Of particular interest is the chemical aspect of ET, since this process is the primary step in many chemical transformations.[14–19] One can vary the rate of initiation of chemical reactions over a wide range and make them follow a required path by varying the properties of CTC components. This allows one to study reaction mechanisms, detect intermediate compounds, and determine their structures.

Received 6 March 1995
Uspekhi Khimii **64** (8) 755–768 (1995); translated by S S Veselyi

In the present review we consider the photochemical reactions of complexes formed from aromatic amines (Am) with polyhalomethanes (PHM). The amine complexes have been known for a long time, but the use of PHM, particularly the chloro-substituted ones, in complexation reactions started only in the 1960s, when it was found that they could act as acceptors in complexes with comparatively strong donors, such as Am.[20] Since PHM correspond to 'sacrificial' acceptors (which decompose irreversibly when they capture an electron), irradiation of an Am + PHM mixture inevitably results in the initiation of chemical transformations. For this reason, studies of the photochemical properties of PHM started shortly after the discovery of their complexation ability.[21–26]

Two main aspects can be distinguished in the photochemical studies of Am – PHM systems: (1) the study of primary reactions and properties of primary photogenerated species; (2) the isolation of end products (dyes) formed under the irradiation of solutions simultaneously containing an Am and a PHM, and the determination of their structures and mechanisms of formation. Although the viewpoints of scientists on the first aspect are well founded and common, the data on the structures of dyes and the mechanisms of their formation are contradictory. The subject of the present review is analysis of these data, and we shall hardly deal at all with the rather broad and important aspect relating to study of the possibility of practical use of Am · PHM complexes, in particular in systems for information recording. These problems have been thoroughly discussed in works by Vannikov and Grishina.[27–30]

Prior to discussing the photochemical reaction of CTC we should also mention the complexation reaction itself, which occurs before light irradiation of the system is started. A detailed analysis of this reaction is a subject for special consideration. We shall note only the particular features of the donor – acceptor interaction of amines with PHM which affect considerably the photochemical properties of the complexes.

An important photochemical parameter is the action spectrum, i.e. the spectral region in which the irradiation results in light absorption and initiation of a chemical reaction. The action spectrum of Am · PHM complexes is generally located in the near UV region, e.g., in the 330–380 nm region for the CTC of diphenylamine (DPA) with CBr_4.[21,31] It has traditionally been accepted that CBr_4 forms 1:1 complexes with amines.[31–33] However, it was shown recently that DPA derivatives can form higher complexes, the so-called polycomplexes,

whose absorption spectra are shifted bathochromically relative to that of the 1:1 CTC.[34,35] Owing to the formation of such complexes, whose absolute content in an equilibrium mixture increases with increasing concentrations of the components, the action spectrum of the CTC of diphenylamine (and its derivatives) with CBr_4 expands significantly into the visible region up to 500–550 nm.[27,34] On the other hand, the relative content of polycomplexes in the mixture is small in comparison with that of the free amine, and hence they do not affect the kinetics of secondary chemical reactions initiated by light absorption.[36]

II. Primary photochemical processes during irradiation of amine–polyhalomethane systems

To date, it has been established unambiguously that the transfer of an electron from an amine to a halohydrocarbon (HC) is the primary photochemical act during the irradiation of mixtures of amines with PHM or, more widely, with HC. Depending on the structure of the donor and acceptor components, three routes for the photoinitiation of ET exist: excitation of CTC, selective excitation of Am, and selective excitation of HC. All three ways do not necessarily actually occur for any arbitrary Am–HC pair, since this would require that the absorption bands of Am, HC and CTC are sufficiently different.

Relatively strong donors (alkylarylamines, di- and triarylamines, diamines) and/or acceptors (polybromohydrocarbons, nitrohalo-derivatives, halocarbonyl compounds) form complexes whose absorption spectra are shifted bathochromically relative to the spectra of the components, since selective excitation of their complexes in the CT bands is possible.[27,37–39] In this case, ET occurs within the complex and, in essence, corresponds to an intramolecular process[40] (static quenching of Am luminescence,[41] or innersphere ET, according to the terminology accepted in the literatire[1,42]).

$$Am + RX \rightleftharpoons (Am \cdot RX) \xrightarrow{h\nu} (Am^{+\cdot} RX^{-\cdot}) \qquad (1)$$

Chlorohydrocarbons form weak complexes with amines (with stability constants $< 0.1\ l\ mol^{-1}$), whose concentrations are much less than those of the starting components and whose absorption spectra almost coincide with those of the amines. When such mixtures are irradiated, an Am reacts with a HC to give a radical cation (RC) of the amine[43–48] (dynamic quenching of Am luminescence, outersphere ET).

$$Am \xrightarrow{h\nu} (Am)^* \xrightleftharpoons{RX} \rightleftharpoons [(Am)^* \cdot RX] \longrightarrow (Am^{+\cdot} RX^{-\cdot}) \qquad (2)$$

Although it is assumed that reaction (2) occurs via quasistable intermediates, exciplexes,[44,45,49,50] their formation in the reactions of amines with alkyl halides has not been proved, unlike e.g. photochemical reactions of amines with carbonyl[51,52] or aromatic compounds,[53–57] including aryl halides.[58–62]

Selective excitation of a HC results in homolytic cleavage of a C–X bond (see Ref. 63)

$$RX \xrightarrow{h\nu} R^{\cdot} + X^{\cdot}, \qquad (3)$$

(heterolytic cleavage with formation of a carbonium ion is also possible for branched R).[64] Several authors assume that reaction (3) occurs when mixtures of aromatic amines with CX_4 (X = Cl, Br) are irradiated.[21,65,66] Probably, photoinitiation of Am + RX reactions by excitation of RX in their own absorption bands to a noticeable extent is possible only for aryl halides,[67–69] whose absorption spectra are shifted relative to those of the amines. Since the absorption spectra of alkylated HC overlap considerably with those of amines, selective excitation of the former in Am–HC mixtures is unlikely.

In some cases, it was possible to determine the nature of the excited state involved in the ET process. It was shown by the chemically induced nuclear polarisation (CINP) method for the $Et_3N \cdot CCl_4$ complex that ET occurs by reaction (1) in a excited singlet state.[70,71] The reactions of arylamines with chloro-containing HC also occur by the singlet mechanism.[59,72–75]

A study of the photochemical properties of the system *N*, *N*, *N'*, *N'*-tetramethyl-*p*-phenylenediamine–carbon tetrachloride showed that the reaction in a benzene solution occurs via an excited triplet state,[76] while in pure CCl_4 it probably occurs in a singlet state.[77] In both cases, the quantum yield of the contact ion pair $Am^{+\cdot}/Cl^-$ is close to unity and decreases somewhat when tetramethylbenzidine is used as the electron donor.[78]

It was found in a study of photo-ET from excited *N*,*N*-dimethylaniline (DMA) to chlorobenzene that both the singlet and the triplet states of DMA are reactive.[79,80] It was assumed that photodebromination of bromoanthracene by amines also occurs by the triplet pathway,[81] but recent studies by nanosecond laser photolysis has shown that an excited singlet state is reactive and that an intermediate anion radical ($RX^{-\cdot}$) is formed.[68]

A triplet mechanism was proposed[82–86] for the photochemical reaction of arylamines with CBr_4 in a polymer matrix. A reaction scheme was considered which involved transfer of triplet energy from the excited CTC to the free amine followed by the formation of a triplet exciplex, which gives the final dye.[82]

$$\begin{aligned} &Am \cdot CBr_4 \xrightarrow{h\nu} (Am \cdot CBr_4)^1 \longrightarrow (Am \cdot CBr_4)^3, \\ &(Am \cdot CBr_4)^3 + Am \xrightarrow{k_4} Am \cdot CBr_4 + (Am)^3, \\ &(Am)^3 + CBr_4 \longrightarrow (Am)^3 \cdot CBr_4 \longrightarrow Dye. \end{aligned} \qquad (4)$$

The authors assume that an additional reaction occurs in the presence of naphthol (NP)

$$(Am \cdot CBr_4)^3 + NP \xrightarrow{k_5} Am \cdot CBr_4 + (NP)^3, \qquad (5)$$

It was noted that $k_5[NP] \gg k_4[Am]$.[83] Such a relation of reaction rates is reasonable as the energies of the triplet levels are ~ 3.5 eV (CTC) and 2.5 eV (NP), respectively, i.e. NP is an effective triplet 'trap'. In this case, the formation of a dye should be suppressed completely at high NP concentrations, which contradicts the experimental data: at $[NP] \sim [Am] \sim 1\ mol\ l^{-1}$, the quantum yield of the reaction (~ 0.1) is almost the same as that in the absence of NP.[83]

In the case when triplet energy is transferred from an excited CTC to the amine, the nature of this excited state and the reasons for its stability in comparison with the triplet exciplex remain unclear. Excitation of a weak CTC leads to the transfer of an electron from the donor to the acceptor, and formation of a radical-anion of the latter. Since the radical-anion of CBr_4 is unstable, excitation of an Am – CBr_4 CTC results in irreversible decomposition of the complex with formation of an amine radical-cation, a tribromomethyl radical and a bromide ion (see below).

Obviously, studies on the dependence of the quantum yield of photo-ET processes on the presence in solution of various admixtures, energy acceptors of various types, would throw light on the problem of the stability of excited CTC. But, although many studies on the primary processes in Am – PHM systems have been reported, unfortunately no data on the quantum yields φ_i of primary photochemical reactions are available for diarylamines.

If chain processes are absent in the system, φ_i cannot be lower than the sum of the quantum yields of all products of the photoinitiated reaction. Bearing in mind the wide variety of pathways in the transformation of primary photogenerated species, the fact that the quantum yield of dye formation exceeds 0.1,[27] and

that the quantum yield of acridines reaches 0.2,[87] one can assume that the quantum yield of the primary process involved in photo-ET during the excitation of Am–PHM complexes is close to unity, which is consistent with the dissociative nature of this process.

III. Reactions of radical-anions of halohydrocarbons

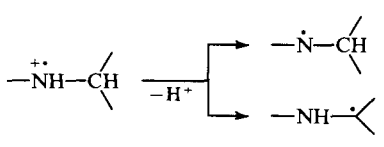
The properties of radical-anions of HC ($RX^{-\bullet}$) and the fact of their existence as separate species have been considered in a number of reports.[88–92] It was believed that when ET occurs to HC with R = Alk, the latter 'instantly' decompose releasing X^- (see Refs. 93, 94) ($HC^{-\bullet}$ exist only for a few vibration periods[95]). Therefore, the whole process was named (photo)dissociative transfer (capture) of an electron. When $RX^{-\bullet}$ is generated in frozen matrices (4–77 K), the problem discussed was: to what extent can we distinguish between a σ* ion ($RX^{-\bullet}$)[95] and a $R^{\bullet}\cdot X^-$ complex (see Ref. 96), which appears in a matrix 'cage' due to cleavage of a C–X bond.

To date, several anion radicals have been detected experimentally. The $CCl_4^{-\bullet}$ radical-anion absorbs at 354 nm (4.2 K)[97] or 365 nm (77 K).[98] According to the EPR spectrum and ab initio calculations, the unpaired electron in $CCl_4^{-\bullet}$ is located at the antibonding σ* orbital of a C–Cl bond.[99] At room temperature, $CCl_4^{-\bullet}$ decomposes in $\tau < 18$ ps.[100] The $C(NO_2)_4^{-\bullet}$ radical-anion, whose properties are similar, decomposes in less than 10 ps.[101] Recently the $CBr_4^{-\bullet}$ radical-anion was detected by mass spectroscopy of positive ions.[102] Perhaps femtosecond laser techniques would also make it possible to observe these species in the photoexcited state. In a solid matrix (77 K), absorption at 365 nm was ascribed to $CBr_4^{-\bullet}$.[103]

The location of negative charge in products of decomposition of a HC radical-anion can be estimated by comparing the electron affinities (EA) of the fragments. For example, the values of EA (eV) of radicals formed owing to decomposition of $CX_4^{-\bullet}$ are: Cl$^{\bullet}$ 3.61; Br$^{\bullet}$ 3.36 (see Ref. 104), $CCl_3^{\bullet}$ 1.88, $CBr_3^{\bullet}$ 0.57 (see Ref. 105), i.e. the formation of a halide anion is much more favourable energetically than the formation of a trihalomethyl anion. It should be noted that considerably different EA values are available in the literature for the starting CCl_4 and CBr_4: from 0.15 and 1.2 (see Ref. 106) to 2.12 and 2.06 eV.[107] Obviously, the data in Ref. 106 are more suitable for a consideration of the complexation properties of these compounds, since they have been obtained under similar conditions from the energies of excited complexes of CCl_4 and CBr_4 with tetramethylbenzene. According to the data in Ref. 107, the electron-accepting properties of CCl_4 and CBr_4 should almost coincide, which contradicts numerous experimental data on the properties of CTC of these PHM.

In quantum-chemical calculations, various authors considered, in essence, four different pathways of decomposition of PHM radicals.

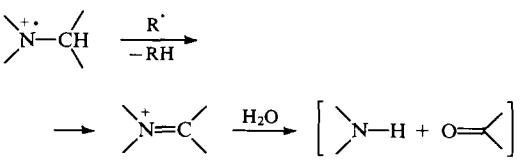
$$RCH_nX_{3-n}^{-\bullet} \longrightarrow \begin{cases} RCH_nX_{2-n}^{\bullet} + X^- & (6) \\ RCH_nX_{2-n}^{-} + X^{\bullet} & (7) \\ RCH_nX_{3-n} + e^- & \\ RCH_{n-1}X_{3-n}^{-} + H^{\bullet} & (8) \end{cases}$$



According to the data in Ref. 108, the most frequently occurring pathway (6) leading to a halide anion is characterised by the minimum energy. The formation of a halogen radical, pathway (7), is possible only through decomposition of iodine derivatives, since iodine has the lowest EA among halogens;[109] moreover, it is important that the remaining radical should contain strong electron-accepting substituents stabilising the anion. It has been shown by MNDO and AM1 methods for chloro- and bromomethanes[110] that for $n = 1, 2$, ET directly results in decomposition of the C–X bond by pathway (6). Decreasing n and the polarity of the medium favours stabilisation of the primary radical-anion as a kinetically independent species, which subsequently also decomposes by pathway (6). Fragmentation by pathway (8) is energetically unfavourable. According to the opinion of the authors,[110] it can occur by the mechanism of dissociative electron capture only in the presence of additional factors facilitating this reaction.

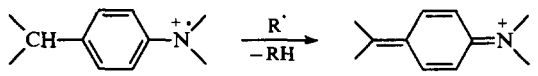
Aromatic radical-anions $RX^{-\bullet}$ are much more stable than aliphatic ones. For example, the rate constant for dissociative capture of a solvated electron measured for R = Ph ($l\ mol^{-1}\ s^{-1}$) increased in the series: Cl (5×10^8) < Br (4×10^9) < I (1.2×10^{10}).[111]

IV. Reactions of radical-cations of amines



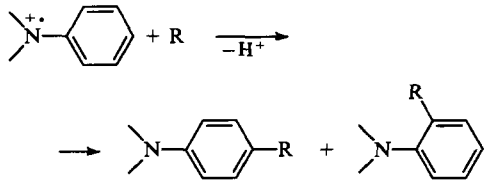
Unlike radical-anions of HC, the radical-cations of aromatic amines formed owing to ET during a chemical reaction have been reliably detected by many authors from their typical absorption spectra.[43,91,112–119] The radical-cations of monoarylamines, $(ArNRR')^{+\bullet}$, display absorption bands in the short-wave spectral region at 400–500 nm.[119–122] The radical-cations of diarylamines $Ar_2NR^{+\bullet}$ and triarylamines $Ar_3N^{+\bullet}$ absorb in the long-wave region at 600–800 nm.[123–126] In comparison with the $Ar_2NHm^{+\bullet}$ radical-cation, the spectra of the corresponding neutral radicals $Ar_2N^{\bullet}$ are shifted bathochromically and have lower intensities:[127,128] e.g., λ_{max} (nm) and ε_{max} (litre $mol^{-1}\ cm^{-1}$) are 670 and 1.8×10^4, for $Ph_2NH^{+\bullet}$ (see Ref. 128) and 770 and 3.9×10^3 for $Ph_2N^{\bullet}$ respectively (see Ref. 129).

As is evident from the previous section, the reverse electron transfer from decomposition products of an HC radical-anion to an amine radical-cation is unlikely, since the latter cannot oxidise a halide anion or a $RCH_nX_{2-n}^{\bullet}$ radical. The amine radical-cation therefore undergoes various chemical reactions. The simplest one is deprotonation,[130] which, in the general case, can occur via two pathways.

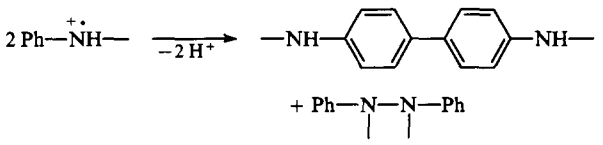


The acidity of the NH group does indeed increase considerably when an Am is oxidised into the radical-cation. For example, pK_a = 30.6 for $PhNH_2$ and 6.5 for $PhNH_2^{+\bullet}$ (see Ref. 131); 24.9 for Ph_2NH and 4.2 for $Ph_2NH^{+\bullet}$ (see Ref. 128). In both cases the acidity increases by more than 20 orders of magnitude. Values of the same order were obtained for the α-CH group in DMA: pK_a(DMA) is ~ 34, whereas pK_a($DMA^{+\bullet}$) is ~ 9 (Ref. 132). However, Nelsen and Ippoliti[133] consider that the acidity of the α-CH group in the radical-cation is usually unduly overestimated: for example, they obtained pK_a ~ 15 for the radical-cations of trialkylamines.

Not only heterolytic cleavage of the α-C–H bond is possible but also homolytic cleavage resulting in an iminium cation.



This is probably one of the pathways of dealkylation of radical-cations followed by hydrolysis.[140–142] Homolytic cleavage of a benzyl C–H bond with the formation of quinonoid compounds is known for radical-cations of amines that are toluidine derivatives.

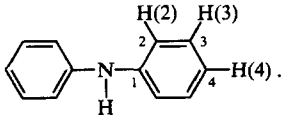


This class of reactions includes photooxidation of leuco-dyes with diverse structures in the presence of HC into the corresponding dyes.[46,143–146] It is suggested that the reaction may occur in two consecutive steps, first with abstraction of a proton and then of an electron, rather than by abstraction of a hydrogen atom.[147]

One of the typical and practically important reactions of radical-cations of aromatic amines is recombination, which occurs predominantly at the *ortho* and/or *para* positions of the benzene ring.

The ratio of reaction products is determined by the nature of the substituents on the nitrogen atom and on the aromatic ring and by the properties of radical R.[58,61,113,140,148–151]

The typical mode of recombination of radical-cations of aromatic amines with one another is C–C-dimerisation into benzidine derivatives (for radical-cations of amines having a free *para* position) and N–N-dimerisation into hydrazines (for radical-cations of primary and secondary amines).[125,152–157]

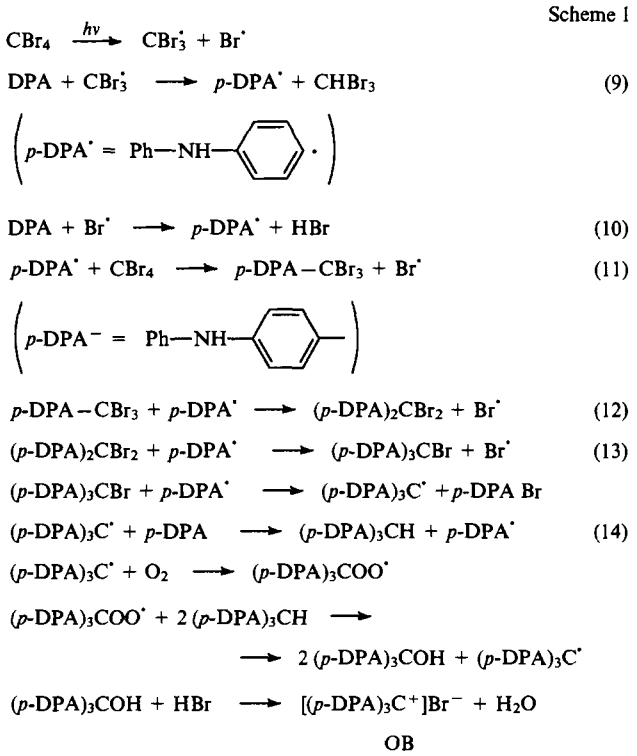


In addition to this, radical-cations of certain diarylamines dimerise into phenazines.[125,154,156]

It should be noted that C–C-dimerisation precedes deprotonation,[158] whereas N–N-dimerisation is likely to occur after deprotonation, i.e. it involves neutral radicals.[159] For example, it has been shown that protonation of the $Ar_2N^{\bullet}$ radical blocks the interaction at the reaction centre, the nitrogen atom.[160] In addition to C–C- and N–N-dimerisation, C–N-dimerisation is also observed for diarylnitrogen radicals.[161,162] According to quantum-chemical calculations and in agreement with the experiment, the labile N–N dimer is formed quickly and reversibly in one step, whereas stable C–N- and C–C-dimers are formed slowly and in two steps, the final step being irreversible.[163]

As to the electronic structure of the $Ar_2NH^{+\bullet}$ radical-cation and the neutral $Ar_2N^{\bullet}$ radical, the density distributions of the unpaired electrons in both radical species virtually coincide, judging from the coupling constants in the ESR spectra (Table 1). About 1/3 of the spin density is located on the nitrogen atom, while ~ 2/3 is located on the benzene rings at the *ortho* and *para* positions. Depending on the method, quantum-chemical calculations give somewhat differing results, but the preference for the *ortho* and *para* positions in delocalisation over the benzene rings is maintained. On the whole, one can conclude that the calculated data agree with the above main pathways in the interactions of these reactive species: the attack on the N, C(2) and C(4) atoms.

Table 1. EPR spectra (A) and data of quantum-chemical calculations (B) for radicals formed from DPA



Radical	N	H(N)	H(2)	H(3)	H(4)	Ref.
A. Coupling constants (a_i, G)						
$Ph_2N^{\bullet}$	8.9	–	3.7	1.49	4.34	134
$Ph_2NH^{+\bullet}$	9.17	11.14	3.51	1.36	4.88	135

V. Photoinduced chain radical reactions

It has been suggested that several types of chain radical processes can be involved in photoinduced reactions of amines with PHM, but the existence of some of them has not been proven. For example, a scheme for the formation of a triphenylmethane dye (TPMD), Opal Blue (OB), in a photochemical reaction of DPA with CBr_4 has been proposed. The scheme involves the following radical-chain reactions (Scheme 1).[21]

Scheme 1

This scheme has been accepted by many authors (see, for example, the relevant reviews[164–167]), but the feasibility of these reactions is doubtful. Reactions (9), (10) and (14) are assumed to occur by the abstraction of a hydrogen atom from the aromatic ring, which is an unlikely process. In the case of reaction (14), this is a highly improbable process, since the stable triphenylmethane radical with a delocalised electron is transformed into an energy-rich unstable radical with an electron localised on an sp^2 orbital. For example, when benzophenone was used as acceptor instead of CBr_4 in the reaction with amines, it was found that the H atom was abstracted only from the α-carbon of the alkyl substituent, giving stable radicals of the type $PhN(R)C^{\bullet}HR'$ (see Ref. 168) or from the

N atom in Am, giving radicals of the $Ph_2N^{\bullet}$ type.[169,170] It was shown that similar radicals are formed in the reaction of DPA with $CCl_3^{\bullet}$ (see Ref. 43) and with fullerene.[171] However, the abstraction of an H atom from the aromatic ring has never been observed in these reactions.

Reactions (11) – (13), which involve radical substitution of a halogen radical at a saturated carbon atom, also look improbable (no reactions of this type have been reported in the literature).[172,173] If they occurred in the system under consideration, chain transfer (10) → (11) → (10) etc. would appear, and the quantum yield (φ) of the dye would exceed 1. It will be shown below that reactions of amines with HC can sometimes involve a chain process with $\varphi > 1$, but this is related to another reaction pathway, and the φ values for TPMD are always less than one.

A radical scheme for the formation of Opal Blue has been adopted in studies[43,44,50,114,115] dealing with reactions of Am with HC. Since the authors[114] have observed experimentally the formation of the $Ph_2N^{\bullet}$ radical, they tried to reconcile this result with the participation of the *p*-DPA$^{\bullet}$ radical, formed due to the inversion $Ph_2N^{\bullet} \rightarrow p$-DPA$^{\bullet}$, in the above reaction scheme. However, it was shown later that photochemical generation of the $Ph_2N^{\bullet}$ radicals resulted in their transformation into carbazole in a good preparative yield.[174] The reaction did not occur if methyldiphenylamine (MDPA) was used instead of DPA, also supporting the view that the formation of carbazole occurs via the $Ph_2N^{\bullet}$ radical. It is known that direct excitation of both DPA and MDPA results in carbazole by cyclisation directly in the excited state without the participation of radicals.[175]

However, the reactions of completely *N*-substituted amines with PMH also led to the isolation of TPMD, which confirms that *N*-radicals, whose generation from these amines occurs with difficulty, do not play a predominant role in TPMD formation.[43,176] It follows from the data in Ref. 177 that a dye results from the reaction of a $CX_3^{\bullet}$ radical with a radical-cation $Am^{+\bullet}$ (a dye does not form when $CX_3^{\bullet}$ is generated in the presence of neutral Am).

In the next section we present a scheme for the synthesis of TPMD, including OB, through a series of reactions of electrophilic aromatic substitution involving Am and intermediate dyes, together with experimental evidence for this scheme.

In the context of the discussion of chain radical reactions, it is of interest to consider a series of works by Latovskii et al.,[141,176,178–181] the purpose of which was to study the characteristics of the photochemical behaviour of the system of bonds Ph–N–Me in reactions with polychloromethanes. DMA and MDPA were used as reagents.

The reaction of DMA with CCl_4, as with many other compounds, gave a TPMD, Crystal Violet (CV). The quantum yields of many compounds were measured. The focus of attention of the authors was drawn to reactions related to the formation and transformations of an α-methylene radical $>N-CH_2^{\bullet}$, and they tried to explain the formation of all of the photoproducts on the basis of this radical. Although the quantum yield of the formation of CV did not exceed unity, the authors proposed a scheme of chain radical reactions,[141] which, although it differs from Scheme 1, is also rather unlikely.[182]

During the studies of simpler systems of DMA with CH_2Cl_2 (Ref. 179) and $CHCl_3$ (Ref. 180), results were obtained suggesting that interaction of $Cl_nH_{3-n}C^{\bullet}$ type radicals with the benzene ring of the DMA radical-cation, rather than with the α-methylene radical, is important (these results are considered in more detail in the following section).

However, chain reactions still occur in the DMA–CCl_4 system, which is evident from the experimentally found high quantum yields for the formation of HCl and the disappearance of DMA, $\varphi(HCl) \approx \varphi(DMA) > 10$. This fact was explained[183] by reactions involving an α-radical, a CTC, and an amine.

$$Ph(Me)NCH_2^{\bullet} + PhNMe_2 \cdot CCl_4 \longrightarrow$$
$$\longrightarrow Ph(Me)NCH_2C_6H_4NMe_2\text{-}p + HCl + CCl_3^{\bullet}$$

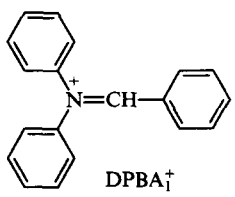
$$CCl_3^{\bullet} + PhNMe_2 \longrightarrow Ph(Me)NCH_2^{\bullet} + HCCl_3$$

However, this scheme seems doubtful. First, it is more likely that a radical would attack a free amine rather than a CTC, since the concentration of the former is much higher, [DMA] ≫ [CTC]. Second, it is unlikely that a CCl_4 molecule can accept an H atom giving the $CCl_3^{\bullet}$ radical; more probably, the latter captures H to give chloroform. Third, if the assumption in Ref. 183 is valid, the DMA·CCl_4 complex is the chain carrier. In this case, increasing DMA concentration should lead to elongation of the chain. But, the authors observed a reverse dependence: when the concentration of DMA in CCl_4 increased, the quantum yield decreased,[183] and conversely, when the reaction was carried out in dioxane, the quantum yield increased with increasing CCl_4 concentration.[178] It follows from these data that a CCl_4 molecule is the chain carrier.

$$Ph(Me)NCH_2^{\bullet} + CCl_4 \longrightarrow Ph(Me)NCH_2Cl + CCl_3^{\bullet}$$

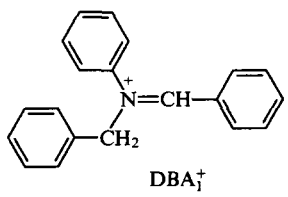
$$CCl_3^{\bullet} + PhNMe_2 \longrightarrow Ph(Me)NCH_2^{\bullet} + HCCl_3$$

A similar sequence of transformations occurs in reactions of CX_4 with alkylamines, which do not contain an aromatic ring but contain an H atom in the α-position relative to the nitrogen atom; the quantum yields of these reactions can be as high as 100.[184–186]



It should be emphasised once more that a $\varphi > 1$ in reactions of DMA and isomeric toluidines with CCl_4 is observed only for HCl formation and results from a different reaction, which is a side reaction with respect to CV formation. The φ value for the latter, like the values for the formation of other dyes from amines, is always less than one.

VI. Formation reactions of triphenylmethane dyes



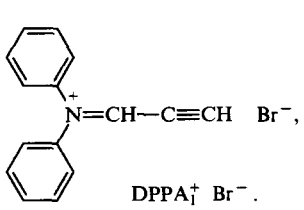
To date, the formation of two types of dyes during the photolysis of complexes of aromatic amines with PHM has been proved reliably. These include triphenylmethane dyes, which absorb light at 600–700 nm, and acridine dyes absorbing light at 450–550 nm and possessing luminescent properties. Studies on the mechanisms of their formation revealed a number of common features. Of the primary reactions, we should mention the formation of radical-cations or, in some instances (for secondary amines), neutral amine radicals on irradiation of CTC and the recombination of these radicals with halomethyl radicals. Their participation in the electrophilic alkylation of the free amine (which is present in excess in the reaction mixture) is a general feature. As noted in the Introduction, different viewpoints exist concerning the structure of the intermediates and the mechanism of their transformation into the final dyes, as well as for the structure of the dyes absorbing in the region of 600–700 nm. Below we present these viewpoints and make a reasoned choice of one of them.

The extensive experimental data concerning the photochemical reactions of Am with CBr_4 and $CBr_3SO_2CBr_3$ in solution and in polymer layers are presented in studies by Vannikov and Grishina et al.[27,82,83,187–196] DPA, diphenylbenzylamine (DPBA), and dibenzylaniline (DBA) were used mainly as the amines. It was found that irradiation of all three amines with CBr_4 first gave dyes with $\lambda_{max} \sim 665$ nm, which were given a general conventional designation D665, and which were then thermally ('in the dark') transformed into dyes with $\lambda_{max} \sim 605$ nm (D605). The activation energy for the D665 → D605 transformation for DPA was found to be half of that for DPBA (43 and 86 kJ mol^{-1}, respectively), whereas the activation energies for the sensitised formation of D665 were the same for all three amines (24 kJ mol^{-1}).[189]

The quantum yields for the formation of dyes D665 measured during direct photolysis of the complexes were $\varphi = 0.14$ (DPBA) and $\varphi = 0.07$ (DBA).[27] As shown above, the D605 formed from DPA is Opal Blue. The structures of D605 dyes obtained in the reactions with DPBA and DBA, and the D665 obtained from DPA, are not reported in the works cited. The authors [27] propose diarylmethyleneiminium structures (Am_I^+) for the D665 formed from DPBA and DBA. Diarylmethyleneimines are formed due to abstraction of H atoms from the benzyl groups of the amine radical-cations.

$DPBA_I^+$

DBA_I^+



To substantiate the structures of the Am_I^+ type, the authors drew an analogy with photochemical reactions of amines with CBr_4 and with the Methylene Blue dye (MB^+). It was found that MB^+ was reduced on illumination by various benzylamines through the transfer of an H atom from the CH_2 group.[197,198]

$$MB^+ + \mathbf{Am} \xrightarrow{h\nu} MB^{\cdot} + Am^{+\cdot} \longrightarrow MBH + Am_I^+$$

The reactivity of the amines in this reaction increases with increasing number of benzyl groups, i.e., DPBA is less reactive than DBA. However, judging from the quantum yields of D665 formation, a reverse order of reactivity is observed in the reaction with CBr_4: DPBA > DBA, in agreement with the number of phenyl groups, which are obviously involved in formation of the dyes.

In addition, it is clear that an Am_I^+ structure is not feasible for DPA, although its photochemical properties coincide with those of DPBA and DBA. Probably the structures of all three dyes (based on DPA, DPBA, and DBA) should be similar, hence the Am_I^+ structure is inappropriate for them.

To confirm the Am_I^+ type structure for D665, the authors of a book (Ref. 27) cite the previously published data (Ref. 199), where a dye with $\lambda_{max} = 670$ nm, obtained from diphenylpropargylamine and CBr_4, is assigned the following structure:

$DPPA_I^+ \ Br^-$.

Let us consider the arguments presented in Ref. 199 in order to confirm this structure: (1) the retention of phenyl groups and an acetylene group, according to IR and ^1H NMR spectral data; (2) instead of the signal of two methylene group protons, the appearance of a new broadened signal around 5.2 ppm, which disappeared in a deuteriated solvent; (3) the presence of bromine, according to mass spectrometric data. Strictly speaking, the first argument does not confirm the structure $DPPA_I^+$ but merely does not contradict it, as well as many other possible structures. The second argument is qualitatively consistent with the structure $DPPA_I^+$; however, it follows from various known data [200–202] for the chemical shifts of the methine proton in the iminium moiety that the value of 5.2 ppm is too low for such a structure, since the normal signal for this proton is found at 9–9.5 ppm. The third argument in the form presented is inconsistent with the structure of $DPPA_I^+$, since the presence of bromine in the molecular ion implies that the bromine atom is covalently bonded to the skeleton of the molecule. However, $DPPA_I^+$ does not incorporate the bromide ion, and the latter is merely the counterion of the dye cation. Unfortunately, the authors do not report the m/z value measured experimentally.

It is known that phenyliminium salts have absorption bands in the middle UV region,[203–205] spectra considerably different from the postulated spectrum of Am_I^+. Diphenylmethyleneaniline $Ph_2C{=}NPh$ and triphenylethene $Ph_2C{=}CHPh$, whose molecules are isoelectronic with DPBA, also absorb in the UV region: $\lambda_{max} = 346$ and 298 nm, respectively.[206] Thus, the validity of the structure $DPPA_I^+Br^-$ for the dye with $\lambda_{max} = 670$ nm obtained in Ref. 199 and the structure Am_I^+ for D665 described in Vannikov and Grishina's book [27] is doubtful.

The Am_I^+ type structure for D665 also contradicts flash photolysis data.[119] The formation of Am_I^+ should involve abstraction of an H atom from an $Am^{+\cdot}$ radical-cation, hence the accumulation of Am_I^+ should occur in parallel with the disappearance of $Am^{+\cdot}$ and over the same time interval. Such a reaction occurs during photooxidation of leuco-dyes in the presence of HCs. The final dye is formed in <100 μs, which is comparable with its lifetime.[207] When a D665 is formed in the system $Am \cdot CBr_4$, the lifetime of $Am^{+\cdot}$ also does not exceed 100 μs, but the appearance and increase of D665 absorption occurs over seconds,[119] and even more slowly (over minutes) at low concentrations of the amine.[36] The time difference between the two processes is several orders of magnitude. Obviously, the transformation of $Am^{+\cdot}$ into D665 is a more complex reaction (or a sequence of reactions) than simple removal of a hydrogen atom from the benzyl group.

In order to determine the structural moiety of amines involved in the formation of D665 and D605, photochemical reactions of CBr_4 with several groups of amines, differing in the presence of an unsubstituted benzene ring and an *N*-benzyl group in their molecules, were studied.[208] It was found that dyes are formed only from amines whose molecules contain a benzene ring unsubstituted at the *para*-position and linked to the amine nitrogen atom (an 'aniline' ring). If the *para*-position is blocked, dyes are not formed, irrespective of the presence of a *N*-benzyl group. For example, irradiation of the complex of CBr_4 with MDPA, which does not contain an *N*-benzyl substituent, resulted in the formation of a dye. However, the reaction of *N*-benzyl-di(*p*-tolyl)amine under the same conditions did not give products absorbing in the visible region, although a benzyl group was present.

Based on an analysis of experimental data on primary reactions, reactions in solutions and in polymer layers, and taking into account analogies with photochemical and thermal reactions of Am with PHM, we proposed a general scheme for the photochemical synthesis of dyes (Scheme 2; for simplicity, the positive charge is shown as localised at one of nitrogen atoms),[182] which was then confirmed experimentally [209] for all of the above aromatic amines whose reactions gave D665 and D605 (the latter are di- and triphenylmethane dyes, respectively).

Scheme 2 shows reaction initiation by excitation of a CTC, which is easily performed for X = Br by irradiation of the reaction mixture by light with $\lambda > 350$ nm. The free components virtually do not absorb in this region, hence selective excitation of the CTC occurs, since the absorption spectra of the $Am \cdot CBr_4$ complexes are shifted bathochromically relative to the spectra of the components. Then the first steps of the process (15) – (17) correspond to the sequence of the static quenching [reaction (1)] and dissociation [reaction (6)] reactions discussed above. During amine photoexcitation ($\lambda < 300$ nm), which is the more probable in the case of X = Cl, the ET changes somewhat in nature and occurs by the dynamic quenching pathway (2).

For any initiation pathway, the primary reactive species are an amine radical-cation $Am^{+\cdot}$, a $CX_3^{\cdot}$ radical, and an X^- anion. Subsequently, reaction (18) involves recombination of radicals into a *p*-amino-substituted trihalotoluene, which undergoes ionization giving a *p*-quinonoid ('monophenylmethane') dye

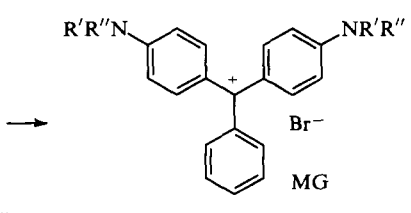
ICIII DIII



X = Cl, Br; R', R'' = H, Alk, Ar.

DI; ionisation is facilitated by the strong mesomeric effect of the nitrogen atom and the thermodynamic stability of the halide ion. It was noted in studies by flash photolysis [50,65,114,115] dealing with the primary steps of the reactions of Am with CBr_4 that the destruction of $Am^{+\cdot}$ obeys second-order kinetics, which corresponds to a recombination of the two radical species present in solution in equal concentrations.

After that, the amine present in excess acts as a nucleophile with respect to DI [reaction (19)]. In turn, this is an electrophilic aromatic substitution (alkylation) reaction with respect to the amine, in which DI is the alkylating agent. This results in diphenylmethane dye DII (named as D665 owing to its spectral properties [27]). Subsequently, DII reacts as an electrophile with respect to a new Am molecule in reaction (20), which is similar to reaction (12), giving the final TPMD — DIII, i.e. D605.

The lability of compounds such as DI and DII and the ease of their reaction with Am were described in Ref. 210, where a TPMD was obtained in the cold simply by mixing an amine with the corresponding halo-derivative. The reaction of Am with tribromotoluene, which is, in essence, the simplest model of intermediate compound (IC) I without an amino group in the *para*-position, also occurs readily to give dyes like Malachite Green (MG). The reaction can occur both thermally and under light irradiation. [36]

$$PhNR'R'' + PhCBr_3 \xrightarrow{\Delta\ (\text{or } h\nu)}$$

R' = R'' = Me.

Thermal synthesis of di- and triphenyl dyes directly from Am and PHM is carried out under pressure at an elevated temperature in the presence of metal salts. [211,212] The reaction occurs as a Friedel–Crafts alkylation of Am. [213] The amino group, which is a type I substituent, directs the attack predominantly to the *ortho*- and *para*-positions. The behaviour of aromatic amines in thermal reactions of arylamines with PHM, as in photochemical reactions, is exactly the same, irrespective of the presence or absence of the *N*-benzyl group in their molecules.

The spectral properties of arylmethane dyes are characterised by a clear relation between the positions of the absorption band maxima and the number of donor (amine) groups in the benzene rings for related mono- (λ_I), di- (λ_{II}) and triphenylmethane dyes (λ_{III}): introduction of the second substituent into the molecule results in a marked red shift of the colour — the maximum shifts considerably towards longer wavelengths, whereas introduction of the third substituent causes a slight blue shift of the colour, and the maximum slightly shifts towards shorter wavelengths, i.e. $(\lambda_I) < (\lambda_{III}) < (\lambda_{II})$. [212,214,215] For example, for Crystal Violet and its analogues (Scheme 2, R' = R'' = Me), the values of λ_I, λ_{II}, and λ_{III} are ~ 415, ~ 610, and ~ 590 nm, respectively. [182]

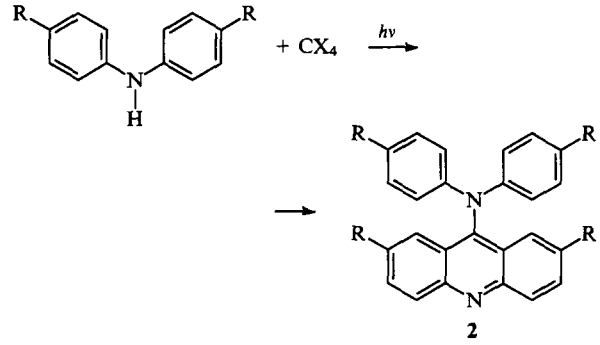
According to Scheme 2, when the number of halogen atoms in an HC molecule is gradually decreased from 4 to 1, the reaction can be terminated at any of steps (18)–(20), since the absence of a halogen atom in the corresponding intermediate makes the latter unable to participate in subsequent substitution reactions with Am. All of the six possible compounds, ICI–ICIII and DI–DIII, have been obtained in the case of DMA in the above studies by Latovskii et al. Along with the *para*-substituted derivatives shown in Scheme 2, similar *ortho* isomers were also obtained, in agreement with the directing effect of the amino group in aromatic electrophilic substitution reactions. When the free amine is present in deficit, the reaction stops at the recombination step (18), since subsequent reactions of electrophilic alkylation become impossible under these conditions. [112,182]

The process presented in Scheme 2 can be controlled by varying the temperature and by using matrix effects. For example, if the reaction is carried out at 77 K in frozen solutions, irradiation leads only to ET and generation of an amine radical-cation, [43,115,119] which is stable under these conditions. When the reaction is carried out at −15 °C in a polystyrene matrix, recombination (18) already occurs giving DI; however, further reaction is impossible owing to limited diffusion of the reagents. [209] When polystyrene layers containing a CTC of Am with CBr_4 are irradiated at room temperature, reaction (19) occurs in several minutes, and DII is detected immediately. A longer time or heating are required for reaction (20) to occur. [189,209]

Obviously the difference in the rates of reactions (19) and (20) involving the same amine is explained by the different alkylating power of DI and DII. The reactivity of these compounds depends on the positive charge on the reaction centre, the exocyclic carbon atom. The conjugation chain in DII, which stabilises the charge, is twice as long as that in DI, which results in a decrease in the charge on DII in comparison with DI and manifests itself by reaction (20) being slower than reaction (19).

The difference between the alkylating activities of DI and DII was used for determining the rate constants for reactions (19) and (20) during the formation of Opal Blue in a toluene solution.[216] Since the process was carried out with a great excess of DPA, pseudounimolecular constants were measured which were directly proportional to amine concentration. Relatively low activation energies (16.8 and 40 kJ mol^{-1}) and high negative entropies of activation (−187 and −155 J mol^{-1} K^{-1}), typical of bimolecular processes, were found for reactions (19) and (20), respectively.

Interesting results were obtained by comparing the rates of formation of DII and DIII during the photoionisation of DPA and DPBA with CBr_4 in polystyrene.[36] It was found that the rate constants for reaction (19) are ca. 10^{-2} for both amines, and those for reaction (20) are ca. 10^{-4} l mol^{-1} s^{-1}. For reactions (19) and (20), the ratio of the reaction rate constants for the two amines is $k_i(DPA)/k_i(DPBA) \approx 3$, and the ratio of the rate constants for both reactions is $k_{19}/k_{20} \approx 90$ for both amines. Obviously such a coincidence of kinetic parameters indicates the similarity of the reactions of formation of D665 and D605 from these amines.



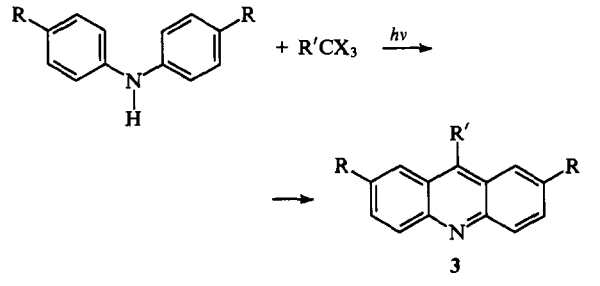
Although an analogy exists between aromatic amines with respect to the formation of TPMD, this reaction, as shown in the previous section, is not the only possible process during the photochemical irradiation of amine – CBr_4 complexes. Therefore, the experimentally observed difference in, say photochemical behaviour and photographic properties of DPA·HC and DPBA·HC complexes,[217] can be explained by various side processes in these systems, which occur in parallel with the formation of dyes but are not related to them. For example, in the case of DPBA these can be reactions involving the α-aminyl radical, which is readily formed from DPBA but not from DPA, whereas in the case of DPA these are reactions involving the amine hydrogen atom, which is absent in DPBA. The side processes result in sets of products possessing different properties and specific to different amines. However, it should be emphasised once more that these features refer to side processes, whereas, as shown experimentally, the formation of TPMD from all amines studied, whose molecules contain a benzene ring unsubstituted in the *para*-position and linked to an amine nitrogen atom ('aniline' ring), react via a common mechanism giving D665 and D605, i.e. DII and DIII (Scheme 2), respectively.[208,218]

VII. Formation reactions of acridine compounds

The formation of acridine compounds upon irradiation of DPA·CX_4 complexes was found in the early 1980s independently by two scientific groups.[219,220] In both studies, the authors reported that 9-diphenylaminoacridine (DPAA) was isolated as one of the reaction products, and the possible pathways for its formation were considered. Scheme 3 shows the sequence of reactions suggested in Ref. 219. This sequence involves recombination of primary radicals into intermediate **1** of *o*-quinonoid structure, which undergoes cyclisation directly into 9-bromoacridine. The latter reacts with a second amine molecule to give DPAA, which (like bromoacridine) exists in the reaction medium as a hydrobromide.

As already noted, direct irradiation of DPA results in carbazole through unimolecular photocyclisation.[221] Unlike this reaction, the formation of the acridine ring involves at least two molecules, an Am and a PHM, and several consecutive reactions result in photoinduced bimolecular cyclisation.

A study of the preparative possibilities of this reaction showed that DPAA analogues, the corresponding 9-diarylaminoacridines **2**, can be obtained in up to 40% yield and in up to 0.08 quantum yield from DPA derivatives substituted in the *para*-position.[36,222]

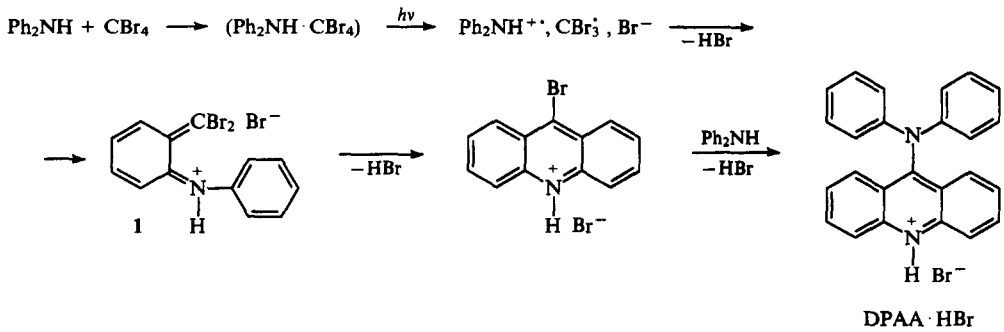


2

R = Me, $PhCMe_2$; X = Cl, Br.

The use of *para*-substituted derivatives instead of DPA increases the yields of cyclisation products considerably, since in this case the above TPMD formation reaction, which is a side process with respect to cyclisation, is blocked.[223]

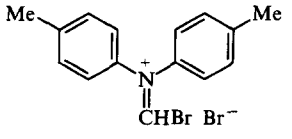
A similar effect, i.e. an increase in the yield of acridine to 50% and above with R ≠ H, has been observed in reactions of diarylamines with trihalomethanes.[224] In this case acridines **3** containing no amino-substituent in position 9 are the end products. Thus, as in the case of the formation of TPMD, a decrease in the number of halogen atoms in a PHM molecule results in a decrease in the number of steps in the chain of consecutive photoinduced reactions, and the whole process ends at the ring closure step due to the absence of a halogen atom in the acridine molecule after cyclisation.



3

R = H, Me, Br; R′ = H, Ph; X = Cl, Br.

The reaction of amines with tribromotoluene occurs not only photochemically but also thermally to give the corresponding 9-phenylacridines (R′ = Ph).[225]



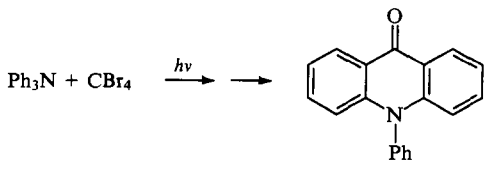
Scheme 2

DPAA·HBr

Although the experimental data considered above were consistent with Scheme 3 and even seemed to confirm it, data were accumulated during studies of photoinduced bimolecular cyclisation that could not be completely explained within the process described. According to Scheme 3, the last step of the reaction is nucleophilic substitution of a halogen atom by an amine molecule. Modelling this step by examples of reactions of 9-bromo- or 9-chloroacridine with various aromatic amines showed that only primary amines undergo the reaction at room temperature.[225] Thermal reaction involving diarylamines occurred only at high temperatures (>100 °C), which differed from the conditions of the photoinduced reaction (< 25 °C). In addition, according to Scheme 3, *N*-methylated amines should give *N*-methylated acridines, but the latter were not found in the reaction mixture.[226] Thus, both the structures of the intermediates and the overall mechanism of the formation of aminoacridines proved to be doubtful.

A study of photochemical reactions of complexes of di-*p*-tolylamine (DTA) with tetra- and tribromomethane by pulse methods showed that in both cases an amine radical-cation absorbing around 700 nm was formed as the primary product.[227,228] As a subsequent intermediate in the reaction with bromoform, a product was detected which absorbed at 540 nm. It was formed by a pseudo-first-order reaction with a rate constant proportional to the amine concentration and was then transformed into acridine by a unimolecular reaction.[228] A comparison of spectral and kinetic properties of the intermediates detected and the time scales of the transformations of compounds into each other led to the conclusion that one more intermediate, which does not absorb in the visible region, exists on the coordinate of the photoinduced reaction of DTA with $CHBr_3$. This intermediate was assigned the bromomethyleneiminium structure **4**.[87]

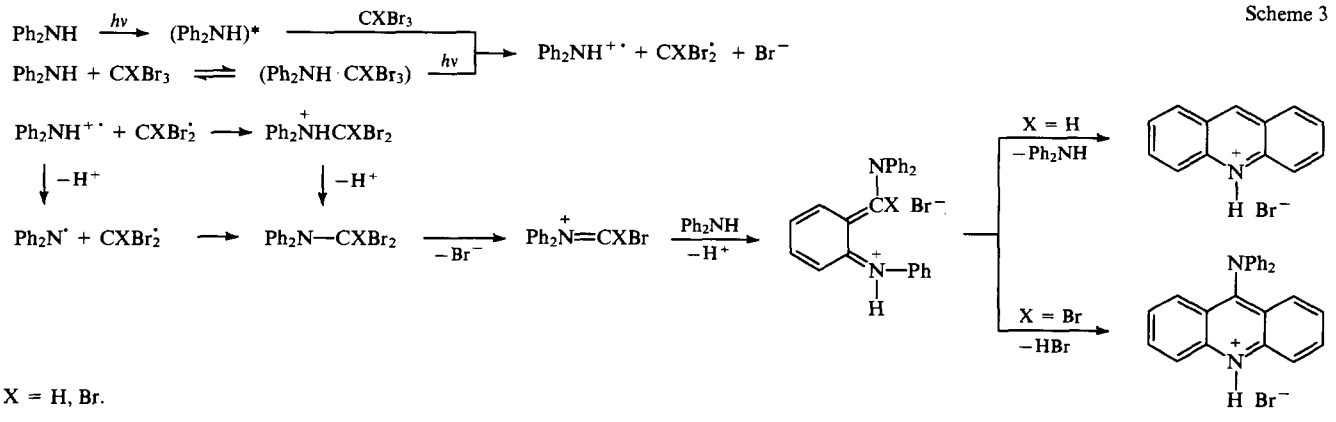
4



This compound is formed by recombination of primary radicals with participation of the nitrogen atom in $Am^{+\cdot}$ rather than of the *ortho*-positions of the benzene ring, as was assumed according to Scheme 3. Since methyleneimine salts possess pronounced electrophilic properties,[229] compound **4** readily reacts with a new amine molecule to give the next intermediate, which was detected by spectral methods.

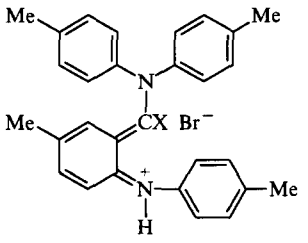
Attempts were made to detect a similar intermediate in the reaction of DTA with CBr_4, but only data on the kinetics of the formation of aminoacridine **2** (R = Me) were obtained in this case.[230,231] However, analysis of the kinetic curves of spectral changes in various wavelength ranges confirmed the assumption of the absence of a haloacridine as an intermediate compound during the formation of aminoacridine.

The results of the works cited can be generalised as Scheme 4, where (for DTA as an example) the sequence of photoinduced reactions that occur during the interaction of diarylamines with tri- or tetrahalomethanes to give acridine compounds is shown. The scheme shows: first, that the incident light can be absorbed both by the complex and by the free amine (this is determined by the spectral range of the incident light), and second, that the methyleneiminium intermediate can really be formed owing to recombination involving not the nitrogen atom of the amine radical-cation but a neutral diarylnitrogen radical formed after deprotonation of the radical-cation (see Section IV). Since the data available are insufficient for making an unambiguous choice, both possible recombination pathways are shown.



It should be noted that Scheme 4 reflects the main but not the only pathway for the formation of acridine compounds in photochemical reactions of amines with PHM. As shown above (see Table 1), in agreement with quantum-chemical calculations and in conformity with EPR spectra, the maximum density of the unpaired electron in radicals of the type $Ph_2NH^{+\cdot}$ and $Ph_2N^{\cdot}$ is located at the central nitrogen atom, which serves as the main reaction centre for the recombination of primary radicals. The recombination involving the carbon atoms of benzene rings also occurs, although with a lower probability. But, if the nitrogen atom is blocked by a third substituent, this becomes the main reaction pathway, e.g. as in the formation of TPMD.

Obviously recombination in the *ortho*-position of the benzene ring is also the only pathway in the photochemical reaction of triphenylamine with CBr_4, which results in *N*-phenylacridone (from the intermediate *N*-phenylbromoacridinium after treatment of the reaction mixture with water).[33]

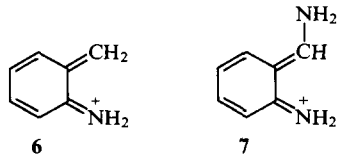


Interesting data were obtained by comparing the rates of the formation of intermediate compounds **5a,b** in reactions of DTA with $CHBr_3$ (**5a**, X = H) and CBr_4 (**5b**, X = Br). These compounds are formed by alkylating DTA with type **4** methyleneiminium salts. It was found that the rate constant for the formation of compound **5a** is more than an order of magnitude higher than the constant for compound **5b**; these constants were 10.8 and 0.32 l mol^{-1} s^{-1} (toluene, 20 °C), respectively.[232] The activation enthalpies (kJ mol^{-1}) and entropies (J mol^{-1} K^{-1}) for the formation of compounds **5a** and **5b** were found to be 36.3 and −101 (**5a**) and 24.6 and −169 (**5b**), respectively. It follows from these data that the entropy factor makes the greatest contribution to

Scheme 3

X = H, Br.

the retardation of the reaction for compound **5b** compared with compound **5a**, and the entropy decreases so much that the simultaneous decrease in the activation enthalpy does not compensate for the former effect.



5

X = H (**a**), Br (**b**).

In comparison with the alkylation reaction, the intramolecular cyclisation of compound **5a** into 2,7-dimethylacridine is characterised by a higher activation energy (68 kJ mol^{-1}) but a lower magnitude of entropy of activation (−58 J mol^{-1} K^{-1}).

As mentioned above, the efficiency of the processes shown in Scheme 3 (formation of *N*-substituted diarylamines) is lower than that of the reactions shown in Scheme 4 (for Ar_2NH diarylamines). A comparison of Schemes 3 and 4 shows that, in both cases, *ortho*-quinonoid compounds are the key structures in the cyclisation process. An analysis of the structures of these compounds and a comparison of this process with similar processes of thermal intramolecular cyclisation[233,234] leads to the conclusion that cyclisation is possible only in *cis*-isomers, whereas compounds **5a** and **5b** obviously exist at room temperature in the *trans*-forms, which are thermodynamically more stable. Thus, the general sequence of reactions should include a step involving the isomerisation of the C=N double bond, omitted in Schemes 3 and 4.

The potential barrier to rotation about the C=N bond was calculated for model compounds **6** and **7** by the MNDO method. It was found that the activation energy for isomerisation is twice as high for compound **6** as that for compound **7**: 77.5 and 44.4 kJ mol^{-1}, respectively.[232]

6 **7**

This effect is related to a decrease in the multiplicity of the C=N bond in compound **7** in comparison with compound **6** due to delocalisation of the positive charge onto the second nitrogen atom. It should be noted here that isomerisation of compounds of type **1** and **5** can occur not only by rotation around the C=N double bond, but also by inversion of the sp^2-orbital of the nitrogen atom in the neutral compound after deprotonation. As a result, the energy barrier to isomerisation decreases. The isomerisation of *N*-substituted diarylamines can result only in type **1** *o*-quinonoid compounds, in which, owing to the impossibility of deprotonation, the only isomerisation pathway is rotation in which a high potential barrier is overcome. This makes it possible to explain the low effectiveness of *N*-substituted diarylamines in the photoinduced bimolecular cyclisation.

VIII. Conclusion

The review of the available data on the photochemical reactions of complexes of aromatic amines with halohydrocarbons shows that these systems attract the attention of researchers because of two factors. First, they are convenient systems for studying the process of electron transfer, the main primary chemical reaction occurring upon the irradiation of complexes. Second, they provide a broad range of compounds, including triphenylmethane dyes (reactions of photoinduced consecutive aromatic substitution), acridine derivatives (photoinitiated bimolecular cyclisation), carbazoles (intramolecular cyclisation of diarylamines on their direct excitation), benzidines (photooxidation of amines), etc. The ratio of reaction products is primarily determined by the structures of the amine and the halohydrocarbon, and also by the spectral range of the incident light (excitation of the complex, local excitation of the amine or the acceptor) and by the ratio of reagent concentrations.

In many cases, the nature of the excited state (singlet or triplet) involved in the reaction and the structures of the reacting primary species (radical-cation or neutral amine radical) remain unclear. The mechanism of secondary thermal reactions occurring after irradiation of the complexes has been studied in more detail. Reaction schemes have been proposed that are confirmed by direct observation of the corresponding intermediates, their spectral and kinetic properties, and by modelling separate steps in the general sequence of photoinitiated reactions.

We may note that the photoinitiated formation reactions of triphenylmethane dyes and acridine compounds involve common photochemical and some thermal stages. In both cases, the reactions start as photo-transfer of an electron due to excitation of a charge transfer complex or a free amine. One of the intermediate stages involves electrophilic alkylation of the amine by cations of dyes or by iminium salts. The alkylation reactions are characterised by relatively low activation energies (no higher than 40 kJ mol^{-1}) and high negative entropies of activation (up to −190 J mol^{-1} K^{-1}) typical of bimolecular reactions of this class.

III. Intergrowth structures with alternation of fragments along the threefold axis of the perovskite subcell 724
IV. Conclusion 728

Abstract. The review deals with the characteristic features of the formation of certain complex perovskite-like oxides. In the crystal structures of these compounds, it is possible to differentiate fragments with different structures, which alternate along the three-fold or four-fold axis of the perovskite sublattice. This approach has been applied successfully to the synthesis of a large number of new complex transition metal oxides, in particular those belonging to the family of Hg-containing high-temperature superconductors with the highest transition temperatures for superconduction. The bibliography includes 79 references.

I. Introduction

Fragments with different structures, for example blocks of the perovskite ($CaTiO_3$), sodium chloride (NaCl), and fluorite (CaF_2) types or individual layers alternating along the large period of the unit cell may be conventionally differentiated in the structures of many complex oxides. In many instances, the differentiation of such fragments is conventional [for example, the differentiation of the (TiO_2) layers in the perovskite structure]. However, in the structures of the superconducting complex copper oxides, which will be considered in the second section of the present review, the differentiation of the (CuO_2) layers is justified, since the Cu – O distance in these layers is much shorter than the distances between the atoms of the neighbouring layers. A necessary condition for the formation of structures consisting of alternating blocks is the geometrical compatibility of fragments with different structures, for example in the *ab* plane. The cubic unit cell parameters a of oxides with structures of the NaCl and CaF_2 types are in the range from 5.4 to 5.7 Å. The cation–cation distance in these structures is close to the corresponding distances in perovskite-type structures — 3.8 – 4.2 Å ($a_{NaCl} \approx a_{fl} \approx \sqrt{2}a_{per}$). The face-centred unit cells of the NaCl and fluorite types can be transformed into tetragonal body-centred cells with the parameter a close to a_{per}. We may note that the motif in the arrangement of the cations in the perovskite structure and in the transformed cells of the fluorite and NaCl types is the same, but the coordinates of the oxygen atoms are different (Fig. 1).

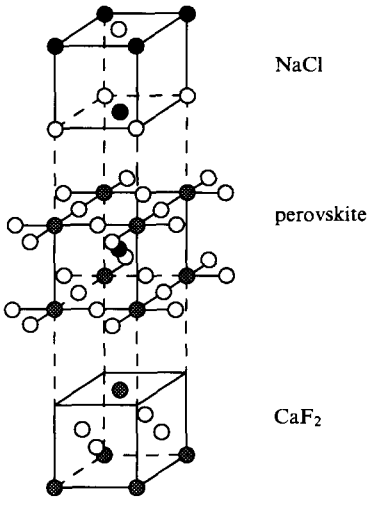

Figure 1. Schematic illustration of the formation of intergrowth structures for the alternation of NaCl- or fluorite-type blocks and (CuO_2) layers along the fourfold axis.

The third section of the review deals with compounds in the structures of which the common elements of the fragments are close-packed layers. In this case, the coalesceing fragments are oriented at right angles to the threefold axis of the perovskite sublattice. An obligatory condition for the formation of coherent intergrowth structures is also the chemical compatibility of the ions entering into their composition (for example, the situation where powerful oxidants and reductants are not present simultaneously) and the electrical neutrality of the unit cell. One should also note that the consideration of structures in inorganic chemistry as sequences of simpler structures arranged in a definite order is to some extent analogous to the description of homologous series of organic compounds. The difference consists in the fact that the alternating elements in the latter case are isolated groups of atoms, whereas in inorganic compounds these are layers or blocks of infinite extent in two directions.

The use of such a treatment of the structures makes it possible to predict the feasibility of synthesising new compounds having the necessary structural fragments giving rise to unique physical properties. For example, we have used this to synthesise new superconducting complex copper oxides.

II. Structures with alternation of fragments with different structures along the fourfold axis

1. Complex copper oxides having the general formula A_2BO_4

The simplest coherent intergrowth structure is that of K_2NiF_4. Numerous complex lanthanide and transition element oxides crystallise in this structural type.[1,2] The structure contains fragments of the perovskite and NaCl types (Fig. 2). The structure of K_2NiF_4 can be represented schematically as the following arrangement of layers along the threefold axis:

$$\cdots(NiF_2)-(KF)-(FK)-(F_2Ni)-(FK)-(KF)-(NiF_2)\cdots$$
$$\longleftarrow\!\!\!

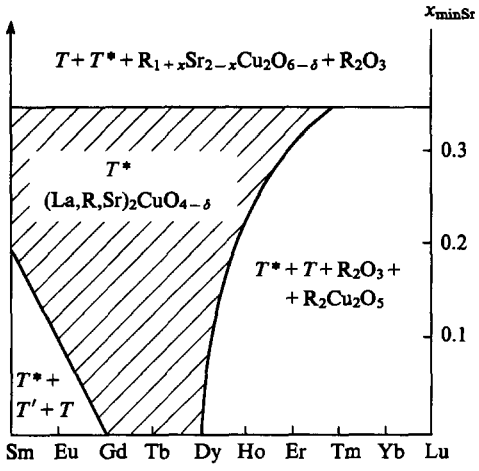

Figure 5. Dependence of the minimum concentration of strontium on the nature of the lanthanide for solid solutions with the structure of the T^*-phases.

cations Sr^{2+} or Ba^{2+} makes it possible to obtain the T^*-phases also with other lanthanide elements. Such phases have been obtained in systems with R = Sm – Lu and Y (Fig. 5).[13–16]

It is noteworthy that the X-ray diffraction patterns of the T-, T'- and T^*-phases are very similar. This is due to the fact that the cations in the structures of the phases populate the same positions. However, the unit cell of the T^*-phases is primitive, in contrast to the body-centred cells of the T- and T'-phases. Furthermore, the ratios of the unit cell parameters of the above phases differ significantly: the ratio $c/3a$ is ~ 1.15 for the T-phases, $\sim 1.06 - 1.08$ for the T^*-phases, and ~ 1.02 for the T'-phases.

It has been suggested on the basis of the analysis of the tolerance factors $t(t = d_{A-O}/\sqrt{2}d_{B-O})$ for a large number of the compounds A_2BO_4 that the structures of phases with a given composition can be predicted from the value of t.[17] The authors established that $0.87 \leqslant t \leqslant 0.99$ for the T-phases and $0.83 \leqslant t \leqslant 0.855$ for the T'-phases, while the T^*-phases exist (if they are formed in the given system) within the very narrow range $0.855 \leqslant t \leqslant 0.87$. Naturally, in the latter case at least two A-type cations are needed for the ordered population of two different positions.

Undoubtedly the employment of the tolerance factor is useful and in many cases makes it possible to predict correctly the structures of the compounds. However, the limitations and disadvantages of this method must be noted. Firstly, the above model presupposes the purely ionic character of the A–O and B–O bonds, which is not quite correct when B is a transition element, since in this case the B–O bond is to a large extent covalent. Secondly, the model ignores the electronic structure of the B cations. It is well known that the T'-phases are formed only for $B = Cu^{2+}$, whereas the square coordination is characteristic also of other cations (Ni^{2+}, Pt^{2+}, etc.). However, the compound Gd_2NiO_4, for example, which should have the structure of a T'-phase in terms of the value of t, has in fact the structure of a T-phase.[18] Thirdly, with the aid of this model it is impossible to explain why a compound with the same cationic composition subjected to different heat treatment conditions has different structures. For example, the compound $La_{1.2}Dy_{0.7}Ce_{0.1}CuO_{4+\delta}$, synthesised at $p_{O_2} = 1$ bar, has the structure of a T^*-phase, whereas after annealing under a nitrogen atmosphere a T'-phase is formed.[19]

In our view, apart from the purely geometrical criteria, it is also necessary to take into account electronic structure factors. For example, Ni-containing compounds with the structure of a T'-phase are not formed, apparently because the pairing energy of the e_g electrons is higher for the Ni^{2+} cation with the $3d^8$ electronic configuration than the energy gain in the subsequent removal of degeneracy when the environment of Ni^{2+} is altered to the square form. Furthermore, the geometrical dimensions of the (CuO_2) layer also depend on the electronic factors. We shall consider this in greater detail.

The size of the perovskite block in the *ab* plane is to a large extent determined by the length of the Cu – O bonds in the (CuO_2) layer. The length of these bonds is determined by the degree of filling of the σ^*-zone, formed mainly as a result of the overlap of the $3d_{x^2-y^2}$ orbitals of copper and the $2p_{x,y}$ orbitals of oxygen. An increase in the degree of filling of the σ^*-zone (an increase in the height of the Fermi level), which corresponds to a decrease in the formal oxidation state of copper, leads to an increase in the length of the Cu–O bonds in the (CuO_2) layer. When electrons are removed from the σ^*-zone (this corresponds to an increase in the formal oxidation state of copper), the lengths of these bonds diminish. The degree of filling of the above zone can therefore determine to a large extent whether the perovskite and other structural fragments have common dimensions. It can be altered by the heterovalent substitution of the cations in the structure and by varying the heat treatment atmosphere.

In the La–R–Cu–O systems, T^*-phases are formed only for R = Gd – Dy. The lanthanide atoms in the structure of the T^*-phase populate in an ordered manner two different crystallographic sites. For the lanthanides at the beginning of the series with ionic radii similar to that of lanthanum, such ordering does not occur. Instead, the formation of extended regions of solid solutions with T'-phase structures is energetically more favourable. When R = Ho – Lu and Y, an appreciable decrease in the effective radius of the cation in the fluorite fragment leads to the disappearance of common dimensions between this fragment and the (CuO_2) layer. As a result, the corresponding T^*-phases are not formed.

However, the partial substitution of La^{3+} by Sr^{2+} or Ba^{2+} in the NaCl-type fragment leads to the stabilisation of the T^*-phase structure. It has been established in relation to the solid solutions $La_{1.2-x}Dy_{0.8}M_xCuO_{4-\delta}$ (M = Sr or Ba) that such substitution leads to an increase in the average formal oxidation states of copper.[16] The Cu–O distance then diminishes in the (CuO_2) layer, which is reflected by a decrease in the unit cell parameter a with increase in the concentration of the alkaline earth metal cations despite the fact that their ionic radii are greater than that of La^{3+}.

With decrease in the R^{3+} radius in the series of lanthanides, there is an increase in the oxygen nonstoichiometry indices of the compounds obtained (Table 1). This results in an increase in the concentration of electrons in the antibonding σ^*-zone (or in the 'reduction' of copper), which should be accompanied by an increase in the Cu–O distance in the (CuO_2) layer. Thus, the decrease in the size of the fluorite fragment owing to the decrease in the ionic radius of the lanthanide is accompanied by an increase in the linear dimensions of the (CuO_2) layer and the T^*-phase is not formed as a result. However, the addition of an alkaline earth element, accompanied by a decrease in the equatorial Cu–O distance as a consequence of the 'oxidation' of the (CuO_2) layer, makes it possible to stabilise the T^*-phase structure also in systems with R = Ho – Lu and Y. It is noteworthy that the minimum Sr concentration required in the given series of lanthanides increases steadily with decrease in the ionic radii of the latter (Fig. 5).

Table 1. The unit cell parameters (a), the oxygen nonstoichiometry indices (δ), and the formal oxidation states of copper (V_{Cu}) for the T^*-phases $LaR_{0.8}Sr_{0.2}CuO_{4-\delta}$ (R = Sm, Gd, or Ho).

Compound	a/Å	δ	V_{Cu}
$LaSm_{0.8}Sr_{0.2}CuO_{4-\delta}$	3.8710(4)	0.06	2.08
$LaGd_{0.8}Sr_{0.2}CuO_{4-\delta}$	3.8583(2)	0.08	2.04
$LaHo_{0.8}Sr_{0.2}CuO_{4-\delta}$	3.8375(4)	0.11	1.98

In the systems with R = Sm and Eu, the addition of strontium or barium also leads to a decrease in the Cu–O distance in the (CuO_2) layer, whereupon the resulting 'contraction' of the structure in the *ab* plane leads to a decrease in the M–O interatomic distances for the cations in the fluorite fragment. The filling of the cationic sites in the latter by lanthanum atoms becomes energetically unfavourable. This results in the formation of a T^*-phase structure in which the La and Sr atoms populate statistically the cationic sites in a NaCl-type block, while the Sm and La atoms populate the sites in the fluorite fragment.

As noted above, the degree of filling of the σ*-zone depends on the oxygen pressure employed in the synthesis. For example, after synthesis at 950 °C in a stream of oxygen, $La_{1.5}Nd_{0.5}CuO_{4-\delta}$ has a T-phase structure ($\delta = -0.01$), whereas heat treatment under less oxidising conditions (1050 °C, air) leads to a phase transformation with formation of a T'-phase ($\delta = +0.02$).[19] The decrease in the Cu–O distance in the (CuO_2) layer and the stablisation of the phase with a smaller unit cell parameter a during synthesis under an oxidising atmosphere are a consequence in this case of the increase in the formal oxidation state of copper.

2. Compounds of the 223 and 1222 types

Another example of compounds in the structures of which it is possible to differentiate fragments with different structures are the 223 phases. The first representatives of this family of phases having the composition $(R_{1-x}Ba_x)_2(R'_{1-y}Ce_y)_2Cu_3O_{8+\delta}$ (R = R′ = Nd, Sm, or Eu, $x = 0.67$, $y = 0.33$) have been obtained by Japanese investigators.[20] The structure of these phases (Fig. 6) is derived from the tetragonal modification of the 123 phases ($RBa_2Cu_3O_{7-\delta}$), but the $(R'_2O_2)^{n+}$ fluorite fragment is located between the (CuO_2) layers instead of the $(R\square)^{3+}$ layer. This results in the doubling of the unit cell parameters c, since in the (R′)(O_2)(R′) fluorite block the (R′) layers are displaced relative to one another by the $\frac{1}{2}(\vec{a}+\vec{b})$ translation. The 223 phases have superconducting properties, but the transition temperatures for superconduction in these phases are lower than for the 123 phases ($T_c^{max} = 59$ K).[21] The 223 phases have a tetragonal body-centred cell ($a \approx a_{per}$, $c \approx 7a_{per}$). The model of their structure can be described as of the 14-layer type in which the layers are arranged in the following manner along the c axis:

$$\cdots(CuO_2\square_{2-\delta})-(RO)-(R'_2O_2)-(O_2Cu)-(OR)-(\square_{2-\delta}O_\delta Cu)\cdots$$
$$\longleftarrow\!\!\!

formed only in systems with R = La or Pr.[22] The effective radius of the cation in the perovskite fragment of Th-containing compounds must increase compared with the Ce-containing phases. This can be achieved not only by replacing Nd^{3+} by La^{3+} in the perovskite fragment but also by increasing the Ba^{2+} concentration in the cationic sites of the perovskite block.

The 223 phases $(R,M)_2(R',Th)_2Cu_3O_{8+\delta}$ are not formed for M = Sr, whereas in the Ba-containing system such compounds have been obtained for R′ = La – Gd. However, when the sites in the fluorite block are populated statistically by the Ce^{4+} and R^{3+} cations, the size of the cationic vacancies diminishes significantly, as a result of which the formation of Sr-containing 223 phases becomes possible in systems with R = Pr – Gd.[25] We may note that the phases with R = Sm and Eu possess superconducting properties, whereas the large Cu – O distance in the (CuO_2) layer in the Th-containing compounds is responsible for the localization of the electronic states. On further contraction of the fluorite fragment for R = Dy – Yb and Y, Ba-containing phases were not obtained, while in the case where M = Sr the 1222 phases, differing from the 223 phases in composition and structure, were produced. The partial or complete substitution of the copper cation in the $(CuO_\delta\square_{2-\delta})$ layer by another cation takes place in the structure of the 1222 phases. The filling of the oxygen sites in this layer is determined by the crystal chemistry of the given cation. Such change in the structure leads to a marked deformation of the CuO_2 layers and to the loss of superconducting properties. On the basis of experiments of this kind, one may conclude that the synthesis of superconducting complex copper oxides with a fluorite fragment requires the presence of Ce^{4+} and $Nd^{3+} - Gd^{3+}$ in the latter, since this leads to the optimum Cu – O distances for the manifestation of superconductivity.

The 1222 phase was first obtained in the Pb – Pr – Sr – Cu – O system.[26] Instead of the $(CuO_\delta\square_{2-\delta})$ layer, its structure contains the $(Pb_{0.5}Cu_{0.5}O_\delta)$ layer in which the anions populate statistically both the sites at the centre of the square $(\frac{1}{2}, \frac{1}{2}, 0)$ and the perovskite sites $(0, \frac{1}{2}, 0)$. The $TlSr_2(Nd,Ce)_2Cu_2O_{8+\delta}$ phase is close to those described above, but the $(CuO_\delta\square_{2-\delta})$ layer in its structure is fully replaced by the (TlO_δ) layer.[27] The compounds $(R_{1.5}Ce_{0.5})Sr_2Cu_2Nb(Ta)O_{10}$ (R = Pr – Eu), the structures of which contain the (NbO_2) or TaO_2 layers instead of the $(CuO_\delta\square_{2-\delta})$ layer, have also been described.[28,29]

There is a possibility also of a further increase in the complexity of the structures of the 223- and 1222-phases as a result of the incorporation in the fluorite fragment of additional (R′) and (O_2) layers. In this case, the fluorite block has the composition (R'_3O_4). The 233-phases $Sr_2(R,Ce)_3Cu_3O_{10+\delta}$ [30] and the 1232-phases $(Pb,Cu)Sr_2(R,Ce)_3Cu_2O_{11+\delta}$, as well as $(Tl,Cu)Sr_2.(R,Ce)_3Cu_2O_{11+\delta}$ [31] are derivatives of the 223- and 1222-phases with 'doubled' fluorite fragments.

3. The superconducting mercury-containing family of layered cuprates: $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ ($n = 1-4$)

The structures of the Bi-, Tl-, and Pb-containing high-temperature superconductors (HTSC) can be regarded as intergrowth structures of the perovskite and sodium chloride blocks, the Bi^{3+}, Tl^{3+}, and Pb^{2+} cations being located in the NaCl-type fragment. It is noteworthy that the ideal equatorial M – O distance for these cations is to a large extent determined by the Cu – O distance in the CuO_2 layer: $d_{M-O} \approx \sqrt{2}d_{Cu-O}$. However, the calculated values significantly exceed the characteristic values d_{M-O}. As a consequence of this, marked displacements of these cations and oxygen atoms from the ideal positions take place in the (MO) layers in order to diminish the corresponding interatomic distances and the CN of the cations M. The presence of the lone pair in the Bi^{3+} and Pb^{2+} cations also causes their appreciable displacements, required for the formation of an asymmetric coordination environment.

It is possible to synthesise layered cuprates with structures of this kind by employing Hg^{2+} cations, a characteristic feature of which is the dumbbell-like coordination of the oxygen atoms. In this case, the oxygen sites in the layers with mercury atoms may be partly filled or even remain vacant, since the Hg – O bond in this layer must be very weak. Under these conditions, there should be no incompatibility between the dimensions of the structural NaCl and perovskite fragments.

The new layered oxides $HgBa_2CuO_{4+\delta}$ [32], $HgBa_2CaCu_2.O_{6+\delta}$ [33], $HgBa_2Ca_2Cu_3O_{8+\delta}$, and $HgBa_2Ca_3Cu_4O_{10+\delta}$ [34] (the Hg-1201, Hg-1212, Hg-1223, and Hg-1234 phases respectively) have been obtained. These compounds belong to the homologous series of layered cuprates with the general formula $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$, in which $n = 1 - 4$ (Fig. 7). In the structures of the Hg-1212, Hg-1223, and Hg-1234 phases, two, three, and four (CuO_2) layers, separated by $(Ca\square)^{2+}$, respectively are located in the perovskite block. The NaCl-type fragment has a similar construction in these structures and is characterised by the sequence of layers $(BaO)(HgO_\delta)(BaO)$. The unit cell parameter c in these compounds is determined by the following relation: $c(Å) \approx 9.5 + 3.2\,(n-1)$.

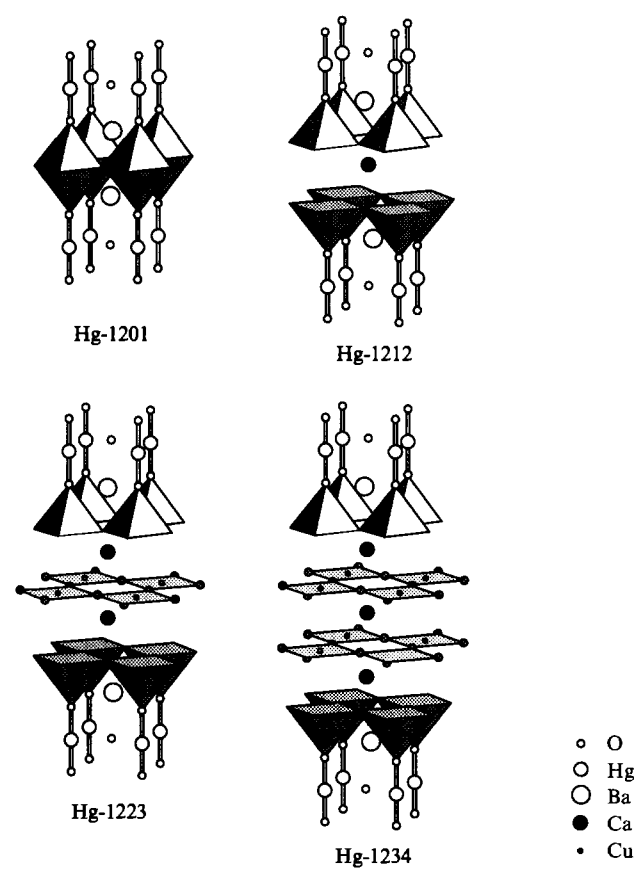

Figure 7. The crystal structures of $HgBa_2Ca_{n-1}Cu_{2n}O_{2+\delta}$ ($n = 1 - 4$).

The results of resistance and magnetic measurements have shown that the Hg-1201, Hg-1212, Hg-1223, and Hg-1234 phases are superconductors with maximum transition temperatures for superconduction of 94, 126, 134, and 126 K respectively.[32,34] The transition temperatures of these compounds can be significantly raised (to 157 K at 235 kbar for Hg-1223) at ultrahigh hydrostatic pressures.[35] The temperature of ~160 K is nowadays the highest at which superconductivity has been recorded. Unfortunately, when the external pressure is removed, the transition temperature falls to the values usual for these compounds.

Neutron and X-ray powder diffraction made it possible to locate the positions of the superstoichiometric oxygen in the Hg-1201 and Hg-1212 structures.[32,33,36,37] It was established that

such oxygen is present in a single layer with mercury atoms and that its content is appreciably less than unity, in contrast to the Tl-containing analogues. Annealing of such phases at different temperatures and partial oxygen pressures leads to a change in the degree of population of this site and hence to an alteration of the concentration of holes in the conduction band and of the transition temperature for superconduction.[32,37]

The family of Hg-containing phases obtained is a promising subject for the investigation of the nature of high-temperature superconductivity in the series of layered cuprates, since high values of T_c are characteristic of these compounds (they are higher than for the Tl-containing phases having a similar cationic composition), this being combined with a fairly simple crystal structure, which is reflected by the absence of modulations and statistical displacements of the atoms and by the high cell symmetry.

III. Intergrowth structures with alternation of fragments along the threefold axis of the perovskite subcell

The structure of the ideal cubic perovskite ABX_3 can be regarded as the spherical close packing of AX_3 layers alternating along the threefold axis. The shift of part of this layer leads to the formation of different types of close packing as regards the layered structure and symmetry, which are also referred to as hexagonal analogues of the perovskite structure. In certain structures of complex perovskite-like oxides with highly layered types of close packing, it is possible to distinguish blocks alternating in an ordered fashion along the c axis (which coincides with the threefold axis of the perovskite subcell), their composition and structures corresponding to those of simpler compounds with less layered packing. Formally, this justifies their consideration as intergrowth structures with alternation of perovskite-like blocks along the threefold axis.

The main geometrical criterion of the possibility of the formation of intergrowth structures is the common dimensions of the initial fragments, i.e. the correspondence of their dimensions in the *ab* plane. In the presence of the same skeleton, formed by close-packed AX_3 layers, the difference between the values of the parameter a is determined by the size of the cations occupying the octahedral vacancies in the close-packed structure.

We shall henceforth consider mainly only compounds in which the close-packed structure is made up of MO_3 (or $MO_{3-\delta}$) layers, where M = Ba, Sr, Ca, or La.

The formation of intergrowth structures is facilitated by the presence of stable structural fragments, the formation of which in the majority of cases is due to the presence of groups of face-linked octahedra arising when part of the layers are displaced by the vector $\frac{1}{3}$, $\frac{2}{3}$, 0 [under these conditions, the 'cubic' (c) layers are transformed into 'hexagonal' layers (h)]. As a result of the presence of common faces in the neighbouring octahedra forming an h-type layer, the distance between the metal cations in these octahedra should correspond to the average thickness of the close-packing layer (for the packing of BaO_3 layers, this range may be 2.2–2.6 Å). This leads to an appreciable electrostatic repulsion of the B cations in the face-linked octahedra. It is useful to discuss the factors stabilising such structural fragments. The electrostatic repulsion of the highly charged B cations may be diminished by the partial population of the B sites by cations with smaller formal charges. This occurs in structures of compounds such as $Ba_4M_3LiO_{12}$ [M = Ta, Nb; 8-layer $(hccc)_2$ packing] and $Ba_5W_3Li_2O_{15}$ [10 layer $(hcccc)_2$ packing].[38–40] In the compound $Ba_5W_3Li_2O_{15}$, chains of vertex-linked octahedra are alternately populated by lithium and tungsten atoms, while pairs of face-linked octahedra are populated statistically: 45% Li + 55% W. A similar motif in the arrangement of the cations is observed also in the structures of the compounds $Ba_4M_3LiO_{12}$. This arrangement of cations leads to minimum repulsion between the highly charged cations M^{6+} or M^{5+}, which is expressed by shortened metal–metal distances (for example, the Ta/Li – Ta/Li distance is 2.258 Å, while the W/Li – W/Li distance is 2.196 Å).

On the other hand, the compounds $Ba_4Ru_3Mo_{12}$ (M = Na, Li) have a different type of distribution of the B cations among the octahedral sites.[41] In the case of the compound $Ba_4Ru_3NaO_{12}$ [8-layer $(hccc)_2$ packing], and $Ba_4Ru_3LiO_{12}$ [6-layer $(hcc)_2$ packing], the face-linked octahedra are populated predominantly by ruthenium, which can be explained by the formation of Ru–Ru bonds.

If the average formal charge of the cations in the B sublattice of the close-packed $A^{2+}O_3$ layers is greater than 4, then, in accordance with the requirement for electroneutrality, cationic vacancies should arise. In the hexagonal analogues of perovskite with cationic vacancies in the B sublattice, the vacancies are located in the blocks of face-linked octahedra. If two types of layers adjoin one another, then there are groups of three face-linked octahedra. When a metal–metal bond cannot be formed owing to electrostatic repulsion forces between cations with a high formal charge, the filling of the middle octahedron is unfavourable and it remains empty. This leads to the formation of phases having the composition $A_nB_{n-1}O_{3n}$, where n is the number of close-packed layers or (for rhombohedral symmetry) the number of layers in one-third of a period. Examples of compounds with such structural organisation are $Ba_5Ta_4O_{15}$ [(hccch) packing][42,43] and $Ba_3Re_2O_9$[$(hch)_3$ packing][44] (Fig. 8), where each octahedron between two type-h layers remains unoccupied by the metal atoms. Members of this homologous series with types of close packing containing 5, 9, 12, 18, and 21 layers are known, all types of packing being trigonal and (apart from the five-layer packing) R-centred.[45–58]

The stability of the chhc fragment justifies the hypothesis that a hexagonal analogue of perovskite exists in which fragments of the $Ba_5Ta_4O_{15}$ and $MZrO_3$ structures (M = Ba, Sr) alternate in

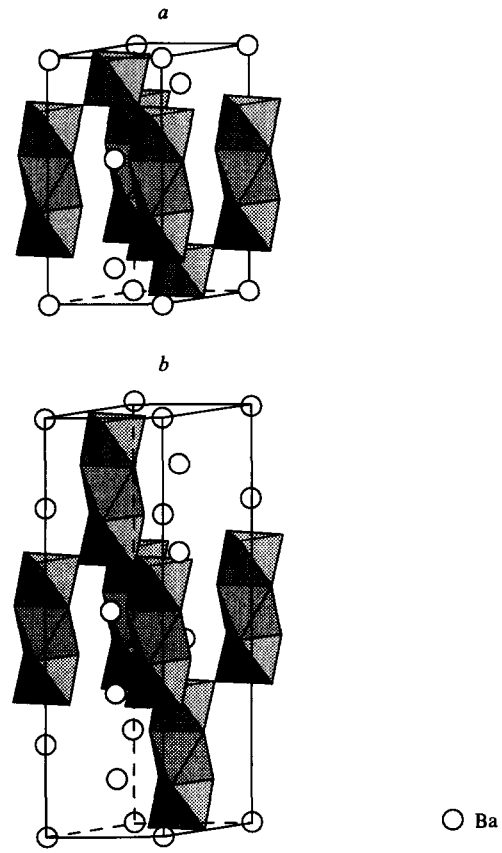

Figure 8. Crystal structures: (*a*) $Ba_5Ta_4O_{15}$; (*b*) $Ba_3Re_2O_9$.

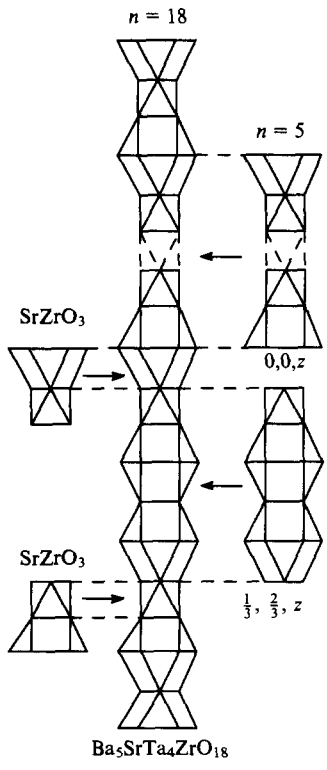

Figure 9. The structure of the compound $Ba_5SrTa_4ZrO_{18}$ resulting from the intergrowth of the $Ba_5Ta_4O_{15}$ and $SrZrO_3$ fragments.

