30 years ago [136] and included in most of the standard handbooks [137,138] were obtained in a manometric study of the monovariant equilibrium in the $Si-Si_3N_4-N_2$ system using pure components (99.95% Si, and Si_3N_4 in the form of a nitrided layer with a purity of 99.94%) at nitrogen pressures up to 10^4 Pa. The results of our experiments on the determination of the dissociation pressure by using powders were higher, which we attribute to the effect of oxygen though the detailed mechanism of this effect is not yet clear. This is because before the determination of the dissociation pressure all the powders were degassed to remove adsorbed gases (see Fig. 5 and Table 3), i.e. a substantial part of the oxygen was eliminated. However, the proportion of remaining (lattice) oxygen and its distribution in the surface layers and in the bulk of the particles, and therefore the mechanism of the effect of oxygen on the dissociation pressure, need to be more accurately determined.

It should be noted that no singularities associated with the $\alpha \rightarrow \beta$ transition can be seen in the $\lg p_N = f(T)$ plots, probably because of the close similarity between the thermodynamic properties of these modifications. The results of the determination of the dissociation pressure (see Fig. 21) also suggest that more attention should be paid to the oxygen content in the determination of the melting points and the ignition temperatures in the $Si-N_2$ system (see the already mentioned reports, [21,129] and Figs 1 and 2), because it can affect the dissociation pressure by a substantial factor and erroneously identify the character of the melting.

Values of the enthalpy and of the Gibbs free energy of formation of silicon nitride are shown in Table 8. The values of $\Delta_f H_{298}$ were calculated by the writer by the second and the third law of thermodynamics from data on the dissociation of Si_3N_4. As we know, the agreement between $\Delta_f H_{298}$ values calculated in this way and their closeness to independently obtained calorimetric data confirm the validity of the evaporation or dissociation effects. Only one paper [139] on the calorimetric determination of the heat of formation of Si_3N_4 ($\Delta_f H_{298}$ = 787.8 kJ mol^{-1}) has been published so far. Thus our results appear to be reasonably good, though the need for further studies is evident.

Values of the specific heat and entropy, and also of the thermodynamic functions of silicon nitride over a wide range of temperatures have been reported, [140,141] but no allowance was made for the purity of the samples.

The self-diffusion parameters of silicon nitride have been studied in several laboratories. [142-145] These results are shown in Table 9. The higher diffusional mobility in the β phase as compared with the α phase is noteworthy. The practical problems met in the study of diffusional processes in silicon nitride were analysed by Kunz et al. [144] Comparing the results obtained by different workers [145] reveals a difference of 2-4 orders of magnitude in the absolute values of D. A TEM study of dislocation loops [146] gave an estimate of the diffusion coefficient of the vacancies of $\sim 10^{-18}$ $m^2 s^{-1}$ (T = 1700 °C), which is more than 5 orders of magnitude greater than the value of the same coefficient obtained [142] by extrapolation to this temperature. Therefore the need for further detailed studies of the self-diffusion over a wide range of temperatures and using monocrystalline samples is obvious.

Problems of oxidation and corrosion resistance in silicon nitride materials have recently achieved prominence, and call for a special discussion. Related problems are dealt with in several monographs, handbooks, and reviews, [147-152] and we shall only briefly mention these sources. It should be noted that materials based on Si_3N_4 have undergone substantial corrosion when under stress, and that both tensile and compressive stresses can influence the oxidation processes. [152,153] It is also evident that the dissociation and the oxidation of silicon nitride at high temperatures are two factors which seriously limit the application of materials of this type above 1500-1600 °C. [154] Therefore further studies of the high-temperature thermodynamics of Si_3N_4 in conjunction with corrosion tests under the same conditions, including the development of satisfactory coatings, are urgently needed.

Data on the contact angles and on the energy parameters of wetting of silicon nitride materials by liquid metals and alloys have been reported. [4,147]

3. Physicochemical aspects of the high-temperature strength

Some information on the mechanical properties and structure of silicon nitride has already been given above in the discussion of the consolidation of these materials (see Figs 8 and 9). More detailed information on the physico-mechanical properties can be found in various monographs, handbooks, and reviews, [4,6-12,155-158] in addition to the many original papers in scientific journals, and therefore a complete analysis of this problem goes beyond the scope of the present review. Some of the characteristics obtained recently for single crystals of the α modification are listed in Table 10. [44-46] As can be seen, some properties of the single crystals have been redefined and made more specific, [45,46] though it should be noted that the results of Ref. 45 apply to thin fibres.

Table 9. Parameters of the self-diffusion in silicon nitride.

T/°C	Component	D_i/$m^2 s^{-1}$ (see [a])	Method	Notes	Ref.
1200-1410	Nitrogen	$1.2 \times 10^{-16} \exp(-233.2/RT)$ $6.8 \times 10^{2} \exp(-777.5/RT)$	Isotope exchange	α-Si_3N_4 β-Si_3N_4	142
1230-1450	Nitrogen	$2 \times 10^{-15} \exp(-132.7/RT)$ $4 \times 10^{-4} \exp(-212.8/RT)$	Nuclear microanalysis	Bulk diffusion in the β phase Grain boundary diffusion in the β phase	143
1400-1600	Silicon	$(0.45-2) \times 10^{-19}$	Spectrometric analysis	α-Si_3N_4	144
900-1300	"	$6 \times 10^{-10} \exp(-183/RT)$	Processing of data obtained by hot isostatic pressing	Effective grain boundary diffusion in (α+β)-Si_3N_4	145

[a] The activation energy is given in kJ mol^{-1}.

Table 10. Some physicochemical characteristics of α-Si_3N_4.

Parameter	Value[a]	Ref.
Young's modulus, GPa	550–750	45
	(380)	44
Tensile strength, GPa	30–50	45
	(3–11)	44
Temperature of the transition from the brittle to the ductile state, °C	1760–1820 (> 1800)	46
Slip system at 1820 °C	$\{1\bar{1}01\}\langle 11\bar{2}0\rangle$ ($\{1\bar{1}01\}[0001]$)	46
K_{Ic}/MPa $m^{1/2}$	1.5–2.0	46
H_V $[P = (2-5)H]$/GPa	34 ± 5 $\{1\bar{1}00\}$	
	(32–36)	
	26 ± 5 (0001)	
	(26–28)	46

[a]The values shown in parentheses are known for single crystals and polycrystals,[4] and also for whisker crystals.[44,46]

The temperature dependence of the hardness for two crystallographic planes is shown in Fig. 22. For the (0001) plane these results are similar to those reported earlier.[100] The high values for the $(1\bar{1}00)$ and $(11\bar{2}0)$ plane denote a substantial anisotropy of the hardness. Furthermore the high-temperature hardness values for monocrystalline Si_3N_4 are much greater than those for polycrystalline and for amorphous samples, even ignoring the values for silicon nitride containing oxide impurities.[77,100,158,159] At 1400–1500 °C the hardness of silicon nitride exceeds that in all the data previously reported for other substances, as was first pointed out by Niihara and Hirai.[100]

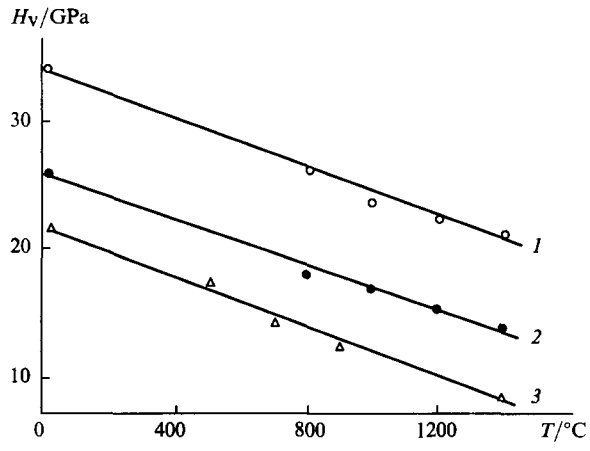

Figure 22. Temperature dependence of the hardness for the $\{1\bar{1}00\}$ (*1*) and (0001) (*2*) of a single crystal,[46] and for a sample of Si_3N_4 containing 2–4.6 mass% of O (*3*).[159] Data for relationships (*1*) and (*2*) were kindly supplied by I E Reimanis.[46]

In this section we shall confine ourselves to an analysis of only a limited number of the physicochemical aspects of the high-temperature strength, in view of the wide range of possible applications of Si_3N_4 in high-temperature technology. In this context problems of impurity effects are of major importance.

It has long been recognised that the presence of oxide additives, introduced in order to activate sintering and hot pressing processes, is accompanied by the formation of liquid interlayers during heating, which in its turn leads to a substantial lowering of the strength indices at temperatures above 1100–1200 °C. The formation of silicate or oxide nitride phases at the grain boundaries and at triple joints has been established by electron microscopy (see Fig. 9).[10] Analyses of the effects of various additives (MgO, Al_2O_3, Y_2O_3, SiO_2, SiC, and REE oxides) on the high-temperature and other properties have been reported by several workers (see, for example, Refs 4, 76, 85, 160–165). We can distinguish at least two approaches to improving the high-temperature behaviour. Firstly the use of silicon nitride powders without oxide additives,[51,77,160,163,166] and secondly the use of a special doping designed to avoid the formation at grain boundaries of vitreous low-melting phases and to encourage the formation of high-temperature crystalline compounds (see, for example, Refs 56, 85, 165).

In a high-temperature study of the strength, rate of propagation of subcritical cracks, elastic modulus, and internal friction it was shown that silicon nitride without added oxides can retain its mechanical properties up to 1450 °C.[51,77,166] It was also pointed out that calcium and halogen impurities play an important role in the high-temperature degradation of the strength, and that the presence of these impurities affects the crystallisation and the behaviour of the silicate phases.

As was pointed out above, oxygen impurities are invariably found in silicon nitride powders. It was shown[85] that samples of Si_3N_4 containing 3.4 mass% of oxygen (in which the oxide nitride Si_2N_2O was detected by XPA in addition to the α phase) retained their strength at the level of ~600 MPa at 1600 °C. However, the microstructure of these samples did not contain the characteristic columnar β crystals (see Figs 8 and 9), and the overall level of strength and crack resistance in this case (as also found by other workers)[51,77,166] was low. According to one report[165] substantial additions of yttrium oxide (up to 15–18 mass%), like additions of other REE oxides,[85] improve both the level and the retention of the strength: at 1400–1500 °C we have σ = 800–850 MPa, the fracture surface being characterised by transgranular features and the K_{Ic} value reaching 13 MPa $m^{1/2}$. These high indices are associated with the formation of a complex Y–Si oxynitride having a high melting point (1850 °C) and with the formation of columnar crystals 7–10 μm long and having a diameter of 0.2–0.7 μm. It is also interesting to note that according to microprobe measurements the distribution of yttrium in the structure was uniform.

The findings mentioned above offer only an empirical outline of new developments in heat-resisting silicon nitride materials. Other data include the effect of the surroundings on the mechanical properties,[148,149,152] the problem of compatibility of the components in composite materials,[12,167] and problems of high-temperature superplasticity.[162,168,169] All these conclusions underline the importance of the concept of controlling the grain boundaries in silicon nitride, as was mentioned above. Unfortunately the nature of the boundaries in these materials has been studied only on a very limited scale.

V. Conclusion

Because of their many desirable physicochemical and physico-mechanical characteristics materials based on Si_3N_4 are finding increasingly wide applications in ordinary industry and in industrial chemical equipment, electronics, turbine construction, and other parts of modern technology.[6–9,170] One of the most promising scientific areas for the application of these materials is in high-temperature techniques. It is thought that the striking progress in the measurement of the melting point could lead to the creation of a new generation of silicon nitride refractory materials, working at temperatures of ~2000 °C. The results shown in Fig. 22 also suggest major possibilities for the use of Si_3N_4 as a material for cutting tools, allowing an increase in the temperature of the cutting site and in the corresponding machining parameters. Of course, these forecasts assume the solution of many nontrivial research and construction technology problems, some of which are mentioned above. Another recent

review[154] also deals with problems in the fundamental study of the creation of a new generation of refractory ceramic materials for use at temperatures up to ~2000 °C.

Silicon nitride is far from having been fully studied as an objective of physicochemical research, and has continued to attract the attention of researchers. Because of the very large number of publications and of the shortage of space, our treatment of some aspects of the silicon nitride problems has been unavoidably superficial. The results of studies carried out mainly during the past 5–10 years have been selectively considered. Again we must stress the large number of publications and the important results obtained in the synthesis of the material and in the study of its high-temperature properties. Recent data on the properties of films of silicon nitride and oxynitride have been reviewed by Habraken and Kuiper.[171] It should also be noted that the unique properties of silicon nitride have allowed the prediction[118] of the new compound carbon nitride, which is now being studied intensively in thin film form.[172]

This review was written as part of a project supported by the Russian Basic Sciences Foundation (No. 95-02-03518a).

VI. Average enthalpies, entropies, and Gibbs free energies of the breaking of chemical bonds in the organic compounds of selenium and tellurium 313

Abstract. Experimental values of the enthalpies of formation (ΔH_f°) and of the specific heat (C_p°) of the organic compounds of selenium and tellurium are discussed, including their complexes with dialkylzinc and dialkylcadmium. Different forms of the methods of combustion enthalpy and of reaction calorimetry, used to determine the ΔH_f° values, are examined. The enthalpies of breaking of the chemical bonds formed by selenium and by tellurium are calculated from the ΔH_f° values. Data on the temperature dependence of the specific heat are used to find the absolute entropy of these compounds, their temperature, enthalpy, and entropy of melting, their entropy of formation, and other thermodynamic parameters. Special features of the changes in enthalpy, entropy, and Gibbs free energy of the breaking of the chemical bonds are pointed out. The bibliography includes 62 references.

I. Introduction

The organic compounds of selenium and tellurium are used in the preparation of semiconductor and optoelectronic materials. A thermodynamic analysis of the thermal dissociation, hydrogenation, and oxidation processes in these materials should provide a better understanding of their properties. Data on the thermodynamic characteristics of the reactants (in particular, on their enthalpies of formation and vaporisation, and on their entropy) are needed for the calculation of the parameters of the corresponding reactions. These data are important also in relation to the theory of the chemical bond and the theory of heterogeneous catalysis.

Until recently published data on the thermochemistry of this class of compounds were scarce.[1,2] Thus, a detailed review[1] gave the enthalpies of formation of only two organic compounds of selenium and one of tellurium. A substantial volume of information on these topics is now available, and should allow us to establish general trends in the changes in the thermodynamic characteristics of several compounds of this class. The need to correlate the published data is made even more urgent by the fact that the thermodynamic parameters of some of these compounds are given in the relatively inaccessible symposia and abstracts of specialised conferences.

In the present review we shall discuss the enthalpies of formation (ΔH_f°) and other thermodynamic characteristics of organic compounds of selenium and tellurium published up to the middle of 1994, and we shall tabulate those shown to be the most reliable. In the selection of the ΔH_f° values consideration was given to the method of determination, the purity of the starting preparations, the statistical significance of the results obtained in the analysis of the products given by the reactions under test, and the level of precision of the calorimetric experiment (allowance for all the necessary corrections and measurement and calculation errors).

An analysis of the published information showed that the true precision of the determinations of ΔH_f° for these compounds is not usually better than 3–4 kJ mol^{-1}. The achievement of higher precisions is limited partly by the specific properties of the given calorimetric experiment and partly by the need to use several auxiliary thermochemical quantities in the calculations. Their values are tabulated in the standard handbooks,[3–5] but often their precision is low and they are not mutually consistent. Therefore the experimental values of ΔH_f° are rounded off in the present review.

The vaporisation enthalpies, needed in the calculation of the ΔH_f° value of these substances in the gaseous monomeric state, are quoted (in most cases) in the papers which give the experimental values of their enthalpies of formation in the condensed state. In other cases they are quoted from Refs 6–9.

Experimental values of the enthalpies of formation, the specific heats, and other thermodynamic functions were used in calculations of the average enthalpies, entropies, and Gibbs functions of the breaking of the chemical bonds formed by selenium and tellurium in the various compounds. The error in the thermodynamic quantities corresponds to a 95% confidence level.

II. Auxiliary parameters

To ensure mutual compatibility of the thermochemical parameters discussed in this review the parameters were calculated from a single set of key values, listed in Table 1.

The most important quantities in these calculations were the ΔH_f° parameters for crystalline SeO_2 and TeO_2.

SeO_2 (cr)	−225.5 ± 2.1	10	i-C_5H_{11} (g)	32 (estimate)	12
TeO_2 (cr)	−328.9 ± 1.7	11	C_6H_5 (g)	325 ± 8	12
CH_3 (g)	146.3 ± 0.5	5	$C_6H_5CH_2$ (g)	188 ± 4	12

[a] Here and elsewhere the physical states of the substances for which thermodynamic parameters are denoted by cr (crystal), l (liquid), and g (gas).

The ΔH_f° value for SeO_2(cr) taken from Barnes and Mortimer[10] had been determined from measurements of the enthalpy of combustion of hexagonal selenium by the rotating bomb method (a high-precision measurement). Their result was indistinguishable from those of other workers,[13,14] who used a stationary calorimetric bomb for the combustion of selenium.

On the other hand the ΔH_f° values for TeO_2 obtained in different laboratories differed by ~80 kJ mol^{-1} (Table 2). Therefore the present writers redetermined[11] the enthalpy of formation of TeO_2 by burning very pure crystalline (hexagonal) tellurium in a calorimetric bomb. The value thus obtained for TeO_2(cr) (Table 1) was significantly higher than some reported values,[15,19,20] and differed very markedly from others.[16–18]

Table 2. Enthalpies of formation of crystalline tellurium dioxide (298.15 K).

$-\Delta H_f^\circ$/kJ mol^{-1}	Method of determination	Ref.
321.7 ± 5.0	Combustion calorimetry	15
379.1 ± 1.3	"	16
351.9 ± 12.0	Mass spectrometry	17
301.2 ± 2.1	Measurement of the emf of a reaction involving TeO_2 (cr)	18
321.1 ± 1.3	"	19
320.4 ± 3.0	Reaction calorimetry	20
328.9 ± 1.7	Combustion calorimetry	11

Some of the previous measurements[15,16] had been made by burning tellurium in oxygen in a stationary calorimetric bomb. However, the need to use relatively large samples of tellurium in these experiments led to incomplete oxidation and to the formation of combustion products having a complex composition. The difficulty of determining the appropriate energy corrections is mainly responsible for the inconsistency of the previous results[15,16] and for the difference between those results and ours.[11]

The high value of ΔH_f° for TeO_2(cr) obtained mass-spectroscopically (see Table 2) is probably due to the difficulty of allowing for the excess energy of the products formed from the starting material under the influence of electron collisions.[21]

Cordfunke et al.[20] determined the enthalpy of formation of TeO_2 by two independent methods: by studying the enthalpy of dissolution of solid Te, TeO_2, UO_3, and U_3O_8 in an aqueous solution of H_2SO_4 + $K_2Cr_2O_7$ + $MnSO_4$ and the enthalpy of dissolution of Te, TeO_2, Na_2SO_3, and Na_2SO_4 in an aqueous solution of NaClO + NaOH. By combining the measured effects, enthalpies of dissolution of tellurium dioxide equal respectively to −318.74 ± 7.35 and −320.71 ± 3.22 kJ mol^{-1} were obtained (an averaged value is given in Table 2). Obviously, the reliability of these results[20] depends on the reliability of the auxiliary data. Thus, the use of the parameter ΔH_f° (Na_2SO_3) = −1096.78 ± 0.81 kJ mol^{-1} instead of that used by the writers[20] (−1101.83 ± 0.72 kJ mol^{-1}) makes the value of ΔH_f° for Te_2O(cr) −330.8 ± 3.3 kJ mol^{-1} (see Refs 22 and 23), which differs by more than 10 kJ mol^{-1} from the value given in Table 2 but agrees with our value within experimental error.

III. Enthalpies of formation of organoselenium compounds

The combustion of Se compounds in a calorimetric bomb leads to the formation of solid selenium dioxide, which is easily soluble in the water present in the bomb. The energy corrections associated with the dissolution are applied during the processing of the experimental data.

Because of the rapid dissolution of the SeO_2 in water the combustion of selenium compounds can be carried out successfully in calorimeters with both stationary and rotating bombs. This conclusion is confirmed, in particular, by the good agreement between the enthalpies of combustion (ΔH_f°) of crystalline selenium obtained in a rotating[10] and in a stationary bomb respectively.[13,14]

Because of the relatively small enthalpy of dissolution of selenium dioxide in an excess of water (3.85 ± 0.08 kJ mol^{-1}) possible differences in the concentration of the aqueous solutions in different parts of the stationary calorimeter can be ignored.

The method of combustion in a stationary bomb has been widely used for selenium compounds.[24–29]

In a series of experiments in our laboratory[26–29] the compounds (held in thin-walled glass bulbs) were placed in the bomb in a quartz crucible together with a wafer of the benzoic acid standard. The mass of substance burned was determined from the amount of carbon dioxide formed during the experiment. It was established calorimetrically (from the depression of freezing point) that the total content of organic impurities in samples of dialkyl compounds purified by fractional distillation was not more than 0.05–0.10 mol%, and the content of metals was found (by spectroscopic analysis) to be 1×10^{-3} mol%.

Our value[28] of ΔH_f° for liquid diethyl selenide (−59.8 ± 3.3 kJ mol^{-1}, Table 3) differs markedly from the value reported by Merten and Schlüter[24] (−90.8 ± 3.8 kJ mol^{-1}). The latter was obtained by a low-level calorimetric technique, and it cannot be considered reliable. Thus, though the method of synthesis of the diethyl selenide was stated,[24] the purity of the resulting samples was not characterised, the completeness of the combustion was not established, and only ~20% of the total energy evolved in the experiment was ascribed to the compound under study.

Tsvetkov and Kozyrkin[30] obtained ΔH_f° for liquid $(C_2H_5)_2Se$ by studying the reaction of diethyl selenide with an excess of bromine. It was assumed that $SeBr_4$ was the only product containing selenium formed under these conditions. However, as has been reported,[31] the reaction of $(C_2H_5)_2Se$ with liquid bromine can lead to the formation of $(C_2H_5)_2SeBr_2$: even a trace of this compound among the reaction products could seriously distort the results.[30] Our ΔH_f° value[28] for $(C_2H_5)_2Se$ is given

Table 3. Standard enthalpies of formation (in kJ mol^{-1}) of organoselenium compounds at 298.15 K.

Compound	ΔH_f° (l or cr)	ΔH_f° (g)	Method of determination[a]	Ref.

[a] Here and elsewhere the following symbols are used: SB for combustion in a stationary bomb; RB for combustion in a rotating bomb; R for reaction method.

as the recommended value in Table 3. The combustion of organoselenium compounds in a rotating bomb was first used by Mortimer and coworkers [10,32] to determine the enthalpy of combustion of diphenyl selenide and diphenyl diselenide. The diphenyl selenide (in a polyester bulb) was burned in a thin-walled quartz crucible. By determining the mass of carbon dioxide in the resulting products it was shown that the extent of combustion in the compound under study was not less than 99.94%. 50 cm^3 of distilled water was previously placed in the bomb to dissolve the selenium dioxide produced by the combustion. In order to allow for various side effects (for example, the dissolution of carbon dioxide in the aqueous solution of SeO_2) the authors [10,32] carried out a set of 'comparison experiments'. In these experiments they burned benzoic acid, choosing its mass and the concentration of the aqueous solution of SeO_2 added to the bomb so as to ensure that the final states of the reacting systems in the comparison experiments and in the experiments on the combustion of selenium compounds were as nearly as possible identical.

The rotating bomb method was used also in a study [33] of a series of organic compounds of sulfur, selenium, and tellurium (see Tables 3 and 4).

A calorimetric determination of the enthalpy of interaction of $(C_6H_5)_2Se_2$ with one and with three moles of bromine, dissolved respectively in carbon tetrachloride and in trichlorobenzene, has been reported. [34] In the first case C_6H_5SeBr was formed quantitatively, in the second $C_6H_5SeBr_3$. The enthalpies of formation of crystalline and of gaseous C_6H_5SeBr and $C_6H_5SeBr_3$ were calculated from the results thus obtained and from the ΔH_f° value for crystalline $(C_6H_5)_2Se_2$ previously obtained. [32] Recommended values of the enthalpies of formation of these organoselenium compounds are shown in Table 3.

There are several reports [35–40] of the enthalpy of reaction (ΔH_r°) of the selenides SeR_2 (R = CH_3, C_2H_5) with the compounds MR_2 (M = Zn, Cd). In the liquid phase this interaction led to the formation of the corresponding equimolecular complexes of the donor-acceptor type. In some cases the ΔH_r° values were obtained directly (by studying a mixture of the compounds in a 1:1 ratio) [35,36] in other cases they were obtained by studying the liquid–vapour equilibrium of the corresponding equimolecular mixtures. [37–40]

The enthalpies of vapour formation of the $R_2Se \cdot MR_2$ complexes and of the starting substances were determined [38–40] at 298.15 K in an isothermal differential micro-calorimeter. It had previously been established that the compounds under study were fully dissociated in the gas phase. This allowed the ΔH_r° values to be calculated as the difference between the vaporisation enthalpies of the equimolecular solution and the corresponding individual substances.

The vaporisation enthalpies (ΔH_v°) of the complexes, the reaction enthalpies of the starting components in the liquid phase calculated from them, and the enthalpies of formation of the liquid complexes (in kJ mol^{-1}), obtained experimentally, [38–40] are listed below:

Complexes	ΔH_v°	$-\Delta H_f^\circ$	ΔH_f°
$Zn(CH_3)_2 \cdot Se(CH_3)_2$	66.3 ± 1.9	6.2 ± 2.0	6 ± 8
$Zn(C_2H_5)_2 \cdot Se(C_2H_5)_2$	79.9 ± 0.8	4.2 ± 1.1	-48 ± 4
$Cd(CH_3)_2 \cdot Se(CH_3)_2$	74.6 ± 1.4	6.0 ± 1.4	49 ± 9

In the calculation of the ΔH_f° values allowance was made for the enthalpies of formation of the selenides (see Table 3) and for published data [1] on the enthalpies of formation of liquid $Zn(CH_3)_2$ (23.8 ± 2.1), $Zn(C_2H_5)_2$ (16.3 ± 2.1), and $Cd(CH_3)_2$ (66.9 ± 4.2) kJ mol^{-1}. ΔH_r° values close to those in the above tabulation have also been obtained in a calorimetric study [35,36] of the mixing of the initial components.

IV. Enthalpies of formation of organotellurium compounds

In spite of the large number of organotellurium compounds whose synthesis has been reported [41] and of their great practical interest a systematic study of the thermochemistry of these materials was only recently started: in 1988, when the present writers' laboratory reported a determination [42] of the enthalpies of combustion of dimethyl and divinyl tellurides (see Table 4). The combustion enthalpies of these substances were determined in a calorimeter fitted with a stationary calorimetric bomb. The weight of sample consumed was determined from the quantity of carbon dioxide formed by its combustion to within ~0.1%.

According to the X-ray phase analysis results the solid combustion product was a mixture of tetragonal tellurium dioxide and a small amount (not more than 5%) of the orthorhombic modification. The amount of tellurium in the washings of the bomb after the combustion of the starting compounds was determined by atomic absorption spectroscopy, thus allowing the energy corrections associated with the dissolution of the tellurium products in the water produced by the reaction to be calculated.

A similar method was used[27,28,43-45] to find the enthalpies of formation of several alkyl and phenyl tellurides (see Table 4).

Several tellurium compounds were studied by the rotating bomb method.[33] The sample in a Terylene bulb was placed on an iridium grid below which a platinum crucible containing a wafer of benzoic acid was located. The experimental compounds were located in the maximum temperature region of the burning wafer, and therefore were oxidised almost completely.

An aqueous solution of HNO_3 has been used[33] as the bomb liquid. According to the authors this procedure led to the formation of amorphous hydrated TeO_2, whose enthalpy of formation had been determined in separate experiments. However, the report[33] omits many essential experimental details needed to substantiate the correctness of the proposed method. In particular, combustion equations for the experimental substances are not given, and therefore the chemical mechanism of the processes taking place in the calorimetric bomb cannot be established. The formation of stable hydrates of TeO_2 among the combustion products is arguable, because of the very low solubility of this dioxide in water (1 g TeO_2 dissolves in 15×10^4 g of H_2O).[46] Furthermore the use of a platinum crucible may cause alloying of the platinum with the combustion products containing tellurium.[46] Nevertheless some of the results from Ref. 33 are included in Tables 3 and 4, and have been used to calculate the enthalpies of the breaking of the corresponding bonds.

The only reported use of reaction calorimetry[30] is in an investigation of the enthalpy of interaction of diethyl telluride with an excess of liquid bromine. It was assumed[30] that the products of this interaction are solid $TeBr_4$ and ethyl bromide dissolved in bromine. However, as was pointed out,[31] the products of this reaction can include diethyl dibromotelluride, which requires an allowance for the appropriate energy corrections.

Pavlovskii and coworkers[39,40] determined the enthalpies of vaporisation of the complexes of dimethyl telluride with the methyl compounds of zinc and cadmium. By combining their results with the ΔH_v° values previously obtained for the starting components they calculated the enthalpies of their interaction in the liquid phase, as was done for the selenide complexes discussed above.

The enthalpies of vaporisation of the tellurium complexes, the reaction enthalpies of the starting components in the liquid phase, and the enthalpies of formation of the liquid complexes (in kJ mol^{-1}, the latter two calculated from the former) are listed below:

Complex	ΔH_v°	$-\Delta H_r^\circ$	ΔH_f°
$Zn(CH_3)_2 \cdot Te(CH_3)_2$	70.4 ± 1.1	4.8 ± 1.3	10 ± 6
$Cd(CH_3)_2 \cdot Te(CH_3)_2$	80.4 ± 1.2	6.4 ± 1.3	52 ± 7

The enthalpy of formation of dimethyl telluride (shown in Table 4) and the enthalpies of formation of the dimethyl compounds of zinc and cadmium recommended in Ref. 1 were used to calculate the ΔH_f° values.

We may conclude from these results that the ΔH_f° values for $(CH_3)_2Te$ and those of the same parameter for dimethyl selenide are indistinguishable within the uncertainties of the determination. the enthalpy of the reaction

$$(NH_4)_2PdCl_4(cr) + 2\,Te(C_2H_5)_2(l) \longrightarrow$$

$$\longrightarrow PdCl_2 \cdot 2\,Te(C_2H_5)_2(cr) + 2\,NH_4Cl(cr),$$

was determined calorimetrically[47] as -175.7 ± 4.8 kJ mol^{-1}.

ΔH_f° for $PdCl_2 \cdot 2Te(C_2H_5)_2(cr)$ was calculated from the enthalpies of formation of liquid $(C_2H_5)_2Te$ (see Table 4) and of crystalline $(NH_4)_2PdCl_4$ (-841.0 ± 1.7) and NH_4Cl (-314.4 ± 0.1 kJ mol^{-1}).[47] The result was -480 ± 10 kJ mol^{-1}, which is close to the previously reported value $\Delta H_f^\circ = -456 \pm 10$ kJ mol^{-1} for $PdCl_2 \cdot 2Se(C_2H_5)_2(cr)$, recalculated by the present writers[48] by using a new value of the enthalpy of formation of $(C_2H_5)_2Se$ (see Table 3).

By using the calculated[47] enthalpies of sublimation of the tellurium (192 kJ mol^{-1}) and the selenium complex (160 kJ mol^{-1}) the following ΔH_f° values were obtained: -288 for $PdCl_2 \cdot 2Te(C_2H_5)_2(g)$ and -296 kJ mol^{-1} for $PdCl_2 \cdot 2Se(C_2H_5)_2(g)$.

In this calculation[47] the enthalpy of mixing of liquid diethyl telluride with liquid bromine (-188 ± 4 kJ mol^{-1}) was erroneously taken from Ref. 30 instead of its enthalpy of formation (see Table 4), and this led to an erroneous determination of the ΔH_f° value for crystalline $PdCl_2 \cdot 2Te(C_2H_5)_2$ (-763.8 ± 14.6 kJ mol^{-1}).

V. Specific heats, entropies, and Gibbs free energies of formation of organoselenium and organotellurium compounds

The temperature dependence of the specific heat (C_p°) for a series of alkyl and vinyl compounds of selenium and of tellurium has been determined[49-56] experimentally at 5–310 K. The measurements were made in a vacuum adiabatic calorimeter whose design and methods of calibration, measurement, and calculation offered results with an uncertainty of ~0.2% at 30–310 K, 0.5% at 12–30 K, and 1.5% at even lower temperatures. The experimental materials were specially purified, and according to chromatographic and mass spectrometric analyses their purity was 99.9 mol%. According to the depression of freezing point, measured during the study of the specific heat for each of the samples, the total content of impurities not forming solid solutions with the main substance was less than 0.1 mol%.

In these studies of the specific heat it was found that when rapidly cooled divinyldipropyl-, and dibutyl telluride are easily supercooled with formation of glasses, whereas the dimethyl and the diethyl compound show polymorphism. The thermodynamic characteristics of these transitions were determined in the course of these studies. The melting point (T_m) and the enthalpy (ΔH_m°) and entropy (ΔS_m°) of melting of the compounds were also determined (Table 5).

A special feature of liquid alkyl compounds of selenium and tellurium is an anomalous change in their specific heat. Immediately after melting the specific heat falls a little with increase in temperature, but after going through a minimum it shows the normal behaviour and begins to rise again. It has been suggested that these liquids are partially associated at temperatures close to T_m. Therefore the observed heat capacity includes both the true heat capacity of the liquid and the heat capacity contributed by the dissociation of the associated species. The decrease in the degree of association with increase of temperature suppresses this contribution to the specific heat, leading to the appearance of a minimum on its temperature dependence.

The entropy $[S^\circ(T)]$, the enthalpy of heating $[H^\circ(T) - H^\circ(0)]$, and the Gibbs function $[G^\circ(T) - H^\circ(0)]$ of these compounds in the condensed state were calculated from experimental data on the temperature dependence of the specific heat. The values thus obtained for 298.15 K are shown in Table 5.

From the absolute entropy values for a group of selenium and tellurium compounds their entropies of formation (ΔS_f°) from the elements in the condensed and the gaseous state were calculated. Published data[6-9] on the vapour pressure and on the enthalpies of vaporisation were used in these calculations. The entropies of the elements (needed in these calculations) were taken from standard tabulations.[4,5]

The Gibbs free energy of formation for these compounds (ΔG_f°) were calculated from the enthalpies of formation (see Tables 3 and 4). The results are shown in Table 6.

Table 5. Thermodynamic functions (298.15 K) and melting parameters of selenium and tellurium compounds

Compound	C_p°	S°	$[H^\circ(T)-H^\circ(0)]$	$-[G^\circ(T)-H^\circ(0)]$	T_m°/K	ΔH_m°	ΔS_m°
$(CH_3)_2Se$	121.1	210.8	31.78	31.08	185.14	8.499	49.90
$(CH_2=CH)_2Se$	165.7	262.0	39.94	38.17	178.08	9.374	52.64
$(C_2H_5)_2Se$	174.0	284.9	44.17	40.77	175.30	12.60	71.85
$(CH_3)_2Se_2$	155.0	261.4	38.78	36.16	190.89	8.545	44.76
$(CH_3)_2Te$	125.1	220.5	33.10	32.64	201.87	7.766	38.47
$(C_2H_3)_2Te$	166.1	268.1	41.26	38.67	182.65	9.593	52.52
$(C_2H_5)_2Te$ [a]	183.4	291.0	42.48	44.27	161.50	7.621	47.20
					153.33	7.525	40.87
$(C_3H_7)_2Te$	233.7	362.2	56.38	51.60	191.80	14.28	74.43
$(C_4H_9)_2Te$	286.4	426.0	65.73	62.08	177.05	14.57	82.30
$(C_5H_{11})_2Te$	345.9	501.0	80.88	69.42	215.41	23.11	107.8
$(C_6H_5)_2Te$	305.7	332.4	57.04	42.05	268.53	15.35	57.16

Notes. The parameters C_p°, S°, ΔS_m° are in J mol^{-1} K^{-1}; the functions $[H^\circ(T)-H^\circ(0)]$ and $-[G^\circ(T)-H^\circ(0)]$, and ΔH_m°, are in kJ mol^{-1}. [a] Crystallises in two modifications.

Table 6. Absolute entropies (S°, J mol^{-1} K^{-1}), entropies ($-\Delta S_f^\circ$, J mol^{-1} K^{-1}) and Gibbs free energies (ΔG_f°, kJ mol^{-1}) for the formation of selenium and tellurium compounds at 298.15 K.

Compound	S° (g)	$-\Delta S_f^\circ$ (l)	$-\Delta S_f^\circ$ (g)	ΔG_f° (l)	ΔG_f° (g)
$(CH_3)_2Se$	302.7	234.8	145.5	58	61
$(CH_2=CH)_2Se$	357.6	195.0	99.4	224	237
$(C_2H_5)_2Se$	386.1	431.8	330.6	69	77
$(CH_3)_2Se_2$	–	226.4	–	76	–
$(CH_3)_2Te$	317.7	231.5	130.9	78	83
$(CH_2=CH)_2Te$	361.7	194.7	101.3	274	291
$(C_2H_5)_2Te$	392.4	432.9	331.5	83	95
$(C_3H_7)_2Te$	496.6	633.7	526.3	100	113
$(C_4H_9)_2Te$	534.9	841.8	732.9	144	162
$(C_5H_{11})_2Te$	617.8	1038.7	921.9	114	138

The specific heat and the entropy of the dimethyl compounds of selenium and tellurium in the ideal gas state were calculated also by statistical thermodynamics from spectroscopic data and from information on the structure of the molecules.[57] The calculations were carried out in the rigid rotator–harmonic oscillator approximation for the 273–1500 K temperature range.

The reliability of the calculated results [57] can be established by comparing them with experimental data. For example, the calculated entropies of $(CH_3)_2Se$ and $(CH_3)_2Te$ at 298.15 K are 300 and 309 J mol^{-1} K^{-1} (see Ref. 57), whereas calorimetric measurements for these compounds gave 302.7 and 317.7 J mol^{-1} K^{-1} (see Table 6).

It can be seen that for $(CH_3)_2Se$ the agreement between calculated and experimental results is good, but for $(CH_3)_2Te$ the calculated entropy differs from the calorimetric value by almost 3%, suggesting that the method of calculation used by Mosin et al. [57] should be reconsidered.

Studies of the specific heat in the 6–10 K range have been reported also for some complexes formed by selenium and tellurium compounds with zinc and cadmium alkyls.[58–60] From these values of the specific heat the absolute entropies were calculated, and by using the entropies of the starting components [61] (see Table 6) and their interaction enthalpies the entropies and Gibbs free energies of the reaction (ΔS_r° and ΔG_f° respectively) were also calculated:[38–40]

$$R_2M\ (l) + R_2M'\ (l) \longrightarrow R_2M \cdot R_2M'\ (l),$$

where R = CH_3, C_2H_5; M = Se, Te; M′ = Zn, Cd.

The results of these calculations are shown in Table 7.

Table 7. Specific heats (J mol^{-1} K^{-1}) and entropies of the complexes, entropies (J mol^{-1} K^{-1}) and Gibbs free energies (kJ mol^{-1}) of the synthesis reactions of the liquid complexes at 298.15 K.

Complex	C_p°	S°	$-\Delta S_r^\circ$	$-\Delta G_r^\circ$
$(CH_3)_2Se \cdot Zn(CH_3)_2$	287.2	401.1	11.3	2.8 ± 2.0
$(CH_3)_2Se \cdot Cd(CH_3)_2$	277.7	413.6	−0.8	6.2 ± 1.4
$(CH_3)_2Te \cdot Zn(CH_3)_2$	284.0	420.7	1.4	4.3 ± 1.3
$(CH_3)_2Te \cdot Cd(CH_3)_2$	275.2	413.1	9.5	3.5 ± 1.3
$(C_2H_5)_2Te \cdot Zn(C_2H_5)_2$	399.0	556.9	10.6	–

The uncertainties in the determination of the $\Delta G_r^\circ(l)$ values shown in Table 7 are determined mainly by the errors in the enthalpies of interaction of the corresponding components.[38–40] As can be seen from Table 7 the $\Delta G_r^\circ(l)$ values for all the complexes have small and not very different negative values.

VI. Average enthalpies, entropies, and Gibbs free energies of the breaking of chemical bonds in the organic compounds of selenium and tellurium

It is interesting to consider the dependence of the strength of chemical bonds on the nature of the atoms and radicals from which the bonds are formed. The determination of the enthalpy of breaking of individual bonds in various compounds is usually a difficult experimental problem, and therefore the average enthalpies of bond breaking ($\bar{D}$) are often calculated.

The $\bar{D}$ values shown in Table 8 for the M–R bonds in the compounds MR_2 (M = Se or Te, R is a radical) are the enthalpy of the reaction $MR_2(g) \rightarrow M(g) + 2R(g)$ divided by the number of bonds. This quantity is calculated by using the formula

$$\bar{D}(M-R) = \tfrac{1}{2}[\Delta H_f^\circ(M, g) + 2\Delta H_f^\circ(R, g) - \Delta H_f^\circ(MR_2, g)],$$

and employing data for the enthalpies of formation of the gaseous reactants in the appropriate reaction.

The $\bar{D}(M-M)$ values in the compounds (MR_2) were calculated by means of the equation

$$\bar{D}(M-M) = 2\Delta H_f^\circ(M, g) + 2\Delta H_f^\circ(R, g) - \Delta H_f^\circ[(MR)_2, g] - 2\bar{D}(M-R).$$

It is assumed that the enthalpies of breaking of the M–R bonds are identical in the corresponding MR_2 and $(MR)_2$ compounds.

Table 8. Average enthalpies of bond breaking (298.15 K).

Compound	Bond	$\bar{D}$/kJ mol^{-1}	Compound	Bond	$\bar{D}$/kJ mol^{-1}
$(CH_3)_2O$	$O-CH_3$	360 ± 4	$(C_4H_9)_2Se_2$	$Se-Se$	211 ± 22
$(C_2H_5)_2O$	$O-C_2H_5$	356 ± 4	$(C_6H_5)_2Se_2$	$Se-Se$	280 ± 13
$(C_6H_5)_2O$	$O-C_6H_5$	427 ± 8	C_6H_5SeBr	$Se-Br$	258 ± 12
$(CH_3)_2S$	$S-CH_3$	297 ± 4	$C_6H_5SeBr_3$	$Se-Br$	172 ± 4
$(C_2H_5)_2S$	$S-C_2H_5$	285 ± 4	$(CH_3)_2Te$	$Te-CH_3$	220 ± 3
$(C_6H_5)_2S$	$S-C_6H_5$	347 ± 8	$(CH_2=CH)_2Te$	$Te-C_2H_3$	227 ± 9
$(CH_3)_2Se$	$Se-CH_3$	251 ± 4	$(C_2H_5)_2Te$	$Te-C_2H_5$	206 ± 5
$(CH_2=CH)_2Se$	$Se-C_2H_3$	271 ± 8	$(C_3H_7)_2Te$	$Te-C_3H_7$	206 ± 8
$(C_2H_5)_2Se$	$Se-C_2H_5$	232 ± 5	$(i\text{-}C_3H_7)_2Te$	$Te-i\text{-}C_3H_7$	192 ± 4
$(i\text{-}C_3H_7)_2Se$	$Se-i\text{-}C_3H_7$	241 ± 5	$(C_4H_9)_2Te$	$Te-C_4H_9$	195 ± 8
$(C_5H_{11})_2Se$	$Se-C_5H_{11}$	238	$(C_5H_{11})_2Te$	$Te-C_5H_{11}$	202
$(C_6H_5)_2Se$	$Se-C_6H_5$	294 ± 8	$(i\text{-}C_5H_{11})_2Te$	$Te-i\text{-}C_5H_{11}$	202
$(CH_3)_2Se_2$	$Se-Se$	192 ± 12	$(C_6H_5)_2Te$	$Te-C_6H_5$	267 ± 9
$(C_2H_5)_2Se_2$	$Se-Se$	222 ± 13	$(C_3H_7)_2Te_2$	$Te-Te$	119 ± 5
			$(C_4H_9)_2Te_2$	$Te-Te$	149 ± 6

Table 9. Average values of the entropy (J mol^{-1} K^{-1}) and the Gibbs free energy (kJ mol^{-1}) for the breaking of bonds at 298.15 K.

Compound[a]	Bond	$\Delta\bar{S}$	$\Delta\bar{G}$
$(CH_3)_2O$	$O-CH_3$	141	318
$(C_2H_5)_2O$	$O-C_2H_5$	161	308
$(CH_3)_2S$	$S-CH_3$	135	257
$(C_2H_5)_2S$	$S-C_2H_5$	152	240
$(CH_3)_2Se$	$Se-CH_3$	131	208
$(CH_2=CH)_2Se$	$Se-C_2H_3$	143	229
$(C_2H_5)_2Se$	$Se-C_2H_5$	147	188
$(CH_3)_2Te$	$Te-CH_3$	126	182
$(CH_2=CH)_2Te$	$Te-C_2H_3$	143	184
$(C_2H_5)_2Te$	$Te-C_2H_5$	147	162

[a] Because of the lack of the appropriate auxiliary data the quantities $\Delta\bar{S}$ and $\Delta\bar{G}$ cannot be calculated for all the compounds listed in Tables 3 and 4.

For comparison we show in Table 8 the $\bar{D}$ values for various bonds which include oxygen or sulfur. These calculations relied on data given in Tables 1, 3, and 4 and in published tabulations.[3-5,12,62]

In Table 9 we list the average entropies ($\Delta\bar{S}$) of bond breaking, obtained by the expression

$$\Delta\bar{S}(M-R) = \tfrac{1}{2}[S^\circ(M,\ g) + 2\,S^\circ(R,\ g) - S^\circ(MR_2,\ g)],$$

where S° are the standard entropies of the reactants in the dissociation of the compound MR_2 (see Table 6) into the fragments M and 2R (see Refs 3-5).

The $\Delta\bar{S}(M-R)$ and $\bar{D}(M-R)$ values were used to calculate the average values of the Gibbs free energy ($\Delta\bar{G}$) for the breaking of the M-R bonds, which we used as a measure of their thermodynamic stability (Table 9). The calculations for a temperature of 298.15 K were carried out using the equation

$$\Delta\bar{G}(M-R) = \bar{D}(M-R) - 298.15\,\Delta\bar{S}(M-R).$$

* * *

An analysis of the calculated and the experimental data reported above or previously published has established the following features of the thermodynamic characteristics of the bonds formed by selenium and by tellurium.

1. In the compounds R_2M (where M = O, S, Se, Te) of the same radical R the average enthalpy, entropy, and Gibbs free energy of the breaking of the M-R bond decrease as the atomic number of the element M increases.

2. For a given element M the average enthalpies of bond breaking vary in the following sequence:

$$M-C_6H_5 > M-C_2H_3 > M-CH_3 > M-C_2H_5$$

$$\approx M-C_3H_7 \approx M-C_4H_9 \approx M-C_5H_{11}.$$

3. The enthalpy of breaking of the $Te-C_3H_7$ bond in $Te(n\text{-}C_3H_7)_2$ is higher by 14 kJ mol^{-1} than the same parameter in $Te(i\text{-}C_3H_7)_2$, as is also found in the propyl compounds of mercury, boron, and tin.[1]

4. The parameters $\bar{D}(M-M)$ in the compounds $(RM)_2$ (except diphenyl diselenide) are not markedly dependent on the nature of the R radical; they are much smaller than the $\bar{D}(M-R)$ values in the R_2M compounds with the same radicals (see Table 8) and $\bar{D}(M-M)$ in the M_2 (g) molecules,[11] for which $D(Se-Se)$ = 305 and $D(Te-Te)$ = 259 kJ mol^{-1}.

In spite of the experimental ΔH_f° values available for the crystalline dibenzyl selenide and diselenide (see Table 3) a precise calculation of the enthalpy of breaking of the Se-Se bond in $(C_6H_5CH_2)_2Se_2$ is impossible because of the lack of data on the enthalpy of sublimation of $(C_6H_5CH_2)_2Se$, needed to calculate ΔH_f° for this compound in the gas phase. However, an approximate estimate of $\bar{D}(Se-Se)$ in dibenzyl diselenide can be made by assuming that $\bar{D}(Se-CH_2C_6H_5)$ in dibenzyl selenide is $\sim$63 kJ mol^{-1} lower than $\bar{D}(Se-C_2H_5)$ in diethyl selenide (see Table 8), i.e. as is observed in tetraethyl- and tetrabenzyl-germanium,[1] for which $\bar{D}(Ge-C_2H_5) = 243 \pm 4$ and $\bar{D}(Ge-CH_2C_6H_5) = 180 \pm 4$ kJ mol^{-1}. In this case the calculation of $\bar{D}(Se-Se)$ in dibenzyl diselenide by the equation given above gives a value of 192 kJ mol^{-1}, identical to $\bar{D}(Se-Se)$ for $(CH_3)_2Se_2$ (see Table 8).

The large difference between the $\bar{D}(Se-Se)$ values for the diphenyl and the dialkyl compounds can be ascribed to lack of precision of the available experimental data or to specific properties of the chemical bonds formed by selenium in these compounds.

5. By using the given values of ΔH_f° for gaseous $PdCl_2 \cdot 2\,M(C_2H_5)_2$ and $M(C_2H_5)_2$ (M = Se or Te) and the ΔH_f° ($PdCl_2$, g) value 128.4 $\pm$ 10.5 kJ mol^{-1} (see Ref. 4) the $\bar{D}(Pd-M)$ values for these complexes were calculated by the equation

$$\bar{D}(Pd-M) = \tfrac{1}{2}\{\Delta H_f^\circ(PdCl_2,\ g) + 2\,\Delta H_f^\circ[M(C_2H_5)_2,\ g]$$

$$- \Delta H_f^\circ[PdCl2.2M(C2H5)2, g].$$

This calculation gave the very similar values $\overline{D}$(Pd–Se) = 191 ± 10 and $\overline{D}$(Pd–Te) = 204 ± 10 kJ mol^{-1}.

It is interesting to note that $\overline{D}$(Pd–Se) is close to $\overline{D}$(Se–Se) in dialkyl diselenides, and $\overline{D}$(Pd–Te) coincides within the error of the determination with $\overline{D}$(Te–R) in dialkyl tellurides and is significantly higher than $\overline{D}$(Te–Te) in the alkyl compounds R_2Te_2 (see Table 8).

6. The main contribution to the parameter $\Delta\overline{G}$(M–R) comes from the enthalpy factor $\overline{D}$, whereas only 15%–20% of the $\overline{D}$ value contributes to the entropy component (298.15$\Delta\overline{S}$). It follows that the relative thermodynamic stability of these compounds can be established from the $\overline{D}$(M–R), values, which are experimentally much better characterised than the $\Delta\overline{G}$(M–R) values.

Further developments in the experimental thermochemical studies of selenides and tellurides should offer a more detailed understanding of the special features found in the thermodynamic characteristics of compounds of this type.

This work was made possible by the financial support of the Russian Fund for Basic Studies (Project 93-03-04627) and also (in part) of the International Science Foundation (Grant No. NP70000).

IV.	Synthesis of five- and six-membered heterocycles containing nitrogen and sulfur atom	342

Abstract. The review surveys and gives a systematic account of literature data concerning the application of carboxylic acid iminoesters in the synthesis of five- and six-membered nitrogen-containing heterocycles with several heteroatoms as well as heterocycles containing in the ring oxygen and sulfur atoms together with nitrogen atoms. The bibliography includes 350 references.

I. Introduction

Carboxylic acid iminoesters (imidates) and their salts, first obtained and described by Pinner[1] as early as the end of the previous century, have been attracting increasing attention by investigators, in view of their high reactivity, as synthons in the preparation of compounds of various classes — esters, amides, orthoesters, amidines, amidrazones, hydrazidines, amidoximes, etc. However, iminoesters and their salts are of special interest as key compounds in the syntheses of a wide variety of five- and six-membered nitrogen-containing heterocycles — imidazoles, benzimidazoles, 1,2,4-triazoles, pyrimidines, triazines, etc., as well as heterocycles containing nitrogen, oxygen, and sulfur atoms (oxazoles, oxazines, oxadiazoles, thiadiazoles, etc.).

The available information about the synthesis, structures, and chemical reactions of iminoesters and their salts is described in monographs[2-4] and reviews.[5,6] However, the data concerning the reactions of iminoesters which lead to the formation of heterocyclic structures, examined in the above communications, are far from complete from our point of view and the systematic treatment employed there requires improvement. We may note, in particular, that a review devoted to the synthesis of compounds of the 1,3,5-triazine series from carboxylic acid iminoesters was published in 1992.[7] In addition, new effective methods have been developed for the synthesis from iminoesters of heterocyclic compounds possessing practically useful properties. Thus, there has been recently a considerable growth of the number of publications on this field. In the present review, we have attempted to give a systematic account and to examine critically the information on the use of iminoesters in the synthesis of heterocycles, which has appeared during the period between 1975 and 1994. Earlier data concerning the preparation of heterocycles from iminoesters may be found in a monograph[4] published in 1975. We shall make use of them only when necessary.

We have arranged the relevant data in terms of the type of the heterocycle formed — initially five- and six-membered nitrogen-containing heterocycles in order of increasing ring size and increasing number of nitrogen atoms in the ring and then five- and six-membered nitrogen heterocycles containing also oxygen and sulfur atoms. Such systematic treatment provides a clear idea about the synthetic possibilities of the method and may be useful in selecting the direction of further research.

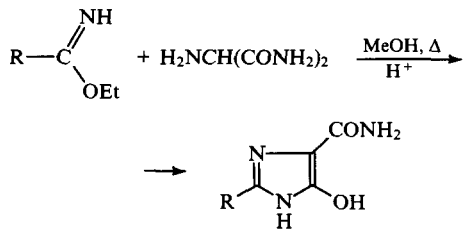
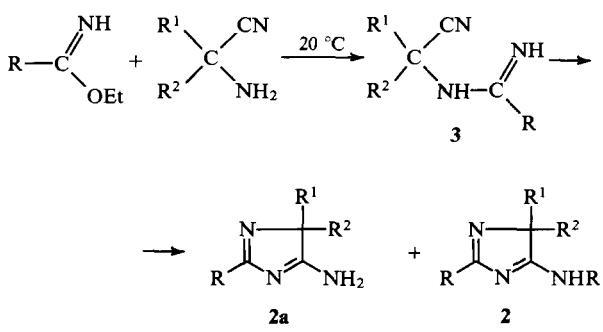
II. Synthesis of five- and six-membered nitrogen-containing heterocycles

1. Synthesis of substituted imidazoles and Δ^2-imidazolines



When the hydrochlorides of the iminoesters of various acids are condensed with the acetals of α-aminoketones in ethanol (refluxing for 1 – 6 h), the hydrochlorides of *N*-substituted amidines **1** are formed. On treatment with hydrochloric acid (50 – 100 °C, 0.5 – 6 h), these cyclise to substituted imidazoles (yield 30% – 85%)[8-16]

R = Me, Ar, $ArOCH_2$,  ;

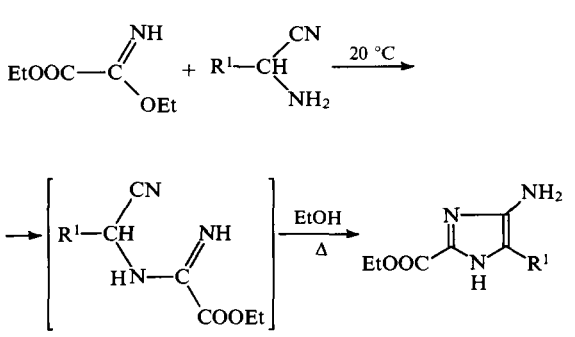


R^1 = H, Me; R^2 = H,  ; R^3 = Me, Et.

According to patent data,[17-19] the interaction of carboxylic acid iminoesters with aminomalonic acid diamide leads to the amides of 2-substituted 5-hydroxy-1*H*-imidazole-4-carboxylic acids, which exhibit an immunostimulating activity.

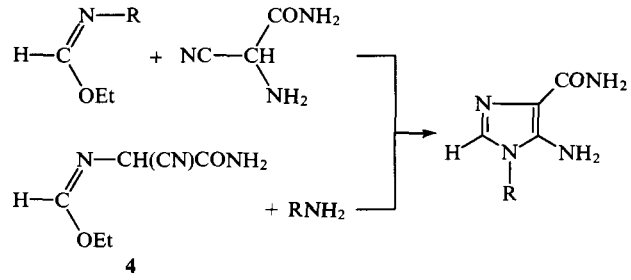
R = H, Alk, cyclo-(C_3–C_7), 1-Ad, Ar, $PhCH_2$, Ph_2CH, 3-Py, 

It has been reported[20] that the interaction of equimolecular amounts of α-aminonitriles with the iminoesters of pyridine-2-carboxylic and ethoxycarbonylformic acids results in the formation of 5-amino-4*H*-imidazoles **2a** in 44%–86% yield together with insignificant amounts (4%–10%) of *N*-substituted 5-amino-4*H*-imidazoles **2**.



R = 2-Py, EtOOC; $R^1 = R^2$ = Me;

R^1 = Me, R^2 = Et; $R^1 + R^2 = -(CH_2)_4-$, $-(CH_2)_5-$

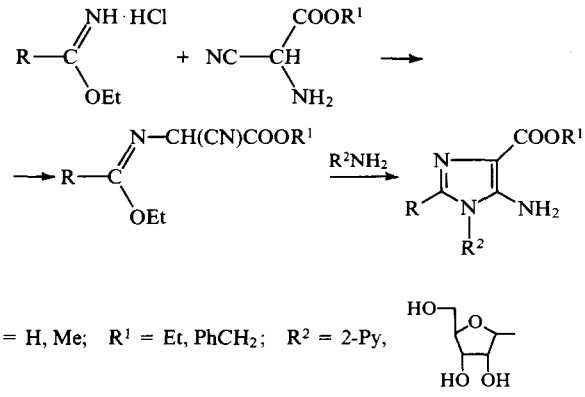


The authors suggest that the *N*-substituted amidine **3** is an intermediate in this reaction and also note that the iminoesters of other acids (R = Me, Ph, Cl_3C, 4-$NO_2C_6H_4$) do not form the imidazoles **2a** at all, but in certain cases afford *N*-substituted 5-amino-4*H*-imidazoles **2** in a low yield (4%–12%).

The condensation of the ethyl iminoester of ethoxycarbonylformic acid with α-substituted α-aminonitriles in ether leads to the amidines **3** (R = EtOOC), which cyclise on refluxing in alcohol to the ethyl esters of 4-amino-5-substituted 1*H*-imidazole-2-carboxylic acids (yield 51%–92%).[21,22]

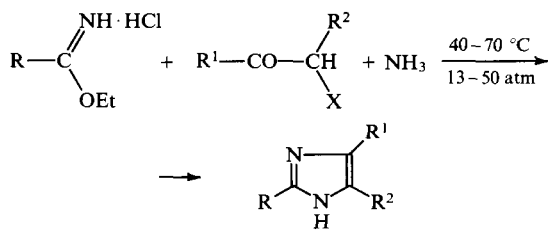
R^1 = H, Me, EtOOC, H_2NCO, Ar

The condensation of *N*-substituted formic acid iminoesters with α-aminocyanoacetamide or the condensation of the *N*-substituted iminoester **4** with aromatic amines have been used to synthesise the amides of 1-substituted 5-amino-1*H*-imidazole-4-carboxylic acids.[23]



4

R = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-ClC_6H_4



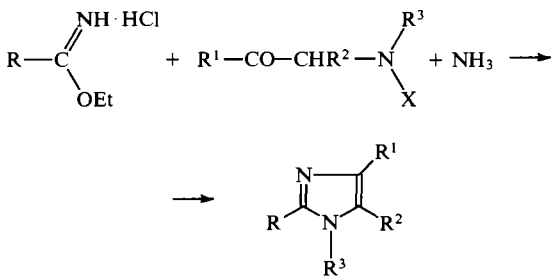
The iminoester **A** was obtained in its turn from the hydrochloride of the iminoester of formic acid with α-aminocyanoacetamide.

English investigators[24,25] used the latter method to obtain the esters of 1-substituted 5-amino-1*H*-imidazole-4 carboxylic acids, which are key compounds in the synthesis of purines.

R = H, Me; R^1 = Et, $PhCH_2$; R^2 = 2-Py,

In 1973, German investigators[26] proposed a convenient method of synthesis of imidazoles, which consists in the interaction of equimolecular amounts of the hydrochloride of an iminoester and of an α-substituted carbonyl compound in liquid ammonia under pressure. The carbonyl compounds employed in this reaction were 1,3-dihydroxyacetone,[26,27,29-31] α-hydroxyketones,[28,31] α-haloketones,[28,32] and α-acetoxyketones.[28] The reactions were carried out by heating the reactants (40–70 °C) under a pressure of 13–50 atm for 3–48 h; the yields of the target 2,4,5-trisubstituted 1*H*-imidazoles were then 10%–90% (Table 1).

(1)

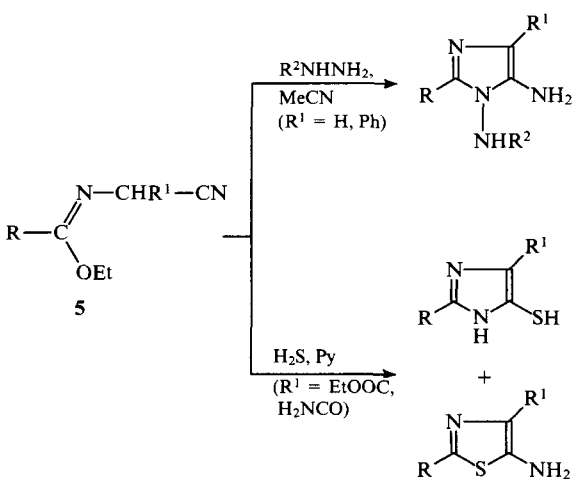


R = H, Me, Pr^i, Ar, $PhCH_2$, α-$C_{10}H_7CH_2$, cyclo-C_6H_{11}, Py, $ClCH_2CH_2$, $TsNHCH_2CH_2$, Me_2NCH_2, $Me_2NCH_2CH_2$, cyclo-$C_5H_{10}NCH_2CH_2$;

R^1 = H, $HOCH_2$, $HOCH_2CH_2$, Alk, Ph;

R^2 = H, Me, Ph, $MeOCH_2$; $R^1 + R^2 = -(CH_2)_4-$;

X = HO, Br, Cl, AcO.



It was shown subsequently that *N*-substituted 1*H*-imidazoles are formed in a satisfactory yield from α-amino- and α-acylamino-ketones under similar conditions (80 °C, 35 atm, 15 h).[33,34]

R = Me, Ar, 4-$ClC_6H_4CH_2$, cyclo-C_6H_{11}, 3-Py;
R^1 = Alk, Ph;
R^2 = H, Alk, Ph, $PhCH_2$, $MeSCH_2CH_2$;
R^3 = H, Me, Ph, cyclo-C_6H_{11}; X = H, Ac.

The *N*-cyanomethylimidates **5** are convenient intermediates in the synthesis of 1*H*-imidazoles with functional group substituents. For example, treatment of compound **5** (R^1 = H, Ph) with hydrazine or phenylhydrazine afforded 1,5-diamino-1*H*-imidazoles — key compounds in the synthesis of azaindoline heterocycles.[35] The interaction of compounds **5** (R^1 = EtOOC, H_2NCO) with hydrogen sulfide in pyridine results in the formation of 5-mercapto-1*H*-imidazoles (yield 20%–35%) together with 5-aminothiazoles (yield 10%–20%, see Scheme 1).[36]

Scheme 1

R = H, Me, Ph, $PhCH_2$;
R^1 = H, Ph, EtOOC, H_2NCO; R^2 = H, Ph.

Table 1. Synthesis of 2,4,5-trisubstituted 1*H*-imidazoles by the condensation of iminoester hydrochlorides with α-substituted carbonyl compounds reaction (1) in liquid ammonia.[26–30]

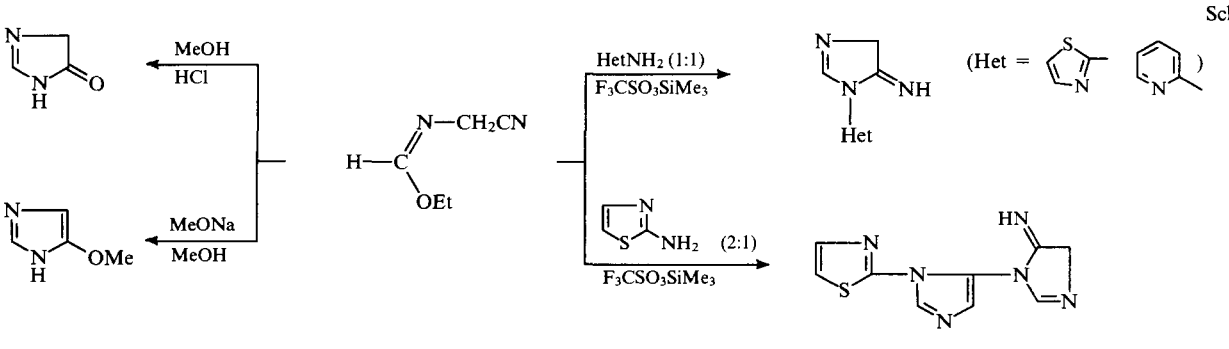
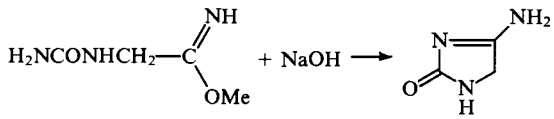
4-MeC_6H_4	Me	H	25	50–60	10	90



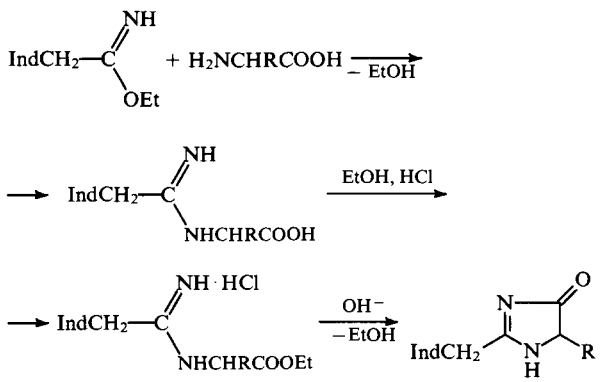
The reaction of the *N*-cyanomethyliminoester of formic acid with a methanol solution of HCl (20 °C, 0.5 h) leads to Δ^2-imidazolin-4(5)-one (yield 90%),[37,38] whilst refluxing with sodium methoxide in methanol gives rise to 4(5)-methoxyimidazole (yield 60%, see Scheme 2).[38]

The interaction of the same *N*-cyanomethyliminoester with heterocyclic amines (in molar proportions of 1 : 1) in the presence of trimethylsilyl triflate in acetonitrile (20 °C, 2 h) led to the synthesis of 1-heteroaryl-5-imino-Δ^2-imidazolines in 82%–91% yield.[38,39] On the other hand, the reaction of 2-aminothiazole with two equivalents of the *N*-cyanomethylimidate under similar conditions leads to the formation of the 1,5-disubstituted imidazole **6**.[38,39]

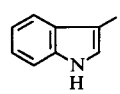


The condensation of the iminoester of ethoxycarbonylformic acid with *N*-phenylurea in tetrahydrofuran (THF) in the presence of HCl results in the formation of 3-phenylimidazolidine-2,4,5-trione (yield 56%).[22]

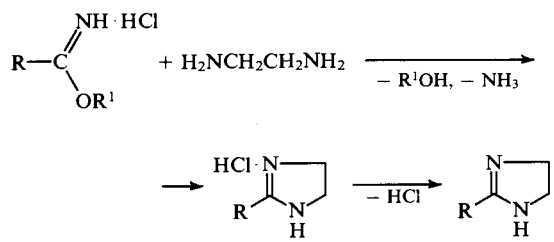
According to patent data,[40] 4-amino-Δ^3-imidazolin-2-one is formed in 95% yield on refluxing the iminoester of uredioacetic acid with alkali in aqueous alcohol.