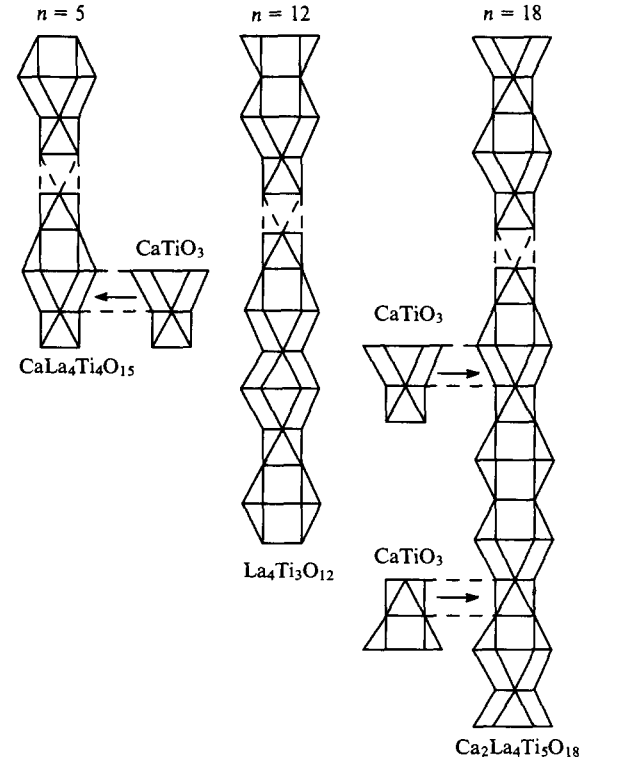

Figure 10. The structures of compounds of the $A_nB_{n-1}O_{3n}$ homologous series resulting from the intergrowth of fragments of the $CaTiO_3$ and $La_4Ti_3O_{12}$ structures.

an ordered fashion along the unit cell *c* axis (Fig. 9). The common dimensions of the fragments in the compound $Ba_5SrTa_4ZrO_{18}$ [(hcccch)$_3$ packing] are attained as a result of the statistical population of the A sites jointly by barium and strontium and of the B sites jointly by tantalum and zirconium, the statistical population of the sites by atoms of two kinds occurring at the block boundaries. Within the $Ba_5Ta_4O_{15}$ blocks, the A sites are occupied only by barium, while the B sites are occupied only by tantalum.

When Ti^{4+} cations are used instead of Zr^{4+}, compounds with structures resulting from the coherent intergrowth of the $Ba_5Ta_4O_{15}$ and $BaTiO_3$ fragments are not formed since the appre-ciably smaller ionic radius of Ti^{4+} (0.605 Å) compared with Zr^{4+} (0.72 Å) gives rise to a lack of common dimensions of the initial structural fragments. Compounds with such structures are formed when barium is replaced by A cations of smaller radius (La, Ca) and when only titanium cations are located in the B sublattice. Obstacles associated with the lack of common dimensions of the fragments do not arise under these conditions and several members of the homologous series are formed — $La_4Ti_3O_{12}$, $CaLa_4Ti_4O_{15}$, and $Ca_2La_4Ti_5O_{18}$.[59] If the 12-layer (hcch)$_3$ packing of the compound $La_4Ti_3O_{12}$ is regarded as a matrix, the subsequent members of the series can be represented as a result of the incorporation in this fragment of a c-type layer corresponding to a fragment of the $CaTiO_3$ perovskite subcell. Structures of this series can be regarded as resulting from intergrowth along the *c* axis of fragments of the $La_4Ti_3O_{12}$ and $CaTiO_3$ packing (Fig. 10). When a single c-type layer is incorporated in the hcch fragment of the initial 12-layer packing of $La_4Ti_3O_{12}$, the compound $CaLa_4Ti_4O_{15}$ with a cell having a P-type symmetry is formed, since the formation of an R-centred cell is impossible in the resulting hccch packing. When two c-type layers are incorporated in the initial fragment, the next member of the homologous series is formed — $Ca_2La_4Ti_5O_{18}$, in the structure of which an 18-layer (hcccch)$_3$ packing is achieved and the symmetry is restored to $R\bar{3}m$. In the case of compounds belonging to this homologous series, an additional factor ensuring the common dimensions of the fragments of the initial types of packing is the joint population of the A sites by lanthanum and calcium atoms. A similar homologous series is formed when the $LaFeO_3$ perovskite fragment is incorporated in the $La_4Ti_3O_{12}$ matrix, two members of this series being known — $La_5FeTi_3O_{15}$ and $La_6Fe_2Ti_3O_{18}$.[60] By using the fact that quadrupole splitting of the Mössbauer signal for Fe(III) in a high-spin state depends only on the degree of distortion of the coordination environment, which is much greater for the octahedra located between the h and c layers owing to the presence of a cationic vacancy, it is possible to show that the iron ions are located predominantly in the octahedral vacancies within the perovskite blocks. Such distribution of the cations among the B sites agrees well with the intergrowth structures model.

Apart from the structures of compounds which are formed as a result of an increase in the number of type $LaTiO_3$ blocks, a series of phases with different ratios of structural blocks exist along the $La_4Ti_3O_{12} - LaTiO_3$ section.[61] The simplest example of such phases is the oxide $La_9Ti_7O_{27}$. The structure of this compound can be represented as a result of the intergrowth of $2 \times La_4Ti_3O_{12} + LaTiO_3$ blocks. Formally, this structure can be more conveniently considered as a result of the intergrowth of higher homologues ($n \leqslant 6$): $La_4Ti_3O_{12} + La_5Ti_4O_{15}$ (or ...4545..., in terms of the number of blocks). The results of detailed microscopic studies of the phases formed along the $La_4Ti_3O_{12} - LaTiO_3$ section have been published.[62] The authors demonstrated the existence of a large number of ordered polytypes — $La_{11}Ti_9O_{33}$: $2 \times La_4Ti_3O_{12} + 3 \times LaTiO_3$ or ...5656...; $La_{13}Ti_{10}O_{39}$: $3 \times La_4Ti_3O_{12} + LaTiO_3$ or ...445...; etc. However, in practice, it is difficult to synthesise these compounds in a pure form because of the decrease in the energy differences between the homologues with increase in their ordinal number.

The population by B cations of the entire group of three face-linked octahedra is possible in the presence of an additional stabilising factor such as the formation of metal–metal bonds. Thus, in the $BaRuO_3$ structure, where the valence state

of ruthenium permits the formation of Ru–Ru bonds, all three adjacent octahedra are populated with formation of the $[Ru_3O_{12}]$ clusters.[63] The Ru–Ru distance in this structure is 2.55 Å.

When the chhc structural fragment cannot be stabilised, the incorporation of the cation in the middle of the three face-linked octahedra is unfavourable as a result of the short metal–metal distances arising under these conditions and the strong electrostatic repulsion and leads to a change in the type of close packing and the formation of hexagonal analogues of perovskite with the joint population of the B sites by cations and vacancies. Thus a trigonal primitive hccch close packing arises in the compound $Ba_5Ta_4O_{15}$. The heterovalent substitution of Ta^{5+} by Ti^{4+} leads to the appearance of an additional amount of B cations,[64] which exerts a decisive influence on the type of close packing produced. On passing from $Ba_5Ta_4O_{15}$ to $Ba_{10}Ta_{8-0.8x}Ti_xO_{30}$ solid solutions [$(hcccc)_2$ close packing, $0.6 \leqslant x \leqslant 1.2$], the type of close packing changes, the unit cell parameter c is doubled, and the symmetry is altered from $P\bar{3}m1$ to $P6_3/mmc$. This is accompanied by the delocalisation of the cationic vacancies and the joint population of the cationic sites by tantalum atoms and vacancies takes place in the chc structural fragment present in the $Ba_{10}Ta_{7.04}Ti_{1.2}O_{30}$ structure.

If the sum of the formal charges on the A and B cations is less than six, the formation of anion-deficient hexagonal analogues of perovskite having the composition $ABO_{3-\delta}$ is possible. In this case, the formation of stable structural fragments may be associated with the location of anionic vacancies outside the B cations for which CN < 6.

A group of hexagonal perovskite-like oxides is known where the appearance of anionic vacancies is induced by the introduction of aluminium atoms into the B sublattice. The structure of β-Ba_2RAlO_5 (R = Sc, In) (Fig. 11) is based on the eight-layer $(hccc)_2$ close packing.[65,66] The arrangement of the scandium and aluminium atoms is entirely ordered, the B-sites in the vertex-linked octahedra being populated by scandium alone. The ordered population of the B sites leads to the location of the oxygen atom on the 6_3 axis and the formation of a tetrahedral environment around the aluminium atoms. The group of two face-linked octahedra is then transformed into a group made up of two Al_2O_7 tetrahedra linked via the vertices. The ordering of the scandium, aluminium, and oxygen atoms leads also to a change in the coordination polyhedra around the barium atoms. One-fourth of the barium atoms are located in an almost ideal cubooctahedron. For another fourth of barium atoms, the appearance and ordering of the anionic vacancies lead to the removal of three out of the six oxygen atoms of the equatorial environment of the barium atoms, the three remaining oxygen atoms being displaced from the ideal positions (the Ba – O distance is 3.345 Å) and building up the coordination polyhedron of the barium atom to a truncated trigonal bipyramid (CN = 9). For the remaining half of the barium atoms, the displacement of the oxygen atoms in the $BaO\square_2$ layer leads to the appearance of a kind of open polyhedron in the form of a nonagon produced after the removal of the oxygen atoms making up the common face of the cubooctahedra in the h layer.

The fragments of the β-Ba_2RAlO_5 and $Ba(Sr)ZrO_3$ close packing (type c layers) in the structures of compounds with the general composition $Ba_{5-y}Sr_yR_{2-x}Al_2Zr_{1+x}O_{13+x/2}$ (R = Sc, In, Y, Gd–Lu) having a 10-layer close packing of BaO_{3-x} $(hcccc)_2$ layers alternating along the sixfold axis may be regarded as intergrowth structures (Fig. 12).[67] We may note that the compounds Ba_2RAlO_5 (R = Nd – Lu, Y) crystallise in the monoclinic system. When the ratio of the structural fragments corresponds to $2 \times (Ba_2RAlO_5) + (BaZrO_3)$, the ideal composition of the compounds is described by the formula $Ba_5R_2Al_2ZrO_{13}$. The establishment of common dimensions of the fragments in the given instance should be facilitated by the joint population of the B sites by zirconium and R^{3+} cations.

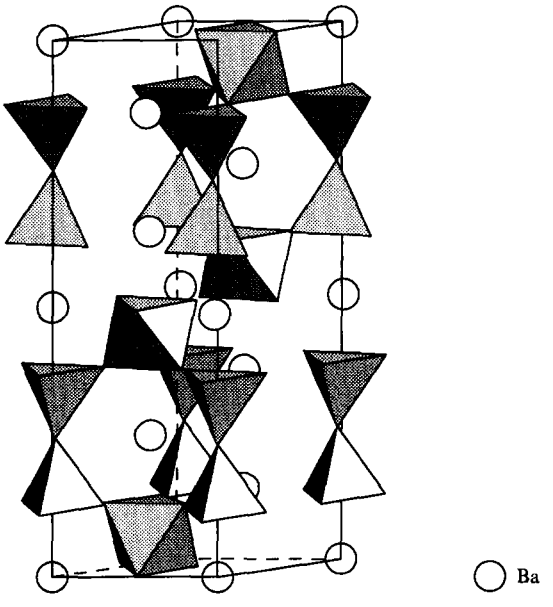

Figure 11. The crystal structure of β-Ba_2ScAlO_5.

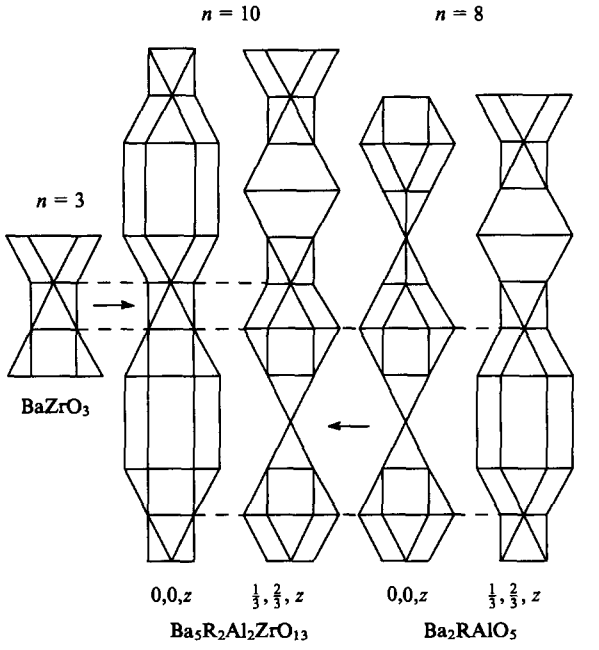

Figure 12. The structure of the compounds $Ba_5R_2Al_2ZrO_{13}$ resulting from the intergrowth of the Ba_2RAlO_5 and $BaZrO_3$ fragments.

The ionic radius of the R^{3+} cations exerts a significant influence on the stability of the compounds formed. Thus the formation of the compounds $Ba_5R_2Al_2ZrO_{13}$ was not observed for R = La – Eu. In this case, the radius of R^{3+} is too large for the accommodation of the ion in the octahedral vacancies within the close-packed BaO_{3-x} layers.

The significant difference between the ionic radii of R^{3+} (R = Gd – Lu; radii in the range 0.94–0.95 Å) and Zr^{4+} (0.72 Å) gives rise to the possibility of the existence of an ordered structure. The lanthanide cations are located in the octahedral vacancies of the type-β-Ba_2RAlO_5 block, whereas the Zr^{4+} cations are in the

$BaZrO_3$ block. In contrast to the $Ba_5R_2Al_2ZrO_{13}$ structures (R = Gd – Lu, Y), the structure of the Sc-containing compound is more disordered. In this structure, Sc^{3+} and Zr^{4+} occupy jointly the octahedral vacancies, which can be accounted for by the similarity of their ionic radii: 0.73 and 0.72 Å respectively. As a result of the statistical distribution, the cationic composition of the compound differs from the ideal composition and is expressed by the formula $Ba_5Sc_{1.33}Al_2Zr_{1.67}O_{13.33}$.

As in the β-Ba_2ScAlO_5 structure, in the $Ba_5R_2Al_2ZrO_{13}$ structures the oxygen vacancies are located in the h-type layers, which have the composition $BaO\square_2$. The remaining oxygen atom in this layer occupies a double position on the 6_3 axis, forming a common vertex of two Al_2O_7 tetrahedra. Under these conditions, some of the barium atoms achieve the same coordination environment as in the β-Ba_2ScAlO_5 structure. The change in the cationic composition following the substitution of some of the scandium atoms by zirconium atoms leads to the appearance of excess oxygen (compared with the ideal composition) and the composition of the h-type layer becomes $BaO_{1.33}\square_{1.67}$. The stable tetrahedral environment of the aluminium atoms prevents the delocalisation of the oxygen atom in the $\frac{1}{3}$, $\frac{2}{3}$, $\frac{1}{4}$ position and in the case of $Ba_5Sc_{1.33}Al_2Zr_{1.67}O_{13.33}$ the additional oxygen atom occupies the 0, 0, $\frac{1}{4}$ position, building up the nona-coordination polyhedron of the barium atoms to a decagon.

A characteristic feature of the crystal structure of $Ba_5In_2Al_2ZrO_{13}$ is the joint population of the B sites in the chc close packing fragment by indium and aluminium atoms, which is the cause of the delocalisation of the oxygen atom in the $\frac{1}{3}$, $\frac{2}{3}$, $\frac{1}{4}$ position. However, the compound with this structure is apparently metastable and has been obtained only on fusion of the specimen.

It is possible to distinguish three cases of the distribution of the cations among the B sites, which leads to three different types of location of the oxygen atoms in the BaO_{3-x} layers in the structures of the complex oxides $Ba_{5-y}Sr_yR_{2-x}Al_2Zr_{1+x}O_{13+x/2}$:

(1) the B sites in the chc fragment are occupied only by aluminium: the x, y, $\frac{1}{4}$ and x, y, $\frac{3}{4}$ layers have the composition $BaO\square_2$ and the arrangement of the oxygen atoms and of the anionic vacancies is fully ordered (the crystal structures of $Ba_5R_2Al_2ZrO_{13}$; R = Gd – Lu, Y);

(2) the B sites in the chc fragment are occupied statistically by atoms with stable octahedral and tetrahedral coordinations: the anion-deficient layers have the composition $BaO\square_2$ and the disposition of the oxygen atoms and the anionic vacancies is disordered (the crystal structure of $Ba_5In_2Al_2ZrO_{13}$);

(3) following the partial substitution of the R^{3+} cations by Zr^{4+}, the B positions in the chc fragments are occupied only by aluminium; the anion-deficient layers have the composition $BaO_{1.33}\square_{1.67}$ and the arrangement of the oxygen atoms is partly ordered (the crystal structure of $Ba_5Sc_{1.33}Al_2Zr_{1.67}O_{13.33}$).

In the cases examined above, the intergrowth structures are formed when the 'cubic' ABO_3 layers are incorporated in a multilayer close-packed structure. However, there exist hexagonal perovskites, where structurally isolated blocks, consisting of several 'cubic' and 'hexagonal' layers, alternate along the c axis.

The identical parameters a for the compounds $Ba_3Sc_4O_9$ [69–72] and β-Ba_2ScAlO_5 (5.794 Å) create ideal conditions for the formation of intergrowth structures. High-resolution electron microscope studies indicate the formation of two homologous series based on these compounds.[73,74] The compounds of the first series have the composition $Ba_{3n+8}Sc_{4n+4}Al_4O_{9n+20}$ (n = 2, 3, ...) (or, in a clearer form, $n \times Ba_3Sc_4O_9 + 2 \times Ba_4Sc_2Al_2O_{10}$). It is easily seen that for $n = 2$ the formula of the compound is $Ba_7Sc_6Al_2O_{19}$ (Fig. 13) and each succeeding member of the series is formed after the incorporation of an additional $Ba_3Sc_4O_9$ fragment. Compounds of the second series have the formula $Ba_{2n+3}Sc_{n+4}Al_nO_{5n+9}$ (n = 2, 3, ...) (or $Ba_3Sc_4O_9 + n \times Ba_4Sc_2Al_2O_{19}$), which is obtained following an increase in the number of $Ba_4Sc_2Al_2O_{10}$ blocks in the $Ba_7Sc_6Al_2O_{19}$ structure.

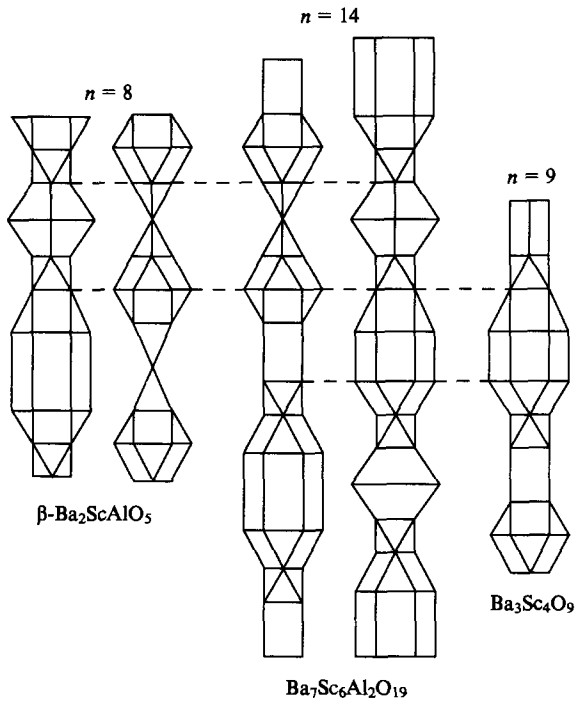

Figure 13. The structure of the compound $Ba_7Sc_6Al_2O_{19}$ resulting from the intergrowth of the β-Ba_2ScAlO_5 and $Ba_3Sc_4O_9$ fragments.

It is noteworthy that the members of homologous series with $n > 3$ were hardly observed or were present in the form of irregularly alternating sequences.

Barium ferrites form yet another group of hexagonal perovskites with intergrowth structures.[75,76] This family of compounds is obtained on 'by intergrowth' of $BaFe_{12}O_{19}$ structural blocks [M-type; $P6_3mmc$ (cchcc)$_2$] with $Ba_2M^{II}Fe_{12}O_{22}$ [Y-type: $R\bar{3}m$ (cchhcc)$_3$] or $M^{II}_2Fe_4O_8$ (M^{II} = Mg, Zn, Co) (*S*-type: $Fd3m$ spinel structure) in different proportions and sequences. The so called series of compounds M_2Y_n is formed along the $BaFe_{12}O_{19} - Ba_2M^{II}Fe_{12}O_{22}$ section. If the repeating parts of the sequences are denoted by M and Y, the compounds obtained have the composition M_2Y_n. Ordered phases with the ratios M : Y ranging from 2 : 1 to 2 : 11 have been obtained for them. Phases with even more complex ratios of the fragments have been discovered with the aid of high-resolution electron microscopy.

Compounds in the structures of which blocks having similar constructions and compositions alternate were described above. Thus a single principle governing the disposition of the cations among the crystallographic sites is maintained in all the structures based on the close packing of AO_3 layers. However, there are examples of crystal structures resulting from the intergrowth of blocks, which have at first sight both different compositions and constructions. Such compounds are chloro-oxoruthenates. Their structures are made up of fragments alternating in an ordered manner, one of which has the composition $[Ba_2Cl_2]^{2+}$, while the other is a fragment of the close-packed BaO_3 layers.[77–79] The structure of $Ba_5RuTaO_9Cl_2$ (Fig. 14) is made up of the close-packed fragments separated by two $[BaCl]^+$ layers, each of which is constructed in the same way as the $BaO\square_2$ layer in the compounds $Ba_5R_2Al_2ZrO_{13}$. Some of the barium atoms have under these conditions a coordination environment with CN < 12, where some of the oxygen atoms have been replaced by chlorine.

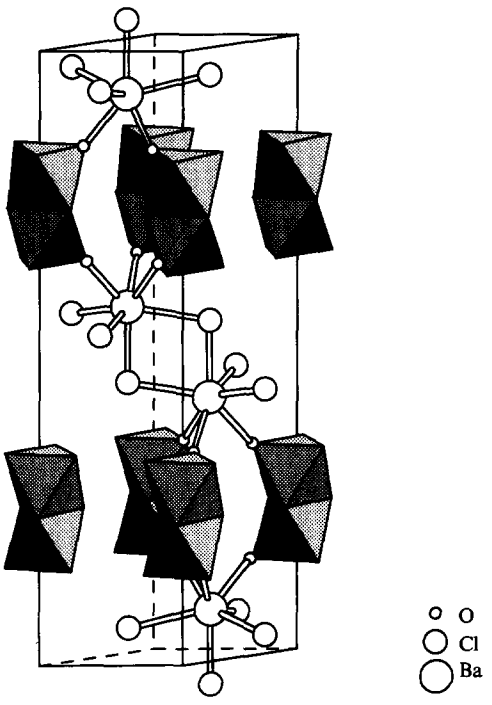

Figure 14. The crystal structure of $Ba_5RuTaO_9Cl_2$.

IV. Conclusion

The value of the prediction of the composition of new phases with high-temperature superconducting properties has been demonstrated in relation to complex copper oxides. New ternary copper, mercury, and barium oxides having high transition temperatures for superconduction have been obtained with the aid of this principle. This is a consequence of the fact that in this instance the CuO_2 layers are least distorted. The replacement of mercury by thallium, bismuth, or lead decreases T_c owing to the distortions of the CuO_2 layer under the influence of the lone pairs of the cations of the given elements.

The formation of oxygen vacancies in coherent intergrowth structures containing blocks of the NaCl and CaF_2 types together with CuO_2 layers alters the type of coordination from the octahedron to the tetragonal pyramid or a dumbbell, depending on the electronic structures of the corresponding ions.

A series of phases, differing in the layered structure and symmetry in the close packing, arise in compounds with alternation of structural blocks along the threefold axis of the perovskite structure (which is a prototype structure). In this case, the common dimensions of the fragments are achieved by altering the cationic composition in the A and B sublattices of the initial structural blocks.

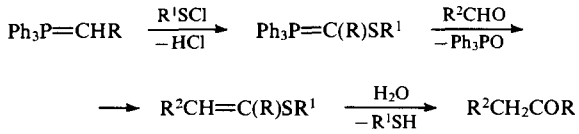
Sulfenyl† chlorides in organic synthesis

I V Koval'

Contents



I. Introduction	731
II. Methods of synthesis	731
III. Syntheses based on sulfenyl chlorides	735

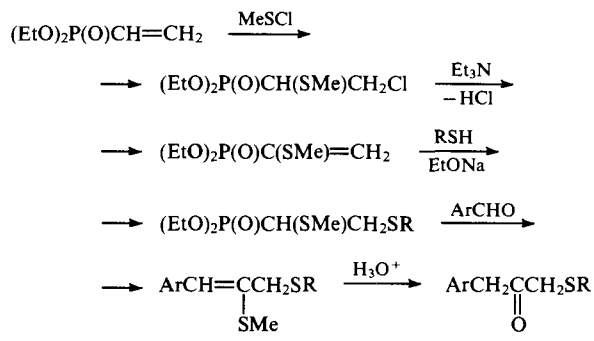
Abstract. The results of studies concerned with the use of sulfenyl chlorides in organic synthesis are described systematically and surveyed. The methods of synthesis of sulfenyl chlorides are also considered. The bibliography includes 271 references.

I. Introduction

Sulfenyl chlorides, which are compounds of divalent sulfur, are highly reactive, and this has led to their extensive employment in organic synthesis. As a consequence of the high polarity and low strength of the S–Cl bond, sulfenyl chlorides readily react with both nucleophiles and electrophiles, which permits their employment for the synthesis of compounds with S–C, S–N, S–O, S–S, S–P, S=O, S=N, etc. bonds. These compounds include sulfides, disulfides, sulfenamines, sulfenates, sulfonates, sulfonyl chlorides, and other valuable products of fine organic synthesis.

Sulfenyl chlorides play an important role in multistep reactions, where they are employed to generate the sulfide functional group, the subsequent specific transformation of which may lead to a wide variety of products of organic synthesis.[1,2] For example, the synthesis of ketones from phosphorus ylides includes a stage in which the sulfide group is generated with the aid of sulfenyl chlorides, this being followed by its removal in the last stage of the synthesis.[3,4]

R = H, Me, COOEt, CN, COPh, 2-$NO_2C_6H_4$;



R^1, R^2 = Alk, Ar.

† It is appreciated that the name 'sulfenyl' is no longer accepted terminology under IUPAC recommendations [*A Guide to IUPAC Nomenclature of Organic Compounds, Recommendations 1993* (Oxford: Blackwell Scientific)]. The extensive use of the term, however, in the Russian literature makes it impracticable to effect a change in this review, but modern nomenclature is more likely in any subsequent review.

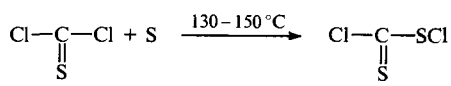
A similar synthetic procedure is employed in the preparative synthesis of α-alkylthioketones from diethyl vinylphosphonates.[1]

The primary products of the reactions of sulfenyl chlorides, for example β-chloroalkyl aryl sulfides, which play an extremely important role in β-arylthioalkylation reactions, have also found extensive applications in organic synthesis.



Bifunctional sulfenyl chlorides, i.e. compounds containing together with the sulfenyl chloride group also other functional groups (Cl, Br, C=O, S–Cl, ClC=O, ClC=N, etc.) are synthetically very important. A whole series of preparative methods of synthesis of diverse sulfur-containing heterocyclic compounds from these products have been developed.

Apart from fine organic synthesis, certain sulfenyl chlorides are employed in macromolecular chemistry as monomers,[5] in the production of widely known biologically active preparations such as phthalan, captan, euparen, and euparen M,[6–8] and also in the manufacture of pharmaceutical preparations[7] and vulcanising agents,[9] which makes them promising for practical purposes.

II. Methods of synthesis

1. Syntheses based on elemental sulfur and its inorganic derivatives

Elemental sulfur is relatively rarely employed in the synthesis of sulfenyl chlorides, which is due to the need for its activation.[10] A single instance of the direct application of elemental sulfur in the synthesis of chlorothiocarbonylsulfenyl chloride by its reaction with thiophosgene has been described in the literature.[11]

Inorganic derivatives of sulfur, for example sulfur chlorides, are much more frequently used in the synthesis of sulfenyl chlorides. Sulfur monochloride is employed in the form of the $SF_4-HF-S_2Cl_2$ system. Several ways of using this system in the synthesis of sulfenyl chlorides have been developed. One of them involves the interaction of the system with alkenes. For example, the reaction of the system with 1,2-dichlorodifluoroethene leads to the formation of 1,2-dichloroperfluoroethanesulfenyl chloride.[12] It is believed[13] that SF_4 and HF promote in this instance the ionisation of S_2Cl_2 and hence its addition to the double bond. The formation of a sulfenyl chloride is also favoured by the presence of fluoride and chloride anions in the reaction mixture.

$$S_2Cl_2 \xrightarrow{HF,\ SF_4} Cl^- + \overset{+}{S}SCl$$

$$SF_4 + 4\,Cl^- \xrightarrow[-4\,F^-]{} SCl_4 \longrightarrow SCl_2 + Cl_2$$

$$CFCl{=}CFCl + \overset{+}{S}SCl \longrightarrow \left[\overset{+}{C}FClCFClSSCl \xrightarrow{F^-} CF_2ClCFClSSCl\right] \xrightarrow{Cl_2} CF_2ClCFClSCl + SCl_2$$

Perfluoroethane-, perfluoro(1-methylethane)-, and perfluoro(1-methylpentane)sulfenyl chlorides have been synthesised similarly.[14,15]

It has been established[12] that the interaction of the $SF_4-HF-S_2Cl_2$ system with asymmetric alkenes, for example with chlorotrifluoroethene, leads to the formation of a mixture of two regioisomers, which is a disadvantage of the method.

$$CF_2{=}CFCl \longrightarrow CF_3CFClSCl + CF_2ClCF_2SCl$$

A second aspect of the use of this system to synthesise sulfenyl chlorides involves its reaction with certain inorganic and organic reagents and subsequent chlorolysis of the products.[16,17]

$$(EtOOC)_2CH_2 \xrightarrow[60\,^\circ C,\ 12\ h]{SF_4-HF-S_2Cl_2} [(EtOOC)_2CFS-]_2 \xrightarrow[28\,^\circ C,\ 4\ h]{Cl_2} (EtOOC)_2CFSCl$$

$$RCF{=}CF_2 \xrightarrow{SF_4-HF-S_2Cl_2} \left[\begin{matrix}RCFSCl\\|\\CF_3\end{matrix} + \begin{matrix}RCFSSCl\\|\\CF_3\end{matrix} + \begin{matrix}RCFSSSCFR\\|\quad|\\CF_3\quad CF_3\end{matrix}\right] \xrightarrow[100\,^\circ C]{Cl_2} \begin{matrix}RCFSCl\\|\\CF_3\end{matrix}$$

R = F, CF_3, Bu, C_6H_{13}.

$$CS_2 \xrightarrow{SF_4-HF-S_2Cl_2} [CF_3SSCF_3 + CF_3SSSCF_3] \xrightarrow{Cl_2} CF_3SCl$$

Several versions of the synthesis of sulfenyl chlorides from sulfur dichloride have been developed. The first of these consists in its addition to the multiple bonds of unsaturated compounds. For example, the synthesis of phosphorus-containing sulfenyl chlorides by the addition of SCl_2 to the C=C bonds of vinyl- and allyl-phosphonates has been described.[18]

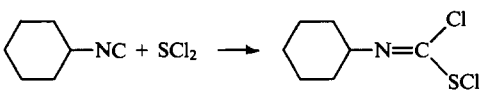
$$(AlkO)_2P(O)CH{=}CH_2 \xrightarrow{SCl_2} (AlkO)_2P(O)CH(CH_2Cl)SCl$$

$$R_2P(O)CH_2CH{=}CH_2 \xrightarrow{SCl_2} R_2P(O)CH_2CH(Cl)CH_2SCl$$

R = Cl, C_2H_5O.

The formation in certain cases of a mixture of two isomeric sulfenyl chlorides which are difficult to separate, as happens, for example, in the reaction of SCl_2 and methyl methacrylate,[19] should also be included among the disadvantages of this method.

$$MeOCOC(Me){=}CH_2 + SCl_2 \longrightarrow \begin{cases} MeOCOC(Me)(SCl)-CH_2Cl & 71\% \\ MeOCOC(Me)(Cl)-CH_2SCl & 29\% \end{cases}$$



In the presence of fluorosulfonic acid, sulfur dichloride reacts with hexafluoropropene by a coupled addition mechanism, the subsequent elimination of hydrogen chloride, and the formation of the corresponding sulfenyl chloride.[20,21]

$$CF_3CF{=}CF_2 \xrightarrow[-HCl]{SCl_2,\ HSO_3F,\ 40-60\,^\circ C} \begin{matrix}CF_3-CF-CF_2OSO_2F\\|\\SCl\end{matrix} \quad 75\%$$

Under the conditions of specific solvation of the S–Cl bond (in acetonitrile, benzonitrile, SO_2, etc.), SCl_2 reacts with hexafluorodimethylketene, affording the corresponding sulfenyl chloride.[22]

$$(CF_3)_2C{=}C{=}O + SCl_2 \longrightarrow (CF_3)_2C\begin{matrix}C(O)Cl\\SCl\end{matrix}$$

The addition of sulfur dichloride to isonitriles is used in the synthesis of chloroiminomethanesulfenyl chlorides.[11]

The second version of the use of sulfur dichloride in the synthesis of sulfenyl chlorides involves the sulfenylation of CH acids, for example isobutyronitrile in the synthesis of α-cyanoisopropanesulfenyl chloride.[23]

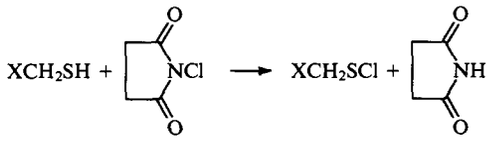
$$Me_2CHCN + SCl_2 \longrightarrow \begin{matrix}Me_2C-SCl\\|\\CN\end{matrix}$$

2. Syntheses based on thiols

The chlorolysis of the S–H bond in thiols on treatment with chlorinating agents is used very frequently in the synthesis of sulfenyl chlorides. A series of preparative methods of synthesis of arene-,[24] polyfluoroalkane,[25,26] and trichlorothiophene-sulfenyl chlorides[27] have been developed on the basis of this reaction. In order to avoid the hydrolysis of the sulfenyl chlorides formed and also to diminish the possibility of *C*-chlorination, the reaction is carried out in anhydrous inert solvents in the absence of ultraviolet light. This is a three-stage process with participation of disulfides as intermediates.[24,28]

$$RSH + Cl_2 \longrightarrow RSCl + HCl$$

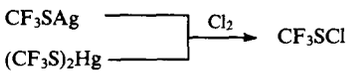
$$RSH + RSCl \longrightarrow RSSR + HCl$$



$$RSSR + Cl_2 \longrightarrow 2\,RSCl$$

Sulfuryl chloride is a milder chlorinating agent than chlorine.[24,28] It too can induce *C*-chlorination, which has been observed in the case of methane-thiols with functional group substituents.[29,30]

$$XCH_2SH + 3\,SO_2Cl_2 \longrightarrow XCCl_2SCl + 3\,HCl + 3\,SO_2$$

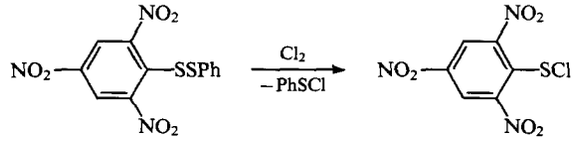


X = CN, $PhSO_2$, ArNHCO, RCO etc.

N-Chlorosuccinimide is frequently employed as a chlorinating agent in order to avoid the chlorination of α-C–H bonds.[31,32]

X = Ph, EtOOC, HOOC.

In the case of unstable or gaseous thiols, the use of their silver or mercury salts is more convenient.[33]



3. Syntheses based on disulfides

The chlorolysis of the S–S bond in disulfides on treatment with chlorine or other chlorinating agents in anhydrous organic solvents is one of the commonest methods of synthesis of sulfenyl chlorides.[24,28,32–44]

$$RSSR + Cl_2 \longrightarrow 2\,RSCl$$

R = Alk, Ar, Het, $CH_2ClCH(CF_3)$, $CF_3CHClCH_2$, $CF_3OCFClCF_2$, CF_2ClCF_2, CCl_2FCF_2, $CF_3CF_2CF_2$, $CF_3(CF_2)_6$, $(CF_3)_2CFOCF_2$, $(CF_3)_2CF$ etc.

Since the rate of chlorolysis of the S–S bond in disulfides depends on the nucleophilicity of the sulfur atoms, electron-accepting groups attached to a sulfur atom hinder the process. In such cases, it is recommended[45,46] that catalysts such as iodine, aluminium and iron chlorides, oleum, sulfuric acid, etc. be employed. In order to reduce the influence of strong electron-accepting groups on the chlorination process, asymmetric compounds, containing an electron-donating group as well as an electron-accepting group, are sometimes employed instead of symmetrical disulfides.[47]

In the case of disulfides containing α-C–H bonds, there is a possibility, of the chlorolysis also of C–H bonds together with that of the S–S bond.[24,28,48] In order to avoid this process, it is recommended that sulfuryl chloride,[49–53] *N*-chlorosuccinimide,[54] and other *N*-halo-derivatives[55,56] be used as chlorinating agents.

4. Syntheses based on sulfides

One of the important methods of synthesis of sulfenyl chlorides is the specific chlorolysis of one of the C–S bonds in sulfides. This method makes it possible to obtain sulfenyl chlorides with a wide variety of structures, including those containing powerful electron-accepting groups attached to the sulfur atom. The ease of chlorolysis of the C–S bond in sulfides is determined primarily by the nature of the leaving group, the structure of the initial sulfide, and the chlorolysis conditions. Sulfides containing a readily removable group such as the benzyl,[57–65] acyl,[61,66–68] and *tert*-butyl[69] groups are most often employed in the synthesis of sulfenyl chlorides.

$$RSCH_2Ph + Cl_2 \longrightarrow RSCl + PhCH_2Cl$$

R = 2,4,6-$(NO_2)_3C_6H_2$, CHF_2, CCl_2F, CF_3, C_2HF_4, $(CF_3)_2CHCF_2$, CF_3CFCl, $(CF_3)_2CF$, $CHFClCF_2$, $(CF_3)_2C{=}CF$, $(CF_3)_2C{=}C(I){-}C_2F_5$ etc.

$$RSAc + SO_2Cl_2 \longrightarrow RSCl + AcCl + SO_2$$

R = Me, Bu, Bu^i, Bu^t, 2-MeC_6H_4, Ph, $PhCH_2$, 4-$NO_2C_6H_4$, $MeOCOCH_2CH_2$, $PhC{\equiv}C$.

$$RSCMe_3 \xrightarrow[10\,^\circ C]{SO_2Cl_2} RSCl + Me_3CCl + SO_2$$

R = $MeOCOCH(CF_3)CF_2$, $MeOOC{=}CF(CF_3)$.

A series of methods of synthesis of sulfenyl chlorides involving the chlorination of sulfides containing leaving groups such as the chloromethyl,[33] methyl,[70] and ethyl[71] groups have been described.

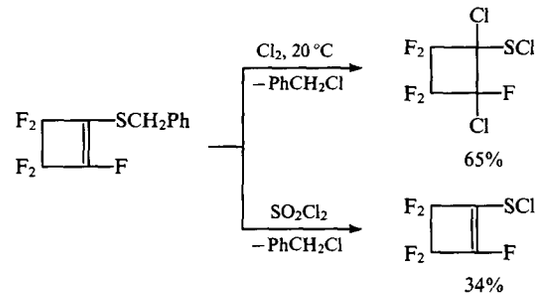
$$CF_3SCH_2Cl + Cl_2 \longrightarrow CF_3SCl + CH_2Cl_2$$

$$XC(=O)CH_2SMe + 3\,SO_2Cl_2 \longrightarrow XC(=O)CCl_2SCl + MeCl + 3\,SO_2 + 2\,HCl$$

X = Ph–N(CHMe$_2$)–

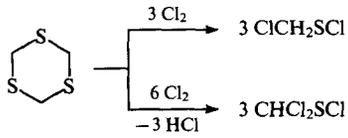
$$MeOCOCF_2CF_2SEt + Cl_2 \xrightarrow[-EtCl]{CF_3COOH,\ 25\,^\circ C} MeOCOCF_2CF_2SCl$$

It has been noted[72] that the interaction of 1-thiocyanatobutan-3-ol with phosphorochloridous tetraethyldiamide in the presence of triethylamine at 30 °C proceeds with the cleavage of the C–S bond and the formation of 3-hydroxybutanesulfenyl chloride.



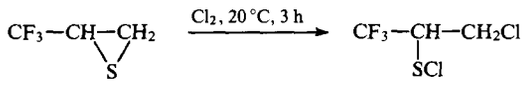
$$HOCH(Me)CH_2CH_2SCN + (Et_2N)_2PCl \longrightarrow HOCH(Me)CH_2CH_2SCl + (Et_2N)_2PCN$$

The chlorolysis of the C–S bond in sulfides containing active α-C–H bonds is accompanied by the *C*-chlorination of the alkyl group, which is used in the synthesis of dichloromethanesulfenyl chlorides with functional group substituents.[70,73]



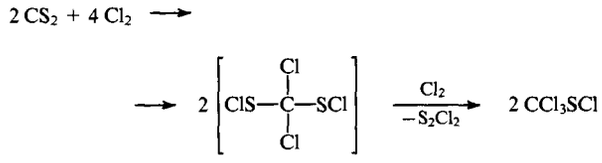
$$XCH_2SCH_2Ph + 2\,SO_2Cl_2 \xrightarrow[-2\,SO_2,\ -2\,HCl]{} [XCCl_2SCH_2Ph] \xrightarrow[-SO_2]{SO_2Cl_2} XCCl_2SCl + PhCH_2Cl$$

X = CN, $C_6H_4SO_2$, EtOCO, 4-ClC_6H_4OCO, HOCO, Alk_2NCO, ArNHCO, CF_3 etc.



The chlorolysis of the C–S bond in alkenyl benzyl sulfides is accompanied as a rule by the addition of chlorine to the C=C bond.[58,63] The use of sulfuryl chloride instead of chlorine rules out the side reaction, as happens, for example, in the chlorination of benzyl pentafluorocyclobutenyl sulfide.[58]

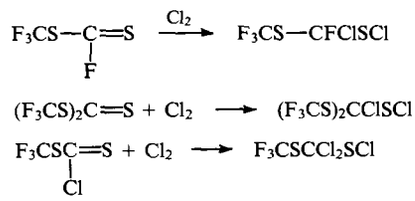
Cyclic sulfides undergo chlorolysis to form sulfenyl chlorides. For example, the chlorination of trithiane with chlorine leads to chloromethane- and dichloromethane-sulfenyl chlorides depending on the conditions.[74]



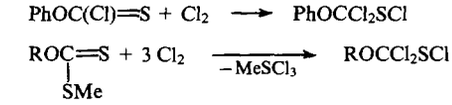
The analogous chlorination of trifluoromethylthiirane yields 1-chloro-2-chlorosulfenyl-3,3,3-trifluoropropane.[75]

5. Syntheses based on thiocarbonyl compounds

The use of thiocarbonyl compounds in the synthesis of sulfenyl chlorides is based on the addition of chlorine to the C=S bond. For example, reaction of Cl_2 with carbon disulfide is the basis of the industrial synthesis of trichloromethanesulfenyl chloride (TCMSC).[33]

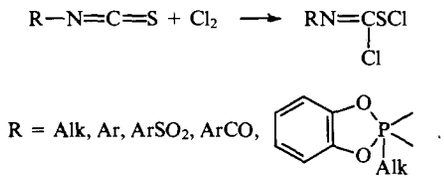


This reaction has been used to synthesise perhaloalkanesulfenyl chlorides.[63,76-83]

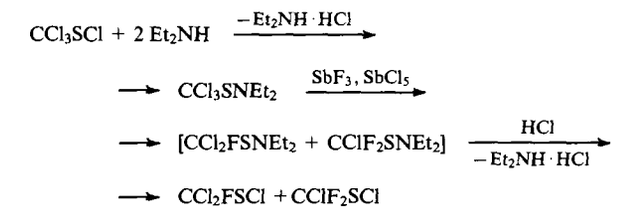


X = Cl, Br, F, CF_3, Et; Y = Br, F, $(CF_3)_2CH$, $(CF_3)_2CCl$.

X = Cl, Br, F.

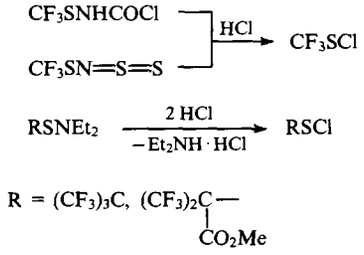


The addition of chlorine to the C=S bond in chlorides and esters of thiocarbonic and dithiocarbonic acids is the basis of the synthesis of α,α-dichloromethanesulfenyl chlorides with functional group substituents.[74]



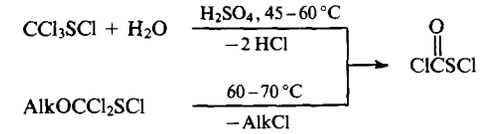
R = Me, Et.

One of the methods of synthesis of chloroiminomethanesulfenyl chlorides is based on the addition of chlorine to the C=S bond in isothiocyanates.[28,83,84]



6. Syntheses based on sulfenamides

A familiar procedure for the formation of the sulfenyl chloride group involves heterolytic cleavage of the S–N bond in sulfenamides on treatment with gaseous HCl.[85-87] However, this reaction is used fairly rarely, since in most cases sulfenamides are obtained from the sulfenyl chlorides into which they are converted on hydrochlorolysis of the S–N bond. As a synthetic procedure, the conversion of the sulfenyl chloride group into the sulfenamide group with subsequent hydrochlorolysis of the S–N bond is used to protect the sulfenyl chloride group in the modification of groups attached to the sulfur atom, as happens, for example, in the conversion of TCMSC into dichlorofluoro- and chlorodifluoro-methanesulfenyl chlorides.[33]



Instances of the synthesis also of other fluoroalkanesulfenyl chlorides using the hydrochlorolysis of the S–N bond in the corresponding sulfenamides are known.[88-90]

7. Modification of the functional groups in sulfenyl chlorides

The specific modification of the various functional groups attached to the sulfur atom in sulfenyl chlorides has been used very frequently in the synthesis of new types of these compounds. TCMSC is particularly valuable in this respect. Its partial hydrolysis in concentrated sulfuric acid leads to chlorocarbonylsulfenyl chloride,[11,33,74] which is also formed on thermolysis of alkoxydichloromethanesulfenyl chlorides.[11]

Alk = Me, Et.

The interaction of TCMSC with potassium fluoride can lead to the stepwise substitution of the chlorine atoms by fluorine.[33]

$$CCl_3SCl \xrightarrow[-KCl]{KF} CFCl_2SCl \xrightarrow[-KCl]{KF}$$

$$\longrightarrow CF_2ClSCl \xrightarrow[-KCl]{KF} CF_3SCl$$

A relatively large number of sulfenyl chlorides have been obtained by modification of the COCl group of chlorocarbonylsulfenyl chloride. For example, the replacement of the chlorine atom in this group by fluorine can be achieved with the aid of antimony trifluoride.[82]

$$ClC(=O)SCl \xrightarrow{SbF_3} FC(=O)SCl$$

The chlorine atom is replaced by the alkoxy-group in the interaction of chlorocarbonylsulfenyl chloride with alcohols in molar proportions of 1:1.[11]

$$ROH + ClC(=O)SCl \xrightarrow[-HCl]{} ROC(=O)SCl$$

R = Me, Et, Pr, C_8H_{17}, $ClCH_2CH_2$, $PhCH_2CH_2$, $MeOCH_2CH_2$.

8. Other methods of synthesis

Among other methods of synthesis, mention may be made of (a) the addition of sulfenyl chloride to the C=S bond in thiocarbonyl compounds:[82]

$$F_2C{=}S + F_3CSCl \longrightarrow CF_3CSCF_2SCl;$$

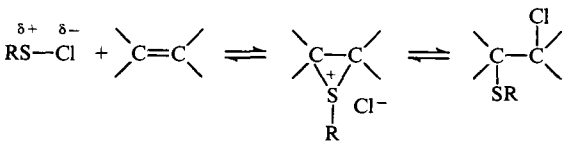
(b) the chlorolysis of the S–P bond in the alkyl esters of phosphorothioic acids:[68]

$$RSP(=O)(OEt)_2 \xrightarrow{SO_2Cl_2} RSCl + (EtO)_2P(O)Cl + SO_2,$$

R = $(CF_3)_2CHCF_2$, $(CF_3)_2CHCO$;

(c) the chlorolysis of the S–Si bond in thiosilanes.[91]

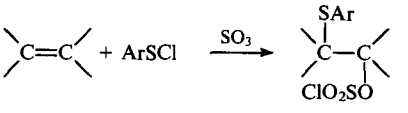
$$RSSiMe_3 \xrightarrow[-Me_3SiCl]{Cl_2} RSCl$$



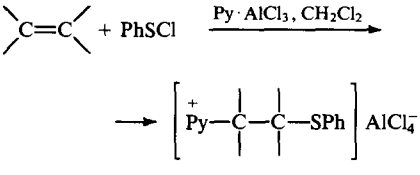
III. Syntheses based on sulfenyl chlorides

1. Syntheses of sulfides

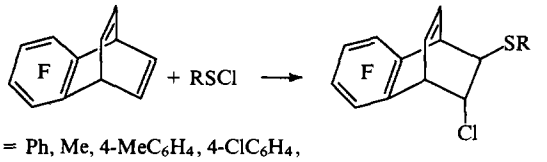
The synthesis of sulfides from sulfenyl chlorides has been described in detail in the present author's earlier review[2] and in the literature quoted therein and only the synthesis of sulfides with functional group substituents, which play an important role in organic synthesis, will therefore be considered in the present review.



a. Synthesis of aryl β-chloroalkyl sulfides

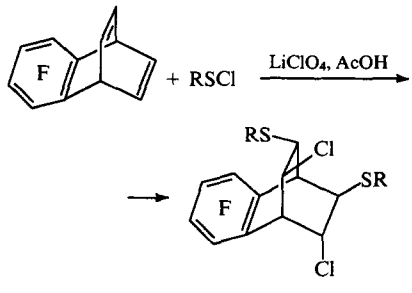


A classical method of synthesis of β-chloroalkyl sulfides involves the addition of sulfenyl chloride to the C=C bond in unsaturated compounds, which proceeds under mild conditions and with high yields.[2,4,24,28,46,92–97] The mechanism of this reaction has been discussed in detail in a series of review publications.[2,4,24,28,46] It has been suggested that the reaction proceeds via an Ad_E2 mechanism, in which an episulfonium ion is a cationic intermediate and which leads as a rule to stereospecific *trans*-addition.[28]

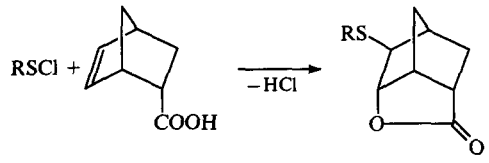


Quantum-mechanical calculations for the $C_2H_4SH^+$ ion have shown[98] that the bridged episulfonium ion is more stable as an intermediate than a linear carbenium ion. When the process is subject to kinetic control, the composition of the products of the addition reaction reflects the relative rate of substitution at the ring carbon atom of the episulfonium ion. The presence of α-substituents, which increase the reactivity in reactions of the S_N2 type (Ph, C=O, C≡N, CH=CH_2, etc.), increases the relative rate of addition, whereas alkyl groups or other bulky substituents diminish the relative rate of this reaction. Terminal alkenes therefore react with sulfenyl chlorides by anti-Markovnikov addition, whereas styrenes, acrylic acid derivatives, and dienes combine with sulfenyl chlorides in accordance with the Markovnikov rule.[28,99]

In order to increase the effective electrophilicity of the episulfonium ion and to substitute the chloride anion by other nucleophiles, it has been suggested that the coupled addition of sulfenyl chlorides be carried out in the presence of strong electrophiles such as $LiClO_4$,[100–103] SO_3,[104] and $PyAlCl_3$.[105] The episulfonium cations formed under these conditions react even with weak nucleophiles such as acetonitrile.[100–103]

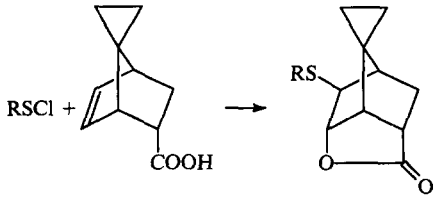


The use of lithium perchlorate in the reaction of sulfenyl chlorides with polycyclic dienes induces various side processes (skeletal rearrangements, etc.). For example, the addition of sulfenyl chlorides to tetrafluorobenzobarrelene in CH_3COOH, CH_3NO_2, and CH_2Cl_2 takes place in the *exo*-position with formation of *trans*- β-halo-substituted sulfides, whereas in the presence of lithium perchlorates the reaction proceeds with participation of two C=C bonds.[106]



R = Ph, Me, 4-MeC_6H_4, 4-ClC_6H_4,
2-$NO_2C_6H_4$, 4-$NO_2C_6H_4$, 2,4-$(NO_2)_2C_6H_3$.

R = 4-MeC_6H_4.



It has been noted[107] that the addition of polyfluoroalkanesulfenyl chlorides to norborn-5-ene-2-carboxylic acid under mild conditions (−20–0 °C) is accompanied by the lactonisation of the adducts.

R = $ClCH_2CH_2\underset{\displaystyle CF_3}{\underset{|}{C}}H$, CF_2ClCF_2, $CFCl_2CF_2$,

$ClCH_2\underset{\displaystyle CF_3}{\underset{|}{C}}Cl$, $MeOOC\overset{\displaystyle CF_3}{\overset{|}{C}}CF_3$

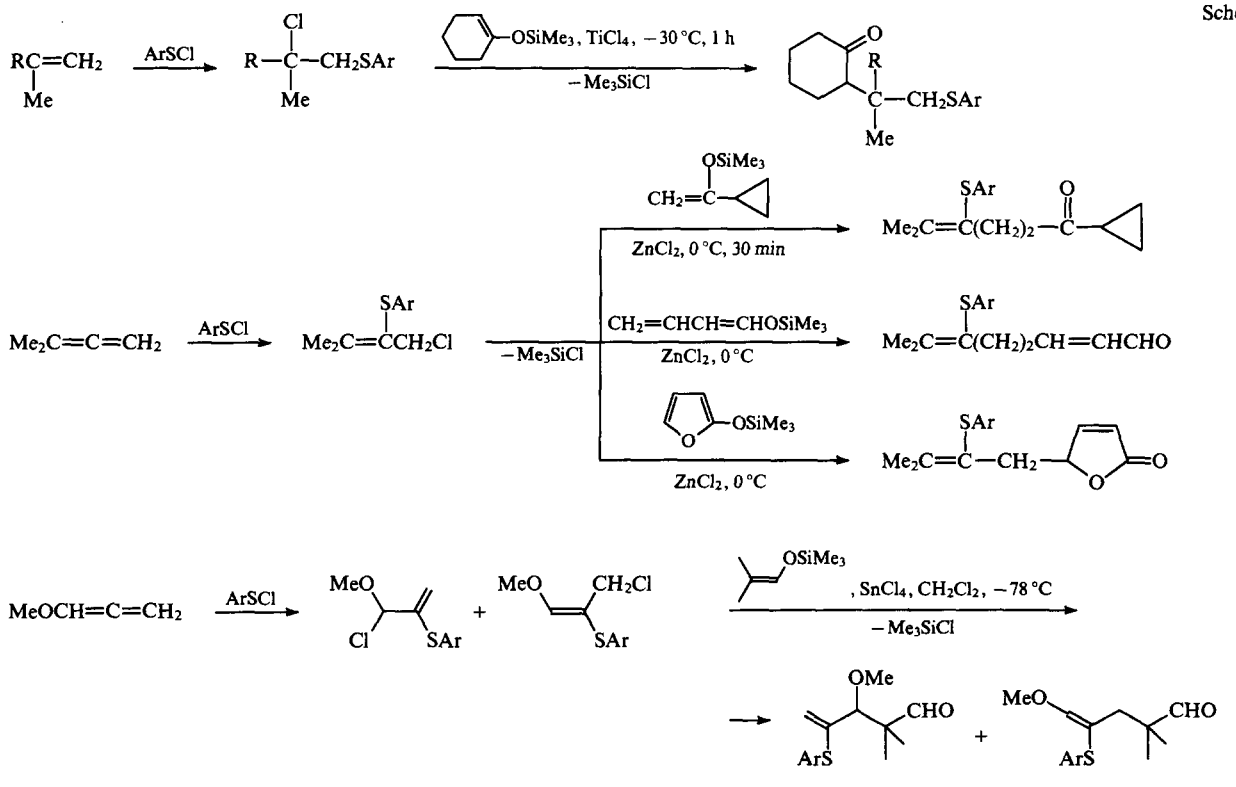
Spiro(2-carboxybicyclo[2.2.1]hept-5-ene-7,1'-cyclopropane) reacts similarly with sulfenyl chlorides.[108]

R = $ClCH_2\underset{\displaystyle CF_3}{\underset{|}{C}}H$, $MeOOC\overset{\displaystyle CF_3}{\overset{|}{C}}CF_3$

Under more severe conditions (20 °C and above), the formation of mixtures of the corresponding lactones and the products of the *endo*- and *exo*-addition to the C=C bond was observed.[108]

In certain cases, the stability of the episulfonium ion diminishes so much that the addition of sulfenyl chlorides to the C=C bond proceeds with participation of an open-chain carbenium ion with loss of stereospecificity.[15] Examples of such reactions are the addition of 2,4-dinitrobenzenesulfenyl chloride to *cis*-anethole[109] and also the addition of benzenesulfenyl chloride to strained cyclobutenes.[110] It has been noted[111] that the addition of sulfenyl chlorides to alkenes in weakly polar solvents proceeds via intermediates less polar than episulfonium salts. Kinetic studies of the addition of arenesulfenyl chlorides to *para*-substituted styrenes led to the conclusion[111] that a whole range of structures from nonpolar (σ-sulfurane) to ionic (episulfonium ion) as intermediates is possible. It has also been suggested that an ion-pair mechanism may be possible in the case of the addition of sulfenyl chlorides to alkenes in acetic acid.[112]

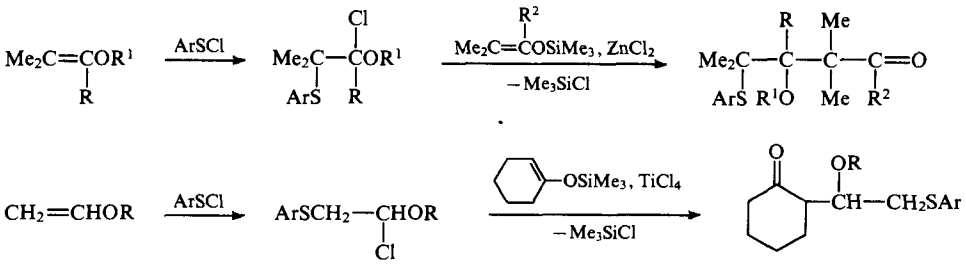
In the presence of Lewis acids ($TiCl_4$, $LiClO_4$) and also on dissolution in liquid SO_2, β-chloroalkyl sulfides are readily converted into episulfonium salts, which are widely used in β-arylthioalkylation reactions in order to expand the range of sulfides with functional group substituents.[10,112,113] However, it has proved more convenient to carry out this reaction using the aryl β-chloroalkyl sulfide–$TiCl_4$ (or $ZnCl_2$, $SnCl_4$) system, by-passing the stage involving the formation of a stable episulfonium salt, as happens, for example, in the interaction with trimethylsilyl ethers of enols (Scheme 1).[10,114–119]



According to Ibragimov and Smit,[117] the β-arylthio-α-alkoxyalkylation of various types of trimethylsilylenol ethers is accompanied by their reaction with the products of the addition of arene-sulfenyl chlorides to vinyl ethers (Scheme 2).

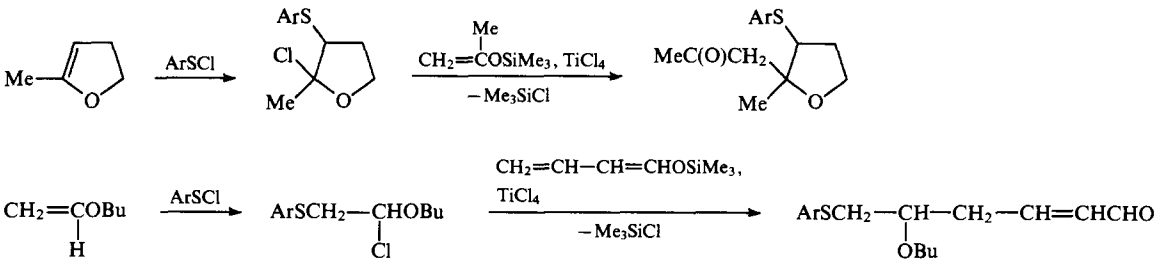
According to Belen'kii[10] and Ibragimov et al.,[120] the overall outcome of these reactions reduces to the chemoselective aldol condensation of two carbonyl compounds with the simultaneous introduction of a γ-arylthio-substituent, which leads to the additional possibility of subsequent reactions at this centre.

Similar results have been obtained when methyl trimethylsilyl acetals of ketene were used as π-donors (Scheme 3).[10,121]

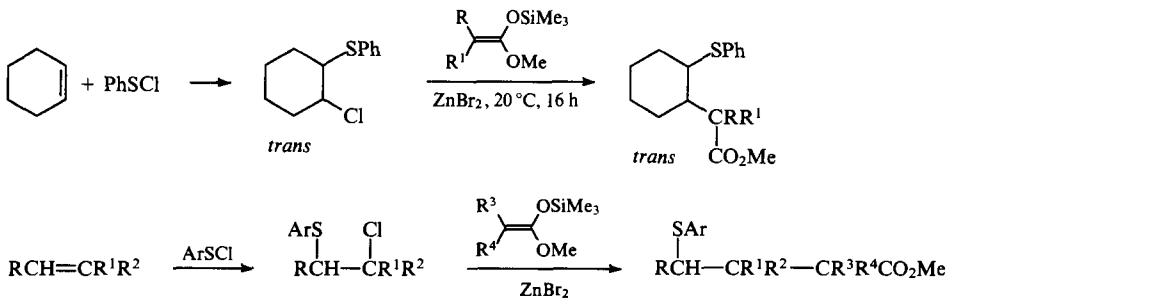


In the presence of $TiCl_4$ or $ZnBr_2$, allylsilanes also react with aryl β-haloalkyl sulfides (Scheme 4).[121–123]

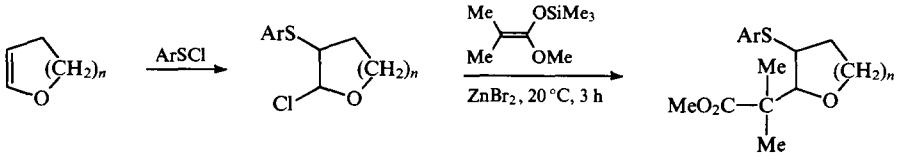
Scheme 1



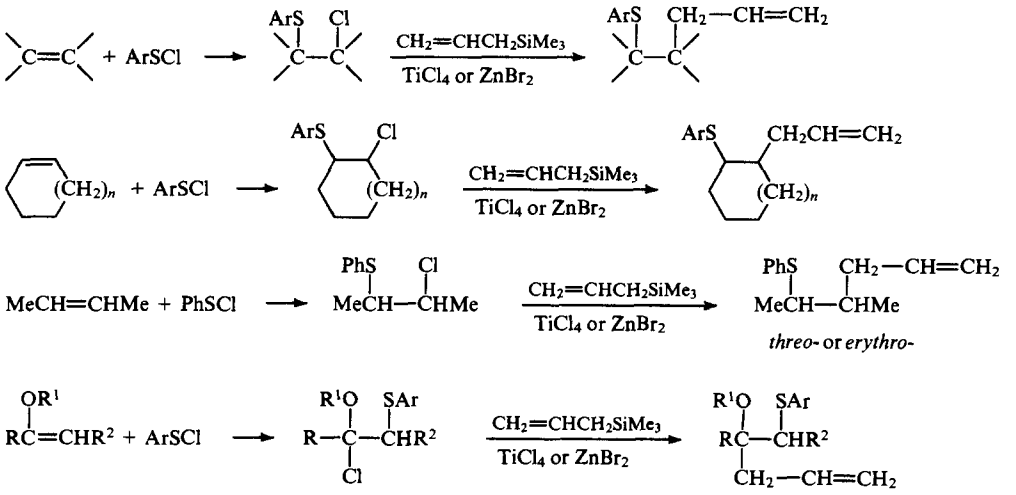
Ar = 4-MeC_6H_4, 4-ClC_6H_4, 2,4,6-$Me_3C_6H_2$.



Scheme 2

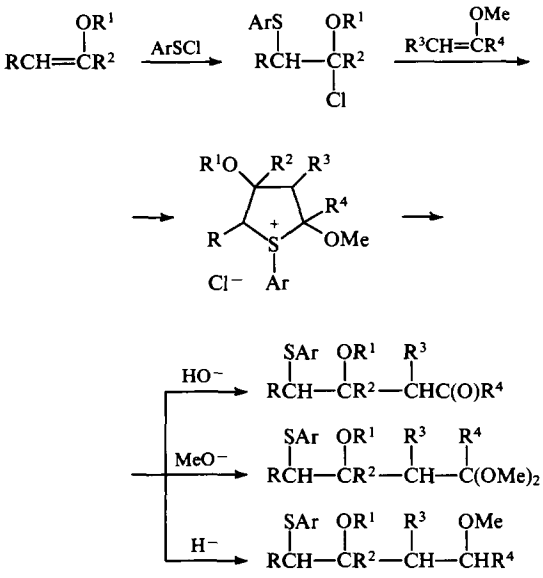


R = Me, Bu^t.

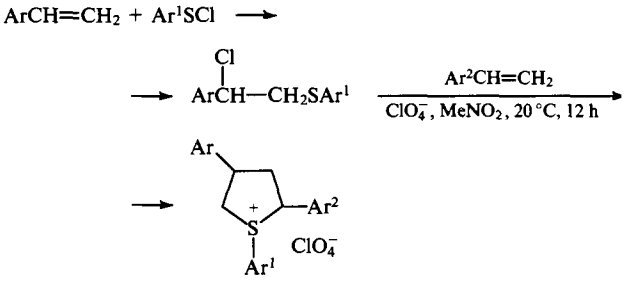


Scheme 3

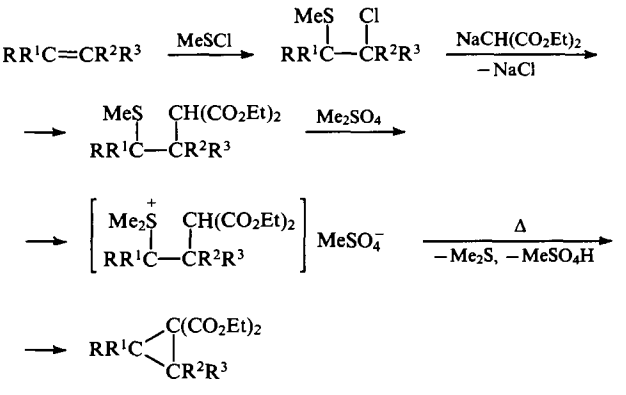
R = R^1 = R^2 = R^3 = R^4 = H, Alk.



Scheme 4

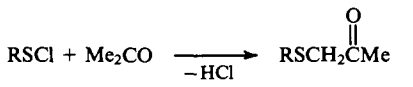


R = R^2 = H; R^1 = Et; R = H, R^1 + R^2 = $-(CH_2)_2-$; R = Me, R^1 + R^2 = $-(CH_2)_2-$.

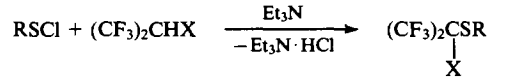


In the interaction of aryl β-chloroalkyl sulfides with vinyl ethers in proportions of 1:1, cyclic S-cationoid intermediates are formed. These react further with nucleophiles to form various sulfides having functional group substituents.[10,122,123]

β-Chloroalkyl sulfides react similarly with styrene and its homologues,[124] which involves the stabilisation of the intermediates in the form of tetrahydrothiophenium perchlorate.



The reaction of β-chloroalkyl sulfides with *C*-nucleophiles, which may be used to create new carbon–carbon bonds, is synthetically very important. However, it is not always possible to achieve this reaction, since it has been noted,[10] for example, that, in the presence of *C*-nucleophiles such as organolithium or organomagnesium compounds, β-chloroalkyl sulfides undergo elimination. Only when sodiomalonic ester was used as the *C*-nucleophile was it possible to obtain the corresponding β-aryl(alkyl)thioalkylation products, which were subsequently converted into cyclopropane derivatives.[125]

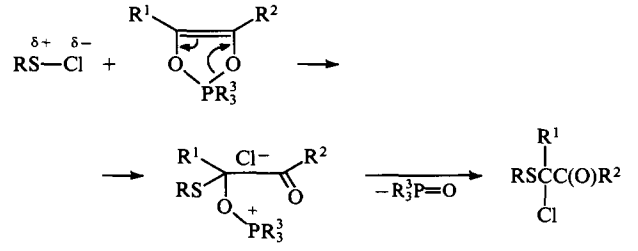


b. Syntheses of oxo-substituted sulfides

One of the commonest methods of synthesis of oxo-substituted sulfides is the sulfenylation of carbonyl compounds containing reactive C–H bonds. For example, sulfenyl chlorides react relatively easily in the cold with ketones having α-hydrogen atoms, forming β-oxo-substituted sulfides.[33]

R = Ar, Alk.

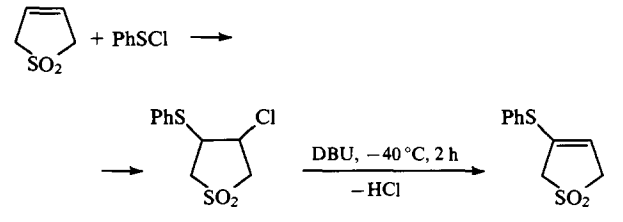
Fluorine-containing CH acids interact with sulfenyl chlorides only in the presence of triethylamine.[126]



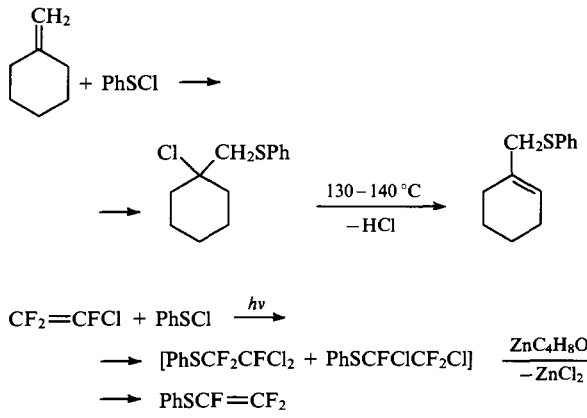
X = PhCO, CF_3CF_2CO, FCO.

In their reactions with sulfenyl chlorides, phosphorus ylides containing a carbonyl group readily exchange a hydrogen atom of the methylene group for an alkylthio- or arylthio-group even in the absence of bases.[3]

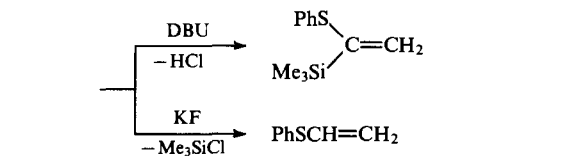
Dibenzoylmethane,[127,128] acetoacetic ester,[129,130] acetylacetone,[131] and even malonic ester[132,133] react similarly with alkanesulfenyl chlorides.



Another aspect of the use of sulfenyl chlorides in the synthesis of oxo-substituted sulfides involves the reaction of sulfenyl chlorides with vinyloxy[131–137] and divinyloxy-silanes[138] and also with the enols of dibutylborinates.[139] This reaction proceeds via stages involving 1,2-addition of the sulfenyl chloride and the elimination of chlorotrimethylsilane or dibutylchloroborane.

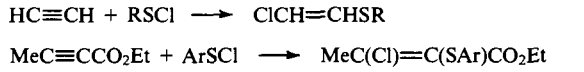


The synthesis of β-oxoalkyl sulfides from sulfenyl chlorides and 1,3,2-dioxaphospholenes has been described.[140] It has been suggested[28] that this reaction proceeds via a polar mechanism.



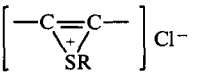
c. Synthesis of unsaturated sulfides

Several variants of the synthesis of unsaturated sulfides from sulfenyl chlorides have been developed. One of them involves the addition of sulfenyl chlorides to the C=C bond of unsaturated compounds with subsequent dehydrochlorination or dechlorination of the adducts. This variant has been used widely in the syntheses of vinyl[8,141] and allyl sulfides.[142,143] Potassium *tert*-butoxide, 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU), triethylamine, and other organic bases are used as the dehydrochlorinating agents.

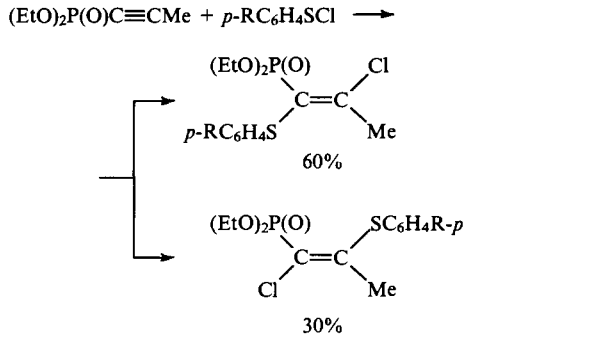


β-Chloro-α-(trimethylsilyl)ethyl phenyl sulfide, which is a product of the reaction of benzenesulfenyl chloride with trimethylvinylsilane, can undergo dehydrochlorination or dechlorotrimethyldesilylation, depending on the conditions, with formation of two different vinyl sulfides.[144]

2-Chlorovinyl sulfides are formed as a result of the reaction of sulfenyl chlorides with ethyne and its homologues.[10,145,146]

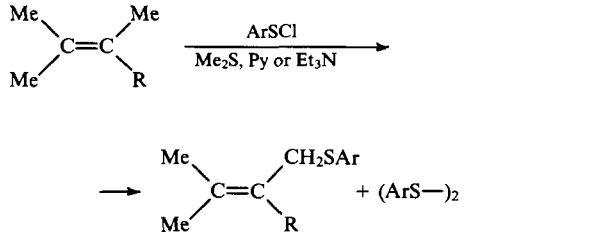


This reaction is slower than that of sulfenyl chlorides with alkenes, catalysts, for example aluminium chloride, being used sometimes to accelerate it.[10] The addition of sulfenyl chlorides to alkylethynes is mainly anti-Markovnikov and the products formed are not isomerised further.

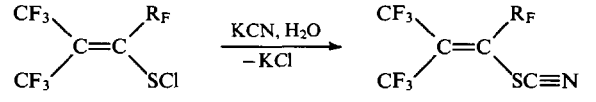


The mode of addition is influenced appreciably by the nature of the solvent and of the substituents. For example, the content of the Markovnikov addition product increases in acid media, a small amount of the *cis*-adduct being also formed together with the *trans*-adducts under these conditions.

It has been suggested[10] that Markovnikov addition occurs predominantly in those cases where the reaction conditions and the nature of the substituents favour the formation of a highly polar intermediate of the thiirenium salt type.

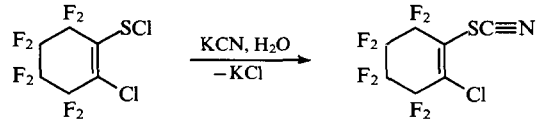


In anti-Markovnikov addition, the intermediate formed initially apparently decomposes. The addition of arenesulfenyl chlorides to diethyl propynylphosphonate takes place stereoselectively with formation of two regioisomers having the (*E*)-configuration in proportions of 2:1.[147]



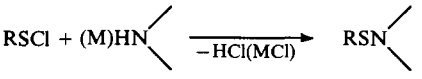
R = H, Me.

It has been noted[148] that, when internal alkenes reacted with arenesulfenyl chlorides in the presence of dimethyl sulfide, pyridine, or triethylamine, the hydrogen of the alkene methyl group is substituted by the arenesulfenyl fragment with formation of unsaturated sulfides. A proportion of the sulfenyl chloride is then converted into the disulfide.



R = CH_3, 4-$MeOC_6H_4$; Ar = 4-MeC_6H_4, 4-ClC_6H_4.

The synthesis of perfluorinated α,β-unsaturated thiocyanates, by reaction of perfluorinated α,β-unsaturated sulfenyl chlorides with potassium cyanide in an aqueous medium, has been described.[149] This reaction proceeds under mild conditions (5–10 °C, 20 min) and gives high yields of the target products (50%–70%).



R_F = F, C_2F_5.

2. Syntheses of sulfenamides

One of the most important reactions of sulfenyl chlorides is that with compounds containing N–H or N–M (M = Na, K, Ag) bonds.

A whole series of preparative methods of synthesis of sulfenamides, including biologically active preparations, have been developed on the basis of this reaction.[13,85–87,150] Depending on the nature of the sulfenyl chloride and the compound containing the NH group, the sulfenylation is carried out in anhydrous inert organic solvents in the presence of hydrogen chloride acceptors (pyridine, triethylamine) or aqueous alkaline media. The sulfenylation of ammonia,[151–154] primary[155–159] and

secondary[160–165] amines, hydrazines and hydrazides,[28] the amides of carboxylic,[165–171] sulfonic,[172–177] and phosphoric[178,179] acids, cyanamide,[180,181] imides,[27,160] phosphine imines[182–184] and sulfine imines,[185,186] imidoesters,[187] sulfinamidines,[188] silazanes,[89,189–191] glycine derivatives,[192–197] and nitrogen-containing heterocyclic compounds[33,198] has been described. Instead of amines and amides, their silylated derivatives are introduced in certain cases into the reaction with sulfenyl chlorides. The interaction of these derivatives with sulfenyl chlorides entails the cleavage of the N–Si bond and the formation of the N–S bond.[199,200]

$$2\,ArSCl + (Me_3Si)_2NR \xrightarrow[-2\,Me_3SiCl]{} (ArS)_2NR$$

Ar = 4-$NO_2C_6H_4$, $PhCH_2$, Ac, $PhSO_2$

$$RSCl + Me_3SiN(Me)_2 \xrightarrow[-Me_3SiCl]{} RSN(Me)_2$$

R = Me, CCl_3, Ph, 2-$NO_2C_6H_4$.

The second aspect of the use of sulfenyl chlorides in the synthesis of sulfenamides involves their addition to the C≡N bond.[33] The reactions of TCMSC with 2,4-dimethylphenyl cyanate[33,201] and *N*-benzoylcyanamide,[202] of dichlorofluoromethanesulfenyl chloride with chlorocyanogen,[203] and of trifluoromethanesulfenyl chloride with tetracyanoethene[203] and chloro-cyanogen[204] take place in this way.

$$X{-}C{\equiv}N + ClSR \longrightarrow X{-}\underset{\displaystyle Cl}{\underset{|}{C}}{=}NSR$$

X = 2,4-$Me_2C_6H_3O$, PhCONH, $(NC)_2C{=}CCN$, Cl;

R = CCl_3, CF_3.

In the presence of mercury difluoride, trifluoromethanesulfenyl chloride adds readily to the C=N bond of chlorocyanogen and trifluoroacetonitrile and trichloroacetonitrile.[205] The interaction is accompanied by the substitution of chlorine by fluorine.

$$CF_3SCl \xrightarrow{HgF_2,\ 20\,^\circ C} \begin{cases} \xrightarrow{ClCN} CF_3N(SCF_3)_2 \\ \xrightarrow{CF_3CN} CF_3C(F){=}NSCF_3 \\ \xrightarrow{CCl_3CN} CCl_3C(F){=}NSCF_3 \end{cases}$$

The reactions of sulfenyl chlorides with cyanamide and its *N*-alkyl derivatives are accompanied by the sulfenylation of the amido-group.[206,207]

$$3\,XNHC{\equiv}N + 4\,RSCl \xrightarrow{0\,^\circ C,\ Et_2O} 2\,RSN(X)C(Cl){=}NSR + XNHCN\cdot 2\,HCl$$

R = CCl_3, $CFCl_2$, CF_3.

The third aspect of the use of sulfenyl chlorides in the synthesis of sulfenamides involves their conversion into sulfenyl isocyanates and subsequent treatment of the latter with ammonia, amines, or alcohols.[208–211] As a rule sulfenyl isocyanates are synthesised in situ by the interaction of sulfenyl chloride with AgOCN or NaOCN in anhydrous inert organic solvents.

$$RSCl + MOCN \xrightarrow[-MCl]{} RSNCO \longrightarrow$$

$\xrightarrow{NH_3}$ RSNHCONH$_2$

$\xrightarrow{R^1NH_2}$ RSNHCONHR^1

$\xrightarrow{R^2_2NH}$ RSNHCONR$^2_2$

$\xrightarrow{R^3OH}$ RSNHCOOR^3

$R^1 = R^2$ = Alk, Ar; R^3 = Alk, Bz; M = Ag, Na.

3. Syntheses of thiocarbonyl compounds

On treatment with bases (triethylamine, NaOH, etc.), sulfenyl chlorides containing reactive α-C–H bonds generate thioaldehydes, which are used in organic synthesis as highly reactive intermediates.[1,43]

$$EtOCCH_2SCl \xrightarrow[-HCl]{Et_3N} EtOC(=S)-CH$$

Certain sulfenyl chlorides give rise to thioaldehydes as a result of photolysis. For example, the photolysis of ethanesulfenyl chloride by irradiation with UV light at a wavelength of 365 nm has been recommended[212] as a preparative method of synthesis of thioacetaldehyde. Sulfenyl chlorides containing a *sp*-hybridised C atom at the S atom readily isomerise to thioketenes.[67]

$$PhC{\equiv}CSCMe \xrightarrow{SO_2Cl_2} [PhC{\equiv}CSCl] \longrightarrow \begin{matrix} Ph \\ \diagdown \\ Cl \end{matrix}\!\!>C{=}C{=}S$$

Treatment of perhaloalkanesulfenyl chloride with a solution of Na_2CS_3 in chloroform or of $BaCS_3$ in the CH_3CN-H_2O mixture leads to the formation of the polysulfide derivatives of polythiocarboxylic acids $(RSS)_2C=S$ (R = CCl_3, CCl_3CCl_2, CF_3CCl_2, $CClF_2CCl_2$).[213] A series of preparative methods of synthesis of thiocarbonyl dihalides, based on the reduction of perhalomethanesulfenyl chlorides, have been developed. For example, heating of TCMSC with tetralin leads to the formation of thiophosgene.[24,33]

$$CCl_3SCl \xrightarrow[-Cl_2]{C_{10}H_{12},\ 200\,^\circ C} \begin{matrix} Cl \\ \diagdown \\ Cl \end{matrix}\!\!>C{=}S$$

In the presence of tin, dichlorofluoromethanesulfenyl chloride and chlorodifluoromethanesulfenyl chloride are reduced to thiocarbonyl chloride fluoride and thiocarbonyl difluoride respectively.[33]

$$CFCl_2SCl \xrightarrow{40\,^\circ C} \begin{matrix} F \\ \diagdown \\ Cl \end{matrix}\!\!>C{=}S$$

$$CF_2ClSCl \xrightarrow{20\,^\circ C} \begin{matrix} F \\ \diagdown \\ F \end{matrix}\!\!>C{=}S$$

4. Syntheses of sulfenic acid esters

Sulfenic acid esters are formed in the reactions of sulfenyl chlorides with alkoxides (phenoxides) or with alcohols (phenols) in the presence of pyridine or triethylamine.[13,24,33,159] The reaction does not always proceed smoothly, especially in the case of aliphatic sulfenyl chlorides and alcohols. This is due to the fact that, by virtue of the high nucleophilicity of the sulfur atom, the sulfenate formed may react with the sulfenyl chloride to form a disulfide and other side products, which reduce the yield and hinder the isolation of the sulfenates.[28] The reaction proceeds more smoothly in the case of sulfenyl chlorides containing powerful electron-accepting groups at the sulfur atom, which reduce the nucleophilicity of the sulfur atom in the resulting sulfenate and therefore hinder its interaction with the sulfenyl chloride. For example, relatively stable sulfenates have been obtained in the reaction of polyfluoroalkanesulfenyl chlorides with alcohols on heating[69] and also in the presence of hydrogen chloride acceptors (triethylamine, pyridine)[214–216] or with alkali metal[217] and mercury[218] alkoxides and phenoxides.

$$R_FSCl + ROH \xrightarrow[-HCl]{\Delta} R_FSOR$$

$R_F = CF_3, (CF_3)_2CHCF_2$;

R = Et, 4-$MeOC_6H_4CH_2$, $CF_3SNHCH_2CH(Ph)$.

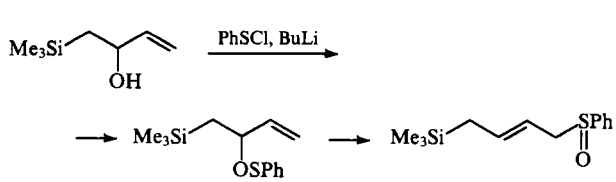
$$R_FSCl + ROH \xrightarrow[-HCl]{Et_3N \text{ or } C_5H_5N} R_FSOR$$

$R_F = CF_3, (CF_3)_2CHCF_2$; $CF_3CH(CH_2Cl)$;

R = Alk, Ar, 4-$MeOC_6H_4CH_2$.

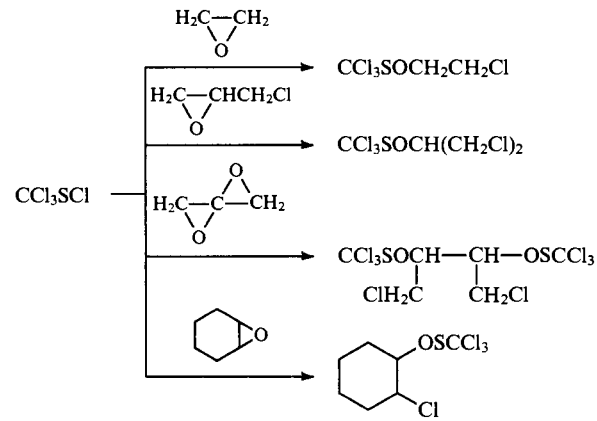
$$R_FSCl + RONa \xrightarrow[-NaCl]{THF,\ 20\,^\circ C,\ 3\ h} R_FSOR$$

$R_F = CF_3CPh_2$;



R = Bu^tCH_2, $PhCH_2O(CH_2)_2$, 4-$NO_2C_6H_4$, $Me(CH_2OCH_2)_3CH_2$.

$$R_FSCl + ROHgCl \xrightarrow[-HgCl_2]{0\,^\circ C,\ 24\ h} R_FSOR$$



R_F = CF_3, CF_3CO; R = $(CF_3)_3C$.

The stable esters of 2,4,6-trinitrobenzenesulfenic,[47] 2,4-dinitrobenzenesulfenic,[4,28] trichloromethanesulfenic,[33] and dichlorofluoromethanesulfenic[33] acids have been described. In the sulfenylation of phenols and naphthols, it is better to employ their sodium salts, which rules out the competing electrophilic substitution of the hydrogen atoms of the benzene ring.[8] The introduction of the corresponding alkoxides instead of alcohols into the reaction with TCMSC, especially in the presence of an excess of the alkoxides, leads to the formation of alkyl orthocarbonates.[219] The above methods are unsuitable for the synthesis of allyl sulfenates, with the exception of the allyl esters of 2,4-dinitrobenzenesulfenic acid, because the esters formed are readily converted into allyl sulfoxides as a result of a 2,3-sigmatropic rearrangement.[33]

$$RSCl + HOCH_2CH{=}CH_2 \xrightarrow[-HCl]{C_5H_5N} [RSOCH_2CH{=}CH_2] \longrightarrow R\overset{\overset{O}{\|}}{S}CH_2CH{=}CH_2$$

The chloroalkyl esters of trichloromethanesulfenic acid are formed in the reaction of TCMSC with 1,2-epoxides.[33]

5. Syntheses of the thiolo-esters of sulfinic, sulfonic, carboxylic, and phosphoric acids

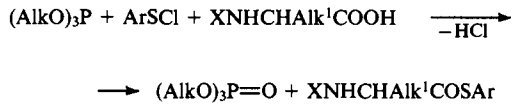
The hydrolysis of sulfenyl chlorides leads to the formation of a mixture of products in which the thiolo-esters of sulfinic or sulfonic acids predominate. This is determined both by the structure of the initial sulfenyl chloride and the hydrolysis conditions.[13,33] For example, in a study of the hydrolysis of dichlorofluoromethane- and chlorodifluoromethane-sulfenyl chlorides in a neutral medium, it has been possible[220] to isolate the thiolo-esters of sulfinic acids. The thiolo-esters of sulfonic acids are one of the products of the hydrolysis of sulfenyl chlorides in acid media.[221]

$$4\,RSCl + 2\,H_2O \xrightarrow{H^+} RSO_2SR + RSSR + 4\,HCl$$

The formation of the corresponding thiolosulfonate in the reaction of *p*-chlorobenzenesulfenyl chloride with anhydrous formic acid has been noted.[222] The interaction of sulfenyl chlorides with sulfinic acids[28,223] or their silver[28] and sodium[174] salts leads to asymmetric thiolosulfonates.

$$RSO_2H(M) + R^1SCl \xrightarrow[-HCl(MCl)]{} RSO_2SR^1$$

R, R^1 = Alk, Ar.



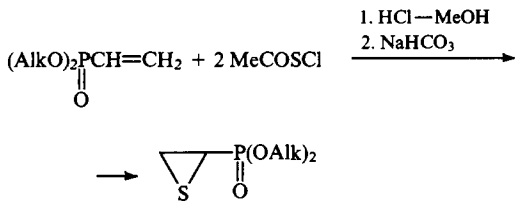
M = Na, Ag.