Scheme 2

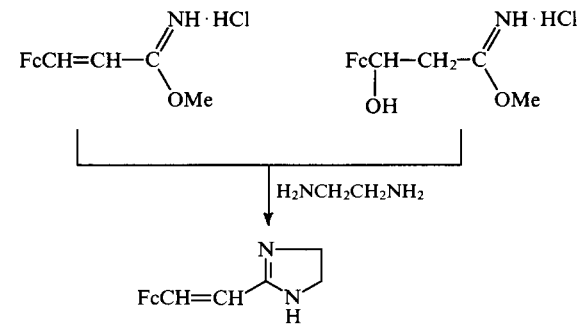


6



Fel'dman et al.[41] synthesised 2-(3-indolylmethyl)-Δ^2-imidazolin-4-ones, which are unstable under the usual conditions, from the ethyl iminoester of 3-indolylacetic acid and α-aminoacids in accordance with the following scheme:

R = H, Pr^i, Bu^i, Bu^s, $IndCH_2$;

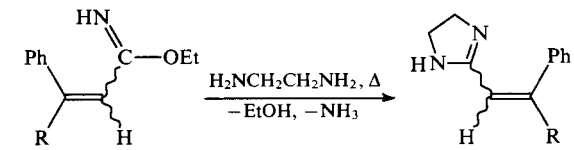


Ind = 

Some of the most interesting derivatives of the imidazole series are 2-substituted Δ^2-imidazolines, in view of their high and varied biological activity and valuable applied properties.[42,43] Compounds of this type are formed on condensation of iminoester salts with aliphatic 1,2-diamines.[4,5,42] It is noteworthy that investigators have devoted considerable attention in recent years to the synthesis of Δ^2-imidazolines from the hydrochlorides of ring-substituted iminoesters of benzoic,[44-49] phenylacetic,[44,47-49] 3,4-dihydro- and 1,2,3,4-tetrahydro-naphthalene-2-carboxylic acids,[50] adamantane-1-carboxylic acid,[51,52] ferrocenecarboxylic acid,[53] heterocyclic acids derived from furan,[54-57] benzofuran,[58] indole,[55,59-64] benzimidazole,[55] pyridine,[55] 4,5,6,7-tetrahydrobenzothiophene,[55] imidazo[1,2-a]-pyrazine,[65] isoxazoline,[66] etc., as well as aliphatic acids with functional-group substituents containing nitro-groups,[67-69] silylalkyl groups,[70-72] *N*-acylamino-groups,[73] alkoxy- and aryloxy-groups,[74-77] alkylthio- and arylthio-groups,[49,78] and organophosphorus fragments,[79,80] sterically hindered phenols,[81] etc.

R = Alk, cyclo-C_nH_{2n-1}, 1-Ad, $AlkOCH_2CH_2$, $ArOCH_2$, $MeC(NO_2)_2CH_2CH_2$, $Me_2C(NO_2)CH_2CH_2$, $Me_3SiCH_2CH_2$, $PhCH_2$, $XC_6H_4CH_2$, Ar, $ArCH_2SCH_2CH_2$, $(EtO)_2P(O)CH_2$, $(AlkO)_2P(O)CH_2CH_2$, Het; R^1 = Me, Et, $MeOCH_2CH_2$.

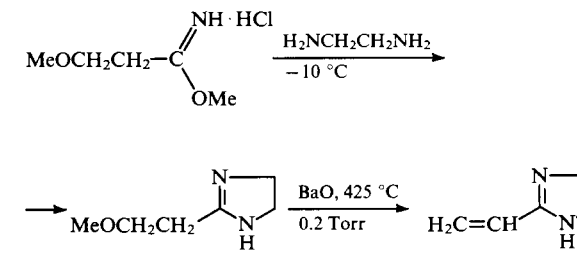
There are also isolated literature data concerning the synthesis of 2-substituted Δ^2-imidazolines from the iminoesters of α,β-unsaturated acids and their hydrochlorides. For example, (*E*)- and (*Z*)-2-(β-ferrocenylvinyl)-Δ^2-imidazolines **7** have been synthesised in 82%–88% yield by the reaction of the hydrochlorides of the methyl iminoesters of (*E*)- and (*Z*)-β-ferrocenylacrylic acids with ethylenediamine (0 °C, 0.5 h; 50–60 °C, 2 h).[82]



(*E*)- and (*Z*)-**7**

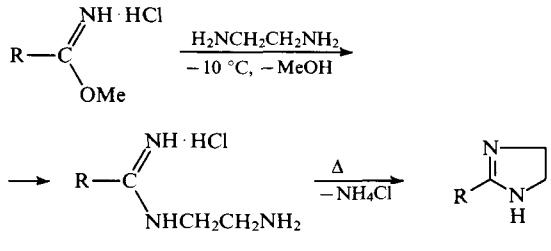
Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$–

The same workers showed[83] that a 3:1 mixture of the (*E*)- and (*Z*)-isomers **7** is formed under similar conditions from the hydrochloride of the methyl iminoester of 3-hydroxy-3-ferrocenylpropionic acid.

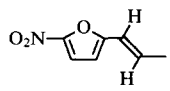


The *p*-tosylate of 2-[β-(5-nitro-2-furyl)vinyl]-Δ^2-imidazoline, which inhibits the growth of pathogenic bacteria, has been obtained in 83% yield by the reaction of the iminoester of β-(5-nitro-2-furyl)acrylic acid with the di-*p*-tosylate of ethylenediamine in ethanol (50–55 °C, 18 h).[84,85]

Ishikawa[86] synthesised (*E*)- and (*Z*)-(β-R-styryl)-Δ^2-imidazolines in 54%–88% yield by refluxing the ethyl iminoesters of (*E*)- and (*Z*)-β-R-cinnamic acids with ethylenediamine (molar ratio 1:2) in ethanol. These compounds exhibit a hypoglycemic activity.

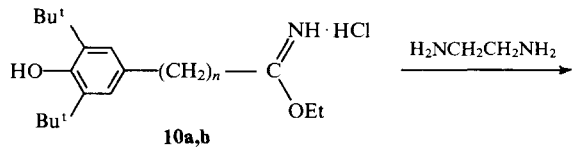


R = Ph, Py

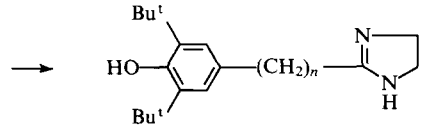


We may note that 2-vinyl-Δ^2-imidazoline, which is used as the monomer in the synthesis of water-soluble polymers, may be synthesised in a high yield from 2-(β-methoxyethyl)-Δ^2-imidazoline.[74-77,87]

Despite the extensive application of the condensation of iminoester salts with ethylenediamine for the synthesis of Δ^2-imidazolines, there is hitherto hardly any information about the mechanism of this reaction. The condensation apparently proceeds with the intermediate formation of the hydrochlorides of *N*-(2-aminoethyl)amidines **8**, which subsequently cyclise to Δ^2-imidazolines.[88] In certain cases, when the reaction was carried out at −10 °C, it was possible to isolate and identify intermediates of this type, which on refluxing in ethanol (2–3 h) were converted quantitatively into 2-substituted Δ^2-imidazolines.[89]



8

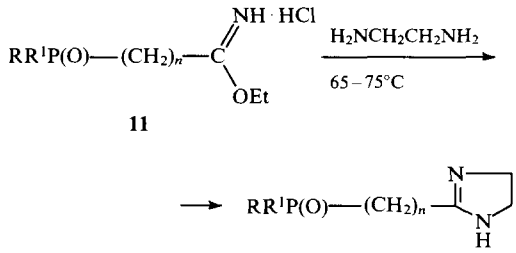


R = PhCH(OH), 4-$O_2NC_6H_4$, Ind, 3-Py, 

Since the first stage of the reaction proceeds with evolution of heat, the hydrochlorides of the iminoesters are mixed with ethylenediamine in an anhydrous solvent (methanol, ethanol, dioxane, methylene chloride, etc.) whilst cooling the system (0–10 °C). In order to complete the cyclisation, the reaction mixture is heated (40–78 °C) for several hours. The hydrochlorides of Δ^2-imidazolines formed under these conditions are converted into the free bases by treatment with a solution of sodium alkoxide in methanol or ethanol and also with a saturated solution of alkali whilst cooling. This results in the formation of the target 2-substituted Δ^2-imidazolines in fairly high yields (73%–95%) and without impurities.

There are only isolated literature data on the correlation between the structure of the acid components of the iminoester molecule, the reaction time, and the yields of the corresponding Δ^2-imidazolines. For example, the synthesis of the Δ^2-imidazoline **9a** from the hydrochloride of the iminoester of 3,5-di-*tert*-butyl-4-hydroxybenzoic acid **10a** requires prolonged heating (8–10 h), whereas the formation of the Δ^2-imidazoline **9b** from the hydrochloride of the iminoester of 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionic acid **10b** is completed in 1.5–2 h.[44,45,81]

10a,b



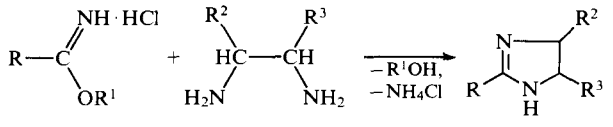
9a,b

n = 0 (**a**), 2 (**b**).

The lower reactivity of the iminoester hydrochloride **10a** with respect to ethylenediamine can be accounted for by the influence of the electron-donating hydroxyaryl group, which diminishes the positive charge on the carbon atom of the iminoester group and lowers its electrophilicity. In the case of the iminoester hydrochloride **10b**, the influence of this group is much smaller, since the groups are separated by two methylene units.[44,45]

A similar behaviour was found in a study of the condensation of ethylenediamine with the hydrochlorides of the iminoesters of indole-3-carboxylic and 3-indolylacetic acids containing the electron-donating indolyl group.[61]

It has been noted,[79] that the hydrochlorides of the iminoesters of β-phosphorylated propionic acids **11** (n=2) react with ethylenediamine twice as slowly as the corresponding acetic acid derivatives **11** (n=1).

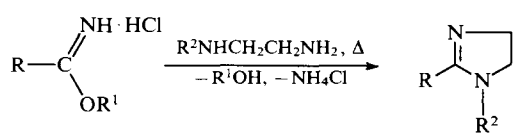


11

R = Ph, AlkO; R^1 = AlkO; n = 1, 2.

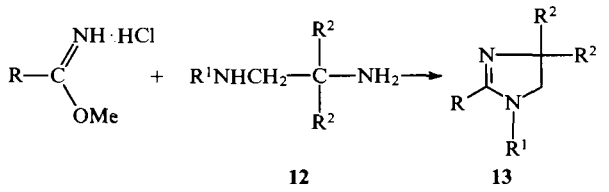
The authors explained this by the fact that the approach of the electron-accepting phosphoryl group to the reaction centre increases its electrophilicity, which facilitates the reaction with ethylenediamine.

One should also note that iminoester hydrochlorides are much more reactive in the reaction with ethylenediamine than the iminoesters themselves. In the latter case, the formation of Δ^2-imidazolines in a satisfactory yield requires prolonged (10–22 h) refluxing of the reactants in ethanol or in another suitable solvent,[52,59,73] while the iminoesters of phosphorylated acids do not react with ethylenediamine at all.[79] This finding can be explained by the increase in the electrophilicity of the carbon atom of the C=N group in the iminoester hydrochlorides as a consequence of the greater shift of the π-electron pair of the double bond towards the nitrogen atom of the iminoester group.[4]



Apart from ethylenediamine, other aliphatic 1,2-diamines have been condensed with iminoesters and their hydrochlorides, for example, 1,2-diaminopropane,[90,91] 2,3-diaminopropan-1-ol,[49] and erythro-1,2-diamino-4,4,4-trifluoro-1-phenylbutane.[46] The 2,4-disubstituted or 2,4,5-trisubstituted Δ^2-imidazolines formed as a result of these reactions exhibit hypotensive,[92] hypertensive,[49] analgesic, and anti-inflammatory[46] activities.

R = Et, Ar, $PhCH_2OCH_2$,
$PhCHR^4CH_2$ (R^4 = Ph, cyclo-C_6H_{11}, 4-Py);
R^1 = Me, Et; R^2 = Me, $HOCH_2$, Ph; R^3 = H, F_3CCH_2.

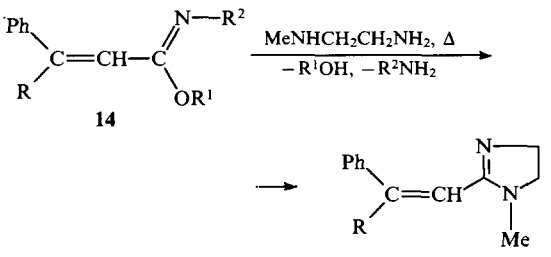


The condensation of iminoester hydrochlorides with *N*-monosubstituted ethylenediamines, leading to 1,2-disubstituted Δ^2-imidazolines which are difficult to obtain by other methods, is of definite interest.[42]

There are literature data on the condensation of iminoester hydrochlorides with *N*-alkyl-,[48,81] *N*-(2-cyanoethyl)-,[55,61,62,89,93] *N*-(1-adamantylmethyl)-,[52] *N*-(trimethylsilylmethyl)-,[71,94] *N*-aryl-,[95–97] *N*-benzyl-,[54,55,61,62,81,89,98] *N*-(2-aryl-2-hydroxyethyl)-,[99] *N*-furfuryl-,[54,55,64,89,100] *N*-tetrahydrofurfuryl-,[64,100] *N*-(2-thienylmethyl)-,[54,89] *N*-(4-phenyl-2-thiazolyl)-, *N*-(2-benzothiazolyl)-,[89,101] and *N*-(1-benzotriazolylmethyl)-ethylenediamines.[89]

R = Alk, $HOCH_2$, Ph, $PhCH_2$, $XC_6H_4CH_2$,
cyclo-C_nH_{2n-1}, Het, 1-Ad;
R^1 = Me, Et; R^2 = Alk, Ar, $PhCH_2$, Het.

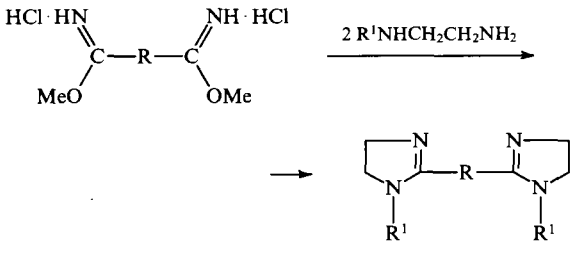
The interaction of iminoester hydrochlorides with the 1,2-diamines **12** — ethylenediamine, *N*-(trimethylsilylmethyl)-ethylenediamine, and 2-amino-2-methyl-1-(trimethylsilylmethyl)aminopropane — has been studied in detail.[71,94]



12 **13**

R = Me, Ph, $PhCH_2$, $Me_3SiCH_2CH_2$;
R^1 = H, Me_3SiCH_2; R^2 = H, Me.

It was established that the yield of the Δ^2-imidazolines **13** depend to a greater extent on the structure of the initial 1,2-diamine and to a much lesser extent on the structure of the iminoester hydrochlorides. This fact can evidently be accounted for by the steric hindrance generated by the presence of bulky substituents next to the reaction centres in the 1,2-diamine. The yields of the Δ^2-imidazolines **13** decrease from ethylenediamine (yield 68%–90%) to the *N*-substituted ethylenediamine **12** ($R^1 = Me_2SiCH_2$, R^2 = H; yield 53%–58%) and to the *N*-substituted 1,2-diaminopropane **12** (R^1-Me_3SiCH_2, R^2 = Me) (yield 23%–34%).

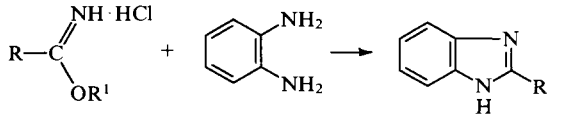


Heating of the *N*-substituted iminoesters **14** with *N*-methylethylenediamine (120–130 °C, 1.5 h) leads to 1-methyl-2-(β-R-styryl)-Δ^2-imidazolines, which exhibit a hypoglycemic activity.[102]

14

R = Me, Ph, Py; R^1 = Alk; R^2 = Pr^i, Bu^t.

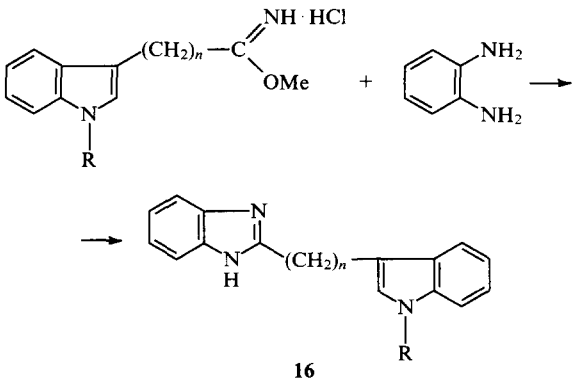
There are also literature data on the condensation of the dihydrochlorides of the bisiminoesters of dicarboxylic acids with ethylenediamine[103,104] and *N*-(1-adamantylmethyl)ethylenediamine,[52] which leads to the bisimidazolines **15** in 80%–97% yield.



15

R = $-CH_2CH_2CMe(NO_2)CH_2CH_2-$,
$-CH_2CH_2C(NO_2)_2CH_2CH_2-$,
$-CH_2CH_2OCH_2C{\equiv}CCH_2OCH_2CH_2-$;
R^1 = H, 1-$AdCH_2$.

2. Synthesis of substituted benzimidazoles

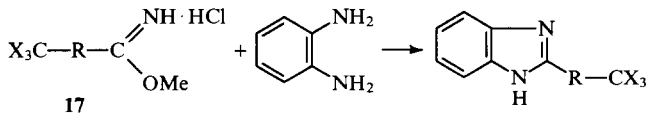


The condensation of the hydrochlorides of the iminoesters of aliphatic, aromatic, and heterocyclic acids with *o*-phenylenediamine leads to 2-substituted benzimidazoles.[4,42,44,51,52,55,57,61,62,69,71,72,80,82,89,103,105–114] Reactions of this type are usually carried out by refluxing (for 1.5–5 h) equimolecular amounts of the reactants in methanol or ethanol; the benzimidazoles are then formed in 36%–92% yields.

R = Me, $EtOOCCH_2$, $Me_2C(NO_2)CH_2CH_2$, $MeC(NO_2)_2CH_2CH_2$, $(O_2N)_3CCH_2CH_2$, $Ac(CH_2)_3$, $Me_3SiCH_2CH_2$, $ArNHCH_2CH_2$, 4-HO-3,5-$Bu^t_2C_6H_2(CH_2)_n$ (n = 0, 2), Ar, $PhCH_2$, Fc, 1-Ad, Het;
R^1 = Me, Et, $MeOCH_2CH_2$.

It has been noted[115,116] that the interaction of iminoesters with *o*-phenylenediamine is rapid only when the reaction is carried out in an acid medium. For example, when the iminoester of *N*-phenylalanine was heated with *o*-phenylenediamine in dioxane or isopentyl alcohol (140 °C, 3 h), the yield of 2-(2-phenylaminoethyl)benzimidazole reached only 55%, whereas the reaction with the dihydrochloride of this iminoester proceeds exothermically and the yield of benzimidazole is 70%–80%.[116]

The 2-substituted benzimidazoles **16**, containing indole fragments, are formed in 85%–92% yield on refluxing equimolecular amounts of the hydrochlorides of the iminoesters of acids of the indole series and *o*-phenylenediamine in ethanol for 4–6 h.[55,61,62,89]

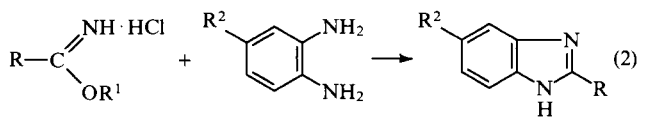


16

R = H, Me; n = 0, 1.

The benzimidazoles **16** have also been synthesised by condensing the iminoesters of the above acids with *o*-phenylenediamine. These reactions were carried out under more severe conditions — at 140–150 °C in dimethylformamide (DMF) for 15–20 h, but the yield of the target products did not then exceed 44%–52%.[89] In view of this, iminoester hydrochlorides are employed as a rule as the initial compounds in the synthesis of benzimidazoles by the above procedure. In those cases where the iminoester hydrochlorides are difficult to obtain or are unstable (for example, the hydrochlorides of the iminoesters of trichloroacetic acid[117]), the hydrochloride of *o*-phenylenediamine is condensed with the iminoesters. For example, 2-trichloromethylbenzimidazole is formed in 85%–95% yield on interaction of the iminoester of trichloroacetic acid with the monohydrochloride of *o*-phenylenediamine in ethanol[118] or in acetic acid.[119]

The condensation of equimolecular amounts of the hydrochlorides of the iminoesters of polyhalogenated carboxylic acids **17** and *o*-phenylenediamine in methanol (refluxing for 1–2 h) afforded 2-polyhaloalkylbenzimidazoles in 45%–86% yields.[114]



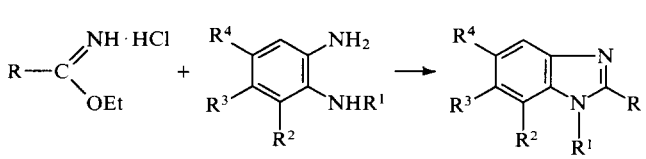
17

X = Br, R = $-(CH_2)_2-$;
X = Cl, R = $-CH_2CHCl-$, $-(CH_2)_2-$.

At the same time, the authors[114] noted that they were unable to synthesise the corresponding benzimidazoles from the hydrochlorides of the iminoesters of 2,4,4,4-tetrabromobutyric acid **17** (X = Br, R = $-CH_2CHBr-$), 4,4,4-tribromobut-2-enoic acid **17** (X = Br, R = $-CH=CH-$), and 4,4,4-trichlorobut-2-enoic acid **17** (X = Cl, R = $-CH=CH-$). According to the authors, the presence of the double bond in the α-position relative to the carbon atom of the iminoester group lowers its electrophilicity, which prevents the occurrence of the target reaction.

The condensation of the hydrochlorides of the iminoesters of various acids with 4-substituted 1,2-diaminobenzenes containing both electron-donating and electron-accepting groups has been widely used in recent years for the synthesis of 2,5(6)-disubstituted benzimidazoles.[107,112,113,120-127]

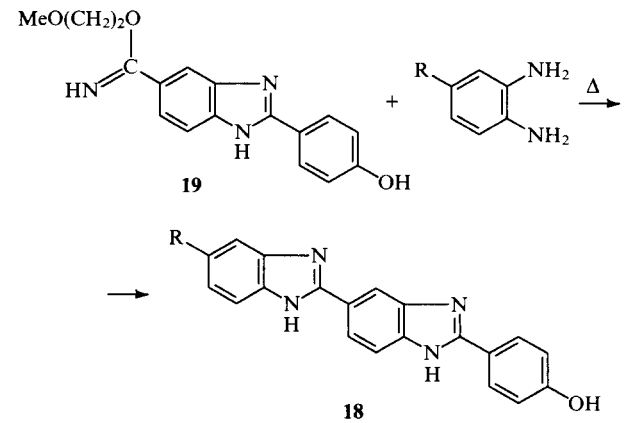
(2)



R = $PhCH_2$, $XC_6H_4CH_2$, Ar, Het;
R^1 = Me, Et, $MeOCH_2CH_2$;
R^2 = Alk, AlkO, ArO, O_2N, NC, MeOOC, F_3C, Het.

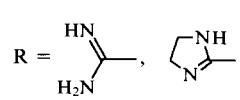
The above reactions were carried out by refluxing (for 2–8 h) equimolecular amounts of the reactants in methanol, ethanol, dioxane, or acetic acid, the yield of the target benzimidazoles amounting to 30%–62% depending on the structures of the initial iminoester hydrochlorides and on the nature of the substituents R^2 in the *o*-phenylenediamine (Table 2, see over).

It has been noted[121-123,125] that, when the methoxyethyl iminoesters of aromatic acids are condensed with 4-substituted 1,2-diaminobenzene, the yield of the target benzimidazoles increases appreciably compared with the methyl and ethyl iminoesters.

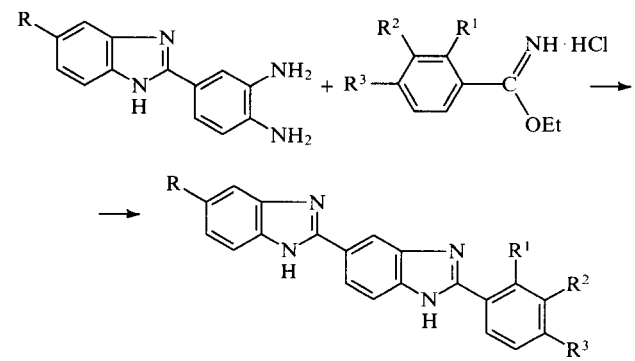


Some of the 2,5(6)-disubstituted benzimidazoles synthesised from the iminoester hydrochlorides possess antihelminthic and fungicidal properties,[107] exhibit antihypertensive, spasmolytic, and vasodilating activities,[120] as well as high cytotoxic,[123] antiproteolytic,[125] analgesic, and anti-inflammatory activities.[127]

The condensation of iminoester hydrochlorides with *N*-monosubstituted *o*-phenylenediamines leads to 1,2-disubstituted benzimidazoles. For example, when the hydrochlorides of aliphatic acid iminoesters are refluxed with *N*-alkyl-*o*-phenylenediamines in ethanol, polysubstituted benzimidazoles are formed in 58%–79% yields. They can be used as selective herbicides.[128-132]

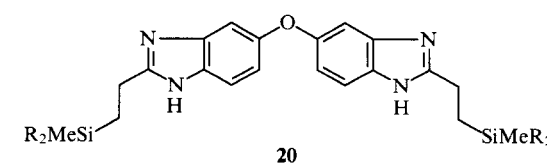


R = H, Alk, $HOCH_2$;
R^1 = Alk; R^2, R^3 = H, Hal, NO_2, NH_2, MeNH, MeO, Me_2N;
R^4 = Alk, cyclo-(C_3–C_6), F_3C, F_2CHSO_2.



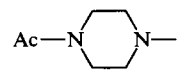
Derivatives of 2,5-bisbenzimidazolyl **18** are of definite interest from the standpoint of the search for new substances with antiproteolytic[125] and chemotherapeutic[126] activities. For example, when the methoxyethyl iminoester **19** is condensed with 4-R-*o*-phenylenediamines in methanol (refluxing for 3 h), 5-(5-R-2-benzimidazolyl)-2-(4-hydroxyphenyl)benzimidazoles **18** are formed in 25%–28% yields.[125]

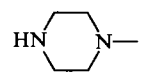
19 18

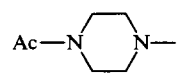


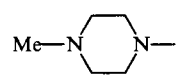
The corresponding bisbenzimidazolyls have also been synthesised in 55%–83% yields by the interaction of 2-(3,4-diaminophenyl)-5-R-benzimidazoles with the hydrochlorides of aromatic acid iminoesters in ethanol (refluxing for 3–5 h).[126]

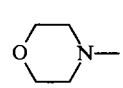
R = Et_2N,  ;
R^1 = H, HO; R^2 = H, Cl, Me, NO_2, MeO;
R^3 = H, AlkO, Me, Cl, Ph, PhO, NH_2;
R^1 + R^2 = OCH_2O; R^4 = Alk, $PhCH_2$, $HOCH_2CH_2$, Ph, Et_2NCO.

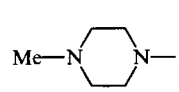


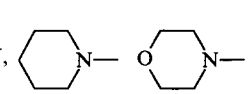


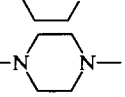


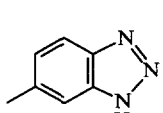


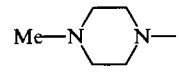


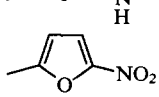




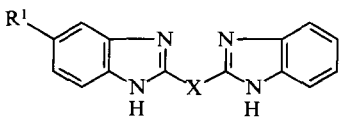








The condensation of the hydrochlorides of the iminoesters of β-trialkylsilylpropionic acids with di(3,4-diaminophenyl) ether (molar ratio 2:1) afforded a 70%–72% yield of the organosilicon dibenzimidazolyl ether **20**.[72]



20

R = Me, Et.

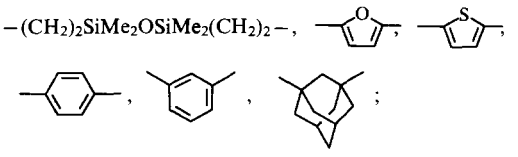
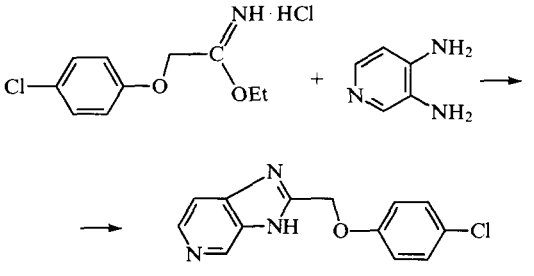
The interaction of the bisiminoesters of dicarboxylic acids or their hydrochlorides with *o*-phenylenediamine or 4-substituted 1,2-diaminobenzenes (molar ratio 1 : 2) results in the formation of the derivatives **21**, in which the benzimidazole fragments are separated by a chain of carbon atoms or by an aromatic or a heterocyclic group.[52,103,104,125,133]



21

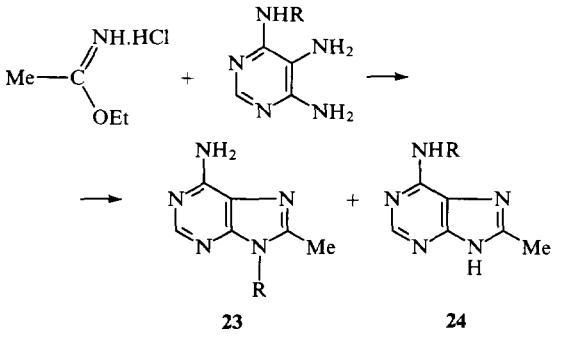
X = $-(CH_2)_n-$, where n = 1–3, 5, 6, 8;

$-(CH_2)_2CMe(NO_2)(CH_2)_2-$, $-(CH_2)_2C(NO_2)_2(CH_2)_2-$,



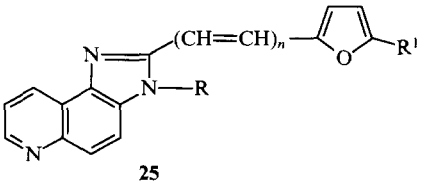
$-(CH_2)_2SiMe_2OSiMe_2(CH_2)_2-$,

R^1 = H, $-C(NH)NH_2$, $-C(NBu)NH_2$,

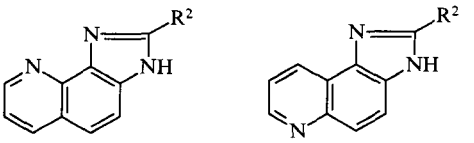


The condensation of iminoester hydrochlorides with heterocyclic *o*-diamines leads to condensed imidazole systems. For example, the interaction of the hydrochloride of the (4-chlorophenoxy)acetic acid iminoester with 3,4-diaminopyridine in ethanol (refluxing for 20 h) gives rise to the imidazo[4,5-*c*]pyrimidine derivative **22** (yield 20%), which exhibits an antihypotoxic activity.[134]

22



The ring closure in the reaction of 4-*N*-substituted 4,5,6-triaminopyrimidines with the hydrochloride of the acetic acid iminoester proceeds much more readily with participation of the secondary 5-amino-group and not the primary 6-amino-group.[135] This results in a 70%–85% yield of 6-amino-9-R-8-methylpurines **23** together with 6-*N*-substituted 6-amino-8-methylpurines **24** (yield 6%–17%).



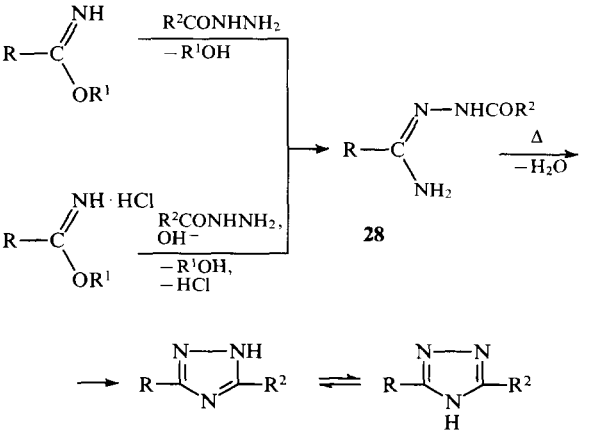
23 **24**

R = Ph, $PhCH_2$.