The thiolo-esters of carboxylic acids are formed on interaction of arenesulfenyl chlorides with triphenylphosphine or with trialkyl phosphites in the presence of carboxylic acid salts. It has been suggested[224] that the quasi-sulfonium salt **A** is an intermediate in this reaction. Its interaction with the carboxylate anion leads to the final products.

$$R_3P + ArSCl \longrightarrow \underset{\mathbf{A}}{(R_3PSAr)^+Cl^-} \xrightarrow[-NaCl]{R^1COONa} (R_3PSAr)^+R^1COO^- \longrightarrow (R_3POCOR^1)^+(SAr)^- \longrightarrow R_3P{=}O + RCOSAr$$

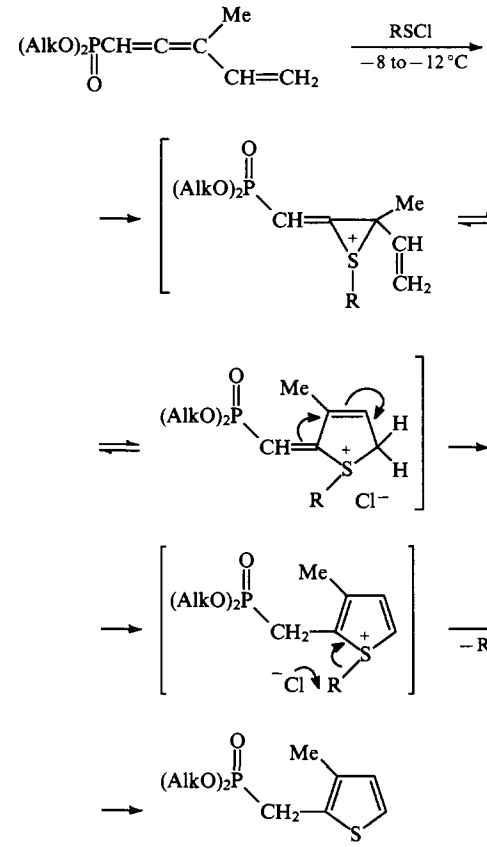
R = Ph, AlkO; R^1 = Ar, Alk.

The analogous reaction of arenesulfenyl chlorides with trialkyl phosphites and *N*-acylaminoacids in the presence of bases has been proposed as a preparative method of synthesis of the aryl thiolo-esters of carboxylic *N*-acylaminoacids.[225,226]



X = CF_3CO, Ph, $PhCH_2OCO$.

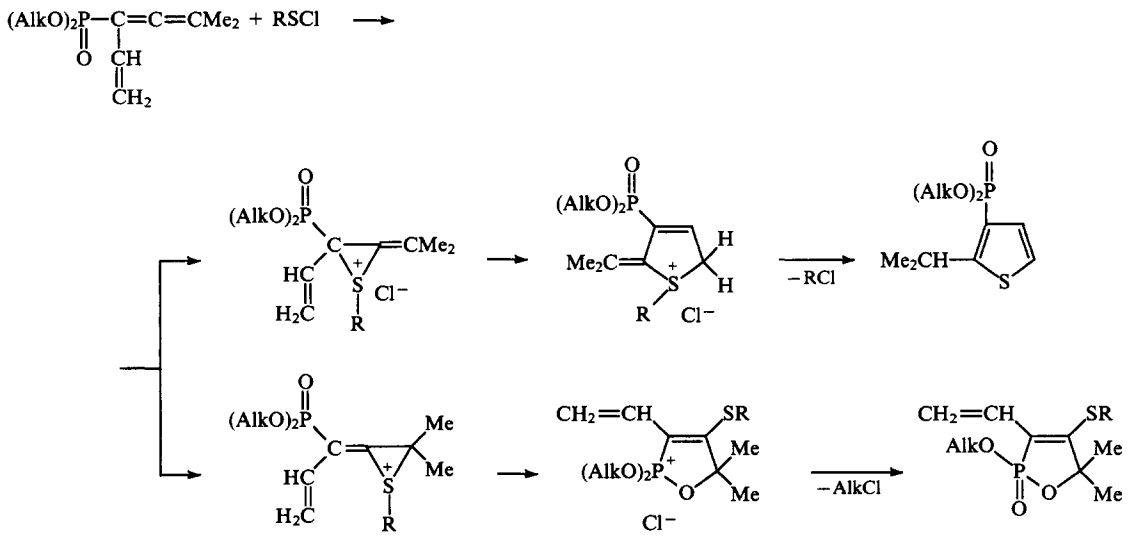
The syntheses of the thiolo-esters of phosphonic acids and other phosphorus-containing compounds from sulfenyl chlorides have been described in detail in a monograph[4] and also in a review[33] and in the literature quoted therein. For this reason they will not be considered here.



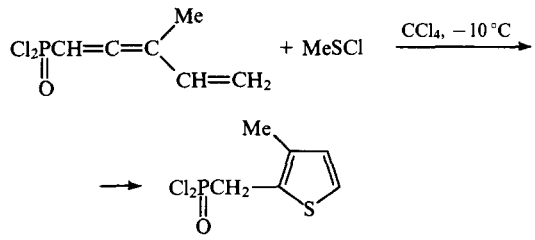
6. Syntheses of heterocyclic compounds

a. Syntheses based on monofunctional sulfenyl chlorides

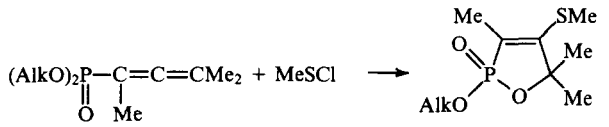
The use of monofunctional sulfenyl chlorides in the synthesis of heterocyclic compounds is based on their addition to the C=C bond of unsaturated compounds with subsequent cyclisation of the resulting intermediates.[4,13,33] For example, the synthesis of the dialkyl esters of 1,2-epithioethylphosphonic acid has been described.[227] It is based on the addition of acetylsulfenyl chloride [1-oxoethanesulfenyl chloride (Ed. of translation)] to the alkyl esters of vinylphosphonic acid and subsequent treatment of the resulting adduct with a solution of hydrogen chloride in methanol and then with sodium bicarbonate.



It has been noted[4,228,229] that the introduction of the vinyl group in the 3-position in allenylphosphonate leads to a system of double bonds, to which alkanesulfenyl chlorides add relatively easily with formation of an episulfonium ion capable of ring expansion to a five-membered cyclic compound followed by conversion into a thiophene derivative.

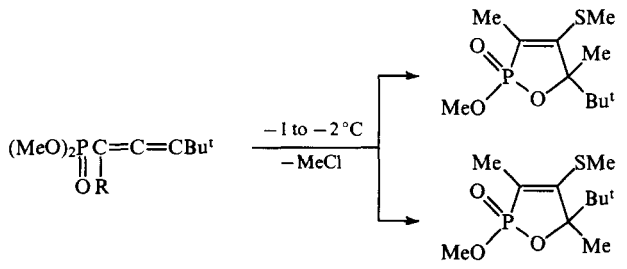


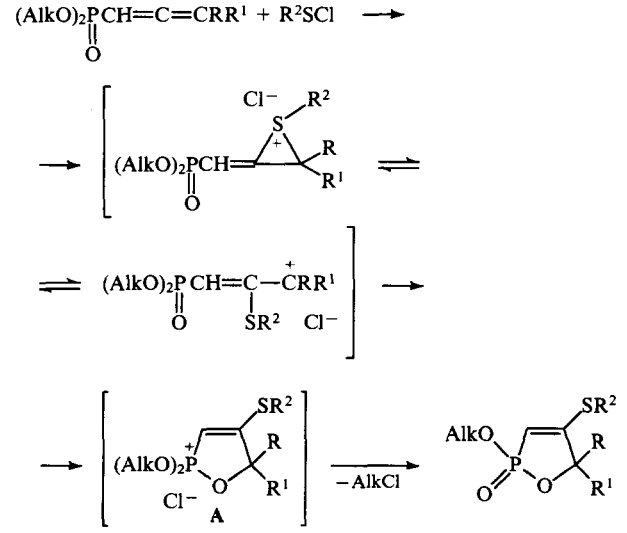
The analogous reaction of alkanesulfenyl chlorides with allenylphosphonates containing a vinyl substituent in the 1-position leads to a mixture of 3-vinyl-1,2-oxaphosphol-3-enes and phosphorylated thiophenes, the ratio of which is influenced by the reaction temperature (Scheme 5).[4,228,230]



Derivatives of 2,2-dichlorophosphorylmethylthiophene are formed in 53% yield as a result of the addition of methanesulfenyl chloride to alkyl-1,2,4-trienylphosphonic dichlorides.[231]

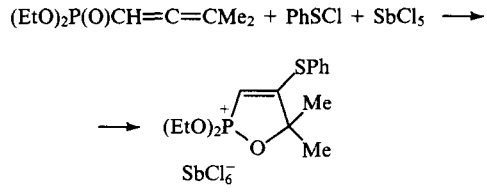
Scheme 5



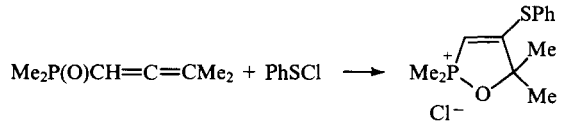


The addition of methanesulfenyl chloride to 1,3,3-trimethylallenylphosphonates leads to the derivatives of 1,2-oxaphosphol-3-ene.[228]

In the case of 1,3,3-trisubstituted allenylphosphonates containing the *tert*-butyl group in the γ-position, a mixture of two stereoisomers is formed. This has been demonstrated by NMR spectroscopy.[232]

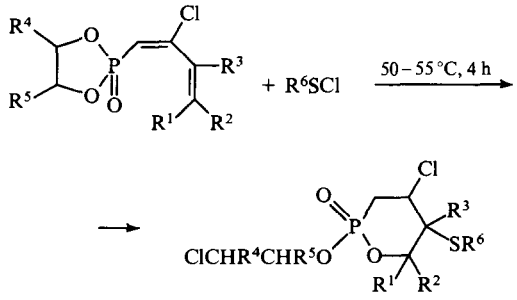


The addition of sulfenyl chlorides to the dialkyl esters of 3,3-disubstituted allenylphosphonic acids, the rearrangement of the episulfonium ion, cyclisation, and dealkylation result in the formation of 4-organylthio-1,2-oxaphosphol-3-enes.[233–237]



R, R^1 = Alk or R + R^1 = $-(CH_2)_5-$.

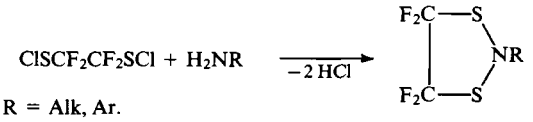
R^2 = Me, Et, Pr^i, Ph, 2,4-$(NO_2)_2C_6H_3$.



The formation of the intermediate phosphonium salt **A** has been demonstrated by its isolation in the form of 1,2-oxaphosphol-3-enium hexachloroantimonate.[238]

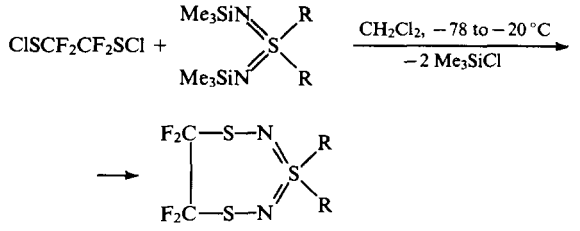
A quasi-phosphonium salt has also been isolated in the reaction of benzenesulfenyl chloride with dimethyl(3-methylbuta-1,2-dienyl)phosphine oxide in the cold.[234]

In chloroform or dichloroethane, alkanesulfenyl chlorides react with 1,3,3-dioxaphospholane 2-oxides to form 1,2-oxaphosphorines.[239]



R^1 = R^2 = R^3 = R^4 = R^5 = H, Me; R^6 = Me, Pr^i.

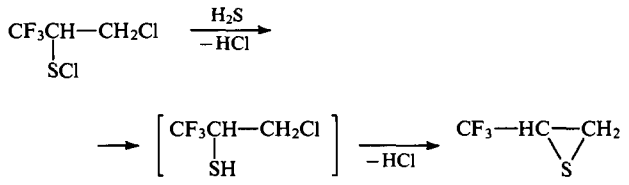
The addition of arenesulfenyl chlorides to 2-allylphenols and subsequent cyclisation of the resulting adducts lead to the formation of 2-phenylthiomethylbenzofurans.[240]



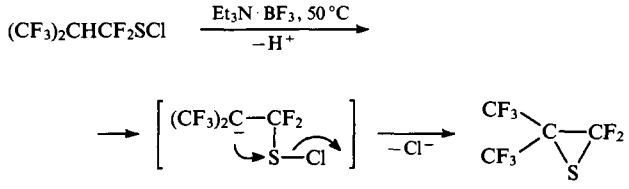
b. Syntheses based on bifunctional sulfenyl chlorides

Bifunctional sulfenyl chlorides are more widely used in the synthesis of heterocyclic compounds.[13] For example, a series of *N*-substituted 1,3,2-dithiazolidines have been obtained by the reaction of tetrafluoroethane-1,2-disulfenyl chloride with primary amines.[156]

R = Alk, Ar.

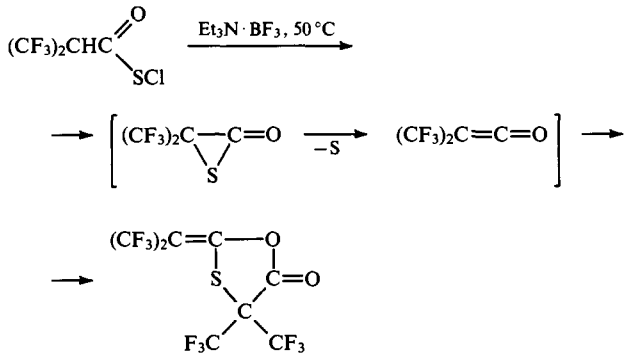


The interaction of the same disulfenyl chloride with *N*,*N*′-bis(trimethylsilyl)sulfodiimides affords high yields of 1,3,5-trithia-2,4-diazepines.[13]

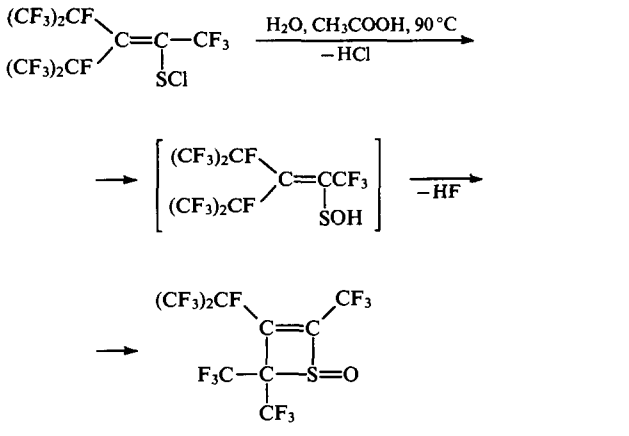


R = Alk, Ar.

Numerous heterocyclic compounds have been obtained from other polyfluoroalkanesulfenyl chlorides. The capacity of these sulfenyl chlorides for ring formation is determined primarily by



anionotropic transformations in the C–C–S three-centre systems.[13,241] It has been noted[242] that, on treatment with H_2S in *N*-methylpyrrolidinone, 3-chloro-1,1,1-trifluoropropane-2-sulfenyl chloride is readily converted into trifluoromethylthiirane. 3-Chloro-1,1,1-trifluoropropane-2-thiol is an intermediate in this reaction.



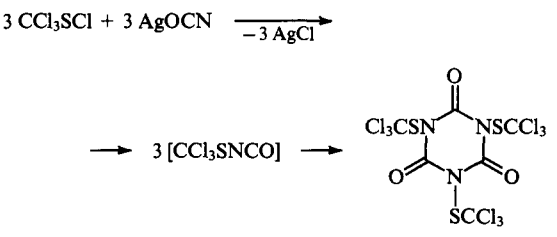
The dehydrochlorination of 2-hydroperfluoroisobutanesulfenyl chloride in the presence of the complex $Et_3N \cdot BF_3$ leads to the formation of perfluoro-2,2-dimethylthiirane.[69]

In the case of 3,3,3-trifluoro-2-(trifluoromethyl)-1-oxopropanesulfenyl chloride, the reaction proceeds in a more complex manner. The thiirane formed as a result of the 3-chlorination of this sulfenyl chloride is desulfurised under the reaction conditions, being converted into bis(trifluoromethyl)ketene, which subsequently react with the thiirane via a [3 + 2]-cycloaddition mechanism.[69]

The formation of the thietene ring has been observed[13,243] in the acid hydrolysis of perfluoro-3-isopropyl-4-methylpent-2-ene-2-sulfenyl chloride. An unstable sulfenic acid is an intermediate product of this reaction.

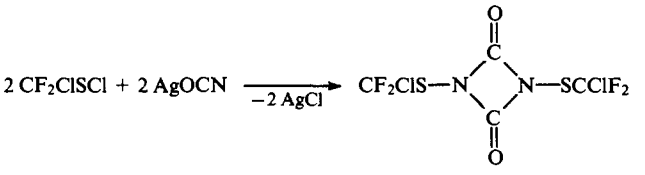
TCMSC has found extensive applications in the synthesis of heterocyclic compounds.[33] Thus the interaction of this compound with a 25% aqueous solution of ammonia in the benzene–water two-phase system leads to the formation of 2,3,7,8-tetrachloro-5,10,11,12-tetrathia-1,4,6,9-tetrazatricyclo-[5.3.11^{2,6}]-dodeca-3,8-diene.[244]

The interaction of TCMSC with aromatic amines results in the formation of unstable *N*-aryltrichloromethanesulfenamides, which are converted into 2,5-diaryl-3,3,6,6-tetrachloro-1,4-dithia-2,5-diazines in the presence of bases or on heating.[201]



The reaction of TCMSC with 2-aminopyridine leads to the formation of 2-(*N*-trichloromethanesulfenyl)aminopyridine, which is converted into 3-(2-pyridylimino)-3*H*-1,2,4-thiadiazolo-[4,3-α]pyridine in the presence of an excess of the aminopyridine.[201,245]

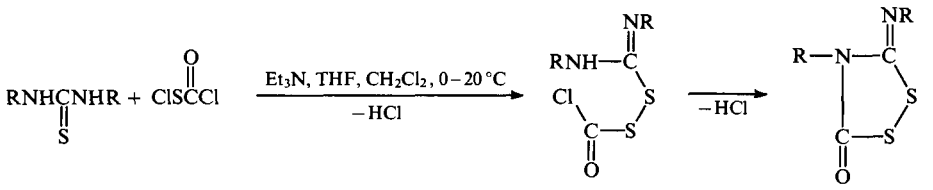
When TCMSC is heated with carboxylic acid amides in dioxane, 5-aryl-1,3,4-oxathiazol-2-ones are formed.[246] *N*-Aroyltrichloromethanesulfenamides are intermediates in this reaction. In the presence of bases, they undergo the heterocyclisation reaction.[86,175,247,248]



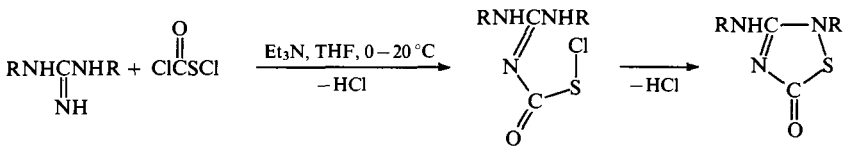
A series of 1,2,4-thiadiazole derivatives have been obtained by the reaction of TCMSC with carboxylic acid amidines and *S*-alkylisothiuronium salts.[33]

Dichloromethane- and dichlorofluoromethane-sulfenyl chlorides react similarly with carboxylic acid amidines.[28,33]

Treatment of TCMSC with silver isocyanate leads to the unstable trichloromethanesulfenyl isocyanate, which trimerises to 1,3,5-tris(trichloromethanesulfenyl)-2,4,6-trioxo-1,3,5-triazine.[249]

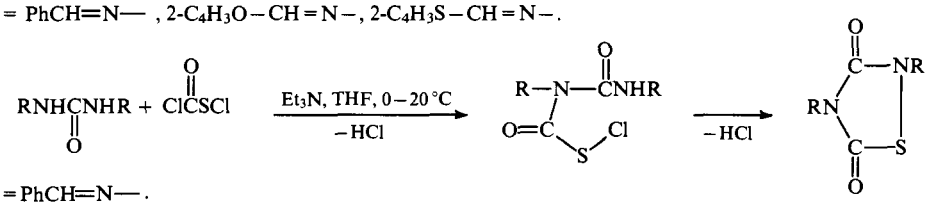


The analogous reaction of silver isocyanate with chlorodifluoromethanesulfenyl chloride leads to the formation of 1,3-bis(chlorodifluoromethanesulfenyl)-2,4-dioxo-1,3-diazetidine.[208,209]



Chlorocarbonylsulfenyl chloride is of considerable preparative importance for the synthesis of various five-membered nitrogen and sulfur-containing heterocyclic compounds.[11] The two reaction centres (sulfur and carbon) as well as the high lability of the S–Cl and C–Cl bonds impart to this reagent a set of properties which are extremely valuable for heterocyclisation reactions. Depending on the nature of the bifunctional compound, chlorocarbonylsulfenyl chloride may react with the latter, a C or the S atom participating in the first stage of the reaction, while in the second stage the second reaction centre is involved, as happens, for example, in the interaction of chlorocarbonylsulfenyl chloride with thiourea, urea, and guanidine derivatives (Scheme 6).[250]

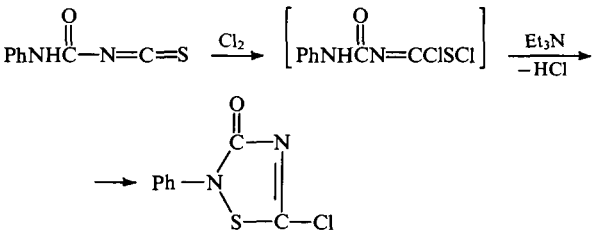
A whole series of preparative methods of synthesis of various five-membered heterocyclic compounds from chlorocarbonylsulfenyl chloride and 1,3-bifunctional compounds, presented in Scheme 7, have been developed.[11]



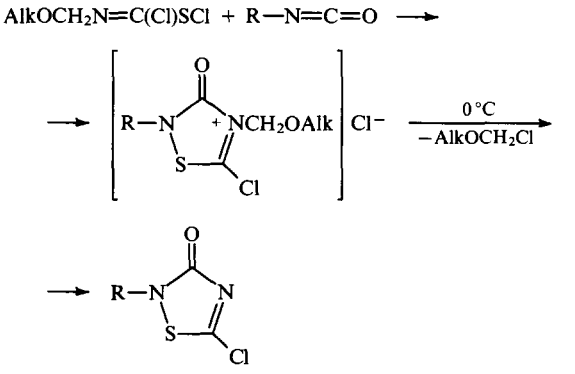
Scheme 6

R = Ph, XCH=N— (X = Ph, 2-C_4H_3O, 2-C_4H_3S, 2-C_5H_4N, 3-C_5H_4N).

R = PhCH=N— , 2-C_4H_3O–CH=N–, 2-C_4H_3S–CH=N–.



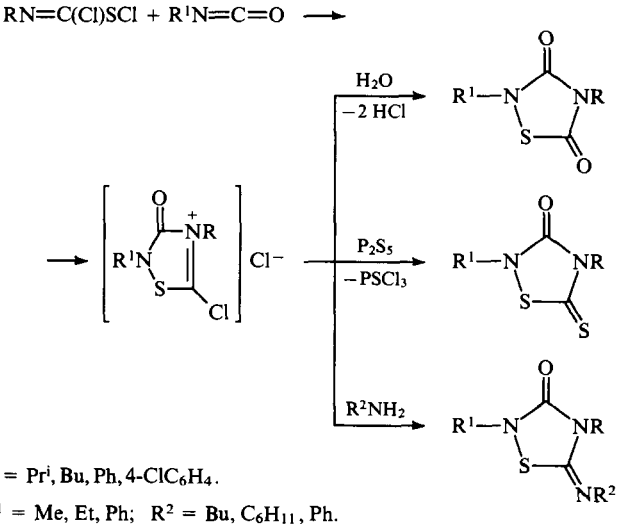
R = PhCH=N—.



The interaction of chlorocarbonylsulfenyl chloride with derivatives of benzamide oxime in acetonitrile in the presence of triethylamine leads to the formation of two products — 3-aryl-1,2,4-thiadiazol-5-ones and 3-aryl-1,2,4-oxadiazol-5-ones.[251]

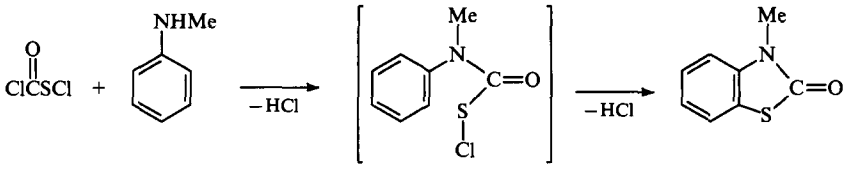
The condensation of chlorocarbonylsulfenyl chloride with 2-aminothiazole in tetrahydrofuran in the presence of bases takes place with formation of 2,3 fused thiadiazolone, whereas the condensation in chloroform leads to 3,4 fused thiadiazolone.[252]

Numerous methods of synthesis of five-membered nitrogen-containing heterocycles have been developed on the basis of chloroiminomethanesulfenyl chlorides. However, many of these methods have so far been inadequately tested and it is not clear whether they are of a general character. On the other hand, the majority of these compounds are unstable, their synthesis and their reactions being carried out in situ, which also limits their application in the syntheses of heterocycles. For example, the synthesis of 5-chloro-3-oxo-2-phenyl-1,2,4-thiadiazoline, described in the literature,[11] involves the chlorination of phenylcarbamoyl isothiocyanate followed by the treatment of the intermediate chloro(phenylcarbamoylimino)methanesulfenyl chloride with a tertiary amine.

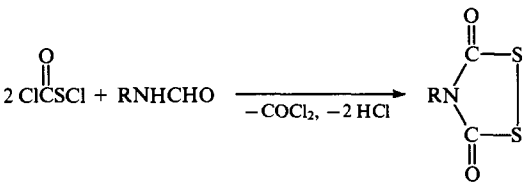


Similar compounds are formed in the interaction of alkoxymethylimino(chloro)methanesulfenyl chlorides with isocyanates. The intermediate formed in the first stage of this reaction is converted into the final product by elimination of an alkyl chloromethyl ether.

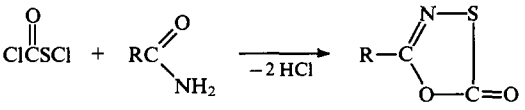
R = Me, Pr^i, Ph, 2-BrC_6H_4, 3,4-$Cl_2C_6H_3$, 4-$EtOC_6H_4$.



The intermediates formed in the reactions of chloro(imino)-methanesulfenyl chlorides with isocyanates interact relatively easily with various nucleophiles, affording five-membered heterocyclic compounds containing both sulfur and nitrogen.[253,254]

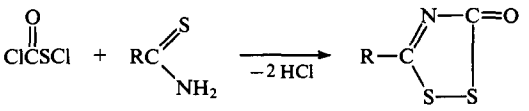


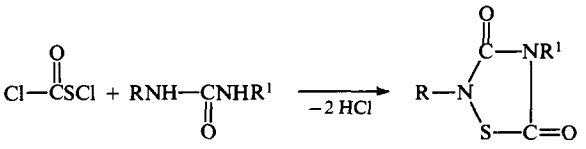
R = Pr^i, Bu, Ph, 4-ClC_6H_4.



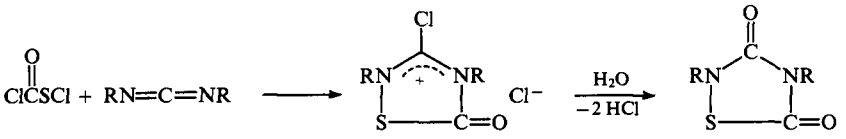
R^1 = Me, Et, Ph; R^2 = Bu, C_6H_{11}, Ph.

Scheme 7

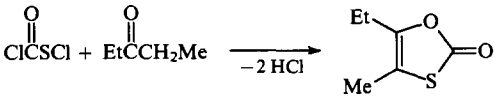


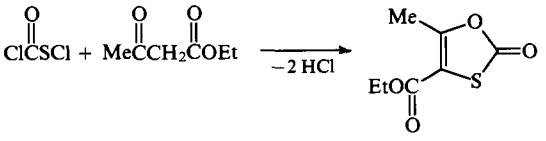


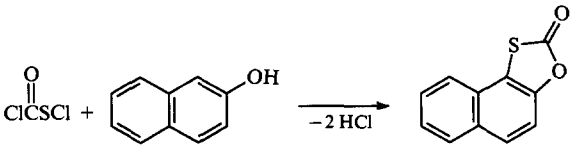
R = Me, C_5H_{11}, Ph, 3,4-$Cl_2C_6H_3$, 3-Cl-4-$MeOC_6H_3$.



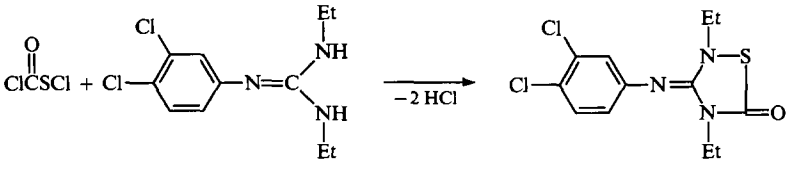
R = 2-$MeOC_6H_4$, 3-$MeOC_6H_4$, 4-$MeOC_6H_4$, 2-BrC_6H_4, 2-IC_6H_4, 2-MeC_6H_4.



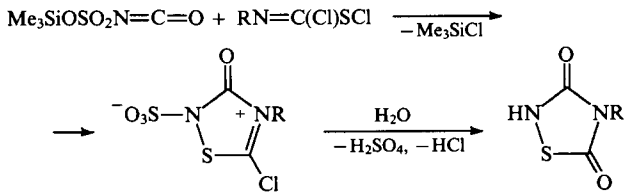


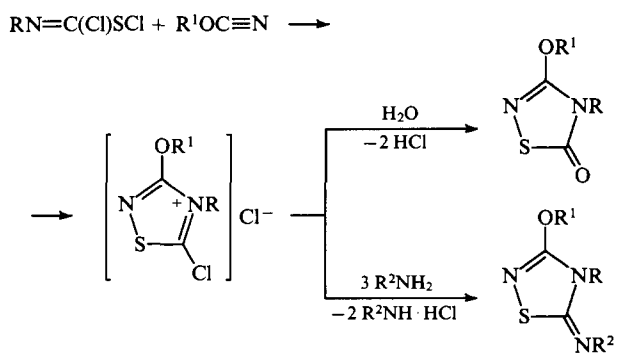


R = Me, $MeOCH_2$, C_6H_{11}, Ph, 2-$CF_3C_6H_4$, 3,4-$Cl_2C_6H_3$, 3-Cl-4-MeC_6H_3;



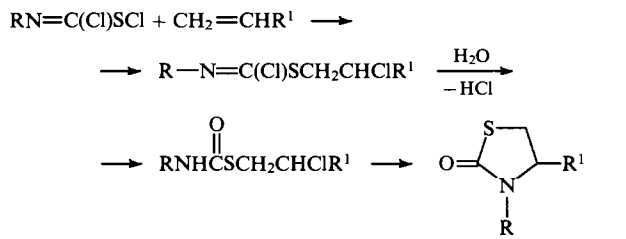
R^1 = Me, $MeOCCH_2$, C_6H_{11}, Ph.





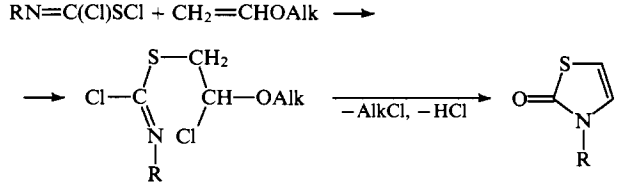
The interaction of chloro(imino)methanesulfenyl chlorides with trimethylsiloxysulfenyl isocyanate takes place with cleavage of the Si–O bond and the formation of a product having a dipolar structure, the hydrolysis of which affords 1,2,4-thiadiazolidine-3,5-diones.[254]

R = Me, Bu, $PhCH_2$, Ph, 3,4-$Cl_2C_6H_3$.



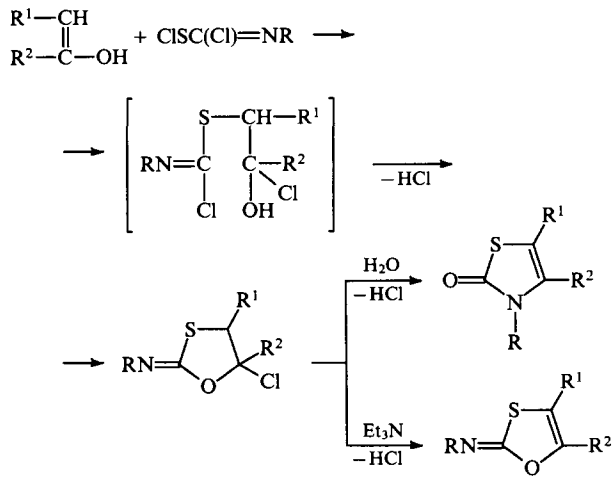
The addition of chloro(imino)methanesulfenyl chlorides to the C≡N bond of cyanates also proceeds with formation of intermediates, the hydrolysis and aminolysis of which lead to derivatives of 1,2,4-thiadiazoline.[11]

R = Me, Ph; R^1 = CCl_3CH_2, Ph, 3-$NO_2C_6H_4$.



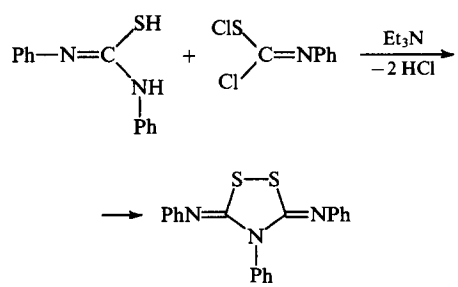
R_2 = Me, 4-ClC_6H_4.

The addition of chloro(imino)methanesulfenyl chlorides to the C=C bond of alkenes is accompanied by the formation of adducts, the hydrolysis of which leads to the S-esters of thiocarbamic acid, which cyclise to 2-oxo-1,3-thiazolidines.[255]



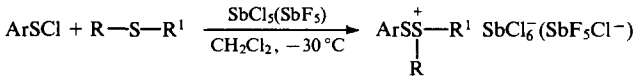
R = Me, Ph, R^1 = Alk.

In additions to vinyl ethers, the cyclisation of the adducts proceeds with elimination of an alkyl halide and hydrogen chloride and the formation of 2-oxo-1,3-thiazolines.[256]

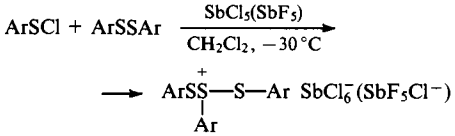


R = Me, Bu, Ph.

The enolic form of ketones react with chloro(imino)-methanesulfenyl chlorides to give adducts which are stabilised on intramolecular cyclisation.[256]



Diphenylthiourea reacts with chloro(*N*-phenylimino)-methanesulfenyl chloride in the thiolo-form with formation of 3,5-bis(phenylimino)-4-phenyl-1,2,4-dithiazolidine.[11]

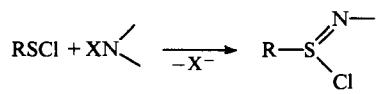


7. Syntheses of compounds of tetravalent and hexavalent sulfur

a. Syntheses of arylthiosulfonium and aryl(bisarylthio)sulfonium salts

Arylthiosulfonium and aryl(bisarylthio)sulfonium salts belong to a special type of derivatives of tetravalent sulfur, namely to the class of S-cationoid compounds with a positive charge on one of the sulfur atoms. These salts are formed relatively easily on interaction of sulfenyl chlorides with sulfides[257] and disulfides[258] in the presence of Lewis acids such as $SbCl_5$ or SbF_5.

Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4; R = R^1 = Me, Ph;



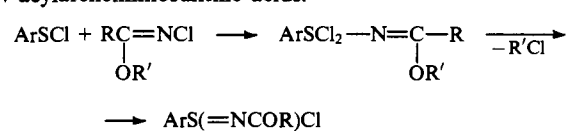
Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4.

Arylthiosulfonium and aryl(bisarylthio)sulfonium salts have found applications in organic synthesis as agents transferring the RS^+ groups in Ad_E reactions with alkenes.[259]

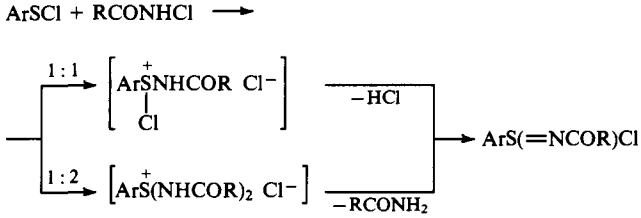
b. Syntheses of iminosulfinic acid chlorides.

The use of sulfenyl chlorides in the synthesis of iminosulfinic acid chlorides is based on their oxidative imination by *N*-halo-compounds, as a result of which the valence of the sulfur atom of the sulfenyl chloride increases by two units and combines with the imino-group.[186,260,261]

X = Cl, Br.

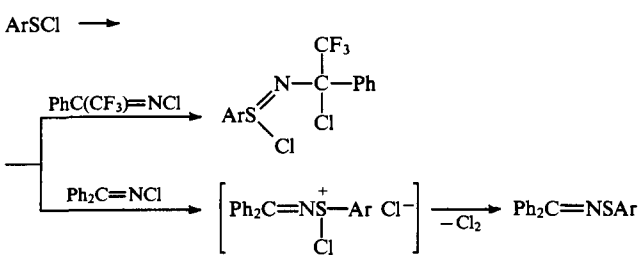


For example, it has been noted that arenesulfenyl chlorides react in anhydrous organic solvents with *N*-chloro- and *N,N*-dichloroamides of arenesulfonic acids with formation of the chlorides of *N*-arenesulfonylareneiminosulfinic acids.[260,261]



R = Ph, 4-MeC_6H_4, 4-$NO_2C_6H_4$, 4-ClC_6H_4, 2-$NO_2C_6H_4$.

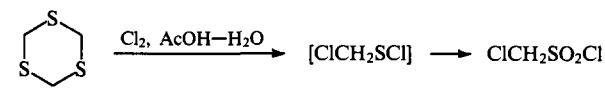
Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4; X = Na, Cl, Me_3Si.



N,N-Dichlorourethanes and esters of *N*-chloroiminocarbonic acid,[260] *N*-chloro-*N*-trimethylsilyl-*tert*-butylamine,[262] the *N*-chloroamides of carboxylic acids,[263] and *N*-chloroketimines[264] are used as iminating agents in order to obtain the chlorides of *N*-substituted iminosulfinic acids containing other substituents at the nitrogen atom. The reactions of arenesulfenyl chlorides with *N*-chloroiminocarbonic acid esters proceed with formation of sulfuranes in the first stage. As a result of the elimination of an alkyl halide, the sulfuranes are converted into the chlorides of *N*-acylareneiminosulfinic acids.[265]

Depending on the reactant ratio, *N*-acylamino(aryl)chlorosulfonium chlorides or bis(*N*-acylamino)(aryl)sulfonium chlorides are intermediates in the reactions of arenesulfenyl chlorides with the *N*-chloroamides of carboxylic acid.[263]

Arenesulfenyl chlorides do not react unambiguously with *N*-chloroketimines.[264] The formation of the corresponding acid chlorides has been observed in the reaction of arenesulfenyl chlorides with *N*-trifluoromethylphenylketimine, whereas the reaction with *N*-chlorodiphenylketimine leads to the corresponding sulfenamide.



Arenesulfenyl chlorides do not react with *N*-chlorobis(trifluoromethyl) ketimine.[264]

c. Syntheses of sulfonic acid chlorides

Sulfenyl chlorides which are resistant to hydrolysis are relatively easily converted into sulfonic acid chlorides on treatment with oxidants, which is sometimes used in preparative organic chemistry.[13,33] For example, the oxidation of trichloromethanesulfenyl chlorides by various oxidants constitutes the basis of a preparative method of synthesis of trichloromethanesulfonic acid chloride.

Chlorine in an aqueous medium,[266] chlorine in acetic acid,[267] nitric acid,[268] and hydrogen peroxide[269] are used as oxidants. The same oxidants are employed in the synthesis of trifluoromethanesulfonic acid chloride[270] from trifluoromethanesulfenyl chloride. It has been noted[271] that the hydrolysis of trithiane in dilute acetic acid, which results in the formation of chloromethanesulfonic acid chloride, proceeds via an intermediate stage involving the formation of chloromethanesulfenyl chloride.

* * *

It is seen from the present review that the use of sulfenyl chlorides in fine organic synthesis, which has reached a large scale in recent years, is based on the characteristic features of their reactivity and in the first place on the high lability of the S–Cl bond, as a result of which sulfenyl chlorides are widely employed in reactions with diverse reagents in order to generate the S–C, S–N, S–O, S–S, S–P, S=O, S=N, etc. bonds. The ease of addition of sulfenyl chlorides to the C=C bond of unsaturated compounds with formation of β-chloroalkyl sulfides is likewise widely used in fine organic synthesis for the introduction of the β-arylthioalkyl groups into the molecules of various organic compounds. A feature of the reactivity of bifunctional sulfenyl chlorides which is of very great synthetic importance is their tendency to form heterocycles on interaction with various polyfunctional compounds, which has also been reflected in the present review.

Abstract. The results of studies on the molecular structures of cellulose nitrates and related saccharide nitrates are surveyed. The inhomogeneity of the structures of cellulose nitrates can be analysed on three hierarchical levels: in terms of the composition of the elementary units, in terms of the distribution of the elementary units along the chain, and in terms of their distribution in the bulk phase. The possibilities of the NMR and FT-IR spectroscopy for studies of these structural levels are discussed. A simple method has been developed for the estimation of the molecular-structural inhomogeneity of cellulose nitrates. It is shown that this inhomogeneity is determined by the inhomogeneity of the nitration process. A procedure is proposed for taking into account the diffusion of the nitrating agent in studies of the kinetics of the inhomogeneous reactions. The bibliography includes 121 references.

I. Introduction

Cellulose nitrates (CN) are polymers the production of which always took place long before studies of their structural characteristics. For this reason, the technology of the preparation of cellu-lose nitrates has been largely based on empirical rules and has been developed by the method of trial and error. Despite the large scale production of cellulose nitrates for gunpowders, rocket fuels, varnishes, dyes, biological membranes, ionising radiation detectors, etc., the characteristics of their molecular structure, as manifested in the properties of these polymers, have not so far been investigated: the structure–property correlations have not been found. There are comparatively few surveys of studies on the structure of cellulose nitrates.[1–14] However, recently studies on the detailed molecular structure of cellulose nitrates have received a fresh stimulus from the development of molecular spectroscopic methods yielding data with a high information content — high-resolution ^{13}C and ^{15}N NMR and FT-IR spectroscopy.

The present review is devoted mainly to studies on the molecular structure of cellulose nitrates and on their structural inhomogeneity.

II. Molecular structure of cellulose nitrates

Cellulose nitrates constitute a family of incompletely substituted cellulose esters having the general formula $-[-C_6H_7O_2.(ONO_2)_x(OH)_{3-x}-]_n-$, where $0 < x \leqslant 3$. Cellulose nitrates with different values of x have different properties, the most important of which are solubility and plasticisability. The principal feature of cellulose nitrates is their heterounit structure. In the general case, cellulose nitrate chains include eight types of elementary unit: one unsubstituted glucopyranose ring; three monosubstituted (2-, 3-, and 6-monosubstituted) pyranose rings; three disubstituted (2,3-, 2,6-, and 3,6-disubstituted) pyranose rings; and one 2,3,6-trisubstituted pyranose ring (Fig. 1).

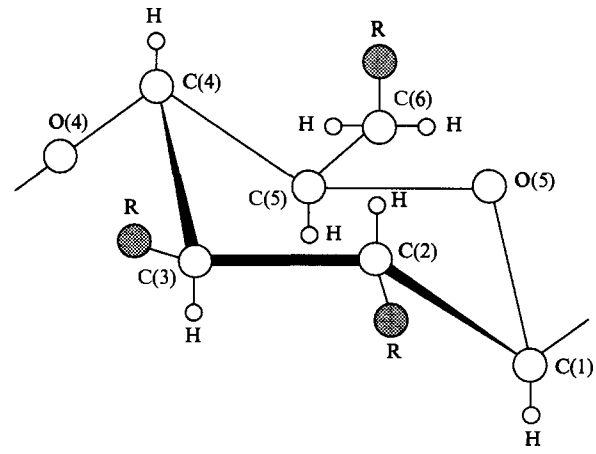

Figure 1. The numbering of the atoms in the elementary unit of cellulose nitrate. R = —OH or $-ONO_2$.

1. Conformation of the cellulose nitrate macromolecule

Like the majority of crystalline polymers, cellulose nitrates give rise to a diffraction pattern with a small number of reflections, from which it is difficult to obtain complete information about the conformation of the cellulose nitrate chains. The unit cell parameters of cellulose nitrates (with a nearly limiting degree of substitution) have been found.[1,15–17] The parameters of the orthorhombic unit cell found by different workers agreee fairly closely, which makes it possible to regard them as reliable (Table 1).

Table 1. The unit cell parameters of cellulose nitrate.

Degree of substitution	a/nm	b/nm	c(IP)/nm[a]	Ref.
2.8	0.90	1.39	2.56	1
2.8			2.57	15
2.8	0.855	1.230	2.54	16
2.9	0.90	1.224	2.54	17
2.9	0.90	1.46	2.54	17

[a] The parameter c corresponds to the identity period.

The identity period (IP) of 2.54 nm and the corresponding meridianal reflections on the diffraction patterns of cellulose trinitrates (CTN) indicate directly that the cellulose nitrate chains are packed in the form of a 5_2 helix (five elementary units for two turns of the helix). Cellulose has IP = 10.3 Å, which corresponds to a 2_1 helix (a planar zig-zag conformation with two units per identity period).[18]

Consequently the appearance of bulky nitrate substituents on passing from cellulose to CTN is accompanied by the uncoiling of the macromolecular helix (the twist angle of the helix varies from 180° for cellulose to 144° for cellulose nitrate). The question of the parallel or antiparallel arrangement of the chains in crystalline cellulose nitrates has so far remained open.[17] We are aware of only one study[19] in which the most favourable conformations of isolated chains of CTN and cellulose di- and mono-nitrates were calculated by the method of molecular mechanics. Structural models, consistent with experimental data and corresponding to the deepest minima on the potential energy surface for the macromolecules, were constructed. A chain conformation close to 2_1 obtains for cellulose mononitrates, which probably reflects the smaller 'saturation' of the polymer skeleton by nitrate groups compared with CTN. Conformational states of the chains ranging from the 2_1 helix to the 5_2 helix, depending on the degree of substitution of the cellulose nitrates, are probably possible for cellulose nitrates with degrees of substitution less than three.

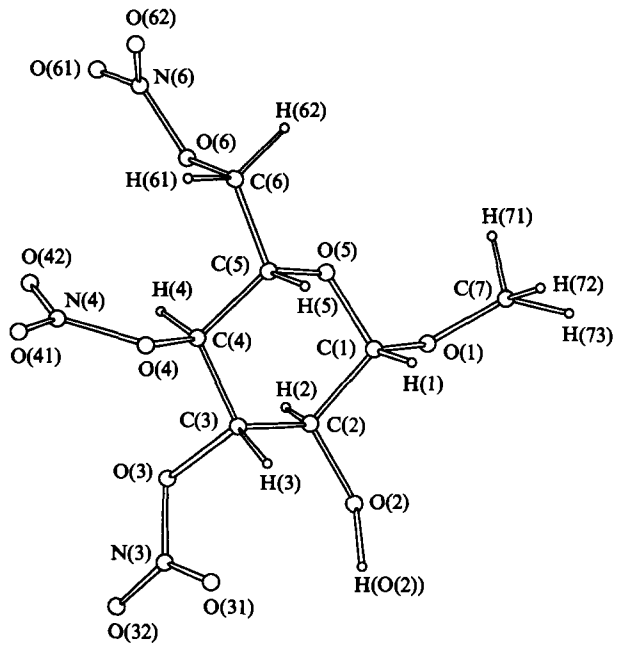

Figure 2. The geometry of the molecule of the 3,4,6-trinitrate of methyl β-D-glucopyranoside.[26]

2. Conformation of the glucopyranose ring

Unfortunately there are no direct experimental data concerning the conformation of the pyranose ring in cellulose nitrates. It has been demonstrated in a review[18] that the glucopyranose ring in cellulose and model saccharides[20] has the $^4C_1$ (chair) conformation with an equatorial disposition of the substituents. The ring conformations in the cellulose nitrate chain have been calculated by the method of molecular mechanics and it has been shown that the $^4C_1$ chair conformation is the most favourable.[11,21,22] A series of studies on the X-ray diffraction of model glucoside and cellobioside nitrates have been published recently.[23–29] They were concerned with the 2,3-dinitrates of methyl 4,6-*O*-ethylidene-β-D-glucopyranoside (2,3-DNMEG) (the α- and β-anomers), the 3,6-dinitrate of methyl 4-*O*-methyl-β-D-glucopyranoside (3,6-DNMMG), the 2,4,6- and 3,4,6-trinitrates of methyl β-D-glucopyranoside (2,4,6- and 3,4,6-TNMG) (Fig. 2), the 2,3,4,6-tetranitrate of methyl β-D-glucopyranoside (2,3,4,6-TNMG) (Fig. 3), and the 6,6′-dinitrate and the 2,3,6,2′,3′,4′,6′-heptanitrate of methyl β-D-cellobioside (6,6′-DNMC and 2,3,6,2′,3′,4′,6′-HNMC) (Figs 4 and 5).

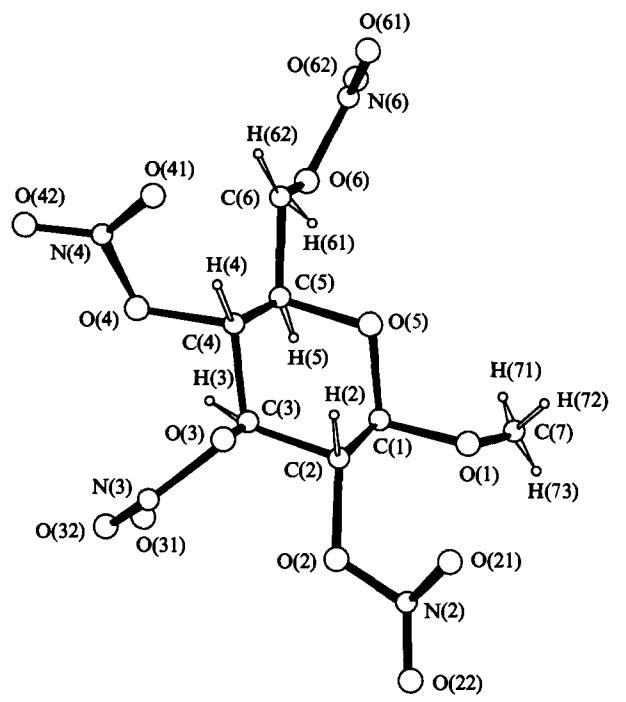

Figure 3. The geometry of the molecule of the 2,3,4,6-tetranitrate of methyl β-D-glucopyranoside.[27]

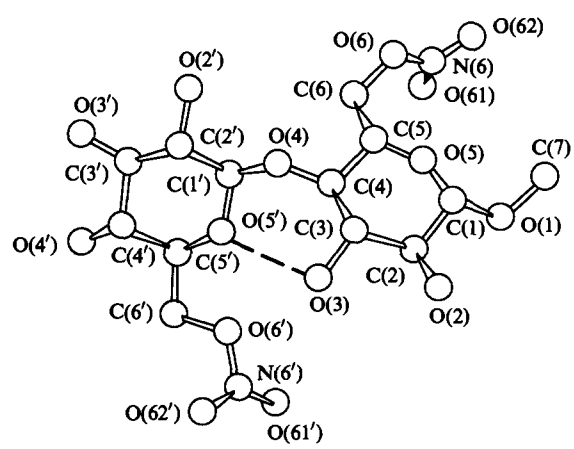

Figure 4. The geometry of the molecule of the 6,6′-dinitrate of methyl β-D-cellobioside.[28]

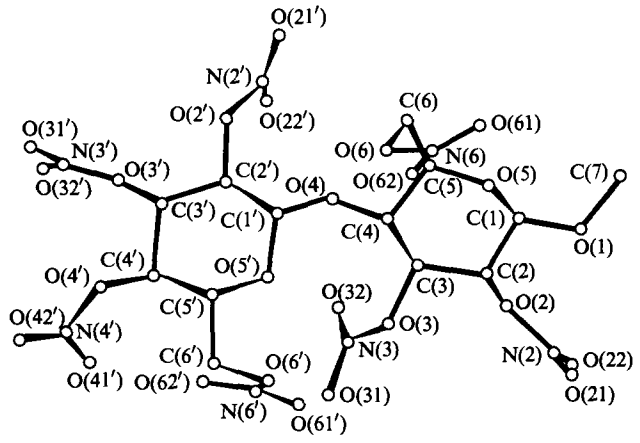

Figure 5. The geometry of the molecule of the 2,3,6,2',3',4',6'-heptanitrate of methyl β-D-cellobioside.[29]

Without exception, they all have the $^4C_1$ conformation of the glucopyranose ring regardless of the number of substituting nitrate groups or the presence of the second ring in 2,3-DNMEG.

Thus it is evident that the conformation of the glucopyranose ring is fairly stable. One must recall that, in an attempt to describe the conformation of the CTN chain, Watanabe and coworkers[15,30] used the 'half-boat' conformation, assuming erroneously that the conformation of the nitrate groups along the cellulose nitrate chain is more 'rigid' than the conformation of the pyranose rings. The 'half-boat' conformation has also been used for the description of the model of the folded chain of cellulose II.[31] However, later studies demonstrated that this model conflicts with the concept underlying the biosynthesis of cellulose.[9]

3. Conformations of the nitrate groups

Calculations for cellulose and cellobiose nitrates[32] as well as for fragments of the CTN chains,[11,21,22] carried out by methods of molecular mechanics, have shown that a large number of stable conformers are possible for the nitrate group in the C(6) position†. This is evidently determined by the presence of two conformational degrees of freedom — the internal rotations relative to the C(5)–C(6) and C(6)–O(6) single bonds. X-Ray diffraction studies on model saccharide nitrates confirm the results of the calculations: different C(4)C(5)C(6)O(6) and C(5)C(6)O(6)N(6) torsional angles for the given fragment are observed in the crystal (Table 2).

The nitrate groups in all the compounds investigated are planar. The internal rotation of the nitrate groups in cellulose nitrates in the 2- and 3-positions takes place relative to the C(2)–O(2) and C(3)–O(3) bonds [C(1)C(2)O(2)N(2) and C(2)C(3)O(3)N(3) torsional angles]. However, their close proximity limits their mutual orientation. These groups have different locations relative to the pyranose ring. The results of calculations have shown that both groups 'tend' to achieve a mutually perpendicular disposition.[32] According to X-ray diffraction data, the angles between the planes of the nitrate groups, for example in 2,3-DNMEG,[23] are 82° for the α-anomer and 76° for the β-anomer, whereas in 2,3,4,6-TNMG the angle is 75°.[27] The $-CONO_2$ groups are significantly nonplanar. The maximum displacement of the carbon atom from the plane of the nitrate group reaches 23° for 2,3-DNMEG and 21° for 2,3,6,2',3',4',6'-HNMC.

In conclusion of this section, we emphasise that its main aim was not so much the discussion of controversial problems concerning the conformational state of cellulose nitrates as the description of the most important and reliable parameters necessary for the consideration of the molecular-structural inhomogeneity of cellulose nitrates. Readers who are interested may obtain the necessary details from the literature sources quoted.

† The term 'conformer' is understood as the mutual disposition of atoms in the molecule or its fragment which corresponds to global or local energy minima, whilst the term 'conformation' implies any kind of their mutual disposition.[81]

Table 2. The torsional angles (deg) in the molecules of the monosaccharide and disaccharide nitrate single crystals.

Angle	2,3-DNMEG[a]	3,6-DNMMG	2,4,6-TNMG	3,4,6-TNMG	2,3,4,6-TNMG	6,6'-DNMC[b]	2,3,6,2',3',4',6'-HNMC[b]

III. High-resolution NMR studies on the molecular structure of cellulose nitrates

The development of the experimental NMR technique has significantly expanded the scope of studies on the detailed molecular structure of cellulose nitrates. Interesting results have been obtained with the aid of high-resolution ^{13}C NMR spectroscopy in solution.[33-44] At the beginning of the 1980s, two publications appeared independently on the analysis of the NMR spectra of cellulose nitrates and their analogues,[33,34] in which the ^{13}C NMR spectra of cellulose nitrates were interpreted for the first time. Wu[33] showed that, with the aid of NMR, it is possible not only to distinguish the signals of the carbon atoms sensitive to the location of the nitrate groups but also to determine the ratio of the types to units with different numbers of nitrate groups. A rigorous interpretation of the NMR spectra of cellulose nitrates has now been achieved based on numerous studies of the NMR spectra of model nitrates[34,39,43] and specially synthesised cellulose nitrates,[33,35,36,41] as well as on calculations of the chemical shifts of the nuclei from their increments[41,44] (Table 3).

Cellobiose octanitrate (CON) is the closest structural analogue of CTN. In CON, it is possible to differentiate a molecular fragment (Fig. 6) which gives rise to NMR signals least perturbed by the terminal sections of the molecules which are not similar to those in the CTN. Analysis of the chemical shifts of the nuclei (Table 3) showed that the positions of these particular signals in the spectra are closest to the positions of the CTN signals. It has been suggested that the neighbouring elementary units exert a significant influence on the chemical shifts of the nuclei of the glucoside ring.[34,36] Together with this, it is also necessary to take into account the conformational state of the chains and substituents in cellulose nitrates. The 10% solutions of cellulose nitrates employed in the NMR experiments are very different from the equilibrium solutions, in which there is no interchain interaction and homogeneous conformations of the macromolecules are achieved.[9] In this case, the differences between the chemical shifts of CON and CTN under identical experimental conditions may be accounted for by the following factors: (1) the inadequacy of the model (Fig. 6), (2) the more extensive conformational set of the CTN chains, (3) the influence of neighbouring units on one another, and (4) the heterounit structure in the case of cellulose nitrates with a degree of substitution less than 3. The differences between the positions of the signals of the tetranitrate of methyl glucoside, cellobiose octanitrate, and CTN hardly exceed 1 ppm (Table 3). This is evidence indicating that the mutual influence of the units in cellulose nitrates is insignificant (for example, a change of solvent leads to similar differences between the chemical shifts and one may expect that different solvents may ultimately act specifically on the conformations of the cellulose nitrate chains). Consequently the parameters which influence significantly the magnitudes of the chemical shifts of cellulose nitrates are the heterounit structure of the polymer and the differences between

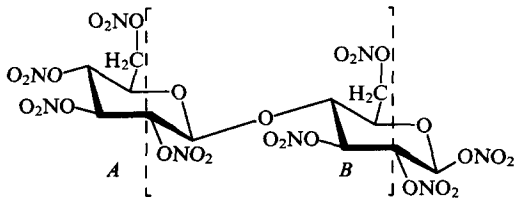

Figure 6. The structural formula of cellobiose octanitrate. The molecular fragment modelling CTN is shown in square brackets.

the conformational states of the cellulose nitrate chains. An important conclusion which follows from the analysis of the data in Table 3 is that the NMR spectrum actually corresponds to a single elementary unit of CTN; the influence of the neighbouring units (at least for the modern apparatus with a resolution corresponding to 100 MHz) is negligible.

The ^{13}C NMR spectrum of a cellulose nitrate specimen with a degree of substitution of 1.2 in solution in DMSO shows clearly (Fig. 7) that the main group of lines is concentrated in the region of 70-90 ppm where the signals of different nuclei overlap. The most remote and nonoverlapping region, 95-105 ppm, belongs to the signals from the C(1) atoms. By analysing carefully the chemical shifts for selectively substituted nitrates of methyl glucosides and cellulose nitrates with different degrees of substitution (Table 4), it is possible to separate reliably the signals obtained from different elementary units of cellulose nitrates.

Table 4. The chemical shifts (ppm) for the resonances of the C(1) carbon atom in the nitrates of methyl β-D-glucosides (NMG) and in cellulose nitrate.

Positions of nitrate groups	NMG[39]	CN[41]	CN[44]
2	101.6	99.7	(99.0)
2,3	101.6	(100.9)	(98.6)
2,4	101.4	–	–
2,6	101.4	98.8	(97.3)
2,3,6	101.6	100.0	(98.3)
2,4,6	101.35	–	–
2,3,4,6	101.4	–	–
Unsubstituted unit	104.8	104.4	(103.1)
6	104.85	103.5	(102.8)
3	104.3	(106.1)	(102.4)
3,6	104.95	105.2	(103.0)
3,4,6	104.45		

Note. The chemical shifts calculated from the increments are given in brackets.

Table 3. The chemical shifts (δ/ppm) of the 2,3,4,6-tetranitrate of methyl β-D-glucoside, β-cellobiose octanitrate, and cellulose trinitrates.

Atom	δ(2,3,4,6-TNMG) according to data in Refs		δ(CON-*A*) according to data in Refs		δ(CON-*B*) according to data in Refs		δ(CTN) according to data in Refs		
	39	43	34	43	34	43	34	43	41
C(1)	101.4	101.35	100.1	100.26	96.1	96.64	100.1	100.14	100.0
C(2)	79.1	79.06	78.5	78.58	74.8	74.73	78.3	79.28	80.6
C(3)	78.8	79.06	78.6	78.58	79.0	78.96	79.4	78.06	79.5
C(4)	76.9	76.88	76.0	75.94	76.75	77.02	76.8	77.02	77.2
C(5)	70.35	70.30	69.8	69.66	72.6	72.50	71.7	71.37	71.9
C(6)	71.1	71.12	70.5	70.65	70.1	70.23	70.6	70.72	71.9

Note. Here and henceforth the chemical shifts corresponding to those of CTN are underlined (Fig. 6). The last column presents data for a solution of CTN in dimethyl sulfoxide, while the remaining columns present data for solutions in acetone-d_6.

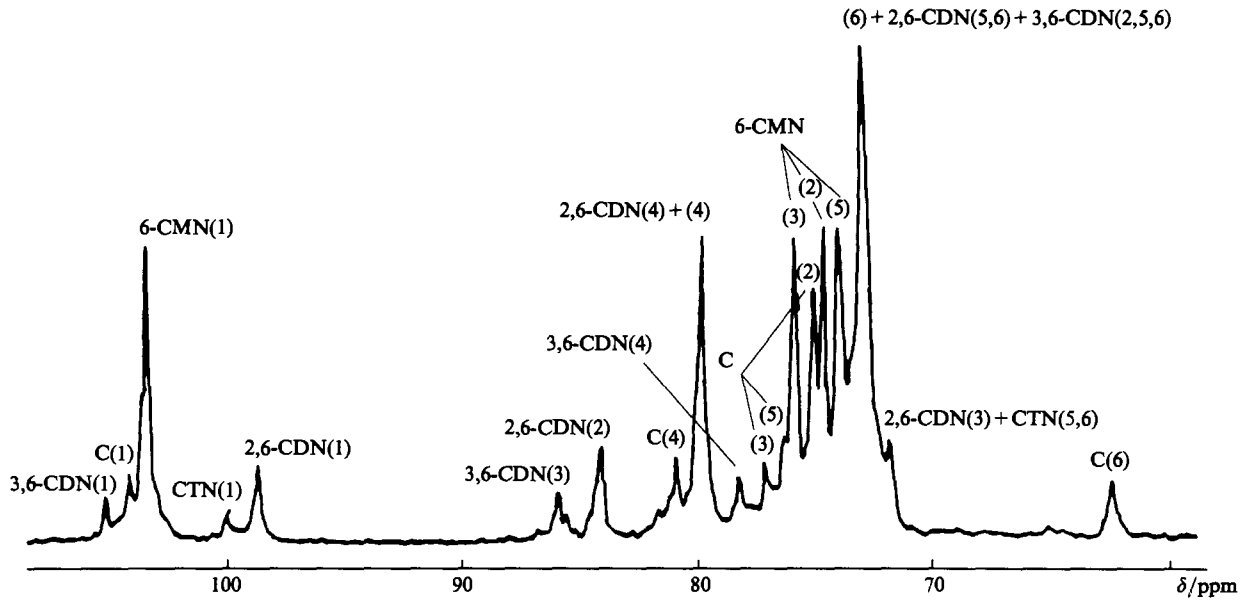

Figure 7. The ^{13}C NMR spectrum of a cellulose nitrate specimen with a degree of substitution of 1.2 in solution in DMSO showing the assignments of the signals to the corresponding units (the number of the ring carbon atom is indicated in brackets).[41]

The presence of the nitrate group in the 2-position is characterised by the presence of C(1) signals in the region of 100 ppm for any types of substitution in the remaining positions (see Table 4), whilst its absence leads to the displacement of the signals of the C(1) atom to the region of 104 ppm. Apparently this is a convenient analytical feature for the determination of the type of substitution. Analysis of the chemical shifts of the C(1) atom for model nitrates of methyl β-D-glucosides has confirmed the above conclusion that the conformational state of the cellulose nitrate chains influences significantly the positions of the signals in the NMR spectrum. Evidently the conformer most stable for the given solvent is formed in the model nitrates, this being indicated by the small differences between the maximum and minimum chemical shifts (Table 4). They also indicate that the C(1) nucleus is less 'sensitive' to the type of substitution in a small molecule than in a chain molecule and this is also evidence for the greater conformational freedom of the cellulose nitrate macromolecules. In order to detect more detailed effects (such as the influence of neighbours), it is necessary to increase significantly the resolution afforded by the spectrometer. For example, comparison of the spectra of the same cellulose nitrate specimen obtained on instruments with different working frequencies shows a marked increase in the complexity of the spectrum, which undoubtedly reflects the influence of secondary effects. However, the interpretation of such spectra still remains difficult.

Analysis of the NMR spectra demonstrated the similarity of the Overhauser effects and the spin–lattice relaxation times for all the carbon nuclei of the glucopyranose ring of cellulose nitrates, which had been indicated earlier by Wu[33] and Clark.[35] This agrees well with the fact that the charges on different oxygen atoms in glucose and its nitrates, obtained from quantum-chemical calculations, are similar.[46] Taking this into account, it is possible to carry out quantitative measurements of the partial degrees of substitution in the 2-, 3-, and 6-positions and also to find the fractions of units with different types of substitution in cellulose nitrates. A series of publications have appeared[33, 35–37, 40, 44, 47–54] whose authors measured the contents of the principal types of units in cellulose nitrates. It is noteworthy that the contents of 2-mono-, 3-mono-, and 2,3-di-nitrate units in cellulose nitrates are very low and for this reason they are usually not measured. (An exception is a study[44] where it was shown that the fractions of the above units are 0.039, 0.021, and 0.047 respectively.)

Progress in the study of the detailed structure of cellulose nitrates was achieved after high-resolution ^{13}C NMR spectra had been obtained in the solid state.[7, 8, 55–59] New results were obtained with the aid of this method, from which it was possible to trace the characteristic features of the formation of the cellulose nitrate matrix during the nitration of cellulose and, at the same time, to assess the conformational rearrangement of the macromolecules. A characteristic feature is that the transition of solutions to the solid phase of cellulose nitrates leads to appreciable downfield shifts and a significant broadening of the lines in the ^{13}C NMR spectra.[58] Thus the following values of δ were obtained for CTN:

C(1)	C(2)	C(3)	C(4)	C(5)	C(6)
101.8	72.1	72.1	72.1	72.0	72.0

The main cause of the change in δ (cf. Table 3) may be, first, the loss of mobility by the chains and, second, the differences between the conformational states of the cellulose nitrate macromolecules in solution and in the bulk phase. The latter are characterised by a much more diverse set of conformations of the chains and substituents. For the C(1) nucleus in solutions of cellulose nitrates (Table 4) it is possible to differentiate two groups of signals for the cellulose nitrate unsubstituted, or substituted, in the 2-position: (1) from the unsubstituted unit and the 6-mono-, 3-mono-, and 3,6-di-substituted units; (2) from the 2-mono-, 2,3-di-, 2,6-di-, and 2,3,6-tri-substituted units. This subdivision can be readily detected also in the NMR spectra of the solid[58, 59] in the form of broad maxima in the regions of 105 and 100 ppm respectively. Evidently, with increase in the degree of substitution of the cellulose nitrate, the increase in the maximum at 100 ppm and the decrease in that at 105 ppm are associated with the increased content of the trinitrate units and the decrease in the fraction of the mono- and di-substituted and unsubstituted units. It is therefore wrong to attribute the changes in the intensities of these signals solely to the conformational rearrangement of the cellulose nitrate with increase in the degree of substitution during the course of nitration.[59]

We are aware of only two papers devoted to the study of high-resolution ^{15}N NMR spectra in solution.[42, 43] The principal signals of the nitrogen nuclei of the nitrate groups, occupying the 2-, 3-, and 6-positions, were assigned in both studies (Table 5).

Table 5. Positions of the signals (ppm) in the high-resolution ^{15}N NMR spectra of solutions of cellulose nitrates and model nitrates.

Position of the nitrate group	2,3,4,6-TNMG[43]	CON[43]		CN[43]	CN[42]
		A	*B*		
2	335.2	332.8	333.7[a]	335.5[b]	−1.0[c]
3	335.3	335.2	334.5	336.9	−2.4
6	340.6	339.6	340.1	341.1	3.2

[a] See Fig. 9.
[b] Degree of substitution 2.72, solution in acetone-d_6, external standard — $^{15}NH_4Cl$ + HCl. [c] Degree of substitution 2.35, solution in dimethyl sulfoxide, external standard — $H^{15}NO_3$.

As can be seen from the data presented, there are significant discrepancies in the interpretation of the signals from the N(2) and N(3) atoms. The reasons for these are so far obscure, but the authors[42] confirm the validity of their interpretation by showing that the relative intensities of the signals agree well with the partial degrees of substitution determined from the ^{13}C spectra. Nevertheless, a detailed analysis of the ^{15}N NMR spectra is lacking to date.

Proton magnetic resonance of cellulose nitrates yields much less information than ^{13}C NMR.[33,43] Systematic analysis of the ^{1}H, ^{13}C, and ^{15}N NMR spectra combined with the analysis of the NMR spectra of selectively substituted model saccharide nitrates will probably assist progress in studies on the detailed molecular structure of cellulose nitrates.

IV. Infrared spectroscopic study of the structure of cellulose nitrates

The vibrational spectroscopy of cellulose nitrates is almost fully represented by IR spectroscopic studies. The measurement of the Raman spectra of cellulose nitrates still constitutes a difficult experimental task.

The first IR spectrum of cellulose nitrate was recorded about 25 years ago.[5,15] Since then, there have been numerous publications devoted to the experimental study of the molecular structure of cellulose nitrates and their analogues by IR spectroscopy[6,7,11,14,44,60–77] and also to theoretical calculations of the vibrational spectra of the latter.[66,78,79] The low-frequency IR spectra of cellulose nitrates[64,68,70] and the nitrates of low-molecular-mass hydrocarbons[73] have been investigated particularly vigorously at the present time (undoubtedly as a result of the appearance of commercial FT-IR spectrometers). A detailed analysis of these spectra and also of the low-frequency spectroscopic characteristics of structural modifications of cellulose has been presented in another review[14] and will not therefore be considered here‡.

The IR spectroscopic data obtained by Watanabe et al.[15] and Panov and Zhbankov[5] were subsequently refined and supplemented by Kovalenko et al.[76] on the basis of the analysis of the IR spectra of cellulose nitrate enriched in ^{15}N and also of the polarised IR measurements for oriented cellulose nitrate fibres.

In the study of the region 2800–2950 cm^{-1} corresponding to absorption due to the $\nu(CH)$ and $\nu(CH_2)$ stretching vibrations of cellulose nitrates enriched in ^{15}N, it was observed for the first time that there is a Fermi resonance of the $\nu_a(CH_2)$ stretching vibration and of the $\nu_a(NO_2)$ + $\nu_s(NO_2)$ sum frequency. The observed redistribution of the intensities and the frequency shifts due to the Fermi resonance explain satisfactorily the dependence of the intensities of the absorption bands due to the CH and CH_2 groups in this spectral range on the degree of substitution of cellulose nitrate which had been discovered earlier.[11,60,71]

Analysis of the IR spectra of highly dilute solutions of cellulose nitrates in tetrahydrofuran (THF) in the range 1600–1700 cm^{-1}, where the $\nu_a(NO_2)$ stretching vibration of the nitrate groups is observed, indicates a doublet structure of the band[44,63,76] with 1662 and 1646 cm^{-1} components (Fig. 8); the first was assigned to the absorption by the nitrate groups occupying the 2- and/or 3-positions and the second was assigned to the absorption by the nitrate groups in the 6-position in the pyranose rings of cellulose nitrate.[44,76] The second derivatives of the spectrum in this range have been obtained[44] and a third high-frequency component of the band was detected. According to the authors, it is associated with the steric hindrance generated by the pair of neighbouring nitrate groups in the 2- and 3-positions in the pyranose ring of the cellulose nitrate. However, it follows from X-ray diffraction and calculated data[21–23,27,29,32] that such hindrance does not occur even in crystals of the model nitrates and it is therefore difficult to expect their appearance in dilute cellulose nitrate solutions. In their next study, the same workers[80] present the spectrum of the same cellulose nitrate specimen but this time without the third component. We emphasise that the doublet structure is readily manifested on an FT-IR spectrometer, with a resolution of 1 cm^{-1}, whereas on the usual dispersion instruments it had been previously impossible to observe it.[11,61]

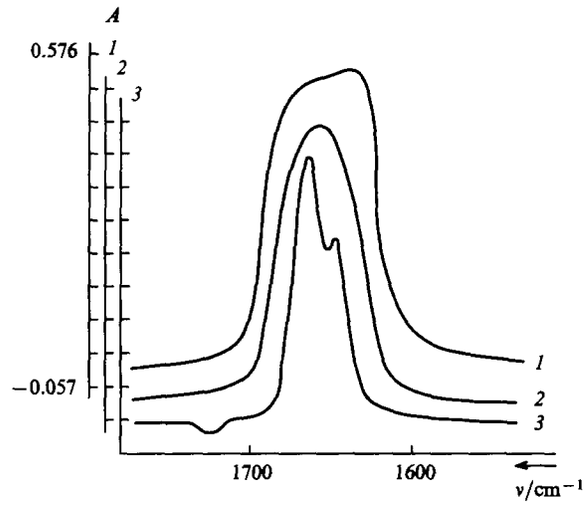

Figure 8. IR spectra of cellulose nitrate with a degree of substitution of 2.8. Specimen: (*1*) fibre; (*2*) film cast from an acetone solution; (*3*) dilute solution in THF.

A complex, diffuse contour of the $\nu_a(NO_2)$ band, the width of which reaches 90 cm^{-1}, can be observed in the IR spectra of fibrous and powdered cellulose nitrates (Fig. 8).[76,77] This width is due to the large set of conformational states of the chains and substituents. It has been suggested[11] that the extensive set of conformations can be accounted for by the inhomogeneity of the nitration of cellulose, where there is insufficient time for the chains to relax after the removal of the liquid phase and the conformations of the chains and the 'appendages' in cellulose nitrate are frozen. Comparison of the IR spectroscopic[77] and X-ray diffraction[82] data for the plasticisation of cellulose nitrates shows that the crystallinity of the cellulose nitrates does not contribute to the widening of the $\nu_a(NO_2)$ band; the narrowing of the band occurs before the plasticiser reaches the crystalline regions of the cellulose nitrate (Fig. 9). Consequently the conformational rearrangement of the chains accompanying their relaxation when the plasticiser is introduced leads to a decrease in

‡ We may note that the 516 and 490 cm^{-1} bands, which have a high dichroic ratio,[76] are due to the vibrations of the pyranose skeleton of the cellulose nitrate chain and are not associated with the vibrations of the trinitrate units as suggested in our earlier communication.[64]

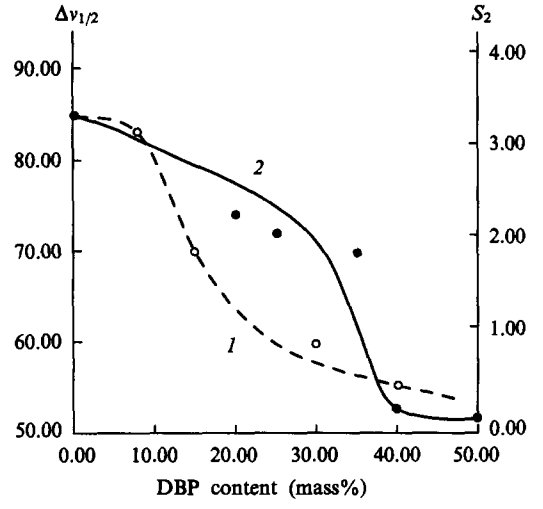

Figure 9. Dependence of the $\nu_a(NO_2)$ band width (curve *1*) in the IR spectra and of the crystallinity of cellulose nitrate S_2 (curve *2*) on the dibutyl phthalate content in the composition with cellulose nitrates.

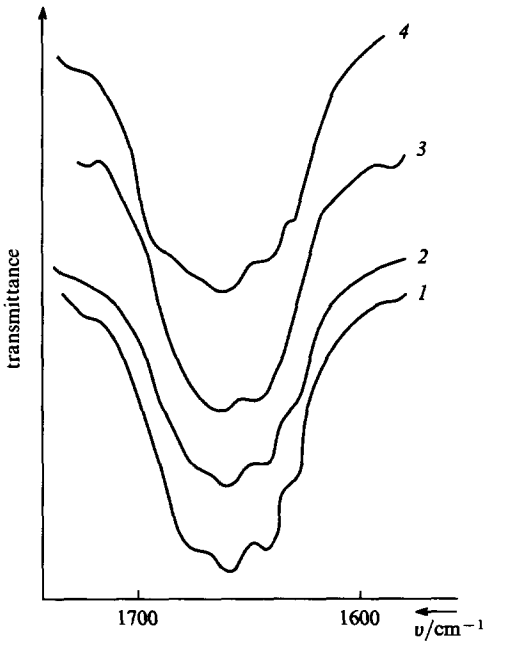

Figure 10. IR spectra of amorphous 2,3-DNMG (curve *1*), 2,3-DNMMG (curve *2*), 2,3,6-TNMMG (curve *3*), and 2,3,4,6-TNMG (curve *4*).

the diversity of the conformations of the nitrate groups and hence to a narrowing of the $\nu_a(NO_2)$ as well as the $\nu_s(NO_2)$ bands.[77]

Studies of the IR spectra of crystalline low-molecular-mass carbohydrate nitrates have been resorted to in the analysis of the complex contour of the $\nu_a(NO_2)$ band in the spectra of cellulose nitrates.[65-67,74] Unfortunately, in this case the transfer of the spectroscopic information obtained, which is itself extremely valuable, to cellulose nitrates is not always justified. Both the static field of the crystal and the Davydov (resonance) splitting are known to exert a significant influence on the position of the absorption band in the IR spectra of organic crystals. In all the crystalline nitrates of glucopyranosides investigated,[23-27] the primitive cell (which in this case is identical with the crystallographic cell) contains four molecules, and one must therefore expect four components due to the splitting of the band in the IR spectrum. Under these conditions, for example in the case of the 2,3,4,6-TNMG crystal, each molecule contains four nonequivalent nitrate groups: the primitive cell, which is in fact reflected in the IR spectrum, includes 16 spectroscopically nonequivalent nitrate groups. The contour of the $\nu_a(NO_2)$ band proves to be complex.[66,74] Effects characteristic of molecular crystals are virtually absent from cellulose nitrates as a consequence of the low crystallinity and defectiveness (owing to the heterounit structure) in the crystal packing of cellulose nitrates.[85] Incidentally, the picture is significantly different in the spectra of amorphous low-molecular-mass glucoside nitrates (Fig. 10): the triplet, doublet, and single $\nu_a(NO_2)$ bands observed in the spectra of 2,3,4,6-TNMG, 2,3-DNMMG, and 2,3-DNMG crystals are converted into bands which are now determined solely by the positions of the nitrate groups in the ring and by the conformational equilibrium in the molecules. For the same reason, it is necessary to treat with caution the application to cellulose nitrates data obtained for the $\nu_s(NO_2)$ band in the spectra of crystals of low-molecular-mass carbohydrate nitrates. In the cellulose nitrate spectrum, this band, like the $\nu_a(NO_2)$ band, is 'sensitive' to conformational rearrangements.[77]

The band due to the antisymmetric stretching vibrations of the nitrate groups in the cellulose nitrate spectra proved useful in determining the compositions of the elementary units[72] (in addition to ^{13}C NMR data): by measuring the ratio A_{1662}/A_{1648} of the optical densities of the components in the IR spectra of dilute cellulose nitrate solutions in THF, it is possible to estimate the ratio of different kinds of substituted cellulose nitrate units from the formula

$$\frac{A_{1662}}{A_{1648}} = \frac{[C_2] + [C_3] + 2\,[C_{23}] + [C_{26}] + [C_{36}] + 2\,[C_{236}]}{[C_6] + [C_{26}] + [C_{36}] + [C_{236}]}, \quad (1)$$

where $[C_{ijk}]$ is the fraction of units with a given type of substitution.

The ν(OH) stretching vibration bands are observed in the form of a broad band having a complex contour in the range 3300–3600 cm^{-1} in the IR spectra of cellulose nitrates with a degree of substitution less than three (Fig. 11). They are due to the hydroxy-groups of cellulose nitrate involved in the formation of hydrogen bonds. The most probable proton acceptors are the nitrate groups, the OH groups themselves, and the O(5) oxygen atoms of the pyranose rings. It has been shown[5-7,11,60-62] that the ~3570 cm^{-1} maximum is due to the hydroxy-groups involved in a weak hydrogen bond with the nitrate groups. At the same time, an absorption region with a maximum at 3430 cm^{-1} may be noted in the cellulose nitrate spectra (Fig. 11). It characterises the OH...OH type of intermolecular hydrogen bond and the O(3)H...O(5) intramolecular hydrogen bond in neighbouring glucopyranose rings.[86,87] Calculations by the method of molecular mechanics showed[19] that a hydrogen bond of the latter type occurs in cellulose mono- and di-nitrates and that the energies of the hydrogen bonds of both types

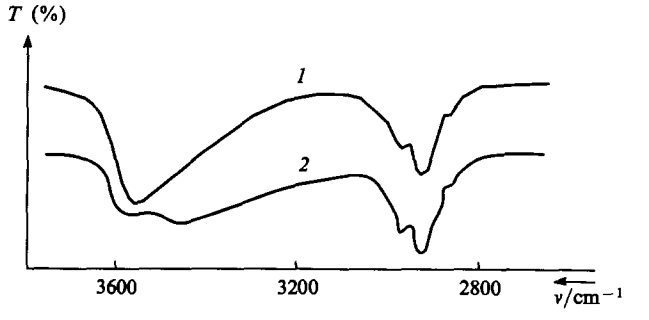

Figure 11. IR spectra of cellulose nitrates with a degree of substitution of 2.0 obtained by nitration in $HNO_3 + CH_2Cl_2$ (curve *1*) and $HNO_3 + H_2SO_4 + H_2O$ (curve *2*).

are similar§. As will be shown below, the ratio of the intensities of the ν(OH) bands at 3570 and 3430 cm^{-1} may be used to estimate the inhomogeneity in the mass distribution of the elementary units of cellulose nitrates.

V. Molecular spectroscopic study of the molecular-structural inhomogeneity of cellulose nitrates

The inhomogeneity in molecular-structure of cellulose nitrates with a degree of substitution less than three is associated with their heterounit structure and is determined by the inhomogeneity of the nitration process, where the final composition of the products depends significantly on the diffusional characteristics of the reaction system. In most cases, the initial cellulose and the final product (cellulose nitrate) are insoluble in the liquid reaction mass, and the morphological and fibrous structures of the initial cellulose are retained after nitration. By estimating the inhomogeneity of the cellulose nitrate with the given degree of substitution, it is possible to find a multiplicity of combinations of heterotypical units, which undoubtedly influence the properties of the cellulose nitrates. However, it has not previously been possible to estimate quantitatively the inhomogeneity of the cellulose nitrates. The methods based on the chemical or enzymic hydrolysis, which have been used successfully to determine the compositions of the elementary units of cellulose ethers, for example by Spurlin[88] and Reuben,[89] proved unsuitable for cellulose nitrates, since the elimination of the nitrate groups from the latter takes place significantly more readily than the dissociation of the glycosidic bonds.[90,91] For this reason, the determination of the composition of the elementary units and of the molecular-structural inhomogeneity of cellulose nitrates became possible only recently by virtue of the advances made in the study of the detailed molecular structures of cellulose nitrates by the high-resolution ^{13}C NMR and FT-IR spectroscopic methods.

1. Terminology

Since there is some terminological confusion in the literature on the molecular structure of cellulose esters, and the number of studies devoted to the inhomogeneity of such esters has been growing continuously, it has become necessary to define the terms used in the analysis of the molecular structure of cellulose esters — in this instance cellulose nitrates.

The degree of substitution γ is defined as the average number of substituting groups per glucopyranose ring in the cellulose nitrate macromolecule. The partial degree of substitution at the given carbon atom γ_i is the average number of substituting groups occupying the given position C_i. Clearly for cellulose nitrates we have

$$\gamma = \gamma_2 + \gamma_3 + \gamma_6.$$

For example, in the fully substituted CTN with a degree of substitution $\gamma = 3$, we have

$$\gamma_2 = \gamma_3 = \gamma_6 = 1.$$

The composition of the elementary units is expressed in fractions of unity and is defined by the relations[88]

$$s_0 + s_2 + s_3 + s_6 + s_{23} + s_{26} + s_{36} + s_{236} = 1,$$

where s_{ijk} is the fraction of units with the given type of substitution, and

$$c_0 + c_1 + c_2 + c_3 = 1,$$

where c_i are the fractions of unsubstituted and mono-, di-, and trisubstituted cellulose nitrate units. Evidently $c_0 = s_0$ and

$$c_1 = s_2 + s_3 + s_6,$$

$$c_2 = s_{23} + s_{26} + s_{36},$$

$$c_3 = s_{236}.$$

Here one may speak of six hypothetical cellulose nitrate homopolymers (cellulose 2-, 3-, and 6-mononitrates and 2,3-, 2,6-, and 3,6-dinitrates). The seventh homopolymer (CTN) does actually exist.

In the general case, the cellulose nitrate macromolecule represents an assembly of elementary units of eight types and an analogy with copolymers is appropriate here: statistical, block, etc.

2. Distribution of the units along the chain

The distribution of heterotypical units along the chain is also referred to as the microstructure or configuration of the chain.[92] By analogy with biopolymers, one may assume that each heterotypical cellulose nitrate unit represents a letter of the alphabet, so that the cellulose nitrate chain constitutes an eight letter 'word'. Unfortunately the current level of experimental technique does not permit the decoding of these cellulose nitrate 'words'. However, it is possible, in principle, to solve the problem of the frequency of the appearance of particular combinations of 'letters' for different methods of synthesis of cellulose nitrates. This problem has not yet been solved although the first attempts have already been made.[36,53]

3. Distribution of units in the bulk phase (in the matrix)

For the statistical distribution of the elementary units along the cellulose nitrate chain, one may expect that their distribution in the matrix is also statistical or homogeneous. The extreme case is the block character of the distribution of units along the chain. There is then a possibility of the aggregation of blocks of isotypical units into domains — three-dimensional regions of the cellulose nitrate matrix containing mainly chain fragments consisting of isotypical units. As a result of the inhomogeneous nature of the nitration of cellulose, a state intermediate between the cases quoted above occurs in the cellulose nitrate obtained.

The possibility of determining or estimating the composition of the elementary units, and of determining their distribution along the chain or in the bulk of the cellulose nitrate, gives rise to ways of analysing the inhomogeneity of cellulose nitrates, which is necessary both for the study of the mechanism and kinetics of the nitration of cellulose and for the preparation and processing of industrial cellulose nitrates.

4. Levels of inhomogeneity of cellulose nitrates

The molecular-structural inhomogeneity of cellulose nitrates is determined by a complex set of parameters: the composition of the nitrating mixture, the morphological structure of the initial cellulose determined by its origin (cotton, wood, linen, etc. celluloses), the conditions in the preparation of cellulose for nitration (activations of different kinds), and the nitration regimes. Naturally, without a logically well-founded subdivision in terms of the levels of inhomogeneity of cellulose nitrates, analysis of their properties becomes virtually impossible. For this reason, it has been suggested that their molecular-structural inhomogeneity be divided into several hierarchical levels:[72] in terms of the composition of the elementary units (compositional inhomogeneity); in terms of the distribution of heterotypical elementary units along the chain (configurational inhomogeneity); and in terms of the distribution of heterotypical elementary units in the cellulose nitrate matrix (matrix inhomogeneity).

5. Inhomogeneity of cellulose nitrates in terms of the composition of the elementary units

The compositions of the elementary units of cellulose nitrates[33,35,36,44,48–54] and of a number of other polysaccharide derivatives[93–96] have now been quite reliably determined by

§O K Nugmanov. Personal communication.

high-resolution ^{13}C NMR in solution. Systematic analysis of the inhomogeneity at this level is only possible when a single methodological approach, permitting a comparison of data obtained for different nitrating mixtures, initial celluloses, etc., is employed. Attempts to achieve such an approach have been undertaken,[36,97] but, in our view, they have not been successful, because the criteria employed were not clearly defined and there were no 'reference points' for the inhomogeneity of the cellulose nitrates. A simple scheme for the determination of the inhomogeneity of cellulose nitrates in terms of the composition of elementary units (suitable, incidentally, for any derivatives of cellulose and of polysaccharides in general) has been proposed.[86] The concepts of cellulose nitrates with limiting homogeneity and limiting inhomogeneity were introduced in the above study. Cellulose nitrates with integral degrees of substitution are assumed to have the limiting homogeneity: 1 — cellulose mononitrate, 2 — cellulose dinitrate, and 3 — cellulose trinitrate. Here no account is taken of the specific positions of the nitrate groups in the elementary unit. For degrees of substitution of 1.2 and 2.5, cellulose nitrates containing respectively 20% of disubstituted and 80% of monosubstituted units, and 50% of dinitrate and trinitrate units, are considered to be homogeneous to the limiting extent. Cellulose nitrates consisting only of trinitrates and unsubstituted units are considered to have the limiting inhomogeneity.

In order to measure the inhomogeneity of cellulose nitrates in terms of the composition of the units, one determines the sum of the deviations, $\Sigma\Delta_i$, of units of the given type (tri-, di-, and monosubstituted as well as unsubstituted) from cellulose nitrates homogeneous to the limiting extent and with the same degree of substitution:

$$\Delta_i = |a_i - a_i^0|,$$

where a_i and a_i^0 are the measured and calculated fractions of the ith type units respectively. Analogous calculations are performed for the hypothetical cellulose nitrates which are inhomogeneous to the limiting extent, whereupon the dependence of $\Sigma\Delta_i$ on the degree of substitution of the cellulose nitrate is represented graphically by the 'inhomogeneity trapezium' (Fig. 12), the base of which is the cellulose nitrate homogeneous to the limiting extent in terms of the composition of the elementary units ($\Sigma\Delta_i = 0$), while the other three sides bound the region of existence of cellulose nitrates with any homogeneity (with respect to the composition of the units).

Models of the esterification of cellulose have been analysed[88] in terms of the quasi-homogeneous approximation (with thermodynamic and kinetic monitoring of the reaction products) and calculations have been made of the fractions of the unsubstituted, monosubstituted, disubstituted, and trisubstituted units in accordance with the constants for the substitution of the hydroxy-groups in the 2-, 3-, and 6-positions in the glucopyranose rings. These were subsequently revised for cellulose nitrates.[33,40,97] The values of $\Sigma\Delta_i$ were calculated from these data and plotted (Fig. 12). The figure includes also all the available experimental data for cellulose nitrates. The inhomogeneity with respect to composition of elementary units is determined by the distance from the abscissa axis of the values of $\Sigma\Delta_i$ calculated from the experimental measurements. The cellulose nitrates obtained by nitration in mixtures of nitric and sulfuric acids and in solutions of nitrogen oxides in nitric acid, as well as denitrated cellulose nitrates, proved to be the most inhomogeneous. These results will be examined in detail in the next section. Here we may note the clarity of the proposed procedure and the possibility of comparing polysaccharide derivatives with any compositions of the elementary units. For example, in the selectively substituted cellulose 2,3-diacetate (degree of substitution 1.69), the compositional inhomogeneity is very low and $\Sigma\Delta_i = 0.18$.[93] Carboxymethylcellulose with a low degree of substitution (0.7) has $\Sigma\Delta = 0$,[94] whilst a cellulose ether (degree of substitution 1.27) also exhibits a high inhomogeneity

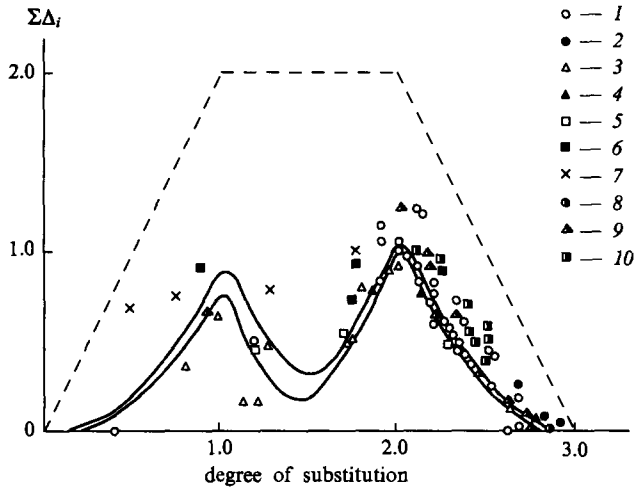

Figure 12. The sums of the deviations $\Sigma\Delta_i$, measured by ^{13}C NMR, of the compositions of the elementary units of cellulose nitrates obtained by nitration in the $HNO_3+H_2SO_4+H_2O$ [33,36,40,44,48–50,53] (curve *1*), $HNO_3+H_2SO_4$ [49] (curve *2*), HNO_3+H_2O [50,53,54] (curve *3*), and $HNO_3+CH_2Cl_2$ [40] (curve *4*) mixtures, in HNO_3 vapour [50,53,54] (curve *5*), in the $HNO_3+N_2O_5$ [50] (curve *6*), $HNO_3+N_2O_5+N_2O_4$ (Yu M Kargin, personal communication) (curve *7*), and $HNO_3+H_3PO_4+P_2O_5$ [35] (curve *8*) mixtures, and by denitration in the HNO_3+H_2O [35,50,53] (curve *9*) and $HNO_3+H_2SO_4+H_2O$ [48] (curve *10*) mixtures. Calculated sums of the deviations $\Sigma\Delta_i$: continuous curves — according to Spurlin:[88] upper curve — for the equilibrium constant ratios $K_6 : K_2 : K_3 = 10 : 1 : 1$, lower curve — for the rate constant ratios $k_6 : k_2 : k_3 = 10 : 1 : 1$; dashed line — calculated sums of the deviations $\Sigma\Delta_i$ for cellulose nitrates with the limiting inhomogeneity.

with respect to the composition of the elementary units with $\Sigma\Delta_i = 0.36$.[95] It is of interest that the amylose nitrates obtained by inhomogeneous nitration and having degrees of substitution of 1.69 and 2.17 are characterised by $\Sigma\Delta_i = 0.68$,[96] which is close to the value calculated by Spurlin's method (Fig. 12), whereas the homogeneously denitrated amylose nitrate with a degree of substitution of 1.89 has $\Sigma\Delta_i = 0.08$.

The limitation of the applicability of high-resolution NMR to polymer solutions should be noted. Only the dissolved part of the polymer contributes to the signal intensities, and for low degrees of substitution the solubility of cellulose nitrates in organic solvents is low. This is in fact the reason why the limiting homogeneity of the cellulose nitrate specimen with a degree of substitution of 0.4, found by Wu,[33] is a 'consequence' of neglecting this limitation.

Results obtained by IR spectroscopy may be used to estimate the inhomogeneity from the ratio of the optical densities of the 1662 and 1648 cm^{-1} bands by using Eqn (1). Unfortunately, this method too, which is simpler than the NMR procedure, suffers from a disadvantage — no account is taken of the unsubstituted units, i.e. the applicability of the method is limited to the region where the degree of substitution is greater than two, in which the fraction of these units becomes negligible.

6. Distribution of elementary units along the cellulose nitrate chain

Currently, the distribution of the elementary units along the cellulose nitrate chain is not susceptible to direct measurement, although it is possible in principle. Such distribution can, however, be inferred indirectly from combined data on the compositional and matrix inhomogeneities of cellulose nitrates. We may note that both the compositional and the configurational inhomogeneities of cellulose nitrates are characteristics of macromolecules; account must be taken of the fact that all the data presented here are estimates of both levels of

inhomogeneity, averaged over the entire assembly of macromolecules. If it is necessary to investigate the compositional inhomogeneity of the macromolecules themselves, one has to resort to methods developed for the investigation of the molecular-mass distribution of cellulose nitrates — for example fractionation, gel-permeation chromatography with different detection procedures, etc.

7. Distribution of heterotypical units in the cellulose nitrate matrix

The distribution of heterotypical units in the cellulose nitrate matrix has been investigated very fully. Most of the results have been obtained by X-ray photoelectron spectroscopy (XPS). This method yields information about the elementary composition of the material on the surface to a depth of the order of tens of nanometers.[8] By comparing the contents of nitrate groups on the surfaces of cellulose nitrate fibres, measured by the XPS method, and in the bulk of the material, it is possible to infer the matrix inhomogeneity of the cellulose nitrate. It has been shown[98] that nitration of cellulose by the $HNO_3 + H_3PO_4 + P_2O_5$ and $HNO_3 + P_2O_5 + H_2O$ mixtures proceeds uniformly on the surface and in the bulk of the fibres, attaining simultaneously identical degrees of substitution, whereas in nitration by the $HNO_3 + H_2SO_4 + H_2O$ mixtures the final degree of substitution is attained rapidly on the surfaces of the fibres but, even after nitration for 2 h, the degree of substitution within the fibres remains smaller than on the surface. Nitration of cellulose by a solution of the nitronium salt $NO_2^+BF_4^-$ in general takes place only on the surfaces of the cellulose fibres without involving the inner region.[99]

The results of X-ray phase analysis (XPA) have shown that the crystal structure of cellulose nitrate is already formed during the nitration process. In the nitration of cellulose by $HNO_3 + H_2SO_4 + H_2O$ mixtures, the reflections due to the nonnitrated regions of the cellulose are still observed, together with the reflections due to crystalline cellulose nitrates, even for a degree of substitution of 2.[100–103] Furthermore, on raising the water content in the above mixture from 0% to 15%, it was observed[52] that the inhomogeneity of the resulting cellulose nitrates diminished: the reflections due to crystalline cellulose vanish at lower degrees of substitution, while the formation of cellulose nitrate crystallites begins at higher degrees of substitution. Nitration of cellulose with the $HNO_3 + CH_2Cl_2$ mixture is characterised by the formation of a more homogeneous cellulose nitrate structure: the reflections due to cellulose have already disappeared for a degree of substitution of 0.1, whereas the crystallinity of the cellulose nitrates begins to be manifested only for a degree of substitution > 1.2.[102,104] It has also been shown by the XPA method that the products of the nitration of cellulose of different origins (cotton and wood celluloses) in the same nitrating mixture are different, the most homogeneous cellulose nitrates being obtained when cotton cellulose is employed.[103] The data obtained by high-resolution ^{13}C NMR in the solid state lead to similar conclusions.[10,105] Seemingly, by employing the XPA method for the analysis of the dynamics of the cellulose nitration process as a function of time, it is possible to discover the characteristics of the establishment of the inhomogeneity of the cellulose nitrates: the lower the degree of substitution at which the reflections due to crystalline cellulose vanish and the higher the degree of substitution at which the crystal packing of cellulose nitrate begins to be established, the more homogeneous is the cellulose nitrate obtained.

The establishment of the inhomogeneity of cellulose nitrates has been analysed by IR spectroscopy for two nitrating media — concentrated HNO_3 and the $HNO_3 + H_2SO_4 + H_2O$ mixture.[106] The ratios of the cellulose nitrate fractions soluble and insoluble in acetone were determined in samples taken during the nitration process, and the degrees of substitution of both fractions were found for each specimen from the formulae

$$\gamma_s = 3 - \frac{3-\gamma}{a_s(1 + a_u b_u/a_s b_s)}, \text{ and } \gamma_u = 3 - \frac{3-\gamma}{a_u(1 + a_s b_s/a_u b_u)},$$

where γ is the degree of substitution of the given cellulose nitrate specimen, γ_s and γ_u are the partial degrees of substitution, a_s and a_u are the mole fractions, and b_s and b_u are the relative optical densities of the ν(OH) bands due to the hydroxy-groups in the soluble (s) and insoluble (u) fractions of the cellulose nitrate respectively (Table 6). In order to estimate the inhomogeneity of the cellulose nitrate, the deviations of the partial degrees of substitution from the overall degree of substitution were calculated from the relations

$$\Delta_s = \frac{\gamma_s - \gamma}{\gamma}, \quad \text{and} \quad \Delta_u = \frac{\gamma - \gamma_u}{\gamma}.$$

Evidently the smaller the values of Δ_s and Δ_u, i.e. the closer the partial and overall degrees of substitution of cellulose nitrates, the greater the homogeneity of the latter. In the course of the nitration by the ternary mixture, the degrees of substitution of the

fractions soluble and insoluble in acetone differ significantly from the degree of substitution of the specimen analysed, so that the inhomogeneity of the latter is appreciably greater than that of the cellulose nitrate obtained by nitrating cellulose with concentrated nitric acid.

The residual hydroxy-groups present in the elementary cellulose nitrate units (with the exception of the fully substituted ones) are a kind of label. They can form hydrogen bonds of different types in the cellulose nitrate matrix. Taking this into account, the distribution of the labels in the bulk of the cellulose nitrate has been estimated quantitatively.[86] Those cellulose nitrates in which there is a statistical distribution of the heterotypical units in the bulk phase are matrix-homogeneous. We therefore calculated[86,87] the ratio of the probabilities of the formation of weak hydrogen bonds between the hydroxy- and nitrate groups, of strong hydrogen bonds of the type OH...OH, and of intramolecular hydrogen bonds of the type OH(3)...O(5) from only the degree of substitution of the cellulose nitrates by means of the formula

$$P_r = k\frac{\gamma}{3-\gamma},$$

where k is a coefficient which takes into account the fraction of the intramolecular hydrogen bonds. The ratios A_{3570}/A_{3440}, reflecting the actual ratios of the different types of hydrogen bonds involving the residual OH groups in the cellulose nitrate and determined experimentally from the IR spectra, were used to plot the $P_r = f(\gamma)$ relation (Fig. 13). The relation between this level of inhomogeneity, determined by a somewhat different method, and the thermal stability of the cellulose nitrates has been demonstrated.[107]

We may note that there is complete agreement between the results of the measurements of both levels of inhomogeneity — compositional (Fig. 12) and matrix (Fig. 13) inhomogeneities. This evidently reflects their hierarchical relation because nitration in all the nitrating media examined above takes place inhomogeneously. It is quite likely that the use of nontraditional nitration methods, for example transesterification under homogeneous conditions or the application of new selectively substituting reagents, will lead to inconsistent data for different levels of inhomogeneity.

Deviations of the optical densities (A_{3570}/A_{3440}) of cellulose nitrates obtained by nitration in $HNO_3 + H_2SO_4 + H_2O$ (*1*, *1'*), $HNO_3 + H_2SO_4$ (*2*), $HNO_3 + H_2O$ (*3*), and $HNO_3 + CH_2Cl_2$ (*4*) mixtures. (*1'*) cellulose nitrate films cast from solutions in acetone; the P_r curves have been calculated for two values of k.[86]

VI. Inhomogeneity of the nitration and inhomogeneity of cellulose nitrates

Cellulose nitrates obtained by nitration with $HNO_3 + H_2SO_4$, $HNO_3 + H_2SO_4 + H_2O$, $HNO_3 + N_2O_5$, and $HNO_3 + N_2O_5 + N_2O_4$ mixtures, as well as the denitrated cellulose nitrates, are most inhomogeneous in terms of the composition of the elementary units and in the matrix. More homogeneous cellulose nitrates have been synthesised in liquid and gaseous nitric acid, in its aqueous solutions, and in nitric acid–dichloromethane mixtures. It was found that such subdivision in terms of inhomogeneity correlates satisfactorily with the presence or absence of nitronium ions NO_2^+ in the initial nitrating mixtures. Thus, in a mixture of sulfuric and nitric acids, the latter is dissociated to a considerable extent[108–111] with formation of the most inhomogeneous cellulose nitrates (Fig. 12). The addition of water to this mixture of acids lowers the NO_2^+ concentration[109,111] and the inhomogeneity of the cellulose nitrates in terms both of the composition of the elementary units and of the matrix (Fig. 13). Nitration with a solution of the nitronium tetrafluoroborate salt[99] leads to the formation of a surface layer of cellulose nitrates on nonnitrated cellulose fibres. The mixture of nitric acid with N_2O_5 is also characterised by a high concentration of nitronium ions.[112,113]

The content of nitronium ions in aqueous solutions of nitric acid with a HNO_3 concentration in excess of 80% is low;[114] the degree of ionisation of the acid varies within the limit of 0.03. The compositional inhomogeneity does not then exceed the values calculated by Spurlin's method and the matrix inhomogeneity of the cellulose nitrates obtained in 98% nitric acid is significantly lower than that of the cellulose nitrates synthesised in the $HNO_3 + H_2SO_4 + H_2O$ mixture (Table 6, Fig. 13). Nitronium ions have not been detected in the $HNO_3 + CH_2Cl_2$ mixtures,[115] which has been confirmed by studies on the Raman spectra of this mixture in the nitric acid concentration range from 30% to 80%. Cellulose nitrates obtained by nitration in this mixture are the most homogeneous (Figs 12 and 13).

Several points of view on the mechanism of the nitration of cellulose exist at the present time. The elementary step in the reaction reduces mainly to the $Cell-OH + NO_2^+$, $Cell-OH_2^+ + HONO_2$, and $Cell-OH_2^+ + N_2O_5$ interactions or their combinations.

In order to elucidate the relation between the inhomogeneity of the cellulose nitrate obtained and the presence of nitronium ions in the initial acid mixture, we shall consider the following scheme: the elementary step of the reaction requires an active pair consisting of the nitronium ion and a hydroxy-group of cellulose, the molecular form of nitric acid or N_2O_5, and the protonated form of the hydroxy-groups of cellulose. In this case, the nitration of cellulose must be regarded as the combination of three proceses occurring simultaneously:

(1) diffusion of the nitrating mixture to the polymer matrix;
(2) the formation of the active pairs;
(3) the interaction of the active pairs (nitration proper).

These processes are followed by the counterdiffusion of the species (molecules and ions) comprising the nitrating mixture and the low-molecular-mass reaction product in microregions of the matrix of the cellulose being nitrated. Since the rate of nitration (process 3) is significantly higher than the rates of the first two processes, the homogeneity of the cellulose nitrates obtained depends on the ratio of the rates of processes 1 and 2.

If the nitrating mixture contains initially the nitronium ions NO_2^+, i.e. both components of the active pair are already present in the reaction mass, process 2 is ruled out and the reaction proceeds topochemically (Fig. 14, curve *1*). The rate of this reaction is limited by the diffusion of nitronium ions into the cellulose matrix, and leads to the formation of an inhomogeneous cellulose nitrate. On the other hand, if process 2 plays a significant role, then the active pairs interact at the site of the increase in their concentration and, what is most important,

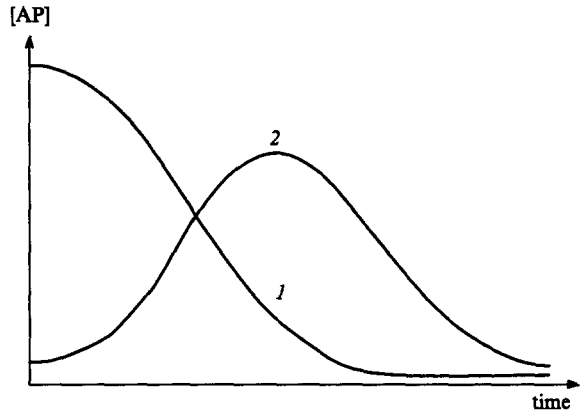

Figure 14. Variation of the concentration of the active pairs [AP] during the diffusion of the nitrating mixture into the cellulose matrix: (*1*) in the presence of both components of the pair at the beginning of nitration; (*2*) on formation of the active pairs during nitration.

under the conditions of a more or less uniform distribution resulting from the diffusion of the nitrating mixture (process 1) into the cellulose matrix (Fig. 14, curve *2*). The reaction then proceeds quasi-homogeneously and a more homogeneous cellulose nitrate is therefore formed. There is no doubt that the real nitration pattern is the average of those illustrated in Fig. 14. The rate of diffusion can evidently vary depending on the ability of the nitrating mixture to 'loosen' the cellulose matrix, but the formation of active pairs probably plays the main role in the establishment of the inhomogeneity.

The products of the denitration of cellulose nitrates obtained by treating the latter with solutions of nitric acid[35,50,53] or the sulfuric acid–nitric acid mixture[48] have the most inhomogeneous elementary units. Seemingly the denitration of cellulose nitrates has different features as regards both the mechanism[116] and the diffusional characteristics. Experimental data (XPA) have shown[36,48] that the denitration involves the cellulose nitrate crystallites to only a slight extent, the diffusion of the denitrating mixture in the latter being significantly limited. For this reason, the denitration proceeds mainly in the nonordered sections of the cellulose nitrate matrix, whereupon a considerable proportion of the dinitrate and trinitrate units, which constitute the bulk of the cellulose nitrate crystallites, are retained and the inhomogeneity of the denitrated cellulose nitrates increases. This has been confirmed by the finding that the last point for the denitration of cellulose nitrates by the acid mixture, corresponding to a degree of substitution of 2.1 (over a period of 7 days) (Fig. 12), fits on the calculated curve. The inhomogeneity of this cellulose nitrate is significantly lower, which can be accounted for by the disruption of the morphological structure,[48] the degradation of the specimen, and hence a sharp increase in the accessibility of the bulk of the cellulose nitrate to the denitrating agent.

Thus, by monitoring the molecular-structural inhomogeneity of cellulose nitrates, it will evidently be possible to estimate directly the role of the diffusional component in the analysis of the kinetics of the inhomogeneous cellulose nitration reaction.

VII. Conclusion

The inhomogeneity of the nitration of cellulose affects significantly the properties of the resulting cellulose nitrates directly via their molecular-structural inhomogeneity. In the synthesis of new cellulose nitrate materials with more stringent requirements as regards homogeneity (for example biological membranes, detectors of ionising radiations, enamels, varnishes, etc.), it becomes possible to alter in a planned manner the conditions in the synthesis by taking into account the results of the analysis of the inhomogeneity of the cellulose nitrates obtained. The molecular-structural inhomogeneity must also be monitored when new selective reagents are used in the nitration of cellulose and in carrying out homogeneous transesterification or nucleophilic substitution reactions, whereupon it is possible to increase the selectivity of substitution in specific positions in the glucopyranose ring; the latter factor makes it possible to obtain new cellulose derivatives which cannot be synthesised directly from cellulose itself.

The theoretical ideas concerning the kinetics of macromolecular reactions have been mainly developed for homogeneous conditions[92,117–119] and all investigators agree unanimously that the development of approaches to the description of the kinetics of heterogeneous reactions closest to the real technological processes is an extremely complex task. The studies in the field of the kinetics of inhomogeneous processes, vigorously prosecuted in recent years,[120] involve the reactions of polymers.[120,121] The creation of models of this kind requires a detailed analysis of the changes in the structures of the reaction products, analogous to that proposed for the cellulose nitration reactions.

The applicability of the approaches developed for the analysis of the molecular-structural inhomogeneity of cellulose nitrates to other cellulose derivatives must be pointed out yet again. This applies primarily to the acetates and ethers for which adequate NMR and IR spectroscopic data are at present available.

Abstract. The theoretical foundations, principle of operation, constructional features, and the latest advances in scanning tunnelling and atomic force microscopy in situ are examined in relation to electrochemical studies on the surfaces of metallic electrodes, and adsorption and electrocrystallisation processes. The bibliography includes 172 references.

I. Introduction

No one is surprised nowadays by communications concerning the observation of the morphology of surfaces at atomic resolution, although the scanning tunnelling microscope (STM) was invented by Binnig and Rohrer only just over 10 years ago.[1] At that time, it was difficult to believe that the observation of the atomic structure of a surface in vacuo or in air was realistic. Nowadays electrochemists are no longer satisfied with observations ex situ but prefer to use the STM or the atomic force microscope (AFM) for the investigation of the state of the electrode surface in situ during the polarisation process.

The term scanning probe microscopy (SPM), which combines tunnelling and atomic force microscopies because these methods have much in common and are frequently used simultaneously, has been established in the English language literature. Scanning probe microscopy is developing rapidly at the present time, an enormous number of publications concerning its use in electrochemical experiments have appeared, and the degree of sophistication of the research has greatly increased—from the demonstration of the possibilities of the instrument, investigators have gone on to a serious analysis of the results and a realistic study of the electrode surface and the mechanisms of the processes occurring on it. These factors have stimulated the writing of the present review. The principles of SPM and the traditional designs of the instruments are examined very briefly, as there are already many excellent review articles and monographs on this topic in the literature,[1–11] and attention is concentrated on the latest results of electrochemical studies and the prospects for the development of this unique method.

II. Theoretical foundations of scanning probe microscopy

1. Principle of the operation of the tunnelling and atomic force microscopes

A real possibility of the tunnelling of an electron through a barrier, the height of which greatly exceeds its energy, is known to exist. If two conductors (electrodes), separated by a dielectric (vacuum, gas, or liquid), are brought together to a sufficiently short distance s and a potential U_t is established between them, then a tunnelling current I_t arises in the circuit, is proportional to the applied potential, and depends exponentially on the distance between the electrodes:

$$I_t = KU_t \exp(-A\sqrt{V_t}s), \quad (1)$$

where K is a constant, V_t the height of the potential barrier (for $s > 2$ nm, the height of the barrier is virtually equal to the electron work function), and $A \approx 10$ nm^{-1} eV$^{-1/2}$ is the proportionality coefficient. This is the Fowler–Nordheim equation, which is valid for planar electrodes and low potentials ($U_t \ll 1$ V). In real experiments such conditions are not always observed, but the exponential dependence of the tunnelling current on distance is retained (see, for example, Behm et al.[2] and Christensen[8]).

Simple calculation shows that, in order to record a tunnelling current of the order of magnitude of a nanoampere, it is necessary to bring the probe electrode to a distance of several angstroms from the surface investigated (for metals, $V_t \approx 5$ eV, and a tunnelling current of 1 nA is observed for $s \approx 0.6$ nm when $U_t \approx 1$ eV).[7]

Theoretically everything is fairly simple and it only remains to solve the problem of how the system is to be constructed.

The concept of the STM was proposed by Binnig and Rohrer in 1979, and in 1981 the first clear cut dependence of the tunnelling current on the distance between the specimen and the point of the probe, characteristic of tunnelling, was recorded. Topographical images of the $GaIrSn_4$ surface with multiatomic steps were soon obtained.[1]

The simplest tunnelling microscope (Fig. 1) consists of a piezoceramic scanner *1* (a tripod or sectioned tube, the geometrical dimensions of which vary in the XYZ directions following the application of an electric potential to the corresponding section) with a tunnelling probe *2* (a sharp needle made from tungsten, a platinum–iridium alloy, carbon, or another material), electronic circuits *4* for the maintenance of the potential and the tunnelling current in the test specimen *3* and the probe, and a recording and controlling computer system *5*.

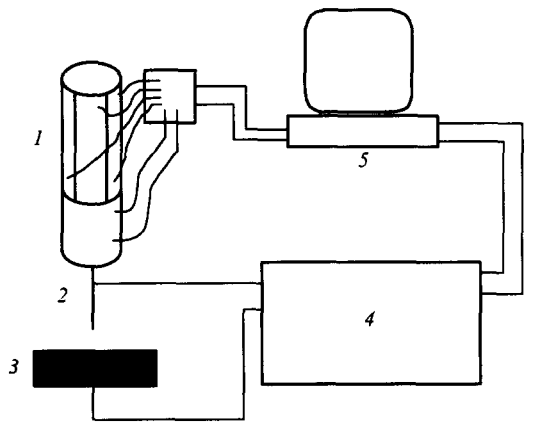

Figure 1. Block diagram of the tunnelling microscope (here and henceforth the explanations are given in the text).

Different designs of piezoscanners make it possible to move the point of the probe to distances ranging from fractions of an angstrom to several tens of micrometers. After the probe has approached the surface to a distance of several angstroms (the moving devices for the solution of this problem will be examined below), the tunnelling current assumes values of the order of magnitude of a nanoampere, and the electronic circuit with a feedback loop makes it possible to stabilise the current by varying the potential on the Z-section of the piezoscanner, i.e. by raising and lowering the probe (Fig. 2*a*) over the surface of the specimen (we recall that the tunnelling current depends greatly on the gap between the electrodes). The galvanostat works similarly, but here the potential on the electrochemical cell is varied in order to maintain a constant current in the working electrode circuit.

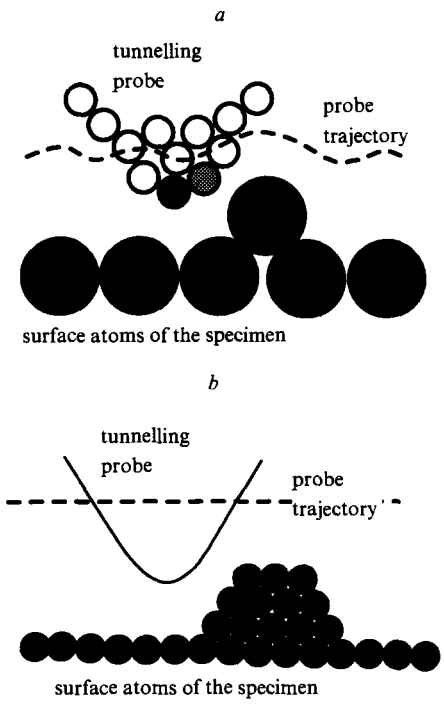

Figure 2. Principal regimes in the operation of the STM: (*a*) maintenance of a constant tunnelling current; (*b*) maintenance of a constant height of the probe over the specimen.

By applying to the X-section of the piezoscanner a potential varying linearly with time, it is possible to move the probe over the surface along a straight line (a ceramic unit, the length of which depends linearly on the applied potential, is used for piezoscanners). By recording the potential on the Z-section of the piezotube which is varied by the feedback loop, one obtains the surface relief along the scanning line. Strictly speaking, the electronic state of the surface and not its relief is recorded, but in most cases these relations are similar on specimens with a homogeneous composition. Thus, by varying the potential on the XY-sections and by measuring the displacements of the probe in the vertical direction, it is possible to scan a section of the surface and to obtain its topographic image. The correct employment of such images requires a careful calibration of the piezoscanners on objects with a known topography.

If the potential on the Z-section of the tube is fixed and the tunnelling current is measured with the probe moving above the specimen, it is possible to record the image of the surface more rapidly (Fig. 2*b*), but there is then an increase in the probability of 'sticking' because the feedback loop does not in this case control the current. This regime is suitable for the investigation of atomically smooth sections of the specimen and makes it possible not only to increase the scanning rate but also to improve the quality of the image by reducing the level of interference.

The sharpness of the probe is important—ideally there should be one atom at its end. Initially investigators wasted much time and effort on the preparation of very sharp needles by electrochemical or gas-phase etching. However, the exponential dependence of the tunnelling current on distance eliminated many problems—nowadays the majority of commercial STM employ mechanically sharpened probes or simply probes sliced at an angle. Under these conditions, some of the surface atoms of the probe are closer to the test surface than others and play the role of the sharp point. Naturally, it is best to have a sharp etched needle, since otherwise in recording the image of a rough surface one may obtain artefacts as a result of the alternate operation of several sections of a blunt needle which are at different times closer to surface projections. For example, in the situation illustrated schematically in Fig. 2*a* a lateral atom, closer to the projection, 'operates' instead of the lowest atom of the probe.

The next step in the development of SPM was the creation of the atomic force microscope.[12] The exponential dependence of the tunnelling current on the distance between the electrodes is of decisive importance for the attainment of the atomic resolution in the STM, whereas in the AFM a similar importance attaches to the pronounced dependence of the force F of the interaction between bodies on the distance between them R,

$$F(R) = \frac{C_1}{R^{13}} - \frac{C_2}{R^7}, \qquad (2)$$

where C_1 and C_2 are constants. The first term in the equation for the Lennard-Jones potential describes the short-range repulsion forces between the electron clouds of the atoms brought into contact, while the second term describes the attraction forces acting over relatively large distances. One of the bodies involved is the probe (the needle *1* fixed on a flat spring *2*), while the other is the test surface *3* (Fig. 3).

The problem of bringing the probe to the required distance from the steps of the specimen and scanning over the latter is solved, as in tunnelling microscopy, with the aid of the piezoceramic XYZ-translator *6*, while the vertical movements of the needle are recorded either with the aid of an optical system [in this case a laser beam is reflected from the mirror *4*, fixed on the spring *2*, and falls on the photodiode *5* (Fig. 3*a*)] or with the aid of the tunnelling probe *7* mounted over the spring *2* (Fig. 3*b*). The second variant requires a more complex control system and is used fairly rarely.

The AFM can operate in two main regimes.

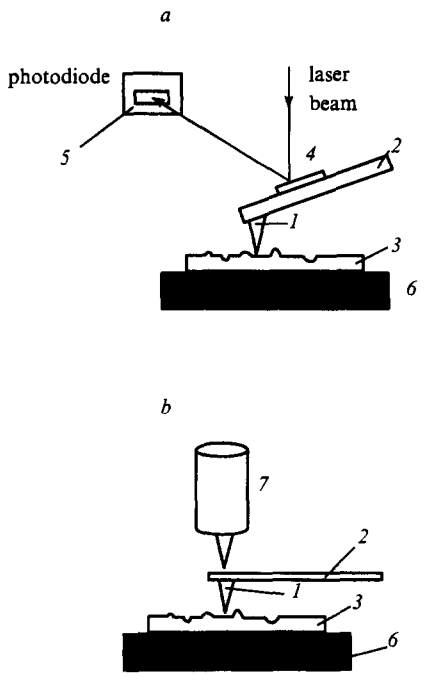

Figure 3. Principle of the operation of the atomic force microscope.

1. Contact-free interaction — the forces of attraction of the probe to the test surface are greater than the repulsion forces [see Eqn (2)]. With the aid of yet another piezocrystal, vibrations are induced in the needle at a frequency ν, which is close to the resonance frequency of the spring ν_r, and with an amplitude of about 2 nm (evidently the distance R between the needle and the specimen must be greater). In this case, the attraction force is determined[8] from the equation

$$\frac{dF(R)}{dR} = \frac{2k\Delta\nu}{\nu_r}, \qquad (3)$$

where $\Delta\nu = \nu - \nu_r$ is the change in the vibration frequency induced by the attraction of the probe to the surface and k is the elastic constant of the spring. The quantity $\Delta\nu$ is determined from the change in the vibration amplitude during the scanning by the needle over the surface of the specimen and the image is formed as the dependence of the force on the XY coordinate of the probe on the plane. Owing to the high vibration amplitudes, the needles must be kept at a considerable distance between the probe and the surface, which lowers the lateral resolution.

2. Contact interaction — repulsion forces predominate over short distances. In the simplest case, the probe acts as a gramophone needle and its vibrations in the vertical direction reflect the surface relief. In another variant of this method, the needle and the spring vibrate at a frequency of several hundreds of Hz with an amplitude of 0.5–2 nm (the needle is periodically in contact with the specimen and accurate values of the vibration parameters are selected for a specific rigidity of the spring). The decrease in the vibration amplitude of the needle as a result of the interaction of the probe with a rough surface is proportional to the height of the rugosities on the latter. During scanning along the XY coordinates, the specimen is moved upwards and downwards with the aid of a piezotranslator (in order to maintain a constant vibration amplitude) and the surface relief is thus recorded.

Atomic force and tunnelling microscopies are undergoing active development; compound devices in which an STM, an AFM, an electron microscope, and instruments for optical studies on surfaces are combined have been built.[13–17] Modifications of the AFM which make it possible to investigate the electrical and mechanical properties of the surface, have appeared,[14,16] but a detailed consideration of all these methods and designs is impossible within the framework of this review.

2. Tunnelling microscopy

As already stated, the tunnelling current is proportional to the potential between the electrodes U_t and depends exponentially on the height of the potential tunnelling barrier and on the distance between the probe and the test surface s. The propor-tionality coefficient K in Eqn (1) is determined mainly by the local density of the electronic states of the needle $[D_t(E_{F,t})]$ and the specimen $[D_s(E_{F,s})]$ at the Fermi level.[8] In the case of the clean uniform surfaces of metals, these quantities are independent and the use of Eqn (1) is fully justified. However, when an adsorbate or formations comprising foreign phases are present on the specimen, the density of the electronic states D_s can no longer be regarded as constant and the tunnelling current depends on the electron work function at the given point on the surface.

In the scanning of an electronically nonuniform surface of a specimen (for example, one with inclusions of foreign atoms) in the constant current regime, the variation of the height of the needle over the plane of the specimen no longer reflects the topography of the surface: a hump is observed over atoms with a low electron work function, whereas hollows are seen over atoms with an increased work function. Thus a problem of separation of the electronic and topographic effects arises in the analysis of the image.

This problem may be solved by means of scanning tunnelling spectroscopy (STS), the essential feature of which involves the measurement of the dependence of the tunnelling current I_t on the potential between the electrodes U_t for a fixed position of the probe above the surface.[2,6,8,18–21] In a modification of the regime involving a constant height of the probe (when a low variable potential is applied to the Z-section of the piezoscanner), it is possible to determine the function $I_t(s)$ for a constant value of U_t and fixed XY coordinates, but with the height of the probe over the surface of the specimen being varied within certain limits. In practice, one usually measures the differential signal dI_t/dU_t or dI_t/ds and then the electron work function at the given point on the surface is determined from the dependence of dI_t/dU_t on U_t (or of dI_t/ds on s). By carrying out such measurements at different points, one obtains a distribution map for the inclusions (the adsorbate, oxides, or other nonuniformities) on the surface of the specimen.

III. Design of the tunnelling and atomic force microscopes

We shall now consider the principal units of the tunnelling and atomic force microscopes. Since foreign commercial microscopes are as a rule not available to Russian investigators because of their high price and the lack of the necessary service arrangements, many investigators have attempted to construct such instruments independently and have achieved considerable success. The information presented here may therefore prove useful to those chemists who recognise the need for the employment of SPM in their research but have not yet gained sufficient experience for the independent construction of an instrument. Furthermore, the knowledge of the design of the apparatus enables beginners in the use of SPM to avoid artefacts in their investigations and in the treatment of the results.

1. The piezoscanner and tunnelling probe

The piezoscanner is the heart of the tunnelling and atomic force microscopes. This device actually makes it possible to move the probe to the required point over the test object and to carry out the measurements necessary to obtain information about the topography or electronic state of the surface.

A tripod (three linked, mutually perpendicular piezoceramic plates), on which a tungsten or platinum needle was mounted, was employed initially for this purpose. By varying the potential of the corresponding plates of the tripod, it is possible to move the probe along three coordinates and to analyse the surface. Recently, however, the tripod has virtually ceased to be used and has been replaced by the piezotube.[22] After special treatment of the piezoceramic (annealing and polarisation in an electric field in order to create the necessary orientation of the domains) and sectioning, such a tube (Fig. 4) makes it possible to scan a section of the surface and ensures the Z-translation of the probe over a range of several micrometers.

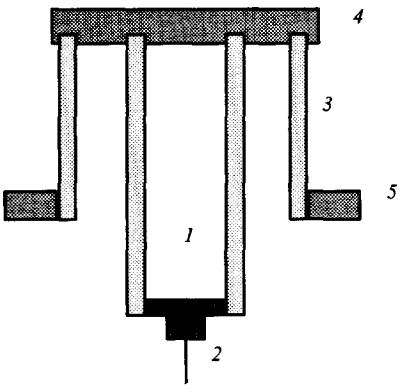

Figure 4. Schematic representation of the piezoscanner: (*1*) inner piezotube with a capacity for XYZ-movements; (*2*) tunnelling probe (needle with holder); (*3*) outer piezotube for the Z-movements and thermocompensation; (*4*) and (5) supports.

The tubular piezoscanner has many advantages over the tripod. It is more compact and more rigid, which means that it has a higher resonance frequency (in the development of the design of the STM, one must endeavour to achieve the highest possible resonance frequency of the scanner and the lowest possible resonance frequencies of the mechanical parts of the instrument in order to reduce the harmful effect of vibrations and acoustic interference). Furthermore, the use of two piezoceramic tubes of different diameter (Fig. 4) makes it possible to extend the scanning range and to reduce appreciably the effect of thermal drift on the measuring process as a consequence of thermocompensation along the Z coordinate.

The range of the movements of the scanner is determined by the nature, structure, and geometrical dimensions of the piezoceramic. For example, the thinner the walls of the tube, the greater the strength of the electric field which can be achieved within the ceramic and the larger the movements of the probe at the end of the tube which can be ensured in scanning the test surface.

The attachment of the probe to the scanner (screw, chuck, magnetic, and other needle holders are used) must ensure the necessary rigidity and at the same time make it easy to replace the needle under operating conditions. Furthermore, this unit must have the smallest possible weight because an increase in the mass of the scanner lowers its resonance frequency. The needle itself must also be fairly rigid and therefore must not be too thin and long.

Needles made of platinum–rhodium or platinum–iridium wire (iridium content 10%–30%) 0.2–1.0 mm in diameter have been most popular recently. In contrast to the tungsten needles, they are hardly oxidised in air at room temperature, are stable in corrosive media (acids and alkalis), and do not introduce impurities into the solution in the course of the experiment.

The platinum–iridium needles are sharpened by electrochemical etching in a 3 M NaCN + 1 M NaOH solution[23] or in a mixture of saturated $CaCl_2$ solution, concentrated HCl, and water in proportions of 60:4:36 by volume[24] at a constant or variable potential $U = 10 - 40$ V. A loop of platinum wire with an electrolyte film is usually employed as the counterelectrode in the cell (Fig. 5*a*).

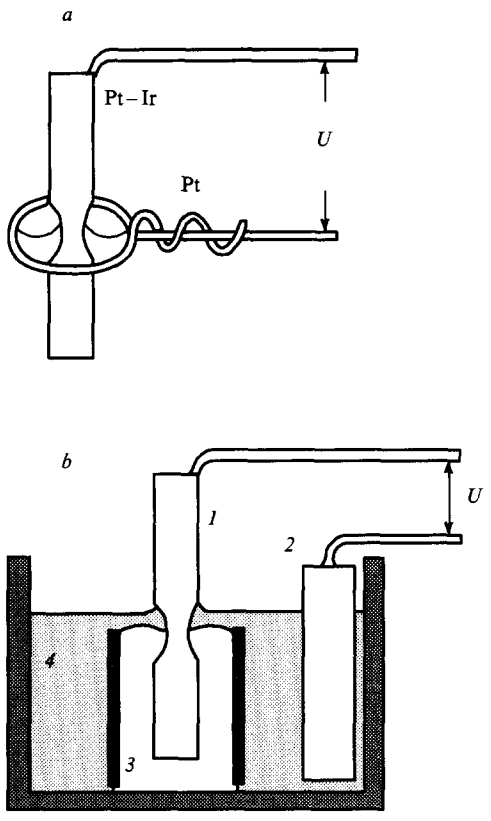

Figure 5. Electrochemical sharpening of the needles: (*a*) etching by means of a wire loop with an electrolyte film; (*b*) etching by immersion in a vessel with electrolyte.

The platinum–iridium alloy dissolves in the meniscus, while the part of the wire (about 1 cm long) below the film of solution serves as a weight which ensures the rupture of the wire when it becomes sufficiently thin. Tungsten needles are etched similarly in 2 M NaOH solution at a constant or variable potential of 1–15 V.[7,8]

The method described is not always convenient. When thick probes are employed, the etching time is several minutes and the electrolyte film can be disrupted as a result of the vigorous gas evolution. In such cases (Fig. 5*b*), the wire *1* from which the needle is to be prepared is lowered vertically into the vessel with the etch solution *4* and the auxiliary electrode *2* to a depth of about 1 cm. The immersed part of the wire is either insulated to prevent its dissolution or an air-filled glass capillary *3* is employed.[25] It is noteworthy that the upper part of the wire also has a sharp end if the current is interrupted immediately after the breaking away of the lower part.

Satisfactory results in the sharpening of platinum or platinum–iridium needles by treatment in a mixture of $CaCl_2$, water, and acetone followed by micropolishing in aqueous sulfuric acid solution have been obtained.[26] The authors were able to avoid the use of toxic cyanide solutions and to obtain smooth readily reproducible needles with a radius of curvature less than 10 nm.

Fairly numerous studies have been devoted to the technology of the preparation of sharp needles and these have been reviewed.[27]

In an experiment in solution, the Faraday current I_F due to the electrochemical reaction on the surface of the needle passes through the latter in addition to the tunnelling current. Reliable information about the topography of the working electrode can then be obtained only subject to the condition $I_F \ll I_t$. This is achieved in two ways: either the probe potential is maintained in the region corresponding to the minimum Faraday current or virtually the entire surface is insulated by a nonconducting material allowing only the minimum possible section on the very end of the needle to remain 'operational'. Glass or polymers are used as insulators; insulation with the aid of the thermoplastic material Apiezon wax is fairly popular.[3]

One of the main problems in the insulation of needles is to ensure that the area of the active surface of the probe does not exceed 1 μm^{-2}, which corresponds to $I_F < 0.1$ nA. It is sometimes simpler to cover the entire surface of the needle with the insulator and then 'expose' its end by means of heat treatment, the application of a powerful electric field, ionic etching, or in some other way.

A novel method for the insulation of needles has been proposed by Mao et al.[28] They use a polymer, deposited from solution by means of an electric current, as the insulating coating. In order to make sure that the insulator on the end of the needle is not too thick (otherwise the problem of the electrical and diffusional screening of the section of the working electrode underneath the probe arises in the course of the STM experiment), electrophoresis is carried out on the needle the end of which is immersed in a drop of mercury. The needle is slowly withdrawn from the drop and at the instant of rupture of the electrical contact between the needle and mercury the coating deposition current is automatically switched off.

The method for the preparation of insulated platinum–iridium needles proposed by Bach et al.[29,30] is the simplest and most convenient. A mechanically or electrochemically sharpened needle is immersed in a solution of polyacrylic acid partly neutralised by a base (Glassophor ZQ 84-3225, produced by the BASF Company, Germany) and electrophoresis is carried out with a platinum cathode at a potential of 25–70 V. The decomposition of water on the anode leads to the acidification of the near-electrode space, as a result of which the polymer passes to a sparingly soluble form and is deposited on the platinum–iridium needle as a film. Further polymerisation, designed to strengthen the coating, is achieved by means of heat treatment ($\sim$200 °C for several minutes), whereupon the chemical stability of the polymer increases and the very end of the needle is exposed as a result of thermocontraction.

With the aid of needles insulated in this way, it has been possible to determine the structures of atomic adsorbed layers of copper on gold.[30] This fact indicates the high quality of the probe and the absence of impurities from the test solution. Stationary Faraday currents of the probe in 0.2 M KCl + 0.01 M $K_3Fe(CN)_6$ solution do not exceed 0.2 nA, which corresponds to an area of the active surface of the needle equal to the area of a circle with a radius less than 0.1 μm.[30] The 0.2 M KCl + 0.01 M $K_3Fe(CN)_6$ solution is frequently used to characterise microelectrodes by means of cyclic voltammetry or stationary methods.[31]

2. The polarisation circuit

When STM is used to investigate the behaviour of electrochemical systems, studies in which the measurements are performed with monitoring of the potential of the working electrode are of greatest interest. In this case, the probe is the fourth electrode in the cell and its potential is specified (measured) relative to the working electrode or the reference electrode. The usual potentiostat and a three-electrode cell were used initially[32–34] for the polarisation of the working electrode, the probe potential being determined from the tunnelling potential between the specimen and the probe:

$$E_t = E_s + U_t, \tag{4}$$

where E_t and E_s are the potentials of the probe and the specimen respectively.

Recently, however, virtually all investigators have used a bipotentiostat, similar to that employed for the polarisation of a disc electrode with a ring.[35] It permits the independent monitoring of the potential of the specimen and the probe relative to the reference electrode (from which the tunnelling potential is equal to the difference between the above potentials).[36–40] The bipotentiostat differs from the usual potentiostat in that, to obtain an image in the STM, it is necessary to ensure the operation of the feedback loop which maintains a constant tunnelling current, i.e. the cell polarisation circuit and the circuit for the control of the Z-movement of the piezoscanner must be adjusted for mutual consistency.

There is one circuit, with optical decoupling, which makes it possible to record the image at high Faraday currents without insulating the needle.[41] A similar circuit has been used[42] to investigate the initial stages in the deposition of copper on pyrographite. After each scan along the X coordinate, the needle is raised, the feedback loop is switched off, and the Faraday current due to the electrochemical reduction of oxygen on the probe is measured (in the quoted instance, $I_F \approx 40$ nA, tunnelling current $I_t \approx 0$). The current I_F is subtracted from the overall current of the needle, lowered to place it in its working state, the appropriate potential being applied from a digital-analogue converter to a summator, and the feedback loop is switched on again to maintain a constant tunnelling current $I_t \approx 4$ nA. Thus, after each scan the Faraday current is corrected, which makes it possible to record the image of the surface. The usual potentiostat-galvanostats with a three-electrode signal are used for atomic force microscopy.

3. Design of the moving device

Piezoscanners usually have a range of Z-displacements of the order of magnitude of 1 μm, so that the maintenance of a constant tunnelling current requires that the probe be brought to a distance $s < 1$ μm from the test surface without sticking the needle into the specimen. This problem is solved in different ways in various designs of the STM.[3,43–48] We shall consider some of them.

a. Mechanical moving devices

The microscrews employed initially in optical apparatus were some of the first to be used. Differential screws combined with a reduction gear ensure fairly small translational displacements of the order of several micrometers of linear movement per turn of the screw. Here it is necessary to solve the problem of play and of the stability of the position of the moved piezoscanner after the attainment of the specified point. Repeated scanning for a long time is sometimes needed for the analysis of the surface in experiments employing the STM. The stability of the position of the piezoscanner is adversely influenced by thermal drift and the relaxation of the mechanical stresses arising as the moving system actually moves.

Computer-controlled step motors are usually employed to automate the moving device — they make it possible to rotate the shaft of the screw by hundredths of a turn with a high accuracy.

b. Piezoelectric moving systems

The range of variation of the geometrical dimensions of the piezo-ceramic tube does not usually exceed several micrometers and the moving device must ensure the movement of the scanner by a fraction of a millimetre. The gap between the specimen and the probe can be set more accurately by hand in the preparation of the experiment, but the probability of random touching increases under these conditions.

The question arises how to increase the range of movement. Imagine the movement of a caterpillar. It gets hold of a leaf with its rear legs, lifts its front legs, and stretches. It then fixes the front legs on the leaf, raises its rear legs, and draws them forward, contracting its body.

The piezotranslator can work similarly. It is only necessary to find a way of fixing a particular end between the expansion/contraction stages.

The piezoelectric 'creeping worm' motor (Inchworm, Burleigh Instruments, Inc.), which ensures the movement of the piezoscanner by several millimetres with a minimum step of 1 nm and a rate up to 0.5 mm s^{-1}, may serve as an example of the mechanical fixing in the majority of commercial STM.[3] Fig. 6 presents a simplified diagram of this motor. The lower part of the motor contains the piezoceramic tube *1*, attached by the holder *5*, with upper (*2*) and lower (*3*) piezofixing devices. The slider *4* with the piezoscanner (not shown in the diagram) is located within the tube.

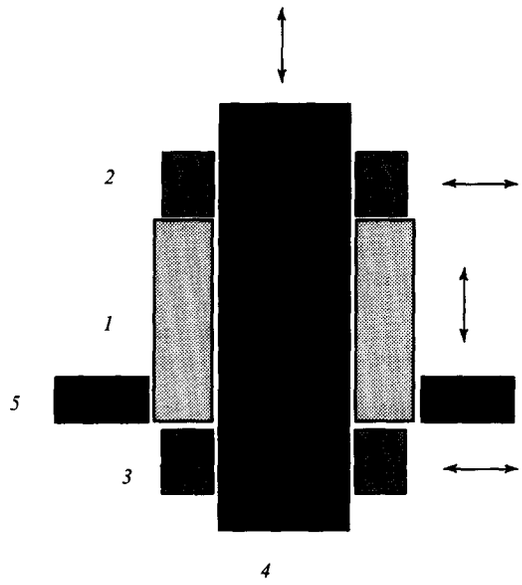

Figure 6. Design of the Inchworm piezoelectric motor. The arrows indicate the directions of the possible movements of the motor components.

In the static state, the fixing devices *2* and *3* grasp the slider from two sides by application of the appropriate pressure. In order to move the slider downwards, the fixing device *2* is released, the pressure on tube *1* is increased, and the latter becomes longer; the fixing device *2* is then applied again, while the fixing device *3* is released, whereupon the pressure on the tube is smoothly reduced. The tube contracts and pulls the slider with the piezoscanner. Thus the slider is alternately 'grasped' by the fixing devices and moves over a distance of up to 2 μm in one step. A very high precision in the treatment of the surfaces and the selection of the appropriate materials, which do not respond to changes in atmospheric humidity and exhibit a high resistance to wear and a low sliding friction, is necessary to ensure the stable operation of the motor.

A motor of simpler design may be made by employing magnetic or electromagnetic fixing devices, but here too it is necessary to overcome numerous difficulties to ensure smooth movement and the stability of the working position.

A somewhat different principle has been applied by Wildoer et al.[43] The slider is held in the resting position not by piezoelectric fixing devices but by flat springs adjusted in such a way that a slow increase in the length of the tube leads to a movement of the slider together with its free end by the frictional force, and a sharp contraction of the tube results in sliding. By applying a sawtooth potential to the piezotube, it is possible to move the slider over considerable distances.

The quality of the treatment and the selection of the materials are also very important in this design—the authors employed stainless steel coated with titanium carbonitride in order to diminish the coefficient of friction and to increase the resistance to wear of the slider and the flat springs.

4. Vibro- and sono-insulation

In order to obtain a high-quality image, it is necessary to achieve a low level of interference from electromagnetic, acoustic, and mechanical influences.[3,8] For this purpose, the measuring block of the STM is mounted on a fairly massive vibroinsulating platform. Spring or rubber suspensions, Viton ring washers,[49] or simply a half-deflated automobile inner tube provide effective protection against mechanical vibrations. In order to reduce the harmful effect of acoustic vibrations, use is made of metallic or glass jackets with sound-absorbing coatings. The earthed metallic jacket at the same time shields the measuring system from electromagnetic influences, but in this case visual monitoring of the state of the electrochemical cell is difficult.

The atomic force microscope is more stable towards low-frequency vibrations than the tunnelling microscope because the resonance frequencies of the springs usually exceed 10 kHz for the AFM whereas the typical vibrations of buildings have frequencies of the order of 20 Hz and an amplitude of about 1 μm. Since the amplitude of the induced vibration, A, is given by

$$A = A_0 \frac{\nu^2}{\nu_0^2}, \tag{5}$$

such vibrations at the resonance frequency induce vibrations with an amplitude of only 0.004 nm. This simple calculation[8] shows that, in contrast to the STM, the atomic force microscope hardly requires special vibroprotection in order to achieve atomic resolution.

5. Treatment of the image

When the test surface is scanned by the tunnelling probe, the primary image is usually produced in the form of a map of the distribution of the measured parameter (tunnelling current, height of the relief, etc.) on the scanning plane. Modern computers ensure a fairly high resolution and a wide colour range for a clear representation of the information obtained as a result of such scanning. There are numerous graphic programs which make it possible to edit the image and view the surface in two and three dimensions, but in work with the STM a special program is needed which combines at least the control of the movement of the probe towards the surface, the monitoring of the electrochemical behaviour of the system, the production of the image, and its primary processing.

We shall deal briefly with the processing of the images, concentrating attention on the risk of artefacts. The principal rule required to avoid such errors is that one should endeavour to obtain a high-quality image without resorting to methods for its improvement by means of computer programs. If all the precautions needed to reduce the level of interference have been taken and the image still remains subject to noise, it is necessary to understand the cause of such noise. It may be that it is a characteristic property of the system investigated and not an induced interference. For example, the presence of halides in the electrolyte is usually accompanied by an increase in the noise in the image because of the increase in the mobility of surface atoms.[50–52]

Digital filtration of images helps in many instances to increase the contrast in the image (or, conversely, to reduce it) for the subsequent analysis of the topography of the surface, but this method must be used with very great caution since, with the aid of Fourier transformations for example, it is possible to see a periodic structure in cases where it has never existed.

There are also computer program methods for the elimination of image defects[5,53] associated with the drift of the system and the nonparallel arrangement of the scanning and specimen planes,[54,55] the nonlinearity of the movement of the tunnelling probe in the scanning of the surface,[56] etc.

IV. Applications of scanning probe microscopy in electrochemistry

Scanning probe microscopy has provided unique possibilities for the investigation of the atomic structure of the electrode and has made it possible to see what happens on the surface when the components of the solution are adsorbed and when the electrode potential is altered. Investigators have become able not only to visualise the mechanism of the electrode process from coulometric, voltammetric, and optical data, as well as data obtained by structural methods, but have also acquired the capacity to 'see' how the atoms and molecules of the adsorbate are arranged, on which active centre the electrode reaction begins and proceeds at a high rate, what happens to the surface in adsorption–desorption processes, etc. So far, the STM is not able to provide answers to questions such as how the elementary step in the electrode process occurs, how the reaction is influenced by the scanning probe, and whether or not the processes occurring on the surface monitored by the probe and on other sections of the electrode are identical. However, there are no grounds for doubting that in the immediate future answers to these questions will be obtained with the aid of the combined use of STM, AFM, and optical and structural methods. However, even now, in the early stages of the development of scanning probe microscopy, many important results requiring comprehensive consideration have been obtained. We shall examine the latest results in this field.

1. Direct observation of the atomic structure of the electrode surface in solution

Even before the STM era, cyclic voltammetry and structural methods made it possible to establish that a change in the potential of the platinum electrode leads to the reconstruction of the surface layers, which is accelerated by oxygen adsorption-desorption processes. The reconstruction of the Pt(111) surface in sulfuric acid has been investigated by the STM method in situ.[57–60] It was established that when the potential is cycled in the range 0.10–0.65 V relative to the normal hydrogen electrode (NHE), the surface of platinum is stable as a function of time and extensive terraces with a monatomic height (0.23 nm) can be seen on it, while cyclic voltammetry (CVA) reveals a high degree of perfection of the Pt(111) single crystal [the shape of the curve resembles a butterfly, there are no distinct peaks corresponding to weakly and strongly bound hydrogen characteristic of a polycrystalline material, and at 0.45 V a sharp peak is observed and is caused, according to STM data obtained in situ, by an order–disorder transition in the monolayer of adsorbed bisulfate having a $(\sqrt{3} \times \sqrt{7})$ structure†].[60] If the potential is displaced to the hydrogen adsorption and evolution region, the CVA curve changes irreversibly and begins to resemble the curve characteristic of polycrystalline platinum,[57–60] while on the STM image a 'noise' appears. Further cycling in the range 0.05–1.5 V leads to an increase in the 'noise' on the image, although after five cycles the monatomic steps can still be seen and their distribution in space does not change.[60] The authors concluded that the adsorption–desorption of oxygen is accompanied by a rearrangement of the surface layers of platinum with the formation of randomly oriented islands 3–5 nm in diameter and with a height corresponding to 1–2 atoms: the adsorbed oxygen is incorporated in the surface layer and displaces some of the platinum atoms, which do not return to their former sites after the desorption of oxygen. It is not surprising that the rearranged surface gives rise to a CVA curve characteristic of a polycrystalline material.

The surfaces of platinum single crystals have been studied in detail[61] by the CVA and STM methods. It was established that the degree of ideality of the surfaces of the single crystals is greatly influenced by the preliminary treatment of the platinum before the electrochemical experiment and by the adsorption of oxygen during the recording of the CVA curve (thus the stage where the platinum heated in a hydrogen flame is cooled in water containing dissolved oxygen may 'spoil' the surface).

The Pt(111) surface, which is relatively insensitive (after heat treatment) to the presence of oxygen in the cooling water and is stable during cycling in the hydrogen and double layer regions, is rapidly spoiled when the potential shifts to +1.4 V (NHE): peaks due to weakly and strongly bound hydrogen appear on the CVA curve, the sharp peak at 0.45 V vanishes, and the STM images reveal a transformation of the atomically smooth terraces into grainy surfaces,[61] while low energy electron diffraction data indicate the loss of long-range order and the presence of a large number of randomly distributed surface defects,[62,63] which agrees well with the results of other studies.[57–60]

A surface of the Pt(100) single crystal has a lower reticular density and exhibits a greater tendency to undergo reconstructions.[64] A freshly polished Pt(100) face contains a large number of defects, which can be 'healed' by annealing at about 1000 °C with subsequent cooling in an oxygen-free atmosphere (cooling in iodine vapour, which is adsorbed on the platinum surface and prevents the influence of oxygen, yields the best results). According to STM and voltammetric data, the Pt(100) surface exhibits a high degree of ideality. The adsorption of oxygen on cooling or at high anodic potentials in solution leads to the appearance of a large number of linear surface defects along continuous rows of atoms: the STM image shows clearly a network of linear defects with rectangular cells, and in addition terraces are clearly seen.[61]

Rougher surfaces can also be observed with the aid of the STM. Polycrystalline platinum has been selected as the object of study.[65–68] After mechanical polishing, washing, and prolonged annealing, the platinum surface is entirely suitable for the investigation of oxidation processes, the electrodeposition of metals, the synthesis of conducting polymers, the mobility of atoms, etc. and even atomic resolution can be achieved on individual sections of the surface.

Gold single crystals have been studied in fair detail.[7,69–82] After treatment in a flame and cooling in pure water, the surface of Au(111) consisted of extensive atomically smooth terraces separated by monatomic steps.[7] The topography of the Au(100) surface was characterised by the presence of a large number of islands with a monatomic height. According to Nichols et al.,[69] the structural rearrangement of the denser hexagonal (5×20) lattice, formed on treatment of Au(100) in a flame, into the less dense cubic (1×1) surface, liberates approximately 20% of the surface atoms. These in fact form the above islands by surface diffusion.

The influence of the adsorption of anions and oxygen on the topography of Au(100) has been investigated.[69] The Au(100) surface is stable in 1 M H_2SO_4 solution at a potential of +0.4 V relative to the saturated calomel electrode, but the displacement of the potential into the +1.0 V region leads to the disappearance of the islands. A similar picture is observed in 50 mM H_2SO_4 + 5 mM HCl solution: the islands dissolve at +0.7 V. The polarisation of Au(100) at +1.25 V in 50 mM $HClO_4$ + 1 mM $Cu(ClO_4)_2$ solution leads to the appearance of a rough surface in which the height of the rugosities is ~1 nm as a result of the formation of oxides. But after the displacement of the potential into the double layer region, the surface is smoothed out — both the rugosities and the islands with a monatomic

† The $(\sqrt{3} \times \sqrt{7})$ structure corresponds to the sulfate superlattice in which the distances between the nodes are greater by factors of $\sqrt{3}$ and $\sqrt{7}$ than the distances between the atoms of the Pt(111) substrate.

height vanish. The authors explain this phenomenon by the increase in the mobility of the gold atoms following the adsorption of anions and the desorption of oxygen.

More vigorous oxidation of Au(111) (a film sputtered onto mica) in perchloric acid occurs when the electrode potential is cycled in the range 0.7–2.0 V relative to a quasi-equilibrium $Ag/AgClO_4$ electrode.[70,71] At potentials of 1.25 and 1.45 V, the CVA curve shows anodic peaks corresponding to the formation of gold oxide, whilst during the reverse scan the oxide is reduced at 1.05 V. At the anodic limit in the cycling of the potential of $E_a = 1.7$ V, small pits arise on the gold surface and rapidly disappear. At $E_a = 1.7$ V, the pits attain dimensions of the order of 4 nm and only vanish after 10 min. After intense oxidation ($E_a = 2.0$ V), many large pits are formed, the boundary of the terrace becomes curved, and the picture then remains unaltered until the introduction of 0.05 mM HCl into the solution. After this, the steps in the terrace become straightened in 15 min.[70] These findings confirm yet again that the fairly high mobility of the surface gold atoms increases still further in the presence of halides.[72] In contrast to gold, the defects on the surface of platinum, arising as a result of the adsorption–desorption of oxygen at high anodic potentials, are not healed during the experiment.[57–63]

The atomic structure of the unreconstructed Au(100) surface has been observed with the aid of the STM in situ.[73–74] The results of studies on the processes involved in the rearrangement of the Au(111), Au(110), and Au(100) surfaces as well as high-index gold faces by means of STM and AFM have been described.[75–82] Scanning probe microscopy has been used to investigate the state of the surfaces of silver,[83–87] copper,[88] carbon glass,[89] highly ordered pyrographite,[90,91] and other electrode materials, but their detailed consideration is outside the scope of the present review.

2. The study of adsorbed atomic layers

Adsorption with charge transfer, leading to the formation of adsorbed atomic layers at potentials more positive than the phase deposition potential [in the English language literature, the term underpotential deposition (UPD) has become established], has become the object of vigorous study during the last 20 years. There are several reasons for this. The structure and properties of adsorbed atomic layers differ from those of bulk-phase deposits; noble metals modified by adsorbed atoms possess unique catalytic properties (increased activity and selectivity, high resistance to catalyst poisons); the formation of adsorbed atomic layers is the first stage in the bulk-phase deposition of metals, the formation of nuclei on them being of fundamental interest in the study of the processes involved in nucleation and the growth of nuclei.

Voltammetry combined with coulometry and vacuum structural methods have been used traditionally to investigate the UPD. The development of SPM has led to new possibilities for monitoring in situ the state of the surface during the adsorption–desorption of atoms.

The deposition of copper on gold is one of the processes that has been investigated in greatest detail. A gold film 100 nm thick with the (111) texture, sputtered onto glass, was used as a support.[92] The reference electrode was a copper wire and the state of the surface was monitored with the aid of the AFM with atomic resolution.

The hexagonal structure of the Au(111) substrate with atomic distances of 0.29 nm is clearly observed at potentials more positive than the copper adsorption potential in sulfate (0.1 M H_2SO_4 + 1 mM $CuSO_4$) and perchlorate [0.1 M $HClO_4$ + 1 mM $Cu(ClO_4)_2$] solutions. Although the sulfate is adsorbed strongly at these potentials (+0.7 V relative to the copper reference electrode), its influence on the structure of the image was not observed. The authors explain this finding by the fact that the needle of the AFM displaces the adsorbed sulfate atoms during the scanning of the surface. A compressed hexagonal close-packed (HCP) Cu(111) copper layer with atomic distances of 0.26 nm (the atomic radii of Cu and Au are 0.175 and 0.142 nm respectively), rotated by 30° relative to the gold lattice, is observed at a cathodic overpotential of 0.05–0.10 V in both solutions after the deposition of several copper monolayers. Copper dissolves layer-by-layer and at +0.7 V the gold support without visible structural changes is observed, which indicates, according to the authors,[92] the complete reversibility of the adsorption–desorption process. This claim appears unduly dogmatic, since experiments in which AFM and STM are employed are carried out as a rule on the smoothest sections of the surface (otherwise atomic resolution cannot be achieved), while the reconstruction processes, induced for example by surface alloy formation, occur most vigorously on defects (dislocations, grain boundaries, etc.).[93]

An hexagonal close-packed copper monolayer with interatomic distances of 0.29 nm, rotated by 30° relative to the substrate, is observed in perchlorate solution at +0.11 V (the potential of the desorption peak on the CVA curve is +0.33 V), while the $(\sqrt{3} \times \sqrt{3})R30°$ open structure with interatomic distances of 0.49 nm is observed in sulfuric acid solution at +0.1 V. The same structure has been observed in situ with the aid of the STM in other investigations.[52,73,94,95] Similar results have been obtained in the analysis of the diffraction of low energy electrons.[96] Auger spectroscopy[97] of electrodes removed from the solution indicates the coadsorption of the sulfate. The adsorption of the sulfate on Au(111) in sulfuric acid solution has been investigated by IR spectroscopy and by means of STM in situ.[98] It has been shown that the SO_4^{2-} anion forms a $(\sqrt{3} \times \sqrt{7})$ superlattice with a degree of occupation of 0.2.

The $(\sqrt{3} \times \sqrt{3})R30°$ structure of the adsorbed copper atoms should correspond to a degree of filling of the monolayer of 1/3. In a sulfate electrolyte, there are two sharp desorption peaks on the CVA curve,[52,99] at +0.05 and +0.21 V, their areas being 0.15 and 0.30 mC cm^{-2} respectively, while the theoretical charge necessary for the adsorption of a monolayer (1×1) is 0.44 mC cm^{-2} (on the assumption of two-electron transfer), i.e. according to the coulometric data 2/3 of a monolayer is adsorbed at 0.1–0.15 V. Among the studies known to the authors, integration of the more anodic adsorption peak yielded a degree of occupation of 0.38 only in the study of Haiss et al.[95] This may be associated with the insufficiently low rate of scanning of the potential, since Shi and Lipkowski[99] maintained the electrode at the required potential for up to 10 min in order to obtain the equilibrium degree of adsorption. Furthermore, for determination of the degree of coverage it is better to employ the anodic branch of the CVA curve so as to eliminate the influence of the diffusion from the dilute solution on the adsorption kinetics.

Detailed thermodynamic analysis of the CVA curve showed[99,100] that the maximum coadsorption of the sulfate (one SO_4^{2-} ion on two adsorbed Cu atoms) occurs for degrees of coverage of the substrate by copper of $\theta = 0.25 - 0.7$ The $(\sqrt{3} \times \sqrt{3})R30°$ structure observed with the aid of STM and AFM corresponds to the adsorbed sulfate ions and not to copper atoms. Gordon et al.,[101] who investigated the adsorption of copper on gold by microgravimetry (quartz microbalance), EXAFS spectroscopy, the GIXS method (grazing incidence X-ray scattering or, more briefly, 'surface X-ray scattering'), which makes it possible to identify the surface structure from X-ray scattering data, and electrochemical methods, arrived at similar conclusions. The degree of charge transfer in the adsorption of copper is close to 2 and depends little on the potential. These results agree well with the multistage adsorption model,[102,103] according to which the adsorbed copper atoms substituted the SO_4^{2-} ions on the gold surface, arranged in such a way that the sulfur atom is located at the copper adsorption site, whilst three oxygen atoms are linked to three neighbouring gold atoms (Fig. 7).

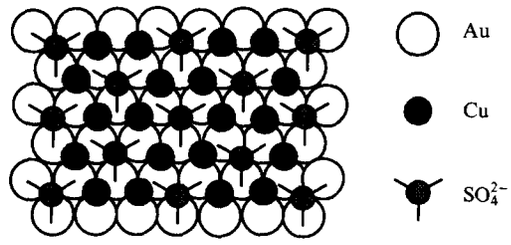

Figure 7. Schematic illustration of the structure of the adsorbate on Au(111) in sulfuric acid solution.

Several interesting features of the Au(111)/Cu/SO_4^{2-} system are noteworthy. Within the limits of a single atomically smooth Au(111) terrace, the sections of the $(\sqrt{3} \times \sqrt{3})R30°$ structure are separated by a phase boundary (the neighbouring rows of adsorbed sulfide ions are displaced to the 1/2 sites) — the situation is analogous to the formation of twinned crystals. At a potential of +0.2 V, the adsorbed copper atoms are partly desorbed [bands of the $(\sqrt{3} \times \sqrt{3})R30°$ lattice 5 – 10 nm wide and several nanometers long are observed].[52] The boundary of the $(\sqrt{3} \times \sqrt{3})R30°$ layer has been detected also in another study.[92] At +0.25 V, the lattice disappears completely, but the atomic resolution for the Au(111) surface cannot be achieved until the complete removal of the adsorbed atoms. At low coverages, the adsorbed copper atoms and sulfate ions apparently possess a high mobility (two-dimensional gas)[52,99] and their movement makes it impossible to obtain a clear-cut STM image.

When the electrolyte contains chloride ions (they can diffuse through the salt bridge when a calomel or a silver/silver chloride reference electrode is employed), the (5 × 5) lattice with interatomic distances of 0.37 nm is observed in addition to the $(\sqrt{3} \times \sqrt{3})R30°$ structure.[73] The STM yields an image comprising approximately ten $(\sqrt{3} \times \sqrt{3})R30°$ and (5 × 5) domains on a (22 × 22) nm section of the surface.[95] According to a study[104] of the coadsorption of copper atoms and halide ions on Au(111) and Pt(111) from 50 mM H_2SO_4 + 1 mM $CuSO_4$ + 0.1 mM KX (X = Cl^-, Br^-, I^-) solutions on gold at a potential of 285 mV (NHE), in the presence of chloride the STM records the (5 × 5) structure. In the bromide solution, the interatomic distances are increased by 6% [the (4 × 4) lattice relative to Au(111)], while in the presence of iodide a further increase in the adsorbate lattice parameter is noted — the (3 × 3) structure is observed [the same structure has been seen[105] on Au(111) in a study of the coadsorption of iodine and silver]. Coulometry yields a degree of coverage of the surface by adsorbed copper atoms (on the assumption of a two-electron transfer) equal to 0.4 of a monolayer regardless of the nature of the halide. According to the authors, the STM yields an image of the lattices of the chlorine, bromine, and iodine adsorbed on a layer of preadsorbed copper atoms, because an increase in the distances between the adsorbed atoms is correlated with the dimensions of the halides. It has been suggested that the adsorbed copper is partly discharged and stabilised by the anions.

Many fewer studies have been devoted to the UPD of copper on platinum.[104,106,107] This is apparently associated with the experimental difficulties in the preparation of platinum single crystals with a high degree of ideality and of clear-cut images of the surface with atomic resolution.

The first publication on the study of the UPD of copper on platinum with the aid of the STM in situ did not appear until 1991.[106] The substrate consisted of a Pt(111) single crystal treated in a burner flame; a 0.05 M H_2SO_4 + 5 mM $CuSO_4$ solution and a hydrogen reference electrode were used to prevent the contamination of the electrolyte with traces of chloride.

When the electrode potential is cycled in the range 0.5 – 0.8 V (NHE) at the rate 1 mV s^{-1}, a CVA curve with two sharp desorption peaks at potentials of 0.67 and 0.69 V and a half-width of about 5 mV is recorded. The overall charge in the desorption of adsorbed copper atoms is 460 μC cm^{-2} (this is twice as great as for the adsorbed hydrogen atoms in sulfuric acid); integration of the more anodic peak yields 270 μC cm^{-2}, which corresponds to approximately 60% coverage of the platinum surface by the adsorbed copper. A clear-cut image of the hexagonal $(\sqrt{3} \times \sqrt{3})R30°$ adsorbate structure with distances between the projections of about 0.5 nm was obtained at a potential of 0.68 V. The authors[106] believe that this is the lattice of adsorbed copper atoms and the discrepancy between the coulometric and STM data [we recall that a degree of monolayer coverage of 1/3, i.e. 160 μC cm^{-2}, and not the experimentally observed 270 μC cm^{-2} should correspond to the $(\sqrt{3} \times \sqrt{3})R30°$ superlattice] is explained by the effects due to the charging of the electrical double layer on desorption of the sulfate and bisulfate anions. However, such a large difference between the charges (110 μC cm^{-2}) can be hardly due to a non-Faraday process. Apparently, as in the case of the UPD of copper on Au(111),[52,73,92,95,100–103] the STM yields an image of the structure of the adsorbed sulfate.

At a potential of 0.8 V, the STM yields, with atomic resolution, the image of a nonperiodic structure in which the height of the projections is 0.04 – 0.06 nm and the average distance between them is 0.5 – 0.6 nm. It was not possible to obtain the image of the hexagonal Pt(111) lattice. On consecutive recording of several images of the same section of the surface, it was found that the disposition of the projections and hollows varies with time; this is probably associated with the mobility of the adsorbed sulfate and bisulfate ions.[106] The influence of organic additives on the UPD of copper on platinum has also been investigated in another study[107] with the aid of STM in situ, but it was not possible to record the structure of the adsorbate with a lateral (side) atomic resolution.

A study has been made[104] of the sorption of copper on platinum in the presence of halides from 50 mM H_2SO_4 + 1 mM $CuSO_4$ + 0.1 mM KX solutions, where $X^- = Br^-$ or I^-. An image of platinum with atomic resolution was obtained initially in sulfuric acid solutions at 380 mV (NHE) and the interatomic distances and the orientation of the substrate were determined. After this, in the solution with added KI the $(\sqrt{3} \times \sqrt{3})R30°$ structure was observed at the same potential for several hours. This superlattice was not observed in ex situ studies after the removal of the electrode from the cell; it apparently exists only in solution. The same structure has been observed in a solution with added KBr at a potential of 400 mV. In both cases, a copper monolayer (1 × 1) is deposited on the platinum surface according to coulometric data. The authors believe that the recorded $(\sqrt{3} \times \sqrt{3})R30°$ structure corresponds to a second layer of the superlattice consisting of iodide or bromide ions adsorbed on the copper monolayer [the $(\sqrt{3} \times \sqrt{3})R30°$ iodine lattice on Pt(111) in perchloric acid solution with added iodine has been observed by Yau et al.[108]].

The adsorption of lead atoms on silver single crystals may serve as an example of yet another system which has been studied in detail by means of electrochemical and structural methods and also in situ with the aid of STM.

Several absorption – desorption peaks in the UPD region have been observed on the CVA curve for the Ag(*hkl*)/Pb^{2+} system, which indicates the stepwise formation of dimeric monolayers with different superlattice structures depending on the crystallo-graphic orientation of the substrate and the electrode potential.[109] The use of the STM with lateral atomic resolution in situ demonstrated the formation on Ag(111) of a compressed HCP Pb monolayer, rotated by 4.5° relative to the lattice of the support, with distances between the nearest neighbours of 0.34 nm in the region of potentials more positive than the equilibrium value by 0 – 100 mV.[110]

A completely different picture is observed on Ag(100) in the same potential range. At 50 mV, the application of the STM in situ

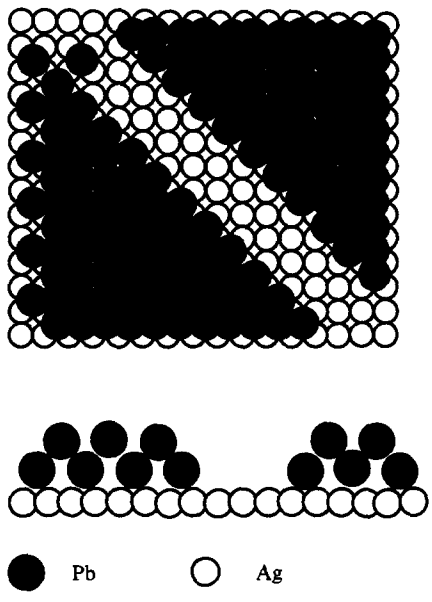

Figure 8. Schematic illustration of the two-layer $c(2 \times 2)$Pb–$c(2 \times 2)$Pb adsorption lattice with a twin boundary between the domains.

demonstrated the presence of a square lead superlattice with a relatively low reticular density. The symmetry of the superstructure and the distances between the first (0.40 nm) and second (0.59 nm) nearest neighbours are satisfactorily consistent with the 'Ag(100) upper layer–$c(2 \times 2)$–$c(2 \times 2)$Pb' double layer superlattice (Fig. 8), as postulated previously.[111] However, measurements of the degree of surface coverage, Monte Carlo mathematical modelling, and tunnelling microscope data indicate that the adsorbed lead atoms form ordered domains separated by boundaries (the chess board effect).[109]

At relatively high anodic potentials (more positive than the equilibrium value by 120–200 mV), the structure of the first Ag(100)–$c(2 \times 2)$Pb adsorbed layer cannot be observed with the aid of the STM. This can be explained by the high mobility of the adsorbed lead atoms at low and moderate surface coverages (the exchange current of the adsorbed lead atoms increases sharply at low surface coverages[112]). The Ag(100)–$c(2 \times 2)$Pb structure corresponds to $\theta = 0.5$ (each adsorbed atom occupies two adsorption sites in the square lattice), which also agrees well with the results of mathematical modelling for an energy of interaction between nearest neighbours of 2.5×10^{-21} J atom^{-1}.[113]

The structural transformation of the square Ag(100)–$c(2 \times 2)$–$c(2 \times 2)$Pb bilayer into a compressed HCP monolayer has been observed in situ with the aid of STM with the potential being varied from 50 mV to zero. It was postulated that this process begins at the boundaries of the ordered domains of the bilayer, the relative compression of the adsorption layer agreeing well with STM and X-ray scattering data for a hexagonal close-packed layer of adsorbed lead atoms on Ag(111).[109]

Thus, regardless of the crystallographic orientation of the silver substrate, the adsorbed lead atoms form an HCP Pb(111) monolayer. This unexpected result emphasises yet again the unique possibilities of the use of the STM in situ for the investigation of electrode processes.

In the Au(*hkl*)/Ag^+ system, there is a strong adsorbate–substrate interaction and the lattice parameters differ only slightly (0.2884 nm for gold and 0.2890 nm for silver), which makes it possible to expect the operation of the Frank–Van der Merwe mechanism, i.e. the formation of dimeric nuclei and subsequent layer-by-layer growth of the deposit. The silver adsorption–desorption process on gold depends greatly on the crystallographic orientation of the substrate. The degree of surface coverage by the adsorbed atoms was determined[109] from the anodic desorption curves after brief (not longer than 2 min) polarisation of the electrode in dilute (10^{-5}–10^{-3} M $AgClO_4$) solutions at the equilibrium silver deposition potential. The formation of noncompressed silver monolayers with an orientation epitaxial relative to the substrate was observed with the aid of the scanning tunnelling microscope.[109,114–119] In experiments with prolonged (of the order of 40 min) maintenance of the electrode at potentials close to the equilibrium value (0–15 mV), evidence for the formation of the Au–Ag alloy, beginning on the surface defects and the boundaries of the projections, was obtained.[119]

The UPD of silver on Au(111) in a sulfate solution has been investigated.[120] The $(\sqrt{3} \times \sqrt{3})R30°$ structure was observed for this system for the first time with the aid of the STM. According to coulometric data, this lattice corresponds to 1/3 of the silver monolayer. The authors attribute the STM image to the silver superlattice, but in this case the microscope can record both adsorbed silver atoms and sulfate anions (the probable structure of the adsorbate is illustrated schematically in Fig. 9). The results of a detailed study of this system with the aid of in situ and ex situ methods have been published.[121]

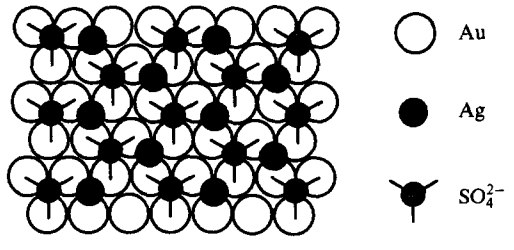

Figure 9. Schematic illustration of the $(Ag\sqrt{3} \times \sqrt{3})R30°$ adsorption lattice on Au(111).

The influence of the nature of the anion on the UPD of silver and mercury on Au(111) has been studied[117,122,123] with the aid of atomic force microscopy. It was shown that the mercury monolayers have an hexagonal structure with an interatomic distance of 0.58 nm (the crystal lattice parameter of solid mercury at low temperatures is 0.31 nm) in sulfate, nitrate, and perchlorate electrolytes. The adsorbed silver atoms are extremely sensitive to the size of the anion: the packing density of the adsorbate increases in the sequence sulfate (44%) < nitrate (56%) < perchlorate (64%) < acetate (100%, HCP).

The structure of the surface of gold modified by adsorbed atoms and its influence on the catalytic properties of gold have been investigated.[124–126] The structure of the bismuth monolayer on Au(111) depends on the applied potential: at potentials of 10–190 mV (more positive than the bulk-phase deposition potential), a rectangular $(p \times \sqrt{3})$ lattice, compressed along one of the axes and with an interatomic distance of 0.34 nm and a degree of surface coverage of about 60%, is formed. At potentials of 200–280 mV, there is a stable (2×2) phase with the angle $\theta = 0.25$ and a lattice parameter of 0.57 nm. The catalytic activity of the (2×2) structure in the oxidation of hydrogen peroxide is higher, since in this case the gold and bismuth atoms are accessible to the H_2O_2 molecules (Fig. 10). For the denser monolayer, only bismuth atoms are accessible, whilst for zero surface coverage only gold atoms are accessible. The maximum activity is observed when the Au and Bi atoms act jointly [124,125] When Au(111) is modified by adsorbed lead atoms, the potential at which the surface is coated by islands of the Pb(1×1) HCP phase corresponds to the highest catalytic activity,[126,127] whereas the clean surface of gold and the complete lead monolayer on Au(111) are catalytically inactive. The increased activity of the heterometallic centres is apparently associated with spatial effects

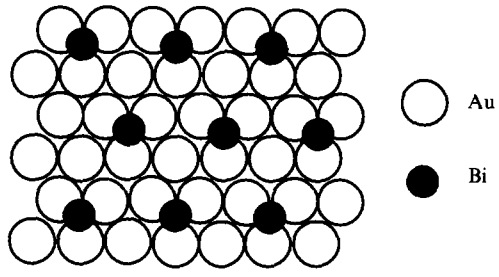

Figure 10. Schematic illustration of the Bi(2 × 2) adsorption lattice on Au(111).

and the different adsorption capacities of the adsorbed atoms and the surface atoms of the support in relation to oxygen and hydrogen atoms.

The examples of studies on the structures of adsorbed atomic layers examined here demonstrate convincingly that tunnelling and atomic force microscopes are powerful instruments for the study of adsorption processes. However, scanning probe microscopy cannot as yet do without the employment of traditional electrochemical methods (cyclic voltammetry, coulometry, etc.), in which the necessary requirements as regards purity in the experiments and in the preparation of the objects of study are met. Only comprehensive combined investigations make it possible to reach conclusions, with a high degree of reliability, about the mechanism of the adsorption process and the influence of various factors on the latter.

3. Scanning microscopy of the initial stages of the electrodeposition of metals

Scanning probe microscopy proved extremely useful for the investigation in situ of the initial stages of the electrocrystallisation and corrosion of metals, because the size of the nuclei of the new phase does not as a rule exceed several tens of atoms.[128,129] There are numerous publications devoted to the use of SPM for the observation of processes involving the phase deposition of metals from model and industrial electrolytes under potentiostatic, galvanostatic, and pulsed electrolytic conditions.[2,3,5,7,11,32–34,42,73,91,109,130–155] The influence of organic additives on the mechanism of electrocrystallisation has been studied in a series of investigations.[152–155] An increasing number of publications have been appearing on the use of SPM for the study of the structure and mechanism of formation of passive films in anodisation and also of the initial stages of corrosion processes.[156–166]

Despite the diversity of the systems investigated and the characteristic features of each of them, the following general conclusions can be made: (1) nucleus formation always begins on the active centres of the substrate, which consist of the projections on the boundaries of the terraces and of crystal lattice defects (as a rule, dislocations); (2) the nuclei of the new phase are formed later on the flat terraces, where the number of defects is small, and then on the defects themselves; (3) in the vast majority of studies, it has been concluded that the height of the nuclei is several times smaller than their transverse dimensions, which indicates a high energy of interaction of the atoms of the deposited metal with the atoms of the substrate.

We shall consider certain examples of the investigation of the initial stages of electrocrystallisation by use of the STM in situ. Generalised results of the study of the 'adsorption layer–phase' transition on the surface of gold in 10^{-5} M $AgClO_4$ solutions have been published.[109] The processes, involving the formation of a monolayer of adsorbed atoms and of the three-dimensional silver phase, are controlled by diffusion under these conditions and are slow. A special polarisation procedure, in which the electrode is maintained at specific potentials, was used to achieve the deposition of the required number of silver monolayers on gold. The number of monolayers was monitored coulometrically by the successive etching of the deposit. The formation of three-dimensional silver crystals was not observed microscopically up to the deposition of 40 monolayers. The mechanism of the layer-by-layer deposition of silver was supported by the formation of the lead UPD on such a silver deposit. Cyclic voltammetry in a lead-containing solution yields adsorption–desorption curves typical of the Ag(*hkl*)/Pb^{2+} systems, which are characteristic of the deposition of two or more silver monolayers on Au(*hkl*). Scanning tunnelling microscopy also indicates the layer-by-layer epitaxial growth of the silver deposit on Au(*hkl*). The uniform distribution of the deposit on the surface of the substrate is further confirmed by data obtained by scanning Auger spectrometry.[114–116]

In the deposition of fewer than two silver monolayers, slow alloy formation between the gold atoms of the surface layer and the silver atoms of the deposit is observed. In this case, CVA in solution with added lead gives rise to a curve with features characteristic of two systems: Ag(*hkl*)/Pb^{2+} and Au(*hkl*)/Pb^{2+}.

The observed layer-by-layer growth of the silver deposit on gold can occur in different ways depending on the degree of ideality of the substrate and on the overpotential.

1. The monolayer growth of a single nucleus on a surface free from screw dislocations at relatively low overpotentials (the growth of a new two-dimensional nucleus begins after the layer of silver has spread over the entire surface).

2. The formation of several nuclei on a surface free from screw dislocations at relatively high overpotentials and the subsequent growth of a packet of layers (polynuclear multilayer growth).

3. Multilayer spiral growth on the surface screw dislocations at low overpotentials.

In the study of the 'adsorption layer–phase' transition in more concentrated solutions (10^{-1} M $AgClO_4$), a time dependence of the current (current transients) with two characteristic sections was observed. For short times, the descending part of the transient corresponds to the formation of several monolayers of the deposit. The subsequent increase in the current is associated with the change in the nature of the deposition and the formation of three-dimensional multilayer growth packets. The dependence of the stationary current on the overpotential is evidence in support of the multilayer growth on the screw dislocations on the silver layers inherited from the gold substrate.[109]

The study of the phase deposition of lead on silver single crystals at potentials more negative than the equilibrium value showed that, regardless of the crystallographic orientation of the substrate, the lead films and three-dimensional crystallites have the (111) texture.[110,111,130–133] This means that the compressed two-dimensional HCP layer of adsorbed lead atoms constitutes the base for the subsequent epitaxial three-dimensional formation and growth of the bulk phase of lead. The influence of this sublayer on the nucleation process and the growth kinetics has been analysed on the basis of the atomistic theory of nucleation.[134]

Parallel monatomic steps have also been observed[135] in situ with the aid of STM in the three-dimensional growth of a lead film. According to the authors, these were generated by a screw dislocation (the image of an 80 × 80 nm section of the surface clearly shows five growth steps). The specific boundary energy of a monatomic step was estimated[135] from the average distance between the steps and the overpotential employed. It proved to be 3×10^{-14} J cm^{-1}.

Measurements of the tunnelling current under the conditions of a constant height of the probe above the electrode surface showed that the effective heights of the tunnelling barrier differ from the pure Ag(100) and Ag(111) substrates, whereas in the presence on the latter of a HCP monolayer of adsorbed lead atoms they are the same and are virtually equal to the height of the barrier for the Pb(111) bulk phase. For the Ag(100)–$c(2 \times 2)$–$c(2 \times 2)$Pb bilayer superlattice, which exists at potentials of

40 – 100 mV (more positive than the equilibrium value), the height of the tunnelling barrier is appreciably lower.[109]

These results demonstrate unambiguously that the Stranskii – Krastanov mechanism operates in the Ag(*hkl*)/Pb^{2+} system: a three-dimensional lead phase is formed on a silver substrate modified by a two-dimensional layer of adsorbed atoms.[110,130,131]

Electrolytes with organic additives are employed in the majority of technological processes to ensure the necessary decorative, protecting, and physicochemical properties of the galvanic coatings. The mechanism of the effect of the additives has always interested specialists and the introduction of SPM made it possible to obtain unique new information about this problem.

The influence of benzotriazole (BTA) on the nucleation and growth of copper crystals on platinum in sulfuric acid and perchlorate electrolytes has been investigated under potentiostatic and galvanostatic conditions.[152] The density of the nuclei was determined with the aid of a Fourier transformation of the profile of the surface of the deposit, and by assuming that the characteristic frequency of the rugosities of the profile is inversely proportional to the average width of the nucleus. It was shown that in the presence of BTA the faceting of the deposit is suppressed (the crystallites have a nearly hemispherical form) and the deposition overpotential increases appreciably, but the number of nuclei hardly changes.