The condensation of *N*-substituted 5,6-diaminoquinolines with the hydrochlorides of the iminoesters of acids derived from furan afforded 40%–75% yields of 2-(5-R^1-2-furyl)- and 2-[β-(5-R^1-2-furyl)vinyl]-3-substituted 3*H*-imidazo[4,5-*f*]quinolines **25**.[136]

25

26 **27**



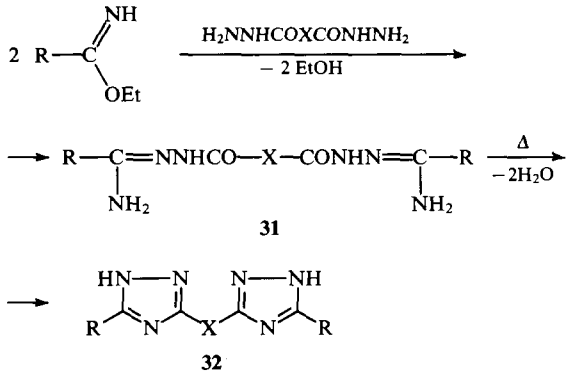
R = H, Me; R^1 = H, Br, NO_2; n = 0, 1; R^2 = Me, Ph, $PhCH_2$.

Refluxing of equimolecular amounts of 7,8-diaminoquinoline and the hydrochlorides of carboxylic acid iminoesters in ethanol gives rise to 60%–67% yields of 2-R-3*H*-imidazo[4,5-*h*]quinolines **26**.[137] 2-R-3*H*-imidazo[4,5-*f*]quinoline **27** have been synthesised from 5,6-diaminoquinoline under similar conditions.

3. Synthesis of substituted 1,2,4-triazoles and derivatives of 1,2,4-triazole with functional group substituents

The interactions of carboxylic acid iminoesters of *N*-acylhydrazines (acid hydrazides) are known to give rise to carboxylic acid *N*-acylamidrazones **28**, which can serve as convenient intermediates in the synthesis of 3,5-disubstituted 1*H*-1,2,4-triazoles.[4,5,138–142]

The *N*-acylamidrazones **28** are formed in high yields (70%–94%) when equimolecular amounts of an iminoester and an acid hydrazide are refluxed in methanol or ethanol[89,142–146] (in the case of *N*-formylhydrazine, the reaction is carried out at 0 °C)[140] or when iminoester hydrochlorides interact with acid hydrazides in the presence of bases—triethylamine,[147,148] aqueous NaOH solution,[139] or sodium ethoxide in absolute ethanol.[149]

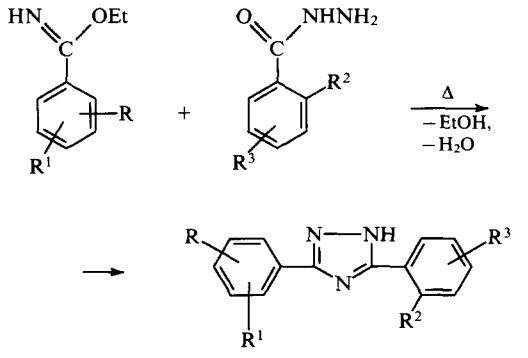


29 **30**

R = Alk, $Me_3SiCH_2CH_2$, $PhCH_2$, $PhCH_2OCONHCH_2$, EtOOC, Ar, Het;

R^1 = Me, Et; R^2 = H, Alk, Ar, Het.

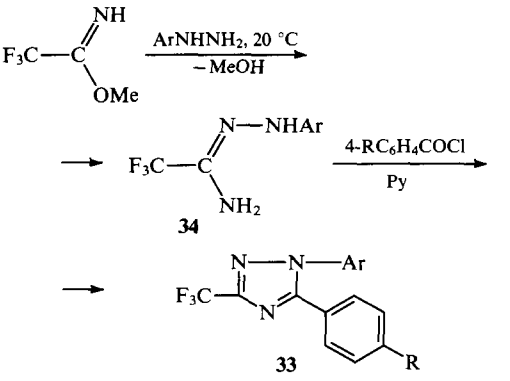
The *N*-acylamidrazones **28** readily undergo cyclodehydration to 3,5-disubstituted 1*H*-1,2,4-triazoles **29**, which can exist in the form of the tautomeric 4*H*-1,2,4-triazoles **30**.[150,151] The cyclodehydration of the *N*-acylamidrazones **28** takes place on heating to a temperature higher by 5–10 °C than the melting point for several minutes[20,89,143–146] and in certain cases on heating in vacuo[142] and in high-boiling solvents (toluene, DMSO).[147,149]



When iminoesters interact with dicarboxylic acid dihydrazides (molar ratio 2:1), the bis-*N*-acylamidrazones **31** are formed. On heating to 200–220 °C in vacuo, the latter give rise to 3,5-disubstituted bis-1*H*-1,2,4-triazoles **32** (yields 31%–74%).[142,149]

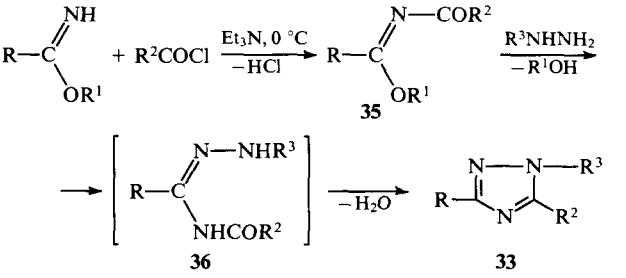
R = Me, $Me_3SiCH_2CH_2$, Ph, $PhCH_2$, 4-MeC_6H_4;

X = $-(CH_2)_n-$,  , where n = 0, 1, 4.



There are literature data concerning the synthesis of 3,5-disubstituted 1*H*-1,2,4-triazoles **29** from acid iminoesters and hydrazides without the isolation of the intermediate *N*-acylamidrazones **28**. For example, when substituted benzoic acid iminoesters were heated with aromatic acid hydrazines (110–125 °C, 10–24 h), 3,5-diaryl-1*H*-1,2,4-triazoles were synthesised in satisfactory yields. They exhibit high sedative and contraceptive activities.[152–155]

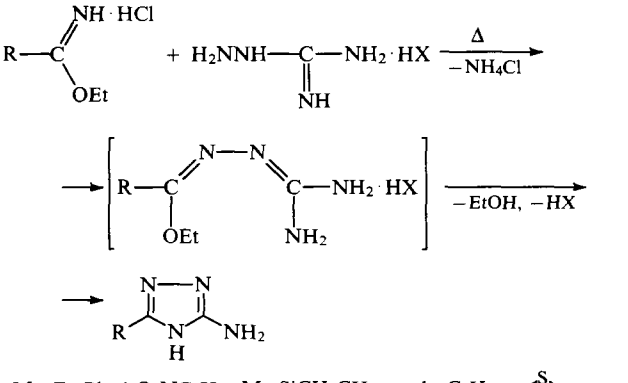
R = H, F, Cl, Alk, AlkO, Me_2N, Ph, F_3C;
R^1 = H, F, Cl, Alk; R + R^1 = OCH_2CH_2;
R^2 = Alk; R^3 = H, F, Cl, Alk, AlkO.



Certain 1*H*-1,2,4-triazoles are also formed in 30%–80% yields when iminoesters are refluxed in ethanol or methanol with reactive hydrazides — *N*-formylhydrazine,[139,156] the hydrazides of carboxylic hydroxyacids,[157,158] and the hydrazides of cyano-,[159,160] methoxy-,[159] and dimethoxy-acetic acids.[159]

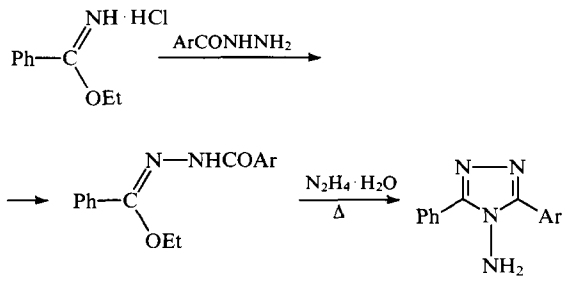
As a result of the search for promising substances with anti-inflammatory activity, Hungarian investigators[161,162] proposed a method of synthesis of 1,3,5-trisubstituted 1*H*-1,2,4-triazoles **33** (yield 16%–28%), which involves treatment of the *N*-substituted amidrazones **34** with acid chlorides in dioxane in the presence of pyridine.

R = H, Cl, F.



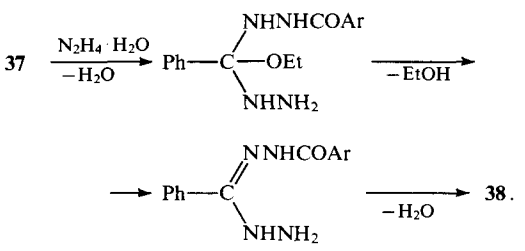
The interaction of the reactive *N*-acyliminoesters **35** with hydrazine or *N*-substituted hydrazines at 20 °C is apparently a more promising method of synthesis of 1,3,5-trisubstituted 1*H*-1,2,4-triazoles **33**.[163,164] The initial *N*-acyliminoesters **35** are formed in satisfactory yields (54%–95%) when iminoesters are acylated by acid chlorides in the presence of triethylamine at 0 °C.[163,165]

R = Me, Ar, Het; R^1 = Me, Et;
R^2 = Me, Ph, 4-ClC_6H_4, 2-$F_3CC_6H_4$;
R^3 = H, Me, Ph, C_nH_{2n-1}.



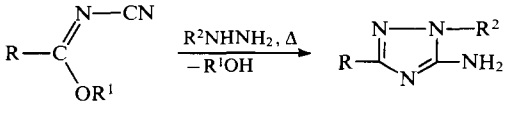
It has been suggested[163] that the intermediate **36** is formed initially as a result of the attack by the NH_2 group of the substituted hydrazine on the carbon atom of the iminoester. The intermediate cyclises at a temperature as low as 20 °C to the 1,2,4-triazole **33** with elimination of a water molecule. When the reaction is carried out under the conditions indicated, the yield of the target 1*H*-1,2,4-triazoles is 55%–87%.

Carboxylic acid iminoesters are also used as the reactants in the synthesis of 1*H*-1,2,4-triazole derivatives with functional group substituents. For example, when the iminoester hydrochlorides were refluxed with aminoguanidine hydrochloride or nitrate in pyridine or tripropylamine, 3-amino-5-substituted 4*H*-1,2,4-triazoles were synthesised in 35%–86% yields.[166,167]



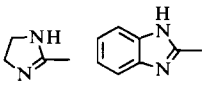
R = Me, Et, Ph, 4-$O_2NC_6H_4$, $Me_3SiCH_2CH_2$, cyclo-C_6H_{11},  .

French investigators isolated the benzoic acid *N*-acylhydrazones **37** in 65%–90% yields after the interaction of the benzoic acid iminoester hydrochloride with aromatic acid hydrazides in ethanol at 0 °C.[168] On refluxing with hydrazine hydrate in 1-propanol, the *N*-acylhydrazones were converted into 4-amino-4*H*-1,2,4-triazoles **38** in 52%–83% yields.

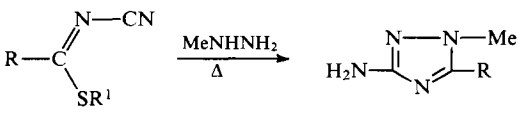


37 **38**

The authors proposed the following mechanism of the formation of 4-amino-1,2,4-triazoles **38** from the *N*-acylhydrazones **37** and hydrazine hydrate:



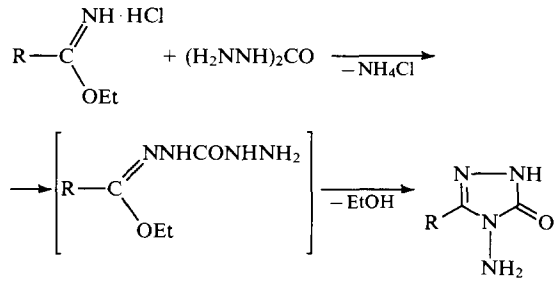
The reactive carboxylic acid *N*-cyanoiminoesters **39** are convenient compounds for the synthesis of amino-1*H*-1,2,4-triazoles. The *N*-cyanoiminoesters are formed when iminoester hydrochlorides react with chlorocyanogen[169] in the presence of triethylamine (yield 70%–80%) or with cyanamide in water in the presence of phosphate buffer (yield 34%–74%).[170]



For example, the condensation of the *N*-cyanoiminoester **39** with *N*-substituted hydrazines in ethanol (refluxing for 1–2 h) afforded 73%–82% yields of 1,3-disubstituted 5-amino-1*H*-1,2,4-triazoles.[171–173]

39

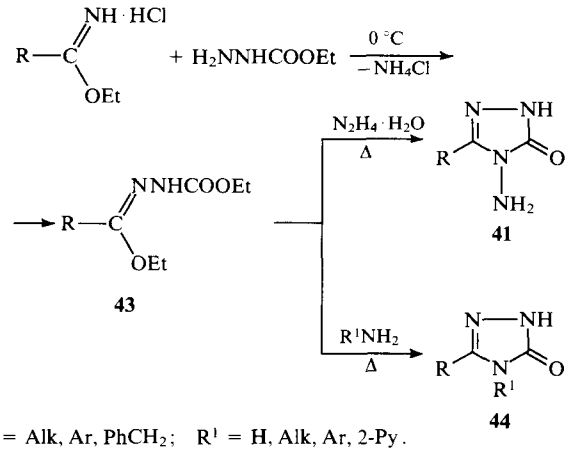
R = H, Me, $EtOOCCH_2$; R^2 = Me,  .



On the other hand, 3-amino-1-methyl-5-substituted 1*H*-1,2,4-triazoles are formed regioselectively in 82%–84% yield on refluxing the *N*-cyanoiminothioesters **40** with methylhydrazine in chloroform.[171]

40

R = Me, Pr^i; R^1 = Me, Et.

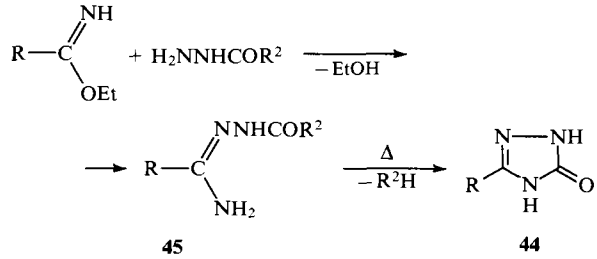


The condensation of equimolecular amounts of iminoester hydrochlorides and carbodihydrazide in ethanol (refluxing for 48 h) leads to 40%–45% yields of 4-amino-3-substituted 1*H*-Δ^2-1,2,4-triazolin-5-ones **41**.[174,175] The intermediate formation of the *N*-substituted hydrazones **42** in this reaction has been postulated.[174]

42 **41**

R = Me, Bu^t.

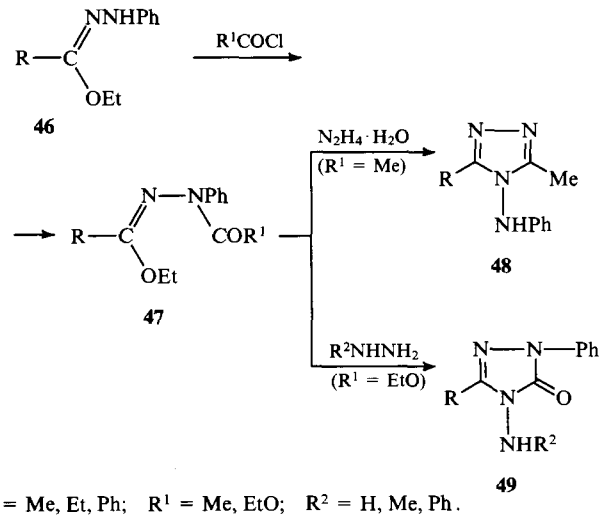
The interaction of iminoester hydrochlorides with *N*-(ethoxycarbonyl)hydrazine at 0 °C in ethanol affords 60%–85% yields of carboxylic acid ester N^2-(ethoxy-carbonyl)hydrazones **43**, which are convenient intermediates for the synthesis of Δ^2-1*H*-1,2,4-triazolin-5-ones.[174,176,177]



43 **41** **44**

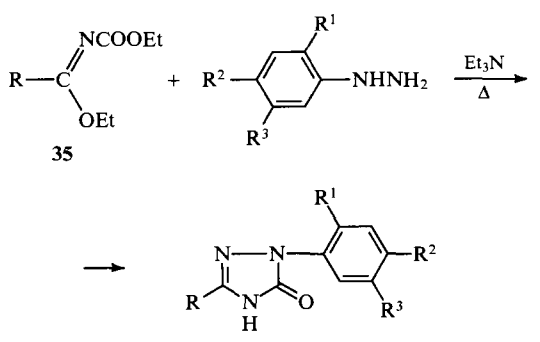
R = Alk, Ar, $PhCH_2$; R^1 = H, Alk, Ar, 2-Py.

On heating with ammonia or primary amines, the hydrazones **43** are converted into 3,4-disubstituted Δ^2-1*H*-1,2,4-triazolin-5-ones **44**,[176,177] while on prolonged refluxing (30 h) with hydrazine hydrate in 1-butanol they cyclise to 4-amino-Δ^2-1,2,4-triazolin-5-ones **41** (yield 62%–95%).[174]



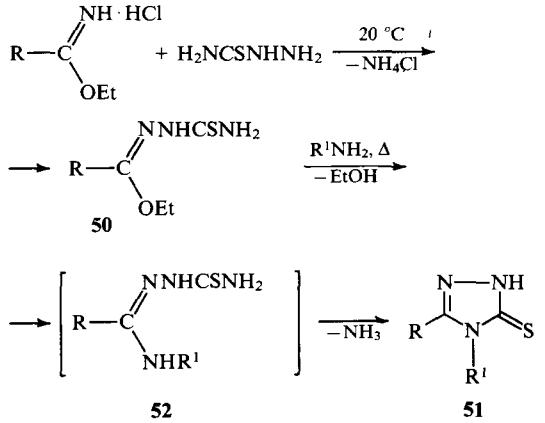
It is noteworthy that reactions of iminoester bases with *N*-(ethoxycarbonyl)hydrazines and semicarbazides give *N*-(R-carbonyl)amidrazones **45**, which cyclise on heating to 3-substituted Δ^2-1*H*-1,2,4-triazolin-5-ones **44** (R^2 = H).[22,176,178,179]

45 **44**



R = Alk, Ar, EtOOC; R^2 = EtO, NH_2, PhNH

The interaction of carboxylic acid *N*-phenylhydrazones **46** with ethyl chloroformate or acetyl chloride in the presence of pyridine or triethylamine gives rise to the formation of the *N*-disubstituted hydrazones **47**, the reactions of which with hydrazine hydrate and monosubstituted hydrazines in methanol lead to 4-phenylamino-4*H*-1,2,4-triazoles **48** or to 1,3-disubstituted 4-amino-Δ^2-1,2,4-triazolin-5-ones **49**.[180,181]

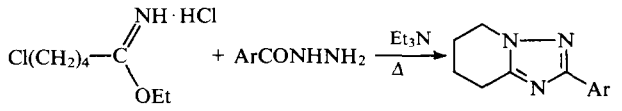


R = Me, Et, Ph; R^1 = Me, EtO; R^2 = H, Me, Ph.

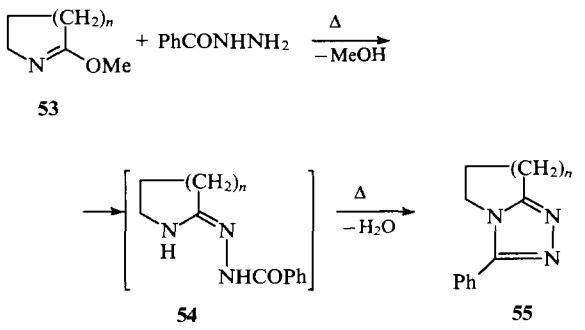
According to patent data,[182-187] 1,3-disubstituted Δ^2-1*H*-1,2,4-triazolin-5-ones, used as intermediates in the synthesis of herbicides, are formed in 50%–95% yields on heating equimolecular amounts of the *N*-(ethoxycarbonyl)iminoesters **35**, *N*-arylhydrazines, and triethylamine (40–90 °C, 3–12 h).

R = H, Alk; R^1 = H, Cl, F, NO_2; R^2 = H, Cl, F, HO, AlkO; R^3 = H, NO_2, COOH, $NCCH_2O$.

The interaction of iminoester hydrochlorides and thiosemicarbazide in DMF at 20 °C affords carboxylic acid ester thiosemicarbazones **50** in 53%–74% yields.[188,189] On heating with primary amines or arylhydrazines in DMF for 2–3 h, the latter are converted into 4,5-disubstituted Δ^2-1*H*-1,2,4-triazoline-5-thiones **51** (yield 20%–95%). The authors suggest that this involves the intermediate formation of the *N*-(thiocarbamoyl)-amidrazones **52**.[188]



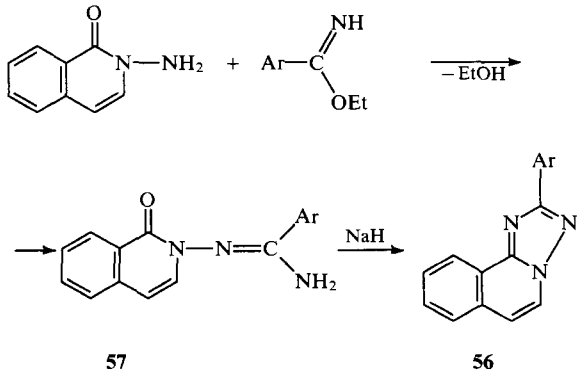
R = Alk, Ar, $PhCH_2$;
R^1 = $PhCH_2$, $HOCH_2CH_2$, Ar, 2-Py, cyclo-C_6H_{11}, ArNH.



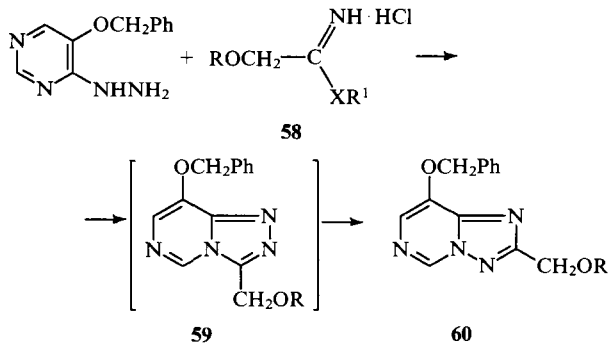
3-Substituted 4-phenyl-Δ^2-1,2,4-triazoline-5-thiones have been obtained in 42%–65% yields by condensing iminoester hydrochlorides with 4-phenylthiosemicarbazide in the presence of bases (pyridine, tripropylamine).[89,167,190,191]

Iminoester hydrochlorides are also convenient key compounds in the synthesis of condensed heterocyclic systems incorporating 1,2,4-triazole fragments.

Refluxing of the 5-chlorovaleric iminoester hydrochloride with aromatic acid hydrazides and triethylamine (molar ratios 1:1:2) in ethanol leads to 2-aryl-5,6,7,8-tetrahydro-1,2,4-triazolo[5,1-*a*]pyridines (yield 26%–35%).[8]

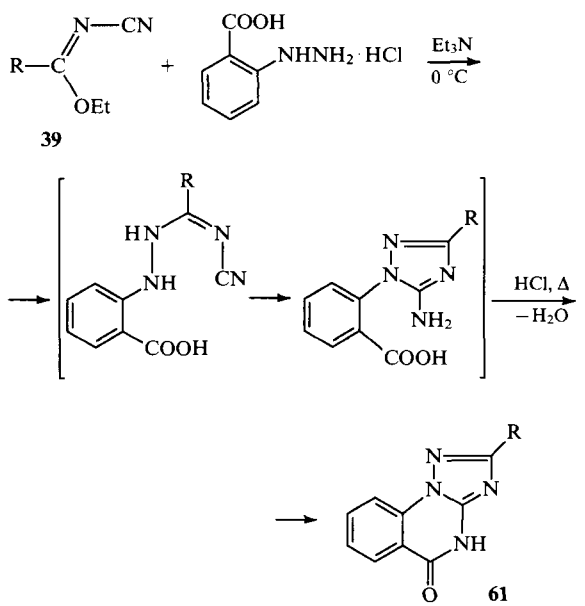


The condensation of the cyclic iminoesters **53** with benzoic acid hydrazide results in the formation of the *N*-acylamidrazones **54**, which, on refluxing in acetic acid (n = 1) or in xylene (n = 2), undergo intramolecular cyclisation to 3-phenyl-6,7-dihydro-5*H*-pyrrolo[2,1-*c*]-1,2,4-triazole **55** (n = 1) or 3-phenyl-5,6,7,8-tetrahydro-1,2,4-triazolo[4,3-*a*]pyridine **55** (n = 2).[8]

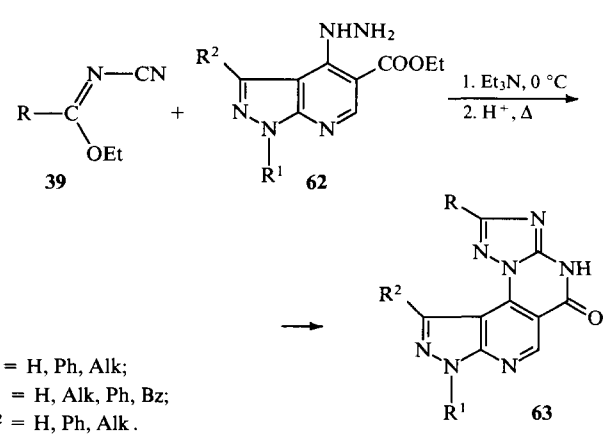


n = 1, 2.

The synthesis of 2-aryl-1,2,4-triazolo[5,1-*a*]isoquinolines **56** by the reaction of 2-amino-2*H*-isoquinolin-1-one with aromatic acid iminoesters and subsequent cyclisation of the intermediate amidrazones **57** on treatment with sodium hydride has been described in patents.[192,193]



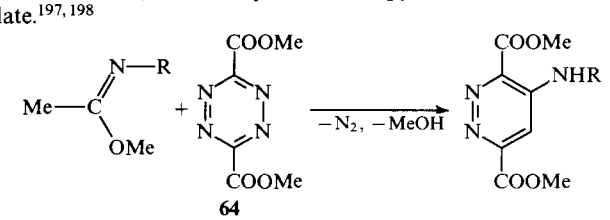
The interaction of 5-benzyloxy-4-hydrazinopyrimidine with the iminoester or iminothioester hydrochlorides **58** in pyridine (80 °C, 3 h) leads initially to 1,2,4-triazolo[4,3-*c*]pyrimidine **59**, which is converted into 2-substituted 8-benzyloxy-1,2,4-triazolo[5,1-*c*]pyrimidine **60** (yield 32%–53%) as a result of the Dimroth rearrangement.[194]



R = $PhCOOCH_2CH_2$; R^1 = Me, Et; X = O, S

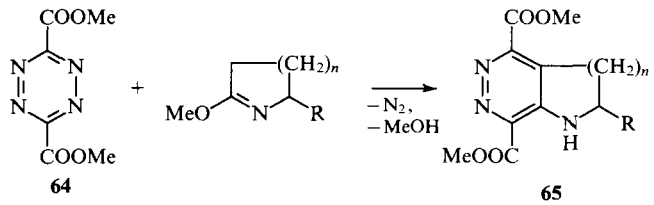
2-R-1,2,4-triazolo[5,1-*a*]quinazolin-5(4*H*)-ones **61** have been synthesised in 70%–94% yields by condensing the hydrochloride of 2-hydrazinobenzoic acid with the *N*-cyanoiminoesters **39** and triethylamine (molar ratios 1:1.2:3) in ethanol at 0 °C and subsequent treatment with aqueous HCl (80 °C).[195]

R = H, Me, $NCCH_2$.



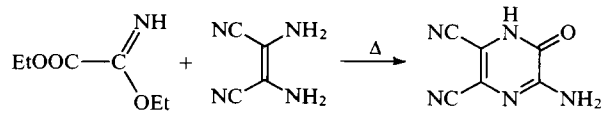
Derivatives of pyrazolo[4',3':5,6]pyrido[3,4-e]-1,2,4-triazolo-[1,5-*a*]pyrimidine **63**, which exhibit an anti-inflammatory activity and a depressant activity on the central nervous system, have been obtained under similar conditions from the *N*-cyano-iminoesters **39** and the 4-hydrazino-derivatives of pyrazolo-[3,4-*e*]pyridine-3-carboxylic acid esters **62**.[196]

R = H, Ph, Alk;
R^1 = H, Alk, Ph, Bz;
R^2 = H, Ph, Alk.



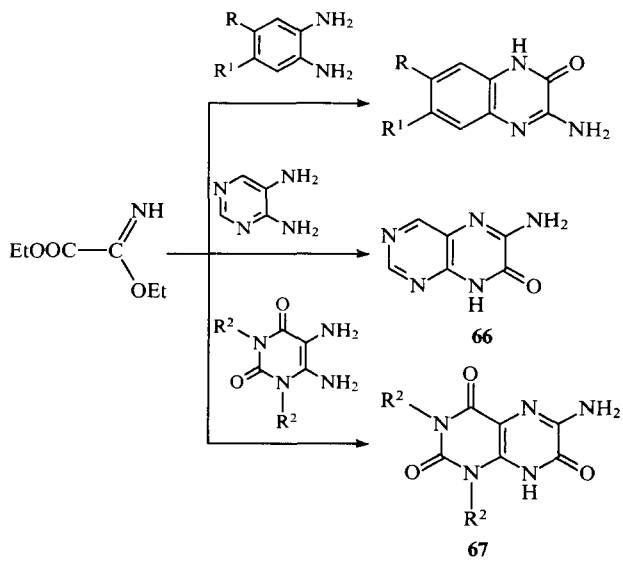
4. Synthesis of pyridazine, pyrazine, and quinoxaline derivatives

Only isolated data on the syntheses of pyridazine, pyrazine, and quinoxaline from iminoesters are so far available in the literature. Thus the interaction of *N*-substituted acetic acid iminoesters with dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate **64** leads to a low yield (9%–12%) of dimethyl 4-R-aminopyridazine-3,6-dicarboxylate.[197,198]



R = Me, Ph

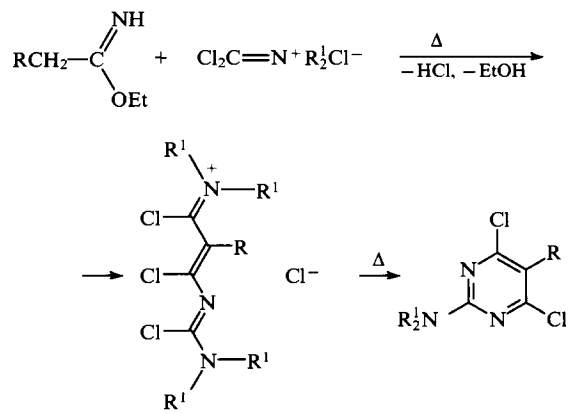
The condensed pyridazines **65** have been synthesised similarly from the *sym*-tetrazine **64** and cyclic iminoesters (yield 8%–47%).[197]



R = H, Me; n = 1–3.

When the ethoxycarbonylformic acid iminoester was refluxed with 1,2-diamino-1,2-dicyanoethene in ethanol, 3-amino-5,6-dicyano-1*H*-pyrazine-2-one was isolated in 72% yield.[21,22]

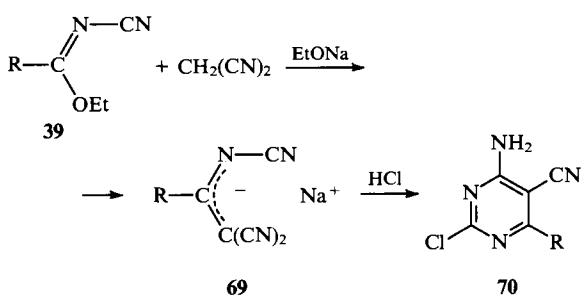
The interaction of this iminoester with aromatic and heterocyclic 1,2-diamines afforded derivatives of quinoxaline and pteridine.[21,22] For example, on refluxing with substituted *o*-phenylenediamines in ethanol, 6,7-disubstituted 3-amino-1*H*-quinoxalin-2-ones are formed in 58%–99% yield.



R = H, Me, Cl; R^1 = H, Me, Cl, NO_2; R^2 = H, Me.

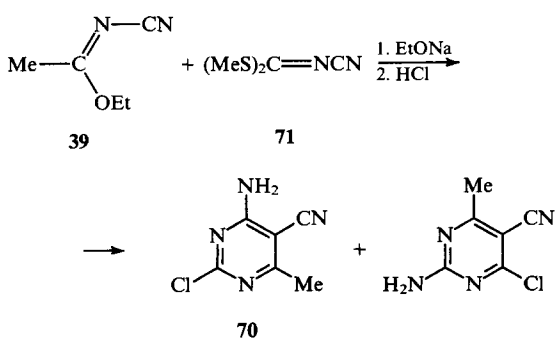
6-Amino-8*H*-pteridin-7-one **66** was obtained in 80% yield under similar conditions from 4,5-diaminopyrimidine and trioxopteridines **67** have been synthesised from 5,6-diaminouracils (yield 60%–94%).

5. Synthesis of pyrimidine and quinazoline derivatives



When aliphatic acid iminoesters interact with phosgene iminium salts (molar ratio 1:3) in chloroform (refluxing for 3–4 h), 2,4,6-trichloro-1,3,7-triazaheptatrienium chlorides **68** are formed in 85%–87% yield. On heating in vacuo, these products cyclise to 2-dialkylamino-4,6-dichloro-5-R-pyrimidines (yield 33%–90%).[199]

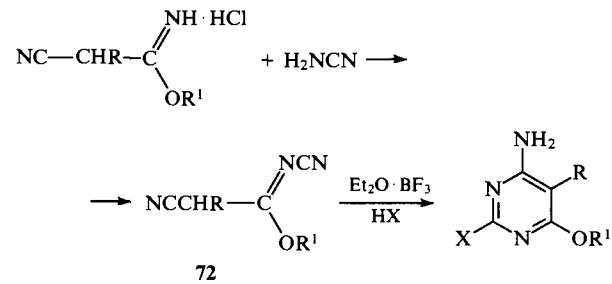
68



R = H, Me; R^1 = Me, Et.

By treating malonodinitrile with the *N*-cyanoiminoesters **39** in the presence of sodium ethoxide at 20 °C, Kristiansson obtained the reactive sodium salts **69**, which, on treatment with an ethereal solution of HCl, were converted into 4-amino-5-cyano-2-chloro-6-R-pyrimidines **70** in 83%–87% yield.[200]

39 **69** **70**

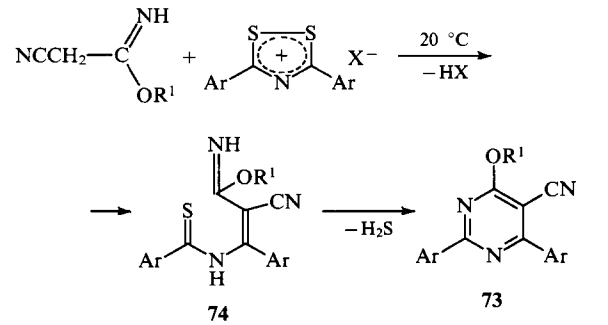


A 2:3 mixture of the 2-chloropyrimidine **70** (R = Me) and 2-amino-6-chloro-5-cyano-4-methylpyrimidine is formed in 88% yield under similar conditions from the acetic acid *N*-cyanoiminoester **39** (R = Me) and the *N*-substituted cyanamide **71**.

39 **71** **70**

On the other hand, it has been reported[201] that, when the *N*-cyanoiminoesters **39** were refluxed with malonodinitrile in methanol in the presence of sodium methoxide (molar ratios 1:1:2), 2-amino-5-cyano-4-methoxy-6-R-pyrimidines (R = H, Me, Ph) were synthesised in 17%–40% yield.

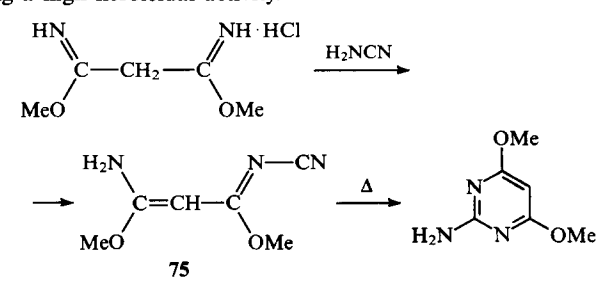
Japanese investigators established[202–205] that the interaction of the hydrochlorides of the iminoesters of carboxylic α-cyanoacids with cyanamide in benzene in the presence of 4 Å molecular sieves (25 °C, 4 h) leads to the formation of the *N*-cyanoiminoesters **72**. On treatment with boron trifluoride etherate and a hydrogen halide in nonpolar solvents (ether, benzene), the latter cyclise to 6-alkoxy-4-amino-2-halo-5-R-pyrimidines in 70%–92% yield.



72

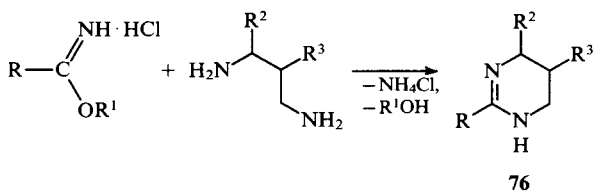
R = H, Me, Ph; R^1 = Alk; X = Cl, Br.

It is worth noting that, when the *N*-cyanoiminoester **72** (R = H, R^1 = Me) is treated with gaseous HCl at −15 °C, 2-amino-6-chloro-4-methoxypyrimidine is formed in 70% yield.[206]



4-Alkoxy-5-cyanopyrimidines **73**, which are intermediates for the synthesis of biologically active compounds, have been obtained in 36%–71% yields by the reaction of cyanoacetic acid iminoesters with 3,5-diaryl-1,2,4-dithiazolium salts in aqueous acetonitrile in the presence of alkali (20 °C, 10 min).[207,208] The authors suggest that the ring in the dithiazolium salt is initially opened with formation of the intermediate **74**, which subsequently cyclises to the pyrimidine **73**.

74 **73**

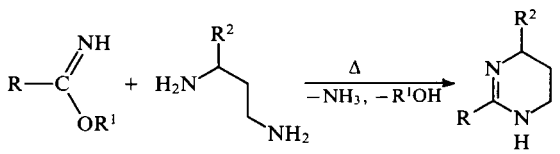


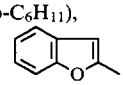
R^1 = Alk; X = ClO_4, I_3, Cl, Br, $FeCl_4$.

The interaction of the monohydrochloride of malonic acid bisiminoester with cyanamide leads to the *N*-cyanoiminoester of 3-amino-3-methoxyprop-2-enoic acid **75**, which, on refluxing in toluene or on heating to the melting point, is converted quantitatively into 2-amino-4,6-dimethoxypyrimidine, exhibiting a high herbicidal activity.[209–211]

75

The cyclocondensation of the hydrochlorides of various carboxylic acid iminoesters with aliphatic 1,3-diamines is a convenient method of synthesis of 2-substituted 1,4,5,6-tetrahydropyrimidines **76**.[47,212,213] These reactions are analogous to the synthesis of 2-substituted Δ^2-imidazolines from 1,2-diamines (see above) and are carried out by refluxing the reactants in ethanol (4–12 h); the yield of the tetrahydropyrimidines **76** is then 50%–86%.

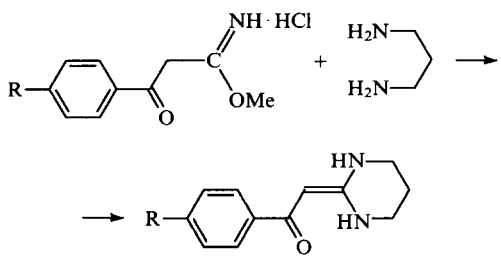




76

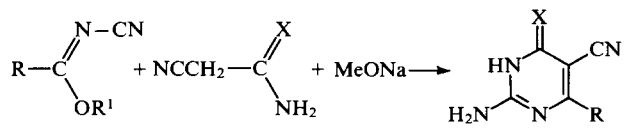
R = PhC(OH)Me, ArCH(OH), 2,4,5,6-$Me_4C_6HCH_2$, 2,4,5,6-$Me_4C_6HSCH_2$, , Ar—CH=CH—;

R^1 = Me, Et; R^2 = H, Me; R^3 = H, OH.



2-Substituted tetrahydropyrimidines have also been obtained in 50%–80% yield by heating iminoesters with 1,3-diamines (80–150 °C, 2–10 h).[58,88,214]

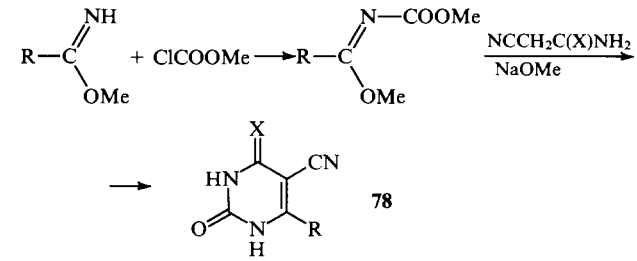
R = $PhCHR^3CH_2$ (R^3 = Ph, 2-Py, cyclo-C_6H_{11}), 4-$R^4C_6H_4CH_2$ (R^4 = Cl, Br, NO_2), 



R^1 = Me, Et; R^2 = H, Me.

It has been reported[214] that the condensation of the hydrochlorides of benzoylacetic acid esters with 1,3-diaminopropane in ethanol (refluxing for 10 h) leads to the formation of 2-(benzoylmethylene)perhydropyrimidines in 35%–56% yield.

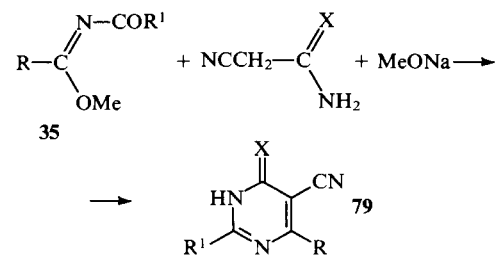
R = H, Cl, Br, MeO.



Cyclocondensation of the *N*-cyanoiminoesters **39** with the amide or thioamide of cyanoacetic acid and sodium methoxide [molar ratios 1 : 1 (1.1–2)] in methanol (refluxing for 2–3 h) gives 41%–77% yields of 2-amino-5-cyano-3,4-dihydropyrimidin-4-ones and the corresponding 4-thiones **77**.[176]

39 **77**

R = H, Me, Et, $PhCH_2$, Ar; R^1 = Me, Et; X = O, S.



The reaction of iminoesters with methyl chloroformate in hexane in the presence of 2,4,6-trimethylpyrimidine leads to the reactive *N*-(methoxycarbonyl)iminoesters. On heating with equimolecular amounts of cyanoacetic acid derivatives and sodium methoxide in methanol, the latter cyclise to 2,4-dioxo- or 2-oxo-4-thioxo-derivatives of 5-cyano-1,2,3,4-tetrahydropyrimidines **78** (X = O, S) in 38%–98% yield.[215]

78

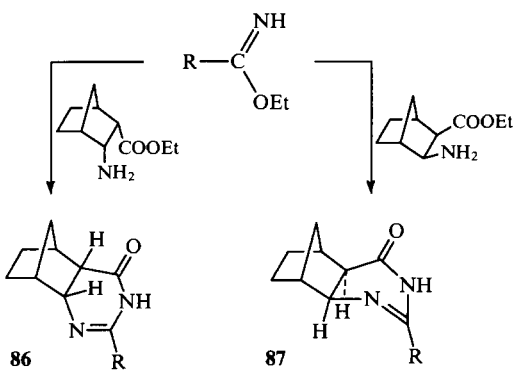
R = Alk, cyclo-(C_3-C_6), $PhCH_2$, Ar,  ;

R^1 = Alk, cyclo-(C_4-C_7), Ph, $PhCH_2$.

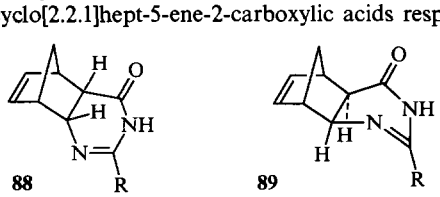


5,6-Dihydro-3*H*-pyrimidin-4-one derivatives **85**, exhibiting anti-inflammatory, antipyretic, and analgesic activities, have been synthesised by condensing *cis*-2-aminocycloalkanecarboxylic acids with iminoesters.[218,219]

85

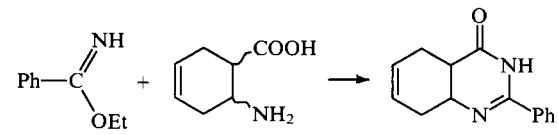
R = H, Alk, cyclo-C_nH_{2n-1}, Ar, $PhCH_2$, 4-Py.

Hungarian investigators[220,221] studied in detail the condensation of the esters of the stereoisomeric aminonorbornanecarboxylic and aminonorbornenecarboxylic acids with the iminoesters of aromatic and cycloalkanecarboxylic acids. It was established that the interaction of the ester of *endo*-3-aminobicyclo[2.2.1]heptane-2-carboxylic acid with the iminoesters in ethanol (refluxing for 10 h) results in the formation of 2-substituted 4*ar*,5*t*,6,7,8*t*,8*ac*-hexahydro-3*H*-5,8-methano-3-*H*-quinazolin-4-ones **86** in 53%–81% yield.



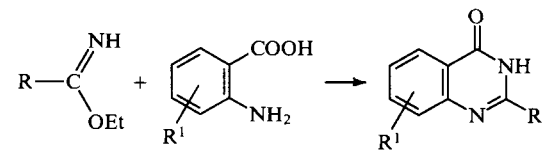
86 **87**

R = Ar, cyclo-C_6H_{11}.



The ester of *exo*-3-aminobicyclo[2.2.1]heptane-2-carboxylic acid reacts with the iminoesters, affording 58%–69% yields of 2-substituted 4*ar*,5*c*,6,7,8*c*,8*ac*-hexahydro-3*H*-5,8-methanquinazolin-4-ones **87**.[220,221]

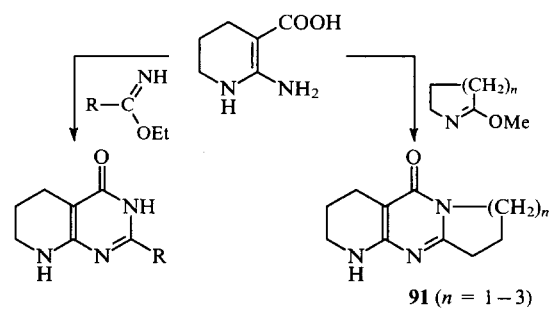
2-Substituted 4*ar*,5*t*,8*t*,8*ac*-tetrahydro-3*H*-5,8-methanoquinazolin-4-ones **88** (yield 54%–68%) and 4*ar*,5*c*,8*c*,8*ac*-tetrahydro-3*H*-5,8-methanoquinazolin-4-ones **89** (yield 56% to 74%) have been synthesised from the esters of *endo*- and *exo*-3-aminobicyclo[2.2.1]hept-5-ene-2-carboxylic acids respectively.[220,221]



88 **89**

By refluxing equimolecular amounts of the benzoic acid iminoester with *cis*- or *trans*-2-aminocyclohex-4-enecarboxylic acid in chlorobenzene, the same workers obtained 2-phenyl-4*a*,5,8,8*a*, tetrahydro-3*H*-quinazolin-4-one in 62%–65% yield.[222]

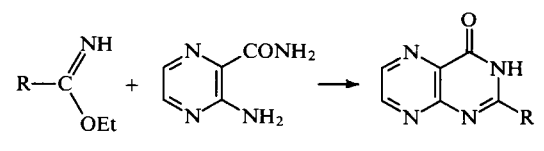
The condensation of iminoesters with substituted anthranilic acids in methanol (20 °C, 2 h) resulted in the formation of 6- and 7-substituted 2R-3*H*-quinazolin-4-ones **90** in 21%–51% yields.[223]



90

R = $PhCH_2$, 4-MeC_6H_4;
R^1 = H, 6-Me, 7-Cl.

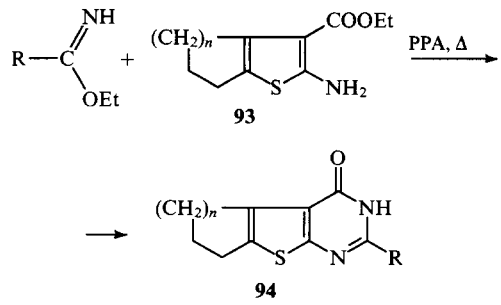
The authors note that this reaction is a convenient method of synthesis of the quinazoline alkaloid glucozymine **90** (R = $PhCH_2$, R^1 = H) and related compounds with a high biological activity.



The interaction of iminoesters with heterocyclic *o*-aminoacids or their derivatives leads to the formation of condensed systems incorporating pyrimidine fragments. For example, when the ester of 2-amino-1,4,5,6-tetrahydropyrimidine-3-carboxylic acid was heated with iminoesters in polyphosphoric acid, 2-R-5,6,7,8-tetrahydro-3*H*-pyrido[2,3-*d*]pyrimidin-4-ones were obtained in 47%–48% yields.[224] Under similar conditions, cyclic iminoesters afford the tricyclic systems **91** (yield 58%–68%).

91 (*n* = 1–3)

R = Ph, $PhCH_2$.

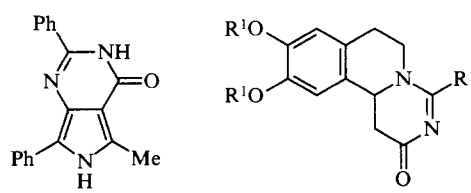


The preparation of 2-substituted 3*H*-pteridin-4-ones **92** by the reaction of iminoesters with the amide of 2-aminopyrazine-3-carboxylic acid has been described in a patent.[225]

92

R = Alk, CHEtCH = CH_2, cyclo-C_3H_5.

Refluxing of iminoesters with the esters of heterocyclic *o*-aminoacids **93** (molar ratio 3:1) in chlorobenzene in the presence of polyphosphoric acid (PPA) leads to derivatives of thieno[2,3-*d*]pyrimidin-4-one **94**.[226]



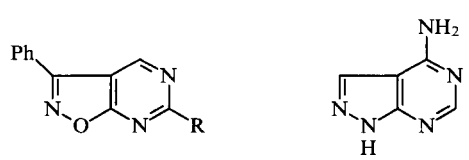
93

94

R = Ph, 3-ClC_6H_4; n = 1, 3.

Italian investigators synthesised derivatives of pyrrolo-[3,4-*d*]pyrimidin-4-one **95** (yield 15%), exhibiting an appreciable anti-inflammatory activity, by heating the benzoic acid iminoester with the ester of 3-amino-5-methyl-2-phenylpyrrole-4-carboxylic acid (140 °C, 18 h).[227]

In the search for new effective substances with analgesic activity, 4-substituted 9,10-dialkoxy-1,6,7,11-tetrahydro-2*H*-pyrimido[6,1-*a*]isoquinolin-2-ones **96** have been obtained by condensing iminoesters with the esters of 6,7-dialkoxy-1,2,3,4-tetrahydro-1-isoquinolinylacetic acids.[228]

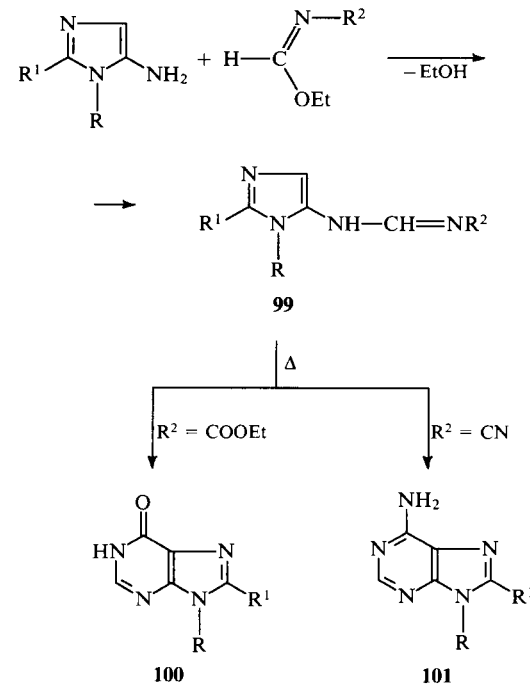


95 **96**

R = Alk, Ar, 4-$ClC_6H_4CH_2$;
R^1 = Me, Et.

The authors note that the pyrimidoisoquinolin-2-ones **96** are formed in 28%–58% yields on refluxing (for 24 h) equimolecular amounts of the reactants in chlorobenzene or are obtained in 40%–70% yields on refluxing (for 16 h) the reactants (molar ratio 10:1) in benzene in the presence of acetic acid.

Japanese investigators synthesised 6-substituted 3-phenylisoxazolo[5,4-*d*]pyrimidines **97** by the reaction of 5-amino-3-phenylisoxazole-4-carbaldehyde with the iminoesters of various acids.[229,230] It is best to carry out the condensation without a solvent at 40–50 °C; under these conditions, the yield of the target isoxazolopyrimidines **97** was 46%–75%.

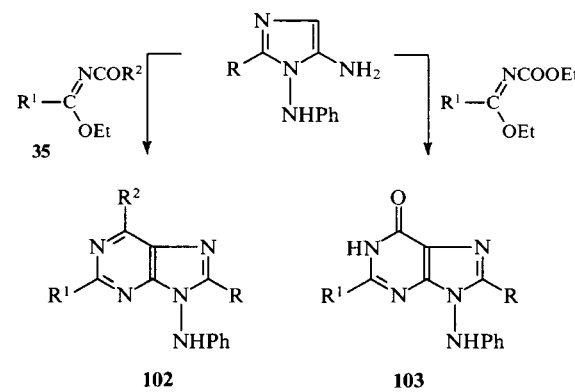


97 **98**

R = Alk, Ph, $PhCH_2$.

Iminoesters are convenient starting materials for the synthesis of purines {imidazo[4,5-*d*]pyrimidines} and their analogues. For example, the synthesis of adenine **98** in 42% yield by the condensation of the formic acid iminoester with 5-(alkoxycarbonylamino)-4-cyanoimidazole in DMF has been described in a patent.[231]

The interaction of 1,2-disubstituted 5-aminoimidazoles with the formic acid *N*-(ethoxycarbonyl)iminoester or *N*-cyanoiminoester leads to the *N,N*-disubstituted amidines **99** (yield 33%–52%), which cyclise to the 8,9-disubstituted hypoxanthines **100** (R^2 = EtOOC) (yield 65%–91%) or to the 9-R-adenines **101** (R^2 = CN) (yield 10%–20%) on heating to 190–260 °C.[232]



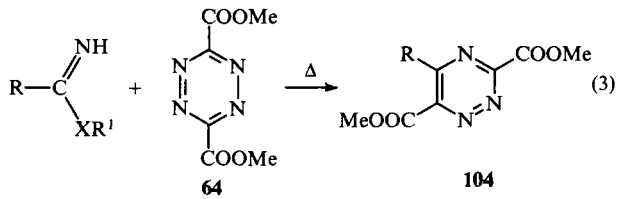
99

100 **101**

R = Me, $HOCH_2CH_2$; R^1 = H, Me; R^2 = EtOOC, NC.

The synthesis of the purine derivatives **102** and the hypoxanthine derivatives **103** by the reaction of 2-substituted 5-amino-1-phenylaminoimidazoles respectively with the *N*-acyliminoesters **35** or with *N*-(ethoxycarbonyl)iminoesters in xylene (refluxing for 1–3 h) has been reported.[233]

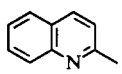
35



102 **103**

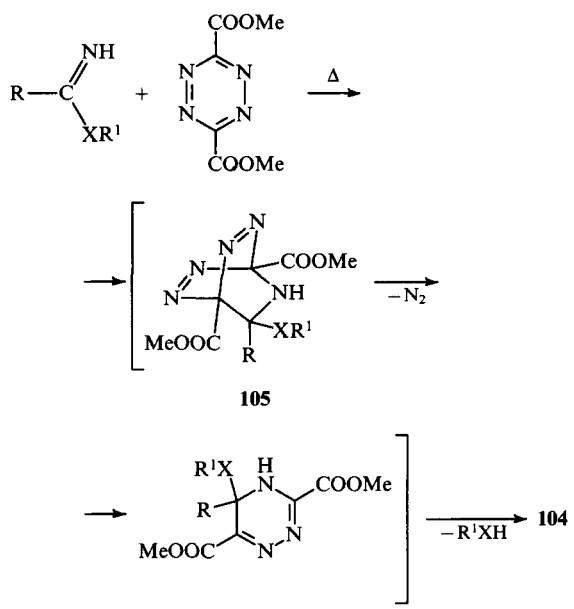
R = Pr^i, Ar, $PhCH_2$, 4-$ClC_6H_4CH_2$;
R^1 = Ph, $PhCH_2$; R^2 = Me, Et.

6. Synthesis of 1,2,4-triazine derivatives



There are hitherto only limited literature data on the synthesis of compounds of the 1,2,4-triazine series using carboxylic acid iminoesters as starting materials.[234]

Boger and Panek obtained the dimethyl esters of 5-aryl-(heteroaryl)-1,2,4-triazine-3,6-dicarboxylic acids **104** (Table 3) as a result of the interaction of dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate **64** with the iminoesters or iminothioesters of aromatic and heterocyclic acids (molar ratio 2:1) in dioxane at 60–80 °C.[235,236]



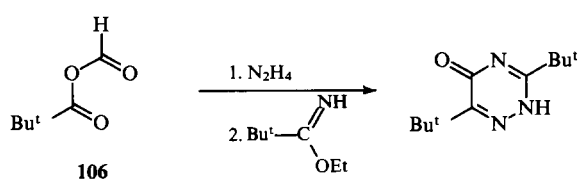
(3)

64 104

R = Ph, 2-Py,  ;

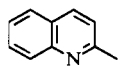
R^1 = Me, Et; X = O, S.

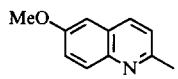
The authors assumed that the initial stage of the reaction is the thermal cycloaddition of the diester **64** to the C=N bond of the iminoester or iminothioester, which in this case are regarded as heterodienophiles. The cyclic adducts **105** formed in this reaction eliminate in succession a nitrogen molecule and an alcohol or mercaptan molecule, being converted into the 1,2,4-triazine derivatives **104.**

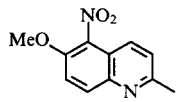


105

The authors note that carboxylic acid amidines and nitriles do not react with the diester **64** under the conditions indicated. Table 3 presents data concerning the influence of the structures of the initial iminoesters and of the reaction time on the yields of the 1,2,4-triazines **104.**

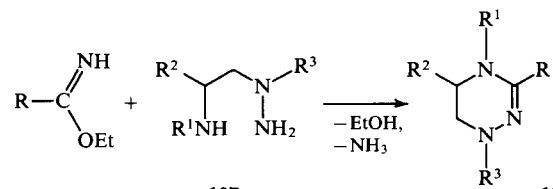






It is noteworthy that the 1,2,4-triazine **104** (R = 6-methoxy-5-nitro-2-quinolinyl) formed in the reaction of the diester **64** with the iminothioester of 6-methoxy-5-nitroquinoline-2-carboxylic acid is a key compound in the total synthesis of the antibiotic streptonigrin.[237]

The successive interaction of equimolecular amounts of the mixed anhydride **106** with anhydrous hydrazine in ethanol (20 °C, 2 h) and then with pivalic acid iminoester (refluxing for 12 h) leads to 3,6-di-*tert*-butyl-1,2,4-triazin-5(2*H*)-one in 40% yield.[238]



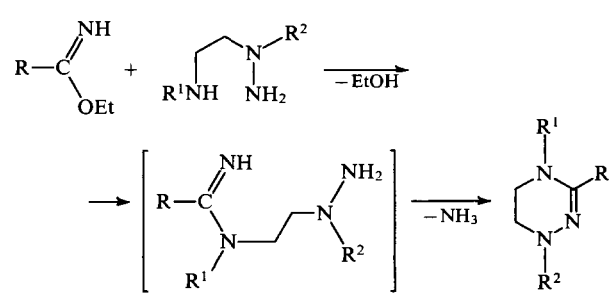
106

Table 3. Synthesis of the dimethyl esters of 5-substituted 1,2,4-triazine-3,6-dicarboxylic acids **104** by the reaction of the dimethyl ester of 1,2,4,5-tetrazine-3,6-dicarboxylic acid **64** with iminoesters or iminothioesters (under a N_2 atmosphere) [reaction (3)].[235,236]

R	R^1X	Reaction conditions		Yield
		T/°C	t/h	(%)
Ph	EtO	60	10	27
	MeS	80	24	64
2-Py	EtO	80	8–12	37
	MeS	80	20	68
	EtO	80	20	33
	MeS	80	4	70
	MeS	80	4	78
	MeS	80	20–24	72–82

The ethyl ester of 3-methyl-5-oxo-2*H*-1,2,4-triazine-6-carboxylic acid has been synthesised in 70% yield by condensing the acetic acid iminoester with the oxomalonic ester hydrazone.[239]

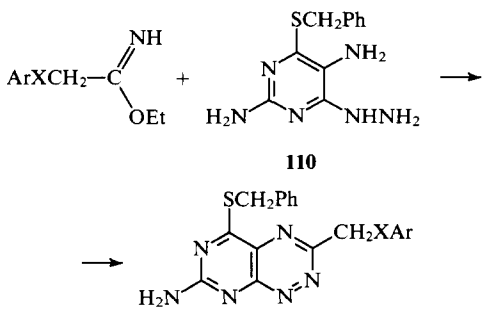
The reactions of *N*-(β-aminoalkyl)hydrazines **107** with iminoester hydrochlorides[240] or iminoesters[241] in ethanol (refluxing for 3–20 h) lead to substituted 1,4,5,6-tetrahydro-1,2,4-triazines **108**, the yield of which varies from 13% to 68% depending on the type of substituents in the initial reactants.



107 108

R = Alk, $Me_3Si(CH_2)_n$ (n = 2, 3), Ph_2CH, Ph_2CHCH_2, $PhCH_2CHPh$, $PhCH_2CH_2$;

R^1 = H, Me; R^2 = H, $HO(CH_2)_2$; R^3 = H, Me.



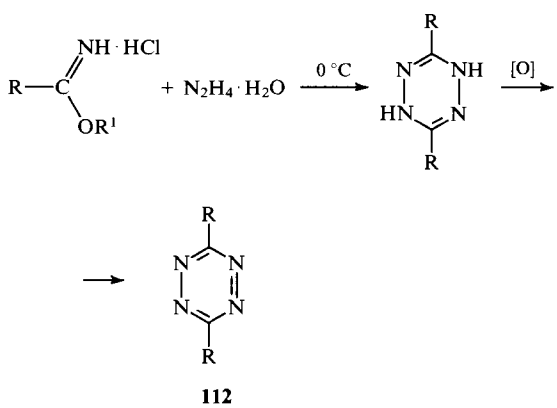
It has been suggested[241] that the electrophilic carbon atom of the iminoester group is attacked by the amine nitrogen atom with formation of the amidine **109**, which cyclises to 1,2,4-triazine with elimination of an ammonia molecule.

109 108

The interaction of equimolecular amounts of aliphatic acid iminoesters and ethylenedihydrazine in ethanol (refluxing for 10 h) led to the synthesis of 3-alkyl-4-amino-1,4,5,6-tetrahydro-1,2,4-triazines in 79%–83% yields.[241]

The condensation of substituted acetic acid iminoesters with 2,5-diamino-6-hydrazinopyrimidine **110** in dioxane at 20 °C results in the formation of derivatives of pyrimido[5,4-*e*]1,2,4-triazine **111** in 37%–64% yields.[242]

110



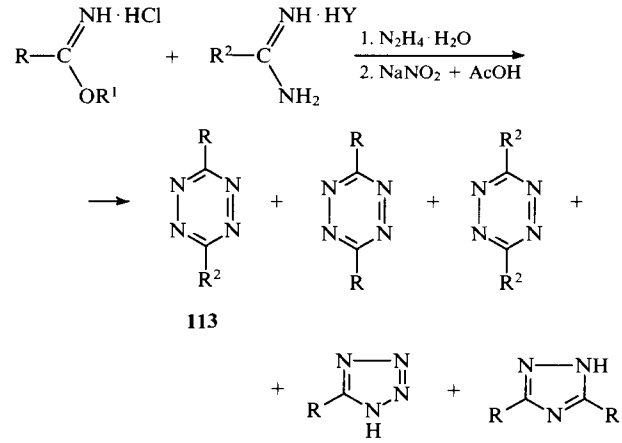
111

Ar = 4-ClC_6H_4, 3,4-$Cl_2C_6H_3$; X = S, NH.

The authors note that the pyrimidotriazines **111** are selective antagonists of folic acid and its analogues.

7. Synthesis of 1,2,4,5-tetrazine derivatives

The interaction of iminoester hydrochlorides with hydrazine hydrate at 0 °C is known[4,5,243–245] to afford 3,6-disubstituted 1,4-dihydro-1,2,4,5-tetrazines, the oxidation of which by atmospheric oxygen, nitrous acid, pentyl nitrite, iron(III) chloride, or hydrogen peroxide leads to symmetrical 3,6-disubstituted 1,2,4,5-tetrazines **112**, the yield of which does not, however, exceed 25%–35%.

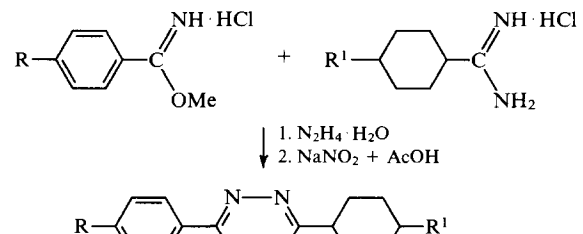


112

R = Alk, Ar, Het.

Investigators have devoted particular attention during the last decades to the development of methods of synthesis of asymmetric 3,6-disubstituted 1,2,4,5-tetrazines **113**, since substances with valuable applied properties have been found among compounds of this type.[198]

In 1975, American investigators[246–248] proposed a method of synthesis of 1,2,4,5-tetrazines **113**, which consists in the condensation of iminoester hydrochlorides with the hydrochlorides or acetates of amidines and hydrazine hydrate in absolute ethanol at −10 to 20 °C (2–3 h) with subsequent oxidation of the intermediate 1,4-dihydro-1,2,4,5-tetrazines (without isolation) by nitrous acid at 5–10 °C. Under these conditions, the target 1,2,4,5-tetrazines **113** are formed in 9%–55% yields together with symmetrical 3,6-disubstituted 1,2,4,5-tetrazines **112**, 5-substituted tetrazoles, and 3,5-disubstituted 1*H*-1,2,4-triazoles.



113

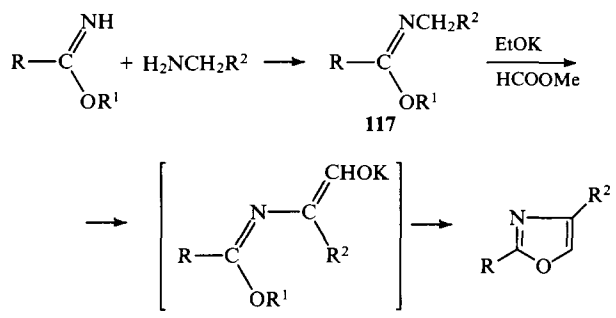
Van der Plas and coworkers[249,250] oxidised the intermediate 1,4-dihydro-1,2,4,5-tetrazines by atmospheric oxygen in solution in methylene chloride or chloroform.