Crystal Violet (CV) and benzotriazole derivatives were selected in other studies[153–155] as additives to sulfuric acid and perchlorate copper-plating electrolytes. The substrate was gold film sputtered onto glass and annealed in a burner flame in order to obtain the (111) texture. It was established that, in solutions without additives at overpotentials of 200 – 400 mV, instantaneous nucleation and three-dimensional growth of crystallites 1 – 10 nm high take place. The introduction of 10 mg $litre^{-1}$ of CV into the 0.1 M H_2SO_4 + 0.05 mM $CuSO_4$ solution suppresses the tangential growth of the crystals — their height does not exceed 1 nm. However, in a solution with 0.1 M H_2SO_4 + 1 mM $CuSO_4$ this additive hardly affects the morphology of the copper crystals.

Regardless of the presence of additives in the solution, the nucleation of the copper crystals takes place on defects; the nuclei are not formed on the flat defect-free terraces. The authors explain this finding by the greater size of the organic molecules, which cannot block tightly the steps and defects on the substrate, allowing access by the adsorbed copper atoms and ions to the nucleation and growth sites.

The influence of organic additives is manifested at later stages. In pure H_2SO_4 + $CuSO_4$ solution, copper crystallites have flat upper faces and stepped edges. In the presence of the benzotriazole derivative BT-A in 50 μM $CuSO_4$, a quasi-two-dimensional growth of the deposit takes place in the electrolyte, whilst in 1 mM $CuSO_4$ both planar and three-dimensional copper crystals are formed.

The addition of another benzotriazole derivative (BT-B) at a concentration of 10 mg $litre^{-1}$ has a more pronounced inhibiting effect. Regardless of the copper sulfate concentration, the tangential growth of the crystals is suppressed and their height does not exceed 1.5 nm.

An AFM with a wide-field (8 μm × 8 μm) piezoscanner was used to observe thicker deposits. In the deposition of copper from a 120 g $litre^{-1}$ $CuSO_4$ + 0.5 M H_2SO_4 solution at −74 mV, a thick deposit, in which the height of the rugosities is ~500 nm, is formed. In the presence of CV, the height of the crystallites reaches 10 nm [the thickness of the monatomic copper(111) layer is 0.209 nm], whilst in the presence of 10 mg $litre^{-1}$ of BT-B the lateral growth of layers with a thickness up to 1.5 nm (4 – 7 monolayers) takes place. These layers then grow together and the sites where this has taken place become the active centres for the nucleation of a new upper monolayer of copper. The authors attribute this sharp decrease in the thickness of the growing layer to the influence of the substrate. We may recall that the interatomic distances in the Cu(111) and Au(111) lattices are 0.256 and 0.289 nm respectively, while the UPD layer has a lattice parameter characteristic of the substrate. Furthermore the energy of the Cu – Au interaction is greater than that of the Cu – Cu interaction, which is indicated by the occurrence of the UPD and the formation of an alloy. The monolayer growth of copper on the extended UPD layer is apparently energetically unfavourable and the spreading of the packet of layers is accompanied by the relaxation of stresses.

The planar organic molecules of the additives are apparently more strongly adsorbed on the top of the growing layer than on the growth steps by virtue of steric factors. In this case, the inhibition of the vertical growth should be manifested to a greater extent than that of the lateral growth. The defects arising in the growing together of the lower layers may serve as the active centres for the nucleation of the new layer. Yet another factor promoting the lateral growth in the presence of additives is the overall inhibition of the process (the discharge of the ions and their incorporation into the lattice), which leads to the formation of less defective layers and hence to a decrease in the number of active centres for secondary nucleation. The principal conclusion reached by Nichols et al.[154] reduces to the statement that the form of the crystallites in electrodeposition is determined by the ratio of the rates of the secondary nucleation and the lateral growth, and that surface-active additives may alter this ratio.

An example of the use of SPM for the monitoring of the technological copper plating of printing plates is provided by another study of Nichols et al.[155] The atomic force microscope was used at the stage involving the preparation of the surface before chemical copper plating and the generation of the adhesion layer, and the STM was employed to investigate the initial stages of the electrocrystallisation of copper from industrial electrolytes with organic additives. Thus the STM has already ceased to be an instrument for purely theoretical research and is being used more frequently as an element of technological monitoring.

V. Prospects for the development of scanning probe microscopy

Naturally, the examples of the employment of SPM examined in the previous sections naturally did not exhaust all the possibilities of this method in relation to electrochemistry. Studies involving tunnelling and atomic force microscopy in biology and bioelectrochemistry,[5] organic electrochemistry, and the electrochemistry of semiconductors and conducting polymers have not been dealt with in this review, and certain studies on the corrosion of metals and alloys have only been touched upon — these require special consideration because the number of publications on these problems have been increasing every year and it is impossible to analyse them within the framework of a single article.

In concluding the survey of the latest advances in the use of SPM in the electrochemistry of surfaces and in the electrocrystallisation of metals, it is desirable to consider the problems and prospects for the development of this method. The inconsistency between the electrochemical parameters averaged over the entire electrode surface (the current – potential – time relations) and the local visual information about the structure of a small section of the electrode and the processes occurring on it (one cannot be certain that the processes under the probe and at a distance from it take place at the same rate) can apparently be regarded as the principal problem of the use of the STM in situ. The size of the tunnelling probe is so great compared with the distance between the latter and the test surface that diffusional and electrical shielding[93] or stimulation[145] [observed in the study of the deposition of copper on Cu(110) with the aid of the AFM] effects inevitably arise. In each specific case, investigators have endeavoured to take this influence into account by selecting

experimental conditions such that it can be neglected. However, they have not always been able to ensure an unambiguous interpretation of the results. The appearance in recent years of wide-field piezoscanners, capable of recording the image of a surface whose size runs into tens and even hundreds of micrometres, has made it possible to scan virtually the entire microelectrode surface with the exception of the edges (in this case, the working feedback loop would stick the probe into the dielectric material), but a satisfactory resolution is so far virtually unattainable over large areas.

The electrical conductivity of the object is not of fundamental importance for atomic force microscopy, so that the employment of the AFM for the analysis of the entire microelectrode surface might eliminate the problem of the correlation between electrochemical data and the topography (here it is necessary to take into account the possible activation of the surface by the probe[145]). The present authors are unaware of any publications of this kind, but the logic of the development of events suggests that they are to be expected in the immediate future.

Yet another problem is the recognition of the image. Scanning probe microscopy yields a picture of the surface, but it is by no means always clear what it represents. The studies on the copper UPD process on gold and platinum examined above may serve as an example. The question arises how one can distinguish an adsorbed copper atom from a sulfate ion. Tunnelling spectroscopy should apparently be relevant here, but the employment of STS in electrochemical systems has significant characteristic features. It has been shown[167] that the change in the electron work function on passing from one metal to another is compensated by the corresponding change in the Galvani potential, so that the rate of the electrode reaction (and also possibly the rate of the tunnelling of electrons to the probe) is independent of the electron work function and is determined solely by the electrode potential. In this case, the use of STS in solutions on metallic electrodes is impossible from the standpoint of the modern theory of the elementary step. However, measurements of the dependence of the tunnelling current on the height of the probe over the Ag(111) and Ag(100) substrates and the calculations of the effective tunnelling barriers have shown[109] that, for an identical potential of +300 mV relative to the Pb^{2+}/Pb electrode, these values are 0.35 ± 0.01 and 0.31 ± 0.01 eV respectively. In the presence of a lead monolayer on the surface of a silver single crystal, the height of the barrier is 0.17 ± 0.01 eV regardless of the potential (0 – 50 mV) and the crystallographic orientation of the substrate. Unfortunately, the potentials of the tunnelling probe in the measurement of the tunnelling barriers are not quoted in the communication of Staikov et al.[109] Such information might throw light on the situation. The resolution of this contradiction apparently requires careful theoretical and experimental studies on the application of STS in situ.

In discussing the prospects for the development of SPM, one can postulate that the range of objects and the different aspects of such investigations should greatly expand and that the method will be used with increasing frequency for the solution of technological problems. To a large extent, this concerns the problems of nanotechnology, which began to develop actively after the invention of the STM. The possibility of observing atomic structures led to the wish to modify the surface at the atomic level.[5,11] Investigators learnt how to draw letters and symbols with a line having a width of several nanometres, and studies on the construction of the nanoelements of integrated circuits, memory devices, elements for quantum electronics, etc. are being vigorously prosecuted. It appears that electrochemistry will not be neglected either. There have already been publications on the local (in the nanometre range) deposition and dissolution of metals, the study of electrode reactions on the surfaces of semiconductors[11] with the aid of the SPM, and the preparation of multilayer coatings with a monatomic thickness of the layers (sandwich heterostructures[109]). The development of tunnelling and atomic force microscopy has led to the development of a series of related methods,[4–6] and so called scanning electrochemical microscopy is extremely promising.[168–170] The essential feature of the method is that it employs as the probe a disc ultramicroelectrode 0.1 – 25 μm in diameter with insulated lateral surfaces on which a potential is maintained, thereby ensuring the occurrence of an electrochemical reaction — for example the oxidation of Cu^+ or the reduction of Cu^{2+} in the investigation of the dissolution of copper on the main electrode. The probe moves over the test surface and the distribution of the active dissolution centres can be inferred from the probe current.

The use of a probe as an auxiliary electrode permits selective deposition, the etching of metals and semiconductors in electrolytes with a low scattering capacity and in polymer films with ionic conductivity, and electropolymerisation. The resolution ensured by the method depends on the size of the probe, the distance between the microelectrode and the specimen, the electrolyte composition, and the electrolysis conditions and can reach 100 nm.[170] Satisfactory results have been obtained when probes consisting of very sharp noninsulated needles were employed.

A probe can be used as a reference electrode and the distribution of the surface potential can be monitored, for example, in the study of corrosion processes.[171,172] The method is called scanning potentiometry and has a very low resolution.

Yet another promising aspect of the development of SPM involves the creation of combined instruments, in which tunnelling and atomic force microscopy as well as its variations are combined with other in situ methods (optical, acoustic, microgravimetric, etc.). Such studies are already being carried out[13–17] and the first results give rise to the hope for their successful development.

Binnig and Rohrer, the inventors of the STM, entitled their Nobel lecture in 1986 'Scanning Tunnelling Microscopy — From Birth to Youth'. Likewise one may say that the youth of scanning tunnelling microscopy has now ended and that it is now an entirely serious method which has justified the boldest hopes concerning it. Scanning probe microscopy is entering the period of maturity and is used very productively in most diverse fields of science and technology. However, its main attainments still remain in the future.

The review has been written with the financial support of the Russian Fundamental Research Fund (projects 93-03-4002 and 95-03-08100), the International Scientific Fund, and the Government of Russia (projects M4X000 and M4X300).

Abstract. Data on the emission phenomena and chemical processes occurring in molecular organic crystals capable of rapid exothermic decomposition when subjected to mechanical influences are surveyed. The influence of the nature, composition, and pressure of the gaseous medium on the probability of initiation of the mechanical decomposition of single crystals is examined. The existing concepts concerning the initiation of fast reactions in organic crystals are analysed. A general scheme is proposed for the electrophysical phenomena and chemical reactions occurring when solids are subjected to mechanical influences. The bibliography includes 132 references.

I. Introduction

The study of the physical phenomena and chemical reactions occurring in solids subjected to mechanical influences may play a notable role in the search for nontraditional ways of carrying out technological processes and in the selection of new methods for controlling the activation of chemicals and materials.

The mechanical stresses acting from outside on a solid can lead to irreversible consequences when they have attained certain values: plastic deformation of the crystal lattice and decomposition of the crystal.

In the course of the decomposition of solids, chemical bonds are broken and active centres are formed, whereupon streams of electrons and ions and electromagnetic radiation are generated. These include X-rays with a wide spectral range[1-7] and various electrophysical phenomena due to the formation on the fresh surfaces of an uncompensated charge that relaxes relatively slowly and persists for a fairly long time (up to several hours in the case of dielectric materials). Naturally, the physicochemical properties of the solid (especially its conductivity) influence the intensity and kinetics of the electrophysical phenomena. Such influence is most marked in the case of dielectric materials. The forms of radiation noted above may be combined under the term cold plasma.[8] The idea of the transition of a substance to a plasma state when a solid is subjected to mechanical influences was first proposed by Thiessen.[9,10] Subsequent experimental studies confirmed the validity of this hypothesis.[1-7]

The emission phenomena and chemical reactions observed when solids are subjected to mechanical influences are summarised in the generalised scheme in Fig. 1.

Fig. 2 presents a scheme of the possible consequences of subjecting polymers to mechanical stresses. The mechanical degradation of polymer macromolecules is also accompanied by the rupture of chemical bonds: reactive free radicals (paramagnetic centres) and low-molecular-mass compounds (fragments of macromolecules down to the monomer) are generated. The mechanochemical transformations in polymers have been considered in detail in a number of studies.[1,3,6] A number of electrophysical phenomena are observed on formation of the disintegration surfaces in polymers (as in dielectrics): the appearance of an excess electrical charge, the emission of electrons, gas discharges, luminescence, and other types of emission (IR, radio waves). The characteristic features of their manifestation have been treated systematically in a number of studies.[1-4,6,7]

For a long time, the objects in the study of the mechanoemission and mechanochemistry of solids have been mainly ionic and homopolar crystals as well as polymers (see, for example, Refs 1-4, 6, and 11-13). When these substances are disintegrated, the rupture of chemical bonds is an obligatory consequence.

The structure of the molecular crystals of organic substances has a number of features, which is reflected in their properties. The structural unit in the crystal lattices of organic substances is the molecule, the atoms of which are linked by strong covalent bonds. Only weak van der Waals interactions exist or hydrogen bonds are formed between the molecules. Such a structure of molecular crystals determines many of their physical and mechanical properties: the high electrical resistivity ($10^{15}-10^{18}$ Ωm), the low melting point (down to ~600 K), and the poor mechanical strength and hardness.

Molecular organic crystals have found extensive practical applications and the study of the variation of their electrophysical and physicochemical properties when the crystals are subjected to mechanical influences is therefore a problem of current interest.

The mechanoemission phenomena and chemical reactions in molecular organic dielectric materials, which disintegrate rapidly when subjected to mechanical forces, are described in the present review. The authors have devoted special attention to the

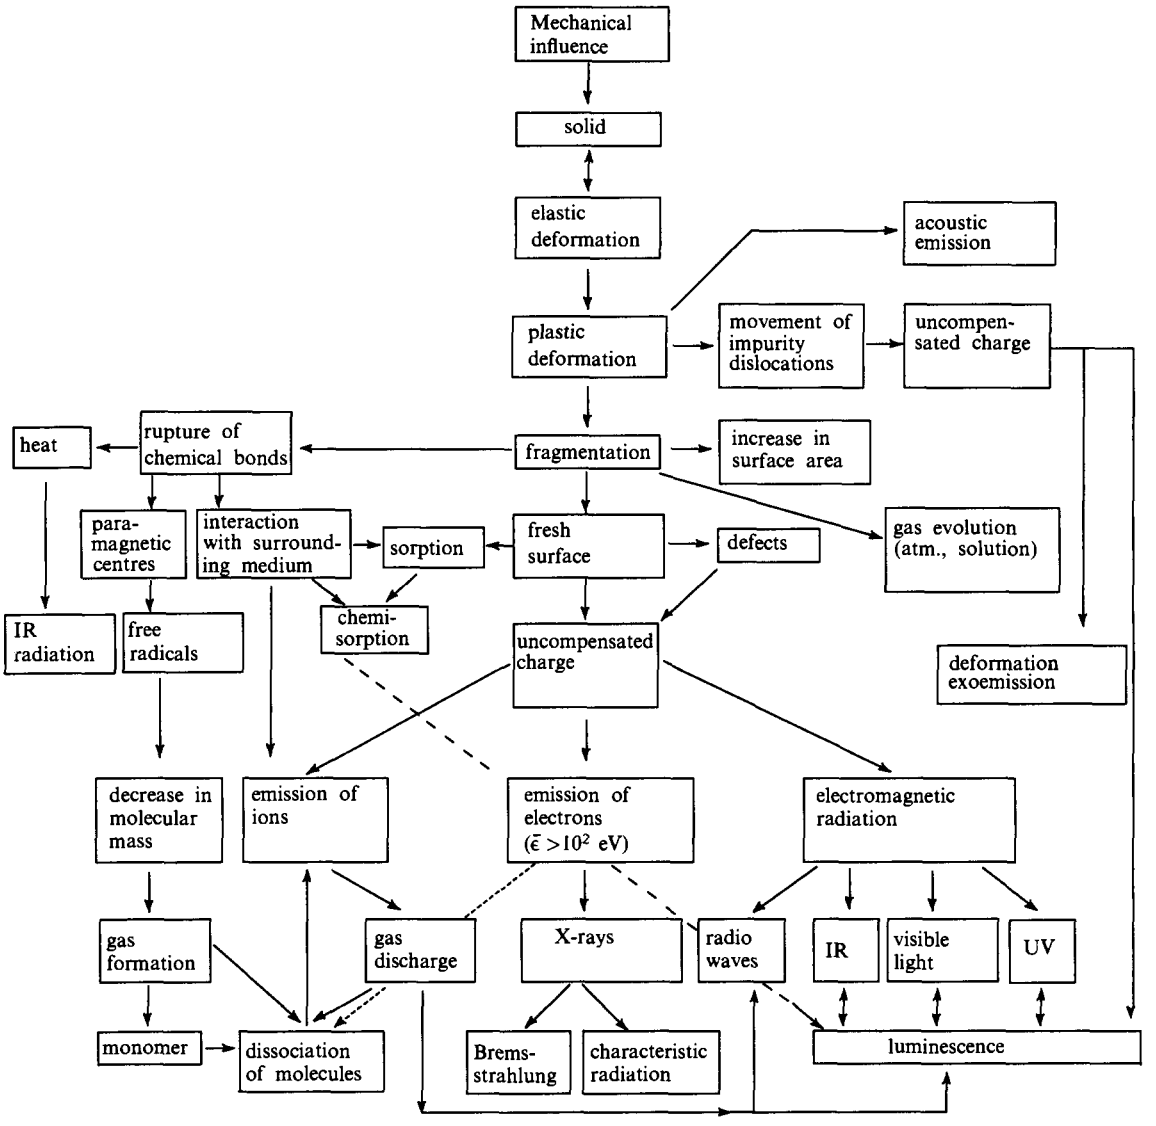

Figure 1. Generalised scheme of the emission phenomena and chemical reactions occurring when solids are subjected to an external mechanical influence.

electrophysical phenomena accompanying the appearance of new disintegration surfaces. These phenomena may induce mechano-chemical reactions in the molecular organic substances. The mechanoemission phenomena accompanied by the rupture of bonds of different nature are in our view not only responsible for the chemical reactivity of the fresh surface but also activate the gaseous medium in its vicinity.

II. Electrophysical phenomena

1. Charges on the fresh cleavage surfaces of ionic crystals

In the disintegration of dielectric solids, uncompensated charges having different signs appear on the walls of the developing crack. The very strong electric fields arising under these conditions are the cause of various emission phenomena leading also to chemical changes in the test substance.

The study of the electric fields on the freshly formed surface and especially in a developing crack is fairly complex owing to the rapid relaxation of the excess charge in the initial instant of the lifetime of the fresh surface and the small size of the electrically active regions. Thus the nonstationary electric field in the cleavage crack (the rate of propagation of which is several hundreds of metres per second) in the case of alkali metal halides (a lithium fluoride single crystal) does not exceed 20% of the initial value ($\sim 60\ \mu Cm^{-2}$) after only 10–20 s.[14]

In real crystals, defects are always present as a consequence of their deviation from the ideal periodicity. One distinguishes point defects (impurity atoms or ions, vacancies, atoms or ions of the test substance itself localised in the intestices, etc.), linear defects (dislocations — breakdown in the regular arrangement of atomic planes, in particular of boundaries between regions with different orientations of the crystal structure) and bulk-phase defects (accumulation of vacancies, pores, gas bubbles, etc.). The defectiveness of the crystal lattice as well as the process involving the rupture of an ionic bond (i.e. the very chemical nature of the ionic crystal) are responsible for the nonuniformity of the distribution of electrons between cations and anions. It must be emphasised that the electrically active structure of real crystals has been pre-programmed, i.e. specified, by the nature and characteristic features of the growth of the nuclei of the future crystals with particular defects,[15] while the process involving the disintegration of crystalline substances itself leads to the additional formation of new charged defects on the fresh cleavage surface.

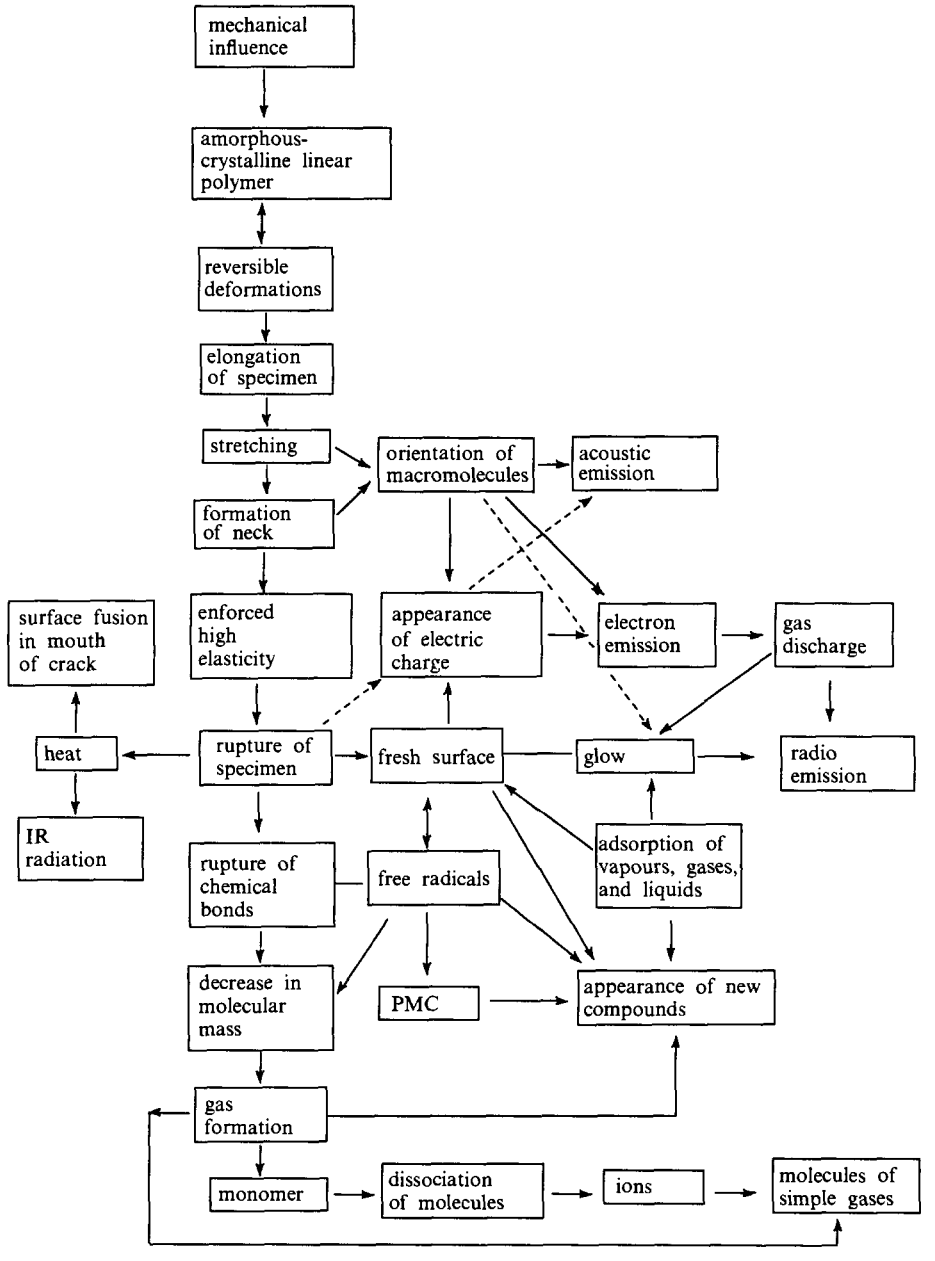

Figure 2. Scheme of possible mechanoemission phenomena and mechanochemical reactions occurring when polymers are subjected to external stresses.

The defective sites constitute electrically active centres and uncompensated ruptured chemical bonds on the disintegration surface of the crystal. Such active centres are frequently detected by the decoration method, where a decorating substance is deposited from the vapour (or liquid) phase (such substances are usually gold, silver chloride, anthraquinone, latexes, etc.). The nuclei are then formed and grow predominantly on the negatively charged section of the surface. The decoration patterns — the topographies of the surfaces and, in particular, of the cleavage surfaces with point defects and their accumulations — are investigated by optical and electron microscope methods.[15] In the case of ionic single crystals, the density of the charged active centres usually attains values of $10^{10} - 5 \times 10^{11}$ cm^{-2}. The results of the study of the electrical nonuniformity (defectiveness) of the cleavage surfaces of various solids by the decoration method have been surveyed in a monograph.[15]

Distler et al.[15] actually observed by the decoration method the electrical breakdowns between positively and negatively charged microregions on the fresh cleavage surface of a quenched sodium chloride crystal for a field strength of $\sim 10^8$ V m^{-1} (see also Deryagin et al.[1]). The decorating gold particles were condensed at the instant of the disintegration of the specimen, i.e. during the growth of the main crack. It has been noted that the charging of the cleavage surface in lithium fluoride does not influence greatly the crack propagation velocity.[16] It is believed[17] that the rate of movement of the main crack can be regulated up to its arrest with the aid of externally applied electric fields.

It has been established by modern physical research methods that the growth of the main crack in ionic crystals, in particular in alkali metal halides, proceeds nonuniformly — in jumps.[17-20] It has been claimed[20] that the power of the emission of the charged particles from the mouth of the crack exceeds by 6 - 10 orders of magnitude the power of the emission of particles from the edges of the crack. It is of interest that the low-temperature chemical reactions occurring on brittle disintegration of solid systems are also of the pulsating type.[21]

Scanning of the surface by means of a special probe electrode using the familiar vibrating capacitor principle may serve as another method for the determination of the electrical surface microrelief, for example of the mirror cleavage plane of the crystal.

Distler et al.[15] concentrated attention on the study of the point defects inducing the appearance of charged microregions on the cleavage surface, i.e. after the fragmentation of the specimen. Among the models of the mechanisms of the generation of a charge in the crack on plastic deformation and disintegration of ionic (in particular, alkali metal halide) crystals, the dislocation model proposed by Molotskii has come to be most widely used.[22] The dominant role of the dislocation mechanism in the charging of a freshly formed disintegration surface in alkali metal halides has been demonstrated.[23] The relaxation of the charge makes it possible to account for the mechanochemical dissociation of the walls of the crack (for example the emission of lithium ions from lithium fluoride).[23,24] The dislocation concept has been supported also by other workers.[18,25,26] Other defects can likewise promote the formation of a charge on the fresh cleavage surface of an ionic crystal.

A possible mechanism for the appearance of deformation luminescence and electron emission in alkali metal halides has been provided[25] by the intersection of dislocations in the course of the plastic deformation of the specimens, where there is a probability of electronic transitions which result in the appearance of electron and hole centres. The recombination of these active centres leads to the emission of electrons and photons. The movement of the dislocations at low rates of deformation (down to 10^{-5} s^{-1}) in a single slip of annealed lithium fluoride specimens leads to the accumulations of charges on the surface of the specimen up to electrical breakdown.[26]

2. Uncompensated charges on the cleavage surfaces of organic crystals

It has been established experimentally at the optical level by the method involving decoration with anthraquinone[27] that electrically charged regions, differing in the sign and magnitude of the potential, are present on the cleavage surfaces of cyclotrimethylenetrinitramine (C3MNA) and trinitrophenylmethylnitramine (3NPNA) crystals. Since the decoration was carried out several minutes after the breakdown of the crystals, the observed mosaic microrelief of the electrically active regions reflects only partially the distribution of the charge density of the electric fields on the fresh cleavage surface and in essence represents the residual charge distribution pattern despite the strong dielectric properties of the test crystals.

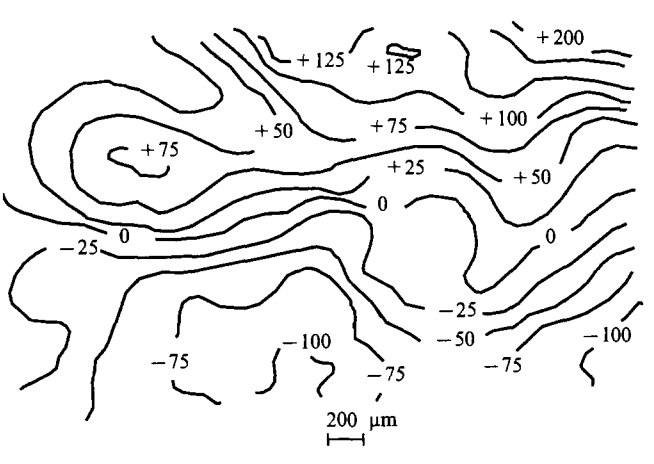

Figure 3. Electric relief of the local fields on the cleavage surfaces of a C3MNA crystal.[27]

The nature of the distribution of the electrical charges on the cleavage surfaces of the same crystals has been investigated by the scanning probe method based on the dynamic capacitor principle.[27] Topograms with a linear resolution of ~ 50 μm obtained (Fig. 3) show that the positive and negative potentials of individual sections of the cleavage surface may reach 10^3 V.

The considerable external similarity between the topograms of the electrical microrelief and the geometrical relief of the breakdown surface, which can be observed visually under a microscope with a magnification by a factor of 50–100, is noteworthy.[27] Polishing of the cleavage surface of the crystal by a solvent, which to a large extent removes the microrugosities, entails the virtually complete disappearance of the electrical microrelief. Rubbing of the solvent-etched surface with a cotton cloth again induced the appearance of an electrical potential up to 10^3 V. The subsequent relaxation of the potential depends significantly on the pressure (the rate of relaxation diminishes on rarefaction) and the humidity (Fig. 4).

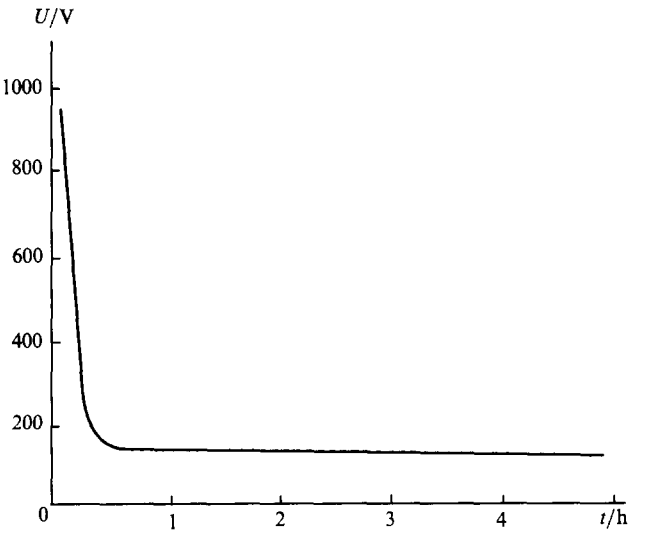

Figure 4. Relaxation of the potential (U) on the surface of a C3MNA crystal after polishing and rubbing against a fabric.[27]

3. Different ways leading to the formation of the electrical microrelief on the breakdown surfaces of organic crystals

The formation of an electrical microrelief on the breakdown surface of an organic crystal may be a consequence of a change in the geometry of the defective surface—the appearance on it of dislocations.

It has been demonstrated experimentally that the cleavage surfaces in the test crystals contain numerous steps and other imperfections.[27] These substances have dipole moments of 3–5 D.[28,29] The microrugosities may generate, in the direction of the measuring electrode, fields of different sign and potential depending on the orientation of the molecular dipoles on the cleavage steps. An experimental test on flat and point electric field sources showed that the dependence of the electrical output signal on the distance between the sources and the electrode (r) is close to exponential for $r > 0.2$ mm.[27]

The presence of steps on the cleavage surface of a sodium chloride single crystal as well as the appearance of new planes, uncharacteristic of the cubic form of the crystals, in particular the [111] plane, has been established.[30]

Thus the microrugosities on the cleavage surface of the crystal investigated may influence significantly the magnitude of the potential determined by the scanning probe method. Consequently the topography of the electrical surface microrelief

represents an electrical map of its geometry. This is also indicated by the disappearance of electric fields after the surface has been etched with a solvent.

The dislocations on the cleavage surface, giving rise to steps, are electrically charged. They distort the pattern of the electron distribution in the crystal lattice. The accumulation of electrons on the cleavage surface become the cause of the appearance of a potential at the fresh surface, where their density is three orders of magnitude higher than for the main bulk of the crystal which has been little deformed.[27]

Experiments have shown[27] that the external pressure and concentration of water vapour play a notable role in the relaxation of charges on the cleavage surface. This is evidently associated with the adsorption and desorption processes on the fresh cleavage surface, which alter the electrical relief.

It is difficult to say which of the mechanisms examined above is decisive because they are manifested simultaneously.

4. Electron emission and electromagnetic radiation emitted from the fresh cleavage surface

When organic molecular crystals of pentaerythritol tetranitrate (PETN), C3MNA, cyclotetramethylenetetranitramine (C4MNA), and 3NPNA were cleaved in a vacuum chamber at a residual pressure of $10^{-3}-10^{-5}$ Pa, the emission of electrons from the cleavage surface was recorded.[31-35] The maximum emission intensity was recorded immediately after the disruption of the specimen, decreasing by a factor of 3–6 after 2–5 s.[34,35] Bearing in mind that the delay in the recording of the emission after cleavage in the experiments of different workers[31-35] was 0.05–1 s, it follows that the initial emission intensity should have been several orders of magnitude higher than the observed value, since the rate of its decrease is nearly exponential.

The electron flux depends on the nature of the substance and the crystallographic orientation of the disrupted specimen. For example, a low electron emission has been noted for 3NPNA compared with other crystals (Fig. 5).[34,35] In C3MNA specimens the maximum electron intensity is higher by a factor of three (6×10^3 counts s^{-1} cm^{-2}) on disruption along the (010) plane than along the (001) plane. Several minutes after disruption, the electron flux as a rule exceeded the background value only by a factor of 1.5–2. In parallel experiments, the variation of the emission flux was 20%–30%. An estimate of the energy of the electrons, by the method involving tunneling through barriers, showed that it can reach values in the range 10^3-10^4 eV for organic molecular crystals.[34,35]

The intensity of the electron emission from PETN decreases by approximately two orders of magnitude 5×10^{-2} s after disruption of the specimen (Fig. 6).[31,32] Unfortunately the method used to disrupt the specimens (crushing of the crystal between two planes) precluded the recording of the emission directly from the fresh surface.

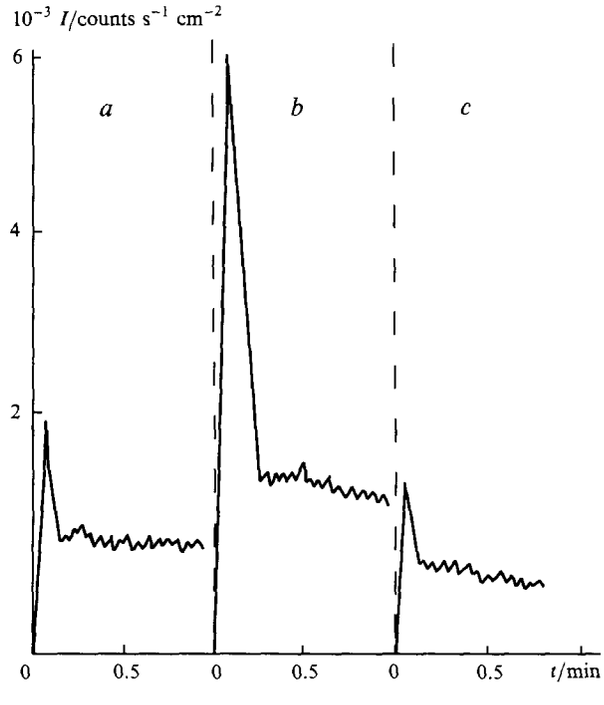

Figure 5. Kinetics of the decrease in the intensity of the emission of high-energy electrons from fresh cleavage surfaces of various crystals:[34] (*a*) C3MNA, (001) plane; (*b*) C3MNA, (010) plane; (*c*) 3NPNA (010) plane.

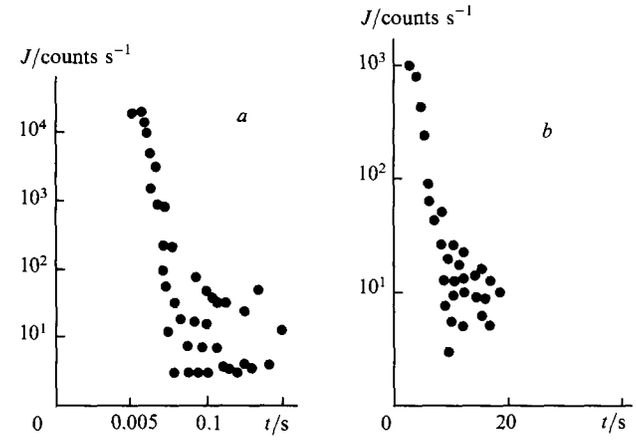

Figure 6. Decrease in the intensity of the emission of electrons (*a*) and protons (*b*) on fragmentation of PETN crystals.[31]

The proton flux was also recorded simultaneously with the electron flux,[31] but its magnitude proved to be an order of magnitude less (Fig. 6). The formation of protons is probably not always related directly to the disruption of the organic crystal, i.e. is not a result of the appearance and development of the cracks leading to the disruption of the specimen. It may be that in effect analogous to that described by Gai et al.[36] was observed in the experiment: the electrons emitted from the breakdown surface of the specimen bombard the metallic surfaces between which the crystal was contained or the metallic surfaces of the vacuum chamber, inducing the dissociative ionisation of the water molecules adsorbed on them to yield protons.

On cleavage of crystals of organic substances in the dark in the immediate vicinity of a highly sensitive photographic film in air, a compact group of individual spots exposed on the film was observed, indicating a nonuniform nature of the emission from the fresh cleavage surface.[34] Since the specimens were disrupted in air, the exposed spots reflected the pattern of the local electric gas discharges in the vicinity of the charged regions of the fresh surface. Furthermore the glow may be due to the interaction of the molecules and ions of the gaseous medium on an initial excited nonequilibrium potential surface.[37,38] The radio emission pulse in the centimetre range recorded on disruption of the crystals in air, confirms the probability of the gas-discharge processes.[34] Nor can one rule out also the possibility that the photographic film is exposed by X-rays, which was observed when crystals of organic substances were cleaved. Apparently this emission represents bremsstrahlung.[35] It is to be expected that the interaction of electromagnetic radiation arising over a wide spectral range (optical, X-ray, etc.) on disruption of a freshly formed surface may be an additional cause of electron emission.

The recording and study of the electromagnetic radiation arising on disruption of rocks and crystals have been examined in a monograph.[39]

We suggest that the very strong electric fields in the developing crack 'accelerate' free electrons, imparting energies up to 10^2-10^4 eV to the latter. Such electrons have in fact been recorded in experiments on the disruption of organic substances.[34,35] The elucidation of the cause of the appearance of the energy necessary to expel an electron from the surface of the crystal remains perhaps the main question to which so far there has been no unambiguous answer.

There exist a series of approaches which explain the appearance of the additional energy in an electron (present at a local level in the vicinity of the surface of the solid) needed to exceed the electronic work function. For example, Krylova[40,41] noted the following possibilities: the utilisation of the high-energy component in the Maxwell distribution, the Auger effect in the electron–hole recombination, the acceleration of the electrons by the internal electric field of the surface layer of the dielectric material. (For further details concerning the acceleration of electrons in internal fields, see Deryagin et al[1]). The energy promoting the expulsion of an electron, for example on photostimulation, can be induced by an external photoeffect.

If the molecule is a component of a condensed phase containing identical molecules, then additional forces begin to operate, which alter the ionisation energy to a considerable extent. In the case of organic crystals, this is the polarisation energy in the crystal (it may be compared with the solvation energy of ions in solution).[42] It has been shown by UV photoelectron spectroscopy that the ionisation potential for different crystalline organic substances is lower by 1.1–3.0 eV than the ionisation potential in the gas phase.[42]

The application of the band theory to the description of electronic processes is justified both experimentally and theoretically for many solids. It constitutes the basis of a qualitative description of the rules governing charge transfer in readily conducting materials, semiconductors with a high mobility of carriers, and dielectric materials of the ionic crystal type. However, the employment of methods of band theory for the description of the physical processes in molecular crystals, a characteristic feature of which is the small overlap of the electronic wave functions and the low mobility of the charge carriers, is by no means always valid.[43,44] For example, in anthracene and naphthalene the temperature dependence of the electron transfer process is consistent with band theory but not in all the crystallographic directions.[44] Band theory describes adequately the properties of organic crystals such as charge-transfer complexes and radical-ion salts with high electrical conductivities in the dark.[42]

It is noteworthy that the nature of the transfer of charge carriers in organic crystals is determined by the presence of capture and scattering centres, the role of which may be assumed by the crystal lattice defects.[45] For this reason, various mechanical, thermal, and radiation influences, altering the concentration and nature of the defects and their distribution, change within certain limits the electrophysical properties of the molecular crystals and thus promote or hinder the charge transfer processes, which is probably a preliminary stage in the appearance of electron emission on disruption.

III. The formation of free radicals

It was noted above that the mechanical disruption of polymers entails the rupture of interatomic bonds with formation of free radicals.[3,6,11–13,46,47] The cleavage and dispersion of crystalline substances with covalent polar bonds leads to the appearance of unsaturated bonds (free radicals).[48–52] The appearance of free radicals on disruption of the cohesion of crystals of organic substances was believed for a long time to be impossible, since it had been postulated that this entails the rupture of only weak van der Waals bonds, the energy of which are lower by one–two orders of magnitude than that of covalent bonds.[53]

An attempt was made[54] to investigate the destruction of PETN during the insertion of a chisel into the crystal under high vacuum conditions at room temperature. Unfortunately, the authors[54] did not present concrete results on the measurement of the mass spectra and merely published their conclusion that the $\dot{C}H_2-O-NO_2$ radicals are formed on rupture of the carbon–carbon bonds and are decomposed further to NO and CO. The claim that the mass spectra of the PETN decomposition products which they obtained on mechanical disruption differ from the mass spectrum of the thermal degradation products is in our view rather unconvincing. The point is that the qualitative and quantitative compositions of the gases evolved on thermal decomposition of unstable substances such as PETN, C3MNA, C4MNA, and 3NPNA depend to a large extent on the temperature range, the heating rate, the external pressure, the amount of impurities, the phase state, and other parameters.[55–60] The absence of thermostatic control or cooling in the experiment[54] on mechanical degradation also do not constitute evidence that thermal degradation did not occur.

Owens and Sharma[61] investigated the changes occurring in trinitrotoluene (TNT) and C3MNA crystals acted upon by weak shock waves. Studies by the EPR method did not permit definite conclusions, since it was not possible to assign the signal due to the paramagnetic centres. Changes in the spectrum of C3MNA subjected to the action of shock waves were detected by X-ray photoelectron spectroscopy. The decrease in the peak with an energy of 407.5 eV, corresponding to the nitrogen atom of the NO_2 group, relative to the 402 eV peak, corresponding to the ring nitrogen atom, showed that ~14% of the N–N bonds in the test substance were ruptured. Such an effect was not observed for the control specimens which had not been subjected to the action of shock waves, i.e. the effect was not induced by the X-rays with an energy of 1.2536×10^3 eV employed in the technique. In the TNT specimens subjected to the action of shock waves, a shift of the 405 eV peaks towards lower energies was observed, which can be accounted for, according to the authors,[61] by the displacement of the hydrogen atom of the $-CH_3$ or $-\rangle CH$ group towards the oxygen atom of an adjoining group.

Analysis of the products obtained under the influence of weak shock waves and the products of the low-temperature decomposition enabled the authors[61] to conclude that different mechanisms operate in the decomposition of the molecules of the initial substance and that high-temperature heating centres probably arise on exposure to shock waves. However, treatment with shock waves involves a series of significant differences from the mechanical treatment.[62] Whereas in the mechanical treatment the time elapsed from the start of the decomposition process to the instant of attainment of the maximum pressure (pulsed influences, impact) or, conversely, the time required for the decrease in the pressure from the maximum value to the end of the removal of the stress (pulsed removal of the stress) is $10^{-3}-10^{-4}$ s, on exposure to shock waves (pressure of 1 – 10 GPa) the time is 10^{-6} s. The passage of the narrow 'peak' pressure front through the bulk of the substance at a rate exceeding the rate of propagation of acoustic waves in the given medium is characteristic of a shock wave.[62] Thus, strictly speaking, treatment with shock waves constitutes a physical process, different from the mechanical process.

When triaminotrinitrobenzene (TATNB) was subjected to shock waves[63] and mechanical[64] influences, the formation of free radicals was observed.

The generation of radicals in arylindanedione dimers (ADD) has been recorded by the EPR method in studies[65,66] involving the shear deformation under a high pressure on Bridgman anvils. The release of pressure led to a rapid and irreversible decrease in the concentration of the paramagnetic centres in the polycrystalline specimen approximately by an order of magnitude. The use of a high-pressure chamber for the recording of radicals under the

conditions of a high hydrostatic pressure led to a completely different result. It was found that radicals are not generated under these conditions.[65,66] Consequently, on rupture of the bonds in ADD, radicals are formed only at high pressure when shear deformation takes place. The kinetic features of the mechanically induced dissociation of molecules under the conditions of shear deformation were established: the pressure dependence of the rate of application of the shear deformation and of the shear angle.[65,66] It was concluded[66] that the rupture of the bonds between the monomers in the dimer, leading to the formation of free radicals, occurs on brittle disruption of the crystalline ADD specimen on newly formed surfaces.

It was established[67] that the fraction of the energy consumed on rupture of the chemical bond in ADD on shear deformation at high pressures does not exceed 1%. On the other hand, most of the mechanical energy (~90%) is dissipated as heat. These data confirmed the above criticism of the study[54] in which a difference was noted between the mass spectra obtained for PETN subjected to mechanical influences and those of the thermal degradation products. Evidently, in the experiments carried out in the above study,[54] the insertion of the chisel into the crystal resulted in the transformation of a large proportion of the mechanical energy into thermal energy. Later it was found[68] that radicals were generated as a result of the mechanostimulated dissociation of the ADD molecules.

It has been established by the EPR technique[35,69] that the dispersion of the PETN, C3MNA, and C4MNA in a vibromill with glass spheres at a frequency of 50 Hz and at the temperature of liquid nitrogen in a helium atmosphere leads to the formation of paramagnetic centres, which were identified as $\dot{N}O_2$ radicals (Fig. 7, Tables 1 and 2). Evidently these radicals are products of the nonthermal decomposition of the test substances. The number of the free radicals is of the order of 10^{16} g^{-1} or 10^{12} cm^{-2}. Thus we observed[69] a fundamentally different pattern in the decomposition of the PETN crystals on disruption from that put forward by Fox and Soria-Ruiz.[54]

Fairly reliable results, indicating the abstraction of the NO_2 group from the PETN molecule, have been obtained by the EPR method, which records the paramagnetic centres directly, in combination with a low temperature (77 K) and thermostatic control. However, the accumulation of 'paired' radicals was not detected.[69] This can be accounted for by their high instability and

their rapid destruction even at 77 K or by the very great width of their signal, which is difficult to observe owing to the triplet of the anisotropic lines due to the NO_2 species. When C3MNA and C4MNA crystals dispersed at 77 K were heated to 293 K, we observed a decrease in the concentration of the $\dot{N}O_2$ radicals almost to the level of the sensitivity of the EPR apparatus, while heating of the ground PETN crystals even to 373 K did not lead to the complete destruction of the paramagnetic centres.[69] This means that the destruction of the $\dot{N}O_2$ radicals on raising the temperature is not associated with the dimerisation reaction $2\,\dot{N}O_2 \rightarrow N_2O_4$ and is induced by their interaction with the products of the decomposition of the 'paired' radicals and the occurrence of the oxidation-reduction reactions

$$\dot{N}O_2 + \dot{R} \rightarrow CO_2 + CO + H_2O + N_2.$$

Neither nitrogen dioxide nor its dimer were detected in the mass spectrum of the gases evolved after heating to 298 K; the PETN dispersed at 77 K.[35] Only peaks corresponding to the products of the decomposition of the PETN molecule were detected: H_2O, CO, CO_2, N_2. The peak observed at $m/e = 30$ may belong to NO as a side product of the degradation reaction, formed in small amounts when NO_2 and the 'paired' radicals interact. Most of the $\dot{N}O_2$ radicals and the products of their reactions with the unstable fragments of the initial molecules may remain trapped in the matrix of the crystalline test substance, which is indicated by the retention of 30% of the paramagnetic centres in the PETN heated to 373 K.

It has been suggested[35,69] that degradation of the PETN molecules with elimination of the NO_2 groups takes place as a result of the action of different types of radiation (electron emission, X-ray and optical radiations, etc.), arising on disruption of the crystal. The fact that an anomalously high radiation yield has been observed in mechanically activated solids may confirm the validity of this hypothesis.

Delpuech and Cherville[71,72] investigated the electronic structures of a series of organic compounds capable of undergoing a rapid exothermic decomposition and the changes in these substances occurring when they are subjected to pulsed mechanical influences. The stable ground state, the structural features of which determine the absorption and distribution of energy, as well as various unstable states arising as a result of impact stresses were examined. Characteristics such as the radiochemical yield of the $\dot{N}O_2$ radicals (G_R) and the primary radiochemical yield of the excited molecules (G_o) have been compared for three groups of organic substances—nitramines, aromatic nitrocompounds, and nitric acid esters. Here G_R corresponds to the number of NO_2 species for each 100 eV of the absorbed radiation energy determined by the EPR method at 77 K and G_o is the number of excited NO_2 molecules in the specified energy range for each 100 eV of the radiation energy.

Table 3. The radiochemical yields of NO_2 molecules and the yields of excited molecules.[71,72]

[a] solvent.

The primary radiochemical yield was determined by UV spectroscopy (in the range 195–360 nm) and theoretically by means of the semiempirical CNDO/2 computational method. The advantage of the theoretical calculation was that the quantity G_o for the molecules of organic substances was calculated in relation to the crystalline state (Table 3).

As a rule, substances with a higher probability of the initiation of rapid exothermic decomposition when subjected to a pulsed influence (impact) have a higher value of G_R and a lower value of G_o. This means that the exothermic reaction can be more readily induced by means of a mechanical influence in organic compounds with a low radiation stability.

For their calculations, Delpuech and Cherville[71,72] selected only organic substances whose structures had been reliably demonstrated. The distribution of the electric charge densities, obtained by the semiempirical INDO method, is presented in Table 4, which indicates the asymmetry of the charge per unit bond length $\Delta c^0/l$ for the most polarised $R-NO_2$ bonds as well as the ionisation energies.[71,72] Evidently the asymmetry of the charge distribution varies in the range 0.5–1.1 for all $R-NO_2$ bonds. The nitramine $N-NO_2$ bonds and the ester $O-NO_2$ bonds are more polarised than the $C-NO_2$ bonds, which are stabilised as a result of resonance with the bonds in the benzene ring. Comparison of the data in Table 4 for substances with related functional groups showed that the parameter $\Delta c^0/l$ is insufficient for predicting the probability of the initiation of the rapid exothermic decomposition. Hence one may conclude that the genesis of the decomposition of the molecules of the test substances cannot be adequately assessed solely on the basis of the structural parameters of the stable ground state. The authors[71,72] suggested that the distribution of the energy absorbed when the substances are subjected to a mechanical influence reflects more fully the variation of the parameter $\Delta c^0/l$ in different excited states.

Calculations have also been made for the excited states with the aid of quantum-chemical methods.[71,72] It was found that the classification of nitramines in terms of the asymmetry of the charge per unit $N-NO_2$ bond length in the excited state is identical to the classification in terms of the probability of the initiation of the decomposition for substances subjected to a pulsed stress. The results of the above studies[71,72] made it possible to differentiate two main criteria for the assessment of the behaviour of nitramines and aromatic nitro-compounds when reactions in the latter are initiated by means of pulsed mechanical influences — the electronic structure in the ground state and the way in which the absorbed energy is distributed.

IV. The influence of the gaseous medium on the initiation of fast exothermic decomposition reactions

If it is assumed that the occurrence of mechanochemical reactions is in some way related to the appearance of a gas discharge in the developing crack, one may expect that the composition and pressure of the gaseous medium are capable of influencing significantly the initiation of reactions involving the fast exothermic decomposition of organic molecular crystals subjected to mechanical influences.

The influence of air and pure oxygen and nitrogen pressures (in the range $10^{-3}-10^{-5}$ Pa) as well as the pressures of argon and helium (with different concentrations of air in the latter as an impurity) on the probability of the initiation of the decomposition of C3MNA, C4MNA, PETN, TNPA, and BP [benzoylhydroperoxide?] has been investigated.[33,35,73–75] The tests were carried out under the conditions of pulsed stresses (over a period of $\sim 10^{-3}$ s) and pulsed relaxation of stresses (over a period of $\sim 10^{-4}$ s). The experimental results showed that changes in the initiation probability W are not observed in the air pressure range 10^2-10^5 Pa (Fig. 8), an appreciable decrease in W was noted in the air pressure range 0.1–1 Pa, while at a pressure of 10^{-2} Pa the probability W was close to zero. This behaviour is qualitatively the same for all the substances investigated, although it is less

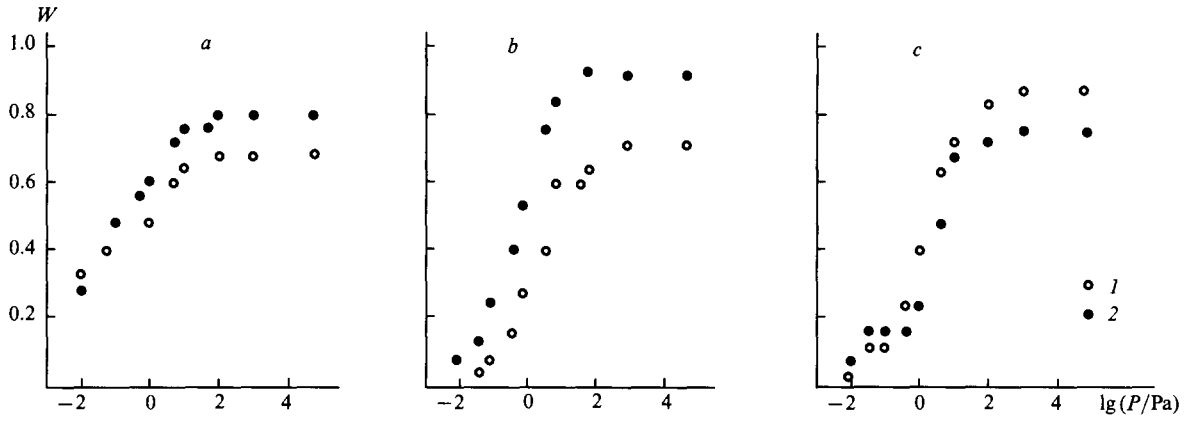

Figure 8. Dependence of the probability of initiation of the rapid exothermic decomposition of BP (*a*), C3MNA (*b*), and C4MNA (*c*) on air pressure[35,75] for a pulsed application of a stress (*1*) and for a pulsed removal of a stress (*2*).

marked in BP. For both types of influences (pulsed stresses and pulsed removal of stresses), the dependences of the probability of initiation of the decomposition on air pressure are identical.

When the experiments were carried out in pure oxygen and nitrogen, it was observed that W in oxygen depends to a considerable degree on the gas pressure in the range $1-10^3$ Pa and that the pressure range is higher in oxygen than in nitrogen (Fig. 9). Tests in argon and helium with air partial pressures in the range $10^{-1}-10^3$ Pa showed that the probability of the initiation of the fast exothermic decomposition of organic molecular crystals is appreciably lower than under an air, oxygen, or nitrogen atmosphere. The concentration of air exerts a marked influence on the mechanochemical decomposition of the test substances. It has been noted that, for equal pressures of atmospheric oxygen, the probabilities W were appreciably lower when, after evacuation, the chamber was filled with an inert gas up to a total pressure of 10^5 Pa. Argon suppressed the initiation process more than helium.

The creation of a vacuum in the system used to subject specimens to various influences (gas rarefaction less than 1 Pa) is a common procedure designed to prevent gas-discharge processes.[76] In terms of this aspect, the experimental results of our investigations[33,35,73-75] constitute evidence indicating that the gas discharge in the developing crack is an important step in the initiation of fast reactions involving the exothermic decomposition of organic substances subjected to mechanical influences. It has been stated[73] that it is incorrect to compare the experimental results of tests of the given substances in gaseous media with Paschen's curve, since Paschen's law is valid only for a discharge in a constant electric field at gas pressures exceeding 10 Pa and for a distance between the electrodes greater than 10^{-3} m.[8,77] The electric discharges in the developing crack arise in the gas flow in a highly nonuniform electric field with 'pulsed' switching on for very short distances between the walls of the crack (micrometres and fractions of a micrometre). Paschen's curve establishes the relation only between the threshold breakdown potential and the product of the gas pressure and the interelectrode distance but yields no information whatever about the nature and intensity of the gas-discharge process.[8,77]

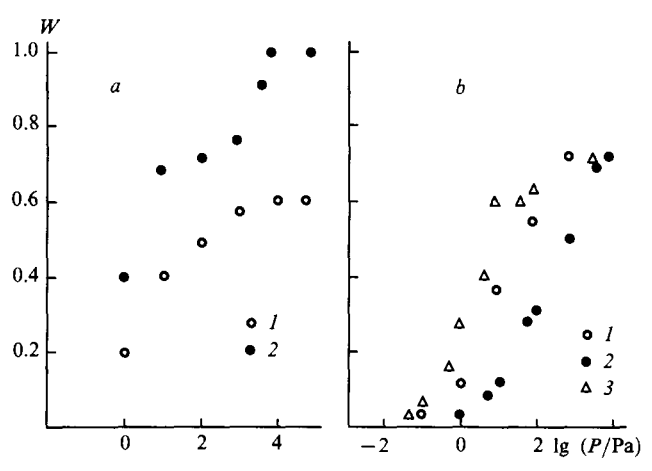

Figure 9. The influence of the nature of the gaseous medium on the probability of the initiation of the fast exothermic decomposition of C3MNA:[74] (*a*) pressure of pure nitrogen (*1*) and pure oxygen (*2*); (*b*) influence of the partial pressure of the air impurity in helium (*1*) and argon (*3*) [the data in vacuo (*2*) are given for comparison].

V. Initiation of fast reactions occurring as an explosion

In order to analyse the relation between the mechanochemical processes and the mechanical emission phenomena and in order to determine the role of the latter in the processes leading to the initiation of fast exothermic reactions, it is necessary to examine the existing concepts concerning the initiation of mechanochemical reactions in organic solids.

The thermal theories of the initiation of fast exothermic reactions have until recently gained the greatest currency in our country in relation to typical organic explosives. In our view, the following conclusions must be regarded as the greatest achievement of the thermal theories applied to typical explosives.

1. The essential preliminary step in the initiation of the decomposition reactions is fragmentation (cohesive or adhesive).

2. The initiation of a chemical reaction when the system is subjected to a mechanical influence is regarded as a multicentre process.

3. The initiation microcentres are localised in the fragmentation zone. These theories are based on the idea that local heating centres (the so called 'hot spots' arise in the solid subjected to mechanical influences). After the attainment of critical parameters (size, temperature, induction period), the surrounding condensed phase is ignited from these 'hot spots'. Next the decomposition reactions proceeds in the form of accelerating combustion and deformation.[78-86] Various mechanisms for the generation of 'hot spots' have been proposed — viscous heating during the rapid flow of the solid under pressure, adiabatic compression of gaseous inclusions, dry friction of the solid impurities. However, they did not receive subsequently a satisfactory experimental and theoretical confirmation. Among the thermal theories, the initiation theory indicating that brittle fragmentation of the organic substance in the condensed phase causes the formation of the heat centre received the greatest

recognition.[78,81,83–86] The following simplifications and assumptions were used in this theory: a solid crystalline substance is regarded as a continuous isotropic medium with certain generalised characteristics, to which the laws of the theory of the resistance of materials are applicable; the decomposition of the substance in the 'hot spot' is merely a solid-phase chemical reaction; the chemical reactions of the 'hot spots' obey the Arrhenius law of kinetics.

Thus the thermal theories do not consider the fragmentation of organic crystals at the atomic-molecular level and do not take into account the fact that, during the application of stresses to specimens, their mechanical properties may vary within fairly wide limits depending on the defectiveness of the crystals, the chemical purity, the crystalline modifications, the crystal habit, etc. The electrophysical phenomena and the physicochemical transformations of the organic substances accompanying the fragmentation of the crystals remain outside the scope of the thermal theories.

Plastic deformation is a preparatory stage in the formation of cracks along local zones (slip bands).[87,88] All these features render the laws of the classical theory of the resistance of materials relatively unsuitable in the present situation.

In our view, the thermal theories do not take into account the primary initiation of chemical reactions proper, i.e. the question of the way in which the mechanical influence on the organic crystal causes chemical changes and reactions. Furthermore, they do not provide a satisfactory basis for the appearance of high-temperature heating centres on fragmentation of solids, although they do describe qualitatively the process involving the propagation of reactions in the thermal regime (combustion, transition to detonation).

The theory of 'short-lived active centres', arising on the freshly formed decomposition surface of the solid, has been proposed.[49,89] It identifies the relaxation processes with the spontaneous destruction of these centres (radicals, broken bonds) in vacuo and with the destruction as a result of interaction with molecules of the surrounding gas in a chemically reactive medium. The theory of 'active centres' describes quite satisfactorily the mechanochemical processes occurring in homopolar crystals, where the rupture of covalent bonds is an obligatory consequence of the mechanical fragmentation.

It is necessary to turn attention to the fact that in this model an important role is assigned to the gaseous medium and its composition and pressures determine to a large extent the course of the chemical reaction on the fresh disintegration surface. However, this model does not consider the possibility of the activation of the gaseous medium itself during the appearance and development of cracks, whereupon the emission of electrons and radiation in various parts of the spectrum and a gas discharge with formation of excited molecules, ions, and atoms are observed.

Benderskii and coworkers[90–94] used the model of the self-activated solid matrix for low-temperature chemical processes. Self-activation occurs as a result of the chemical reaction and the operation of mechanical stresses in frozen reactants. The theoretical ideas concerning the phenomenon of the low-temperature detonation of mixtures of chlorine and hydrocarbons subjected to preliminary irradiation are described in these communications. It is suggested that the mechanical energy accumulating in the solid creates directly conditions for the acceleration of chemical processes, reducing the activation energy. This model of the occurrence of fast low-temperature reactions in a solid is based on the classical kinetic Arrhenius theory. However, it has been established[95] experimentally that the application of a stress to the specimen under the conditions of compression from all sides up to a pressure of 0.6 Pa hinders the cryochemical reactions in the solid matrix subjected to preliminary activation by photo- and gamma-irradiation, which is inconsistent with the concept of the direct influence of mechanical energy of the deformed specimen on the chemical process.

Ideas concerning the nature of the spontaneously developing high-speed autowave regimes of cryochemical reactions have been put forward.[95–100] It is suggested that, after a solid specimen subjected to preliminary irradiation is exposed to a mechanical influence, a narrow zone with a well developed network of freshly formed cracks arises and spreads. Chemical reactions creating conditions for the subsequent intense crack formation in the neighbouring zone of the matrix take place on the surface of these cracks or in its vicinity. As a result of the movement of the zone with a well developed network of fresh cracks through the solid specimen, the seemingly layer-by-layer dispersion of the substance in the travelling field of mechanical stresses takes place. The proposed model includes a sequence of feedback-controlled processes accompanied by the transformation of mechanical energy into chemical energy, i.e. the chemical reaction leads to a further brittle fragmentation of the specimen due to the density or temperature gradients giving rise to the stresses fragmenting the specimen.†

A proportion of the energy of the exothermic process, as it were, accumulates in the matrix in the form of mechanical deformations, while the unreacted portion of the specimen passes at the same instant to a nonequilibrium stressed state. The mechanical energy is then transformed into chemical energy via the brittle fragmentation stage, i.e. reactions on the fragmentation surfaces and in their vicinity are initiated. Preliminary irradiation creates two types of 'active centres' — both physical and chemical in the frozen matrix. The physical centres are local 'perturbations' of the mechanical stresses (associated with the appearance in the crystal lattice of decomposition products which entail an increase in the concentration of crystal defects) and also the centres for the initiation of new phases. The chemical 'active centres' are radicals or fragments of the initial molecules. In the proposed model,[95] the high-speed cryochemical reactions are formally similar to detonation in its classical hydrodynamic sense, although the physical nature of these two phenomena is undoubtedly different. In the irradiated matrix comprising the frozen reactants, the mechanical fragmentation is a kind of trigger which induces the appearance and development of the autowave regime in the chemical reaction.

Solid-phase chemical reactions without the formation of gaseous products over a period shorter than 10^{-7} s (on Bridgman anvils at high pressures with shear deformation), accompanied by the appearance and propagation of a powerful detonation wave, have been described.[101] Explosive decomposition and synthesis have been observed on Bridgman anvils in the study of the monoaxial compression of various substances.[102–104] These chemical reactions are accounted for by the direct transformation of the accumulated mechanical energy into chemical energy without heating.

The theory of the 'magma-plasma' ('tribo-plasma'), in which the fragmentation zone in the solid is represented as the centre of a special plasma has been proposed to account for the set of mechanoemission phenomena from the standpoint of a single general model.[6,9,10] The existence of the plasma state has been confirmed by the broad spectrum of the electron and electromagnetic emissions characteristic of the state. In the region of such high-energy states, there is a possibility of various chemical reactions which cannot be achieved during normal heating.

In relation to substances capable of rapid exothermic decomposition when acted upon by mechanical influences, we proposed a plasmochemical concept,[74] in which it is possible to differentiate two most important aspects. The first is the activation of fresh surface as a result of the fragmentation of the solid and the second is the activation of the gaseous medium in the vicinity of the fresh surface under the influence of mechanoemission phenomena.

† The autowave mechanism of the self-activation of the cryopolymerisation process has been described in a review.[99]

The brittle fragmentation of crystalline bodies, occurring in the form of crack formation, is a result of a complex interaction of the crystal lattice defects, in the first place dislocations.[87] The excited fresh surface with a high concentration of crystal lattice defects has a mosaic electric field microrelief.[15] The electrons emitted from the new surface fall on the opposite wall of the crack during its development and can induce various kinds of radiation damage, the degradation of molecules with formation of fragments and radicals, ionisation, the excitation of the molecules of the organic substance, and the appearance of secondary emissions.[1] The secondary electromagnetic and electron emissions are also capable of inducing further radiation processes in the substance. The activation of the gas phase as a result of ionisation, dissociation and excitation of atoms and molecules, reactions involving the sticking of electrons, etc. under the influence of electrons and electromagnetic waves leads to the formation of species with a high reactivity.[8,105]

The activated gaseous plasma may interact with the fresh surface, which should lead to a further decomposition of the molecules of the organic phase and to various chemical reactions on the walls of the crack. Since the decomposition of the molecules of the organic substances investigated is accompanied by the evolution of energy, this process develops and leads to the formation of a certain critical centre, in the region of which further chemical decomposition may be described within the framework of the thermal theory.[82]

Relaxation phenomena with different mechanisms must necessarily occur at all stages in the development of the process under consideration. In the gaseous plasma, the active species interact with other molecules and atoms, which leads to the transfer of the charge, excitation energy, vibrational energies, etc.[8,105] During the formation of the critical thermal centre, there is a possibility of thermal relaxation due to thermal conduction and convection.

A scheme reflecting the general features of the high speed reactions occurring when solids are subjected to mechanical influences has been put forward.[35] This scheme is applicable to the reactions occurring on Bridgman anvils, in a roller apparatus with pulsed application and removal of stresses, and also to a low-temperature explosion, etc. Plastic deformation (induced by mechanical forces), combined with a high pressure leads to the formation of a fresh surface with a high concentration of crystal defects. Under the influence of various types of emission, accompanying this process, there is a possibility of the appearance on the surface and in the near-surface layer of the substance of local zones with a postcritical density of active species. Such active species may be radicals, ions, point defects, etc. The initiation of reactions in these local zones leads subsequently to their propagation throughout the bulk of the specimen, i.e. the microregion of the explosive reaction arises from the microcentres. The propagation of the reaction through the substance is determined by factors such as its chemical nature and its structural characteristics and takes place in a thermal regime[82] or in the form of an autowave process.[95]

VI. Conclusion

In our view, high-speed chemical reactions in a solid matrix (in particular, during the initiation of the explosion) proceed in three stages, which differ fundamentally in their physicochemical nature.

The first stage is the appearance of active species under the influence of a set of mechanoemission phenomena. The application of the rules of radiation chemistry and photochemistry, taking into account the pulsed regime in the process involving the decomposition of organic molecular crystals or other substances, is valid in this case.

The second stage involves the interaction of active species with 'inactive' atoms and molecules, where the energy is supplied not in the form of heat but via electron, ion, and photon impacts and via interaction with electronically excited atoms and molecules (plasma) with imposition of electric fields generated on the fresh fragmentation surface.

The third stage involves the propagation of the decomposition reactions of organic substances throughout the bulk phase.

A thermodynamically nonequilibrium system, containing highly reactive species (electrons, ions, radicals, etc.) and arising when solids are subjected to a mechanical influence, promotes a course of the processes which is significantly different from that in the usual thermochemistry.[106-108] The characteristic features of these processes are as follows:[106-108] high local bulk-phase and surface energy densities; non-equilibrium conditions (non-Maxwell and non-Boltzmann distribution with respect to the energy of translational motion and the population of the quantum levels for the species comprising the system); the mutual approach and overlap of the characteristic times for the physical phenomena and chemical processes; the leading role in the chemical processes of electrons, ions, excited molecules, and radicals, which do not play a significant role in traditional kinetics; the multipath nature of the processes in the reacting system.

The traditional kinetic energy of chemical reactions and the theory of rate processes are inapplicable in this case. The translational, rotational, and vibrational energies of the molecules and atoms may differ greatly and the system components may have different temperatures. There is actually a possibility of the case where the concept of "temperature" is altogether inapplicable to high-speed chemical reactions. Classical chemical kinetics do not apply in this case and the expression for the chemical reaction rate constants loses its significance.[108]

The fraction of the substance participating in the second stage of the initiation of the explosion depends on the overall area of the fragmentation surface in the specimen. Under the conditions of the intense formation of cracks and rapid dispersion, a considerable proportion of the substance participates in chemical reactions the kinetics of which differ from 'Arrhenius' kinetics. This also explains the unusual, atypical products of the mechanical and chemical reactions which have been frequently observed experimentally.

The third stage in the initiation of the explosion is the propagation of the decomposition reactions throughout the bulk of the substance. Depending on the conditions, this stage can proceed in a thermal regime and can be described satisfactorily by Arrhenius kinetics or it can proceed in the form of an autowave process of the kind observed in low-temperature explosions.[95-100]

For a long time, investigators avoided mentioning certain reliable experimental data in considering various models, since such data had no acceptable explanation. For example, investigators carrying out experiments on the initiation of the explosion in typical explosives know that particles of solid impurities significantly increase the probability of the initiation of the decomposition process (sensitivity) when the system is subjected to mechanical influences. Metallic surfaces in contact with the specimen act slowly when the extent of their treatment is reduced, i.e. with increase in microroughness.[35,109] The current initiation theories cannot explain satisfactorily these seemingly simple phenomena. The concept of the three-stage development of the explosive decomposition of organic substances proposed by the present author readily accounts for the relations indicated. The particles of solid impurities and the microrugosities on flat solid surfaces are factors intensifying the crack formation process, which stimulates in its turn an appreciable increase in the area of the fragmentation surface in the specimen and the occurrence of chemical reactions in the zone of such cracks in the second stage of the initiation of the explosion.

In our view the separation of these three stages of high-speed chemical reactions, differing fundamentally in their nature and occurring when the system is subjected to mechanical influences, may help to eliminate the disagreements arising among

investigators when an attempt is made to extend laws valid for one stage to the entire set of mechanochemical reactions in the given substance.

The chemical reactions occurring when inorganic crystals are subjected to mechanical influences have their characteristic features. Thus it has been found[110] that the mechanical fragmentation of a number of sodium salts leads to the formation of gaseous products different from those produced on thermal decomposition. The differences between the gaseous products detected have been explained by the appearance in the cracks at the top of the specimens of short-lived highly excited ions and radicals, which give rise to low-molecular-weight products on recombination.

The breakdown of stoichiometry on the cleavage plane of a LiF crystal has been noted.[111] The surface undergoes metallisation after fragmentation under these conditions as a consequence of the formation of σ-centres near a dislocation step at a distance not exceeding the critical Auger ionisation radius of the dislocation electron. The acceptor σ-centres may form with the polymer [in particular with poly(vinyl chloride)] surface chemical (irreversibly bound) charge-transfer complexes.[112]

The influence of the concentration of point defects (F-centres) on the adhesion of metals (gold, silver, and copper) for a bulk density of F-centres of 2×10^{16} cm^{-3} and a surface density of $\sim 10^{13}$ cm^{-2} has been observed in LiF crystals.[113] The adhesive interaction has been explained by the formation of the Li^0–metal bond.

The appearance of defects of the type of F-centres on the fresh cleavage surface of an ionic crystal has been established.[114]

The emission of negatively charged (O^-, O^{2-}) and positively charged (Cu^{2+}) species has been observed on cleavage of superconductors.[115] The authors explain this effect by the electron–hole recombination involving the surface active centres with participation of copper ions and neutral oxygen diffusing from the bulk of the $YBa_2Cu_3O_{7-x}$ ceramic during vacuum annealing. The active centres were excited both mechanically (cleavage *in vacuo*) and by the ionisation irradiation of the specimens.

The exciton and dislocation processes occurring on mechanochemical dissociation of ionic crystals have been examined.[116]

The appearance of an excess charge on the surfaces of dielectric materials freshly formed on mechanical fragmentation is a consequence of the appearance of additional defects. As already stated, the charge density on a fresh cleavage surface of a crystal may attain values corresponding to electrical breakdown (10^8–10^9 V m^{-1}).[15] Vorob'ev et al.[117] observed the formation of extended dislocations in alkali metal halide crystals after these had been acted upon by a powerful electric field ($\sim 10^8$ V m^{-1}), which is due to the mechanical stresses already existing in the specimen and which become manifest following the application of an electric field (both pulsed and constant potentials were applied). Zuev et al.[118] demonstrated the aggregation of impurity–vacancy pairs with dislocations in a sodium chloride crystal doped with Ca^{2+} ions, the aggregation being stimulated by an electric field.

Okuyama et al.[119] investigated mass-spectrometrically the desorption of the K^+ and Na^+ ions and of cluster ions from the surfaces of potassium and sodium chloride crystals in a strong electric field.

The results of Laptenkov et al.[120] indicate the possibility, in principle, of regulating with the aid of strong electric fields the kinetics of the chemical reactions in ammonium perchlorate occurring with participation of dislocations. The effect of the electric field on the thermal decomposition of ammonium perchlorate single crystals was explained within the framework of the dislocation model of the development of reactions centres. The increase in the rate of growth of these centres following the application of an electric field may be caused by the Coulombic interaction of the external electric field and the edge-type charged dislocations, which move and multiply under the influence of the mechanical stresses in the crystal during the evolution of the gaseous ammonium perchlorate decomposition products.

The electric field causes the ageing of solid dielectric materials[121] and the initiation of ionic polymerisation processes.[122] It has been shown[123] that prolonged pulsed application of a $5 \times 10^7 - 10^8$ V m^{-1} electric field to solid polymers (polystyrene, organic glass) induces the accumulation in the material of bulk-phase charges (fields up to 1.7×10^7 V m^{-1}). At the same time, microcracks are initiated and develop, which leads to the formation of either a fragmentation zone, comparable in size to the interelectrode distance (1–2 mm), or of a tree-shaped dendrite channel.

Polyethylene films maintained in a 2×10^7 V m^{-1} field for 5–60 h undergo the degradation of macromolecular chains.[124] The appearance of oxygen-containing groups (C=O) in polyethylene following the application of an electric field has been described.[125] Under the influence of a strong electric field, free radicals of two types are formed in polyethylene prior to electrical breakdown. They accelerate the fragmentation of the polymeric dielectric material.[126] According to Gezalov and Kerimov,[126] the appearance of radicals is a consequence of the local heating of the specimen and also of the development of ionisation processes in the polymer.

Zakrevskii and Slutsker[127] discussed the initial stages of the fragmentation of polymers under the influence of mechanical stresses and an electric field. The mechanisms of the rupture of macromolecules in these fields, including the ionisation of the macromolecules as a result of tunnelling electron transfer and subsequent decomposition of the positively charged macroions, are considered. The authors conclude that the mechanical and electric fields exert a 'cross' influence. In their view, the application of an electric field to a mechanically stressed polymer should accelerate the stage involving the tunnelling ionisation of the macromolecules, while the mechanical stress should accelerate the stage involving the fluctuation decomposition of macroions in the electric field. However, in real cases the external field employed should not influence appreciably the tunnelling effect. The mechanical strength (longevity) is reduced in the electric field, whilst the electrical strength is reduced under the influence of the mechanical stress.[127]

The study of the dynamics of the release of a charge carrier from a dipole trap (an analogue of the elementary step in a chemical reaction) in a polymer matrix under the influence of an electric field has been investigated by the Monte Carlo method.[128] The authors suggest a series of experiments to test this calculation.

The emission of negatively and positively charged species from inorganic and organic solids has been investigated[129] in the corrosion of metals and in the exposure of polymers of different nature to thermal influences ('cooling to cryogenic temperatures–heating' cycles). Krylova[129] believes that, regardless of the method of excitation, the emission of charged species is induced by the same phenomena, which are analogous to the Auger relaxation and Auger recombination processes in atomic and ionic collisions on surfaces known in emission electronics. The energy evolved in these exothermic processes is the cause of the low-temperature 'pre-threshold' emission of charged (as well as neutral) species. In other words, the rupture of chemical bonds during corrosion (electrochemical formation of metal ions) and also in the cryolysis of polymers leads to the separation of the charges formed, and their subsequent recombination is accompanied by the evolution of the energy required for the emission of the charge. This approach follows from the development of the physicochemical concept of exoemission.[40]

It has been shown[130,131] that exoemission is a sensitive method for the monitoring of the initial stages in the fragmentation of polymeric materials subjected to mechanical (and radiation) influences as well as cooling–heating cycles. It has

been established[36,132] that the electrons emitted when solids (dielectric materials, metals, and polymers) are subjected to mechanical influences are capable of inducing the dissociative ionisation of the water molecules adsorbed on the surfaces.

The studies mentioned above demonstrate unambiguously an interrelation between the mechanoemission phenomena and the mechanochemical processes. It is at least incorrect to ignore the influence of electroemission phenomena on the chemical processes and reactions occurring when solids are subjected to a mechanical influence.

The principal fluxes of electrons, ions, and other charged and high-energy species, and of electromagnetic radiation are observed during the short period of the movement of the main crack in the solid specimen ($\sim$1 μs) and it is not always possible to record them experimentally. Nevertheless they undoubtedly affect the structural changes and chemical interactions in the vicinity of the charged fresh fragmentation surface. The presence of an excess charge on the cleavage planes of solids, especially dielectric materials, should affect the chemical reactions occurring on application of mechanical stresses. (The appearance of an excess charge on the fragmentation surface of a solid has been explained by its increased defectiveness and the deviation from stoichiometry.) It appears therefore that, in considering the mechanochemical reactions in solids, it is essential to take into account also the electroemission phenomena. The question arises whether they are of decisive importance. The answer to this question should be sought in each specific case when a particular solid is subjected to a mechanical stress, taking into account the experimental conditions.

Synthesis of nucleoside 5′-triphosphates labelled with radioactive phosphorus isotopes

Yu S Skoblov, A E Korolev, R N Maslova

Contents

I. Introduction 799
II. Synthesis of nucleoside 5′-[γ-$^{32(33)}$P]triphosphates 801
III. Synthesis of nucleoside 5′-[α-$^{32(33)}$P]triphosphates 803

Abstract. The review presents an analysis of the chemical chemicoenzymic, and enzymic methods of synthesis of nucleoside 5′-triphosphates labelled with phosphorus isotopes (^{32}P and ^{33}P) in the α- and γ-positions. The major part of the review is devoted to enzymic methods of synthesis, because they have undoubted advantages. The enzymic reactions are described in detail, the specificity and availability of the enzymes are considered, and data on the radiation stability of certain enzymes are presented. The bibliography includes 29 references.

I. Introduction

Radioactive isotopes have long been used in the study of the structures and functions of nucleic acids. Mainly the ^{14}C carbon atom was used initially. As the technique for the measurement of radioactivity developed and liquid scintillators began to be employed, there was a sharp growth of interest by investigators in tritium-labelled compounds. This was due to the much higher molar radioactivity of such compounds, which made it possible to reduce by two orders of magnitude the amount of specimen required for an adequate test of its radioactive emission.

The phosphorus-32 isotope has also long been used. Compounds labelled with ^{32}P were initially obtained by the ^{31}P$(n,\gamma)^{32}$P reaction involving the irradiation of an inorganic compound, usually an orthophosphate salt, with neutrons, whereupon the molar radioactivity of the product was not higher than that of the tritium-labelled compounds.

Instead of the whole nucleic acid molecules, only their small fragments, obtained by genetic-engineering methods, have become the objects of study during the last few years. This required a transition to the use of picomolar amounts of material, whereas a much higher specific radioactivity is needed for a reliable test of the specimen. From this point of view, the most suitable isotope proved to be phosphorus-32 obtained by the ^{32}S$(n,p)^{32}$P reaction involving the neutron irradiation of elemental sulfur. The specific radioactivity of phosphorus-32 without a carrier (for 100% isotope enrichment) is 9131 Ci mAt^{-1}, i.e. is 300 times greater than for tritium. Apart from this isotope, the phosphorus-33 and sulfur-35 isotopes, which also have a fairly high specific radioactivity (see Table 1), have been used successfully to label nucleic acids.

Nucleic acids labelled with radioactive isotopes of phosphorus (^{32}P and ^{33}P) as well as sulfur (^{35}S) are widely used in molecular-biological research and constitute the cornerstone of the principal methods such as hybridisation on filters, hybridisation in situ, sequencing of DNA, and many others. The choice of the radioactive label is determined mainly by two parameters: the sensitivity of the autoradiographic detection and spatial resolution.[1] These parameters depend in their turn on the β-emission energy of the radioactive isotope and its half-life, which determine the maximum specific radioactivity of the corresponding isotope. Table 1 presents the physical characteristics of the above isotopes.

Table 1. Physical characteristics of the radionuclides.

Physical characteristic	Isotope		
	^{32}P	^{33}P	^{35}S
Half-life/days	14.3	25.4	87.4
Maximum β-emission energy/MeV	1.71	0.20	0.167
Theoretical specific radioactivity of the radionuclide/Ci mAt^{-1}	9 120	5 200	1 488
Maximum specific radioactivity (virtually attainable) of the labelled nucleotides/Ci mmol^{-1})	7 000	4 500	1 500

In the determination of single animal genes by Southern's blot-hybridisation method,[2] the decisive factor is the requirement for the maximum sensitivity of the autoradiographic detection needed for subpicogramme amounts, which may be ensured only by use of the phosphorus-32 isotope, which possess the highest specific radioactivity among the isotopes considered here. On the other hand, in the method for the dideoxynucleotide sequencing of DNA, the requirement for sensitivity may be abandoned in favour of the high resolution of the bands on the autoradiogram,[3] which can best be ensured by labelling nucleic acids with sulfur-35

and also with phosphorus-33, which have a low energy and therefore the path traversed by their β-particles in the gel is short. This applies equally to the method of hybridisation in situ, for which spatial resolution is decisive.

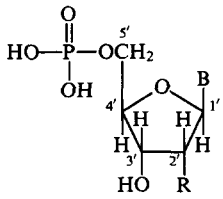
In many instances, phosphorus-33 has an advantage over sulfur-35, because it makes it possible to increase greatly detection sensitivity, whilst only slightly weakening spatial resolution. This has proved particularly important for the method based on the polymerase chain reaction ('cyclic sequencing') which makes it possible to sequence relatively small amounts of the matrix at high temperatures in order to reduce the amount of artefacts in the determination of the structure.[4] The ^{33}P-labelled primer ensures an adequate sensitivity and permits an autoradiographic exposure in the course of one night. This applies also to the method used in the analysis of the polymorphism of single-stranded configurations, in which the requirements for both spatial resolution and for detection sensitivity are fairly stringent.[5] A more detailed justification of the choice of the radioactive isotope for the above research methods has been given in the review by Evans and Read.[1]

One may note yet another advantage of nucleoside 5'-phosphates labelled with phosphorus-33 over the same compounds, labelled with sulfur-35, namely their complete chemical identity with the natural products, which eliminates any artefacts in the enzymic reactions in which labelled nucleoside 5'-triphosphates are employed as substrates. One should note that the majority of the methods impose stringent requirements on the quality of the nucleoside 5'-triphosphates labelled with radioactive phosphorus atoms, especially those with a high molar radioactivity, but it is not always possible to supply these compounds to remote regions in the course of 2–3 days at the appropriate temperatures using dry ice. We therefore thought it useful to survey the known methods of synthesis of these compounds.

The literature on this specific topic is extremely limited, since mainly the outline synthetic schemes are published in the open press without the technological details, which are mostly part of the [classified] know-how. It must be emphasised that even the most thorough and scrupulous copying of the published methods does not always lead to the expected results. In the present review, we attempted to present not only the published synthetic schemes but also to assess their reliability and reproducibility on the basis of the authors' personal experience.

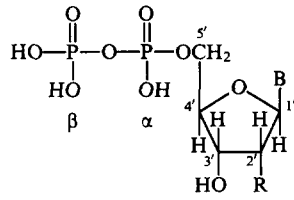
Nucleoside 5'-triphosphates containing the radioactive isotope in the α- or γ-positions in the phosphate groups are usually employed to obtain labelled nucleic acids in vitro. Deoxynucleoside triphosphates with a phosphorus label in the α-positions are used to introduce the label into the 3'-end of DNA with the aid of various DNA polymerases and for the synthesis of a radioactive DNA molecule containing the label in one, two, or all four nucleotides. Adenosine triphosphate with a phosphorus label in the α-position is used to introduce the label into the 5'-ends of DNA and RNA. Scheme 1 presents the formulae of all the nucleoside triphosphates used in molecular-biological research, the synthesis of which is described in the present review.

The synthesis of nucleoside 5'-triphosphates with a phosphorus label in the α- and γ-positions and having a high molar radioactivity (3000–6000 Ci mmol^{-1}) involves a series of specific difficulties.



1. The reactions used to obtain the target compounds must not lead to an uncontrolled isotopic dilution of the radioactive phosphorus by the nonradioactive isotope – phosphorus-31.

2. The location of the radioactive atom must be rigorously fixed. The use of methods which might alter the location of the radioactive atom or introduce the label in different positions in an uncontrolled manner is not permissible.



3. The high molar radioactivity of the nucleoside 5'-triphosphates used in molecular biology makes it necessary to carry out the syntheses with amounts of the radioactive isotope of 10^{-9}–10^{-8} mol, which corresponds to a radioactivity of 10–100 mCi (for phosphorus-32).

4. The low concentration of the radioactive substance requires the use of a large excess of the nonradioactive

components in order to increase the rate and yield of the reaction, which frequently leads to the appearance or side products.

5. For a high bulk-phase radioactivity of the reaction mixture (1 - 10 Ci ml^{-1}), the reaction time must be reduced to a minimum, since considerable amounts of mainly unidentified products, induced by the ionising radiation, accumulate (radiolysis products as well as the products of radical reactions).

6. The purification and especially the analysis of the products are hindered by the small amount of the substance and virtually preclude the use of the classical purification methods applied in organic chemistry (crystallisation, extraction, distillation, filtration, etc.) and analytical methods such as NMR, EPR, and IR spectroscopy, mass spectrometry, and X-ray diffraction.

7. Experiments with radioactive substances make it necessary to ensure the personnel safety, so that all manipulations in the syntheses must be performed observing radiation safety standards, preferably at a distance, in isolated compartments. The available descriptions of the methods of synthesis of nucleotides and nucleoside 5'-triphosphates labelled with radioactive phosphorus atoms are extremely scanty. The starting material in these syntheses is orthophosphoric acid. All the methods can be divided into the following groups:

(a) chemical methods in which chemical reagents are used in all the stages;

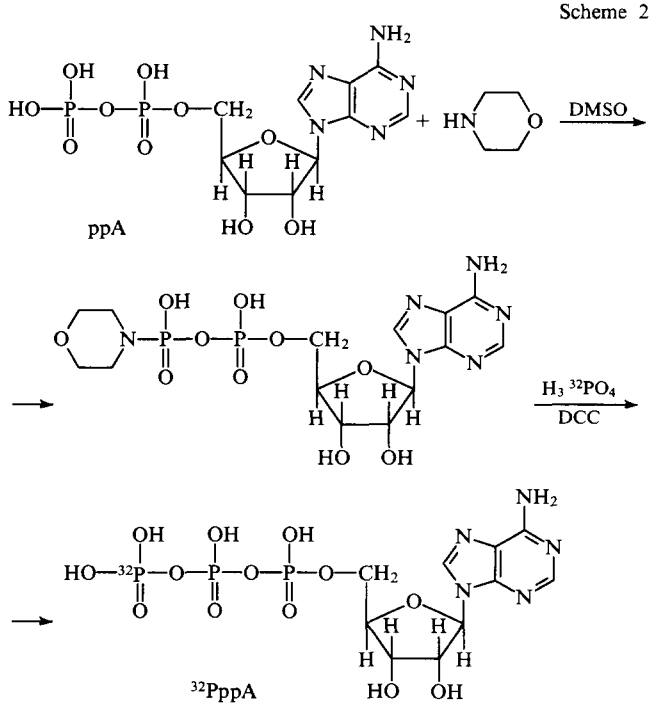
(b) chemicoenzymic methods in which enzymic reactions are employed together with chemical ones;

(c) enzymic methods in which all the stages of the synthesis are carried out with the aid of enzymes.

Nucleoside 5'-triphosphates labelled with radioactive phosphorus atoms in the α- or γ-positions are of greatest interest for molecular biology and the present review is devoted to the analysis of the methods of synthesis of these compounds. Most attention has been devoted to enzymic methods of synthesis because at present these procedures are used on an increasingly wide scale for the synthesis of nucleic acid precursors labelled with radioactive isotopes of not only phosphorus and sulfur but also of carbon, as well as tritium-labelled ones.[6]

The majority of studies considered in the present review were carried out using [^{32}P]orthophosphoric acid, but all the methodological procedures presented are valid also for syntheses in which [^{33}P]orthophosphoric acid is used. This is also confirmed by the personal experience of the authors of the review.