The use of the above method for the synthesis of 3,6-disubstituted 1,2,4,5-tetrazines **114** and **115**, incorporating cyclohexane fragments and alkyl groups with a normal structure, has been described in patents.[251,252]

114

115

R = Alk (C_3–C_5), BuO; R^1, R^2, R^3 = Alk (C_3–C_8).

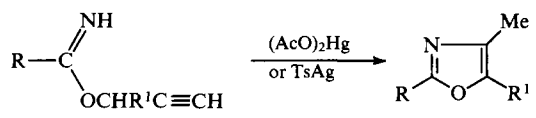


The 1,2,4,5-tetrazines **114** and **115** are used as components of nematic liquid-crystal phases.

III. Synthesis of five- and six-membered heterocycles containing nitrogen and oxygen atoms

1. Synthesis of oxazole and Δ^2-oxazoline derivatives

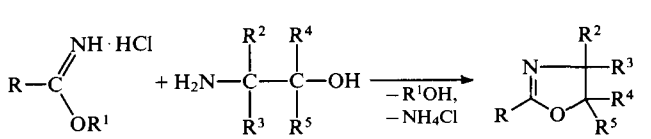
There are limited data in the literature concerning the synthesis of oxazoles from iminoesters as the initial compounds. This method has found an application only in the synthesis of 2-substituted oxazole-4-carboxylic acids **116** with functional group substitutents.[253,254]



The interaction of iminoesters with aminoacid derivatives — esters, amides, *N*-substituted amides, and nitriles — is known[4,5] to afford the *N*-substituted iminoesters **117**. On treatment with methyl formate and potassium ethoxide (0–20 °C), the latter are converted into the unstable intermediates **118**, which cyclise to derivatives of oxazole-4-carboxylic acids **116**.[4,5,255–257]

117 **118** **116**

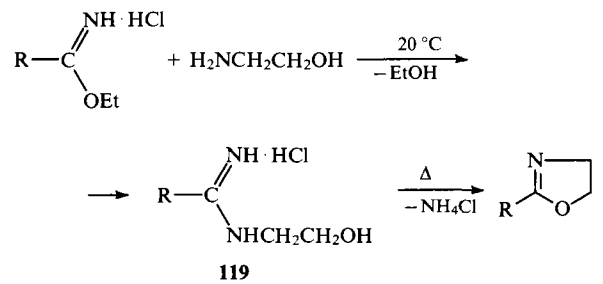
R = H, Me, Pr, cyclo-C_6H_{11}, Ar; R^1 = Et, Pr^i;
R^2 = EtOOC, NC, H_2NCO, R^3NHCO; R^3 = Alk.



A patent[258] describes the synthesis of trisubstituted oxazoles in 90%–97% yield when propargyl iminoesters are treated with mercury acetate or silver tosylate at 200 °C (1 h).

R = Alk, $Cl(CH_2)_3$, Ph, $PhCH_2$, EtC(OH)Me; R^1 = H, Me.

One of the most important derivatives of the oxazole series are Δ^2-oxazolines, which have been used widely in recent years as intermediates in organic synthesis.[259–262] The cyclocondensation of iminoesters or their hydrochlorides with β-aminoalcohols having different structures is used to obtain ring-substituted Δ^2-oxazolines.[4,5,259,262]

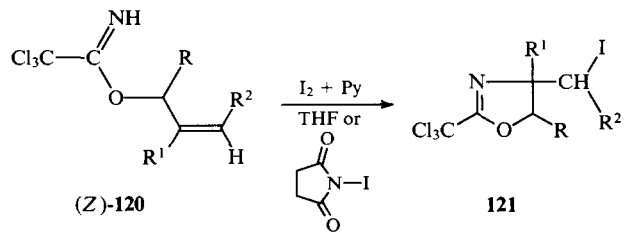


For example, the interaction of equimolecular amounts of iminoester hydrochlorides and β-aminoalcohols in anhydrous solvents (ethanol, methanol, chloroform) affords high yields of substituted Δ^2-oxazolines.[55,62,89,110,263–268]

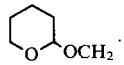
R = Alk, Ph, PhCH(OH), 4-$MeC_6H_4OCH_2CH(OH)$, 4-HO-3,5-$Bu^t_2C_6H_2(CH_2)_n$ (n = 0, 2), Het;
R^1 = Me, Et; R^2 = H, Me; R^3 = H, Me, EtOOC, $HOCH_2$;
R^4 = H, Me;
R^5 = H, Alk, Ph, (*E*)-$C_{13}H_{27}CH{=}CH$, 4-$MeC_6H_4OCH_2$.

It is noteworthy that the reaction temperature and time as well as the yield of the target Δ^2-oxazolines are determined primarily by the nature of the group in the acid component of the initial iminoester. For example, in the case of iminoester hydrochlorides containing the electron-donating 3-indolyl[55,62,264] or 3,5-di-*tert*-butyl-4-hydroxyphenyl[110] groups, the synthesis of the corresponding Δ^2-oxazolines from ethanolamine in satisfactory yields (46%–62%) requires that the reactants be refluxed in ethanol for 10–12 h. On the other hand, when the hydrochlorides of (3-indolyl)acetic or 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionic acids are used, the cyclisation is completed in 1.5–5 h.

It has been established[266] that the interaction of iminoester hydrochlorides with ethanolamine in methanol at 20 °C (2 h) results in the formation of the hydrochlorides of *N*-substituted amidines **119**, which cyclise on heating to 2-substituted Δ^2-oxazolines in high yields.



119



R = Ph, PhCH(OH), 4-$MeC_6H_4OCH_2CH(OH)$.

Substituted Δ^2-oxazolines can also be obtained by condensing iminoester bases with β-aminoalcohols, but in this case the reactions are carried out either with prolonged refluxing in a solvent (chloroform, ethanol)[267] or by heating the reactants without a solvent (160–180 °C) for 16–36 h.[51,264]

Italian investigators have established that the cyclisation of (*Z*)-allyliminoesters of trichloroacetic acid **120** on treatment with iodine and pyridine in THF (20 °C, 12 h)[269] or with *N*-iodosuccinimide in chloroform (20 °C, 12 h)[270,271] leads to the regiospecific formation of 2-trichloromethyl-4-(1-iodoalkyl)-5-R-Δ^2-oxazolines **121** in high yields in the form of a mixture of diastereoisomers. The latter are key compounds in the synthesis of stereoisomeric β-aminoalcohols and certain natural products.[269,270]

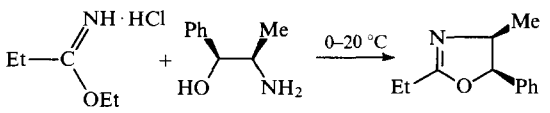
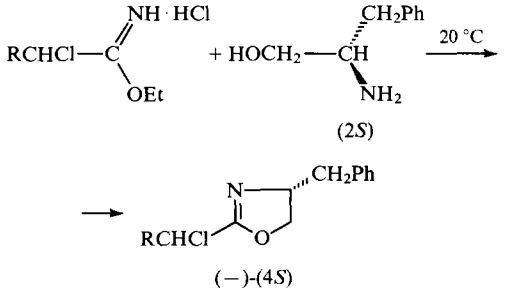
Investigators have devoted much attention in recent years to the synthesis of Δ^2-oxazolines from chiral β-aminoalcohols. The chiral Δ^2-oxazolines formed under these conditions are valuable key intermediates in the asymmetric synthesis of various compounds — 2-hydroxy-, 2-methoxy-, 2-alkyl-, and 2-chloroalkanoic acids, 1,4-dihydropyridines, etc.



Meyers et al. synthesised (−)-(4*S*,5*S*)-2-substituted 5-phenyl-Δ^2-oxazolines **123** with the *trans*-configuration in 59%–87% yield by the reaction of the hydrochlorides of the iminoesters of various acids with (+)-(1*S*,2*S*)-2-amino-1-phenylpropane-1,3-diol **122** (R^1 = H) or with (+)-(1*S*,2*S*)-2-amino-3-methoxy-1-phenyl-propan-1-ol **122** (R^1 = Me) in methylene chloride (0–20 °C, 6 h).[272–278]

(+)-(1*S*,2*S*)-**122** (−)-(4*S*,5*S*)-**123**

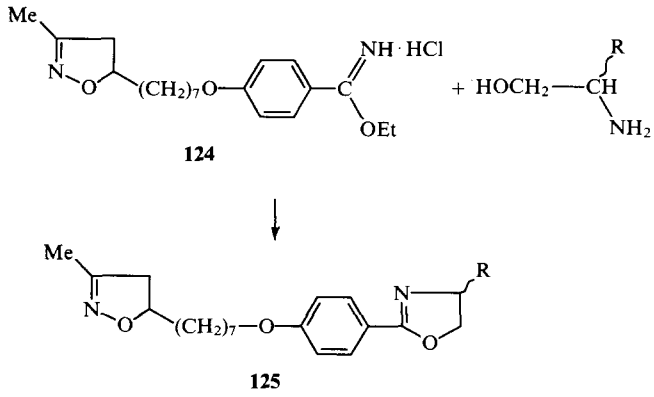


R = Me, Et, Pr, $MeOCH_2$, $ClCH_2$, Ph, $PhCH_2$, 3-Py, 
R^1 = H, Me.

It has been noted[275] that the condensation of the propionic acid iminoester with (+)-(1*S*,2*R*)-2-amino–1-phenylpropan-1-ol in the presence of pyridine in methylene chloride (0 °C; 20 °C, 12 h) affords an 80% yield of (+)-(4*R*,5*S*)-2-ethyl-4-methyl-5-phenyl-Δ^2-oxazoline with the *cis*-configuration.

(+)-(1*S*,2*R*) (+)-(4*R*,5*S*)

Chiral 2-substituted (−)-(4*S*)-4-benzyl-Δ^2-oxazolines have been synthesised in 60%–82% yield by the reaction of equimolecular amounts of 2-chloroalkanoic acid iminoesters with (2*S*)-2-amino-3-phenylpropan-1-ol in methylene chloride at 20 °C.[279,280]



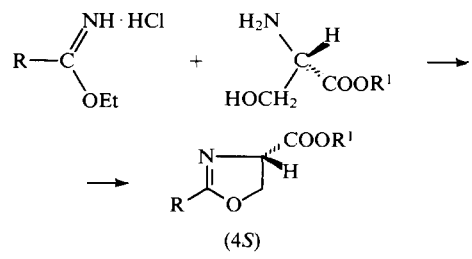
(2*S*)

(−)-(4*S*)

R = Alk.

It has also been noted that, when the phenylacetic acid iminoester is used in this reaction, the corresponding (−)-(4*S*)-2,4-dibenzyl-Δ^2-oxazoline is formed in 71% yield after heating equimolecular amounts of the reactants at 120–130 °C for 12 h without a solvent.[280]

In the search for new effective antiviral preparations — analogues of 3-methyl-5-[7-(4-Δ^2-oxazolin-2-ylphenyloxy)heptyl]isoxazole ('disoxaryl' — an inhibitor of the HPV-14 virus) — individual (4*S*)- and (4*R*)-stereoisomers of the 4-alkyl-Δ^2-oxazolines **125** have been synthesised by condensing the iminoester hydrochlorides **124** with optically active aminoalcohols.[281]

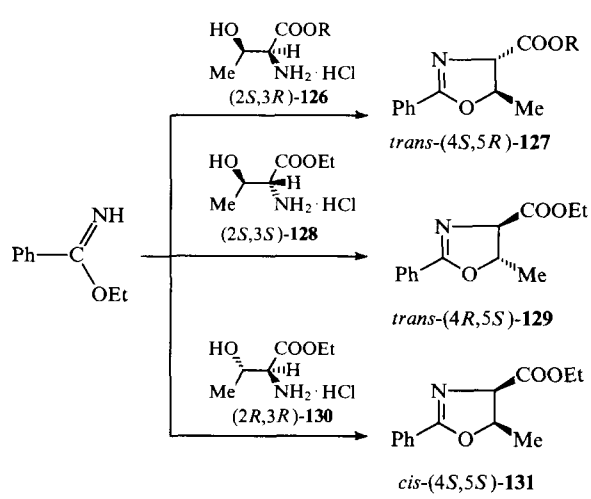


124

125

R = Alk.

The interaction of iminoester hydrochlorides with L-serine esters leads to 75%–76% yields of the chiral esters of 2-substituted (4*S*)-Δ^2-oxazoline-4-carboxylic acids,[282–284] which are used as key compounds in the asymmetric synthesis of 3-substituted alkanoic acids and 3-substituted lactones.[282,283]



(4*S*)

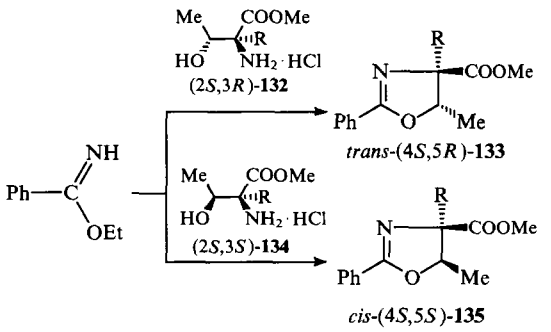
R = Me, Ph; R^1 = Me, Et.

Racemic esters of 2-phenyl-Δ^2-oxazoline-4-carboxylic acid, which are convenient intermediates in the synthesis of 2-deuterio-D-serine and its derivatives, have been synthesised in 65%–72% yield by condensing the hydrochloride of the benzoic acid iminoester with the hydrochlorides of racemic esters of serine in the presence of triethylamine (molar ratios 1 : 1 : 1) in methylene chloride (20 °C, 8 h).[285,286]

The reaction of the benzoic acid iminoester with the hydrochlorides of L-threonine esters **126** (molar ratio 1 : 1.75) in an ether–water mixture at 20 °C results in the formation of esters of *trans*-(4*S*,5*R*)-5-methyl-2-phenyl-Δ^2-oxazoline-4-carboxylic acid **127** is 70%–72% yield.[287–289]

(2*S*,3*R*)-**126** *trans*-(4*S*,5*R*)-**127**

(2*S*,3*S*)-**128** *trans*-(4*R*,5*S*)-**129**

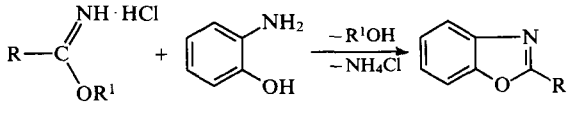


(2*R*,3*R*)-**130** *cis*-(4*S*,5*S*)-**131**

R = Me, Et.

The ester of *trans*-(4*R*,5*S*)-Δ^2-oxazoline-4-carboxylic acid **129** — a key compound in the enantioselective synthesis of the natural azoxyalkene elaiomycin — has been synthesised in 52% yield under similar conditions from the hydrochloride of the D-threonine ester **128**,[290] while the ester of *cis*-(4*S*,5*R*)-Δ^2-oxazoline-4-carboxylic acid **131** — a key compound in the synthesis of L-threonine — has been obtained from the hydrochloride of the ester **130**.[291]

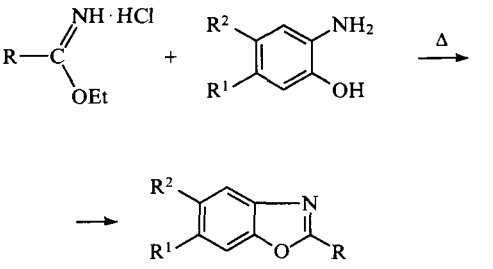
Japanese investigators[292] synthesised the esters of *trans*-(4*S*,5*R*)-Δ^2-oxazoline-4-carboxylic acid **133** (Scheme 3) by the interaction of the benzoic acid iminoester with the hydrochlorides of (2*S*,3*R*)-2-amino-3-hydroxy-2-R-butyric acids **132** (molar ratio 1.2:1) in methanol (refluxing for 14 h). but the yield of the Δ^2-oxazolines did not exceed 12%–18% under these conditions.



Scheme 3

The esters of *cis*-(4*S*,5*S*)-Δ^2-oxazoline-4-carboxylic acid **135** have been obtained in a low yield (12%–16%) under similar conditions from the hydrochlorides of the esters of (2*S*,3*S*)-2-amino-3-hydroxy-2-R-butyric acid **134** (Scheme 3). The authors note that the Δ^2-oxazolines **133** and **135** are convenient key compounds in the asymmetric synthesis of carboxylic α-alkylamino-β-hydroxyacids.

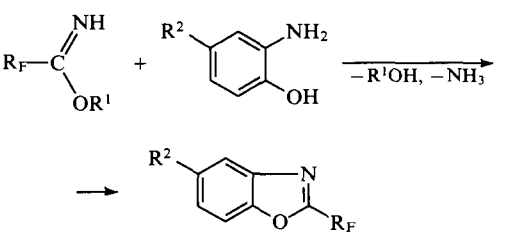
2. Synthesis of substituted benzoxazoles



The condensation of carboxylic acid iminoester hydrochlorides with *o*-aminophenyl is known[4,5] to lead to 2-substituted benzoxazoles. It is noteworthy that recently this method has been used most frequently in the synthesis of benzoxazoles from the hydrochlorides of the iminoesters of aliphatic acids with functional-group substituents containing nitro-groups,[67–69] silylalkyl groups,[71,72] halogen atoms,[114,293,294] or an acyl group[106] as well as substituted benzoxazoles,[110] heterocyclic acids,[55,61,62,66,112] and β-substituted acrylic acids.[55,82,295]

R = Alk, $Me_3SiCH_2CH_2$, $Me_2C(NO_2)CH_2CH_2$, $MeC(NO_2)_2CH_2CH_2$, $(O_2N)_3CCH_2CH_2$, $Ac(CH_2)_3$, $Bz(CH_2)_3$, $ClCH_2$, FCH_2, Br_3CCH_2CHBr, $Br_3CCH_2CH_2$, $Cl_3CCH_2CH_2$, $PhCH_2$, Ar, 1-Ad, $4\text{-}O_2NC_6H_4CH{=}CH$, Het.

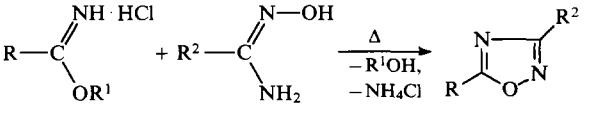
Reactions of this type are usually carried out by refluxing equimolecular amounts of the reactants in methanol or ethanol for 5–10 h, whereupon the yield of the target 2-substituted benzoxazoles is 63%–97%. The reaction time in each specific case depends primarily on the nature of the group in the acid part of the initial iminoester hydrochloride.[296] We may note that, in the case of iminoester hydrochlorides containing electron-accepting groups, which reduce the thermal stability of the iminoesters, the reactions are carried out at 0–20 °C.[69]



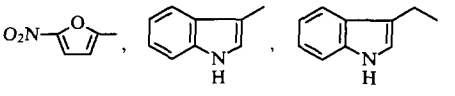
There are isolated literature data on the condensation reactions of iminoester hydrochlorides with ring-substituted *o*-aminophenols, which lead to high yields of 2,5- or 2,6-disubstituted benzoxazoles.[106,297,298]

R = $Ac(CH_2)_3$, $Bz(CH_2)_3$; $R^1 = NO_2$, $R^2 = H$;
R = H, Me, Ph, 3-Py, cyclo-C_6H_{11}; $R^1 = H$, $R^2 = NCCH(Me)$;
R = $ClCH_2$; $R^1 = H$, R^2 = Alk, cyclo-(C_3-C_6).

The synthesis of 1,5-bis(2-benzoxazolyl)-3,3-dinitropentane in 94% yield by the reaction of the hydrochloride of the diiminoester of 4,4-dinitropimelic acid with *o*-aminophenol (molar ratio 1:2) in methanol at 50 °C (1 h) has been reported.[104]



2-Substituted benzoxazoles can also be obtained by condensing iminoester bases with *o*-aminophenol.[296] In the case of iminoesters containing strong electron-accepting groups (for example, the iminoesters of carboxylic perfluoroacids), the condensations take place under mild conditions (20–35 °C, 1–3 h) and the target benzoxazoles are then formed in 75%–86% yields.[296,299]

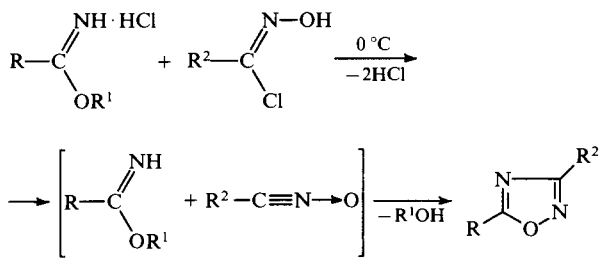


R_F = CF_3, n-C_3F_7, $F_5C_2O(CF_2)_2OCF_2$, n-$C_3F_7O[CF(CF_3)CF_2O]_2CF(CF_3)$;
R^1 = Me, Et; R^2 = H, n-C_3F_7.

3. Synthesis of 3,5-disubstituted 1,2,4-oxadiazoles

Carboxylic acid amidoximes are frequently used as the starting materials for the synthesis of 1,2,4-oxadiazoles.[300] The hydrochlorides of the iminoesters of various carboxylic acids may be used as the second component in the condensation with the amidoximes.[52,56,89,301–305]

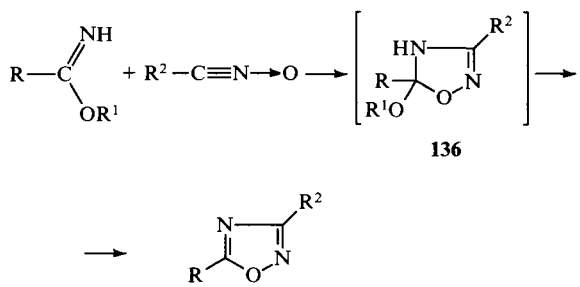
R = Alk, Ar, $ClCH_2$, 1-Ad, Het; R^1 = Me, Et;
R^2 = Me, Ph, $ClCH_2$, $4\text{-}O_2NC_6H_4$, $PhCH_2$, 1-Ad,



Reactions of this type are usually carried out by refluxing equimolecular amounts of the reactants in ethanol or methanol for 1–12 h, whereupon the yield of the 3,5-disubstituted 1,2,4-oxadiazoles in 38%–92%.

The comparatively low yield (38%–47%) of 3-(3-indolylmethyl)-5,-R-1,2,4-oxadiazoles (R = 3-indolyl, 3-indolylmethyl,

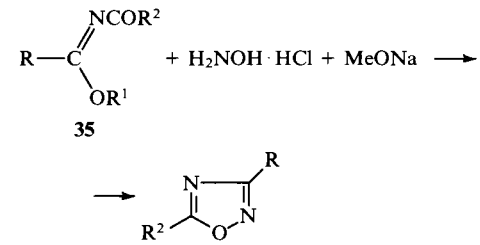
phenyl, *p*-nitrophenyl) has been explained[303] by the thermal instability of the initial amidoxime of (3-indolyl)acetic acid, which decomposes on heating in methanol.



3,5-Disubstituted 1,2,4-oxadiazoles can also be synthesised by the 1,3-dipolar cycloaddition of the *N*-oxides of aromatic and heterocyclic nitriles to the carboxylic acid iminoesters.[107,302,306-312] The 1,3-dipoles (nitrile *N*-oxides) are usually obtained in situ from the chlorides of the corresponding arene- or heteroarene-hydroxamic acids by treatment with bases in the presence of a dipolarophile—the carboxylic acid iminoester. The nitrile *N*-oxides are generated from the hydroxamic acid chlorides by means of either a 5% aqueous solution of sodium carbonate (0–5 °C, 1 h)[302,309] or triethylamine (0–5 °C).[311] In certain cases, the dipolarophile (the iminoester) is also generated from the corresponding iminoester hydrochlorides.[302,308,309]

It has been noted[302,309] that the reactions can be most usefully carried out with a nitrile *N*-oxide : iminoester molar ratio of 1 : (2–2.5) at 0–5 °C for 1 h with subsequent stirring of the reaction mixture at 20 °C for 3 h. When the reactions were performed under the conditions indicated, the yields of 1,2,4-oxadiazoles were 55%–70%.

R = Me, $EtOCH_2CH_2$, 1-Ad, Ar, $PhCH_2$, $PhCH_2CH_2$;
R^1 = Me, Et; R^2 = Ar,  .

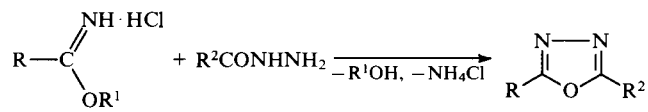


It has been suggested[308,309] that the 1,3-dipolar cycloaddition of nitrile *N*-oxides to the C=N bond of the iminoester involves the formation of Δ^2-1,2,4-oxadiazolines **136** as intermediates, which are subsequently converted into 1,2,4-oxadiazoles as a result of the elimination of an alcohol molecule.

136

An intermediate of this type has been isolated in 34% yield in the reaction of the benzoic acid iminoester with the chloride of 2-methoxycarbonylbenzenehydroxamic acid in the presence of triethylamine.[311] When this intermediate was kept in ether (at 20 °C), it was converted into 3-(2-methoxycarbonylphenyl)-5-phenyl-1,2,4-oxadiazoles in 23% yields.

Certain reactive *N*-substituted iminoesters have also been used as the starting compounds in the synthesis of 1,2,4-oxadiazoles. For example, the interaction of *N*-acyliminoesters with hydroxylamine hydrochloride and sodium methoxide (molar ratios 1 : 1.1 : 1.1) in methanol (20 °C, 12 h; refluxing for 6 h) leads to the formation of 3,5-disubstituted 1,2,4-oxadiazoles in 38%–74% yields.[163]



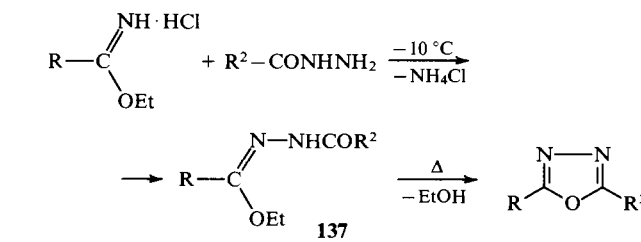
35

R,R^2 = Me, Ar; R^1 = Me, Et.

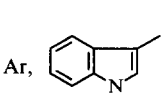
It is striking that in this case the group R from the acid component of the iminoester occupies the 3-position in the 1,2,4-oxadiazole formed, while the group R^2 from the acyl fragment occupies the 5-position.

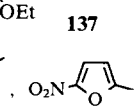
4. Synthesis of 2,5-disubstituted 1,3,4-oxadiazoles

It was noted above that on heating with *N*-acylhydrazines (acid hydrazides), carboxylic acid iminoesters give rise either to the *N*-acylamidrazones **28** or to the 3,5-disubstituted 1*H*-1,2,4-triazoles **29**. In 1963, Weidinger and Kranz established[301] that the condensation of the iminoester hydrochlorides with acid hydrazides leads to 2,5-disubstituted 1,3,4-oxadiazoles. Nowadays this method is widely used in the synthesis of 1,3,4-oxadiazoles from iminoester hydrochlorides and the hydrazides of aliphatic, aromatic, and heterocyclic acids.[52,55,56,89,107,168,293,305,313-320]



R = Me, $ClCH_2$, $EtOOCCH_2$, $AcCH_2CH_2$, $Me_3SiCH_2CH_2$, cyclo-C_6H_{11}, Ar, PhCH=CH, Het, 1-Ad;
R^1 = Me, Et, Bu; R^2 = H, Me, Ar, cyclo-C_6H_{11}, 1-Ad, Het.



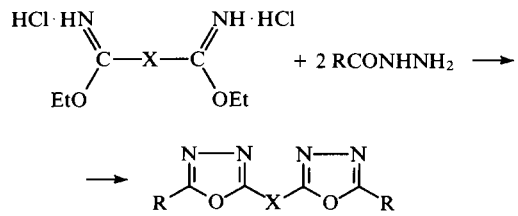


We may note that 1,3,4-oxadiazoles can be obtained by this method in two alternative ways; thus, when the synthesis from two different iminoester hydrochlorides and two hydrazides is planned, the most readily available compounds may be selected.

The condensation of iminoester hydrochlorides with acid hydrazides is carried out as a rule by heating the reactants (78–160 °C) [the iminoester hydrochloride : hydrazide molar ratio is (1–1.35) : 1] in anhydrous solvents—ethanol, DMF, *N*-methylpyrrolidinone, pyridine, or dioxane—for 1–8 h. The yields of the target 1,3,4-oxadiazoles are 55%–94% under these conditions.

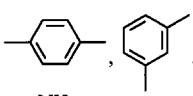
The interaction of iminoester hydrochlorides with acid hydrazides involves the formation of the *N*-acylhydrazones of the corresponding esters **137** as intermediates, which in a number of instances have been isolated in 60%–90% yields when the reaction was carried out in ethanol at −10 to 15 °C for 6–24 h.[89,107,168,301,321]

137

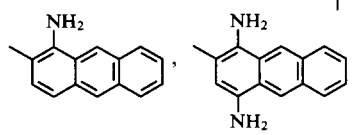


R = Me, Ar,  ,  ;
R^2 = Me, Ar, 4-Py.

On heating to the melting point[89,107,168,301] or on treatment with triethylamine at 20 °C,[321] the esters split off an alcohol molecule and are converted into 1,3,4-oxadiazoles (yield 88%–97%).



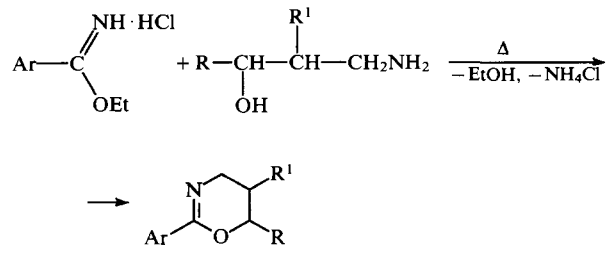
In the search for new substances with anti-inflammatory activity, 2-[ω-(dimethylamino)alkyl]-5-phenyl-1,3,4-oxadiazoles were synthesised by condensing iminoester hydrochlorides with hydrazides.[317] The authors note that, in order to obtain 2-[4-(dimethylamino)butyl]-1,3,4-oxdiazole, it is best to employ the benzoic acid iminoester hydrochloride, while 2-[2-(dimethylamino)ethyl]-1,3,4-oxadiazole is best synthesised from the benzoic acid hydrazide.



According to patent data,[318–320] the condensation of the hydrochloride of the hydroxyacetic acid iminoester with aromatic acid hydrazides leads to 5-aryl-2-hydroxymethyl-1,3,4-oxadiazoles—important intermediates in the synthesis of compounds with anticonvulsant, analgesic, anti-inflammatory, and diuretic activities.

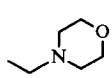
The condensation of the dihydrochlorides of dicarboxylic acid bisaminoesters with acid hydrazides (molar ratio 1 : 2) results in the formation of bis-1,3,4-oxadiazoles **138**.[301,313]

138



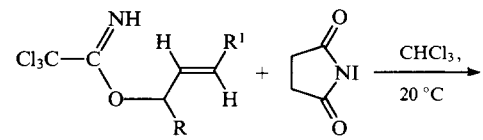
X = $-(CH_2)_n-$ (n = 0, 2, 4),  ;

R = Ar,  .

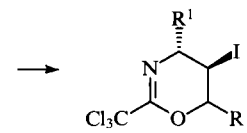


The reactions were carried out by heating the reactants in dioxane, *N*-methylpyrrolidinone, or pyridine and the yield of the bis-1,3,4-oxadiazole **138** was then 40%–80%.

5. Synthesis of 1,3-oxazines and related compounds



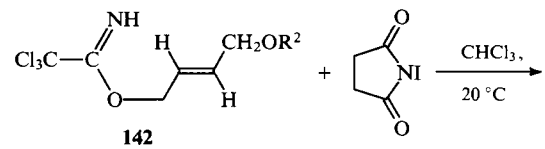
The condensation of aromatic acid iminoester hydrochlorides with substituted 3-aminopropan-1-ols in ethanol (refluxing for 1–2 h) leads to 2,5,6-trisubstituted 5,6-dihydro-4*H*-1,3-oxazines **139**.[322,323]



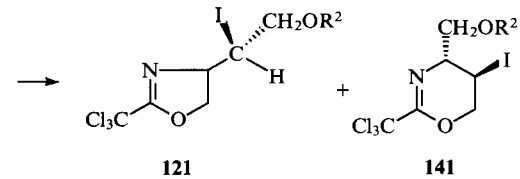
139

R = Ph,  ; R^1 = H, Ph.

It was noted above that the cyclisation of (*Z*)-allyl iminoesters of trichloroacetic acid **120** on treatment with *N*-iodosuccinimide in chloroform (20 °C, 12 h) results in the regioselective formation of 4-(1-iodoalkyl)-2-trichloromethyl-5-substituted Δ^2-oxazolines **121**.[269–271] Under similar conditions, (*E*)-allyl iminoesters of trichloroacetic acid **140** cyclise regioselectively to *trans*-5-iodo-2-trichloromethyl-4,6-disubstituted 5,6-dihydro-4*H*-1,3-oxazines **141**.[271,324]



140



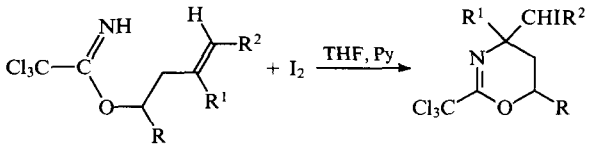
141

R = H, Me; R^1 = Alk, Ph, (*E*)-MeCH=CH, (*E*)-$C_{13}H_{27}$CH=CH.

On the other hand, the (*E*)-allyl iminoesters **142**, containing alkoxy-groups, afford a mixture of Δ^2-oxazolines **121** and 5,6-dihydro-4*H*-1,3-oxazines **141** under the reaction conditions.[318]

142

121 **141**

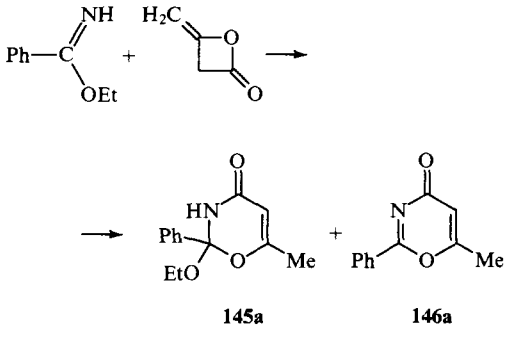


R^2 = Me, $PhCH_2$,  .

Examples of the *trans*-5-iodo-5,6-dihydro-4*H*-1,3-oxazines **141** formed on cyclisation of the (*E*)-allyl iminoesters of trichloroacetic acid **140** and **142** are presented below.

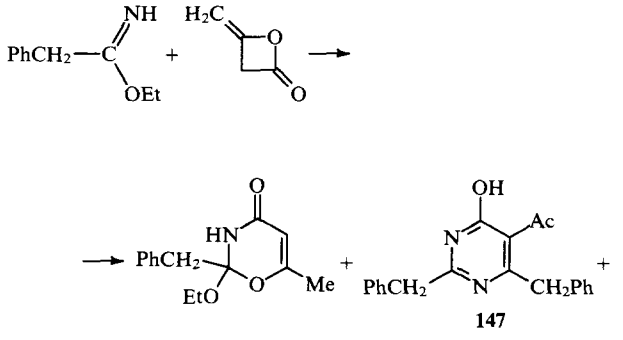
R	R^1	Yield of 1,3-oxazine **141** (%)
H	Ph	80
H	(*E*)-MeCH=CH	90
H	(*E*)-$C_{13}H_{27}$CH=CH	95
Me	Me	85
H	n-$C_{15}H_{31}$	70
H	Et	90
H	Pr	87
H	$MeOCH_2$	30 (61% **121**, R^2 = Me)
H	$PhCH_2OCH_2$	18 (75% **121**, R^2 = $PhCH_2$)
H	CH_2OTHP	38 (55% **121**, R^2 = THP)

(THP = tetrahydropyranyl)



It has been reported[269] that the cyclisation of the homoallyl iminoesters of trichloroacetic acid **143** on treatment with iodine and pyridine in THF (20 °C, 12 h) afforded 4-(1-iodoalkyl)-2-trichloromethyl-5,6-dihydro-4*H*-1,3-oxazines **144** in 65%–90% yields.

143 144

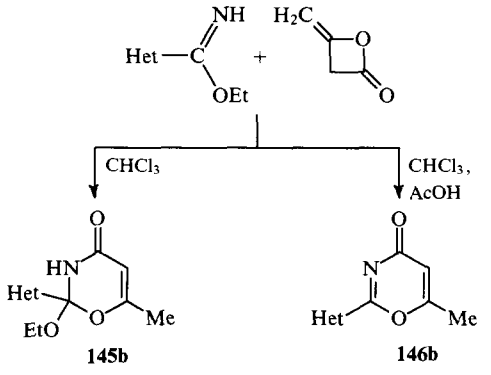


$R = R^2 = H, R^1 = Me$; $R = R^1 = H, R^2 = Et$;
$R = Me, R^1 = R^2 = H$.

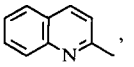
A mixture of 2-ethoxy-6-methyl-2-phenyl-3,4-dihydro-2*H*-1,3-oxazin-4-one **145a** (yield 21.3%) and 6-methyl-2-phenyl-4*H*-1,3-oxazin-4-one **146a** (yield 16.0%) was obtained by the reaction of the benzoic acid iminoester with diketene in ether (refluxing for 5 h).[325] The authors note that, on refluxing in benzene, 2-ethoxy-3,4-dihydro-1,3-oxazin-4-one **145a** is converted qualitatively into the 1,3-oxazin-4-one **146a**.

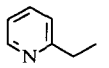
145a **146a**

A mixture of 2-benzyl-2-ethoxy-6-methyl-3,4-dihydro-2*H*-1,3-oxazin-4-one (yield 54.6%), 5-acetyl-2,6-dibenzyl-4-hydroxypyrimidine **147** (yield 27%), and the (*N*-acetoacetyl)amide of phenyl-acetic acid is formed under similar conditions from the phenylacetic iminoester.[325]



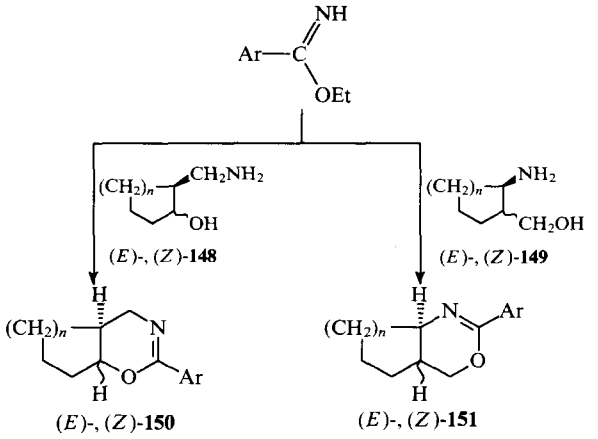
147





+ $PhCH_2CONHCOCH_2COMe$

On the other hand, the 4*H*-1,3-oxazin-4-one **146a** has been synthesised in 70% yield by refluxing (for 3 h) the benzoic acid iminoester with diketene (molar ratio 1:2) in benzene.[326]

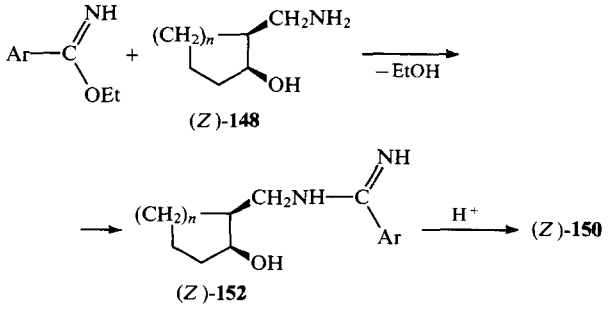


The interaction of the iminoesters of heterocyclic acids with diketene in chloroform in the presence of acetic acid (refluxing for 0.5–2 h) leads to 2-heteroaryl-6-methyl-4*H*-1,3-oxazin-4-ones **146b** in 13%–35% yield.[327] When the reaction is carried out in the absence of acetic acid (20–60 °C, 1–4 h), 2-ethoxy-2*H*-3,4-dihydro-1,3-oxazin-4-ones **145b** are formed in 33%–57% yield.

145b **146b**

Het = 2-Py, 3-Py, 4-Py,  ,  .

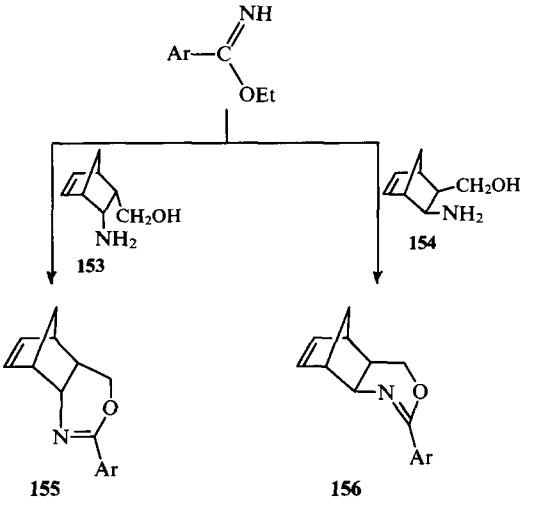
Hungarian investigators have studied in detail the condensation of the 4-chlorobenzoic acid iminoester with the stereoisomeric *cis*- and *trans*-2-aminomethylcycloalkanols **148** and 1-amino-2-hydroxymethylcycloalkanes **149**.[328,329] It was established that, when the reactants are heated in ethanol (for 24 h) in the presence of catalytic amounts of HCl, the (*E*)- and (*Z*)-5,6-tetramethylene- or (*E*)- and (*Z*)-5,6-pentamethylene-5,6-dihydro-4*H*-1,3-oxazines **150** are formed respectively in the case of the aminoalcohols **148**.



(*E*)-, (*Z*)-**150** (*E*)-, (*Z*)-**151**

$n = 2, 3$; $Ar = 4\text{-}ClC_6H_4$.

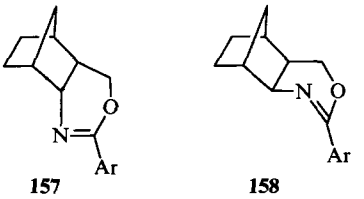
Condensation with the stereoisomeric aminoalcohols **149** leads respectively to the (*E*)- and (*Z*)-4,5-tetramethylene- or (*E*)- and (*Z*)-4,5-pentamethylene-4,5-dihydro-6*H*-1,3-oxazines **151** in 70% yield.



When the (*Z*)-isomers of the aminoalcohols **148** were refluxed (1.5 h) with the 4-chlorobenzoic acid iminoester in ethanol in the absence of an acid catalyst, the *N*-substituted amidines **152** were isolated in 70%–73% yields. On refluxing (for 12 h) in ethanol in the presence of HCl, the amidines are converted into (*Z*)-5,6-dihydro-4*H*-1,3-oxazines **150**.

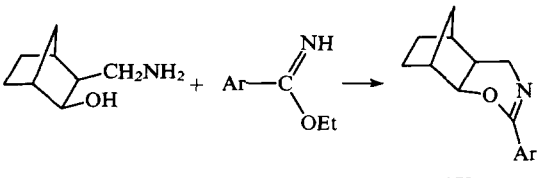
(*Z*)-**148** (*Z*)-**152**

$Ar = 4\text{-}ClC_6H_4$



The interaction of equimolecular amounts of aromatic acid iminoesters and 3-*endo*-amino-2-*endo*-(hydroxymethyl)bicyclo-[2.2.1]hept-5-ene **153** or 3-*exo*-amino-2-*exo*-(hydroxymethyl)-bicyclo[2.2.1]hept-5-ene **154** in ethanol in the presence of catalytic amounts of HCl (refluxing for 6–10 h) affords a 32%–48% yield of 2-aryl-5,8-methano-4*ar*,5*t*,8*t*,8*ac*-tetrahydro-4*H*-3,1-benoxazines **155** and 2-aryl-5,8-methano-4*ar*,5*c*,8*c*,8*ac*-tetrahydro-4*H*-3,1-benzoxazines **156** respectively.[330–332]

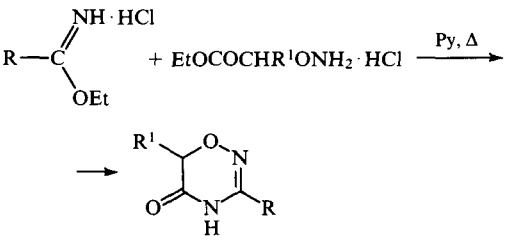
155 **156**



Ar = Ph, 3-ClC_6H_4, 4-ClC_6H_4, 4-MeC_6H_4.

2-Aryl-5,8-methano-4*ar*,5*t*,6,7,8*t*,8*ac*-hexahydro-4*H*-3,1-benzoxazines **157** (yield 34%–45%)[331,332] and 2-aryl-5,8-methano-4*ar*,5*c*,6,7,8*c*,8*ac*-hexahydro-4*H*-3,1-benzoxazines **158** (yield 27% to 38%)[330,332] were synthesised under similar conditions from 3-*endo*-amino-2-*endo*-(hydroxymethyl)bicyclo-[2.2.1]heptane and 3-*exo*-amino-2-*exo*-(hydroxymethyl)bicyclo-[2.2.1]heptane respectively.

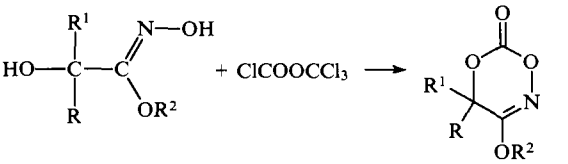
157 **158**



The condensation of aromatic acid aminoesters with *cis,exo*-3-(aminomethyl)bicyclo[2.2.1]heptan-2-ol under the conditions indicated above leads to 2-aryl-5,8-methano-4*ar*,5*c*,6,7,8*c*,8*ac*-hexahydro-4*H*-1,3-benzoxazines **159** in 51%–55% yield.[333]

159

6. Synthesis of 1,2,4-oxadiazine and 1,5,2-dioxazine derivatives



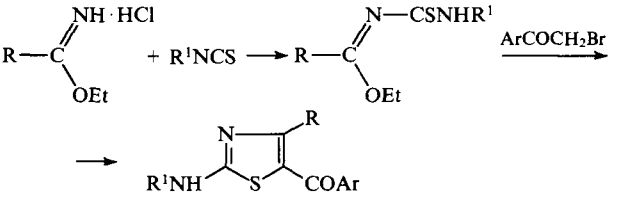
According to patent data,[334] derivatives of 1,2,4-oxadiazin-5-one **160**, which are effective herbicides and plant growth regulators, are formed in satisfactory yields when aromatic and heterocyclic acid iminoester hydrochlorides are refluxed with the hydrochlorides of *O*-substituted hydroxylamine in pyridine.

160

R = Ar, Het; R^1 = H, Me, Et, Ph.

The interaction of the (*E*)-isomers of the *N*-hydroxyiminoesters of carboxylic α-hydroxyacids **161** with trichloromethyl chloroformate at 20 °C leads to 3-alkoxy-4*H*-1,5,2-dioxazin-6-ones **162** in 70%–73% yields.[335]

161 **162**

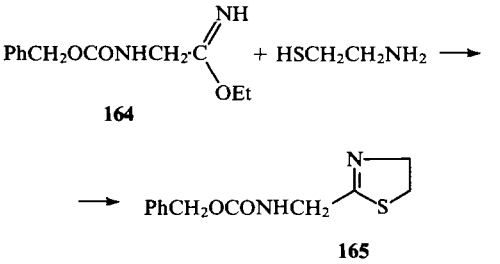


R, R^1 = H, Me, Ph; R + R^1 = $-(CH_2)_5-$; R^2 = Et, $PhCH_2$.

IV. Synthesis of five- and six-membered heterocycles containing nitrogen and sulfur atoms

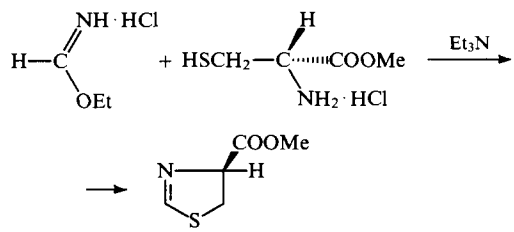
1. Synthesis of thiazole, Δ^2-thiazoline, and benzothiazole derivatives

It was noted above that the interaction of the *N*-cyanomethyl-iminoesters **5** with hydrogen disulfide in pyridine results in the formation of 5-mercapto-1*H*-imidazoles (yield 20%–35%) together with 5-aminothiazoles (yield 10%–20%).[36]



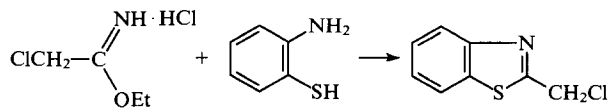
The reactions of aliphatic acid iminoesters with alkyl isothiocyanates lead to *N*-(alkylaminothiocarbonyl)iminoesters, which on treatment with 4-chloro-3-nitrophenylacyl bromide cyclise to 2-aminothiazole derivatives **163** — intermediates in the synthesis of pharmaceutical preparations.[336]

163



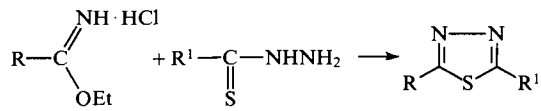
R, R^1 = Alk; Ar = 3-O_2N-4-ClC_6H_3.

The 2-substituted Δ^2-thiazoline **165**, which is a key compound in the synthesis of serine, threonine, allothreonine, and β-hydroxynorvaline, has been synthesised in 75% yield by condensing the *N*-acylated aminoacetic acid iminoester **164** with 2-aminoethanethiol in ethanol (35–50 °C, 3 h).[73]

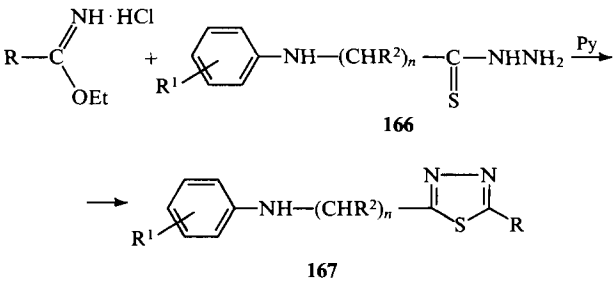


164 **165**

A chiral ester of (4*R*)-Δ^2-thiazoline-4-carboxylic acid has been obtained in 82%–85% yield by the reaction of the formic acid iminoester hydrochloride with the hydrochloride of the methyl ester of D-cysteine in the presence of triethylamine in methylene chloride (20 °C, 3 h).[337,338]

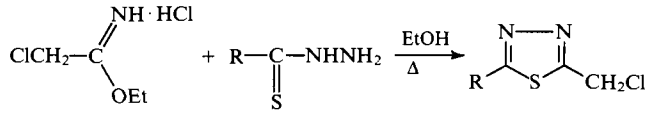


When the chloroacetic acid iminoester hydrochloride is refluxed with *o*-aminothiophenol in chloroform, 2-chloromethylbenzothiazole, which is an intermediate in the synthesis of biologically active substances[339] and functional derivatives of benzothiazole,[293] is formed in 70%–75% yield.[293,339]



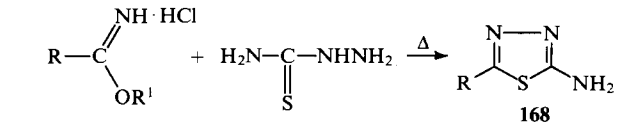
2. Synthesis of 1,3,4-thiadiazole derivatives

In 1963, Weidinger and Kranz[190] proposed a convenient method of synthesis of 2,5-disubstituted 1,3,4-thiadiazoles, which consists in condensing carboxylic acid iminoester hydrochlorides with carboxylic acid thiohydrazides. The reactions were carried out by refluxing equimolar amounts of the reactants in ethanol; under these conditions the yields of 1,3,4-thiadiazoles were 65%–78%.

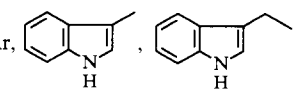


R = Me, Ar; R^1 = Ar.

The interaction of iminoester hydrochlorides with the thiohydrazides of *N*-substituted aminoacids **166** in pyridine leads to the 1,3,4-thiadiazoles **167**, which possess herbicidal properties.[340]

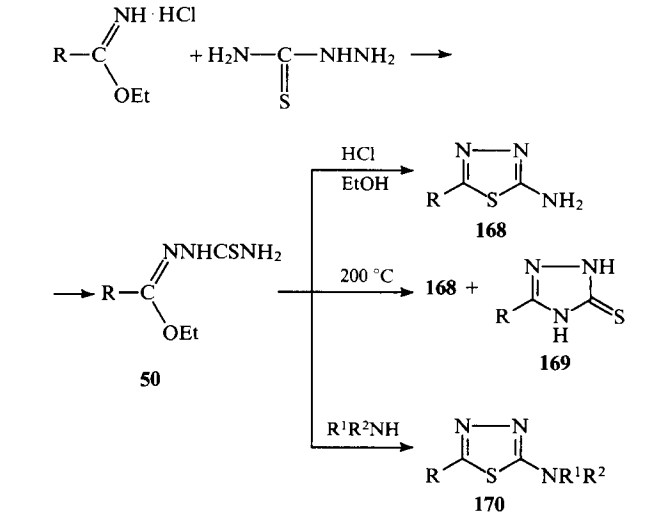


R = H, Me, cyclo-C_nH_{2n-1}, Ar; R^1 = Hal, Alk, AlkO, AlkHal
R^2 = H, Alk; n = 1, 2.



2-Chloromethyl-5-substituted 1,3,4-thiadiazoles, which are intermediates in the synthesis of preparations with an anticonvulsant activity, have been synthesised by the reaction of the chloroacetic acid iminoester hydrochloride with thiohydrazides.[341]

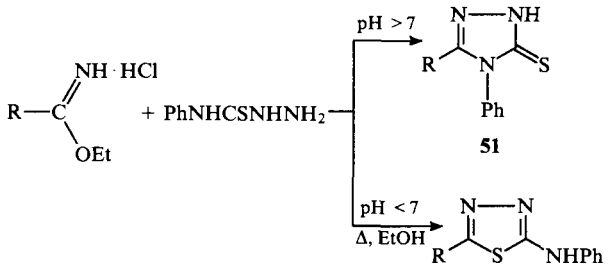
R = Ph, $PhCH_2$, 2-PhC_6H_4, 2-$PhOC_6H_4$, 2-$PhC_6H_4CH_2$.



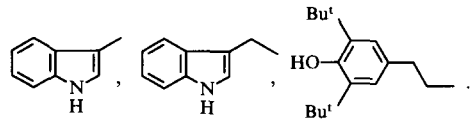
The condensation of carboxylic acid iminoester hydrochlorides with thiosemicarbazide leads to 2-amino-5-substituted 1,3,4-thiadiazoles **168**.[167,190,191,313,342–345] The reactions were carried out by refluxing the reactants in ethanol, dioxane, or pyridine [molar ratio (1–1.2):1; 1–4 h]; the yields of the 2-amino-1,3,4-thiadiazoles **168** were 34%–92%.

R = H, Alk, cyclo-C_6H_{11}, Ar,  ;
R^1 = Me, Et.

It had been noted earlier that the interaction of equimolar amounts of iminoester hydrochlorides and thiosemicarbazide in DMF at 20 °C (20 h) leads to the formation of carboxylic acid ester thiosemicarbazones **50** in 53%–74% yields.[188,189] Under certain conditions, the latter may cyclise to 2-amino-1,3,4-thiadiazoles. For example, 2-amino-5-substituted 1,3,4-thiadiazoles **168** have been synthesised in 31%–85% yields by refluxing the thiosemicarbazones in ethanol (1 h) in the presence of HCl (Scheme 4).

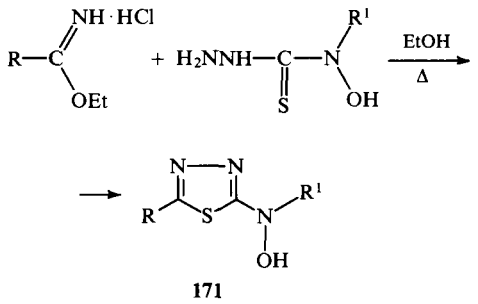


Scheme 4

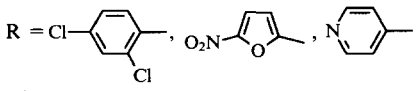


R = Alk, $PhCH_2$, Ar; R^1 = R^2 = Et;
R^1 + R^2 = $-(CH_2)_5-$.

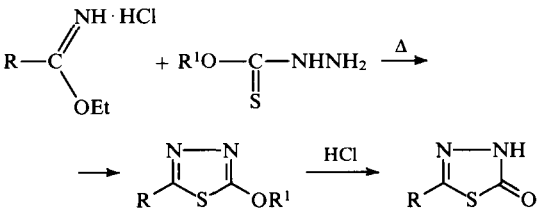
Thermolysis of the thiosemicarbazones (200 °C, 20 min) leads to a mixture of the 2-amino-1,3,4-thiadiazoles **168** (yield 22%–74% and 3-substituted Δ^2-1*H*-1,2,4-triazoline-5-thiones **169** (yield 12%–25%).[188] Substituted 2-amino-1,3,4-thiadiazoles **170** have been obtained in 30%–35% yields by heating the thiosemicarbazone with secondary amines in DMF in a sealed tube (150 °C).[188]



According to literature data,[89,167,190,191,342,343] the mode of the condensation of iminoester hydrochlorides with 4-phenylthiosemicarbazide is determined by the nature of the reaction mixture: in the presence of bases (pyridine, triethylamine, tripropylamine), 3,4-disubstituted Δ^2-1,2,4-triazoline-5-thiones **51** are formed, whereas in an acid medium the products are 2-phenylamino-5-substituted 1,3,4-thiadiazoles (yield 52%–85%).

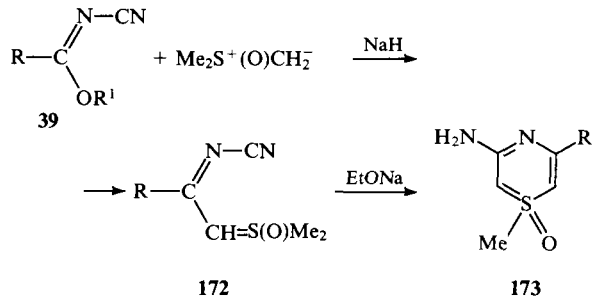


R = Ph, $Me_3SiCH_2CH_2$, $Et_2Si(Me)CH_2CH_2$,



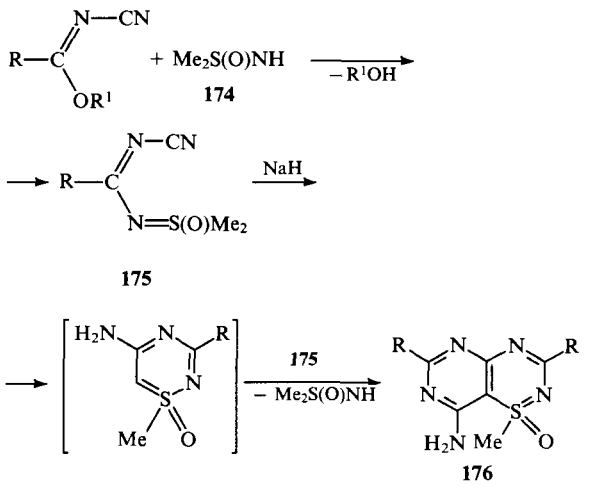
The interaction of equimolar amounts of iminoester hydrochlorides and 4-substituted 4-hydroxythiosemicarbazides in ethanol (refluxing for 0.5 h) leads to 2-hydroxyamino-1,3,4-thiadiazoles **171** in 40%–55% yields.[346]

R^1 = Me, Ar, All.



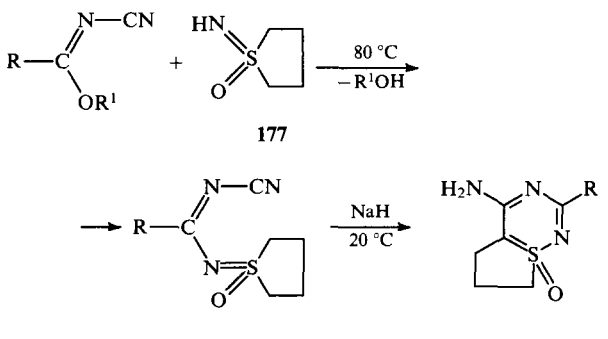
The synthesis of 2-alkoxy-5-substituted 1,3,4-thiadiazoles by the condensation of iminoester hydrochlorides with *O*-alkyl esters of thiocarbazinic acid in ethanol (refluxing for 0.5–1.5 h) has been described in a patent.[347] On treatment with hydrochloric acid, 2-alkoxy-1,3,4-thiadiazoles are converted into 3-substituted Δ^2-1,3,4-thiadiazolin-5-ones, which exhibit insecticidal, acaricidal and fungicidal activities.

R = H, Alk, CH=CH–C_nH_{2n+1} (n = 0–6), Ph;
R^1 = Me, Et, Bu.



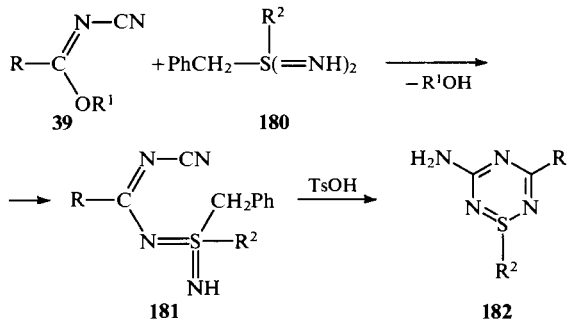
3. Synthesis of thiazine, thiadiazine, and thiatriazine derivatives

It has been reported[348] that the interaction of *N*-cyanoiminoesters with dimethyloxosulfonium methylide (20 °C, 24 h, molar ratio 1:1.2) in DMSO in the presence of sodium hydride leads to the formation of [1-R-2-(dimethyloxo-λ^6-sulfanylidene)ethylidene]cyanamides **172** in 83% yield. On refluxing (for 0.5 h) in ethanol in the presence of sodium ethoxide, the latter cyclise to 3-amino-1-methyl-5-R-1λ^4,4-thiazine 1-oxides **173** (yields 48%–82%).



R = Ar,  ;
R^1 = Me, Et.

The condensation of *N*-cyanoiminoesters with the sulfoximide **174** (80 °C, 18 h) leads to *N,N*-disubstituted amidines **175** (yield 27%–91%), which are converted into 3,6-disubstituted 8-amino-1-methylpyrimido[4,5-*e*]-1λ^4,2,4-thiadiazine 1-oxides **176** (yield 39%–57%) on treatment with sodium hydride in DMSO (20 °C).[349]



R = Me, Ar,  ,  ; R^1 = Me, Et.

The *N,N*-disubstituted amidines **178** have been obtained under similar conditions from the sulfoximide **177**. On treatment with sodium hydride, the amidines undergo intramolecular cyclisation to 2-substituted 4-amino-6,7-dihydro-5*H*-thieno-[2,1-*e*]-1λ^4,2,4-thiadiazine *S*-oxides **179** (yield 46%–74%).[349]

R = Me, Ph, 4-MeC_6H_4,  .

The reactions of equimolecular amounts of *N*-cyanoiminoesters and *S*-alkyl-*S*-benzylsulfodiimides **180** (60 °C, 16–48 h) afford 43%–90% yields of *N*-(alkylbenzylimino-λ^6-sulfanylidene)-N^2-cyanoamidines **181**.[350]

R = Ar,  ; R^1, R^2 = Me, Et.

On refluxing with toluene-*p*-sulfonic acid in ethanol, the *N,N*-disubstituted amidines **181** are debenzylated with simultaneous cyclisation to 1,5-disubstituted 3-amino-1λ⁴,2,4,6-thiatriazines **182** (yield 48%–71%).

Heterogeneous free-radical reactions in oxidation processes

M Yu Sinev, L Ya Margolis, V N Korchak

Contents

I. Introduction 349
II. Heterogeneous factors in homogeneous gas-phase oxidation processes 350
III. Free radicals in heterogeneous-catalytic oxidation processes 352
IV. Conclusion 361

Abstract. The role of heterogeneous reactions of free radicals in oxidation processes of various types is analysed: homogeneous gas-phase, stabilised combustion, and heterogeneous-catalytic processes. It is shown that in all cases the observed kinetics and product compositions may be determined by the set of heterogeneous and homogeneous stages having the same nature, occurring in the systems simultaneously and as interdependent reactions. The possible mechanisms of the heterogeneous formation of free radicals and of their subsequent reactions are discussed. The methods for the investigation of heterogeneous radical reactions are examined. The bibliography includes 198 references.

I. Introduction

Oxidation processes (extensive and partial oxidation) are traditionally considered independently both in the theory of gas-phase reactions and in heterogeneous catalysis. There are a number of reasons for this, associated with the overall kinetic features, the mechanism of the activation of the reactants, and the chemistry of the elementary stages, which are different in homogeneous and heterogeneous processes. Furthermore, even the systems of concepts, terminology, and general approaches to the analysis and description of the processes in these two fields of chemical kinetics differ significantly.

There exist experimental facts and theoretical concepts according to which heterogeneous processes involving the reactor walls or the surface of solid packing can determine the characteristics of gas-phase oxidation processes. However, in heterogeneous-catalytic oxidation processes there is a possibility of the formation of species carrying an excess of free energy (the active and excited molecules, free atoms and radicals). The release of such species into the gas phase may lead to a homogeneous continuation of the process. Under these conditions, the reactions of the radical species play an especially important role. They are highly reactive in homogeneous processes and can also give rise to surface compounds which are intermediates in oxidation reactions.

Various aspects of the mechanisms and kinetics of heterophase processes involving free radicals have been surveyed in a number of publications.[1–13] The hypothesis of heterogeneous–homogeneous reactions, according to which chain carriers are initiated on the surface of the reaction vessel or catalyst, has been formulated in a review.[1] The release of these carriers into space leads to the continuation of the process in which the bulk-phase and surface reactions occurring simultaneously are closely interrelated and are independent.

The reactions including homogeneous and heterogeneous stages have been classified, the possible mechanisms of the heterogeneous formation of radicals have been analysed from the standpoint of thermochemistry, methods for the recording of active species and for the investigation of heterogeneous–homogeneous reactions have been described, and data concerning the mechanisms and kinetics of specific processes have been examined in a monograph.[2]

The possible variants of the combination of homogeneous and heterogeneous stages of a complex process have been discussed and examples of their occurrence in the oxidation reactions of substances belonging to different classes have been presented in a book.[3]

The differences in the description of gas-phase radical-chain processes have been analysed[4] within the framework of the traditional ideas of the chain theory, which do not take into account the possible participation of the surface in the chain propagation and branching stages, and also within the framework of the approach developed by the author, which does take into account such a possibility. It has been shown in relation to the hydrogen oxidation reaction that allowance for heterogeneous factors permits a more complete description of the phenomenology and kinetics of the process.