II. Synthesis of nucleoside 5'-[γ-$^{32(33)}$P]-triphosphates



1. Chemical methods

The synthesis of nucleoside 5'-triphosphates labelled with radioactive phosphorus in the γ-position is not a very complex task. Moffat[7] was the first to propose a method of synthesis of [γ-^{32}P]ATP (^{32}PppA) from ADP (ppA) and [^{32}P]orthophosphoric acid ($^{32}P_i$). The reaction, involving the formation of an intermediate morpholide derivative, was used to activate the β-phosphate of ADP (Scheme 2). The reaction with $H_3\,^{32}PO_4$ was carried out in anhydrous dimethyl sulfoxide (DMSO) in the presence of *N,N'*-dicyclohexylcarbodiimide (DCC).

[γ-^{32}P]ATP with a molar radioactivity of 10 mCi $mmol^{-1}$ was obtained by this method in 65% yield. Such a low molar radioactivity of the product was explained by the lack at the time of [^{32}P]orthophosphoric acid with a high molar radioactivity. At the present time the method makes it possible to obtain a product with a high molar radioactivity (up to 1000 Ci $mmol^{-1}$). The main disadvantage of the proposed method is the instability of the intermediate morpholide derivative (it decomposes at room temperature in several hours).

This method was improved by a group of investigators at the All-Union Institute of Molecular Biology (VNII MB) in Novosibirsk,[8] who were able to select conditions for the stable isolation and storage of the intermediate activated ADP

Scheme 2

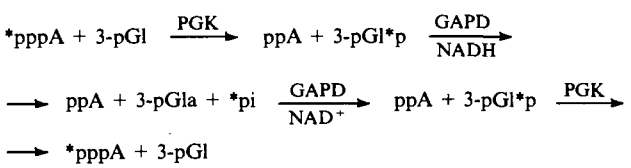
derivative. It was suggested that 4-(*N,N*-dimethylamino)-pyridine be used to accelerate the second stage — the synthesis of [γ-^{32}P]ATP proper. With the aid of this modification, it is possible to obtain comparatively simply [γ-^{32}P]ATP with any specified molar radioactivity up to the limiting value. The method can be applied successfully also to the synthesis of other nucleoside 5'-triphosphates by employing the corresponding nucleoside 5'-diphosphates.

The reaction is also carried out in anhydrous dimethyl sulfoxide and proceeds fairly rapidly (10 - 20 min), but is frequently accompanied by the accumulation of side products of the type AppppA, AppppA, and other unidentified compounds. This factor not only lowers the yield of the target product but also greatly complicates its isolation. On the other hand, the presence of such impurities in the target product is extremely undesirable, because they possess pronounced sorption properties. For this reason, this method has not come to be widely used in laboratory practice or in industrial manufacture.

2. The chemicoenzymic method

The only chemicoenzymic method of synthesis of [γ-^{33}P]ATP described in the literature involves the formation of acetyl [^{33}P]phosphate from acetic anhydride and [^{33}P]orthophosphoric acid and subsequent phosphorylation of ADP by this reagent with the aid of acetyl kinase.[9]

Bearing in mind the wide variety and reversibility of the enzymic reactions with participation of ATP, several versions similar to that already described could be proposed — for example, the synthesis of [γ-^{32}P]ATP from the ^{32}P-labelled phosphoenol pyruvate with the aid of pyruvate kinase or from labelled creatine phosphate with the aid of creatine kinase. Such reactions would proceed rapidly without the formation of side products and with a satisfactory yield. Nevertheless, the cost of the preparation of labelled precursors from [^{32}P]orthophosphoric acid, i.e. acetyl [^{32}P]phosphate, [^{32}P]phosphoenol pyruvate, or creatine [^{32}P]phosphate, and of their isolation from the reaction mixture before the enzymic stage, renders the synthesis laborious and uncompetitive compared with enzymic methods and it has therefore not come to be widely used.



Overall, the chemicoenzymic methods of synthesis of [γ-^{32}P]ATP are nowadays of purely theoretical interest and are not used for preparative purposes.

3. Enzymic methods

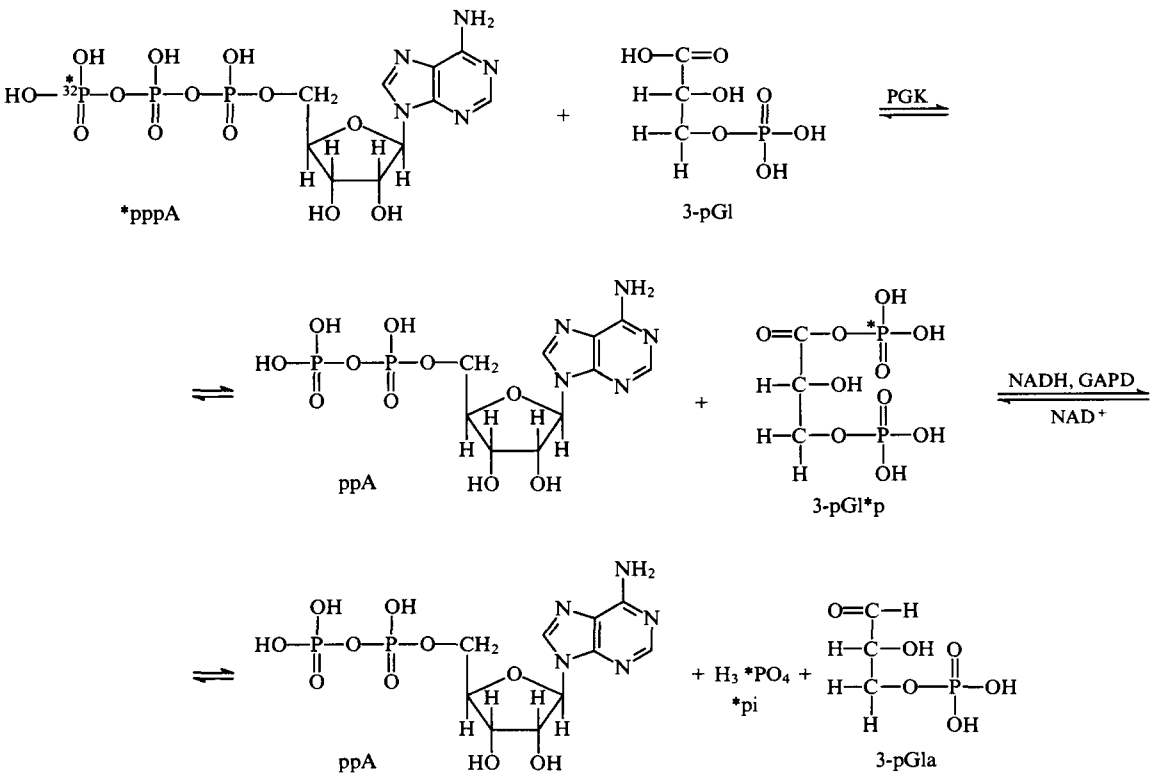
The simplest in execution and most effective method of synthesis of nucleoside 5'-triphosphates labelled with ^{32}P (or ^{33}P) in the γ-position proved to be the enzymic method. The initial idea of the method utilised the reversibility of the glycolytic reactions in the reconstructed fragment of the nucleoside chain (Scheme 3).

With the aid of phosphoglycerate kinase (PGK) and glyceraldehydephosphate dehydrogenase (GAPD), ATP was converted into ADP and orthophosphate via the intermediate 1,3-diphosphoglycerate (pGlp) in the presence of 3-phosphoglycerate (3-pGl). The addition of [^{32}P]orthophosphoric acid to the reaction mixture in the last stage inevitably leads to the formation of [γ-^{32}P]ATP owing to the reversibility of the enzymic reaction during the attainment of equilibrium in the system (Scheme 3a).

Scheme 3a

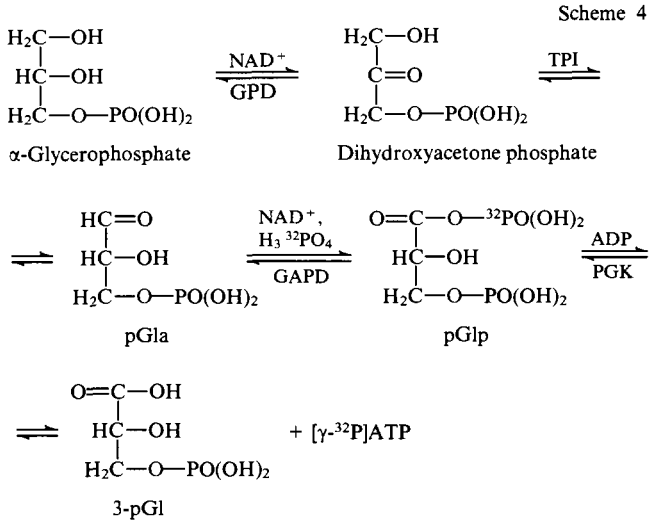
*p = the phosphate group whose exchange is catalysed by the enzymes PGK and GAPD

This method, proposed by Glynn and Chappell,[10] was rapidly incorporated into laboratory practice. The method acquired particular popularity by virtue of the simple and readily reproducible procedure proposed by Maxam and Gilbert[11] for the determination of the DNA sequence. The entire synthesis of [γ-^{32}P]ATP by this method took less than 2 h and the product could be used without isolation for the introduction of the label in the 5'-end of DNA. However, the method does not allow, in principle, the synthesis of [γ-^{32}P]ATP without dilution by the phosphorus-31 isotope and in reality affords the final product in 60%–70% yield and with a molar radioactivity of 1000–1500 Ci mmol^{-1}.



Later Stupar and Leskovac[12] analysed the method of Glynn and Chappell from the standpoint of the optimisation of the reaction yield and the molar radioactivity of the [γ-^{32}P]ATP obtained.

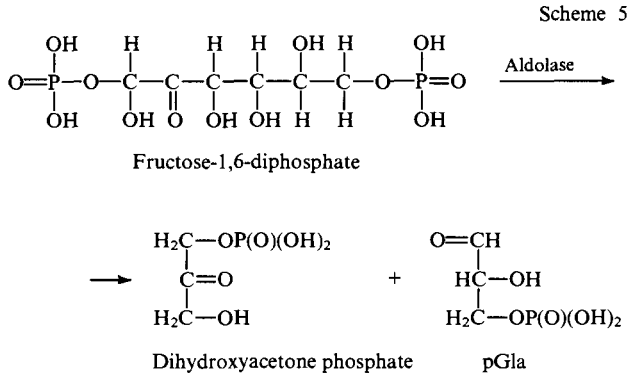
In 1973, Schendel and Wells[13] published a study in which they suggested that the scheme underlying the Glynn–Chappell method be 'inverted' and that the direct synthesis of [γ-^{32}P]ATP from glyceraldehyde-3-phosphate and [^{32}P]orthophosphoric acid be employed. Theoretically, this would make it possible to obtain [γ-^{32}]ATP with the maximum possible molar radioactivity, equal to that of the initial [^{32}P]orthophosphoric acid, i.e. without isotopic dilution. Bearing in mind the instability of glyceraldehyde-3-phosphate, the authors suggested that a stable and commercially available preparation be employed — the diethyl acetal of glyceraldehyde-3-phosphate. Free glyceraldehyde-3-phosphate was then formed in the first stage — the chemical hydrolysis of the diethyl acetal — and this was followed by the enzymic synthesis proper. However, the admixture of inorganic phosphates formed from the unstable glyceraldehyde-3-phosphate in the first stage of the hydrolysis of the diethyl acetal lowers the radioactivity of [γ-^{32}P]ATP sharply and in an uncontrolled manner owing to isotopic dilution. This method has not therefore found extensive application either in laboratory practice or in industry.



In order to increase the molar radioactivity of the preparation, Walseth and Johnson[14] improved the method further — a fragment of the glycolysis chain was supplemented by three more fragments: glycerophosphate dehydrogenase (GPD), triosephosphate isomerase (TPI), and lactate dehydrogenase (LDH). Glyceraldehyde-3-phosphate was then synthesised from α-glycerophosphate, while LDH was added to the system in order to regenerate the NAD^+ (Scheme 4). Since LDH does not participate directly in the synthesis of [γ-^{32}P]ATP, it is not shown in Scheme 4.

The yield of ATP increased to 90%–98% and, which is most important, the molar radioactivity rose to the limiting values, which were determined by the molar radioactivity of the initial [^{32}P]orthophosphoric acid and also by the content of the 'cold' orthophosphate in the reagents employed.

Scheme 3



Scheme 4

Instead of ADP, one can use other nucleoside 5′-diphosphates: GPD, IDP, CDP, UDP, dADP, dGDP, which afford the corresponding triphosphates with the phosphorus label in the γ-position. The method is simple and readily reproducible and has found extensive application in various laboratories. Judging from the extremely scanty and fragmentary literature data, all the principal producer companies obtain [γ-^{32}P]ATP precisely by this method (possibly with some modifications).

Banschke and coworkers[15] proposed yet another method of synthesis of glyceraldehyde phosphate. They used the cleavage of fructose-1,6-diphosphate by aldolase (Scheme 5).

Scheme 5

In our view, this path suffers from at least two disadvantages compared with the synthesis in accordance with Scheme 4. Firstly, fructose-1,6-diphosphate is not very stable in solution and there is therefore a real possibility of isotopic dilution by 'cold' phosphorus. Secondly, in order to increase the yield, the accumulated dihydroxyacetone phosphate must be removed, for example with the aid of the same TPI. Thus the method has no special advantages, since the replacement of GPD by aldolase and hence of α-glycerophosphate by fructose-1,6-diphosphate is not justified. Admittedly, the authors indicate the greater resistance of aldolase to the effect of ionising radiation, which may be important for industrial synthesis. There is no doubt that the thoroughly tested synthesis presented in Scheme 4 is preferable for laboratory use in the range 1 – 10 mCi.

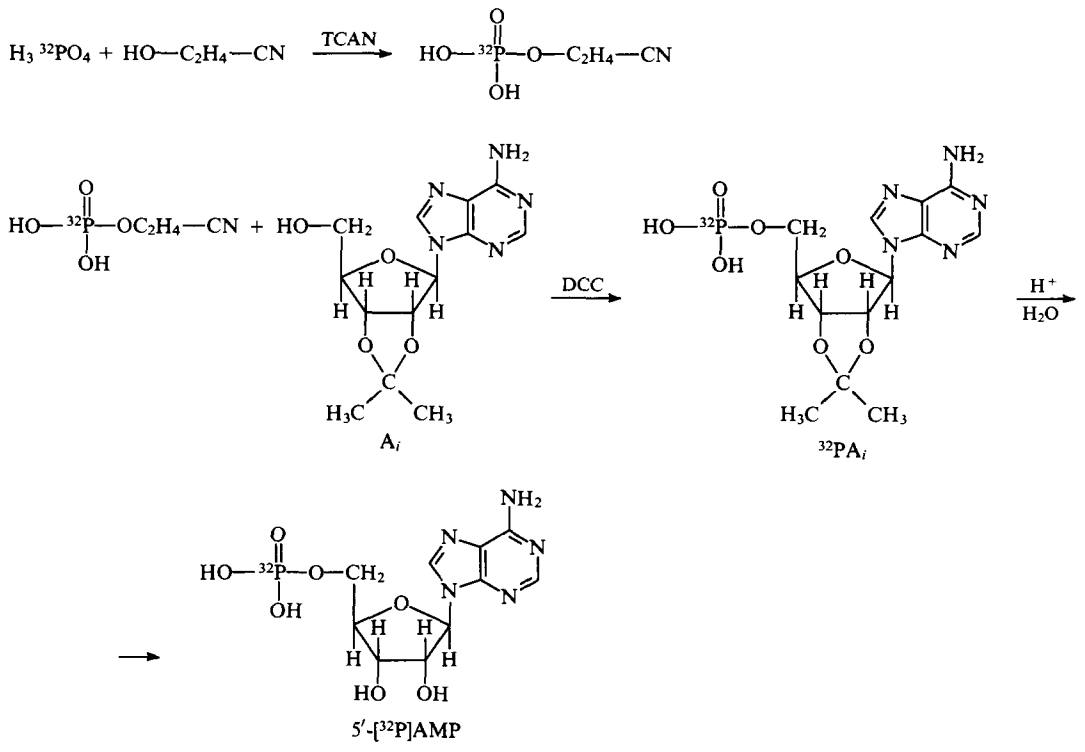
Quite recently, ICN Biomedical, Inc. patented[16] yet another method of synthesis of [γ-^{32}P]ATP — a kind of intermediate variant between the Johnson – Walseth and Schendel – Wells methods. Lynn, the author of this scheme, suggested that α-glycerophosphate and glycerophosphate dehydrogenase be abandoned and that dihydroxyacetone phosphate be used immediately as the initial nonradioactive starting material. In fact, he proposed that the Johnson – Walseth scheme 'be shortened' by one (the first) stage (Scheme 4). At the same time, Lynn suggested that the usual NAD-regenerating system (lactate dehydrogenase – pyruvate) be replaced by a more exotic system (malate dehydrogenase – oxaloacetate). According to the authors' communication, these two changes make it possible to scale up the synthesis to a charge up to 500 mCi of [^{32}P]orthophosphate and an unchanged high yield (~95%) over a period of 15 – 20 min. Bearing in mind existing literature data[17] indicating the low stability of glycerophosphate dehydrogenase towards ionising radiation from phosphorus-32 this is extremely likely. Indeed, the direct application of the Johnson – Walseth method makes it possible to obtain satisfactory results for the synthesis involving 1 – 10 mCi of phosphorus-32 (the usual laboratory synthesis). An increase in the amount of phosphorus-32 to 100 mCi or further to 1 Ci reduces sharply the yield of the reaction.

It must be emphasised that in Lynn's method all the ingredients of the reaction mixture, including the enzymes, are taken in logical and justified amounts, which can be in no way said of the original study of Johnson and Walseth. Nevertheless, the 'ICN' patent appears more like an attempt to 'get round' the Johnson – Walseth patent rather than a serious attempt to improve the technology and is hardly likely to be incorporated widely into practice.

We proposed a fairly simple and convenient modification of the Johnson – Walseth method for the large-scale synthesis (100 – 1000 mCi of phosphorus-32). Its laboratory version has been described in Karamyshev's dissertation.[18] The essential feature of the modification consisted in the preliminary formation of glyceraldehyde-3-phosphate directly in the reaction vessel: after centrifugation, the ammonium sulfate residue of the enzyme mixture was dissolved in a buffer containing dithiothreitol and all the necessary ingredients for the synthesis of [γ-^{32}P]ATP, with the exception of [^{32}P]orthophosphoric acid and ADP, were introduced into the solution. After preincubation for 20 min, the above remaining ingredients were added and the synthesis was carried out. Such changes in the order of the introduction of the reagents into the reaction mixture do not entail any fundamental alterations, but, according to our observations, they increase and stabilise the yield of the product of the synthesis by virtue of the effective generation of glyceraldehyde-3-triphosphate (in accordance with Scheme 4) before the start of the synthesis of [γ-^{32}P]ATP proper.

III. Synthesis of nucleoside 5′-[α-$^{32(33)}$P]-triphosphates

The scheme designed for the synthesis of nucleoside 5′-triphosphates (NTP) labelled with phosphorus-32(33) in the α-position is much more complex than those described above and requires the solution of virtually two independent problems. The first involves the synthesis of nucleoside 5′-monophosphate (NMP) with a phosphorus label by introducing [$^{32(33)}$P]orthophosphate rigorously in the 5′-position in the nucleoside. The second problem involves the synthesis of the nucleoside 5′-[α-$^{32(33)}$P]triphosphates themselves from the corresponding 5′-[$^{32(33)}$P]NMP.



1. Synthesis of nucleoside 5′-[$^{32(33)}$P]monophosphates

a. Chemical methods

Since the majority of the chemical methods for the introduction of labelled orthophosphate into nucleosides are nonspecific, nucleosides with protected 2′- and 3′-hydroxy-groups are employed for the synthesis of 5′-[$^{32(33)}$P]NMP. After the synthesis, the protecting group (the isopropylidene, acetyl, or benzoyl groups) are removed by acid or alkaline hydrolysis.

The first nucleoside 5′-monophosphate labelled by phosphorus-32 was synthesised by Moffat,[7] who employed ^{32}P-labelled β-cyanoethyl phosphate in the presence of DCC in order to phosphorylate 2′,3′-*o*-isopropylideneadenosine (A_i)

Scheme 6

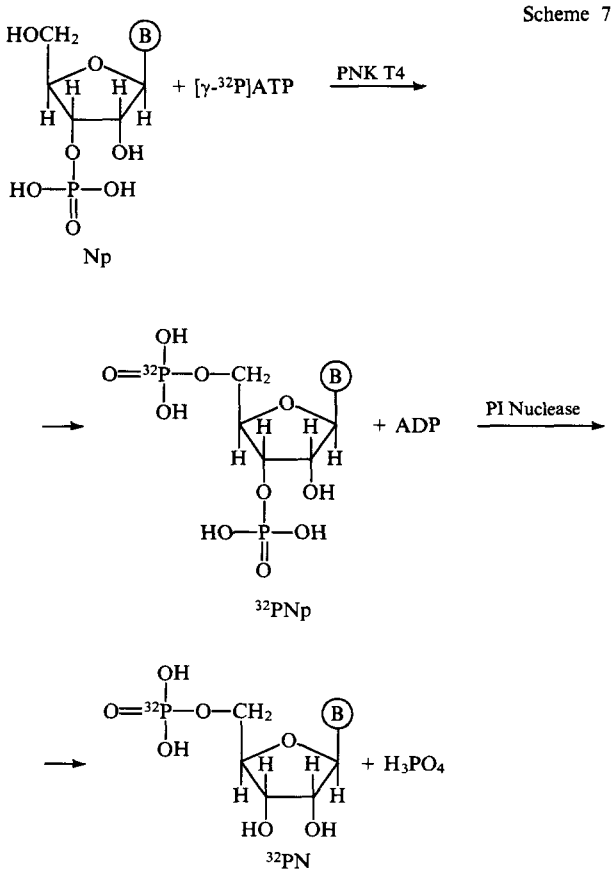
(Scheme 6). The labelled β-cyanoethyl phosphate was obtained by condensing [^{32}P]orthophosphoric acid with β-cyanoethanol in the presence of trichloroacetonitrile (TCAN). $^{32}PA_i$ was hydrolysed in an acid medium to give the ^{32}P-labelled adenosine 5′-monophosphate — 5′-[^{32}P]AMP.

Symons[19] simplified the synthesis of the nucleoside 5′-[^{32}P]monophosphate by employing TCAN in the synthesis of 5′-[^{32}P]AMP directly from the protected adenosine and the triethylammonium salt of [^{32}P]orthophosphoric acid. Such simplification immediately rendered this method extremely popular both in laboratories and in industry. It is noteworthy that, despite its apparent simplicity, the method suffers from a series of disadvantages, the main ones of which — the formation of a considerable amount of side products and the low yield were noted by Maslova et al.[20] The rigorous requirements as regards the quality of the reagents and solvents and also the extremely complex mixture of reaction products forced investigators to continue the search for alternative methods of synthesis.

An improvement of Symons' method was proposed by Ammosov and coworkers.[21] It involved the use of nucleosides with an acetyl protecting group instead of nucleosides with isopropylidene or benzoyl protecting groups. The conditions used in the removal of the acetyl protecting group after the condensation of the protected nucleoside with [^{32}P]orthophosphoric acid are fairly mild (the removal usually involved treatment with an ammonia solution), which makes it possible to obtain the final product in a yield up to 70%–80%. On the other hand, in the case of the isopropylidene protecting group, which is removed under significantly more severe conditions (by treatment with hydrochloric acid), the yield of the pyrimidine nucleosides in the reaction carried out by the Symons procedure does not exceed 40%, while in the case of derivatives of 2′-deoxynucleosides of the purine series the preparation of the nucleoside 5′-[^{32}P]monophosphate becomes altogether problematical.

The attempt by Biebricher[22] to use urea as the condensing agent was interesting. A solution of the corresponding nucleoside, the ammonium salt of [^{32}P]orthophosphoric acid, and urea was evaporated to dryness and the dry residue was heated for several hours at 110–120 °C, cooled, and dissolved in water. Nucleoside 5′-[^{32}P]monophosphates were identified in the solution in yields of 15%–40%, depending on the nature of the heterocyclic base of the nucleoside. Unfortunately, the very complex mixture of unidentified side products of the reaction hinders the use of this method.

The attempt by Hurlbert and Furlong[23] to use a biosynthetic procedure based on *E. coli* to obtain [^{32}P]nucleotides is also of purely historical interest. The main disadvantage of this method is the very low molar radioactivity (10–20 mCi mmol^{-1}). The uncontrolled isotopic dilution and the high requirement by *E. coli* for inorganic phosphate preclude in principle the formation of radioactive phosphorus-labelled nucleotides with a high molar radioactivity.



b. Enzymic methods of synthesis of nucleoside 5′-[$^{32(33)}$P]monophosphates

Johnson and Walseth[24] proposed an enzymic method of synthesis of nucleoside 5′-[^{32}P]monophosphates with the aid of a T4 phage polynucleotide kinase (PNK T4) and the PI nuclease (Scheme 7). The nucleoside 3′-monophosphate (Np) is the acceptor and [γ-^{32}P]ATP is the donor of radioactive phosphate.

The use of [γ-^{32}P]ATP for the synthesis of radioactive phosphorus-labelled nucleoside 5′-monophosphates proved to be entirely justified, since the enzymic method of synthesis of [γ-^{32}P]ATP makes it possible not only to synthesise this product rapidly and in a high yield but also to carry out the subsequent synthesis of ^{32}P-labelled nucleoside triphosphates with the aid of PNK T4 in the same reaction mixture without isolating [γ-^{32}P]ATP. This method is universal because PNK T4 phosphorylates all natural nucleoside 3′-monophosphates. The high rate and specificity of the enzymic reactions ensure a minimal amount of side products. All the advantages listed have attracted attention because of their technological applicability. The only significant disadvantage of the method is the need for a number of extremely expensive and very pure enzymes.

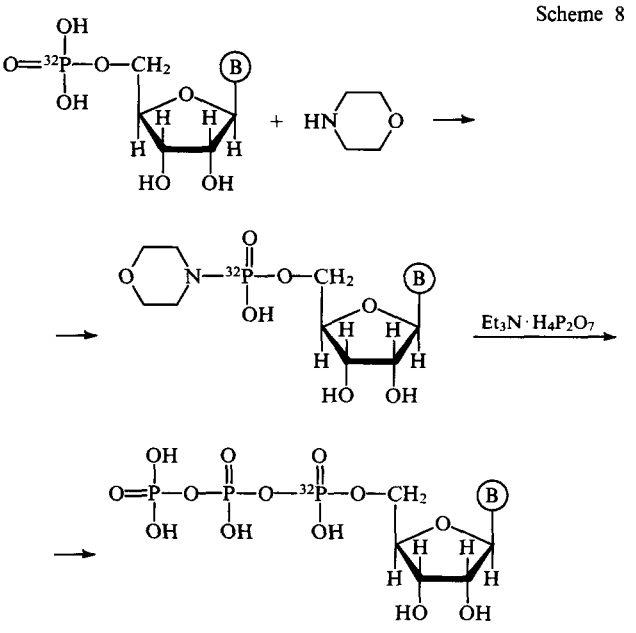
The lack of pure and stable enzymes — nucleoside kinases — precluded hitherto a test of yet another possibility of obtaining radioactive phosphorus-labelled nucleotides. This is the procedure based on the direct transphosphorylation of nucleosides

Scheme 7

with the aid of nucleoside kinases and [γ-^{32}P]ATP. The simplicity of this approach is evident, but nucleoside kinases are as a rule rigorously specific to the nature of the heterocyclic base of the nucleoside and it is therefore necessary to have 4–5 highly purified nucleoside kinases in order to synthesise all the natural nucleoside 5'-[$^{32(33)}$P]monophosphates. Attempts to isolate these enzymes from various sources have been frequently undertaken, but so far as we are aware stable preparations suitable for the preparative synthesis of nucleotides have not been obtained hitherto.

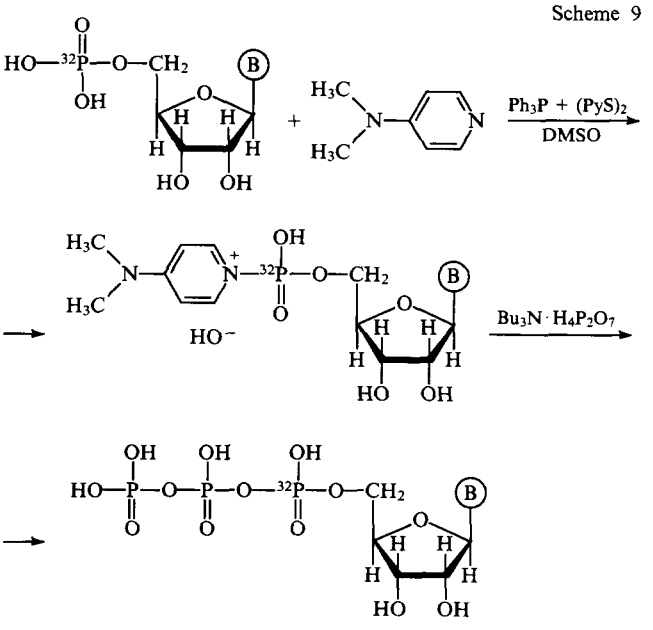
2. Methods for the phosphorylation of nucleoside 5'-[$^{32(33)}$P]monophosphates to nucleoside 5'-[α-$^{32(33)}$P]-triphosphates

a. Chemical methods



Moffat[7] synthesised nucleoside 5'-[α-^{32}P]triphosphates via the morpholide activation of nucleoside 5'-[^{32}P]monophosphate. The morpholide formed reacts with the triethylammonium salt of pyrophosphoric acid, affording a satisfactory yield (Scheme 8).

The [α-^{32}P]ATP obtained according to Scheme 8 had a very low molar radioactivity — about 10 mCi mmol^{-1}. Despite the satisfactory yield (65%), the method has not received recognition, since attempts to increase the molar radioactivity of the product led to a sharp fall in yield and to the accumulation of side products.

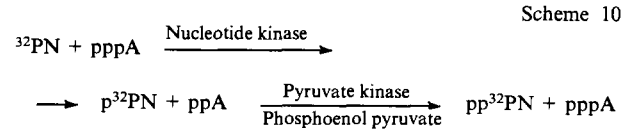


Siberian investigators proposed another more successful method for the activation of the nucleoside 5'-[^{32}P]monophosphate[25] involving the synthesis of an intermediate — a derivative of 4-(*N*,*N*-dimethylamino)pyridine. An oxidation-reduction couple was used as the catalyst: triphenylphosphine and di(4-pyridyl) disulfide. The intermediate formed is extremely unstable — it reacts even with the tributylammonium salt of pyrophosphoric acid directly in the same reaction vessel (Scheme 9).

All the natural nucleoside 5'-[α-^{32}P]triphosphates with a molar radioactivity of 2000–3000 Ci mmol^{-1} and above have

Scheme 8

Scheme 9



been synthesised in accordance with Scheme 9. The yield was 15%–40% relative to the initial [^{32}P]orthophosphoric acid. The method proved very useful in syntheses involving 1–10 mCi of phosphorus-32. An increase in the activity of the radioactive starting material to 100–200 mCi leads to the formation of a very complex mixture and reduces the yield of the target product, apparently as a consequence of the radiolysis of the reaction components.

b. Enzymic methods

The variants of the enzymic phosphorylation of nucleoside 5'-[$^{32(33)}$P]monophosphates to the triphosphates with the aid of the corresponding nucleotide kinases are more promising for the solution of this problem. The phosphorylation reaction can be represented by Scheme 10.

Scheme 10

The kinase fraction of proteins isolated from the bacterial biomass by means of ammonium sulfate fractionation, and not the individual enzymes, was used initially to phosphorylate nucleoside 5′-[^{32}P]monophosphates.[26] Such an enzyme preparation undoubtedly contained a large amount of ballast protein, including undesirable impurities: phosphatases and nonspecific ATP-ases. In order to suppress the degradation of the labelled nucleotides and nucleoside triphosphates and to maintain a constant level of ATP, the reaction mixture was treated with an ATP-regenerating system: creatine phosphate – creatine kinase or phosphoenol pyruvate – pyruvate kinase.[23,26] Acetyl phosphate was sometimes used, whereupon the addition of an exogenic acetate kinase was not required.[27] Nevertheless, the reproducibility of the results was very poor.

This led Biebricher[22] to develop a simple method for the simultaneous isolation of all the required nucleoside monophosphate kinases from *E. coli*. Although the enzymes were not purified to homogeneity, nevertheless the level of the impurity enzyme activities in the preparations employed by Biebricher was many times lower and the reproducibility of the syntheses was significantly increased.

A method for the isolation from *E. coli* of all the necessary nucleoside monophosphate kinases with a fairly high purity especially for the synthesis of all the nucleoside 5′-[α-^{32}P]triphosphates was developed later.[28]

Johnson and Walseth[24] used in the synthesis commercial preparations of pyruvate kinase and nucleoside monophosphate kinases: adenylate kinase (myokinase), guanylate kinase, and nucleoside monophosphate kinase (all the enzymes were produced by the Boehringer – Mannheim Company). Here attention should be drawn to a number of characteristic features of these preparations.

1. Adenylate kinase (myokinase) and guanylate kinase are individual enzymes and although the preparations of these enzymes produced by the Boehringer – Mannheim Company contain a lot of ballast protein and sometimes also undesirable impurities, nevertheless the synthesis of [α-^{32}P]ATP and [α-^{32}P]-dATP and hence of [α-^{32}P]GTP and [α-^{32}P]dGTP proceeds in an entirely satisfactory manner.

2. The nucleoside monophosphate kinase preparation is not an individual enzyme but a protein fraction containing, apart from the ballast protein, at least two of the required enzymes — thymidine monophosphate kinase and cytidine monophosphate kinase. The names of these enzymes in a pure form are missing from the catalogues of the relevant companies.

3. It has come to be assumed that cytidine monophosphate kinase is capable of phosphorylating also UMP (and conversely), i.e. that cytidine monophosphate kinase and uridine monophosphate kinase are the same enzyme.

4. The ratios of the enzyme activities of the 'nucleoside monophosphate kinase' preparation in relation to TMP, CMP, and UMP differ appreciably from batch to batch. The level of the activity of the TMP kinase and to a somewhat lesser extent the UMP kinase is particularly variable. The effectiveness of the use of the nucleoside monophosphate kinase can therefore be different for different substrates — the synthesis of CTP or dCTP usually proceeds most effectively, that of UTP is less satisfactory, and that of TTP is still less effective.

5. Pyruvate kinase — the enzyme catalysing the phosphorylation of NDP to NTP by phosphoenol pyruvate — leads to more ready phosphorylation of purine nucleotides than pyrimidine nucleotides. The phosphorylation of TDP is especially difficult.

Despite the above features of these Boehringer – Mannheim preparations, the enzymic phosphorylation of 5′-[^{32}P]NMP to give 5′-[α-^{32}P]NTP is greatly superior to all other procedures for the phosphorylation of nucleoside monophosphates as regards the effectiveness and technological applicability of the process.

The overall enzymic synthesis of [α-^{32}P]NTP can be represented by Scheme 11.[29]

Scheme 11

$$ppA + {}^{32}P_i \xrightarrow{GPD,\ TPI,\ GAPD,\ PGK,\ LDH} {}^{32}PppA \quad (1)$$

$$^{32}PppA + Np \xrightarrow{PNK\ T4} {}^{32}PNp \quad (2)$$

$$^{32}PNp \xrightarrow{PI\ nuclease} {}^{32}PN + P_i \quad (3)$$

$$^{32}PpN + pppA \xrightarrow{Nucleotide\ kinase} p^{32}PN + ppA \quad (4)$$

$$p^{32}PN \xrightarrow[Phosphoenol\ pyruvate]{Pyruvate\ kinase} pp^{32}PN \quad (5)$$

$^{32}P_i$ — inorganic orthophosphate ion labelled with the radioactive phosphorus-32 (or phosphorus-33) isotope

All the reactions take place in a single reaction vessel and the intermediates do not have to be isolated. Scheme 11 does not include yet another reaction which the authors recommend should be carried out, but this does not affect the principles of the method. This concerns the decomposition of the residual unreacted [γ-^{32}P]ATP after the reaction with PNK T4. In order to avoid the introduction of a label in the β-position in the nucleoside 5′-diphosphate, the authors suggested that, in the stages following the second stage of the phosphorylation reaction, hexokinase should be used to decompose the residual [γ-^{32}P]ATP after the dephosphorylation of the diphosphate by the PI nuclease. After treatment with hexokinase, the mixture was heated for 2 min on a water bath in order to thermally inactivate the enzymes and the synthesis was continued in the same vessel in accordance with Scheme 11.

The method of synthesis of nucleoside 5′-[α-^{32}P]triphosphates proposed by Johnson and Walseth has incontrovertible advantages over all the methods described above and has found extensive application both in laboratory practice and in the corresponding industrial processes.

Analysis of the trends in the development of the methods of synthesis of nucleoside 5′-[$^{32(33)}$P]triphosphates labelled with radioactive phosphorus in the α- or γ-positions shows that the enzymic methods are preferable and are gradually displacing the chemical and chemicoenzymic methods of synthesis from laboratory practice and from industrial manufacture.

V.	Sorting of nuclei in accordance with spin orientations	815

Abstract. The ability of spin-selective chemical reactions to sort nuclei in terms of two features — their spin and orientation — is discussed. The subdivision into spin (magnetic) and spin-free (nonmagnetic) nuclei constitutes the basis of the magnetic isotope effect; the subdivision of nuclei in terms of orientations and the establishment of the nuclear orientation constitute the content of a second phenomenon — chemically induced [dynamic] nuclear polarisation. The bibliography includes 50 references.

I. Introduction

Chemical reactions are selective as to the electron shells of the reacting species and this factor is the principal feature of a chemical process, namely it determines what is referred to as the reactivity. The second feature of a chemical reaction is its selectivity with respect to nuclei — with respect to their mass and angular momentum (spin). The nuclear mass selectivity of chemical reactions has long been widely known as the classical isotope effect — thermodynamic (in equilibrium processes) or kinetic (in nonequilibrium reactions). The nuclear spin selectivity is manifested by the dependence of the reaction rates on the spin, the magnetic moment, and the orientation of the nuclei of the reacting species. The selectivity of the reaction with respect to the nuclear magnetic moment has been called the magnetic (or nuclear spin) isotope effect. The selectivity with respect to nuclear orientation is the cause of the sorting of nuclei with respect to their orientations, which gives rise to magnetic nuclear polarisation in the products of chemical reactions.

Chemical reactions are selective with respect to the electron spin: they are allowed to give rise only to products the overall electron spin of which is identical with the overall spin of the reactants. Reactions are forbidden if the overall spin of the reactants does not correspond to the spin of the products. Thus, among the four spin states of a radical pair (a singlet and three triplets), only the singlet state is capable of reacting to form the standard (in the singlet spin state) molecule; the reaction involving the triplet states of the pair is forbidden. On the other hand, if the reaction product is a molecule in the triplet spin state [for example in the neutralisation of radical-ions: $M^{+\cdot} + M^{-\cdot} \Rightarrow {}^{1,3}(M^{+\cdot}M^{-\cdot}) \Rightarrow M + {}^{3}M$ with formation of the triplet molecule ^{3}M], then the singlet state of the pair $^1(M^{+\cdot}M^{-\cdot})$ is forbidden for the reaction, but the remaining three triplet states $^3(M^{+\cdot}M^{-\cdot})$ are allowed. The reaction $H + O_2 \Rightarrow HO_2$ takes place only with the doublet states of the pair $(H...O_2)$, preceding the chemical interaction. The reaction involving a quartet state of this pair (with the overall spin $S = \frac{3}{2}$) is forbidden, since the reaction product, the radical HO_2, has a spin of $\frac{1}{2}$ and is in a doublet state. The reactions in which both the reactants and the products have a zero spin (molecular and ionic reactions, electrophilic and nucleophilic substitution reactions, etc.) do not require a change of spin and are therefore allowed.

The spin-forbidden reactions are usually encountered among chemical, physical, and biochemical processes involving paramagnetic species (radicals, carbenes, triplet molecules, electrons, holes), in which the spins of the reactants can combine freely but by no means all of the possible combinations are capable of chemical reaction (for example, for a pair of spins, out of the four combinations only one can lead to the combination of the spin-carrying radicals into a diamagnetic molecule).

The spin-reactive intermediate precursors can be altered and the spin-forbidden unreactive spin states can be transformed into spin-allowed reactive states by means of three types of interactions (Fig. 1):

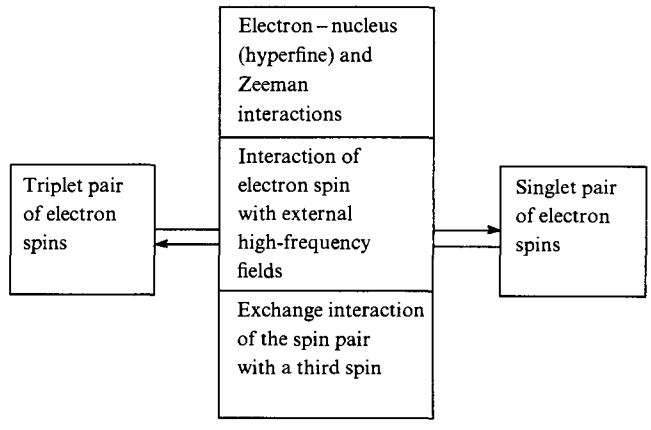

Figure 1. Schematic representation of the interactions inducing the spin conversion of spin pairs.

— magnetic interactions of the electron spin with the nucleus and an external magnetic field (hyperfine and Zeeman interactions);
— interaction of the electron spin with the magnetic component of a high-frequency external field;
— exchange interaction of the electron spins with a third spin, which induces the spin triplet–singlet conversion of this pair.

They all have negligible energies, switch the reaction from spin-forbidden paths to open spin-allowed paths, and thus alter the chemical reactivity of the intermediates.

Three types of interactions, controlled by the electron spin, give rise to three generations of magnetic-spin effects. The first includes the magnetic field effect, the magnetic isotope effect, and chemically induced [dynamic] nuclear polarisation. The second generation includes the phenomenon of the chemical detection of magnetic resonance, the radio-induced magnetic isotope effect, and stimulated nuclear polarisation.

The exchange interaction of two spins with a third is not magnetic but it alters the spin of the pair. This phenomenon can be regarded as the catalytic effect of the third spin, inducing spin conversion in the first pair (spin catalysis) and it should be assigned to the third generation of spin effects.

The set of effects generated by the characteristics of the behaviour of the spins of electrons and nuclei in chemical processes is the subject of spin chemistry, to the establishment and development of which Frankevich, Sokolik, Giatsintov, Molin, Sagdeev, Salikhov, Bargon, Fisher, Ward, Kaptein, Lawler, Atkins, Turro, Closs, Step, Tarasov, Berdinskii, Anisimov, etc. have made major contributions. The principal results obtained in this field have been surveyed in a series of reviews and monographs.[1–5]

Being selective with respect to the electron spin, a chemical interaction is inevitably selective also with respect to the nuclear spin, provided that both spin subsystems — electron and nuclear — are linked by the hyperfine or Fermi interaction. The nuclear spin subsystem then acts on the electron subsystem via a hyperfine interaction (HFI), altering the electron spin and removing the spin prohibition. Since the HFI is a property of magnetic nuclei, it selects the isotopic nuclei in terms of the magnetic moment and ensures the sorting of the magnetic and nonmagnetic nuclei (the magnetic isotope effect). Furthermore, the energy of the HFI depends on the orientation of the nuclei, so that the HFI also effects the sorting of the nuclei with respect to their orientations, giving rise to nuclear polarisation in the reaction products. These two effects are the subject of the part of spin chemistry in which the nuclear spin selectivity of chemical reactions is investigated and to which this review is devoted.

II. Sorting of isotopic nuclei

The magnetic isotope effect (MIE) was discovered by two groups of investigators in Russia in 1976,[6,7] although the possibility of its existence had been mentioned by Lawler and Evans in 1971.[8]

The sorting of the magnetic and nonmagnetic nuclei effected by the MIE is clearly illustrated by the photolysis of dibenzyl ketone, in which the molecule undergoes fragmentation in the excited triplet state into a pair of radicals — benzyl and phenylacyl. Being in the triplet state, this radical pair can recombine again, regenerating the initial molecule, or can dissociate and can generate, via the decarbonylation of the phenylacyl radical, the final photolysis products — bibenzyl and carbon monoxide. However, the recombination of the pair is possible only starting with the singlet state, which means that it must be preceded by the triplet–singlet spin conversion of the pair. The hyperfine interaction of the unpaired electron with the ^{13}C nucleus in phenylacyl accelerates the triplet–singlet conversion of the pairs with magnetic ^{13}C nuclei and stimulates their recombination, since radical pairs with nonmagnetic ^{12}C nuclei lag in their spin conversion and undergo preferential dissociation. As a result, the regenerated ketone molecules accumulate the ^{13}C nuclei, while the photolysis products — bibenzyl and CO — are depleted in this isotope. Hence, as a result of the spin selectivity and the hyperfine interaction, the radical pair sorts the nuclei in accordance with their magnetic characteristics, directing the magnetic and nonmagnetic nuclei along different reaction paths, i.e. into different chemical products.

The degree of sorting, i.e. the degree of isotope enrichment of each ketone in the ^{13}C nuclei is defined by the simple equations[9,10]

$$S = (1-F)^{\alpha}\ ; \qquad \alpha = \frac{1-\alpha_G}{\alpha_G}\ ; \qquad \alpha_G = \frac{1-P}{1-P^*}\ . \tag{1}$$

Here S is the isotope enrichment [$S = \delta/\delta_0$, where δ_0 and δ are the contents of the isotope (for example, ^{13}C) in the initial ketone and in its residue] after the attainment of the chemical conversion $1-F$ (F is the fraction of the remaining ketone), α is the coefficient of the single-stage isotope enrichment, and P^* and P are the probabilities of the recombination of the radical pairs with the ^{13}C and ^{12}C isotopes, i.e. the probabilities of the regeneration of the 'magnetic' and 'nonmagnetic' ketones respectively. Evidently, α_G is the ratio of the rates of the chemical decomposition of the nonmagnetic and magnetic ketones. Since $P^* < P$, it follows that $\alpha_G > 1$, i.e. the magnetic ketone decomposes more slowly and is retained during photolysis to a greater extent than the nonmagnetic ketone.

The ideal isotope separation takes place subject to the condition $P^* = 1$ and $P = 0$, which means that the magnetic ketone is fully regenerated, whilst the nonmagnetic ketone is fully decomposed. This regime corresponds to 'chemical isotope purification'; in this case, $\alpha_G \Rightarrow \infty$ and $\alpha = -1$. The attainment of this regime constitutes a major and intriguing problem and we shall return to its discussion below.

The photolysis of dibenzyl ketone was the first chemical process in which the MIE was observed.[6] It is a classical example of the MIE and serves as a test of the physics of this unique phenomenon.

Isotope enrichment obeys rigorously Eqn (1), while the quantity α_G depends on the properties of the medium, varying from 1.05 in hexane at 20 °C to 1.50 in glycerol and 1.37 in hexadecyltrimethylammonium chloride micelles (Fig. 2).

The studies on the MIE developed in two directions: (1) experimental search for the effects involving nuclei heavier

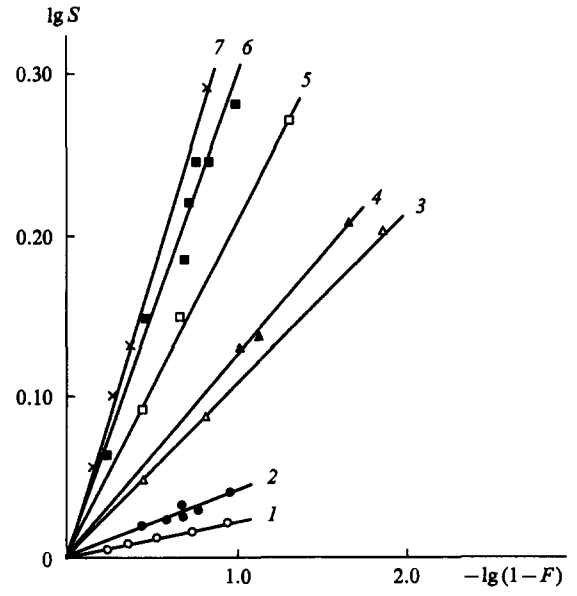

Figure 2. Isotope enrichment (S) as a function of the chemical conversion (F) in terms of the variables of Eqn (1) in the photolysis of dibenzyl ketone: (*1*) benzene; (*2*) hexane; (*3*) cyclohexanol, 20 °C; (*4*) cyclohexanol, 0 °C; (*5*) glycerol, 1700 cP; (*6*) hexadecyltrimethylammonium chloride micelles; (*7*) glycerol, 2400 cP.

than that of carbon and (2) theoretical analysis of the chemical physics of the effect in order to predict the possible ways of increasing it.

Considerable progress has been achieved in both directions: the outcome of the first will be examined briefly in this Section, while that of the second will be discussed below.

The magnetic isotope effect in the $^{13}C/^{12}C$ diad has been known since 1976;[6,7] since then, it has been discovered in the triads $^{16}O/^{17}O/^{18}O$,[11-16] $^{28}Si/^{29}Si/^{30}Si$,[17-18] and $^{32}S/^{33}S/^{34}S$ [19] and also in the diads $^{72}Ge/^{73}Ge$ [20] and $^{238}U/^{235}U$.[21,22]

The magnetic isotope effect of ^{17}O has been discovered in the reactions involving the chain oxidation of carbochain polymers[12] and the liquid-phase oxidation of hydrocarbons[11,13] by molecular oxygen. In the first case, the oxidation reaction and the absorption of oxygen are accompanied by the enrichment of the residual oxygen in the ^{17}O and ^{18}O isotopes (Fig. 3*a*), the enrichment in the magnetic isotope ^{17}O greatly exceeding that in the nonmagnetic isotope ^{18}O, the dependence of the enrichment on the conversion obeying Eqn (1) (Fig. 3*b*). The anomalous behaviour of the magnetic isotope indicates unambiguously that the MIE is the main cause of the isotope selectivity.

The reaction involving the termination of the kinetic oxidation chains, i.e. the interaction of two peroxy radicals in accordance with the scheme

$$RO_2^{\cdot} \Longleftrightarrow (RO_2^{\cdot}\ {}^{\cdot}O_2R) \Longleftrightarrow RO_4R \Rightarrow RO_3^{\cdot} + O^{\cdot}R \Rightarrow 2\,RO^{\cdot} + O_2$$

pin-selective and hence nuclear-selective. Following their encounter, a pair of peroxy radicals either recombines to the unstable tetroxide RO_4R, which subsequently decomposes irreversibly with regeneration of molecular oxygen, or dissociates reversibly, regenerating the initial peroxy radicals. The MIE actually arises

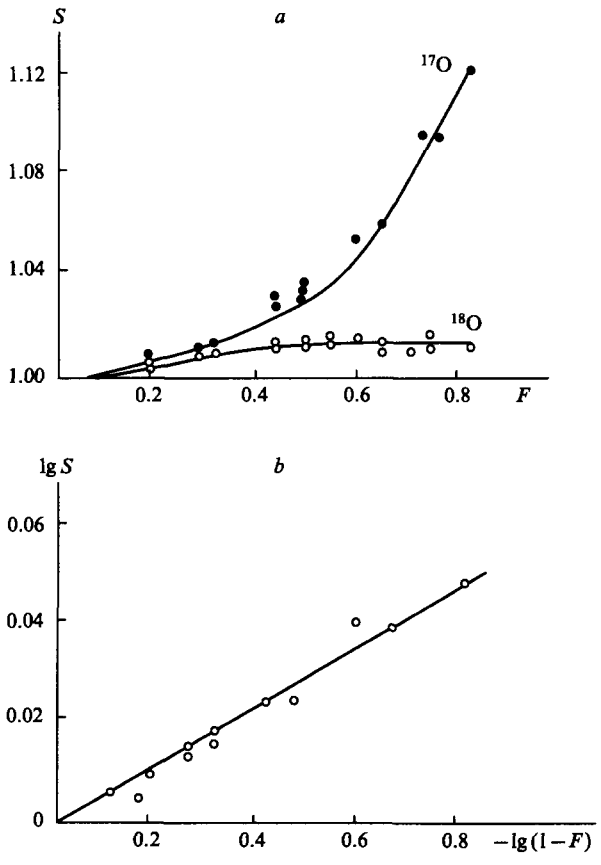

Figure 3. Dependence of the isotope enrichment on the conversion of molecular oxygen in the oxidation of polypropylene at 130 °C (*a*) and its representation in terms of the variables of Eqn 1 (*b*).

in this stage: the pairs containing the $R^{16}O^{17}O^{\cdot}$ radicals recombine faster than the radical pairs with $R^{16}O^{16}O^{\cdot}$ (or $R^{16}O^{18}O^{\cdot}$). As a result, the regenerated oxygen is enriched in the ^{17}O magnetic isotope, while the hydroperoxide $R^{16}O^{16}OH$ is depleted in this isotope. The kinetic theory of this process, developed by Buchachenko et al.,[16] defines the isotope enrichment of the molecular oxygen S as a function of its chemical conversion F in terms of the ratio of the rate constants for the quadratic kinetic chain termination. The ratio of the termination rate constants k_t was found from the $S(F)$ relation (Fig. 3*a*) in terms of the variables of Eqn (1):

$$\frac{k_t(R^{16}O^{17}O + {}^{16}O^{16}OR)}{k_t(R^{16}O^{16}O + {}^{16}O^{16}OR)} = 1.8\ ,$$

i.e. the replacement of the ^{16}O nonmagnetic nucleus by the ^{17}O magnetic nucleus ensures an increase in the rate constant for the annihilation of the peroxy radical almost by a factor of two.

The opposite effect obtains in the liquid-phase oxidation reactions of hydrocarbons[13] — as molecular oxygen is consumed, it is depleted in the ^{17}O isotope, which means that the principal isotope-sorting process in these reactions becomes the addition of the alkyl radicals $R^{\cdot}$ to molecular oxygen. The addition of $R^{\cdot}$ to $^{17}O^{16}O$ is faster than the addition to $^{16}O^{16}O$ and the reason for this is again the acceleration of spin conversion in the pair $(R...O_2)$ as a result of the hyperfine interaction with the ^{17}O magnetic nucleus. However, the quartet–doublet conversion now takes place. The ratio of the rate constants for the $R^{\cdot} + {}^{17}O^{16}O$ and $R^{\cdot} + {}^{16}O^{16}O$ reactions is 1.011, i.e. the $^{17}O^{16}O$ molecules react faster than the $^{16}O^{16}O$ molecules to the extent of 1.1%[16] and this difference between the rates depletes the molecular oxygen in the ^{17}O isotope. The classical mass isotope effect (CIE) in the $R^{\cdot} + {}^{18}O^{16}O$ and $R^{\cdot} + {}^{16}O^{16}O$ reactions is 0.99, i.e. the first reaction is slower than the second by 1%.[16] Clearly the MIE is much greater than the CIE: it fully compensates for the CIE in the $R^{\cdot} + {}^{17}O^{16}O$ reaction and actually reverses the sign of the effect.

The difference in the behaviour of the ^{17}O isotope in two processes — the oxidation of polymers in the viscoelastic state and liquid-phase oxidation — demonstrates the leading role of molecular dynamics in the selection of the spin-selective reaction. Molecular dynamics controls the spin selectivity of the two isotope-sorting reactions (the propagation and termination of kinetic chains). The first of these predominates in solutions with a low viscosity, while the second predominates in viscous systems with greatly retarded molecular motion. The physical cause of the difference between the isotope selectivities of these two reactions is evident: rapid molecular dynamics and a short time of the diffusional 'liquid-phase' trajectories should correspond to rapid spin evolution in the $(R^{\cdot}...O_2)$ pair, while slow dynamics and a long time of the diffusional trajectories in viscous polymers should correspond to slow spin conversion in the $(RO_2^{\cdot}\ {}^{\cdot}O_2R)$ pair. The comparable times of spin conversion and diffusional motions ensure the optimum conditions for the isotope selection in two competing processes — reaction in the pair and diffusional dissociation of the pair.

The high-temperature oxidation of polyaromatic[15] polymers (polypyromellitimide, polyphenylquinoxaline) by molecular oxygen is accompanied by the enrichment of the latter in the ^{18}O isotope and its depletion in the ^{17}O isotope. The kinetics of the oxidation (the absence of autocatalysis and of the inhibiting effect of antioxidants) and the composition of the oxidation products (mainly quinones) indicate a nonchain oxidation mechanism, in which the spin-selective stage is the interaction of molecular oxygen with low-lying excited and thermally accessible triplet states of the polyaromatic fragments of the macromolecules. The product of this reaction is an *endo*-peroxide. Among the nine spin states of the pair of two triplets (oxygen plus the triplet fragment of the macromolecule), only one (singlet) state gives rise to the *endo*-peroxide. The hyperfine interaction in the oxygen with ^{17}O partly removes the spin prohibition and opens an additional reaction path involving other spin states. As a result,

the ^{17}O isotope-containing oxygen reacts faster and its transfer to the products depletes the molecular oxygen in the ^{17}O isotope. The enrichment of the oxygen in the ^{18}O isotope in this reaction takes place due to the CIE.

A magnetic isotope effect of ^{17}O with the opposite sign has been observed by Turro and Chow[14] in the reverse reaction involving the decomposition of *endo*-peroxides. There is no doubt that the decomposition takes place via the singlet state of the biradical $Ar^{\bullet}-OO^{\bullet}$, where Ar is the aryl component of the *endo*-peroxide. The biradical may decompose, generating singlet oxygen, or may be transformed into a triplet state, generating triplet molecular oxygen on decomposition. Clearly in the biradicals with ^{17}O the latter process should predominate and singlet oxygen should therefore be depleted in the ^{17}O isotope, while triplet oxygen should in fact be enriched in this isotope. These predictions have been fully confirmed by experiment.[14]

The discovery of the MIE of ^{29}Si arose from the synthesis of the silicon-containing ketone $PhCH_2COSiMe_2Ph$, which is similar to dibenzyl ketone structurally and to its photolysis in micelles.[18] It was shown with the aid of chemically induced [dynamic] nuclear polarisation that both direct and triplet-sensitised photolysis occur, as in the photolysis of dibenzylketone via radical pairs.

$$PhCH_2\overset{O}{\overset{\|}{C}}SiMe_2Ph \Longleftrightarrow (PhCH_2^{\bullet}\ {}^{\bullet}\overset{O}{\overset{\|}{C}}SiMe_2Ph) \Longrightarrow \text{products}$$

The direct photolysis begins with the excited singlet state, which generates the singlet radical pair (RP). On the other hand, the sensitised photolysis proceeds via the triplet RP.[23] The variation of the silicon isotope composition of the ketone as a function of the chemical conversion of the latter is illustrated in Fig. 4.

The first important result which follows from Fig. 4 is that the enrichment of the ketone in the ^{29}Si magnetic isotope greatly exceeds its enrichment in the ^{30}Si nonmagnetic isotope. Clearly the HFI involving the ^{29}Si nucleus in the triplet RP accelerates its triplet – singlet spin conversion and stimulates the recombination of the pairs with ^{29}Si, whereas the triplet – singlet conversion of the pairs with ^{28}Si lags behind and these pairs dissociate and are converted into other products, the excess ^{28}Si nuclei being removed in these products.

The second striking result which follows from Fig. 4 is that the direct photolysis leads to the depletion of the initial ketone in the ^{29}Si isotope, i.e. the inversion of the spin multiplicity of the RP in the direct and sensitised photolysis is accompanied by the inversion of the sign of the MIE: the enrichment of the ketone in the ^{29}Si isotope in the sensitised photolysis (starting with the triplet) is replaced by depletion in the direct photolysis (starting with the singlet). The cause of the inversion is evident: the initial singlet pairs with ^{29}Si are transformed faster into the triplet pairs and subsequently dissociate, carrying away ^{29}Si and other products and depleting the regenerated ketone in this isotope. We may note that the enrichment of the ketone in the ^{30}Si nonmagnetic isotope is due to the CIE and is therefore insensitive to the spin multiplicity of the RP and to the direction of spin conversion — from the triplet to the singlet or back again.

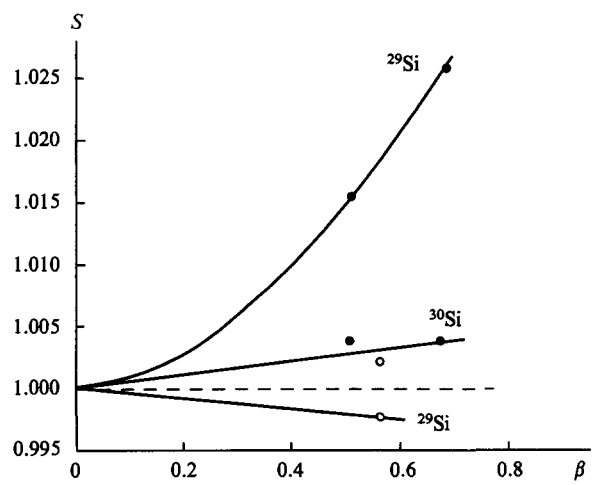

Figure 4. Enrichment in the ^{29}Si and ^{30}Si istopes as a function of the chemical conversion β in the direct (open circles) and sensitised (filled circles) photolysis of silyl ketone.

The ^{33}S magnetic isotope effect was first observed in 1990[19] in the direct micellar photolysis of a sulfur-containing ketone, which was shown with the aid of chemically induced [dynamic] nuclear polarisation to proceed via triplet RP in accordance with the scheme

$$PhC\overset{O}{\overset{\|}{C}}H_2SO_2Ph \rightleftharpoons (PhC\overset{O}{\overset{\|}{C}}H_2^{\bullet}\ {}^{\bullet}SO_2Ph) \Longrightarrow \text{products.}$$

The pairs with the ^{33}S magnetic isotope recombine faster and return this isotope to the regenerated ketone molecules, the enrichment of which in ^{33}S increases with increase in the chemical conversion of the ketone (Fig. 5). The marked predominance of the ^{33}S isotope enrichment over the enrichment in the ^{34}S nonmagnetic isotope demonstrates unambiguously the predominance of the MIE over the CIE.

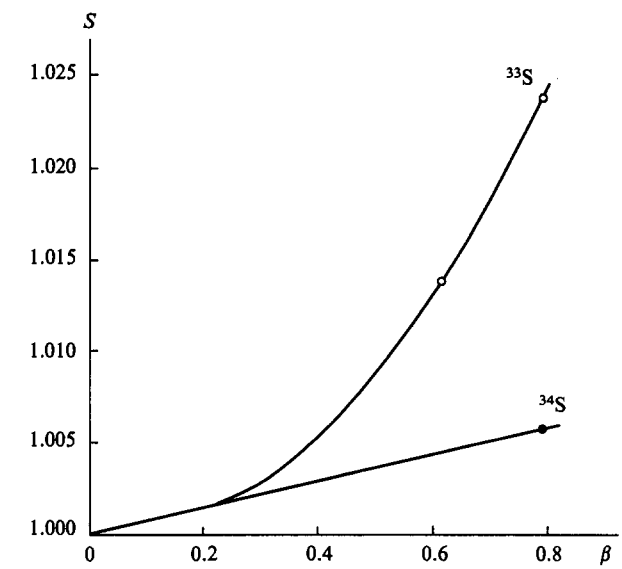

Figure 5. Enrichment in the ^{33}S and ^{34}S isotopes as a function of the chemical conversion in the photolysis of a sulfur-containing ketone.

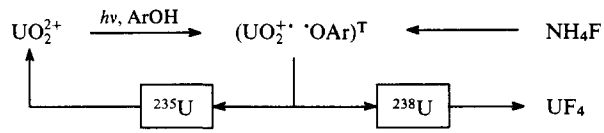
The ^{73}Ge magnetic isotope effect was discovered quite recently[20] in the photolysis of methyltriphenylgermane in micelles; the initial compound was enriched in the ^{73}Ge magnetic isotope relative to the nonmagnetic ^{72}Ge. The enrichment in ^{73}Ge depends greatly on the magnetic field, whereas the content of the ^{72}Ge isotope does not change, demonstrating the 'classical' origin of the effect involving ^{72}Ge.

The mechanism of the decomposition reaction suggests that the selection of the magnetic and nonmagnetic germanium nuclei takes place in accordance with the same principle as the sorting of the ^{13}C nuclei in the decomposition of dibenzyl ketone.

$$Ph_3GeMe \Longleftrightarrow (Ph_2MeGe^{\bullet}\ Ph^{\bullet})^{T} \Rightarrow \text{products}$$



The hyperfine interaction involving the ^{73}Ge nucleus in the radical $Ph_2MeGe^{\bullet}$ is unknown, but one can make the reliable assumption that its magnitude is hardly likely to differ greatly

from that known for the $Ph_3Ge^{\cdot}$ and $Me_3Ge^{\cdot}$ radicals.[24,25] As a result of the HFI, the ^{73}Ge-containing radical pairs rapidly evolve to singlet species and recombine, returning the ^{73}Ge magnetic nuclei to the regenerated methyltriphenylgermane molecule.

Finally, the MIE involving uranium nuclei has been observed independently by two groups of investigators.[21,22] The search for the MIE of uranium nuclei required the solution of three problems: (1) the search for reactions of uranium compounds which could generate paramagnetic intermediates — spin carriers (radicals or radical-ions); (2) the search for spin-selective stages in the reactions of these intermediates; (3) the study of the proportions of the isotopes in the products. The solution of the last of the three problems is the most problematical, because there is no guarantee that the outer unpaired electron in the uranium-containing paramagnetic intermediate is capable of 'breaking through' the thick electron shell consisting of more than 90 electrons and reaching the nucleus in order to give rise to the appreciable HFI necessary to ensure the nuclear spin selectivity.

Among the various reactions of uranium-containing compounds, the photoreduction of uranyl salts was chosen for the search for the MIE. The first stage of this reaction is the reduction of the uranyl ion UO_2^{2+} to the paramagnetic uranoyl ion UO_2^{+}. In three series of elegant experiments {the observation of chemically induced [dynamic] nuclear polarisation in the reactions of the uranyl ion,[26] the observation of the magnetic field effect in a uranyl-photosensitised polymerisation reaction,[27] and the detection of electronic polarisation transferred from the excited UO_2^{2+} ion to the nitroxyl radical[28]}, it was shown unambiguously that the uranyl ion UO_2^{2+} reacts in the excited triplet state, generating the uranoyl ion UO_2^{+}, which subsequently participates in spin-selective reactions, which sort the isotopic nuclei (the magnetic ^{235}U nuclei and the nonmagnetic ^{238}U nuclei).[29]

The most convincing results were obtained in the photolysis of uranyl perchlorate in an aqueous micellar solution of sodium dodecyl sulfate in the presence of NH_4F and 2,6-diphenyl-4-stearoylphenol.[30] The reaction mechanism and the paths followed in the migration of the isotopic nuclei are illustrated below.

The photolysis of uranyl generates a triplet RP made up of the uranoyl ion UO_2^{+} and the phenoxyl radical. The reaction pairs with ^{235}U magnetic nuclei undergo rapid triplet–singlet conversion and disproportionate with regeneration of the initial uranyl enriched in ^{235}U. The 'nonmagnetic' pairs with ^{238}U are converted into tetravalent uranium products (of the type of the insoluble UF_4). The initial uranyl is enriched on photolysis in the light but magnetic ^{235}U isotope, while the product of the photolysis of UF_4 is enriched in the heavy nonmagnetic ^{238}U isotope. This result conflicts with the predictions based on the CIE (it was found that the UO_2^{2+} ions with the heavy isotope are more reactive than those with the light isotope) and indicates unambiguously a contribution by the MIE, which exceeds the CIE in magnitude, compensating for the latter and actually leading to a change in sign. Later the ^{235}U MIE was confirmed in the photolysis of uranyl succinate containing 30% of ^{235}U. On 85%–90% conversion in methanol, the content of ^{235}U in the initial uranyl succinate increases by 6% relative to the initial value.[31]

Fig. 6 summarises the values of α_G for all the MIE discovered hitherto. It provides a clear idea about the quantitative scales of the MIE and the CIE.

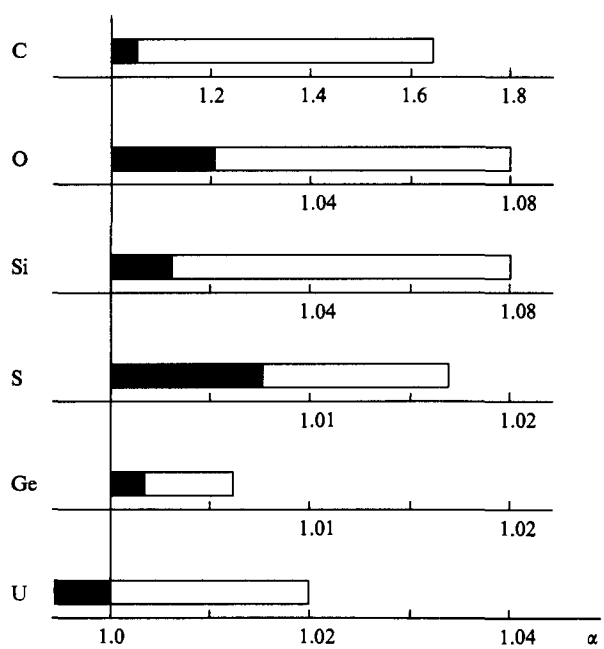


Figure 6. The single-stage isotope enrichment coefficients α_G. The open rectangles indicate the region of α_G for the MIE in the $^{13}C/^{12}C$, $^{17}O/^{16}O$, $^{29}Si/^{28}Si$, $^{33}S/^{32}S$, $^{73}Ge/^{72}Ge$, and $^{235}U/^{238}U$ isotope pairs. The filled rectangles characterise the CIE for the $^{13}C/^{12}C$, $^{18}O/^{16}O$, $^{30}Si/^{28}Si$, $^{34}S/^{32}S$, $^{73}Ge/^{72}Ge$, and $^{235}U/^{238}U$ isotope pairs.

III. Properties of the magnetic isotope effect

Table 1 summarises the characteristic properties and features of the MIE and compares them with those of the CIE. The first fundamental feature of the MIE, which is also its essential feature, is its nuclear spin dependence (in contrast to the nuclear mass dependence of the CIE).

The effectiveness of the nuclear spin selection is controlled by the HFI energy: the higher the HFI energy, the stronger the effect of the nuclear spin system on the electron system with removal of spin prohibition and differentiation of the rates of the triplet–singlet conversions of the 'magnetic' and 'nonmagnetic' radical pairs. The dependence on the HFI energy constitutes the second feature of the MIE, which, in contrast to the CIE, can lead to measurable isotopic enrichments of the atoms at a considerable distance from the reaction centres. The reason for this is that the distribution of the spin density among the chemical bonds in the radicals is not attenuated regularly and may give rise to intense HFI involving remote atoms. At any rate, this attenuation is much gentler than the transfer of perturbations of the molecular vibrations induced by isotope substitution (this is why the CIE is localised at the reaction centre).

The third feature of the MIE is its high sensitivity to molecular dynamics and all the factors influencing the latter: viscosity, temperature, restriction of the reaction in closed volumes — microreactors of the type of micelles or zeolite cavities. The spin conversion develops in a dynamic system — a radical pair, where the partner radicals move apart as a result of diffusion, some of them return and are involved in repeated encounters, move apart again, etc. During the diffusional migrations, spin conversion, induced by the hyperfine and Zeeman interactions, takes place. For the occurrence of nuclear selection, it is important that the diffusional migration times of the partner radicals should be comparable with the spin conversion times of the pair.

The high sensitivity of the isotope enrichment to the molecular-dynamic properties of the medium is demonstrated by Fig. 2. The isotope enrichment coefficient [α_G in Eqns (1)] depends greatly on the visocity: in viscous solutions (cyclohexanol, glycerol), α_G is much greater than in solutions with a low

Table 1. Comparison of the features of the MIE and the CIE.

Feature	MIE	CIE
Selectivity parameter	Nuclear spin and magnetic moment	Nuclear mass
Hyperfine interaction	Strong dependence	No dependence
Magnetic field	Strong dependence	No dependence
Molecular dynamics	Strong dependence	No influence
Chemical dynamics and lifetime of radicals	Dependence	No dependence
Effect of temperature	Strong	Weak
Spin multiplicity	Strong dependence of magnitude and sign	No dependence

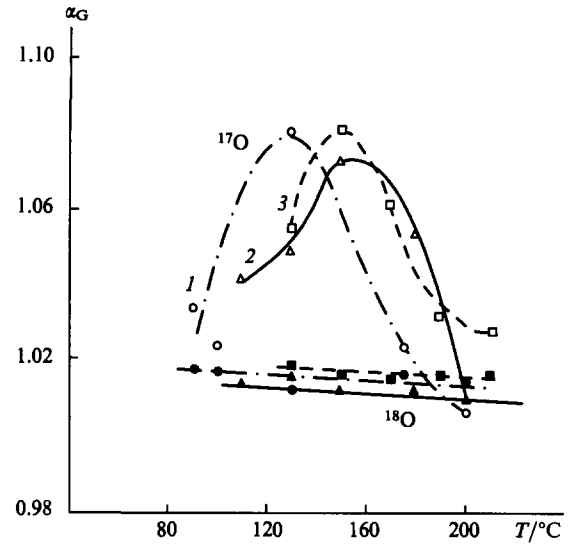

Figure 7. Temperature dependence of the single-stage isotope enrichment coefficient α_G in the oxidation of polyethylene (curve *1*), polypropylene (curve *2*), and poly-4-methylpentene (curve *3*). The open circles, squares, and triangles correspond to ^{17}O, whilst the filled symbols correspond to ^{18}O.

viscosity (benzene, hexane). Thus, for the photolysis of dibenzyl ketone, α_G is 1.054 in hexane[6] and 1.039 in benzene,[32] whereas in vitreous cyclohexanol $\alpha_G = 1.113$[33] and in glycerol (with a viscosity of 2400 cP) $\alpha_G = 1.50$.[34] Turro was the first to show that α_G attains large values when the reaction is carried out in closed microreactors (micelles and the cavities in zeolites or porous glasses). Thus $\alpha_G = 1.37$ in hexadecyltetramethylammonium chloride micelles[35] and $\alpha_G = 1.39$ in the corresponding bromide micelles.[36] The physical causes of such high isotopic selectivity of the reactions in closed microreactors are discussed below.

The magnetic isotope effect depends greatly on the lifetime of the radicals, because the joint molecular and spin dynamics of the pair are limited by its chemical lifetime. For the nuclear spin selection to be successful, it is necessary that the spin conversion time and the lifetime of the pair are comparable. This property of the MIE, namely the dependence on the chemical dynamics of the pair, constitutes its fourth fundamental feature.

Thus the generation of the molecule from the RP is the result of the combined efforts and interactions due to three types of dynamics — spin, molecular, and chemical. Their joint effect prepares the pair for an important event — recombination: the spin dynamics ensures the required (singlet) spin state of the pair, the molecular dynamics guarantees contact between the recombining partners by this instant, and the chemical dynamics ensures the survival of the pair. For this reason, the isotope separation based on the MIE depends on the parameters which influence the molecular and chemical dynamics — temperature[37] and viscosity,[38] the presence of radical acceptors, the wavelength of the photolysis,[39] the size of the micelles,[40] etc.

As an illustration, Fig. 7 shows the enrichment of molecular oxygen in the ^{17}O and ^{18}O isotope as a function of temperature[12] in the chain oxidation of polymers. The enrichment in ^{18}O decreases only slightly with increase in temperature, in conformity with the predictions based on the CIE. However, the MIE-induced enrichment in ^{17}O depends greatly on temperature, passing through a maximum at T_{max}, which reflects the condition for the most effective isotope selection: the time between repeated diffusional encounters of radicals is comparable to the spin conversion time for the pair. On either side of the maximum, the characteristic times of these two dynamic processes (molecular and spin) are not comparable and the MIE decreases sharply. At high temperatures $T > T_{max}$, the lifetime of the RP diminishes sharply (rapid diffusion) and there is insufficient time for the pair to effect spin conversion and isotope sorting. On the other hand, for $T < T_{max}$ the diffusional lifetime of the RP is too long and during it the spin correlation is lost for all the pairs — both 'magnetic' and 'nonmagnetic'. In both extreme cases, the isotope sorting in the pairs is ineffective.

The sign of the CIE is unambiguously dictated by the ratio of the isotope masses; however, the sign of the MIE is determined by the spin multiplicity of the radical pairs (or other electron spin carriers). Strictly speaking, it depends on the direction of the spin conversion — from the triplet to the singlet or conversely. This is an obvious property: in the initial triplet state, the 'magnetic' pairs evolve more rapidly to the singlet state and the recombination product is enriched in the magnetic isotope; in the initial singlet state, the 'magnetic' pairs pass through the triplet state for the same reason and dissociate, depleting the recombination product in the magnetic isotope. An example of the inversion of the sign is provided by the MIE based on the ^{29}Si nuclei (see above). Another example of the inversion of the sign of the MIE is the triplet-sensitised photolysis[7] and thermolysis of benzoyl peroxide.[38] The photochemical reaction involves triplet RP and triplet–singlet conversion, whereas the thermal reaction begins with singlet pairs and involves singlet–triplet spin conversion. These two chemically identical reactions lead to different isotope redistributions: in the first case, the cage product (phenyl benzoate) is enriched in the ^{13}C isotope, while in the second case the excess ^{13}C is found in the reaction product outside the cage — in benzene.[38] Such dependence of the sign of the MIE on the direction of the spin evolution is a reliable test for the identification of the spin multiplicities of the reactants.

Finally, there is yet another important property of the MIE: as a rule, the effect arises in chemical steps which do not limit the overall rate of the process (for example, the formation of chemical bonds on recombination), whereas the CIE occurs in energy consuming chemical decomposition or substitution reactions.

IV. Problems and prospects of the isotopic-spin selectivity

The magnitude of the classical isotope effect is determined by the ratio of the isotope masses, which greatly limits the nuclear mass selectivity of the reactions (provided that tunnelling is excluded). It was shown above that the nuclear spin selectivity is as a rule

much more pronounced, so that the isotope enrichment induced by the MIE can exceed the value expected from the CIE by 1–2 orders of magnitude.

The limiting nuclear spin selectivity and ideal isotope separation are attained for $P = 0$ and $P^* = 1$ [see Eqn (1)]. These are very severe conditions, which fully prohibit the recombination of nonmagnetic RP and at the same time require the complete recombination of pairs with magnetic nuclei. Whether or not these contradictory conditions can be satisfied is a problem which we shall now discuss.

The first step on the way towards a high spin selectivity involves directing the reaction along the path with participation of paramagnetic intermediates (spin carriers), i.e. the adjustment of the chemistry to promote the spin-selective reactions. Naturally, this is not always possible and is not always necessary. For example, it is pointless to seek the nuclear spin selectivity in hydrolytic or nucleophilic substitution reactions. When the reaction proceeds via two parallel competing paths, one of which is radical and spin-selective whilst the other is nonradical, the single-stage isotope enrichment coefficient assumes the following form:

$$\alpha_G = \frac{1 - P\theta}{1 - P^*\theta}, \qquad (2)$$

where θ is the partial contribution of the radical path. For $\theta = 1$, the coefficient α_G is a maximum and Eqn (2) then reduces to Eqn (1). However, if θ diminishes, then α_G also falls and for $\theta = 0$ (the radical path vanishes) there is no nuclear spin selectivity ($\alpha_G = 1$). Eqn (2) may be used also to determine the contribution by the nonradical path. Thus, in the sensitised photolysis of a silicon-containing ketone in micelles, it was found that the radical path (via triplet RP) coexists with the decomposition reaction via a siloxycarbene, which is inserted in the O–H bond of the water molecule; this path amounts to approximately 2/3 of the overall reaction flux and is not spin-selective, which greatly reduces the ^{29}Si MIE.[18]

The second important condition is high reversibility of the spin-selective reaction, which guarantees the possibility that each molecule can undergo repeated reactions of this kind (e.g. dissociation–recombination–regeneration cycles). Each of these repeating cycles is isotope-selective, so that the overall isotope selection is multiplied repeatedly in the multicascade process.

A high reversibility of the reaction can be induced in two ways—by spatial and by physical 'enforcement'. The former implies that the reaction is carried out in closed microreactors (micelles, the cavities in zeolites and porous glasses, microcavities in stressed polymers, etc.), in which the reflecting walls limit diffusion and give rise to the 'capture' of the radical pairs. The theory of microreactors from the standpoint of nuclear spin selectivity has now been fairly thoroughly developed.[33,41]

The physical 'enforcement' is less trivial and merits special consideration. The magnetic isotope effect is a result of the spin conversion induced by the electron-nucleus HFI, so that the greater the extent of the HFI, i.e. the stronger the linkage between the electron and nuclear spin subsystems, the greater the isotope selection. However, the HFI is by no means the only physical interaction giving rise to the triplet–singlet (or any other, for example, quartet–doublet) spin conversion. The spin-rotation, spin-orbit, dipolar, and exchange interactions all induce electron relaxation and hence spin conversion. This additional relaxation path competes with the HFI path and is traditionally regarded as the harmful spin leakage path, because it does not involve the nuclear spin system and thus does not give rise to the MIE. In such cases, the reaction remains selective with respect to the electron spin but loses its selectivity with respect to nuclear spin.

However, even if the contribution of the HFI to the spin conversion is low but the electron relaxation is rapid and stimulates effectively the spin conversion and recombination of the triplet pairs (i.e. forces the radical pairs to recombine), ultimately the isotopic selectivity increases. This paradoxical result has a simple explanation: not only the isotope selection in each reaction step but also the number of such steps undergone by each molecule is important. Here the multicascade nature of the spin-selective process is again manifested.

Thirdly, in order to ensure an appreciable MIE, it is necessary to modify the reaction mechanism in such a way that the spin-selective processes begin with the triplet state of the RP. This is one of the reasons why the triplet-sensitised photolysis is preferable for the observation of the MIE and isotope selection.

The fourth factor controlled by the MIE is the extent of the HFI in radicals participating in spin-selective processes: the greater the extent of the HFI, the greater the difference between the probabilities P and P^*, and the greater the value of α_G. However, the quantities P and P^* themselves are determined by the interaction of three dynamic processes—spin, molecular, and chemical, so that the synchronisation of these dynamic processes in time is an important factor which influences the difference $P^* - P$ (this has already been discussed in the section concerning the properties of the MIE).

Finally, the MIE and isotopic selectivity may be strengthened by the selective microwave pumping of the RP having magnetic nuclei. By acting on the electron spin, the magnetic component of the resonance hyperfine frequency field accelerates the spin conversion and stimulates the selective regeneration of molecules with magnetic nuclei without affecting the RP with nonmagnetic nuclei. This remarkable effect has been called the radio-induced MIE;[42,47] it belongs to the second generation of magnetic effects, namely those which are due to the action of microwave magnetic fields on chemically reacting spin systems.[5] The first generation of magnetic effects are induced by static magnetic fields—external or internal (of the type of HFI). The magnetic field effect, the MIE, and chemically induced [dynamic] nuclear polarisation are effects of this kind.

As an example of the radio-induced MIE, one may quote the enrichment of dibenzyl ketone in the ^{13}C isotope during its photolysis in micelles as a function of the chemical conversion plotted in terms of the variables of Eqn (1). The slope of this plot, which determines the single-stage enrichment coefficient α_G, increases with microwave pumping.[43]

The prospects for the radio-induced MIE are still more promising when one employs a combination of two types of microwave pumping: the low amplitude pumping of the 'magnetic' RP, which stimulates their recombination and the high-amplitude pumping of the 'nonmagnetic' RP, which slows down or altogether suppresses the spin conversion of these pairs, preventing their recombination (the spin locking effect).[44] Under these conditions, the isotope selection is most effective.

Thus there are diverse and almost limitless possibilities for regulating the nuclear spin selectivity of chemical reactions. There is a problem in the choice of the reactions and the methods and conditions for carrying them out; in other words, the problem of controlling the chemistry and physics of the reactions which are a part of spin chemistry—the science of the behaviour of the angular momenta of electrons and nuclei in chemical reactions.

V. Sorting of nuclei in accordance with spin orientations

Thus, by virtue of the MIE, the reaction sorts the magnetic and nonmagnetic nuclei. The next level in nuclear spin selectivity involves the sorting of magnetic nuclei in accordance with their orientations. The hyperfine interaction, which makes it possible to separate nuclei in terms of their magnetic properties, depends on the orientation of the nucleus and in the simplest case is defined as am, where a is the HFI constant proper and m is the projection of the nuclear spin specifiying the orientation of the nucleus. Clearly, the HFI-induced rate of spin conversion depends on m, so that both the conversion and the competition

between the reactions in the RP depend on the orientation of the nuclei. As a result, the reaction directs nuclei oriented in different ways into different products. Thus molecules with oriented (polarised) nuclei are generated. However, the reaction is capable not only of sorting the nuclei in accordance with orientations but also of orienting them. This occurs in very weak magnetic fields, where the external magnetic field $H \ll a$ and is still incapable of rupturing the electron–nucleus linkage. The spin conversion in the electron system is then accompanied by conversion of the nuclear spin. In other words, the change in the electron spin is compensated by the change in the orientation of the nuclear spin (because the overall angular momentum of the electron–nucleus system is conserved).

The phenomena involving the sorting of nuclei and their orientation in chemical reactions are combined under the term chemically induced [dynamic] nuclear polarisation (CIDNP).[1,45,46] The orientation of the nuclei is equivalent to the nonequilibrium (excess) population of the nuclear Zeeman levels in the molecules of the chemical reaction products and is therefore detected by nuclear magnetic resonance methods and is manifested in the NMR spectra as an anomalous absorption or emission (depending on which Zeeman levels are overpopulated and which orientations of the nuclei predominate in the molecules).

Chemically induced [dynamic] nuclear polarisation was discovered independently by two groups of workers (Bargon and Fisher[47] and Ward and Lawler[48]); Sagdeev, Molin, Kaptein, Osterhoff, Closs, Roth, Lippmaa, etc. have made major contributions to the CIDNP. Stimulated CIDNP was a remarkable discovery (Sagdeev, Grishin, Molin, etc.). The idea underlying it was formulated by Sagdeev et al.[49] Stimulated CIDNP is generated by the selective microwave pumping of assemblies of radical pairs with a selected orientation of the nuclei, which leads to the spin conversion of such assemblies and forces them to react. As a result, nuclei with the specified orientation are forcibly directed into the molecules of products and are detected in the latter by NMR methods.

Chemically induced [dynamic] nuclear polarisation is widely used in its diverse variants (in the stationary and time-resolved variants, in the static and flow variants, etc.) in chemistry and biochemistry as a method for the identification of reaction mechanisms, for the detection of radicals and radical stages, and as a method for the study of chemical kinetics and chemical physics (see, for example, Refs 1, 5, and 50).

This review was written with financial support from the Russian Fundamental Research Fund (grant No. 93-03-05227).

Abstract. The state of the art in methods for the determination and study of the molecular state of the water admixture in high-purity volatile inorganic substances used in processes for the preparation of materials for new technologies is considered. Primary attention is given to spectroscopic methods in the IR and microwave regions with the highest information content. The bibliography includes 182 references.

I. Introduction

Volatile substances have relatively low melting and boiling points, i.e. they are characterised by typical van der Waals intermolecular interaction, sometimes with a small contribution from other types of interaction, e.g., intermolecular hydrogen bonds. A vapour pressure of 1333 Pa at 500 K can be chosen as a criterion defining an arbitrary threshold of volatility.[1] Permanent gases, chlorides and hydrides of a number of elements and some other substances are usually regarded as volatile inorganic compounds. The interest in high-purity volatile inorganic compounds is caused by their wide application for obtaining many materials for new technologies. For example, high-purity volatile chlorides and hydrides are used as starting compounds in manufacturing optical fibres, semiconductors and optical elements by chemical deposition from the vapour phase (the CVD technology). In this case, a high-purity permanent gas usually serves as the carrier.

Among the impurities most frequently encountered in ultrapure volatile inorganic compounds and most difficult to remove, water is foremost.[2-4] This results from the relatively high concentration of moisture in the starting compounds and in the technological atmosphere, as well as from the tendency of water molecules to be adsorbed on the walls of the equipment and even to diffuse through them at an appreciable rate from the environment (see, e.g., Ref. 5). Thorough elimination of water from volatile compounds is frequently complicated by the ability of water molecules to form rather stable complexes, both with one another and with molecules of the main compound in the liquid phase and sometimes in the gaseous phase. Such complexes can initiate avalanche-like nucleation processes followed by the formation of suspended ice or gas hydrate particles.

Strict requirements are imposed on the purity of the starting compounds and working gases used in the CVD technology for manufacturing optical fibres and semiconducting epitaxial layers. For example, the water concentration in the starting reagents should not exceed 5×10^{-5} mol% in order to attain the lowest optical loss in quartz optical fibres.[6,7] Perfect crystalline epitaxial GaAs layers on silicon can be obtained by the reaction of arsine with trimethylgallium in a hydrogen atmosphere, provided that the admixture of water in the reactor does not exceed the same value of 5×10^{-5} mol%.[8] On the other hand, the samples presented at the Exhibition-Collection of special purity compounds of the Russian Academy of Sciences, which has been permanently open since 1974 at the Institute of Chemistry of High-Purity Substances of the RAS, contain the following mean water concentrations (mol%): 1×10^{-4} in permanent gases, 1×10^{-2} in chlorides and 5×10^{-3} in hydrides.[9] Therefore, the preparation of high-purity compounds with a water admixture below 5×10^{-5} mol% is an urgent problem. At present, a demand is already felt for compounds with an overall content of admixtures within $10^{-6} - 10^{-8}$ mol%.[6,10] Deep dehydration, storage and transportation of compounds with such a low content of water involve considerable difficulties.

The development of methods for the preparation of volatile compounds with a low water content should be paralleled by the development and improvement of the corresponding analytical methods. In our opinion, two interconnected problems should be taken into account when considering the methods for the determination of water in high-purity volatile compounds: highly sensitive determination of the water admixture and study of the state of admixed water, i.e. study of the nature of the chemical bond in complexes involving water and the thermodynamic characteristics of these complexes.

The present review considers both these problems for volatile inorganic hydrides, chlorides and permanent gases. Attention is concentrated on spectroscopic methods in the IR and microwave ranges, because of their high sensitivity and the possibility of their simultaneous application both for analysis and for studying the molecular state of admixed water.