Analysis of the mechanism of the partial oxidation of methane showed that the formation of the methyl radical on interaction with an oxidative centre on the surface of the oxide catalyst represents the stage involving the activation of the CH_4 molecule in the catalytic process.[5,6] The selectivity of the process as a whole depends on the subsequent reactions of the $CH_3^{\cdot}$ radical both in the gas phase and in heterogeneous reactions.

The study of Driscoll et al.[7] was largely devoted to the employment of instrumental methods for the detection of free radicals formed in heterogeneous processes. Specfic procedures, which permit the application for this purpose of various modifications of mass-spectrometry, matrix isolation of radicals combined with measurement of IR and EPR spectra, photoelectron spectroscopy, and multiphoton and resonance ionisation methods, have been examined. Examples illustrating the role of free radicals in catalytic reactions have been presented.

Data on the generation of free radicals, obtained mainly by the 'freezing out' (or matrix isolation) of radicals in a matrix of

reagents and reaction products with recording of EPR spectra, have been analysed in recent reviews.[8,9] It was shown that radicals form in many heterogeneous processes, including catalytic oxidation reactions.

Analysis of the reactions of the $OH^{\cdot}$ and $HO_2^{\cdot}$ radicals in the atmosphere showed that heterogeneous reactions of the radicals may be a significant factor determining the gas composition of the troposphere and the stratosphere.[10,11]

The kinetics of the catalytic reactions accompanied by the release of active species into space have been examined in two communications.[12,13] The conditions for the appearance of nonstationary regimes, the possible multistage mechanisms of such reactions, and the kinetic equations for the stationary and nonstationary conditions as a function of the nature of the reaction propagated in the gas phase, as well as the role of the mass transfer processes in the catalyst grain were analysed.

In recent years, the number of studies devoted to the heterogeneous reactions of free radicals has continued to grow. Some of the postulates formulated previously require rethinking in the light of the results. Unfortunately, a systematic consideration of the entire set of available data is not available in the literature. This has stimulated their survey and analysis from a single standpoint and the determination of the direction in which further progress in the understanding of the mechanisms of the oxidation processes may be attained.

II. Heterogeneous factors in homogeneous gas-phase oxidation processes

In the traditional theory of gas-phase radical-chain processes (RCP), the involvement of the surface (as a rule the walls of the reaction vessel or the surface of the packing introduced into the reactor) in the chain initiation and termination stages is considered.[14-16] The presence of a lower ignition pressure limit is associated with the decisive role of the heterogeneous termination. Within the framework of this approach, a significant feature is the regime in which the chain carriers are destroyed — in the diffusional or kinetic regime (in the latter case, an important factor is the probability of their destruction in collisions). On the other hand, the destruction itself is considered only as the disappearance of a species in the gas phase, no attention being devoted to the chemistry of the process and its detailed mechanism.

The need to take account of heterogeneous factors exists also when the chain initiation mechanism is considered. Since the work of van't Hoff,[17] the influence of the material and of the preliminary treatment and relative surface area of the reaction vessel walls on the kinetics of the oxidation processes in the gas phase has been frequently noted.

Considerable progress in the study of the role of the surface and radical-chain processes has been associated with the creation of a method for separate calorimetric measurements,[18] the essential feature of which consists in the measurement of the differences between the temperatures at different points in the reaction volume, for example near the walls and at some distance from them. Depending on the location of the process or of its individual stages, the magnitude and sign of these differences may differ. If heterogeneous stages are completely absent, heating takes place in the centre of the cylindrical vessel, and

$$\Delta T_v = \frac{Q_v}{4\pi\lambda},$$

where Q_v is the heat evolved in the volume reaction per unit time and λ is the thermal conductivity of the gas.

If the reaction takes place wholly on the surface of a cylindrical reactor having a radius R with a thermocouple-containing capillary having a radius r placed along the axis of the reactor, then

$$\Delta T_s = \frac{Q_s}{4\pi\lambda}\frac{r}{R+r}\ln\frac{R}{r},$$

where Q_s is the heat evolved in the heterogeneous reaction per unit time.

Finally, if the process takes place partially on the walls and partially in space, then

$$\Delta T = \frac{Q_v}{4\pi\lambda} + \frac{Q_s}{4\pi\lambda}\frac{2r}{R+r}\ln\frac{R}{r}.$$

Expressions similar to those quoted above may be obtained for fully homogeneous or fully heterogeneous reactions.[19]

In essence, the method involving separate calorimetric measurements has been the first direct experimental method for the investigation of heterogeneous–homogeneous processes. Numerous examples of its successful application to the study of the mechanisms of various processes, including gas-phase oxidation, have been quoted.[1,2,19] An evident limitation of the method is associated with the impossibility of using it to investigate the detailed mechanisms of the heterogeneous formation and subsequent reactions of active species. For this reason, until recently the principal conclusions concerning the mechanism of the heterogeneous stages have been reached on the basis of the analysis of the kinetics of the RCP (Radical Chain Process).

Thus the decrease in the effective activation energies for the thermal and oxidative pyrolysis of methane ($E_{ef} = 85-335$ kJ mol^{-1}) has been attributed to the involvement of the surface in the chain initiation.[20] It has been noted that, under conditions ruling out the influence of the surface (shock waves, adiabatic compression, and jets of a heated carrier gas), higher values of E_{ef} (>370 kJ mol^{-1}) are observed. If the primary step involves the chemisorption of methane, i.e.

$$[S] + H-CH_3 \rightarrow [H...S...CH_3], \qquad (1)$$

then the energy of the dissociation of the C–H bond and of the formation of the primary radicals $CH_3^{\cdot}$ diminishes. In a heterogeneous process involving a carbon surface (any initial surface under cracking conditions is of this kind), the energy E_{ef} decreases compared with its value in a purely homogeneous process approximately by 210 kJ mol^{-1} and approaches the experimental values.

There is serious evidence (see, for example, the study of Garibyan et al.[21]) in support of the heterogeneous chain initiation in the oxidation reactions of hydrogen and C_1-C_3 hydrocarbons in a quartz reactor. A break in the Arrhenius relation for the reaction

$$RH + O_2 \rightarrow R^{\cdot} + HO_2^{\cdot}, \qquad (2)$$

is observed in the temperature range 450–715 °C. The low-temperature section ($E_{ef} = 100$ kJ mol^{-1}) is attributed to a heterogeneous process, while the high-temperature section (200–240 kJ mol^{-1}) is attributed to a homogeneous process.

The possibility of the occurrence of heterogeneous chain branching, propagation, and transfer stages and not merely chain initiation and termination has been discussed.[15,22] This hypothesis makes it possible to explain many facts established in the study of the gas-phase oxidation processes (activation energies, nonlinear variation of the rate of reaction as the concentrations of the reactants are varied, dependence of the composition of the product on the coating of the reactor walls). Nevertheless, specific mechanisms involving heterogeneous stages in the reactions of specific radicals have been scarcely considered until recently in the RCP theory.

The analysis of the influence of heterogeneous factors on the rate of RCP was based on the following postulates:[23]

1. When the first ignition limit is stable and the kinetic curves for the variation of the concentrations of the components of the reaction mixture are reproducible, the rate coefficient for the heterogeneous radical destruction reaction is constant.

2. The heterogeneous chain carrier destruction reaction is a first order process.

3. The adsorption of chain carriers is identical with chain termination.

However, there are a whole series of characteristic features of the RCP kinetics which cannot be described without a more detailed allowance for the role of heterogeneous stages. These features include the following:[24] continued acceleration of the isothermal process after the concentrations or pressures of the reactants reach values below those characteristic of the first ignition limit; expansion of the range of self-ignition under the influence of species preadsorbed on the reactor walls; heterogeneous self-inhibition of the chain combustion; hysteresis phenomena; vibrational combustion regimes in a closed volume.

A series of studies, in which the new approach to the role of heterogeneous factors in gas-phase reactions has been developed, have been devoted to the analysis of these features.[23-38] It was shown that the kinetics of many processes, traditionally regarded as homogeneous, are determined by the presence of a feed-back between heterogeneous reactions and RCP in the gas phase. This is associated to a large extent with the involvement of heterogeneous stages not only (and not so much) in the initiation and destruction of chain carriers but also in the propagation and branching of chains. The reactor surface is regarded as a 'reservoir' providing a store of active species (or their precursors) in the reaction zone and ensuring their involvement in the process (in particular their influence on the branching stage).

One of the possible variants of such influence is the increase in the branching factor during the process as a result of the decrease in the effective rate of the heterogeneous destruction of the chain carriers.[25] This may be induced by a decrease in the probability of the destruction of the radicals in their interaction with the surface as the degree of coverage of the latter by various species increases during the reaction.[26] The fact that during the combustion of H_2 and CO the reaction does not stop when the concentration of the reactants falls below the first ignition limit, i.e. the observed degrees of conversion are much higher than might have been expected for a constant rate of chain termination, has also found an explanation.[23]

In certain cases, it has been possible to determine the nature of the active species concentrated on the surface and to put forward a mechanism of their influence on characteristic features of the process. In particular, it has been shown[29] that, under the conditions of the hydrogen oxidation reaction, the walls of the quartz reactor are capable of adsorbing considerable numbers of hydrogen atoms: one adsorbed hydrogen atom is formed per H_2 molecule converted into water, while at a reactor temperature of 450–650 K the coverage of the reactor wall may be 6.5×10^{13} atoms cm^{-2}.

Hydrogen atoms with similar properties, generated by an incandescent tungsten filament in a hydrogen atmosphere, are adsorbed on quartz. The lifetime of the hydrogen atoms on the surface under the conditions of reduced pressure at the reaction temperature (at least tens of minutes at ~500 °C) exceeds by several orders of magnitude the characteristic lifetimes (tens of seconds). However, when molecular hydrogen is supplied, the surface is rapidly cleaned.

The ability of oxygen to clean the surface by removing the adsorbed hydrogen atoms has been demonstrated in a study of the recombination of hydrogen atoms on the surface of a Chromel–Alumel thermocouple.[28] Whereas at 500 °C at a pressure of 3 Torr the stationary recombination temperature rise in a jet of atomic hydrogen was 2–5 °C, after the treatment of the thermocouple for 10 min with oxygen it rose to 30–50 °C.

The $-\rangle Si-OH$, $-\rangle Si-H$, and $SiH_x(OH)_{2-x}$ groups have been detected by IR spectroscopy during the oxidation of monosilane on a silica gel surface. In the absence of oxygen, they did not appear, i.e. these surface compounds are formed during oxidation and are intermediates.[34]

It has been postulated[23] that the stages involving the formation and reactions of the hydrogen atoms on the reactor surface play an important role in the mechanism of the oxidation of hydrogen. It is suggested (in contrast to the traditional point of view) that the collision of a hydrogen atom from the gas phase with the surface leads not to chain termination by recombination but to the formation of an adsorbed hydrogen atom (H_s), the reaction of which with molecular oxygen leads ultimately to chain branching.

$$H_s + O_2 \rightarrow HO_2, \quad (3)$$

$$H + HO_2 \rightarrow 2\,OH, \quad (4)$$

$$H + HO_2 \rightarrow H_2O + O, \quad (5)$$

$$O + HO_2 \rightarrow OH + O_2. \quad (6)$$

It is suggested that in the above scheme reaction (3) is heterogeneous whilst reactions (4)–(6) may be both heterogeneous, i.e. they proceed with participation of adsorbed atoms, and homogeneous.

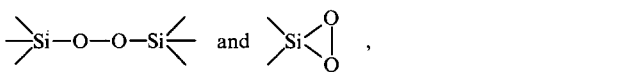
In considering the possible mechanism of the heterogeneous chain self-ignition of SiH_4+O_2 mixtures, Azatyan and Aivazyan[35] suggested that, in addition to reactions (3)–(6), the following process leads to chain branching:

$$H_s + O_2 \rightarrow OH_s + O. \quad (7)$$

On the basis of the proposed scheme, it has been possible to construct a kinetic model and to obtain an equation describing the kinetics of the oxidation of hydrogen over a wide range of pressures of the reactants, including the conditions on either side of the lower ignition limit.[23, 32, 37]

Important evidence for the involvement of heterogeneous stages in chain propagation and branching is provided by nonstationary phenomena. The appearance of, for example, hysteresis phenomena and oscillatory regimes under static conditions without self-heating, detected in the oxidation reactions of CO and P_4 and SiH_4 vapours and also in the decomposition of NCl_3,[23] may be caused only by chemical factors, in particular by the reactions of the adsorbed chain carriers.[30-32, 34-36, 38] For example, in the oxidation of silane the propagation of the process as a function of time and also the variation of the first ignition limit are described by curves with hysteresis, which is associated with the reversible variation of the properties of the surface during combustion.[31]

The existence of decaying oscillations in the isothermal combustion of CO in a closed volume is due to the involvement in the reaction of adsorbed atoms and radicals:[29] repeated filling of the reactor containing MgO with a 'dry' $CO+O_2$ reaction mixture leads to a decrease in the number of pulsations, but, after the H_2+O_2 reaction has been carried out in the same reactor, the initial nature of the oscillations is restored.



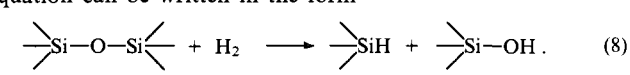
Repeated isothermal ignition in a closed volume has been observed also in the reaction of monosilane with oxygen. Azatyan and Aivazyan[38] were able to show that successive flashes occur at different distances from the reactor wall, have different spectral compositions, and correspond to different overall processes.

The results of kinetic analysis indicate[12] that the presence of several stationary states, including two unstable states responsible for the occurrence of autooscillations, may be associated with the reversible adsorption-desorption of radicals.

The studies considered above have not only created a new approach to the understanding of the kinetics of the RCP but have also posed the question of the chemical behaviour of the 'wall', which is important. Unfortunately, nothing has been said in the above communications concerning the nature of the surface centres of quartz responsible for the strong adsorption of hydrogen atoms and also the possibility of the occurrence of reaction (3), which is a key process in the chain branching induced by the surface.

The results of the study of the surface centres of oxides subjected to mechanical activation[39-45] and of 'reactive silica', obtained by the heat treatment of the large surface area of silica subjected to preliminary methoxylation,[46] have thrown some light on this question. Centres of various types are present on such surfaces and may be converted into one another and modified by means of special chemical treatment.

Centres of the paramagnetic and diamagnetic types, such as the $-\overset{|}{\underset{|}{Si}}^{\bullet}$, $-\overset{|}{\underset{|}{Si}}-O^{\bullet}$, and $-\overset{|}{\underset{|}{Si}}-OO^{\bullet}$, doubly coordinated silicon atoms $=Si:$, strained $-\overset{|}{\underset{|}{Si}}-O-\overset{|}{\underset{|}{Si}}-$ bridges, and the peroxide groups



have been identified by EPR and optical spectroscopy. Their structures and reactivities have been investigated and it has been shown that some of them may induce the dissociation of the C–H and H–H bonds. Quantum-chemical calculations and comparison of the activation energies for the reactions of various surface centres of mechanically activated quartz with H_2, D_2, CH_4, C_2H_6, and C_3H_8 molecules have demonstrated the applicability of the Polanyi–Semenov correlation,

$$E = E_0 + \alpha|\Delta H| ,$$

to the reactions of surface centres with gas phase molecules.

It has been suggested[29] that the siloxane bonds are 'opened' under the influence of hydrogen atoms on the surface of quartz and hydroxy-groups are formed. Bystrikov et al.[40] were able to demonstrate by the NMR and IR spectroscopic methods and by the thermal desorption method in combination with quantitative chemical analysis that, when quartz is ground under a hydrogen atmosphere, $-\overset{|}{\underset{|}{Si}}H$ groups are formed, i.e. the overall reaction equation can be written in the form

(8)

According to the data obtained by Bobyshev and Radtsig,[44] the X–H bond dissociation energies in the surface compounds $-\overset{|}{\underset{|}{Si}}H$, $-\overset{|}{\underset{|}{Si}}OH$, and $-\overset{|}{\underset{|}{Si}}OOH$ are 419, 510, and 389 kJ mol^{-1} respectively. The first two values are comparable with the Si–O bond strength in quartz and, if analogous surface compounds are formed in the interaction of the surface of the quartz reactor with hydrogen atoms under the experimental conditions,[29] then the hydrogenation of the surface by hydrogen atoms is entirely probable. For such bond energies, the lifetime of the hydrogen on the surface should be extremely long even under evacuation at elevated temperatures. The probability of reaction (3) increases with decrease in the hydrogen bond energy. This question will be examined in greater detail below.

We shall consider specially the 'stabilised combustion' process, which will be understood (in accordance with Pfefferle and Pfefferle[47]) as gas-phase combustion occurring in the presence of a catalytically active surface of a solid. This makes it possible to carry out the process in 'weak' mixtures of a fuel with an oxidant at much lower temperatures, with a much lower yield of impurities contaminating the environment (in the first place nitrogen oxides), and with an increased efficiency of utilisation of the heat evolved under these conditions.[48]

Various catalysts, the macrokinetics of the processes, and the design of the reactors employed to achieve the stabilised combustion of various fuels (hydrocarbons, hydrogen, and CO) have been considered in a series of reviews.[47,49–51] Direct measurements of the concentrations of the active species (OH$^{\bullet}$ radicals[52–54] and oxygen atoms[55]) showed that, depending on the conditions and the nature of the surface, they can both decrease monotonically on moving away from the surface (in this case the process apparently proceeds as a heterogeneous reaction or is concentrated in the near-surface layer) and can pass through a maximum. The latter case probably indicates directly the occurrence in space of a chain process initiated by the reaction on the surface.

It is of interest that in the combustion of hydrogen the concentrations of the OH$^{\bullet}$ radicals ($\sim 10^{15}$ cm^{-3}) and the profiles of their concentrations along the normal to the surface are virtually identical for platinum and quartz at 1170 K.[47,52] For the combustion of methane[55] and ethane,[54] the oxygen atom concentration profiles depend on temperature in the case of the platinum catalyst: the concentration of oxygen atoms decreases monotonically on moving away from the surface below 1570 K (methane) and 1450 K (ethane), while at higher temperatures a concentration maximum ($\sim 10^{16}$ cm^{-3}) is attained at distances of 0.5–3.0 mm. In the case of a quartz surface, the concentration of oxygen atoms passes through a maximum, reaching $\sim 4 \times 10^{15}$ cm^{-3} (1580–1665 K, methane) and $\sim(1-2) \times 10^{15}$ cm^{-3} (1315–1560 K, ethane).

A wider range of metals has been investigated in the combustion of hydrogen.[56] The activity of the metals increases in the sequence Pt > Pd > Rh > Ir > Ni. With increase in pressure in the range 0.005–0.2 Torr in the temperature range 950–1300 K, the yield of the OH$^{\bullet}$ radicals passes through a maximum at 0.7 ± 0.1 Torr, but the maxima in the rate of reaction as a whole and in the rate of formation of the radicals may not coincide. The activation energies for the formation of radicals vary in the range from 1150 (Rh) to 172 (Pt) kJ mol^{-1} and are not correlated with the activities of the metals. The OH$^{\bullet}$ radicals are also formed in the reaction of hydrogen with a preoxidised metal in the absence of oxygen from the gas phase, i.e. they may be a product of the reaction of hydrogen with adsorbed oxygen atoms.

The data obtained in the above investigations[47–56] make it possible to return to the analysis of the influence of heterogeneous factors in gas-phase combustion processes at a new level. However, one should note yet again that even the early investigations (see, for example, Polyakov[1] and Gorokhovatskii et al.[2]) demonstrated in relation to the oxidation of hydrogen and hydrocarbons that the 'slow homogeneous' and explosive heterogeneous initiated oxidation processes obey the same rules. The results of the above investigations[47–56] show that the behaviour and role of the surfaces of the traditional 'wall-type' (quartz) and classical catalytic materials (Group VIII metals) in combustion processes may be similar.

III. Free radicals in heterogeneous-catalytic oxidation processes

It is clear from the preceding section that, whilst recognising the important role of the heterogeneous reactions of radicals in gas-phase oxidation processes, the RCP theory does not deal with the detailed mechanisms of these reactions, being restricted to a macrokinetic and in a number of instances a stoichiometric description. The details of the interaction of species with the surfaces of solids have been investigated traditionally in heterogeneous catalysis, resorting to data derived from solid state chemistry and surface science.

Out of the entire wide variety of processes in which both the surface of a solid and the surrounding bulk phase play a significant role, in heterogeneous catalysis one usually considers heterogeneous–homogeneous reactions which begin on the surface and pass to the surrounding space as a result of the release of active intermediate species into the gas phase, where the reactions involving them continue or are terminated.[13] In the present review, only processes with participation of radical species are considered, although there is a possibility that saturated molecules capable of reacting in the gas phase at a high rate[2] as well as molecules in an excited state[57] are released into space.

Generally speaking, the radicals formed in the heterogeneous stages may play yet another role in the process — they may be trapped by another active centre on the surface. In this case, the majority of the radicals are converted into the final reaction products within the catalyst grain or layer and only a small proportion of them, largely generated by the outer surface, may be detected experimentally in the free volume of the reactor.[58,59] There are also grounds for classifying these processes as heterogeneous–homogeneous because, firstly, the nature of the radical generation stage may be different in the two cases and, secondly, the radical may undergo reactions in homogeneous

stages between each generation on one centre and chemisorption on another, which again necessitates the joint consideration of heterogeneous and gas-phase processes. Furthermore, in the 'classical' heterogeneous – homogeneous catalysis it is likewise not permissible to rule out the possibility of a secondary interaction of the radicals with the surface, so that all the important stages in the chemical processes are of the same nature in both cases.

Thus all the reactions, the significant stages of which occur both on the surface and in space regardless of the role of these stages in the process as a whole (activation of the reactants, conversion of the intermediates, formation of the final products), should apparently be regarded as heterogeneous – homogeneous reactions.

This approach may prove to be too broad, but it makes it possible to consider related processes from single standpoints without emphasising the formal difference between them.

Before proceeding to the consideration of the individual stages of heterogeneous – homogeneous catalytic reactions, we shall consider general features. One may postulate that the probability of the formation of radicals should increase with decrease in the probability of the 'adhesion' of the reactant molecules to the catalyst surface, i.e. the heterogeneous – homogeneous character of the process should be more pronounced (a) in the oxidation of saturated molecules (hydrogen, alkanes) compared with alkenes, aromatic hydrocarbons, or organic compounds with functional group substituents, (b) in the case of compounds of one class — organic compounds with a smaller number of carbon atoms, (c) for oxide catalysts compared with metals, (d) for oxides without transition metal ions, and (e) at higher temperatures.[2]

Analysis of the literature data (Table 1) shows that the transfer of the reaction into space has been detected in a wide variety of processes with participation of compounds of different classes and molecular masses on catalysts of different nature. This is also indicated by the compilation of all the data presented by Gorokhovatskii et al.[2] Thus one may conclude that the presence of a homogeneous component in catalytic oxidation reactions is a common phenomenon. Despite the fact that the available literature data refer to catalytic systems and reactant conditions which are difficult to compare, in considering them it is possible to differentiate a series of common key aspects including common kinetics of heterogeneous – homogeneous catalytic reactions, a common mechanism of the formation of free radicals in heterophase processes, and common reactions of the radicals, including their interaction with the surface.

1. Kinetic features of heterogeneous – homogeneous catalytic processes

In a number of cases, the conclusion that heterogeneous-catalytic reactions undergo homogeneous propagation has been based on the analysis of the process kinetics (Table 1). Indeed, the presence of two reaction zones in a heterogeneous – homogeneous process may lead to the appearance of specific characteristics of the kinetics. In a number of cases, it is possible to differentiate the heterogeneous and homogeneous components.

The previously widely used kinetic method for demonstrating the heterogeneous – homogeneous nature of the process by varying the ratio of the surface of the catalyst or an 'inert' material to the free volume of the reactor (S/V) (see, for example, Refs 1, 2, 12, and 13) is based on the variation of the relative sizes of the reaction zones. Such demonstration is more reliable if the selectivity in the formation of various products varies simultaneously with the rate of the process as the S/V ratio is varied. For example, in the oxidation of propene on a bismuth – molybdenum oxide catalyst, it was demonstrated by this method[77] that epoxypropane is formed in a homogeneous process from the radicals released into space, while acrolein is formed in a process occurring on the surface. Similar experiments at higher temperatures have demonstrated that biallyl is a product of the homogeneous reactions of allyl radicals.[97]

The procedure used to demonstrate the involvement of radicals in the reaction, which consists in varying the direction of the flux of reactants in the presence of a large free volume along only one direction from the catalyst bed,[80] may be regarded as a variety of the method examined above. The nonadditivity of the rate of the oxidative dehydrogenation of propane in the free volume and on a thin bed of a V – Mg oxide catalyst has been demonstrated[80] and the observed proportions of the products have been accounted for by the occurrence of a chain reaction in the free volume.

The method involving the variation of the free volume has been used widely also at the present time, but, when applied to catalytic reactions, it can lead to erroneous conclusions. This is associated with the fact that, when the S/V ratio is varied, the rate and selectivity of the process may vary significantly only when the specific rates of the heterogeneous generation and destruction of the radicals are relatively low. Otherwise, the probability of the destruction of the radicals within the grain is close to unity (see the estimates made in a number of investigations[13,59,60]), the degree of conversion of the reactants on the catalyst is also high, and the homogeneous reaction occurring in the free volume does not contribute significantly to the process as a whole.

The nonmonotonic nature of the dependences of the reaction rates on the reactant concentrations has also been attributed to the heterogeneous – homogeneous course of process. Thus it has been assumed[61] that the extremum in the dependence of the rate of the catalytic oxidation of hydrogen on the concentration of oxygen cannot be accounted for within the framework of the equations obtained by the stationary concentrations and active surfaces methods. Since the maximum rate of reaction was attained with mixture compositions corresponding to the explosion limit, the observed features were accounted for by resorting to the concept that the hydrogen combustion is a chain reaction.

In a study of the oxidation of methane on MgO, an abrupt change in the composition of the products was observed when the contact time was varied.[98] The authors suggested that this can be accounted for by the difference between the concentrations of the methyl radicals in the gas phase and by the occurrence of their recombination reaction at higher concentrations (second order with respect to $CH_3^{\bullet}$ radicals) and of the addition of an oxygen molecule, i.e.

$$CH_3 + O_2 \Longleftrightarrow CH_3O_2,$$

at their lower concentration and subsequent formation of the extensive oxidation products (first order with respect to $CH_3^{\bullet}$ radicals).

A similar effect has been observed by other investigators[98,99] in the oxidation of methane on phosphate catalysts: a decrease in temperature and an increase in the oxygen concentration led to the preferential formation of formaldehyde, while the opposite change in conditions resulted in the growth of selectivity with respect to ethane. At a constant temperature, the overall selectivity with respect to $HCHO + C_2H_6$ remained almost unchanged, while the fraction of formaldehyde increased in proportion to the oxygen concentration, differing significantly on different catalysts. The authors postulate that this effect is due to a combination of the following factors: the dependence of the equilibrium position in the reaction involving the addition of oxygen to CH_3 on temperature and oxygen concentration and also the differences in the elementary interactions of the radicals with the surfaces of different catalysts.

The generalised formal kinetic models for heterogeneous – homogeneous reactions have been examined in a number of studies.[12,13,100] It was shown that, when the simplest multistage mechanisms operate, the forms of the kinetic equations for heterogeneous and heterogeneous – homogeneous nonchain reactions may be identical.[13]

Table 1. The release of species into the free volume in catalytic oxidation reactions.

Substance oxidised	Catalyst	Lower temperature limit of release into space/°C	Method of detection[a]	Ref.
H_2	$V_2O_5-MoO_3$	400	KA	60, 61
	Pt	500	LIF	62
	Pt	–	RFM	63

Note. Kiperman's data[13] were used in the compilation of the table.

[a] The following designations have been adopted: KA = kinetic analysis; IR = infrared spectroscopy; RFM = radical 'freezing out' (matrix isolation) method combined with measurements of EPR spectra; MS = mass spectrometry; SC = separate calorimetric measurements; TAP = temporal analysis of product; TPD = thermoprogrammed desorption; PIMS = photoionisation mass spectrometry; LIF = laser indiced fluorescence.

A more complex mechanism, postulating that the heterogeneous conversion of the surface compound into the reaction products takes place via a first order reaction and that the formation of radicals from this product is a second order process (chain branching, propagation, and quadratic termination reactions are possible in the gas phase), has been examined by Berman and Margolis.[12] Analysis of the kinetic equations describing the process shows that one or several stable stationary states with different contributions by the homogeneous component can exist. For other reactions orders, the stationary state becomes unstable and there is a possibility of the occurrence of auto-oscillatory regimes. It also follows from this analysis that smooth or abrupt changes in the reaction rate in the isothermal regime are possible when the reactant concentrations are varied monotonically.

The multiplicity of stationary states may be manifested by the appearance of hysteresis in the rate of reaction when the temperature is varied cyclically. This type of kinetics, observed in the oxidation of cyclohexane on the NaX zeolite, has been attributed to the partial transition of the reaction to the gas phase.[81]

Concluding the brief analysis of the kinetic features of heterogeneous–homogeneous catalytic processes, we may note that, on the basis of their analysis alone, it is impossible to reach a final conclusion concerning the presence or absence of the homogeneous component of the reaction. However, in certain cases such analysis may be fairly informative.

2. Methods for the investigation of heterogeneous–homogeneous radical reactions

The methods based mainly on the analysis of the kinetics and used in the investigation of heterogeneous–homogeneous reactions before the wide scale employment of various physical methods in chemical kinetics have been surveyed.[2] The majority of instrumental methods for the investigation of radical processes in the gas phase can be adjusted in principle to the study of heterogeneous radical reactions. Unfortunately, nowadays only a few of them are employed for such purposes, while in other cases it is still necessary to overcome significant technical difficulties. Here we shall describe briefly the characteristics of certain instrumental methods and new approaches without repeating, as far as possible, what has already been stated in the review[7] concerning the use of mass spectrometry, matrix isolation of radicals combined with measurement of IR and EPR spectra, photoelectron spectroscopy, and multiphoton and resonance ionisation for the study of the role of the free radicals in catalytic reactions.

3. Method involving separate calorimetric measurements

The separate calorimetric measurement method (SC method) was mentioned above when the role of heterogeneous factors in gas-phase reactions was considered. This method has also been employed in the study of the transfer of the reactions on heterogeneous catalysts into free space (see, for example, Ganieva et al.[76] and Nguyen and Kung[80]). One of the modifications of the SC method involves the carrying out of two series of experiments: in the first series, the catalyst in the form of a thin layer is deposited on the walls of the reaction vessel with a radius R, while in the second it is deposited on a capillary with a radius r in which a thermocouple is enclosed, the capillary being placed along the axis of a cylindrical reactor. The ratio of the heats evolved on the surface and in the reactor volume is defined by the relation[19,20]

$$\frac{Q_s}{Q_v} = \frac{\Delta T_2 - \Delta T_1}{2\Delta T_1 \ln(R/r)}.$$

As already mentioned, the limitation of the SC method consists in the impossibility of determining with its aid the nature of the species responsible for the bulk propagation of the process. Furthermore, in the study of processes occurring on granular porous catalysts the SC method makes it possible to differentiate only the fraction of the heat evolved in the free volume of the reactor and the latter may be very small even if the contribution of the volume reaction is high but the reaction itself is localised within the pores of the grain or in the space between the catalyst grains. More informative methods, permitting the direct detection of the active species and the determination of their form and concentration (or the rate of their generation), are therefore needed.

a. The method involving the 'freezing out' of radicals

The method in which the free radicals are isolated in a solid matrix from frozen reaction products, initial reactants, or substances specially added to the gas stream in order to form the matrix with subsequent measurement of the EPR spectra is used widely to investigate radical processes in the gas phase.[100] In the Russian literature, this method is referred to as the radical freezing-out method (RFM). Its description, scope, and specific examples of its application in the study of different processes, including heterophase processes, can be found in a series of reviews and monographs (see, for example, Refs 7–9 and 101). We shall consider only certain modifications of the method, which have given rise to fundamentally new possibilities.

It has been frequently noted (see, for example, Ermolaev et al.[97]) that, depending on the composition of the matrix and its temperature, the form of the EPR spectrum of the radicals frozen out may vary markedly, which hinders their identification. It is particularly difficult to distinguish the spectra of the $RO_2^{\bullet}$ radicals (R = hydrogen atoms or organic fragments) if their mixture is formed in the reaction and the matrix contains a large amount of water. In the presence of oxygen in the reaction mixture, the majority of the radicals are converted into $RO_2^{\bullet}$ in the cold part of the reactor or on the way to the freezing out trap. By employing liquid helium for cooling and argon as the matrix and by carrying out the process at low temperatures or in the absence of oxygen, the problem may be solved.[69,70,75] However, in most cases it is impossible to carry out the reaction under oxygen-free conditions and the use of liquid helium significantly complicates the technique.

A method has been proposed for the identification of radicals stabilised in a solid matrix involving their photolysis by UV light and the re-recording of the EPR spectrum.[95,97–99,102] The authors suggest (see the discussion of the paper of Ismagilov et al.[95]) that the photolysis involves the dissociation of the R–OO bond in the $RO_2^{\bullet}$ radical and that the $R^{\bullet}$ radical remains in the matrix. The spectra of the radicals $R^{\bullet}$ are more informative and the new radicals formed in the reaction can be identified in principle on their basis. This approach has been used in the study of extensive oxidation reactions of alcohols[97–99,102] and amines[96] on oxides and deposited platinum catalysts.

However, it is known that, when various peroxy-radicals $RO_2^{\bullet}$ (R = alkyl, allyl, vinyl, acyl, etc.) are irradiated, the primary step is the dissociation of the O–O bond and not of the C–O bond.[103] Furthermore, the reaction investigated leads to the formation of a mixture of radicals, so that the EPR spectrum obtained after photolysis is a result of the superposition of the spectra of all the paramagnetic species formed, which greatly complicates its analysis.