II. Determination of water

Many publications, including several monographs and reviews,[11-14] have dealt with problems of water determination in various media, including high-purity volatile inorganic compounds. Many chemical, physical and physicochemical methods are known; however, their detection limits are not lower than $10^{-4} - 5 \times 10^{-5}$ mol%. The coulometric method and the dew point method are among the most widespread, rather simple methods.

1. The coulometric method and the dew point method

The coulometric method measures the quantity of electricity required for the electrochemical decomposition of water in an analysed volume of a gas.[15,16] The sensitive element of the corresponding device contains a sorbent, usually phosphorus(V) oxide. For this reason, coulometric hygrometers are used only for analysing compounds that do not react with P_2O_5 or in the cases where the contribution from the corresponding reaction to the overall measurement error is insignificant (see Atamanyuk et al., [17] who report a coulometric analysis of gaseous HCl). The detection limit attainable by this method is $(1-5) \times 10^{-5}$ mol%. The coulometric method usually consumes a large amount ($1-3$ dm^3 s^{-1}) of the analysed gas, which is not always acceptable.

A number of other methods for water determination in volatile compounds have appeared in recent years, such as thermal oscillometry,[18] direct potentiometry,[19] cyclic voltammetry [20] and amperometry.[21] However, these methods also suffer to some extent from the above drawbacks.

The measurement of water concentration by the dew point method is based on the visual or optical monitoring of the fogging of a cooled mirror in a stream of the analysed gas.[15,16] The temperature, at which dew appears on the mirror, is measured and the pressure of saturated water vapour corresponding to this temperature is determined. The detection limit can be as low as 10^{-6} mol%. This method is unsuitable for analysing readily condensing gases, such as ammonia, certain other hydrides and hydrocarbons. Various modifications of this method have been described in Refs 22 and 23.

A novel method for the determination of micro admixtures of water based on measuring the temperature of the start of sublimation of a condensate, which is first placed in a definite volume, has been proposed.[24] The authors determined the solubility of water in liquid nitrogen, which was found to be 4×10^{-7} mol%. In their opinion, there is no limit to the detection of water by this method. However, the authors do not report any comparative analyses or methods for preparing the equipment for assaying such a low water content.

Other fairly sensitive methods for water determination include gas chromatography and mass spectrometry.

2. Gas chromatography

Various problems in the application of gas chromatography for the determination of water in volatile compounds have been discussed in a number of communications.[11,25-28] Both direct determination of the water admixture without changing its chemical form and reaction chromatography are used. In order to determine water in gases by reaction chromatography, reactions transforming water into other compounds (most frequently, ethyne) more convenient for gas chromatographic detection were used.[28,29] Ref. 28 reports an estimation of water content in ammonia at a level of $10^{-3}-10^{-4}$ mol% by passing ammonia through a reactor with calcium carbide. The poor reproducibility of the results obtained by a one-step technique, i.e. when the reactor with calcium carbide was directly connected to the chromatograph, was noted. The error probably appeared because not all the water could undergo reaction due to the insufficient reaction rate. In later work the sample was first passed several times through the reactor and only then analysed.

The determination of water in gases based on its reaction with calcium carbide is applicable to a wide range of compounds inert towards calcium carbide, oxide, and hydroxide.

Ref. 30 describes a technique for water determination in volatile hydrides and permanent gases (detection limit: 1×10^{-5} mol%). The technique is based on the oxidation of methane by water and the products of its dissociation in a spark discharge occurring in the reaction vessel. The change of the amount of methane due to its oxidation is detected by a flame ionisation detector. The relative standard deviation was $0.01-0.2$ in the range of water contents of $1 \times 10^{-2}-5 \times 10^{-5}$ mol%.

The improvement of materials for packing chromatographic columns made it possible to determine the water admixture directly in gases without changing its chemical form and to decrease the detection limit. For example, Snopatin et al.[31] determined the water content in hydrogen sulfide, hydrogen selenide, arsine, and germane using the selective adsorption of the hydrides on a Saran charcoal (detection limit: 5×10^{-5} mol%).

Preconcentration is also used in gas-chromatographic determinations of the water admixture. Ref. 32 reports the gas-chromatographic determination of water in high-purity nitrogen (detection limit: 2×10^{-6} mol%). Water was concentrated by adsorption in columns packed with cooled (3 °C) Porapack T, then blown out of the column and detected with a catharometer. A technique for water determination in ammonia (detection limit: 1×10^{-4} mol.%) was reported in Ref. 33. The lowest detection limit of water in nitrogen (2×10^{-6} mol%) was attained when water was concentrated on a sorbent, while gas chromatographic techniques offered limits of water detection within 10^{-3} to 10^{-5} mol%.

3. Mass spectrometry

Similar or even lower limits for water determination can be attained using mass spectrometry. For example, Ref. 34 reports a technique for the mass-spectrometric determination of water and other admixtures in SiH_4, HCl and other compounds (the detection limit was 1×10^{-4} mol%). The authors draw attention to the correctness of the analysis and consider adsorption-desorption processes in the connecting tubes to the quadrupole mass spectrometer, the 'memory' effect of the ion source, and various background ion-molecule reactions. All of these questions are of primary importance for the determination of microamounts of water in gases. Water can be to a considerable extent adsorbed on the walls of the injection system and the ion source of the mass spectrometer, which adversely affects the detection limit. Refs 35 and 36 report results of mass-spectrometric determinations of the water content in the residual atmospheres of evacuated sealed vessels. It was noted that the results obtained in different laboratories are not reproducible. This probably results from the fact that the vapour pressure in the vessels varied within 0.01–0.1 atm, so that from three to ten water monolayers were present on the vessel walls. The gas was injected into an ion source, whose volume and surface area were greater than those of the vessel by a factor of several tens. As a result, adsorption and desorption of water in the ion source affected considerably the accuracy of the measurement.

Recent publications deal with the mass spectrometric determination of water in gases.[37,38] Hydrogen and nitrogen were added to a sample, which was then ionised at atmospheric pressure. Water reacted with the N_2H^+ ion in the ion source, which resulted in a decrease in the fraction of these ions

$$N_2H^+ + H_2O \rightarrow H_3O^+ + N_2.$$

The concentration of water was determined from the intensity of the N_2H^+ ion peak using a quadrupole mass spectrometer. The authors succeeded in plotting the dependence of water content on the change in the intensity of the N_2H^+ ion band in the low concentration region down to 5×10^{-7} mol%. However, no data were reported to confirm the validity of the above analytical technique.

Although there are several examples of successful application of gas chromatography and mass spectrometry for water determination in volatile high-purity compounds, these methods have not become widespread. This results from the difficulties in specimen preparation, the considerable probability of uncontrolled substance loss and irreversible transformations of the analysed compounds in chromatographic columns [39-41] and/or in the ionisation chamber.[34]

Spectroscopic methods do not suffer from many of the above drawbacks. These methods have high sensitivity, selectivity and accuracy and provide the possibility of the unambiguous

identification of components in the sample. A water molecule is characterised by intense absorption in many regions of the electromagnetic spectrum. The 'strong' lines in the medium IR and sub-millimeter ranges are the most suitable for performing highly sensitive analyses.

The quantitative absorption spectroscopic analysis is based on the relation between the concentration of absorbing atoms and the change in the intensity of radiation passed through the analysed medium, i.e., the Bouguer – Lambert – Beer law:

$$I(\nu) = I_0(\nu)\exp[-k(\nu)x]. \quad (1)$$

Here $I(\nu)$ and $I_0(\nu)$ are the intensity of the radiation passed through the sample and that of the incident radiation, respectively. The x parameter is related to the concentration of absorbing molecules n, and the length of the optical path l:

$$x = nl; \quad (2)$$

$k(\nu)$ is the absorption coefficient,

$$k(\nu) = A f(\nu - \nu_0), \quad (3)$$

where the $f(\nu - \nu_0)$ function characterises the shape of the spectral line contour (the Lorentz, Doppler or Voigt profile or their combination), and ν_0 is the frequency corresponding to the centre of the absorption line. The A parameter is usually called line intensity, line strength, or integral absorption coefficient.

$$A = \int_{-\infty}^{+\infty} k(\nu)\mathrm{d}\nu, \quad (4)$$

Analysis of Eqns (1) and (4) shows that the dimensionality of A is $\nu[x^{-1}]$, where ν is usually expressed as the wave number (cm^{-1}), and the diversity of measurement units for the concentration and optical path length predetermines the existence of various units for A. The relations between these units have been reported, for example, by Pugh and Rao.[42] Some researchers assume that $x = 1$ in equation (1) (unit concentrations and lengths), and in some cases the absorption coefficient γ is used, which is measured in reciprocal centimetres. The minimum γ determined usually characterises the sensitivity of the spectroscopic method.

Given the known values of A or γ for a spectral line (band) and having measured its integral (peak) intensity, one can determine the desired concentration of the analysed compound. If A or γ are unknown, a calibration plot should be used.

Let us consider the main results in determining micro-amounts of water in volatile high-purity compounds by IR absorption and microwave absorption spectroscopy.

4. Infrared spectroscopy

Table 1 presents the average and relative integral absorption coefficients for the main vibrational bands of water molecules in the gas phase. One can see that the band due to deformation vibrations, ν_2, which is the least affected by intermolecular interactions, has the maximum intensity. Refs 43 and 44 report the calculated and experimental integral absorption coefficients of separate lines in the regions corresponding to the stretching and deformation vibrations. Although the IR region contains the most intense vibrational-rotational transitions of water molecules, standard diffraction instruments, even those equipped with multiple-pass cells, probably do not provide detection limits below 10^{-4} mol%.[11,45]

In recent years, IR spectroscopy with Fourier transformation of the spectrum has found wide use. This method has a much higher sensitivity and selectivity, and its application for determining water in gases shows much promise. Ref. 47 presents a procedure for the Fourier-IR spectroscopic determination of traces of water in gaseous nitrogen and hydrogen chloride (detection limit: 10^{-5} mol%). Andreev et al.[46] proposed a procedure for determination of water in oxygen with a detection limit of 6×10^{-6} mol%. According to this procedure, a stream of the gas to be analysed passes through a multiple-pass cell, whose optical path is 20.75 m. The water concentration was found to be 7×10^{-5} mol%, this limit being imposed by the capacity of the device for the drying of oxygen by cryofiltration.[7]

Table 1. Integral absorption coefficients (A/cm^2 atm^{-1}) of the vibrational–rotational bands in the IR spectrum of water in the gas phase.[42]

Frequency (spectral region)/cm^{-1}	A_{mean} (at 300 K)[a]	A_{rel}[b]
1595 (ν_2)	277.8	100
3152 ($2\nu_2$)	1.73	0.6
3657 (ν_1)	10.2	3.7
3756 (ν_3)	202.3	72.8
2.7 μm	182.8[c]	65.8
1.9 μm	20.3[c]	7.3
1.4 μm	16.7[c]	6.0
1.1 μm	1.78	0.6

[a] The mean value of A given is based on data from different authors. [b] The relative value of A is given (the value of 100 corresponds to A for the most intense band, ν_2). [c] The overall value of A for all the lines in the specified range is given.

It was noted above that the limit of water detection in gases below 10^{-4} mol% cannot be attained by diffraction IR spectrometers, primarily because of the low resolution of these instruments. The resolution of the classical molecular spectroscopic methods in the gas phase is generally restricted by the instrumental resolution of the spectrometers. This value is as low as 0.003 cm^{-1} for interferometric spectrometers.[48] The resolution of dispersion spectrometers is normally 0.1 cm^{-1}. For comparison, the interferometric order of magnitude of the Doppler width of the stretching–rotational absorption lines of molecular gases is 10^{-3} cm^{-1} (in the middle IR region).

It can be shown [42] that the following relation is valid for the intensity of the radiation absorbed by a substance (ΔI) and the incident radiation (I_0)

$$\frac{\Delta I}{I_0} = k(\nu)\frac{\delta\nu}{\Delta\nu}, \quad (5)$$

where $\delta\nu$ is the width of the absorption line and $\Delta\nu$ is the spectral resolution.

It follows from the above that the use of instruments with a higher spectral resolution (low $\Delta\nu$) makes it possible to decrease the instrumental detection limit for molecular admixtures.

The creation of more sensitive analytical IR spectrometers became possible owing to the use of lasers with tuneable wavelength as radiation sources. Lasers have a higher spectral power, and the lines generated by them are narrower than the resolution achieved in dispersion and interference instruments. For example, Kreuzer et al.[49] showed, on an experimental basis, the possibility of determining water vapour in nitrogen and air when its content was ca. 1.4×10^{-6} mol%, using a CO laser and an optical-acoustic detector. The measurements were carried out at a wavelength of 5.94 μm ($\nu = 1683.02\,cm^{-1}$).

The use of a Nd laser makes it possible to record ca. 116 absorption lines of water vapour. The most intense line has an absorption coefficient of 10^{-9} cm^{-2} atm^{-1} (1.7×10^{-8} cm^{-1}),[50] which allowed the authors [51] to attain a ca. 10^{-4} mol% detection limit for the concentration of water in air.

It was proposed [52] to determine the content of water by the optical-thermal method. A CO laser served as the radiation source. From an estimate based on the signal/noise ratio, the practical detection limit for the method is 7.5×10^{-6} mol%.

Record-breaking low limits for the detection of water in various gases were attained using spectrometers based on tuneable diode lasers. The use of such instruments in molecular analysis has been reported in Refs 53 – 56.

The authors [57] managed to determine the minimum width of lines generated by semiconductor $PbS_{1-x}Se_x$-based lasers, which

was as low as 7×10^{-7} cm^{-1} at a wavelength of 5.3 μm. The line width of the radiation of diode lasers is usually $\sim 10^{-5}$ cm^{-1}, but this is much less than the width of the Doppler contour of the absorption line, which is, for example, $\sim 10^{-3}$ cm^{-1} near $\lambda = 10$ μm. On the other hand, the spectral density of the power of diode lasers is $\sim 10^9$ times higher than that of thermal radiation sources, which makes it possible to determine the concentration of molecular admixtures below 10^{-5} mol%.

As noted above, the theoretical maximum sensitivity of high-resolution spectrometers can be characterised by the minimum detectable absorption coefficient, γ_{min}. The following expression for this value was found using the data in Refs 58 – 60:

$$\gamma_{min} = \left[\frac{4}{l\sqrt{2}}\right]\left[\frac{N}{P_0}\right]^{1/2}, \quad (6)$$

where $N = 2h\nu\Delta f$ is the power of the quantum noise ($\Delta f = 0.5\pi\tau$ is the transmission band width of the detection system (Hz); τ is the constant of accumulation time, s; ν is the wavenumber, cm^{-1}; and h is the Planck constant); P_0 is the power of the incident radiation; and l is the optical path length, m.

Assuming that $P_0 = 0.71$ mW, $l = 1$ m, and $\tau = 1$ s, and that a signal/noise ratio of $3\sqrt{2}$ is required for a minimum determination,[58] we obtain $\gamma_{min} = 2 \times 10^{-9}$ cm^{-1}. A relation is known between the absorption coefficient and the concentration x (ppm) of molecules absorbing the radiation, the half-width of the analytical line ($\Delta\nu$), and the pressure in the cell (p).[61]

$$\gamma = \frac{kxp}{\Delta\nu} \quad (7)$$

The proportionality coefficient k is determined from the parameters of the analytical line of the additive in the pure state at the same pressure p. When the concentration of the additive is x, we have:

$$x = \frac{\gamma_{min}}{\gamma_0}\frac{\Delta\nu}{\Delta\nu_0}, \quad (8)$$

where γ_0 and $\Delta\nu_0$ are the above parameters for the pure additive.

Taking into account the data in Refs 44, 46 and 62, the $\gamma_0\Delta\nu_0/\Delta\nu$ value for lines in the region of 1600 cm^{-1} (which is usually chosen as the analytical region for water) can be assumed to be 20 cm^{-1}. Then, the theoretical minimum water concentration that can be determined by this method is as low as 9×10^{-9} mol%.

Relatively few studies dealing with the use of diode laser spectroscopy for water determination in permanent gases are known. In Ref. 63, the study was carried out in a multiple-pass cell with an effective length of 500 m using an analytical line at 1135 cm^{-1}. The detection limit was 5×10^{-6} mol%. In Ref. 64, a differential method was proposed for water determination in helium, nitrogen, oxygen, and argon based on the line at 1653 cm^{-1}. Two laser beams were passed through a reference cell ($l = 7$ cm) containing water vapour at a pressure of 6.7 Pa and then through a working cell ($l = 28$ cm) with a stream of the analysed gas at a pressure of 1.3 kPa. The instrument was calibrated by the standard addition method in the concentration range of $2 \times 10^{-7} - 1 \times 10^{-4}$ mol% for a 2 m absorbing path. Mucha[65] used a simplified version of the instrument described in Ref. 64 for determining ca. 5×10^{-4} mol% water in small volumes (of the order of magnitude of the volume of an integrated microcircuit, 0.01 – 0.1 cm^3). The undesirable effect of gas liberation due to adsorption — desorption was eliminated as a result of the short measurement time ($\leqslant 10$ μs). In Ref. 66, an admixture of water was determined in helium serving as the heat carrier for several types of nuclear reactors. The detection limit was $(1 - 6) \times 10^{-5}$ mol% for the analytical line at 1435 cm^{-1} with an absorption path of 100 m.

The authors of a work cited above [46] report the determination of the water admixture in high-purity oxygen, dehydrated by cryofiltration,[67] using the diode laser spectrometer described in Ref. 68. The analytical line at 1675.17 cm^{-1} was used; the gas pressure in a flow cell ($l = 1.5$ m) was 40 Torr. The minimum measurable absorption coefficient was 2×10^{-7} cm^{-1}, and the water detection limit was 8×10^{-7} mol% (the standard deviation was $s_r = 0.4$ for $c_{H_2O} < 8 \times 10^{-7}$ mol%). These values differ from the above theoretical limiting values of γ_{min} and x_{min}. However, one should take into account that the diode laser used in Ref. 46 operated in a pulse mode with an averaging time $\tau \simeq 10^{-3}$ s. Under these conditions, the corresponding limiting values of the γ and x parameters increase by a factor of ~ 30, according to Eqns (6) and (8). The difference between the values of γ and x predicted and obtained experimentally [46] is not high if one bears in mind that the γ_{min} was estimated assuming an ideal receiving system.

Table 2. Detection limits c_{min} (mol%) and relative standard deviations s_r of the water admixture in high-purity permanent gases and hydrides obtained by absorption diode laser IR spectroscopy together with the half-widths of the analytical line $\Delta\nu$ (cm^{-1}) and its broadening coefficients ξ (cm^{-1} Torr^{-1}).[68,69]

Compound	$c_{min} \times 10^5$	s_r (c_{H_2O})[a]	$\Delta\nu \times 10^2$	$\xi \times 10^3$
O_2	0.08	0.4 ($< 8 \times 10^{-7}$)	0.86	0.24
Ar	0.04	0.17 (1.6×10^{-6})	0.66	0.158
He	0.04	0.11 (1.3×10^{-4})	0.66	0.158
GeH_4	4	0.15 (2.0×10^{-6})	0.66	0.158
H_2Se	1	0.08 (2.0×10^{-3})	3.2	1.06
NH_3	6	0.06 (3.0×10^{-2})	7.2	2.40

[a] The s_r values refer to the water concentrations specified in parentheses.

Ref. 69 reports a technique for determining a micro admixture of water in argon, neon, germane, hydrogen selenide, and ammonia. The analytical part of the instrument was first dried by passing through it dry oxygen with a water content below the detection limit of the method (4×10^{-7} mol%). The above gases were analysed by the pumping in – pumping out technique, rather than in a gas stream. Table 2 presents the water detection limits and some spectral parameters of the analytical line.

One can see that diode laser spectroscopy makes it possible to obtain record-breaking low water detection limits in nonpolar high-purity gases, including those whose molecules are characterised by considerable inherent absorption in the regions of the analytical lines of water (germane, ammonia).

An urgent problem is the determination of water in the condensed phases of low-boiling compounds (permanent gases, halides, hydrides, etc.) and in volatile compounds that are liquid under the usual conditions. IR spectroscopy seems to be the most convenient method for this purpose; however, high- and ultrahigh-resolution spectroscopic methods cannot be used because of the strong broadening of spectral lines due to intermolecular interactions. Increasing the thickness of the absorbing layer used in the traditional IR spectroscopic method is often also impossible because of the overlap of absorption bands (in many cases, even the second- and third-overtones) of the main compound. The above restrictions should be of little importance when analysing liquefied monotonic and diatomic permanent gases that are transparent in the IR region. Low temperatures favour the disappearance of the rotational fine structure of the analytical bands of admixed molecules and their narrowing in comparison with the bands of gases and solutions under the usual conditions. In addition, liquefaction leads to concentration of a number of admixtures, so that relatively thin optical layers can be used. In fact, IR cryospectroscopy has been used successfully for analysing liquid oxygen and certain permanent gases.[70,71] However, the use of this method for water determination in the above objects by measuring the intensities of absorption bands in the regions of stretching or deformation vibrations is hindered by the very small solubility of water at low temperatures. In particular, this follows from the experimental data in Refs 70 and 71. For example, only a broad band of varying intensity (depending on the degree of

Table 3. The positions of the maxima of the analytical bands, detection limits, and standard deviations of the determination of the water admixture and hydroxyl-containing hydrolysis products in liquid volatile inorganic chlorides obtained by IR spectroscopy.[74-76]

Chloride	Substance to be determined	ν/cm^{-1}	$c_{min} \times 10^4$ (mol %)	s_r
$SeCl_4$	H_2O	1600	10	4.32
	$Ge(OH)Cl_3$	3603	80	3.60
$SnCl_4$	H_2O	1586	5	3.23
	H_2O	3553	6	2.69

[a]The anticipated hydrolysis products.

drying) in the region of 3000 – 3600 cm^1, which corresponds to an ice solid phase, is observed in liquid oxygen.

Rebiai et al.[72] reported that they recorded intense narrow lines at 3604 and 3707 cm^{-1} in the IR spectrum of liquid nitrogen exposed to air. These lines were attributed to the stretching vibrations of water, indicating an unusually high ($\sim 10^{-3}$ mol%) solubility of the latter. It has been noted that such interpretation of the observed bands is erroneous;[73] more likely, they correspond to the Fermi-resonance doublet of CO_2 molecules. As noted above, the solubility of water in liquid nitrogen is 4×10^{-7} mol%.[24]

Refs 74 – 76 describe an IR spectroscopic technique for the determination of the concentrations of water and/or hydrolysis products in liquid high-purity germanium, tin, arsenic, silicon and phosphorus chlorides. Table 3 presents the detection limits found.

Within the scope of an IR spectroscopic study of the molecular state of the water impurity in liquefied high-purity volatile inorganic hydrides of Group V and VI elements (see below), the following estimates of the detection limit of water at 290 K were obtained (mol%):[77] $\sim 3 \times 10^{-4}$ (PH_3), $\sim 7 \times 10^{-5}$ (AsH_3), $\sim 3 \times 10^{-4}$ (H_2S) and $\sim 2 \times 10^{-4}$ (H_2Se).

5. Microwave spectroscopy

Microwave spectroscopy provides high-resolution spectra of the purely rotational transitions of molecules (the relative width of lines in the spectra can be as low as 10^{-6}). The practical application of microwave spectroscopy for the analysis of mixtures is mostly restricted by technical factors: only the millimetre range (4 – 0.7 cm, 8 – 40 GHz), in which the line intensities for the majority of light molecules are low, has been developed sufficiently. For water, the most intense rotational transitions (whose intensities are, however, by one or two orders of magnitude lower than those in the IR range) are observed in the submillimetre range (10^{-1} to 10^{-2} cm, 100 – 1200 GHz).[78,79]

The 'adoption' of the sub-millimetre range started about 30 years ago after sufficiently powerful coherent tuneable radiation sources, the backward wave oscillators (BWO), had been created. However, the construction of 'classical' spectrometers (in which the useful signal is found from changes in the parameters of the radiation passed through a sample) on the basis of these sources did not give the desired result. In fact, expression (6) allows one to estimate the minimum determinable absorption coefficient for any 'classical' spectrometer (CS). For a typical power of a BWO equal to 1 mW (which is an order of magnitude higher than for diode lasers), $\tau = 1$ s, and $l = 1$ m, we obtain $\gamma_{min} \simeq 10^{-10}$ cm^{-1} (for a $3\sqrt{2}$ signal/noise ratio). It should be noted that the actual sensitivity with respect to the absorption coefficient does not exceed 10^{-6} cm^{-1} of separate points of the range [80] due to the considerable interference in the ultrahigh frequency region. The possibilities of the submillimetre spectroscopy were implemented in a radio-frequency spectrometer with acoustic detection (RAD), whose principle of operation is analogous to the above optical-acoustic spectrometer based on a CO-laser.[81] In this case, the expression for the minimum determinable absorption coefficient has the form [81]

$$\gamma_{min} = \frac{3 \times 10^{-9}}{P_0}. \quad (9)$$

For a power of a BWO equal to 1 mW and for a $3\sqrt{2}$ signal/noise ratio, we obtain $\gamma_{min} = 10^{-8}$ cm^{-1}. The actual sensitivity coincides with the predicted value ($\gamma_{min} = 3 \times 10^{-8}$ cm^{-1}, see Ref. 81) and can be as high as 10^{-10} cm^{-1} when a resonator cell is used (see Ref. 82). Using formula (8), one can also estimate the theoretical detection limit for a water admixture on a RAD. For the analytical line at 556.436 GHz, $\gamma_0 = 0.9$ cm^{-1},[79] $\Delta\nu/\Delta\nu_0 = 10^{-1}$ (water in argon [83]), and $x_{min} \approx 1 \times 10^{-7}$ mol%.

The above method was used for assaying water in certain volatile inorganic hydrides.[84] When the analysed gas was passed through a cell, the detection limit was found to be 1×10^{-5} mol%. The considerable difference between the theoretical and actual detection limits results primarily from the design features of the analytical cell of the spectrometer (the presence of a polymer membrane which hindered heating of the cell) and the imperfection of the receiving device, an amplifying microphone. The following results were obtained:

Hydride	NH_3	GeH_4	H_2S	H_2Se	H_2Te
$x_{H_2O} \times 10^3$ (mol %)	0.3	0.8	0.6	1	70

Water determination by submillimetre radio-frequency spectroscopy in volatile inorganic nonpolar silicon and germanium chlorides was studied in Ref. 85. In order to increase the sensitivity, a cylindrical multi-mode nontuneable resonator 20 mm in diameter and 300 mm long with two fixed reflectors was used as the analytical cell. The detection limit in this technique was 9×10^{-7} mol% at a sample pressure of 2.5 – 13 kPa. It was also reported that, at the optimum pressure in the cell (270 – 800 Pa), determination of water at a concentration of 3×10^{-7} mol% is possible. However, this requires that the water background be diminished by more thorough degassing or by creating a stream of the analysed compound through the measuring cell. The water contents (in the molecular form) in high-purity samples of $GeCl_4$ and $SiCl_4$ were $(5 \pm 0.3) \times 10^{-5}$ and $(2 \pm 0.2) \times 10^{-5}$ mol%, respectively. According to the data in Ref. 85, hydrolysis of the chlorides in the cell during analysis did not lead to a systematic error in the determination.

The use of resonator cells in the RAD increases the amount of radiation absorbed by the sample. It is also a realistic way of increasing the sensitivity of submillimetre spectroscopy. A gain in signal intensity by a factor of 3 – 4 can be attained by using the water line at 1097 GHz with $\gamma = 2.8$ cm^{-1} (see Ref. 79). Note that the power of radiation sources in the submillimetre range is 1 – 2 orders of magnitude higher than that in diode laser spectroscopy, and the averaging times are much longer (by 2 – 3 orders).

Thus, although the sensitivity with respect to the absorption coefficient of submillimetre radiofrequency spectroscopy is somewhat less than that of diode laser spectroscopy, the sub-millimetre radiofrequency spectroscopy with acoustic detection can be used successfully for high-sensitivity assays of water in volatile compounds, such as inorganic hydrides and chlorides of subgroup IVA elements that are transparent in the microwave region. It would be undoubtedly useful to combine microwave spectroscopy with a 'pure' analytic cell (without foreign internal elements) similar to those used in the 'classical' IR spectrometers (preferably, with retention of the sensitivity of the latter). The first step in this direction is the creation of a microwave spectrometer based on coherent spontaneous radiation (CSR), which currently operates in the 70 GHz region. The expression for the minimum absorption coefficient determinable by this spectrometer is similar

to expression (6)[60]

$$\gamma_{min} = \left(\frac{4}{l}\right)\left(\frac{P_t}{P_0}\right)^{1/2}, \quad (10)$$

where $P_t = 4kT\Delta f$ is the power of the thermal noise (Δf is the pass band of the recording system); l is the length of the measuring cell, whose design is analogous to that of the cell used in diode laser IR spectrometers.

For a BWO power equal to 1 mW, $T = 300$ K, $\tau = 1$ s and a $3\sqrt{2}$ signal/noise ratio, we obtain $\gamma_{min} = 8 \times 10^{-10}$ cm^{-1}, which is somewhat better than for a diode laser IR spectrometer. A sensitivity of 1×10^{-10} cm^{-1} has been obtained experimentally in the region of 37–178 GHz.[86] The analytical possibilities of the a CSR spectrometer were also studied in this work for the determination of an admixture of methanol in ethanol. The detection limit was found to be 8×10^{-5} mol%.

Thus, the combination of absorption IR spectroscopic methods with thermal and diode-laser radiation sources as well as microwave spectroscopy in the millimetre and sub-millimetre regions makes possible highly-sensitive determinations of water admixtures in gaseous and liquid inorganic compounds. The preparation of the samples needs particular attention in such cases.

III. Molecular state of water

In order to determine the structural and energetic (thermodynamic) characteristics of complexes formed by water molecules with molecules of the environment, it is necessary to study the properties of such complexes both in the gas and liquid phases. Under real conditions in dilute solutions, the concentration of the complexes is generally low, but they can affect considerably the physicochemical properties of high-purity compounds.[87] Therefore, preliminary investigation of water-based complexes at comparable concentrations of the components or at a small excess of one of them is of great importance. This task is accomplished by theoretical quantum-chemical methods and experimentally, primarily by spectroscopic methods.

1. Water complexes in the gas phase

For most of the gases, the depth of the potential well D_e is of the order of magnitude of the translational energy of molecules at the critical temperature $D_e = kT_k$, where T_k is the critical temperature. At $T < T_k$, the energy of molecular interaction exceeds the thermal energy, and stable complexes are formed. However, the number of complexes is strongly dependent on temperature and pressure. For the equilibrium complex-formation process

$$B..HA \leftrightarrows B + HA \quad (11)$$

the equilibrium constant is expressed as [88]

$$\frac{n_{B...HA}}{n_B n_{HA}} = \left(\frac{h^2}{2\pi kT\mu}\right)^{3/2} \exp\frac{D_0}{RT}, \quad (12)$$

where $n_{B...HA}$, n_B and n_{HA} are the numbers of the corresponding species in a unit volume in the equilibrium vibrational–rotational state; D_0 is the dissociation energy corresponding to this state;

$$\mu = \frac{M_B M_{HA}}{M_B + M_{HA}},$$

where M_i are molecular masses.

The equilibrium constant is determined experimentally by microwave spectroscopy by measuring the absolute intensities of the rotational transitions for two or three participants of reaction (11) in an equilibrium gaseous mixture. This can give the dissociation energy of the complex in the zero-point vibrational–rotational state D_0, which is related to the dissociation energy D_e by the expression [88,89]

$$D_e = D_0 + N_A\sum_i \tfrac{1}{2}h\nu_i(B...HA) - N_A\sum_i \tfrac{1}{2}h\nu_i(B) - N_A\sum_i \tfrac{1}{2}h\nu_i(HA), \quad (13)$$

where the second, third, and fourth terms contain sums of the contributions of zero-point vibrations from all vibrational modes except those of intermolecular deformation vibrations in the complex; N_A is the Avogadro number.

It should be noted that the equilibrium constant of reaction (11) can also be determined purely thermodynamically from the second virial coefficient. In particular, microwave spectroscopy was used to study in detail the dimerisation of water. [88]

In order to calculate theoretically the equilibrium constant of reaction (11), one should know the molecular constants of the complex and its dissociation energy D_e. The latter coincides with the electronic intermolecular interaction energy ΔE, which is found by nonempirical quantum-chemical calculations.

Many studies have been devoted to calculations for complexes of water with light molecules. It is noteworthy that the resulting values of intermolecular interaction energies ΔE depend on the chosen basis set and on the number of corrections introduced additionally, which are related both to physical effects (allowance for the correlation energy ΔE_{cor} in the second- and fourth-order Moeller–Plesset perturbation theory) and the errors in the computational methods (the superposition error due to incompleteness of the basis set ΔE_{BSSE}). These problems are discussed in more detail in Refs 90 and 91 for example.

Table 4 presents the results of a series of studies dealing with the calculation of the energies of the intermolecular interaction of water with certain monotonic and diatomic molecules.

According to the data in Refs 93 and 95, water molecules form linear complexes with molecules of the inert gases, nitrogen, and carbon monoxide. These complexes can be regarded as hydrogen-bonded. Detailed calculations of the potential surface of the HOH...Ar complex showed [94] that other orientations of an argon atom relative to a water molecule are possible, up to a mutually perpendicular orientation of the symmetry axis of the water molecule and the Ar–O axis. In the oxygen complex, the O–O...OH_2 orientation is preferable. On the whole, calculations predict that complexes of water with permanent gases are very weak.

Ref. 100 reports the results of calculations for complexes of water with hydrides. The calculations were performed in terms of the widest possible basis set and took the correlation energy into

Table 4. Results of quantum-chemical calculations of energies of complexes of water and certain permanent gases.

Complex	$-\Delta E$/ kcal mol^{-1}	Method	Ref.

ClH...OH_2	3.243	1.277	2.2	4.1	576	4.4

Note. The following designations are used: R is the distance between the X and Y atoms linked by a hydrogen bond; r is the length of a X–H bond participating in hydrogen bond formation; θ is the angle between the X–H bond and the X–Y line; the structural parameters were calculated by the SCF method in terms of the 6-31G(d) basis set; CF is the electron energy calculated by the SCF method in terms of the 6-31+G(2d,2p) basis set with the geometry optimised in terms of the 6-31G(d) basis set; MP4 is the energy with allowance for electronic correlation calculated by the fourth-order Moeller–Plesset perturbation theory; ΔH is the enthalpy of the complex calculated by the method from Ref 101 using the electronic energy in terms of the MP4/6-31+G(2d,2p) basis and vibrational frequencies in terms of the 6-31G(d) basis set.

account. These results are given in Table 5, together with the complex-formation enthalpies and structural parameters of isolated complexes. The formation of linear H-bonds X–H...Y was found to occur in all the complexes. The HOH...NH_3 complex (C_s symmetry) is the most stable, while the water dimer (C_s symmetry) is markedly less stable. It should be noted that the calculated enthalpy of the latter is in good agreement with the value determined experimentally, [88] which is 3.7± 0.5 kcal mol^{-1}. The structure of the HOH...PH_3 complex is similar to that of the ammonia complex,[100] but the low enthalpy of formation makes it doubtful if the phosphine–water complex exists at room temperature. The same conclusion applies to hydrogen sulfide–water complexes, in which water acts both as a proton donor and a proton acceptor.

An analysis performed for complexes of hydrides with water taking into account ΔE and ΔH_{298} values suggests that their stability changes in the following order:

$$FH...OH_2 > HOH...NH_3 > ClH...OH_2 > HOH...OH_2 >$$
$$> HSH...OH_2 > H_2S...HOH > HOH...PH_3.$$

A comparative calculation of the structures and energies of the complexes of CH_4 and SiH_4 with water [103] in terms of the 6-31G* basis set taking into account the correlation energy showed that the structures of the complexes of CH_4 and SiH_4 with water differ considerably, which is explained by differences in the polarity of the $C^{\delta-}-H^{\delta+}$ and $Si^{\delta+}-H^{\delta-}$ bonds. The water–silane complex ($\Delta E = -2.4$ kcal mol^{-1}) is more stable than the complex with methane ($\Delta E = -1.3$ kcal mol^{-1}).

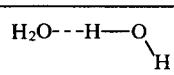
Despite the considerable progress in the quantum-chemical computational methods achieved in the recent years, experiment remains the main source of information about the structure and energy of weak complexes. High-resolution IR and microwave spectroscopic methods are used primarily for this purpose in the gas phase.

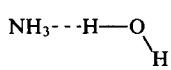
Data on the structure of complexes and their potential surfaces can be obtained by analysing the following spectral features: appearance of new lines corresponding to the complex itself; disappearance or displacement of lines of the starting monomeric components; changes in the intensities of lines corresponding to the monomers and complexes as a function of temperature and pressure.

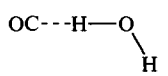
It is convenient to study the above spectroscopic behaviour in high-resolution spectra, i.e. in the spectra of gases at low pressures and temperatures. This, in turn, means highly sensitive equipment is needed. The known methods for studying weak complexes in the gas phase are usually divided into equilibrium and non-equilibrium ones, depending on the thermodynamic state of the complexes under the experimental conditions.

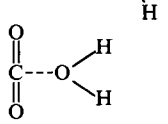
When equilibrium methods are used, one tries to attain the highest possible concentrations of complexes by performing the measurements near the liquid–vapour phase equilibrium line. This approach makes it possible to measure the equilibrium constant and the enthalpy of formation of the complex. However, it is used only for sufficiently stable complexes, due to the low sensitivity of the equipment available at present.

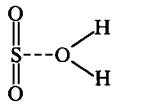
Thomas [104] used IR spectroscopy to study the spectral characteristics of the $H_2O...HF$ gas-phase complex. Three bands characterising intermolecular hydrogen bonds were found, one band in the region of HF stretching vibrations, another in the region of water deformation vibrations, and the third, around 780 cm^{-1}, which corresponds to vibrations of the complex itself. Estimation of the enthalpy of complex formation gave the value of -6.2 kcal mol^{-1}, which corresponds to $D_0 = -5.5$ and $D_e = -7.1$ kcal mol^{-1}.

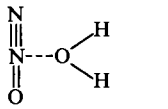


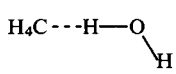


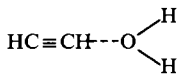


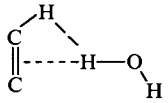


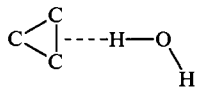


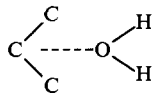


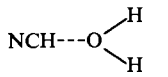


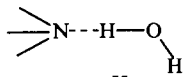


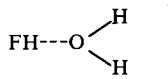


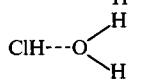


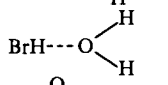


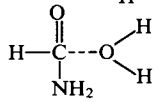


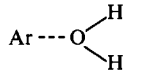












This is the only example, known to us, of a detailed study of a water complex in an equilibrium gas phase by IR spectroscopy in the traditional version using a diffraction spectrometer.

It was noted in a study cited above [47] that, for a resolution of 0.5 cm^{-1}, a broadening of water lines at 3803.8 and 3151.9 cm^{-1} in the region of the stretching vibrations of water was detectable in a gaseous mixture containing 2.6×10^{-3} mol% H_2O. This suggests that a hydrogen-bonded complex is formed in the gas phase between the molecules under consideration even at such a low concentration of water. When the resolution was altered to 2 cm^{-1}, the broadening of lines did not exceed the instrumental function. An indirect confirmation that hydrogen-bonded complexes are formed between water molecules and ammonia and hydrogen selenide in the gas phase at a water concentration of 10^{-2} mol% comes from data on the broadening of the analytical line of water in the region of its deformation vibrations presented in Table 2. Indeed, under the experimental conditions chosen,[47] the width of the absorption bands is mainly determined by the Doppler and collision broadening mechanisms. Taking into account the constancy of the Doppler-type contribution and the gas pressure in the cell, the broadening coefficients, differing by an order of magnitude, may indicate that the type of interaction in mixtures containing water in nonpolar gases (the van der Waals interaction) differs from that in mixtures containing water in polar gases (specific interaction with hydrogen bonds). As predicted by calculation (see Table 5), interaction of water with ammonia is considerably stronger than that with hydrogen selenide.

Thus, new high resolution IR spectroscopic methods, such as diode laser spectroscopy and Fourier-transform spectroscopy, show promise in the studies of weak complexes of water in the gas phase.

Microwave spectroscopy with Stark modulation in the millimetre range up to 75 GHz was used [105,106] to study the above

Table 6. Molecular constants of water complexes in the gas phase according to microwave spectroscopic data.

[a]The symbols in parentheses indicate which pairs of atoms correspond to the distances specified.

H_2O...HF complex in an equilibrium gas phase. The composition of the following equilibrium mixture has been determined[105] at a pressure of 188 mTorr and a temperature of 238 K: $n_{H_2O} = 1.85 \times 10^{19}$, $n_{HF} = 6.66 \times 10^{20}$, $n_{H_2O...HF} = 10.03 \times 10^{15}$ m^{-3}; using Eqn (12), the dissociation energy of the complex was calculated to be $D_0 = -8.1$ kcal mol^{-1}. The total dissociation energy, $D_e = -10.2$ kcal mol^{-1} is in good agreement with the values in Table 5 obtained by quantum-chemical calculations, but is markedly higher than the spectroscopic value, which is -7.1 kcal mol^{-1}.[104]

The rotational spectrum of the H_2O...HF complex in the equilibrium gas phase at low temperatures was first observed in the submillimetre range of 180–350 GHz on a RAD-type spectrometer.[107] In this study [107] the experimental data (including those on the excited states of complexes) were considerably expanded in comparison with the data of previous studies,[105,106] the assignment of the previously observed spectral lines was corrected, and the spectroscopic constants were revised. The usefulness of studies on the submillimetre spectra of molecular complexes in equilibrium gas phases was demonstrated.

At present, the methods of microwave spectroscopy are used quite widely in studies of weakly bound complexes under non-equilibrium conditions. These methods include primarily molecular-beam electroresonance spectroscopy and the microwave Fourier spectroscopy of a pulsed beam.[108,109] In the former method, the complexes are formed in a gas, which flows into a vacuum from a premix chamber containing a mixture of an inert carrier gas and the gases under study at a pressure of 1 – 3 atm and $T = 300$ K. In the second method, the complexes are generated by a pulsed flow of a gas injected into a Fabry – Perot resonator at a frequency of $\sim$ 10 pulses per second.

Table 6 presents some molecular parameters of complexes of water with various proton donors and acceptors found by the specified methods. One can see that water exhibits proton-donating properties with respect to the NH_3, CO, CO_2, C_2H_4 and N_2 molecules. Conversely, water acts as a proton acceptor in other cases. One of the important molecular constants determined experimentally is the centrifugal distortion constant D_j. The latter is linked to the force constant of the vibration of the intermolecular hydrogen bond by the relation [110,111]

$$k_s = \frac{16\pi^2 B^3 \mu}{D_j} \eta , \qquad (14)$$

where B is the rotational constant, μ is the reduced molecular mass of the complex, and η is a correction introduced for complexes of a given type.

In turn, k_s is related to the depth of the potential well of the complex D_e by the expression [109]

$$D_e = \tfrac{1}{72} k_s r_e^2 ,$$

where r_e is the equilibrium intermolecular distance.

It is evident from the data in Table 6 that the complex of water with HF has the highest stability. As noted above, the thermodynamic characteristics of this complex were determined by microwave spectroscopy.[128] At $T = 298$ K and partial pressures of the starting components equal to 1 Torr, ca. 10% of the H_2O and HF molecules are bound in the complex. For comparison, in the case of HCN and HF ($k_s = 11.1$ N m^{-1}), only 5×10^{-4}% of the molecules are involved in complexes.[125] It is impossible to detect such complexes under the usual conditions.

Another method for studying experimentally isolated water-based weak molecular complexes in a nonequilibrium state is IR spectroscopy with low-temperature matrix isolation, in which a mixture of a gas or vapour under study and a diluent gas is rapidly condensed on a support at 4 – 20 K.[139,140] It is possible to observe simultaneously bands of monomers and 1:1 complexes under such nonequilibrium conditions only at high dilution (when the ratio of the concentrations of the gas under study and the diluting gas exceeds 10^3). Otherwise, bands corresponding to more complex associated species manifest themselves as the above ratio decreases. In addition, the important role of the non-uniform broadening in matrices makes it difficult to measure the shapes and intensities of the spectral bands of the complexes and, hence, to obtain quantitative information about their compositions and energies. The relative stability of the complex can be determined qualitatively from the low-frequency shifts of the bands of the stretching vibrations of water. Table 7 shows the results of studies on certain complexes of water with various inorganic proton acceptors, including two hydrides, viz. ammonia and hydrogen sulfide. It is seen that the band due to the symmetric stretching vibrations of water (ν_1) has the highest sensitivity to the electronic structure of acceptor molecules. Among the compounds studied, the maximum shift of this band is observed for the complex with NH_3, in agreement with the maximum value of the force constant of the NH_3...H_2O complex in the gas phase (see Table 6). The complex with H_2S is less stable than that with ammonia, but is more stable than the water dimer under the matrix conditions. It is noteworthy that, according to the results of studies [148,150] on the H_2S...H_2O complex, hydrogen sulfide displays proton-accepting properties with respect to water (Table 8).

The resulting HOH...SH_2 and HSH...OH_2 complexes have a linear structure. A number of bands were attributed to the $H_2S(H_2O)_2$ complex.

In complexes with hydrogen halides,[141,151–156] water also displays proton-accepting properties. Complexes of water with the halogens [149,157–159] and SO_2 in low-temperature matrices[144] are likely to be of the donor-acceptor type. Analysis of IR spectroscopic data for H_2O in Ar, Kr and N_2 matrices shows that the complexes of water with krypton are the most stable.

Thus, there are few hydrogen-bonded complexes of water with light molecules studied by IR spectroscopy in low-temperature matrices and directly in the gas phase, and complexes of only two hydrides, NH_3 and H_2S, have been studied. It should be noted that this is the only experimental evidence that a weak hydrogen-bonded complex is formed in the case of hydrogen sulfide.

2. Molecular complexes of water in the liquid phase

The interaction of water with the main compound in the liquid phase is more complex, since it can be paralleled by the association of molecules of the main compound as a background. To consider this aspect theoretically, one has to calculate the potential surfaces not only of the simple 1:1 water – main compound complex but also of more complex ones, $H_2O...n$ B, where $n \leqslant 4$ (in accordance with the coordination number of the water molecule). An experimental investigation of association processes in the condensed phase is very difficult because it is impossible to use high-resolution spectroscopy. However, much experience has been accumulated in spectroscopic studies of intermolecular interactions in solutions based on shifts and intensity changes of bands in the spectra of complexes with various compositions (see, for example, Refs 160–162). In particular, the IR spectra of complexes containing a hydrogen bond display bathochromic shifts $\Delta\nu$ of the stretching vibration bands of the proton donor in parallel with an increase in the integral absorption coefficient A relative to the spectral parameters of the isolated proton donor. Many empirical and semiempirical equations relating the $\Delta\nu$ and ΔA values to the stability of complexes characterised by the enthalpy of formation of the hydrogen bond have been proposed. The following relation can be taken as an example:[163]

$$\Delta H = (80 \pm 20) \frac{\nu'_{AH} - \nu''_{AH}}{\nu_{AH}} , \qquad (15)$$

where ν'_{AH} and ν''_{AH} are the frequencies of the stretching vibrations of an AH molecule in the free state and in a complex, respectively.

It seems more correct to use the increment of the integral absorption coefficient, for example in the form of the equation proposed by Iogansen,[164]

$$\Delta H = 2.9 \Delta A^{1/2}, \qquad (16)$$

Table 7. Frequencies of the main vibrations of the H_2O molecule (cm^{-1}) in the free state and in complexes with some inorganic molecules according to the data obtained by IR spectroscopy with matrix isolation.

Inorganic molecule	ν_1	$\Delta\nu_1$	ν_3	$\Delta\nu_3$	ν_2	$\Delta\nu_2$	Ref.

[a] The water molecule acts as a proton donor.
[b] The water molecule acts as a proton acceptor.
[c] The ν values for complexes in an argon matrix are given.

where $\Delta A^{1/2} = (A'_c/m)^{1/2} - (A')^{1/2}$ is the difference between the integral absorption coefficients (in 10^4 cm mmol^{-1}) of the molecules bound in hydrogen-bond complexes (liquid phase) and of free molecules (gas or an inert solvent), and m is the number of hydrogen bonds.

It is reasonable to estimate the stability of the complexes using relations such as Eqns (15) and (16) for series of isotypical compounds under similar conditions.

The solubility of water is an important factor in experimental studies of the molecular state of water in liquid volatile compounds by IR spectroscopy. It is lower than the method sensitivity in liquefied permanent gases and in some polar compounds. Therefore, it is impossible to detect the changes in the intensity or positions of the stretching vibration bands of water due to its interaction with molecules of environment. However, the molecular state of water in liquid volatile inorganic chlorides of Subgroup IVA and VA elements has been studied by IR spectroscopy in sufficient detail.[165–167]

The IR spectrum of an aqueous solution of germanium tetrachloride ($c_{H_2O} < 10^{-2}$ M) in the region of 4000–1100 cm^{-1} displays bands at 3691, 3603, 2845 and 1600 cm^{-1}.[165] The relation between the intensities of the first two bands was found to be the opposite to that known from the literature for the ν_1 and ν_3 bands of water in CCl_4, an inert solvent structurally related to germanium tetrachloride. It was concluded that the vibrations of free water molecules correspond to the bands at 3691 (ν_3) and 1600 (ν_2) cm^{-1}.

The small low-frequency shift of the ν_3 band relative to the gas phase results from van der Waals interaction HOH...$GeCl_4$, whose energy, estimated from the relation between ΔH and $\Delta\nu$ proposed in Ref. 168, was found to be −1.4 kcal mol^{-1}. The band at 3603 cm^{-1} was attributed to the ν(OH) vibrations of the hydroxyl groups in the hydrolysis products, while the band at 2845 cm^{-1} was attributed to the stretching vibration of the HCl molecule. The hydrolysis of $GeCl_4$ in accordance with the simplest scheme

$$GeCl_4 + HOH \leftrightarrows Ge(OH)Cl_3 + HCl, \quad (17)$$

probably occurs only at low concentrations of water in $GeCl_4$ (<10^{-2} M). When the concentration is increased, the intensities of the bands at 3691, 3603 and 1600 cm^{-1} increase, while that of the band at 2845 cm^{-1} decreases. Simultaneously, a series of new bands appear. Together these facts led the authors[165] to the conclusion that complex germanium hydroxochlorides $Ge(OH)_n.Cl_{4-n}$ and oxochlorides $Ge_nO_{n-1}Cl_{2n+2}$ are formed in solution.

The equilibrium of reaction (17) was studied directly in liquid $GeCl_4$ and in a CCl_4 solution. The hydrolysis constant $K_c = 1.74 \times 10^{-3}$ at 20 °C and concentrations of water in the range 10^{-3}–10^{-2} M, together with its temperature dependence in the range of 10–60 °C, were determined. It has been shown[169] that an admixture of water in $GeCl_4$ influences decisively the chemical forms of microadmixtures of sulfur, selenium, boron, silicon, aluminium, titanium, phosphorus and carbon.

The IR spectra of water solutions in $AsCl_3$ display bands at 3659, 3574 and 1600 cm^{-1} assigned to the ν_3, ν_1 and ν_2 vibrations of a water molecule respectively. The ν(OH) vibrations of hydroxyl groups correspond to a band at 3525 cm^{-1}, while the stretching vibrations of the HCl molecule are observed as a band at 2800 cm^{-1}.[167] The energy of the HOH...$AsCl_3$ interaction is somewhat higher than that for $GeCl_4$ and equals −2 kcal mol^{-1}. When the concentration of water is below 4×10^{-2} M, the hydrolysis follows the scheme

$$AsCl_3 + HOH \leftrightarrows As(OH)Cl_2 + HCl, \quad (18)$$

while at higher concentrations, arsenic hydroxochlorides $As(OH)_nCl_{3-n}$ and the oxochloride AsOCl are formed. The hydrolysis constant remains unchanged up to a water concentration of $\sim 10^{-2}$ M and equals 4.2×10^{-3} at 20 °C.

The IR spectrum of a solution of water in $SnCl_4$ displays bands at 3636, 3563 and 1586 cm^{-1} assigned to the ν_3, ν_1 and ν_2 vibrations of the water molecule.[166] In contrast to the IR spectra of solutions of water in $GeCl_4$ and $AsCl_3$ and the spectrum of the $SnCl_4 \cdot n H_2O$ crystal hydrate, the ν_2 deformation vibration band undergoes a bathochromic shift relative to its position in the gas phase. Taking into account the much higher intensity of the ν_2 band compared with those of the ν_3 and ν_1 bands (as in the gas phase), the authors[166] concluded that the intermolecular bond in the H_2O...$SnCl_4$ complex, involving an unshared electron pair of the oxygen atom in the water molecule and the unoccupied orbitals of the tin atom is of the donor–acceptor type, unlike the hydrogen bonds between the molecules of H_2O and $GeCl_4$ or $AsCl_3$. The energy of this interaction was estimated as −2.4 kcal mol^{-1}. Unlike germanium, arsenic, and tin chlorides, the concentration of free water in liquid silicon tetrachloride is lower than 10^{-4} mol%, which is in agreement with the above radio-frequency spectroscopic determinations of water in $SiCl_4$ in the gas phase.[85]

Table 8. Frequencies of the main vibrations (ν/cm^{-1}) of H_2O and H_2S in the free state and in complexes in a nitrogen matrix.[148,150]

Type of vibration	H_2O...HSH		H_2O			H_2S

[a] The half-width of the ν^{str} overall band at half-height. [b] The integral absorption coefficient.

Hence, the equilibrium on the hydrolysis of $SiCl_4$ is almost completely shifted to the right.

$$SiCl_4 + n\,HOH \leftrightarrows SiCl_{4-n}(OH)_n + n\,HCl\,. \quad (19)$$

A similar behaviour of water is observed in phosphoryl chloride, in which the equilibrium of the reaction

$$POCl_3 + HOH \leftrightarrows PO(OH)Cl_2 + HCl\,, \quad (20)$$

is also shifted to the right,[76] and free water is not detected.

Information about the molecular state of water in liquid volatile inorganic hydrides of Group IV–VI elements at concentrations ca. $10^{-2}-10^{-3}$ mol% was obtained by a number of workers.[73,77,170-172] The considerable experimental difficulties encountered in studying the IR spectra of dilute solutions of water in hydrides come from the relatively 'narrow range of existence' of the liquid phase of hydrides and their low boiling points (<273 K). However, IR spectra can be recorded at higher temperatures (~ 300 K for all hydrides except silane, whose b.p. is 269.4 K) at increased pressures, but the cells must then withstand pressures of several tens of atmospheres. The appropriate experimental techniques are reported in Ref. 174. As noted above, the very low solubility of water in liquefied permanent gases at their boiling points precludes the recording of the bands of dissolved water even for considerable thicknesses of the absorbing layer (up to 100 mm). It has been shown [73] that the same problems in recording the bands of dissolved water arise in studies of systems based on nonpolar silane and germane. In addition, the region of stretching and deformation vibrations of water includes the rather intense overtone and combination bands of these hydrides.[77]

A different situation is observed in the case of dilute solutions of water in liquid hydrides of Group V and VI elements:[175,176] the 3400–3700 cm^{-1} region displays bands of the antisymmetric (ν_3) and symmetric (ν_1) vibrations of water molecules (similarly to solutions of water in organic solvents [177] and in liquid volatile chlorides) and a band due to deformation vibrations (ν_2); the integral absorption coefficient of these bands increases approximately by an order of magnitude compared with that in the gas phase (Table 9). This suggests that hydrogen bonds are formed between the molecules of dissolved water and the hydrides. The estimated energies of intermolecular interactions are presented in Table 10. For ΔH, the ranges of values estimated by Eqn (16) are given,[170-172] since the exact number m of hydrogen bonds formed by a water molecule with the hydrides in the liquid phase is unknown. For this reason, the limiting values were adopted — one and two H-bonds per molecule of water, representing the upper and lower limits of the strength of the hydrogen bond.

It follows from these data that, first, the stability of complexes of hydrides of Group VI elements with a proton donor — water — is higher than that of the complexes of Group V elements. Second, the stability of complexes of hydrides of the Fourth Period elements is lower than that of complexes of hydrides of the Third Period elements. It should be emphasised once more that these conclusions refer to two-component liquid solutions with a great excess of the proton acceptor. Nevertheless, the trends noted above are also observed in the calculated enthalpies of the hydrogen bond (see Table 5). The ΔH_{298} values for the complexes of PH_3 and H_2S fall within the range of experimental values. On the whole, the above series of the hydrogen bond strengths follow from the analysis of $\Delta\nu_s$, the low-frequency shift of the band due to the stretching vibrations of the proton donor (the HF molecule) in complexes with hydrides in an argon matrix,[178] although, according to these data, the complex of phosphine is more stable than that of hydrogen sulfide. Also, the data obtained do not contradict the results obtained in studies of the microwave spectra of complexes of certain hydrides in the gas phase [179] and by quantum-chemical calculations for such complexes.[180]

IR spectroscopy has been used[77,170-172] to determine the solubility of water in hydrides of Group V and VI elements, which are correlated with the energy of intermolecular interaction. A similar relationship was also established for the liquid–vapour separation factors α in the systems water–hydrides of Group V and VI elements:[77] although the ideal separation factors are much less than unity, the α value determined experimentally from solubility data is only a little less than unity for the H_2S-H_2O system and is markedly higher than unity for the AsH_3-H_2O system. As follows from Table 10, the intermolecular interaction energies in the systems differ markedly.

According to experimental results,[77] gaseous hydrates stable up to ~ 305 K are formed in saturated solutions of water (water concentrations of $10^{-1}-10^{-2}$ mol%) in hydrides of Group V and VI elements. A thermodynamic analysis of the structures of the hydrates and of the conditions governing their formation in processes involving the extensive purification of hydrides has been carried out.[181]

Table 10. Energy characteristics of hydride–water complexes.

Complex	$\Delta\nu_3$/cm^{-1}	$-\Delta H_{298}$/ kcal mol^{-1}, according to data in Refs		$-\Delta H^{theor}$/ kcal mol^{-1}	$\Delta\nu_s$/cm^{-1}
		77	170–172		
HOH...NH_3	–	–	–	4.7	913
HOH...PH_3	60	1.3	0.4–1.6	0.8	327

A review[177] summarises the main spectroscopic parameters of water dissolved in various organic solvents. Some of these data are presented in Table 11. It is seen that an increase in the proton-accepting capacity of solvent molecules (basicity), characterised by the donor number (DN) leads to an increase in the low-frequency shift of the ν_1 and ν_3 bands and a decrease in the difference between them (the bands of symmetric and anti-symmetric vibrations approach each other). Liquid chlorides and hydrides can also be regarded as nonaqueous inorganic solvents. For example, germanium tetrachloride, phosphine and arsine are located in Table 11 between carbon disulfide and toluene, arsenic tetrachloride is located between anisole and epichlorohydrin (DN = 9 – 14), while hydrogen sulfide, hydrogen selenide, and tin tetrachloride occupy a position between benzonitrile and acetonitrile (DN = 13 – 18).

IV. Conclusion

Modern spectroscopic methods make it possible to solve fairly complex problems in the determination and study of the molecular state of water present as an admixture in high-purity volatile inorganic compounds. The theoretical instrumental limit in the detection of water by diode laser spectroscopy and sub-millimetre spectroscopy (10^{-8} mol%) is quite sufficient for analyses in studies on the extensive purification of these compounds. The detection limits actually achieved are generally one or two orders of magnitude higher due to methodologology difficulties resulting from the impossibility of taking full account of all the ways in which background moisture can enter the substance analysed. The use of unique apparatus, the long preparation of spectrometers for analyses, and the use of expensive cooling agents (liquid helium) make the cost of one analysis rather high.

The optimisation of methods for the removal of water from volatile compounds and of the processes for the gas-phase synthesis of materials involving these compounds, as well as investigation of processes associated with the storage of high-purity compounds, especially those tending to react chemically, require data concerning not only the concentration of the water admixture but also the form of its existence in the gas and liquid phases. It was shown above that such information has been obtained for solutions of water in certain liquid high-purity chlorides and hydrides. However, the data on the stability of the resulting complexes, their concentration and the mean number of intermolecular bonds are clearly insufficient. The methods of diode laser spectroscopy and microwave high resolution spectroscopy are promising for investigating the mechanism and thermodynamics of complex formation reactions involving water in the gas phase under equilibrium conditions. However, systematic studies in this field are so far lacking.

It seems very important from the practical viewpoint to study in greater detail the effect of the formation of molecular complexes between the main compound and an admixture in the equilibrium phases on the quantitative characteristics of the processes in the interphase separation of admixtures. It is likely that the weak molecular complexes formed by admixture molecules with those of the main compound due to specific and non-specific interactions can be considered as a new class of admixtures in high-purity substances.

It should be noted that the investigation of the nature of intermolecular interaction in such systems and of the dependences of the characteristics of molecular complexes on the structure of their fairly simple constituent molecules is outside the scope of the chemistry of high-purity compounds but is of definite interest for other branches of chemistry and physics which deal with problems of the theory of intermolecular interactions, as well as for biochemistry.

V.	Conclusion	836

Abstract. The literature data on the photochemical reactions of neptunium, plutonium, and americium in HNO_3, $HClO_4$, HCl, H_2SO_4, and Na_2CO_3 solutions as well as certain extraction systems are surveyed. The mechanisms of the photochemical reactions are discussed and it is concluded that those proposed in the literature do not account for those reactions in solutions occurring without added oxidants or reductants. The possibilities of the practical application of photochemistry in the processing of spent nuclear fuel are examined. The bibliography includes 53 references.

I. Introduction

Numerous photochemical studies have been devoted to the ions of metals with unfilled electron shells. The photochemical properties of uranyl have already been investigated quite fully. The UO_2^{2+} ion can exist in the excited state for hundreds of microseconds, exhibiting strong oxidising properties. Uranyl photochemistry constitutes a large independent field. The principal data accumulated in this field have been presented in a monograph[1] written more than thirty years ago and also in a review.[2] Uranyl photochemistry continues to develop vigorously at the present time.

In recent years, appreciable attention began to be devoted to the ions of other *f* elements: lanthanides (cerium, europium, and samarium) and actinides [the first transuranic elements (TUE) — neptunium, plutonium, and americium]. The photochemistry of the last three elements will be the subject of the present review.

It may be assumed that the photochemistry of TUE began to develop since 1958 when the photochemical reduction of Np(VI) to Np(V) in perchloric acid solutions was observed.[3] Later, in 1965, Indian investigators[4] showed that Pu(VI) is reduced to Pu(IV) in the extraction of plutonium(VI) from acid solutions with a benzene solution of thenoyltrifluoroacetone under illumination and that this process does not occur in the dark. Systematic studies on the influence of light on the chemical behaviour of plutonium and neptunium in solutions began in the 1970s. Reports concerning the photochemical reactions of americium also appeared subsequently.

Despite the more than twenty year history of the photochemistry of TUE, the accumulated data, particularly those obtained in recent years, have not been analysed. There have been only brief reviews on the photochemistry of plutonium and on the application of photochemical processes in the processing of irradiated nuclear fuel. The aim of the present review is to give a systematic account of the available data on the photochemistry of all the transuranic elements and to assess the prospects for its further development.

II. The photochemistry of plutonium and neptunium

1. The photochemistry of aqueous acid solutions

a. Nitric acid solutions

Visible light does not affect the chemical behaviour of plutonium in nitric acid solutions in the absence of additives, but on exposure to UV light (mercury lamps were usually employed) plutonium passes to the Pu(VI) state regardless of the initial valence form — Pu(III) or Pu(IV).[5] The reaction takes place both in air and under a CO_2 atmosphere. Pu(III) is oxidised particularly rapidly. With increase in the concentration of acid (up to 3.5 M), the rate of oxidation also increases. According to the data of Duan Yunfu et al.,[6] the rate of the photochemical oxidation of Pu(III) to Pu(IV) is proportional to the concentrations of Pu(III), H^+, and NO_3^-. The authors[6] believe that the comversion of plutonium to the hexavalent state takes place by disproportionation of Pu(IV) to Pu(III) and Pu(VI). In the presence of H_2O_2, plutonium is quantitatively converted into Pu(III) on UV irradiation and at a higher rate than in the dark.

It is believed[7,8] that, on UV irradiation of any valence form of neptunium — Np(IV), Np(V), and Np(VI) — over a wide range of HNO_3 concentrations (0.1 – 6.0 M), the final form is Np(V). However, it has been noted that other photochemical reactions also occur in solution, for example the oxidation of Np(V) to Np(VI) and the reduction of Np(V) to Np(IV).[8] The quantum yields η of various photochemical reactions of neptunium in nitric acid solutions on irradiation with light at λ = 254 nm have been measured.[8] In the absence of additives in 1.0 M (solution I) and 4.0 M (solution II) of HNO_3, the following values of η were obtained:

Process	η for solutions	
	I	II
Reduction of Np(VI) to Np(V)	0.03	0.003
Oxidation of Np(IV) to Np(V)	0.053	0.017
Oxidation of Np(V) to Np(VI)	0.015	0.022

These reactions proceed also under the influence of light at λ = 300 nm but with much lower yields.

Somewhat different results have been obtained by Galkin et al.,[9] although they employed the same light source as Nemodruk et al.[7] Galkin et al.[9] note that Np(V) accumulates only at $[HNO_3] < 1$ M, whereas at $[HNO_3] = 2$ and 4 M, the concentration of Np(V) increases only during the first 5–10 min of irradiation and then falls as a result of the formation of Np(VI). The authors explained this by the reversibility of the reaction

$$2NpO_2^{2+} + HNO_2 + H_2O \rightleftharpoons 2NpO_2^{+} + NO_3^{-} + 3H^{+}. \quad (1)$$

The passage of air through the irradiated solution leads to the quantitative formation of Np(VI). The difference between the results obtained in the above two studies[7,9] at identical acid concentrations may be associated with the influence of factors which have not been taken into account, for example, micro-impurities inhibiting or catalysing the photochemical reactions.

The introduction of various additives into nitric acid solutions with $[HNO_3] = 0.1-4$ M changes the results of the photochemical experiments. In the presence of urea—a substance which removes NO_2^- ions from the system—it is possible to obtain Np(VI) solutions virtually without an admixture of Np(V).[7,9] However, our data have shown that in weakly acid solutions, even those containing many NO_3^- ions, neptunium(VI) is not formed. Thus, when $NpO_2(ClO_4)_2$ is irradiated in 1×10^{-3} M $HClO_4$ + 1 M $LiNO_3$ in the presence of 0.1 M urea, Np(V) is formed quantitatively. The presence of hydrogen peroxide accelerates the photo-chemical oxidation of Np(IV) to Np(V), but the HNO_3 concentration should not then exceed 1 M,[7] while the introduction of hydrazine leads to the photochemical reduction of Np(V) to Np(IV), but the reaction does not go to completion. Its quantum yield in 4 M HNO_3 was found to be 0.006.[8] In ethanol, neptunium(VI) is reduced photochemically to Np(V) in 0.094 yield $\{[HNO_3] = 4$ M$\}$.[8]

The photochemical reactions of neptunium in nitric acid solutions in the presence of uranyl have been investigated in a number of studies (see, for example, Refs 9–11). The aim of these studies was to investigate the possibility of using the photochemical reactions for the separation of neptunium from uranium and plutonium in technological processes. It was observed that at low concentrations ($\sim$5 g litre^{-1}) uranyl does not influence the photochemical reactions and the dark equilibria involving neptunium. However, at high uranyl concentrations ($\geqslant$100 g litre^{-1}), uranyl is photolysed, which increases the yield of pentavalent neptunium. This effect has been attributed to the sensitising effect of uranyl and the photochemical formation of NO_2^- from NO_3^- [9] and to the stabilisation of Np(V) towards oxidation as a result of the formation of the cation–cation complexes between Np(V) and UO_2^{2+}.[11]

In one of the studies, a photocatalyst, namely Pt/TiO_2, was introduced into a nitric acid solution of neptunium $\{[HNO_3] = 3$ M$\}$ before irradiation.[12] In solutions without added urea, the photocatalyst does not affect the results, i.e. the neptunium is entirely converted, and at the same rate, into Np(V). On the other hand, in the presence of urea the photocatalyst accelerates the transition of neptunium to the hexavalent state to the extent of $\sim$30%, ensuring an almost 100% yield of Np(VI). The authors believe that this acceleration is associated with the occurrence of the reactions on the surface of the photocatalyst (PC).

$$PC \xrightarrow{h\nu} h^{+} + e^{-} \text{ (where } h^{+} = \text{hole)}, \quad (2)$$

Hydrated electrons react with the nitrate ion while the hole participates in the oxidation of the neptunium:

$$NpO_2^{+} + h^{+} \longrightarrow NpO_2^{2+}. \quad (3)$$

b. Perchloric acid solutions

Not only oxidation-reduction reactions of plutonium but also its ability to form polymers have been investigated in perchloric acid solutions exposed to light. In contrast to the behaviour in nitric acid solutions, in $HClO_4$ the final result depends on the initial form of the plutonium. When aerated solutions are irradiated, the Pu(III) is partly converted into Pu(IV). Plutonium(VI) remains unchanged on irradiation.[5] These data were obtained at acid concentrations >0.5 M. Our experiments with dilute $HClO_4$ solutions (10^{-3} M) showed that, on exposure to the UV light from the SVD-120a mercury lamps, Pu(VI) is fully converted into Pu(V).

In the presence of reductants, the photochemical behaviour of plutonium in $HClO_4$ changes. The introduction of H_2O_2 stabilises Pu(III), suppressing fully its oxidation to Pu(IV).[5] Oxalic acid reduces Pu(VI) to Pu(IV), which results in the precipitation of Pu(IV) oxalate.[4] Ethanol reduces photochemically both Pu(VI) to Pu(V) and Pu(IV) to Pu(III).[13] The authors[13] were the first to determine the quantum yields of the photochemical reaction involving plutonium. For the reaction

$$PuO_2^{2+} + C_2H_5OH \xrightarrow{h\nu} PuO_2^{+} + C_2H_5O^{\cdot} + H^{+}, \quad (4)$$

[taking into account the disproportionation of the Pu(V) obtained], η was found to be 0.02, while for the reaction

$$Pu^{4+} + C_2H_5OH \xrightarrow{h\nu} Pu^{3+} + C_2H_5O^{\cdot} + H^{+}, \quad (5)$$

the quantum yield was 0.03.

Irradiation with UV light accelerates sharply the disproportionation of Pu(IV) and a pseudoequilibrium is established, differing appreciably from the dark equilibrium: whereas in the dark or with room illumination, the disproportionation of the 9.9×10^{-3} M Pu(IV) solution in 0.47 M $HClO_4$ continues for tens of hours, on irradiation with UV light only a few hours are required and the degree of conversion of Pu(IV) increases appreciably: the pseudoequilibrium constant for the reaction

$$3\,Pu^{4+} + 2\,H_2O \overset{h\nu}{\rightleftharpoons} 2\,Pu^{3+} + PuO_2^{2+} + 4H^{+}, \quad (6)$$

is 0.025, whereas the constant for the dark reaction is 0.0086.[13–15] The process is reversible, i.e. when irradiation stops the system returns to the dark equilibrium.

Under the influence of UV light, the degradation of the polymeric forms of Pu(IV) accelerates severalfold in 0.47 M $HClO_4$.[13–15] Such solutions were prepared by precipitating plutonium hydroxide with its subsequent dissolution in $HClO_4$ at the required concentration. Under these conditions, both freshly prepared solutions and solutions kept for some time undergo photochemical decomposition. Furthermore, in solutions at a lower $HClO_4$ concentration (0.13–0.16 M) the dark decomposition of the polymers does not occur at all and only the photochemical decomposition is observed.

In the first study on the photochemistry of neptunium,[3] it was established that the UV irradiation of perchloric acid solutions of Np(VI) results in the reduction of the latter to Np(V). The concentrations of ^{237}Np was 0.045 M, while the concentration of the acid was 0.22–1.00 M. The quantum yield of this reaction was measured ($\eta = 0.032 \pm 0.011$). It has been suggested that the reductant is the photolysis product of water. Our data also indicate that, on irradiation with UV light in dilute $HClO_4$ (10^{-3} M), Np(VI) is fully reduced to Np(V). According to other data,[16] in sufficiently concentrated solutions of perchloric acid Np(IV) is oxidised to Np(V), while the latter is oxidised to Np(VI). Friedman et al.[17] believe that mainly photochemical reactions involving the oxidation of neptunium take place in perchloric acid solution without additives. They found that, following an increase in the $HClO_4$ concentration from 0.1 to 4.0 M, the quantum yield in the oxidation of Np(IV) to Np(V) falls from 0.02 to 0.0049, while the quantum yield in the oxidation

of Np(V) to Np(VI) increases from 0.004 to 0.010 and further (for light at $\lambda = 254$ nm).

In the presence of ethanol (acetaldehyde or other moderately strong reductants), the Np(VI), Np(V), and Np(IV) ions are capable of being photochemically reduced.[16,17] Prolonged irradiation results in the conversion of all the neptunium to the tetravalent state, a process which may be used for analytical purposes.[16] The quantum yields of the reactions of different neptunium ions with ethanol are within the limits from several thousandths to several hundredths.[17]

The photochemical oxidation of Np(V) in perchloric acid solutions with xenon trioxide has been investigated.[18] The ionic strength of the solution was kept constant at 2 with the aid of sodium perchlorate. The reaction is first order relative to XeO_3 and zero order relative to Np(V). It obeys the equation

$$\frac{d[Np(V)]}{dt} = k_1[XeO_3].$$

Thus the photochemically active substance in this reaction is XeO_3 and the rate of reaction is limited by the rate of its photochemical decomposition. It does not change when the $HClO_4$ concentration is raised from 0.5 to 2.0 M. The constant k_1 depends on the intensity of the irradiation and the spectral composition of the light. Under the experimental conditions, the average value of k_1 obtained was 6.28×10^{-6} s^{-1}. In the absence of light, the reaction is very slow and proceeds via a different mechanism.

c. Hydrochloric acid solutions

When hydrochloric acid solutions of Pu(III) with [HCl] = 0.5–5.5 M are irradiated with UV light in air, Pu(IV) gradually accumulates. Under a CO_2 atmosphere, the process is somewhat slower. The oxidation of Pu(IV) to Pu(VI) is not observed under these conditions[5] (plutonium concentration $\sim 10^{-3}$ g ml^{-1}). A mixture of Pu(IV) and Pu(VI) hardly changes on UV irradiation. In the presence of hydrogen peroxide, Pu(VI) is reduced to Pu(IV) and partly to Pu(III).

Under the influence of UV irradiation, Np(V) in hydrochloric acid solutions is oxidised to Np(VI), while Np(IV) is initially oxidised to Np(V) and then to Np(VI).[19] At [HCl] > 3 M, the oxidation to Np(VI) is quantitative. Deaeration of the solution does not affect the course of the reaction. Our results show that, in both perchloric and nitric acid solutions, the final form of neptunium depends not so much on the concentration of the anion as on the concentration of H^+. Thus in a solution containing 1×10^{-3} M HCl, 1 M KCl, and 1×10^{-3} M Np(VI), Np(VI) is converted quantitatively into Np(V) on UV irradiation.

In the presence of hydrogen peroxide, Np(IV) and Np(VI) are converted into Np(V), while in the presence of ethanol Np(V) and Np(VI) are quantitatively converted into Np(IV), a reaction which can be used for analytical determinations.[19]

d. Sulfuric acid solutions

The behaviour of plutonium in sulfuric acid solutions is similar to its behaviour in hydrochloric acid solutions. Plutonium(III) is converted photochemically into Pu(IV) but not into Pu(VI). Even daylight is sufficient for this purpose. Plutonium(VI) is inert in sulfuric acid solution, but in the presence of ethanol it is converted into Pu(IV).[5]

On the whole, UV irradiation intensifies the reduction of Pu(VI) to Pu(IV) in acid media by reagents such as ethanol, hydrogen peroxide, oxalic acid, ethylenediaminetetraacetic acid (EDTA), and probably others.[5] The possibility of using the above reactions, occurring on UV irradiation, for the monitoring of oxidation–reduction reactions in the processing of irradiated nuclear fuel has been briefly discussed in a review.[20]

Neptunium(IV) in H_2SO_4 solutions at concentrations from 1 to 2 M is oxidised photochemically to Np(V) and further to Np(VI), the oxidation being quantitative after prolonged irradiation. At $[H_2SO_4] > 2$ M, Np(IV) is also detected in the reaction mixture after prolonged irradiation and its amount is greater the higher the acid concentration.[21]

Neptunium(V) is oxidised photochemically to Np(VI); the rate of oxidation increased with increase in the H_2SO_4 concentration. At $[H_2SO_4] = 1-3$ M, the oxidation is quantitative. Nemodruk et al.,[21] who used at PRK-7 lamp, required 20 min to complete the reaction.

The introduction of ethanol, suppresses the oxidation of Np(IV) and Np(V) and at ethanol concentrations of several per cent Np(V) is reduced quantitatively to Np(IV).[21]

Novikov[22] considered the photochemical reactions of neptunium in acid solutions from the standpoint of its isolation and determination.

e. The mechanisms of the photochemical reactions in acid solutions

The mechanisms of the photochemical reactions of plutonium and neptunium in acid solutions were not investigated in the studies examined above. Only certain hypotheses were put forward. For example, perchloric acid does not absorb light from the mercury lamp, so that in this medium the reaction should begin with the excitation of plutonium or neptunium ions. It has been suggested[17] that, after the excitation of the Np(III), Np(IV), or Np(V) ions, they are oxidised by the perchlorate ions. It has also been suggested that plutonium ions are also excited in sulfuric acid, since the oxidation of Pu(III) takes place even under the influence of the usual room illumination, where the photolysis of sulfate ions is impossible. On the other hand, in nitric acid, UV light leads to the photolysis of the NO_3^- ion.[7]

$$NO_3^- \xrightarrow{h\nu} NO_2^- + O^\cdot. \quad (7)$$

This accounts for the accumulation of the Np(V) ions: oxygen oxidises the lower valence forms of neptunium, while the permanent presence of nitrite in solution leads to the reduction of Np(VI).[7]

According to Nemodruk et al.,[19] the oxidation of Np(IV) and Np(V) in hydrochloric acid is associated with the reactions

$$Cl^- \xrightarrow{h\nu} Cl^\cdot + e_{aq}^-, \quad (8)$$

$$Np^{4+} + Cl^\cdot + 2H_2O \longrightarrow NpO_2^+ + 4H^+ + Cl^-, \quad (9)$$

$$NpO_2^+ + Cl^\cdot \xrightarrow{h\nu} NpO_2^{2+} + Cl^-. \quad (10)$$

These reactions result in the formation of hydrated electrons e_{aq}^-, which react with H^+, affording hydrogen atoms, while the latter recombines at a sufficiently high HCl concentration to form H_2. However, one cannot agree with these hypotheses. According to literature data,[23] the rate constant for the interaction of the H atom with Np(VI) is $(4.0 \pm 0.5) \times 10^8$ litre mol^{-1} s^{-1}, which is ~ 500 times smaller than the rate constant for the recombination of H atoms. However, the stationary concentration of H atoms during the irradiation process is lower by many orders of magnitude than the Np(VI) concentration (especially at the end of the reaction), so that Np(VI) is reduced before the recombination of H atoms. Thus the oxidation state of neptunium does not change. A similar situation is characteristic also of other acids.

An alternative explanation of the photochemical reactions of transuranic elements (TUE) may be, in our view, the formation of excimers (dimers) from the excited and unexcited ions. Two TUE ions then participate simultaneously in the reaction, so that the less reactive molecular products are formed instead of radicals. From this standpoint, the oxidation of Pu(III), for example, in perchloric acid solutions can be represented by the reactions

$$Pu(III) \xrightarrow{h\nu} Pu(III)^*, \quad (11)$$

$$Pu(III)^* + Pu(III) \longrightarrow [Pu(III)^*...Pu(III)], \quad (12)$$

$$[Pu(III)^*...Pu(III)] \longrightarrow 2(Pu^{3+}_{aq} \cdot OH) + H_2, \quad (13)$$

$$Pu^{3+}_{aq} \cdot OH + H^+ \longrightarrow Pu^{4+}_{aq}. \quad (14)$$

A similar mechanism is possible also for the oxidation of Pu(III) and Np(III) in hydrochloric and sulfuric acid solutions and also for the reactions of other oxidation states of plutonium or neptunium in these acids, for example, the reduction of Pu(VI) in dilute perchloric acid:

$$Pu(VI) \xrightarrow{h\nu} Pu(VI)^*, \quad (15)$$

$$Pu(VI)^* + Pu(VI) \longrightarrow [Pu(VI)^*...Pu(VI)], \quad (16)$$

$$[Pu(VI)^*...Pu(VI)] \longrightarrow 2Pu(V) + H_2O_2, \quad (17)$$

$$Pu(VI) + H_2O_2 \longrightarrow Pu(V) + HO_2 + H^+, \quad (18)$$

$$Pu(VI) + HO_2 \longrightarrow Pu(V) + O_2. \quad (19)$$

Bearing in mind that in most cases the preferential formation of higher oxidation states of neptunium is observed with increase in the acid concentration, one may postulate that, at low and high H^+ concentrations, the Np(VI) and Np(V) excimers respectively are formed more effectively, which leads to the respective reduction of Np(VI) or oxidation of Np(V).

In nitric acid, the photolysis of the NO_3^- ion with formation of HNO_2 makes an additional contribution. This is the only medium in which Pu(VI) accumulates photochemically, which is evidently associated with the formation of nitrogen compounds capable of oxidising plutonium to the hexavalent state. In dilute HNO_3 solution, the Pu(VI) reduction reaction predominates, which agrees with the hypothesis of the formation of Pu(VI) [as well as Np(VI) excimers] in dilute solutions. The reaction

$$Pu(VI) + HNO_2 \longrightarrow Pu(V), \quad (20)$$

probably also makes its own contribution.

The acceleration of the disproportionation of Pu(IV) in $HClO_4$ solutions is also associated with the excitation of the plutonium ions themselves. In the presence of reductants, mixed mechanisms are possible where plutonium ions are excited and the additive is photolysed simultaneously.

Thus the studies on the photochemistry of plutonium and neptunium have shown that the reactions in acid media involve the excitation of plutonium and neptunium themselves (similarly to the photochemical reactions of uranyl). However, the mechanisms proposed in the literature do not withstand criticism in our view.

2. The photochemistry of alkaline carbonate solutions

a. The flash photolysis of Pu(VI)

There has been only one communication on the flash photolysis of the ions of transuranic elements.[24] This is the photolysis of the PuO_2^{2+} ions in sodium carbonate solution with $[Na_2CO_3] = (5-30) \times 10^{-3}$ M at pH 12.5. The authors[24] designed and constructed a special apparatus for the flash photolysis of the actinides, which included a glove box and a system for the evacuation of the specimens.[25] During flash photolysis,[24] the reaction is similar to the pulse radiolysis of actinide ions, including their radiolysis in carbonate media (see, for example, Gogolev et al.[26]). The authors were able to demonstrate the possibility of the oxidation of Pu(VI) to Pu(VII) by the CO_3^- radical-ion formed on photolysis of the carbonate ion. However, in the medium investigated, Pu(VII) is very unstable and disappears with a rate constant of $(7.61 \pm 0.09) \times 10^2$ s^{-1}. The constant is independent of the pH in the range from 10 to 12.6, of the initial Pu(VI) concentration, and also of the CO_3^{2-} concentration in the range 5–30 mM. In a CO_3^{2-} free medium Pu(VII) is not formed. These results appear somewhat surprising, since in the pulsed radiolysis of N_2O-saturated neptunium(VI) carbonate solutions Gogolev et al.[26] observed the formation of Np(VII) only in the presence of NaOH at a concentration of the latter not less than 0.01 M.

b. The photochemical oxidation of Np(VI)

In the only study on the photochemistry of neptunium in alkaline carbonate solutions,[27] it was reported that Np(VI) had been oxidised to Np(VII) on irradiation with the light from a mercury lamp in a nitrous oxide-saturated solution containing 0.09 M LiOH and 0.28 M K_2CO_3. It is known[28] that neptunium(VII) can be most readily obtained in an alkaline solution, but the photochemical oxidation of Np(VI) to Np(VII) does not occur in an alkaline solution without additives. Under the influence of UV light, the CO_3^{2-} ion is converted into the radical oxidant CO_3^-, while N_2O captures the hydrated electrons, whereupon yet another oxidant is obtained — the radical-ion O^-:

Thus the reaction does not proceed due to the excitation

$$CO_3^{2-} \xrightarrow{h\nu} CO_3^- + e^-_{aq}, \quad (21)$$

$$N_2O + e^-_{aq} \longrightarrow N_2 + O^-, \quad (22)$$

$$O^- + H_2O \rightleftharpoons OH^\cdot + OH^-, \quad (23)$$

$$OH + CO_3^{2-} \longrightarrow OH^- + CO_3^-. \quad (24)$$

of neptunium itself but is a result of the photochemical decomposition of CO_3^{2-}. The CO_3^- radical-ion or OH is apparently the direct oxidant of Np(VI).

3. The photochemistry of extraction systems containing plutonium and neptunium

In the extraction systems containing plutonium and neptunium organic substances are present, so that the reduction of higher oxidation states of plutonium and neptunium becomes probable and exposure to light can also lead to the photolysis of the organic compounds. As early as 1952, it was noted that, during the extraction of Pu(VI) in the water–hexane system, the partition coefficient decreases as a function of time. The authors[29] postulated that this is associated with the photochemical reduction of Pu(VI) to Pu(IV). The photochemical reduction of microconcentrations of Pu(VI) to Pu(IV) was achieved in nitrate–perchlorate–benzene–thenoyltrifluoroacetone (TTA) and chloride–perchlorate–benzene–TTA extraction systems,[14] Pu(VI) not being reduced in the dark. Somewhat different results were obtained for Pu(VI) in a TTA solution in toluene with [TTA] = 0.5 M:[30] it is reduced slowly over several days even in the dark; on illumination under room conditions or on irradiation with visible light, the rate of reduction increased sharply and became proportional to the light intensity. In benzene, Pu(VI) is reduced photochemically more slowly, while in heptane it is reduced faster than in toluene. The Pu(V) form is reduced further to Pu(IV). No relation was observed between the relative permittivity of the solvents and the rate of the photochemical reduction of plutonium. The influence of added tributyl phosphate on the rate of reduction of Pu(VI) in TTA-containing extraction systems was also investigated.[30] Tributyl phosphate intensifies the extraction and slows down the reduction of Pu(VI) and Pu(V). Choppin and Saito[30] showed that the products of the photochemical decomposition of TTA have a reducing capacity and that plutonium is reduced not only during irradiation but also in its absence — in TTA solutions subjected to preliminary irradiation. The authors were unable to isolate the reductant itself. There have been reports also about the photochemical reduction of Pu(IV) to Pu(III).[31,32] The reduction of Pu(IV) takes place in the aqueous phase and its rate increases with increase in the concentration of H^+ ions. The reduction mechanism is apparently similar to the mechanism of the reduction of Pu(VI) and Pu(V).[31]

Methods for the photochemical reduction of Pu(IV) have been patented in the USA for use in industry.[33,34] The photochemically active substance is in both cases not plutonium itself but uranyl. According to a patent,[33] the organic phase obtained in the extraction purification of irradiated nuclear fuel and containing tributyl phosphate, U(VI), and Pu(IV) is treated with tributyl phosphite and H_3PO_4 and is irradiated with UV light. Uranyl is then reduced by tributyl phosphite to U(IV), which reduces Pu(IV) to Pu(III). Tributyl phosphite is oxidised in this process by uranium(VI) to tributyl phosphate, as a result of which the re-extraction of plutonium is achieved without introducing additional substances. Another patent[34] describes the use of hydrazine for the photochemical reduction of uranyl to U(IV), the latter reducing in its turn Pu(IV) to Pu(III). These reactions are also employed to separate plutonium from uranium with the aid of the tributyl phosphate extraction system.

Thus, in the extraction systems considered, the photochemical reactions involve the photolysis of the additive — TTA or uranyl, and not the excitation of the plutonium ion itself.

Like plutonium(VI), neptunium(VI) can also be reduced by the TTA photolysis product in extraction systems.[30] Thus in the dark Np(VI) is stable in 0.5 M TTA solution in toluene, but on illumination under room conditions it is reduced in several hours.

4. The use of photochemistry for the extraction of neptunium from irradiated nuclear fuel

The photochemical formation of neptunium(V) in nitric acid solutions, including those having a composition similar to those employed in the purex process, may serve as the basis for the extraction of neptunium from irradiated nuclear fuel.[35-37] (This process has been patented in the USA.[38]) Thus it becomes possible to separate Np(V) from plutonium(IV) and uranium(VI). The krypton-fluoride excimer laser may be used to increase the irradiation intensity. The authors[35-37] prepared the neptunium solutions for irradiation in nitric acid with $[HNO_3] = 0.75-3$ M in the following way: Np(IV) was obtained by reducing Np(V) with iron sulfamate, whilst Np(VI) was prepared by oxidising Np(V) with potassium permanganate. On irradiating these solutions with light from a krypton-fluoride laser, neptunium(V) is formed even in the presence of an excess of oxidant or reductant.[35,37] This makes it possible to introduce the photochemical method into the usual extraction process, for example into the purex process, without its significant modification. Fukasawa et al.[39] investigated the stability and extraction of the Np(VI) obtained photochemically in nitric acid solution with $[HNO_3] = 3$ M in the presence of urea. They showed that a 30% solution of tributyl phosphate in dodecane may be used to extract the Np(VI) obtained photochemically and that irradiation in the course of prolonged extraction improves the results, compensating for the partial reduction of Np(VI) in the organic phase.

The possibility of separating neptunium and plutonium in nitric acid solutions with the aid of photochemical methods has also been considered by Wada et al.[40] When a hydrazine-containing nitric acid solution with $[HNO_3] = 3$ M is irradiated with the light from a 150 W mercury lamp, Pu(III) is oxidised to Pu(IV) to an extent greater than 95%, while neptunium remains as Np(V). This combination is optimal for the separation of neptunium and plutonium by extraction with tributyl phosphate in dodecane.

5. The photochemical dissolution of plutonium dioxide

A familiar radiochemical problem, the difficulty of dissolving plutonium dioxide, led Panigrahi et al.[41] to try to use UV light for this purpose. The dissolution was carried out in hydrochloric acid in the presence of uranyl and hydrazine with exposure to the light from a mercury lamp. The authors were able to achieve the dissolution of PuO_2 even at room temperature. For example, at $[HCl] = 5$ M, $[UO_2^{2+}] = 0.015$ M, and $[N_2H_4] = 0.2$ M, 95.6% of PuO_2 dissolved in 5 h. At a higher hydrochloric acid concentration, the dissolution is impaired. This effect is attributed to the excitation of the PuO_2 surface and also to the photochemical generation of U(IV). The following reactions were postulated:

$$PuO_2^*(\text{solid}) + U(IV) \longrightarrow Pu(III)_{aq} + U(VI), \quad (25)$$

$$PuO_2^*(\text{solid}) + N_2H_4 \longrightarrow Pu(III)_{aq} + N_2. \quad (26)$$

III. The photochemistry of americium

1. The photochemical reactions of americium in bicarbonate–carbonate solutions

The possibility of photochemical reactions with participation of americium was pointed out as early as 1981.[42] It was noted that americium is probably more difficult to photolyse than neptunium and plutonium. The first communication concerning the use of photochemistry for the changing of the oxidation states of americium appeared in 1992.[43] In this[43] and subsequent studies,[44-47] the photochemical behaviour of americium in bicarbonate–carbonate solutions was investigated. It was observed that, on irradiation with the UV light from a mercury lamp, Am(III) may be oxidised in such solutions to Am(IV). The most complete conversion of Am(III) into Am(IV) (up to ~60%) occurs at pH 9–10 and $[CO_3^{2-}] = 1-2$ M, the quantum yield of the reaction reaching 0.3 under these conditions. The further oxidation of Am(IV) to Am(V) and Am(VI) was not observed. At pH 11 and above, Am(III) is not oxidised at all.[45] The characteristic features of the photochemical oxidation of americium(III) in bicarbonate–carbonate solutions in the presence of specially introduced oxidants have been discussed in a number of studies.[44,46,47]

By employing XeO_3 and $S_2O_8^{2-}$, BrO^-, and BrO_3^- ions, it is possible to oxidise americium photochemically in bicarbonate–carbonate media to both the IV and the VI states. The quantum yields in the photochemical oxidation of Am(III) to Am(IV) in bicarbonate–carbonate solutions at pH ~ 9.9 are 1.07 for $S_2O_8^{2-}$, 0.56 for BrO^-, and 0.20 for BrO_3^-.[45] The possibility of the further oxidation of americium depends mainly on the pH of the solution and the carbonate concentration: at pH 9–10 and $[CO_3^{2-}] > 1$ M, Am(IV) is obtained quantitatively, while at pH 11 and above or at low concentrations of the bicarbonate–carbonate solution the product is Am(VI). The results for the sodium and potassium solutions are similar; the only difference is the possibility of obtaining Am(IV) in concentrated K_2CO_3 solutions (4 M and above), whereas only Am(VI) is formed in Na_2CO_3 soutions. Americium(III) is oxidised photochemically to Am(IV) also in bicarbonate–carbonate solutions saturated with N_2O.[47] Thus it is possible to obtain an Am(IV) solution without the addition of extraneous substances. It is noteworthy that, before the employment of photochemistry, the only method for the preparation of Am(IV) in bicarbonate–carbonate solutions remained the electrochemical procedure.[48]

Am(V) is also photochemically reactive in bicarbonate–carbonate solutions. On irradiation with UV light, it disproportionates partly to Am(IV) and Am(VI), traces of Am(III) appearing under these conditions.[49] Ultimately the solution contains a mixture of different oxidation states of americium, which enter into both photochemical and dark reactions with one another. The quantitative formation of any oxidation states is not therefore observed. The quantum yield of the photochemical disproportionation of Am(V) has been estimated as ~0.003.

2. The mechanisms of the photochemical reactions of americium

As mentioned above, the carbonate ion is a photochemically reactive species affording the CO_3^- radical oxidant and e_{aq}^- on photolysis [see Eqn (21)]. This feature has been used for the oxidation of plutonium(VI)[24] and neptunium(VI).[27] The oxidation potential of the CO_3^- radical-ion enables it to oxidise also americium (III) in bicarbonate–carbonate media:

$$Am(III) + CO_3^{\cdot-} \longrightarrow Am(IV) + CO_3^{2-}. \quad (27)$$

This reaction does indeed take place, but it is effective only in the presence of N_2O, which reacts with e_{aq}^- [see Eqn (22)]. On the other hand, in solutions without N_2O or oxidant ions, the same difficulties arise as in acid solutions of neptunium and plutonium, namely e_{aq}^- should ultimately reduce the Am(IV) formed. For this reason, according to Shilov and Yusov,[50] Am(III) is oxidised in this case too via the formation of excimers. Within the excimer, Am(III) is oxidised by water, from which a H_2 molecule, which is a relatively weakly reactive reductant, is split off and the dimer decomposes into two Am(IV) complex species.

$$Am(III)^* + Am(III) \longrightarrow [Am(III)^*...Am(III)], \quad (28)$$

$$[Am(III)^*...Am(III)] \longrightarrow 2\,Am(IV) + H_2. \quad (29)$$

The incomplete oxidation of Am(III) to Am(IV) indicates the occurrence also of the reverse photochemical reaction — the reduction of Am(IV) to Am(III).[50] One cannot rule out the possibility that it too proceeds via a stage involving the formation of excimers.

If the photochemical oxidation of americium takes place in a solution containing XeO_3 or the oxidant ions $S_2O_8^{2-}$, BrO^-, or BrO_3^-, the reaction proceeds as a result of the photolysis of the latter, for example:

$$S_2O_8^{2-} \xrightarrow{h\nu} 2\,SO_4^{\cdot-}, \quad (30)$$

$$BrO^- \xrightarrow{h\nu} Br^{\cdot} + O^-, \quad (31)$$

$$Br^{\cdot} + Br^- \longrightarrow Br_2^{\cdot-}, \quad (32)$$

$$Br_2^{\cdot-} + CO_3^{2-} \longrightarrow Br_2 + CO_3^{\cdot-}, \quad (33)$$

$$SO_4^{\cdot-} + CO_3^{2-} \longrightarrow SO_4^{2-} + CO_3^{\cdot-}. \quad (34)$$

This is followed by reaction (27).

3. The photocatalytic properties of Am(III) in bicarbonate–carbonate solutions

Our latest data indicate that Am(III) can serve as a photocatalyst of the oxidation of Np(IV) and Pu(IV) in bicarbonate–carbonate solutions free from other additives. Americium(III) is not itself oxidised quantitatively to Am(IV) under these conditions, but it does catalyse the oxidation of Np(IV) to Np(VI) and of Pu(IV) to Pu(VI).[51,52] The oxidation of neptunium and plutonium is quantitative. The reaction mechanism involves the intermediate formation of Am(IV) (see above) and the subsequent oxidation of Np(IV) and Np(V) or Pu(IV) and Pu(V). Without americium, the photochemical oxidation of Np(IV) or Pu(IV) is not observed.

IV. Reversible charge transfer in americium(III) and curium(III) luminescence quenching processes

It is known that the luminescence of many variable-valence ions may be quenched by an electron transfer mechanism. For example, the luminescence of uranyl is effectvely quenched by many reductants precisely by such a mechanism. This initiates the actual photochemical reduction of uranyl. Reversible electron transfer leading to quenching of the excited states of the Am(III) and Cm(III) ions is a similar reaction. Among the first four transuranic elements, only the ions of these two elements, especially Cm(III), exhibit luminescence in solutions. As a result of the ability of curium and americium to pass to the +4 oxidation state, the luminescence of Cm(III) and Am(III) may be quenched via charge transfer in those cases where the atom of an element capable of being reduced is present in the vicinity of the excited TUE ion. The Am(III) and Cm(III) complexes of unsaturated polytungstate anions of the type $PW_{11}O_{39}^{7-}$ and $SiW_{11}O_{39}^{8-}$, in which the luminescence of curium is significantly weakened while that of americium is altogether absent, may serve as examples. This is associated with the quenching of the luminescence with formation of the Cm(IV)–W(V) or Am(IV)–W(V) charge-transfer state.

An even more pronounced quenching effect with charge transfer is observed in the complexes of the same elements with polymolybdate anions: here there is no luminescence even in the case of curium. As a consequence of the constant close proximity of the TUE and W or Mo ions, the reverse charge transfer takes place after the removal of excitation and ultimately there is no photochemical oxidation of americium or curium. Nevertheless, one cannot rule out the possibility that it may be possible to select conditions under which such a photochemical reaction could be achieved. We emphasise that a reaction of this kind should in fact follow the excitation of the TUE ion and should not be a result of the oxidation of TUE by the products of the photochemical decomposition of the added oxidant. We shall not consider reversible charge transfer here in detail. The reader is referred to a review[53] on the luminescence of TUE, in which there are a series of references to the original studies where the quenching of the luminescence of Am(III) and Cm(III) as a result of charge transfer was investigated.

V. Conclusion

The above survey of the literature permits a series of conclusions.

Firstly, the photochemical method is fairly promising from the standpoint of its application in radiochemical industries. For this reason, its improvement is being continued, including the application of lasers.

Secondly, despite the outward similarity, a significant difference between photochemistry and radiation chemistry should be noted. Oxidation–reduction processes take place in both cases but in radiolysis (be it by γ-quanta, fast electrons, or heavy particles) energy is adsorbed by the medium and the molecules and ions of the latter are excited. On the other hand, in photolysis, the energy entering the system is absorbed preferentially by the solute. The final molecular products in the radiolysis and photolysis of aqueous solutions may be the same: H_2O, H_2O_2, and H_2. However, in radiolysis they are formed as a result of the processes involving the recombination of e_{aq}^-, H, OH, H^+, and OH^- in tracks, whilst in photolysis they are produced by the interaction of the excited molecules with the medium. Certain excited substances decompose, affording radicals. This resembles the situation which obtains on thermal excitation (for example, the decomposition of the $S^2O_8^{2-}$ ions, H_2O_2 molecules, etc.)

Thirdly, the question of the mechanisms of the photochemical reactions in solutions without added oxidants or reductants remains open. We tend to the view that the mechanisms put forward in the literature cannot lead to the occurrence of the observed reactions and believe that the results can be explained by the formation of excimers. However, this hypothesis requires an experimental test.

Fourthly and finally, the photochemistry of transuranic elements has so far been investigated only in acid and carbonate solutions of neptunium and plutonium, in carbonate solutions of americium, and a little in plutonium-containing extraction systems. Thus the possibilities of the photochemistry of TUE have still not been fully discovered and studies involving other media, including neutral, alkaline, complex-forming, etc., may yield very interesting results.

III. Macrocyclic polyunsaturated silicohydrocarbons	843
IV. Physical properties	851

Abstract. The results of studies on polyunsaturated macromolecular and macrocyclic silicohydrocarbons, the skeleton of which is made up of silicon atoms and the $-C\equiv C-$ or $-CH=CH-$ groups or of a combination of these and certain other fragments, are surveyed and treated systematically for the first time. Attention is concentrated on studies in the field of polyunsaturated macrocyclic silicohydrocarbons. The methods of synthesis of macromolecular and macrocyclic silicohydrocarbons, their structures, and physical and chemical properties, are examined. The bibliography includes 110 references.

I. Introduction

Macromolecular polyunsaturated hydrocarbons containing isolated or conjugated multiple bonds have been very widely investigated. They include, in particular, synthetic or natural rubbers, polyethynes, etc.[1] On the other hand, the polymers made up of the $-CR_2CH=CH-$ and $-CMe_2C\equiv C-$ units are little known and difficult to obtain. The question of the existence of organic macrocycles of similar structure was not even formulated for many years and the possibility of the incorporation of $C\equiv C$ bonds in a hydrocarbon ring was regarded at one time as extemely problematical.[2] Macrocycles synthesised by a multistage procedure and having the general formulae $(Me_2CC\equiv C)_n$, where $n = 5-8$, and $(Me_2CC\equiv CC\equiv C)_n$, where $n = 5$ or 6, have been only recently described in a series of publications by Scott and coworkers.[3–10]

The possibility of the existence of macromolecular polyunsaturated silicohydrocarbons, made up of the $-SiR_2CH=CH-$ and $-SiR_2C\equiv C-$ units, was predicted in 1952.[11] It was proposed that they be called polydialkylsilethenes and polydialkylsilethynes respectively. Polymers of this type were obtained in 1960.[12] At the present time, a large number of such polymers with a wide variety of structures have been synthesised and, apart from their theoretical importance, they have acquired a practical importance for the preparation of ceramic materials and fibres and photo- and radiation-sensitive materials. The first macrocyclic silicohydrocarbon — octamethylcyclotetrasilethyne $(Me_2SiC\equiv C)_4$ — was synthesised in 1973. Its preparation initiated fundamental studies on these lines by the authors of the present review and their foreign colleagues. The present review is in fact devoted to the synthesis and study of the macromolecular and macrocyclic silicohydrocarbons and covers the publications in the periodical and patent literature from 1960 up to 1994.

The nomenclature of the compounds considered is fairly simple for polymers and macrocycles with a regular structure. The units from which they are made up are named in accordance with the corresponding hydrocarbon fragment with the prefix sil — for example, polysilbuta-1,3-diene $H(H_2SiCH=CHCH=CH)_nSiH_3$ or permethylcyclooctasil-1,4-but-2-yne $(Me_2SiCH_2C\equiv CCH_2)_8$. The oxa-aza nomenclature is needed to name the polymers and macrocycles under consideration when these have an irregular structure.

II. Macromolecular polyunsaturated silicohydrocarbons

1. Polysilethynes

The first communication on the macromolecular polyunsaturated silicohydrocarbons of the ethyne series — perorganylpolysilethynes $(R_2SiC\equiv C)_n$ — appeared in 1960 when Jenker patented a polymer obtained by the reaction of disodioethyne with diethyldifluorosilane.[12]

Two years later, Korshak and Sladkov[13,14] synthesised analogous polymers from bis(bromomagnesio)ethyne (the lotsich reagent) and dichlorodiorganylsilanes or dichlorodiorganylgermanes.

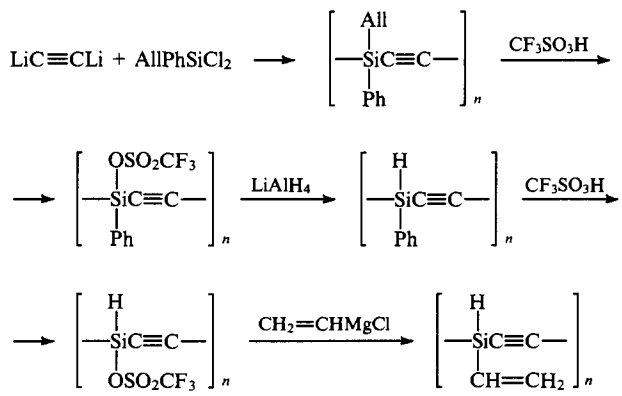
$$BrMgC\equiv CMgBr + R_2ECl_2 \longrightarrow [-R_2EC\equiv C-]_n$$

R = Me, Ph; E = Si, Ge.

The interaction of disodioethyne with dichlorodimethylsilane in hexadecane at 250 °C led to the same polymer $[(Me_2SiC\equiv C)_n]$ in 52% yield.[15,16]

The reaction of dialkylbis(lithioethynyl)silanes with dialkyldichlorosilanes was used for the same purpose.[17,18]

$$R_2Si(C\equiv CLi)_2 + R'_2SiCl_2 \longrightarrow [-R_2SiC\equiv CSiR'_2C\equiv C-]_n$$



R = Me, Ph, $CH=CH_2$; R′ = H, Me, Ph.

The sequence of the monomer units in the copolymer obtained was established by ^{13}C and ^{29}Si NMR spectroscopy.[19]

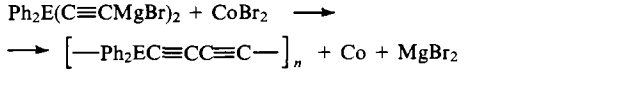
Polyallylphenylsilethyne, synthesised by the reaction of dilithioethyne with allyldichlorophenylsilane, readily splits off the allyl group with formation of the corresponding triflate on reaction with trifluoromethanesulfonic acid. Its reduction with lithium tetrahydroaluminate leads to polyphenylhydrosilethyne. On treatment with trifluoromethanesulfonic acid, the latter splits off also the phenyl group. The resulting triflate reacts with vinylmagnesium chloride to form a polyvinylhydrosilethyne.[20]

All = allyl

Bis(iodomagnesio)ethyne and tetrachlorosilane have been used to obtain materials with a ceramic coating.[21]



2. Polysilalkadiynes

Perorganylpolysilbutadiynes $[-R_2SiC{\equiv}CC{\equiv}C-]_n$ and their germa-analogues $[-R_2GeC{\equiv}CC{\equiv}C-]_n$ were first obtained in 1968 by the thermal polydehydrocondensation of the diethynyldiphenyl derivatives of silane or germane at 150–180 °C under a nitrogen atmosphere.[22]

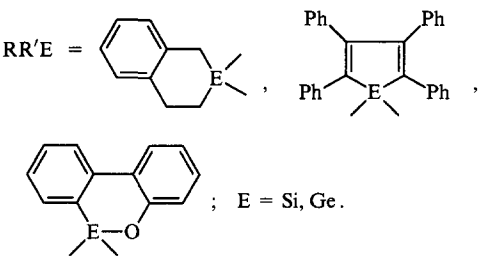
E = Si, Ge.

It proved possible to synthesise the same polymers by treating bis(bromomagnesioethynyl)dimethyl derivatives with $CoBr_2$.[22]

E = Si, Ge.

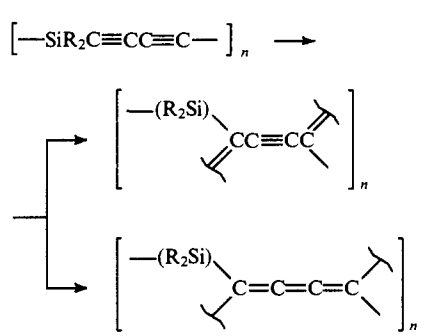
Almost a quarter of a century later, similar polymers were synthesised from dilithiodiethyne and dialkyldihalosilanes or dialkyldihalogermanes.[23–25]

E = Si, Ge; R = Me, Et, Ph, 4-MeC_6H_4; X = Cl, Br.



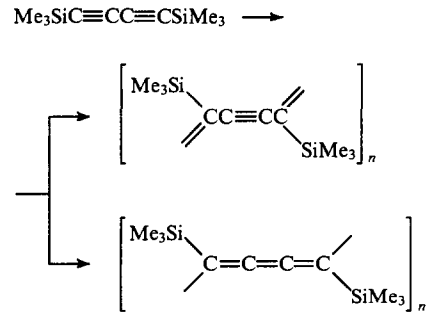
Their pyrolysis at 1400 °C leads to a mixture of silicon carbide and carbon with the ratio SiC : C = 1 : 4.[26,27]

A large series of new preorganylpolysilbutadiynes and their germanium analogues containing fairly complex substituents at the silicon or germanium atoms have been synthesised by thermal polydehydrocondensation of diethynyldiorganylsilanes and the corresponding germanes.[28,29]

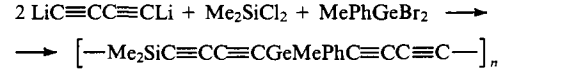


R = Ph, R′ = C_5H_5, $CH{=}CH_2$;

R = R′ = C_6H_5, 4-$MeOC_6H_4$, 4-$Me_2NC_6H_4$;

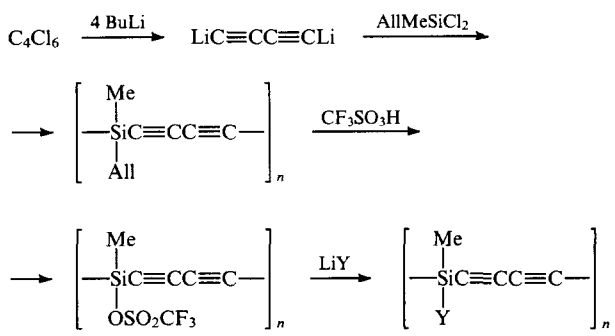


Polymers of the type $[-RR'SiC{\equiv}CC{\equiv}C-]_n$ proved to be high-resistance semiconductors at room temperature.[30]

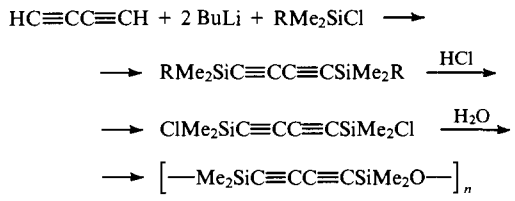


The pyrolysis of organosilicon diethyne polymers in a stream of argon at 1400 °C leads to the formation of a ceramic material containing the SiC group in a yield up to 85%. Before the mineralisation stage (~300 °C), the macrochains are cross-linked with participation of the diethyne fragments.[31]

On heating to 200 °C (for 30 days), bis(trimethylsilyl)-butadiyne gives rise to a polymer with butadienyne and butatriene fragments.[27]

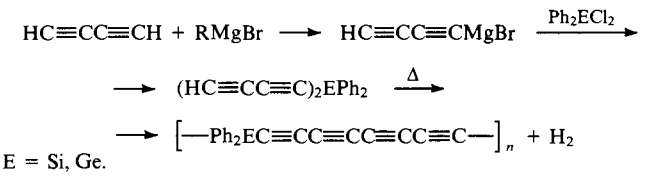


Polymers of the butadiyne series, containing simultaneously silicon and germanium atoms in the main chain, have also been synthesised.[25]



Polyallylmethylsilbutadiyne has been obtained by the reaction of dilithiodiethyne with allyldichloromethylsilane.[20]

Its interaction with trifluoromethanesulfonic acid proceeds with the elimination of the allyl group and the formation of the corresponding triflate. The latter reacts with lithioethynyltrimethylsilane to form polymethyl(trimethylsilylethynyl)silbutadiyne. The reactions with vinyllithium and triphenylsilyllithium proceed similarly.



Y = CH_2=CH, $Me_3SiC{\equiv}C$, Ph_3Si.

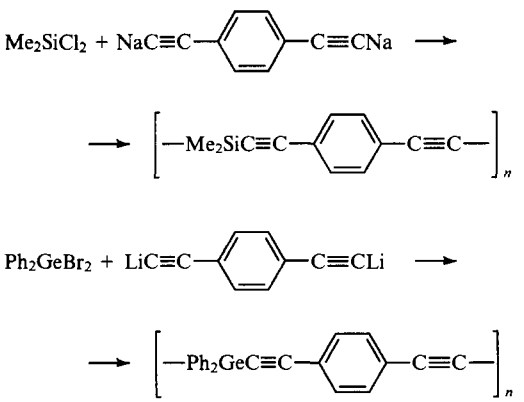
Polymers with alternating SiC≡CC≡C and SiOSi fragments, which are stable up to 700 °C, have been synthesised by the reaction of dilithiodiethyne with chloromethoxydimethylchloro(dimethylamino)dimethyl-, and chlorohydrodimethylsilanes, the monomers obtained being subsequently treated with hydrogen chloride and water.[32]

R = H, MeO, Me_2N.

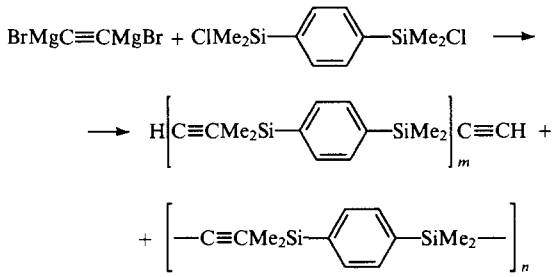
Polymers containing octatetraynyl fragments — perphenylpolysiloctatetraynes [and the corresponding germanium-containing polymers (Ed. of Translation)] — have been synthesised by the thermal polydehydrocondensation of dibutadiynyldiphenylsilane or the corresponding germane.[33]

E = Si, Ge.

3. Polysilethenes

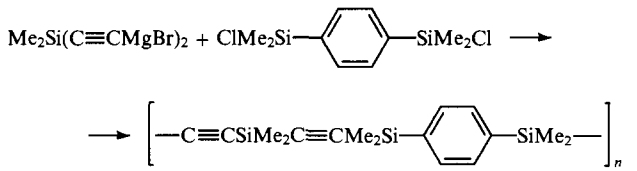


Polydiorganylsilethenes have been obtained by the hydrosilylation of diethynyldiorganylsilanes with the corresponding diorganylsilanes.[34] Their germanium and tin analogues were synthesised by a similar procedure.



R, R′ = Me, Et, Ph; E, E′ = Si, Ge, Sn.

4. Polymers containing the C≡C and C=C multiple bonds and arylene or heteroarylene fragments

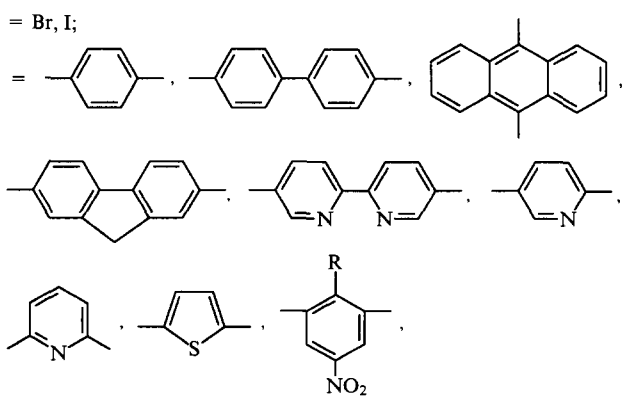


High-molecular-mass polyunsaturated silicohydrocarbons, containing simultaneously triple bonds and phenylene fragments in the macrochain, have been synthesised by the reaction of the sodium or lithium derivatives of 1,4-diethynylbenzene with dichlorodimethylsilane [35,36] or dibromodiphenylgermane.[37]

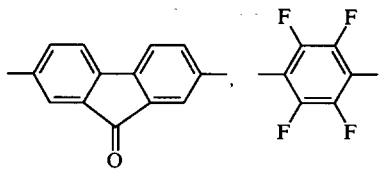
Analogous oligomers and polymers have been obtained from 1,4-bis(chlorodimethylsilyl)benzene and Iotsich reagent or bis(bromomagnesioethynyl)dimethylsilane.[38]

m = 2–6.

Silicoethyne polymers containing ferrocenylene nuclei in the macrochain have been synthesised from dilithio- or bis(bromomagnesioethynyl)ferrocene by reaction with dialkyldichlorosilanes.[39]

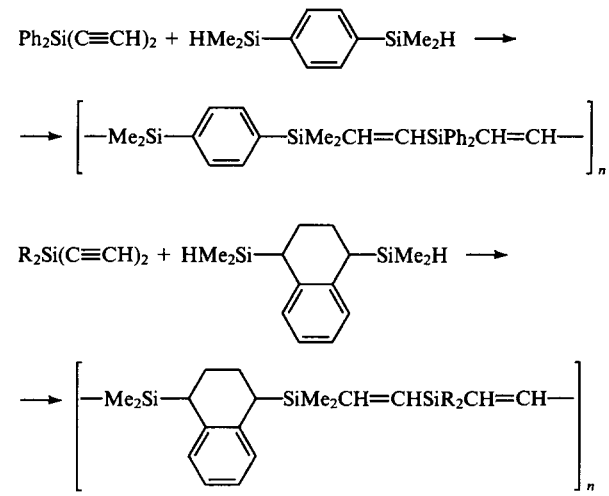


A = Li, MgBr; B = σ-bond, ferrocenylene;

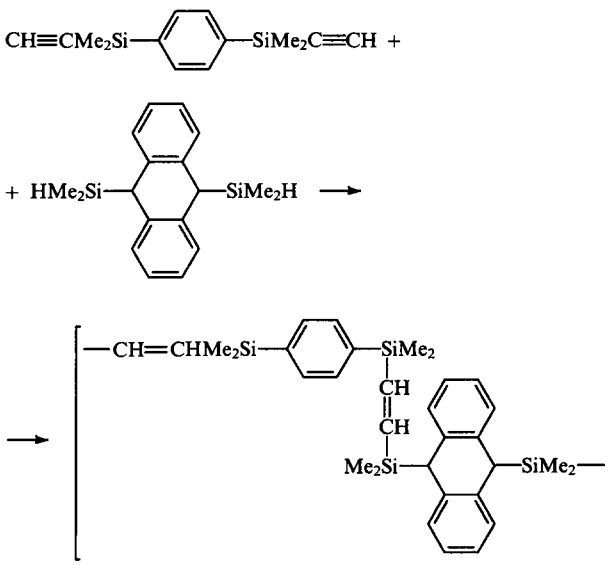


R = H, Me, CH_2=CH, Ph, ferrocenyl.

The palladium chloride-catalysed cross-polycondensation of dihaloarenes with diethynylsilanes affords a large series of silicoethyne polymers with arylene or heteroalylene fragments in the chain.[40]

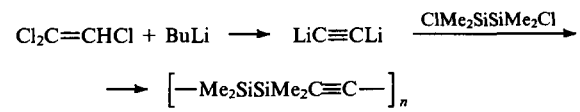


X = Br, I;

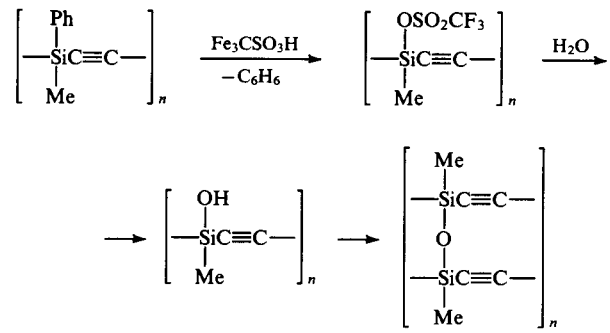


Z = 

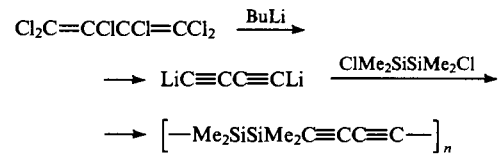
R = NH_2, NMe_2, OH.



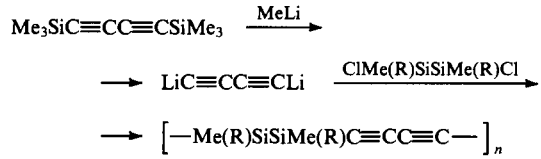
Polymers containing double bonds C=C and arylene fragments in the main chain have been obtained by hydrosilylating diethynyldiorganylsilanes with 1,4-bis-(dimethylsilyl)benzene [41] and 1,4-bis(dimethylsilyl)tetralin [42] and also by hydrosilylating 1,4-bis(ethynyldimethylsilyl)benzene with 9,10-bis(dimethylsilyl)dihydroanthracene.[43]



5. Polymers containing the C≡C and $(R_2Si)_n$ groups

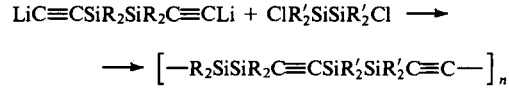


Polymers with triple bonds and disilanyl fragments in the main chain have been synthesised from dilithioethyne and 1,2-dichlorotetramethyldisilane.[44,45]



Polysilethynes have been obtained similarly.[44,45] These polymers were used to obtain fibres which were cross-linked without change in shape after treatment with F_3CSO_3H vapour and subsequent hydrolysis or UV irradiation. When they were subsequently heated to 1300 °C, silicon carbide fibres were obtained.[44,45]

Polymers of the butadiyne series have been synthesised by the same procedure from dilithiodiethyne and 1,2-dichlorotetramethyldisilane.[46,47]



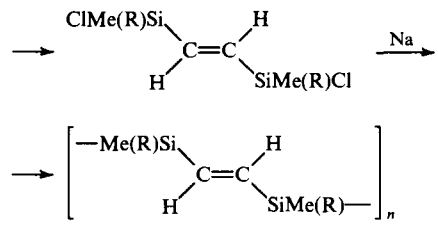
The same polymers have been obtained from bis(trimethylsilyl)butadiyne.[48]

R = Et, Ph.

The reaction of tetraalkyl-1,2-bis(lithioethynyl)disilanes with tetraalkyl-1,2-dichlorodisilanes leads to polymers containing methyl and butyl groups at the silicon atom.[49]

R, R′ = Me, Bu.

Finally, polymers containing the R_2SiO groups in addition to the triple bonds C≡C have been synthesised from dialkylbis(lithioethynyl)silanes and cyclodialkylsiloxanes.[50]

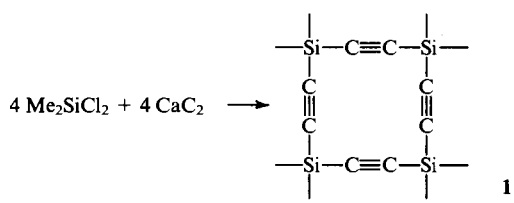


Polymers of this type are also formed from permethylcyclosilethynes $(Me_2SiC{\equiv}C)_n$, where n = 5 or 6 (see Section III), and hexamethylcyclotrisiloxane in the presence of BuLi, MeLi, $Ph_2Si(OLi)_2$, $Me_2Si(C{\equiv}CLi)_2$, and $Ph_2Si(C{\equiv}CLi)_2$ as the catalysts.[51]

The polymers obtained from 1,4-diethynylbenzene and dichloro-1,2-dimethyl-1,2-diphenyldisilane have been recommended as photo- and radiation-sensitive materials.[52]

The reaction of (*E*)-1,2-bis(chlorodiorganylsilyl)ethenes with metallic sodium in benzene leads to polymers which contain simultaneously the CH=CH and R_2SiSiR_2 fragments.[53]

$$ClMe(R)SiC{\equiv}CH + HMe(R)SiCl \longrightarrow$$



R = Me, Ph.

III. Macrocyclic polyunsaturated silicohydrocarbons

1. Cyclosilethynes

It has been suggested that the term cyclosilethynes be given to the cyclic polyethyne silicohydrocarbons made up of alternating $-R_2SiC{\equiv}C-$ groups and corresponding to the general formula $(R_2SiC{\equiv}C)_n$.[11] Compounds of this type, in which the $R_2SiC{\equiv}C$ fragments differ in the substitution at the silicon atom, have to be named in accordance with the extremely cumbersome oxa-aza nomenclature. For example, the macrocycle $(Me_2SiC{\equiv}C)_4$ is octamethylcyclotetrasilethyne, while $[Me_2SiC{\equiv}CSiMe(CH{=}CH_2)C{\equiv}C]_2$ is 1,4,4,7,7,10,10-hexamethyl-1,7-divinyl-1,4,7,10-tetrasilacyclododeca-2,5,8,11-tetrayne.

The first macrocyclic (12-membered) silicohydrocarbon made up of four alternating $Me_2SiC{\equiv}C$ fragments — 1,1,4,4,7,7,10,10-octamethyl-1,4,7,10-tetrasilacyclododeca-2,5,8,11-tetrayne or octamethylcyclotetrasilethyne **1** — was synthesised by Voronkov and Pavlov[54] in 1973 by the reaction of dichlorodimethylsilane with calcium carbide in a fused LiCl–KCl eutectic mixture at 400 °C.†

1

The great importance of this study has been noted in the literature.[55]

This silicohydrocarbon as well as decamethylcyclopentasilethyne **2** were later obtained by the reaction of the potassium–sodium alloy with ethyne and dichlorodimethylsilane in tetrahydrofuran (THF).[56,57]

$$Me_2SiCl_2 + Na/K + HC{\equiv}CH \longrightarrow (Me_2SiC{\equiv}C)_n$$

1, 2

n = 4 (**1**), 5 (**2**).

The reaction of bis(lithioethynyl)dimethylsilane with dichlorodimethylsilane affords dodecamethylcyclohexasilethyne **3**.[58]

$$Me_2Si(C{\equiv}CLi)_2 + Cl_2SiMe_2 \longrightarrow (Me_2SiC{\equiv}C)_6$$

3

Compounds belonging to the homologous series of permethylcyclosilethynes $(Me_2SiC{\equiv}C)_n$, n = 4–10, have been synthesised by Voronkov and Yarosh.[59,60] Thus octamethylcyclotetrasilethyne **1** and hexadecamethylcyclooctasilethyne **4** have been obtained by the reaction of bis(bromomagnesioethynyl)dimethylsilane (EDMS) with (chlorodimethylsilylethynyl)dimethylsilane (CDMS).[59,60]

† In this and a number of subsequent structural formulae, the methyl groups surrounding the macrocyclic silicon are not shown but are only indicated by valence bonds.

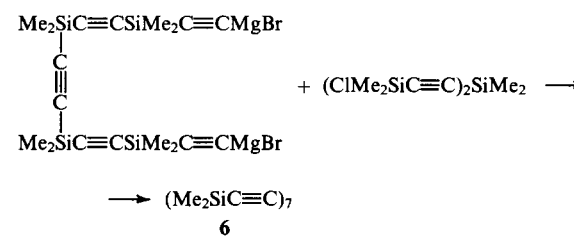
$$Me_2Si(C{\equiv}CMgBr)_2 + (ClMe_2SiC{\equiv}C)_2SiMe_2 \longrightarrow$$

$$\longrightarrow (Me_2SiC{\equiv}C)_n$$

1, 4

n = 4 (**1**), 8 (**4**).

Similarly the interaction of bis(bromomagnesioethynyldimethylsilyl)ethyne (BESA) with bis(chlorodimethylsilylethynyl)silane affords decamethylcyclopentasilethyne **2** and eicosamethylcyclodecasilethyne **5**.[59,60]

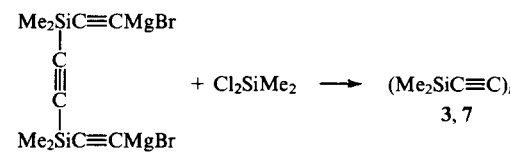


$$BrMgC{\equiv}CMe_2SiC{\equiv}CSiMe_2C{\equiv}CMgBr +$$

$$+ (ClMe_2SiC{\equiv}C)_2SiMe_2 \longrightarrow (Me_2SiC{\equiv}C)_n$$

2, 5

n = 5 (**2**), 10 (**5**).



The reaction of bis(bromomagnesioethynyldimethylsilylethynyl)dimethylsilylethyne (DBES) with CDMS led to tetradecamethylcycloheptasilethyne **6**.[59,60]

$$\longrightarrow (Me_2SiC{\equiv}C)_7$$

6

Dodecamethylcyclohexasilethyne **3** and octadecamethylcyclononasilethyne **7** have been synthesised by the reaction of BESA with Me_2SiCl_2.[60]

3, 7

n = 6 (**3**), 9 (**7**).

Octamethylcyclotetrasilethyne **1**, dodecamethylcyclohexasilethyne **3**, and hexadecamethylcyclooctasilethyne **4** were isolated from the products of the reaction of EDMS with Me_2SiCl_2.[59,60]

$$Me_2Si(C{\equiv}CMgBr)_2 + Cl_2SiMe_2 \longrightarrow (Me_2SiC{\equiv}C)_n$$

1, 3, 4

n = 4 (**1**), 6 (**3**), 8 (**4**).

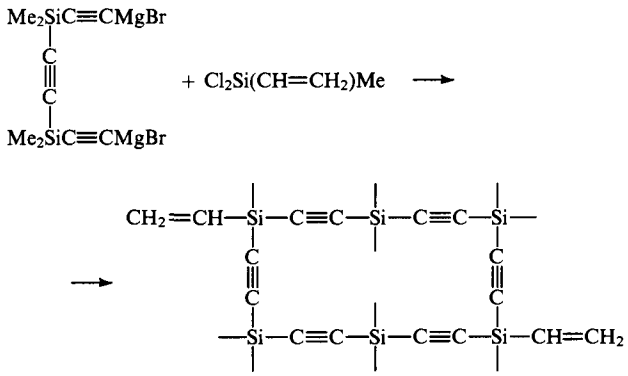
Voronkov and Yarosh[59,60] also synthesised cyclosilethynes containing the substituents H, $CH{=}CH_2$, (*E*)-$CH{=}CHSiMe_3$ and $C{\equiv}CSiMe_3$ at certain silicon atoms in addition to methyl groups. Thus the cyclosilethynes **8** and **9** were obtained by the reaction of EDMS with dichloromethyl(vinyl)silane.[59,60]

$$Me_2Si(C{\equiv}CMgBr)_2 + Cl_2Si(CH{=}CH_2)Me \longrightarrow$$

$$\longrightarrow [-Me_2SiC{\equiv}CSiMe(CH{=}CH_2)C{\equiv}C-]_n$$

8, 9

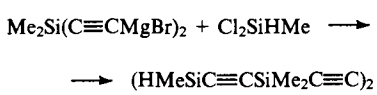
n = 2 (**8**), 3 (**9**).



1,4,7,10-Tetramethyl-1,4,7,10-tetravinyl-1,4,7,10-tetrasilacyclododeca-2,5,8,11-tetrayne **10** has been synthesised by the reaction of bis(bromomagnesioethynyl)methyl(vinyl)silane with dichloromethyl(vinyl)silane.[59,60]

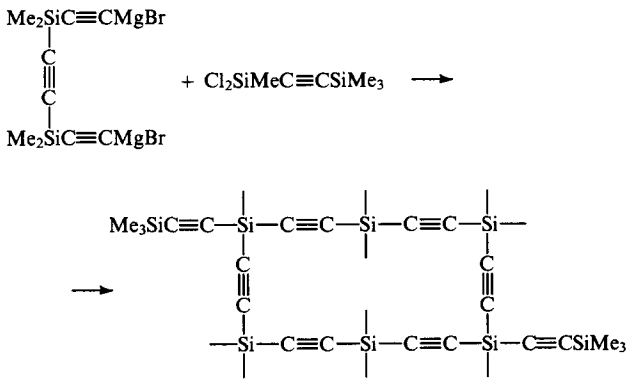
$$Me(CH_2{=}CH)Si(C{\equiv}CMgBr)_2 + Cl_2Si(CH{=}CH_2)Me \longrightarrow$$

$$\longrightarrow [Me(CH_2{=}CH)SiC{\equiv}C]_4$$



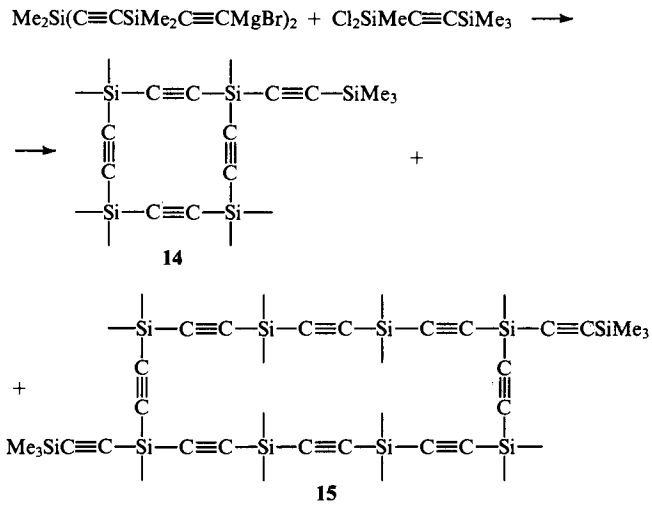
10

The interaction of BESA with dichloromethyl(vinyl)silane led to 1,4,4,7,7,10,13,13,16,16-decamethyl-1,10-divinyl-1,4,7,10,13,16-hexasilacyclooctadeca-2,5,8,11,14,17-hexayne **11**.[59,60]



11

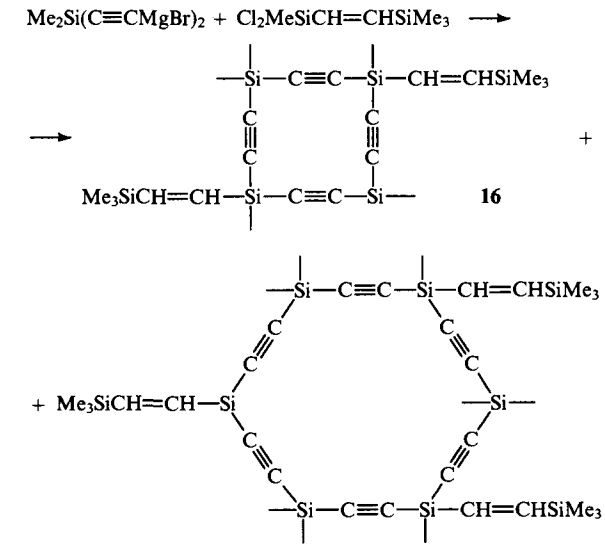
The reaction of EDMS with $MeHSiCl_2$ led to the isolation of 1,4,4,7,10,10-hexamethyl-1,7-dihydro-1,4,7,10-tetrasilacyclododeca-2,5,8,11-tetrayne **12**.[59,60]



12

The interaction of BESA with dichloromethyl(trimethylsilylethynyl)silane (TMSA) affords under the same conditions with disubstituted 18-membered macrocycle **13**.[61]

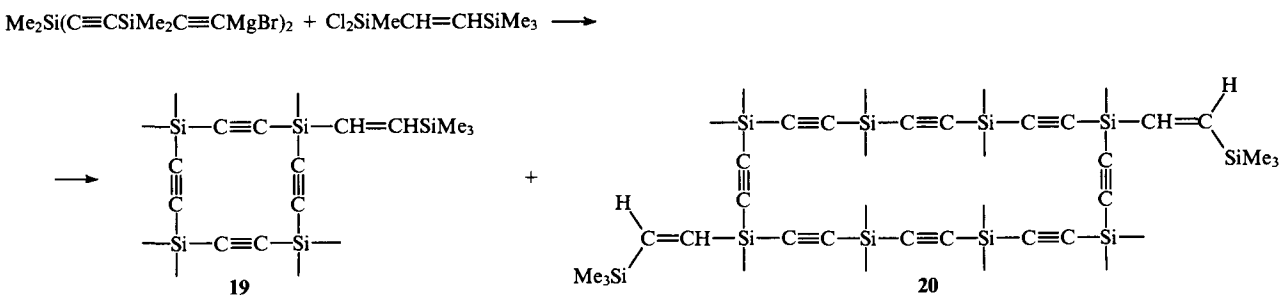
13



Bis[(bromomagnesioethynyldimethylsilyl)ethynyl]dimethylsilane (DMDS) reacts similarly with $Cl_2SiMe(C{\equiv}CSiMe_3)$ to form substituted macrocyclic ethyne silicohydrocarbons — the heptamethyl derivative **14** of 1-(trimethylsilylethynyl)-1,4,7,10-tetrasilacyclododeca-2,5,8,11-tetrayne and the tetradecamethyl derivative **15** of 1,13-bis(trimethylsilylethynyl)-1,4,7,10,13,16,19,22-octasilacyclotetracosa-2,5,8,11,14,17,20,23-octayne.[61]

14

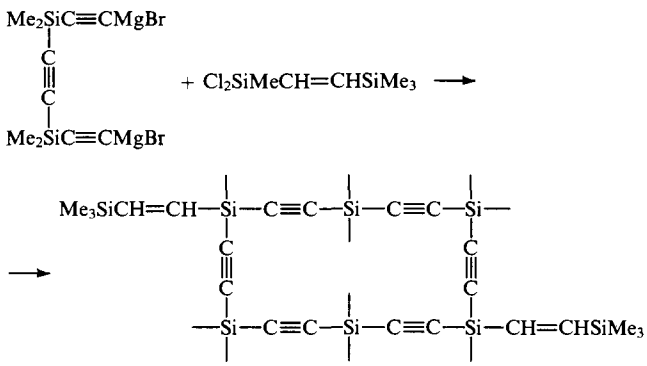
15



The interaction of EDMS with (*E*)-dichloro(methyl)-2-trimethylsilylvinylsilane (ETMS) afforded the cyclosilethynes **16** and **17**.[62]

16

17



Scheme 1

19

20

Compound **18**, the product of the reaction of BESA with ETMS, is an analogue of compound **13**.[62]

18

The analogues of compounds **14** and **15** — the heptamethyl derivative **19** of 1-[(*E*)-2-trimethylsilylvinyl]-1,4,7,10-tetrasilacyclododeca-2,5,8,11-tetrayne and the tetradecamethyl derivative **20** of 1,13-bis[(*E*)-2-trimethylsilylvinyl]-1,4,7,10,13,16,19,22-octasilacyclotetracosa-2,5,8,11,14,17,20,23-octayne — were synthesised in their turn by the interaction of DMDS with ETMS (Scheme 1).[62]

Compounds **1**–**20** were obtained under the conditions of high dilution in THF and were isolated by fractional distillation or sublimation in a high vacuum (10^{-4}–10^{-5} Torr). Their yields were low and amounted to 4%–13%.

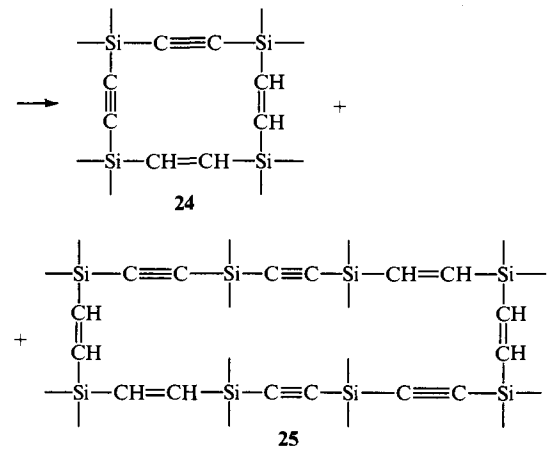
2. Macrocycles containing simultaneously triple and double bonds

Voronkov and Yarosh [63–69] synthesised by methods of fine organosilicon synthesis a series of polyunsaturated macrocyclic silicohydrocarbons containing simultaneously triple and double bonds with different numbers and orders of alternation of the latter (the silicohydrocarbons **21**–**42**). They also include compounds containing exocyclic unsaturated groups (compounds **37**–**42**).[67–69]

The reaction of the Iotsich reagent with (*E*)-1,2-bis(fluorordimethylsilyl)ethene [(*E*)-FSE] produced the 12-, 18-, and 24-membered macroheterocycles **21**–**23** with alternating double and triple bonds.[63,64]

$$BrMgC{\equiv}CMgBr + FMe_2SiCH{=}CHSiMe_2F \longrightarrow \longrightarrow [-Me_2SiCH{=}CHSiMe_2C{\equiv}C-]_n$$

21–**23**

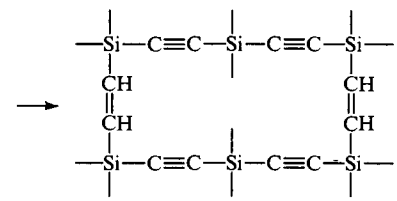


n = 2 (**21**), 3 (**22**), 4 (**23**).

The macrocyclic silicohydrocarbons **24** and **25** with alternating double and triple bonds have been synthesised by the reaction of EDMS with (*E,E*)-bis(2-chlorodimethylsilylvinyl)-dimethylsilane (BCVS).[63,64]

The interaction of EDMS with (*E*)-FSE led to the isolation of 1,1,4,4,7,7,10,10,13,13,16,16-dodecamethyl-1,4,7,10,13,16-hexasilacyclooctadeca-2,11-diene-5,8,14,17-tetrayne **26**.[64,65]

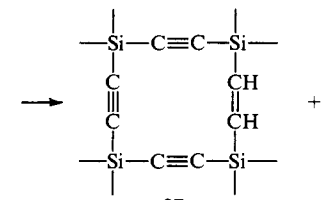
The polyunsaturated macrocycles **27** and **28** were synthesised similarly from bis(bromomagnesioethynyldimethylsilyl)ethyne and (*E*)-FSE.[64,65]



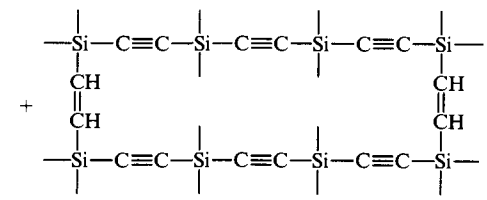
$Me_2Si(C{\equiv}CMgBr)_2$ + $(ClMe_2SiCH{=}CH)_2SiMe_2$ ⟶

24

25



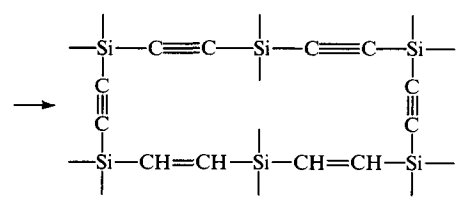
$Me_2Si(C{\equiv}CMgBr)_2$ + $FMe_2SiCH{=}CHSiMe_2F$ ⟶



26

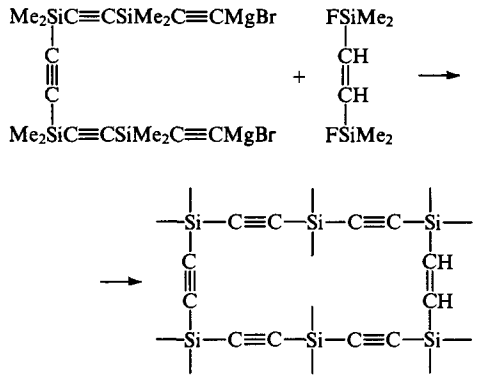
$BrMgC{\equiv}CSiMe_2C{\equiv}CSiMe_2C{\equiv}CMgBr$ +

+ $FMe_2SiCH{=}CHSiMe_2F$ ⟶



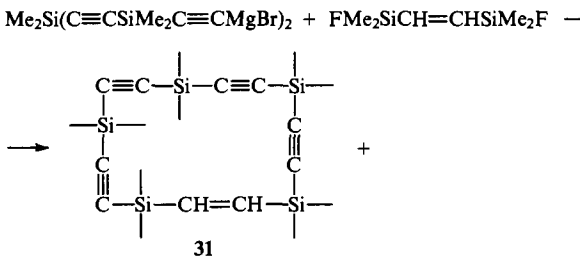
27

28



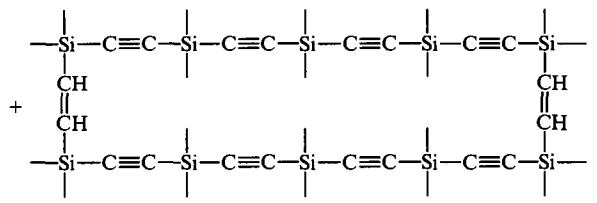
The reaction of DMDS with BCVS produced the dodecamethyl derivative **29** of 1,4,7,10,13,16-hexasilacyclooctadeca-2,5-diene-8,11,14,17-tetrayne.[64,65]

$Me_2Si(C{\equiv}CSiMe_2C{\equiv}CMgBr)_2$ + $(ClMe_2SiCH{=}CH)_2SiMe_2$ ⟶



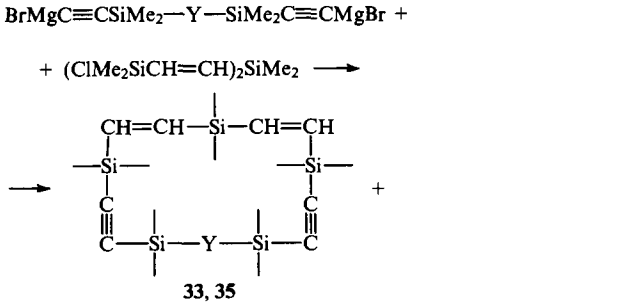
29

The product of the reaction of DBES with (*E*)-FSE is 1,1,4,4,7,7,10,10,13,13,16,16-dodecamethyl-1,4,7,10,13,16-hexasilacyclooctadeca-2-ene-5,8,11,14,17-pentayne **30**.[64,65]

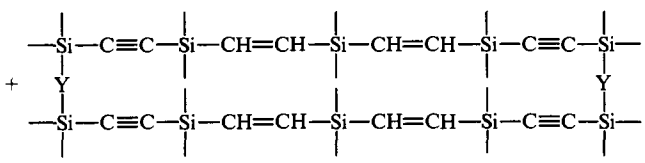


30

The interaction of DMDS with (*E*)-FSE affords the macrocycles **31** and **32**.[64,66]

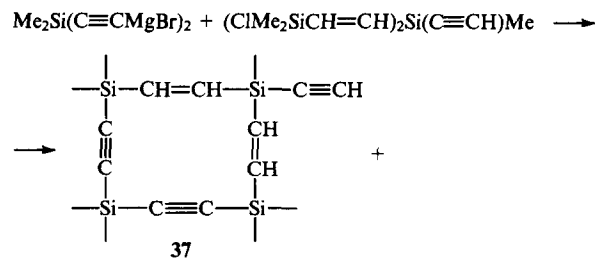


31

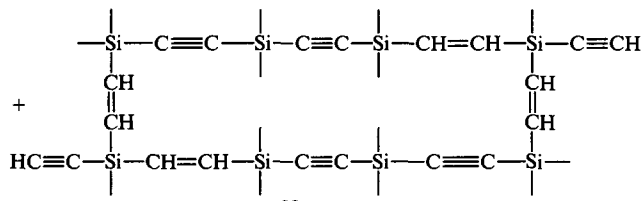


32

The highly unsaturated cyclic systems **33**–**36** were obtained similarly by the reaction of bis(bromomagnesioethynyldimethylsilyl)ethyne or (*E*)-1,2-bis(bromomagnesioethynyldimethylsilyl)ethene with BCVS.[64,66]



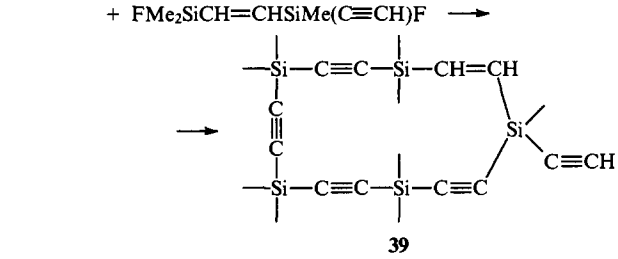
33, 35



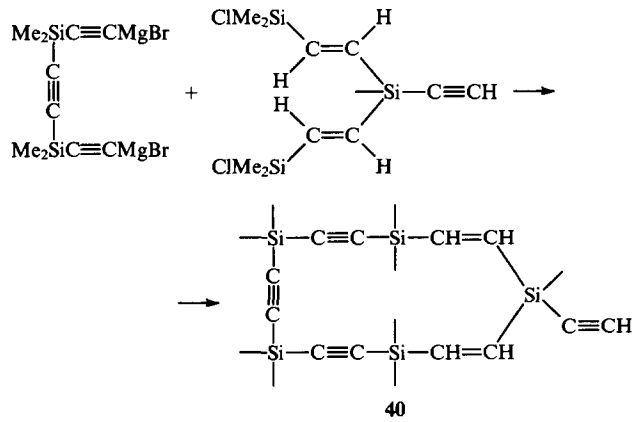
34, 36

Y = C≡C (**33**, **34**), CH=CH (**35**, **36**)

The condensation of EDMS with (*E,E*)-bis(2-chlorodimethylsilylvinyl)ethynylmethyl silane (BCVES) results in the formation of the heptamethyl derivative **37** of 1-ethynyl-1,4,7,10-tetrasilacyclododeca-2,11-diene-5,8-diyne and the tetradecamethyl derivative **38** of 1,13-diethynyl-1,4,7,10,13,16,19,22-octasilacyclotetracosa-2,11,14,23-tetraene-5,8,17,20-tetrayne containing exocyclic HC≡C groups.[67]

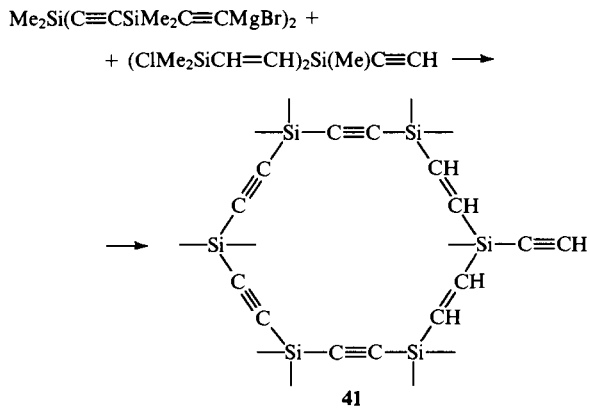


37



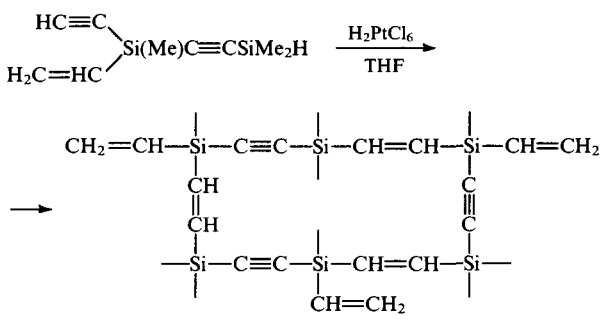
38

Similarly the reaction of DMDS with (*E*)-1-fluorodimethylsilyl-2-ethynylfluoro(methyl)silylethene produced 1-ethynyl-1,4,4,7,7,10,10,13,13-nonamethyl-1,4,7,10,13-pentasilacyclopentadeca-2-ene-5,8,11,14-tetrayne **39**.[68]



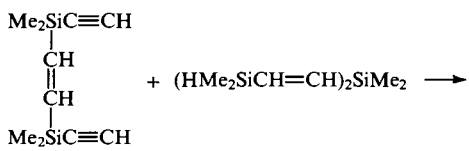
39

The reaction of BESA or DMDS with BCVES led to 1-ethynyl-1,4,4,7,7,10,10,13,13-nonamethyl-1,4,7,10,13-pentasilacyclopentadeca-2,14-diene-5,8,11-triyne **40** and a derivative of 1-ethynylundecamethyl-1,4,7,10,13,16-hexasilacyclooctadeca-2,17-diene-5,8,11,14-tetrayne **41**.[68]



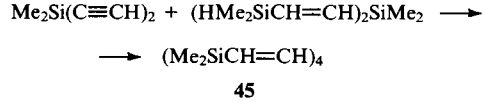
40

41



In the H_2PtCl_6-catalysed autohydrosilylation of 1-ethynyl-methylvinylsilyl-2-dimethyl silylethyne at high dilution in THF, only the ethynyl group reacts. The product of this reaction is 1,4,4,7,10,10,13,16,16-nonamethyl-1,7,13-trivinyl-1,4,7,10,13,16-hexasilacyclooctadeca-2,8,14-triene-5,11,17-triyne **42**.[69]

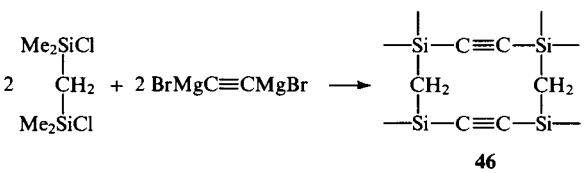
42



3. Cyclosilethenes

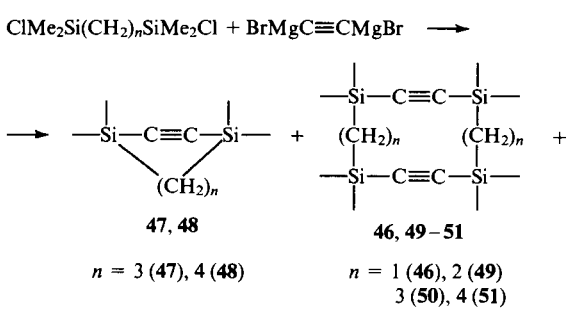
It has been suggested that the polyunsaturated macrocyclic silicohydrocarbons made up of alternating SiCH=CH fragments be called cyclosilethenes or, more precisely, cyclosil-1,2-ethenes.[11] Silicohydrocarbons of this type were first synthesised by Voronkov and Yarosh[70] by means of the autohydrosilylation reaction in the presence of H_2PtCl_6 at high dilution. The *Si*-permethylcyclosilethenes $(Me_2SiCH{=}CH)_n$ (**43**: $n = 5$; **44**: $n = 6$) were obtained in this way from ethynyldimethylsilane.[70] In addition, the specific synthesis of *Si*-decamethylcyclosilethene **43** has also been achieved by hydrosilylating (*E*)-1,2-bis-(ethynyldimethylsilyl)ethene with (*E,E*)-bis(2-dimethylsilylvinyl-dimethyl)silane.[71]

43



Si-Octamethylcyclotetrasilethene **45** was obtained in the same way — by the addition of (*E,E*)-bis(2-dimethylsilyl-vinyl)dimethylsilane to diethynyldimethyl silane.[71]

45

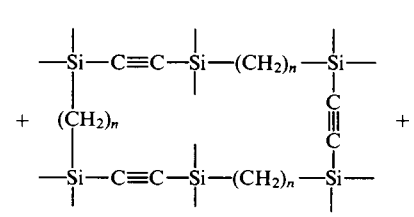


4. Macrocycles containing endocyclic $(CH_2)_n$ ($n = 1-4$) fragments

The first cyclic (10-membered) silicohydrocarbon — 1,1,4,4,6,6,9,9-octamethyl-1,4,6,9-tetrasilacyclodeca-2,7-diyne **46** — was synthesised as early as 1970 by Fritz and Schober[72] by condensing the Iotsich reagent with bis(chlorodimethyl-silyl)methane.

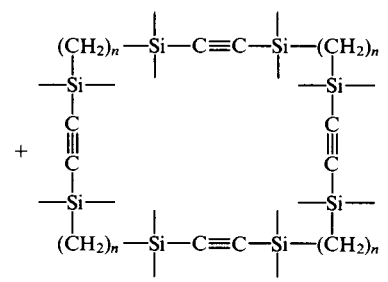
46

A series of cyclic and macrocyclic silicohydrocarbons (compounds **47**–**55**), containing saturated $(CH_2)_n$ ($n = 1-4$) fragments in the ring as well as the triple bonds, have been synthesised by the interaction of the Iotsich reagent with bis-(chlorodimethylsilyl)methane, 1,2-(chlorodimethylsilyl)methane, 1,3-bis(chlorodimethylsilyl)propane, or 1,4-bis(chloro-dimethyl-silyl)butane.[73]



47, 48

n = 3 (**47**), 4 (**48**)

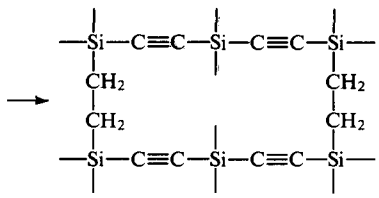


46, 49–51

n = 1 (**46**), 2 (**49**) 3 (**50**), 4 (**51**)

52, 53

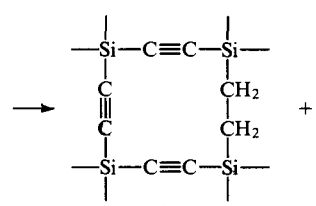
n = 1 (**52**), 2 (**53**)



54, 55

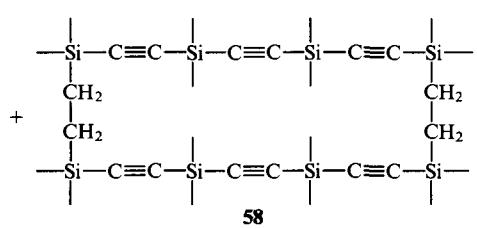
n = 1 (**54**), 2 (**55**)

On the other hand, the 18-membered 1,1,4,4,7,7,10,10,13,13,16,16-dodecamethyl-1,4,10,13,16-hexasilacycloocta-deca-2,5,11,14-tetrayne **56** has been synthesised by the reaction of EDMS with 1,2-bis(fluorodimethylsilyl)ethane[64,74,75] (see over).



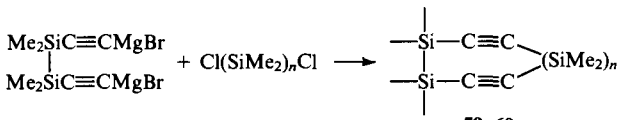
Similarly the reaction of BESA with 1,2-bis-(fluorodimethylsilyl)ethane led to macrocyclic compounds — the octamethyl derivative **57** of 1,4,7,10-tetrasilacyclododeca-2,5,8-triyne and the hexadecamethyl derivative **58** of 1,4,7-10,13,16,19,22-octasilacyclotetracosa-2,5,8,14,17,20-hexayne.[63,64]

$2\ Me_2Si(C{\equiv}CMgBr)_2 + 2\ FMe_2SiCH_2CH_2SiMe_2F \longrightarrow$



56

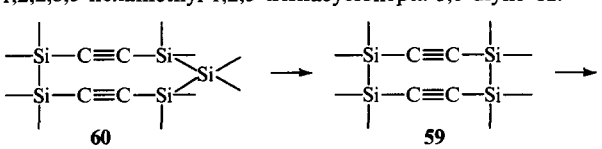
$BrMgC{\equiv}CSiMe_2C{\equiv}CSiMe_2C{\equiv}CMgBr +$
$+\ FMe_2SiCH_2CH_2SiMe_2F \longrightarrow$



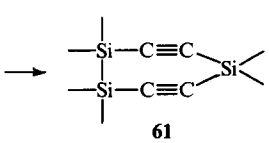
57

58

5. Macrocycles containing the $(SiR_2)_n$ (n = 2, 3) fragments



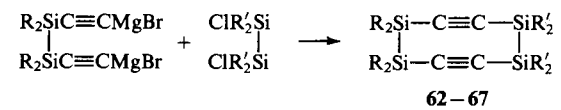
The first cyclic and macrocyclic polyunsaturated silicohydrocarbons containing simultaneously the C≡C and $(SiR_2)_n$ (n = 2, 3) groups were synthesised in 1983 by Sakurai[76-78] by means of the reaction of 1,2-bis(bromomagnesioethynyl)tetramethyldisilane with 1,2-dichlorotetramethyldisilane and 1,3-dichlorohexamethyltrisilane.



n = 2 (**59**), 3 (**60**)

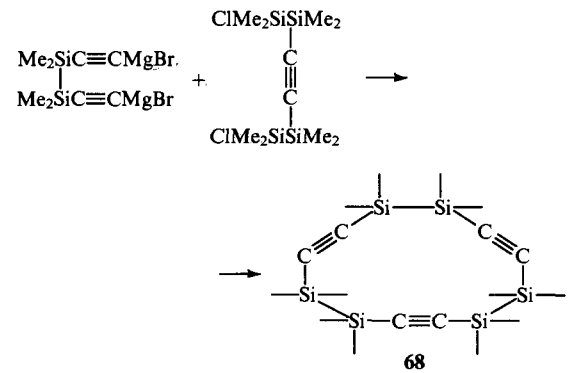
59, 60

When the silicohydrocarbon **60** is heated to 680 °C under an inert atmosphere, dimethylsilylene is eliminated with formation of compound **59**, which is converted in the same way into 1,1,2,2,5,5-hexamethyl-1,2,5-trisilacyclohepta-3,6-diyne **61**.[77]



60 **59**

61



The analogous cyclic silicohydrocarbons with ethyl, butyl, hexyl, and phenyl groups were later synthesised.[78-81]

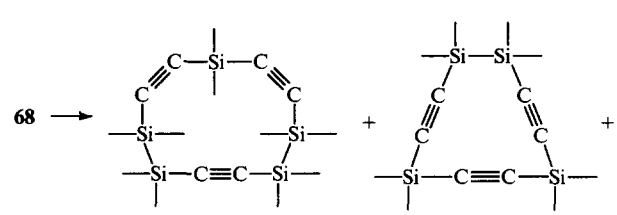
The interaction of 1,2-bis(bromomagnesioethynyl)tetramethyldisilane with bis(2-chlorotetramethyldisilanyl)ethyne led to 1,1,2,2,5,5,6,6,9,9,10,10-dodecamethyl-1,2,5,6,9,10-hexasilacyclododeca-3,7,11-triyne **68**.[82]

62-67

R = R′ = Me (**62**); R = Me, R′ = Bu (**63**); R = R′ = Bu (**64**);
R = Me, R′ = Et (**65**); R = Me, R′ = C_6H_{13} (**66**);
R = Me, R′ = Ph (**67**).

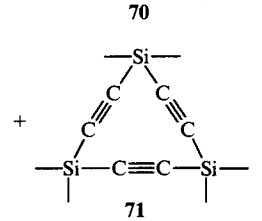
68

The same compound has been obtained in accordance with the following scheme:[83]



$HC{\equiv}CMgBr + (ClMe_2Si)_2 \longrightarrow$

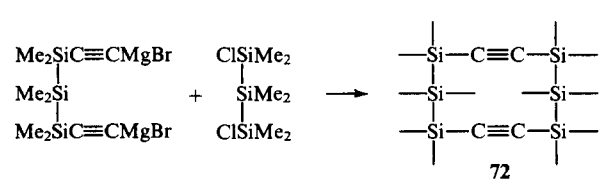
$\longrightarrow ClMe_2SiSiMe_2C{\equiv}CH \xrightarrow{BrMgC{\equiv}CMgBr}$



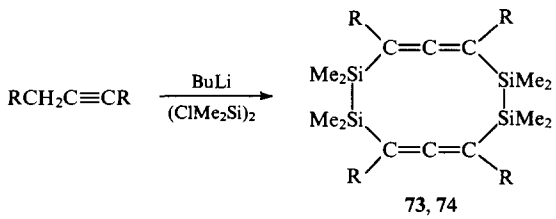
$\longrightarrow HC{\equiv}CMe_2SiSiMe_2C{\equiv}CSiMe_2SiMe_2C{\equiv}CH \xrightarrow[2.\ (ClMe_2Si)_2]{1.\ RMgBr}$

$\longrightarrow$ **68**.

When compound **68** is heated to 540 °C, a mixture of compounds **69**-**71** is obtained in 8%, 27%, and 11% yields respectively. On the other hand, heating of compound **68** to 690 °C results in the formation of only compound **71** in 68% yield.[83]

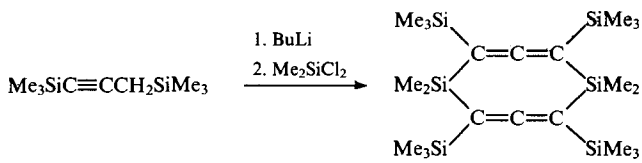


69 **70**



71

1,1,2,2,3,3,6,6,7,7,8,8-Dodecamethyl-1,2,3,6,7,8-hexasilacyclododeca-4,9-diyne **72** was obtained by the reaction of 1,3-bis(bromomagnesioethynyl)hexamethyltrisilane with 1,3-dichlorohexamethyltrisilane.[82,84,85]



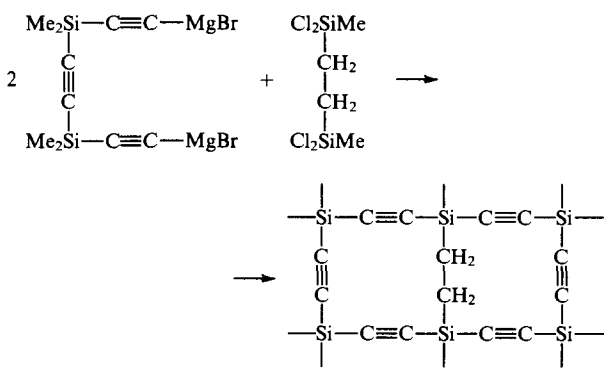
72

The reaction of 1,3-diphenylpropyne or 1,3-bis(trimethylsilyl)propyne with butyllithium and 1,2-dichlorotetramethyldisilane or dichlorodimethylsilane leads to the corresponding allene silicohydrocarbons **73**–**75**.[86,87]

73, 74

R = Ph (**73**), Me_3Si (**74**).

75

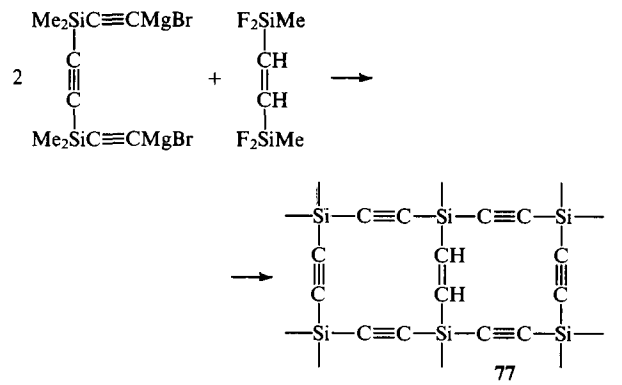


Ishikawa and coworkers[88,89] showed that, on heating to 230 °C or on treatment with a catalytic amount of butyllithium,[81,88] 1,2,5,6-tetrasilacycloocta-3,7-diynes undergo ring opening with formation of polymeric compounds:

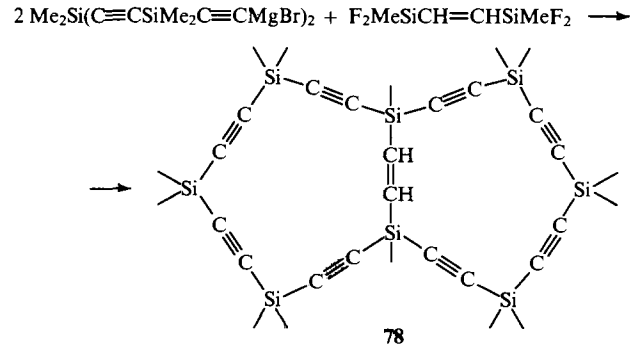
R′ = Me, Et; R″ = Et, Ph, C_6H_{13}.

6. Bicyclic, tricyclic, and spiran systems

Bimacrocyclic trimacrocyclic and spiromacrocyclic highly unsaturated silicohydrocarbons have been obtained by methods of fine organic synthesis. Thus the first silicohydrocarbons of this type — 1,4,4,7,7,10,13,13,16,16-decamethyl-1,4,7,10,13,16-hexasilabicyclo[8′,8′,2′]eicosa-2,5,8,11,14,17-hexayne **76** — was obtained in 1988 by the interaction of BESA with 1,2-bis(chloromethylsilyl)ethane (BCSE).[64,90]

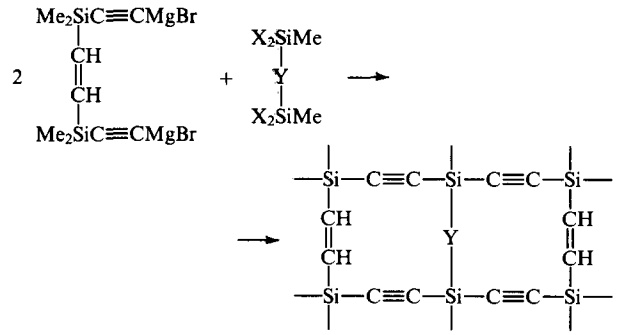


76



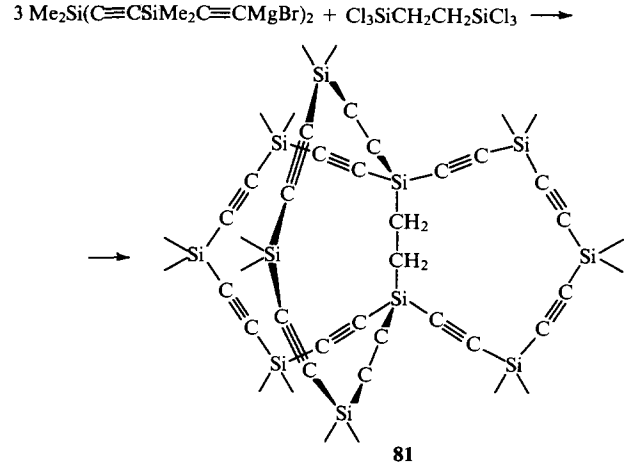
The bicyclic compound **77** was obtained similarly from BESA and (*E*)-1,2-bis(difluoromethylsilyl)ethene (DFSE).[64,65]

1,4,4,7,7,10,10,13,16,16,19,19,22,22-Tetradecamethyl-1,4,7,10,13,16,19,22-octasilabicyclo[11′,11′,2′]hexacosa-25-ene-2,5,8,11,14,17,20,23-octayne **78** was obtained in exactly the same way by the reaction of DMDS with DFSE.[64,65]



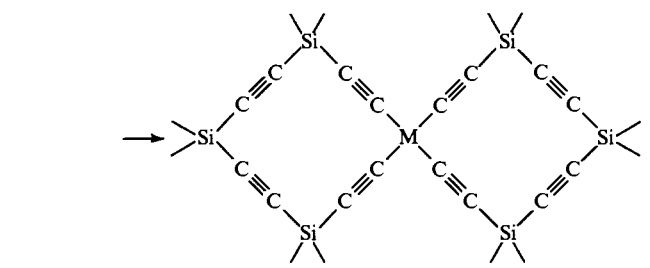
New highly unsaturated bicyclic silicohydrocarbons — the decamethyl derivative **79** of 1,4,7,10,13,16-hexasilabicyclo-[8′,8′,2′]eicosa-5,14-diene-2,8,11,17-tetrayne and the decamethyl derivative **80** of 1,4,7,10,13,16-hexasilabicyclo[8′,8′,2′]eicosa-5,14,19-triene-2,8,11,17-tetrayne — have been synthesised by the reaction of (*E*)-bis(bromomagnesioethynyldimethylsilyl)ethene (BESE) with BCSE and DFSE respectively.[91]

77



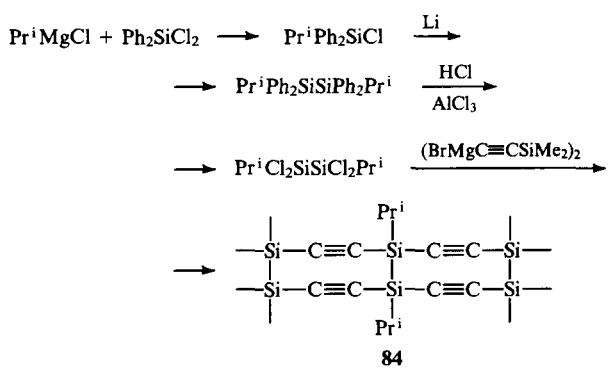
78

79, 80



X = F, Cl; Y = CH_2CH_2 (**79**), CH=CH (**80**).

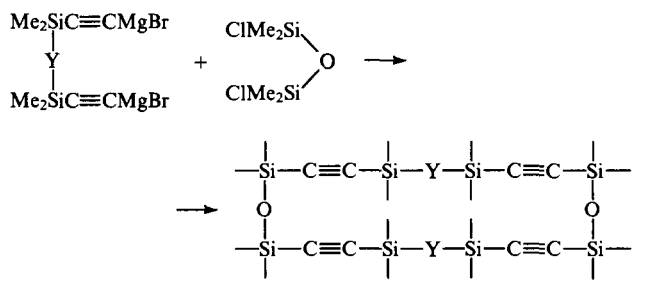
The interaction of DMDS with 1,2-bis(trichlorosilyl)ethane led to the synthesis of the first and hitherto the only trimacrocyclic silicohydrocarbon with the propellane structure — 3,3,6,6,9,9,15,15,18,18,21,21,27,27,30,30,33,33-octadecamethyl-3,6,9,12,15,18,21,24,27,30,33-undecasilatricyclo[11′,11′,11′,2′]heptatriaconta-1,4,7,10,13,16,19,22,25,28,31,34-dodecayne **81**.[92]



81

Finally, the first spiromacrocyclic polyethyne silicohydrocarbons — 3,3,6,6,9,9,15,15,18,18,21,21-dodecamethyl-3,6,9,12,15,18,21-heptaspiro[11′,11′]tricosa-1,4,7,10,13,16,19,22-octayne **82** and its 12-germa-analogue **83** — have been obtained by the reaction of DMDS with $SiCl_4$ and $GeCl_4$.[60,93]

M = Si (**82**), Ge (**83**).

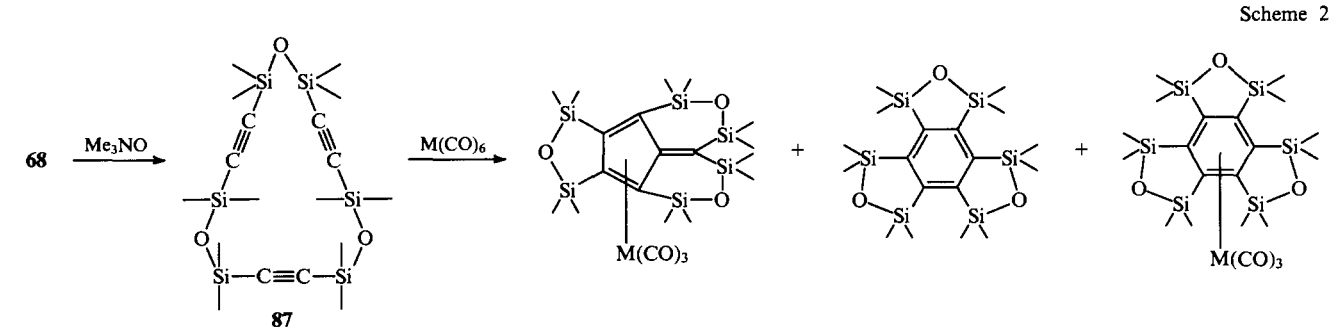


84

Compounds **5** and **15**, containing 10 triple bonds, and compound **81**, containing 12 triple bonds, are unique highly unsaturated molecular record holders. The synthesis of 1,8-diisopropyl-4,4,5,5,11,11,12,12-octamethyl-1,4,5,8,11,12-hexasilabicyclo[6′,6′,0′]tetradeca-2,6,9,13-tetrayne **84** — the only known bicyclic silicohydrocarbon containing Si–Si fragments in addition to the C≡C groups, has been achieved recently.[94]

7. Macrocycles containing endocyclic oxygen atoms

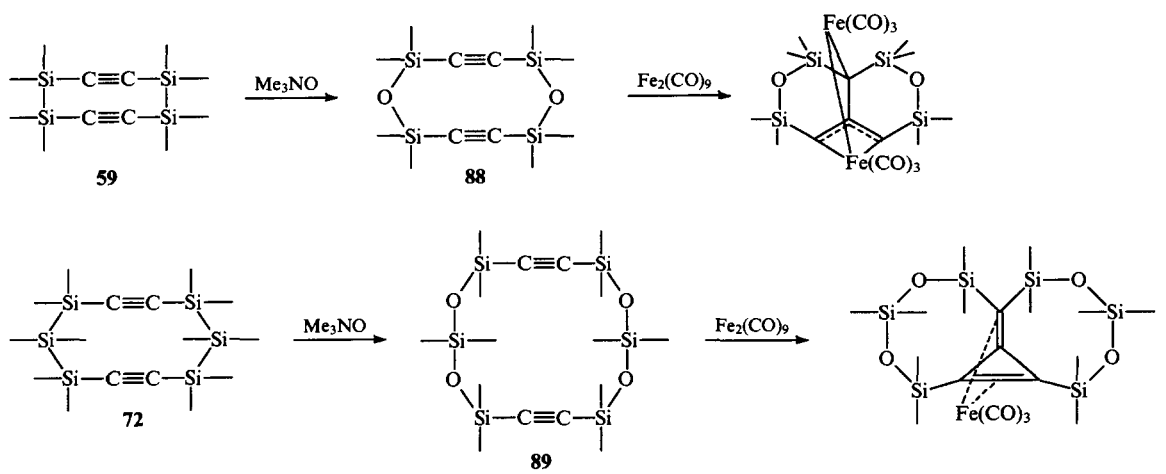
The macrocyclic polyunsaturated tetrasiloxanes **85** and **86** have been obtained by the reaction of BESA and BESE with 1,3-dichlorotetramethyldisiloxane respectively.[95,96]



85, 86

Y = C≡C (**85**), (*E*)-CH=CH (**86**).

The oxidation of the silicohydrocarbon **68** by trimethylamine oxide leads to 1,1,4,4,6,6,9,9,11,11,14,14-dodecamethyl-1,4,6,9,11,14-hexasila-5,10,15-trioxacyclopentadeca-2,7,12-triyne **87**. The interaction of the latter with chromium molybdenum, or tungsten hexacarbonyls led to the remarkable derivatives of benzene and fulvene presented in Scheme 2.[97]



The reactions of the cyclic siloxanes **88** and **89** on treatment with $Fe_2(CO)_9$ have been investigated (Scheme 3).[84,85]

IV. Physical properties

1. Molecular structure

The molecular structures of a series of polyunsaturated macrocyclic silicohydrocarbons have been established by X-ray diffraction. For a better understanding of the latter, we shall consider initially model acyclic structures:

90

and $(Me_3SiC{\equiv}C)_4Si$.

91

The molecule of compound **90** is not linear but has a zig-zag shape.[98] The Si–C(*sp*) bond lengths are 1.832 and 1.834 Å and are close to the standard Si–C(*sp*) distance of 1.837 Å.[98] The C(*sp*)–Si–C(*sp*) angles in the structure (106.6°) are smaller than the tetrahedral angle. Since there is no conformational strain in the molecule of compound **90**, the distortion of the ideal tetrahedral coordination of the silicon atoms is most probably caused by the steric interaction of the methyl substituents.

The central silicon atom in the molecule of compound **91**, surrounded by four linear $Me_3SiC{\equiv}C$ groups, has a tetrahedral configuration.[99] The C(*sp*)–C(*sp*) and Si–C(*sp*) bond lengths are respectively 1.17–1.20 and 1.840–1.871 Å, while the Si–C(*sp*)–C(*sp*) angle is close to the linear value (175–178°).[99]

The cyclic molecules of compounds **46** and **88** contain two triple bonds and have the 'chair' conformation.[100] The lengths of the bonds Si–C(*sp*) (1.839 and 1.842 Å) and C(*sp*)–C(*sp*) (1.215 and 1.216 Å) are respectively almost identical. The average Si–C(*sp*)–C(*sp*) angle is 175.5°.

The macrocyclic molecules of compounds **47**–**55** differ only in the number of methylene groups separating the $SiC{\equiv}CSi$ fragments.[101] The single unit cell of the crystal of compound **47** contains three molecules (space group *P*1), among which one is approximately at the centre of symmetry, whilst the others are in general positions and are linked by the centre of symmetry. The crystals of compound **47** contain two different conformers — the 'chair' and 'boat' conformers. The bond lengths and valence angles in compounds **46** and **49**–**51** (n = 1–4) are presented in Table 1. The rings with an even number n are more strained than those with an odd number. In all these molecules, the silicon atoms are located in one plane. The Si–C(*sp*) and C(*sp*)–C(*sp*) bond lengths in compound **62** (R = R′ = Me) are close to the standard values (1.838–1.848 and 1.182 Å respectively).[57] There are two conformers in the crystal of compound **67** (R = Me, R′ = Ph) — with the *cis,trans*- and *trans,trans*-configurations.[81] The eight-membered ring of the first conformer is planar within ±0.5 Å and has a centre of symmetry. In the first conformer, the phenyl groups are in the *trans*-positions relative to one another at each Si–Si bond and in the *cis*-positions relative to each $Si{-}C{\equiv}C{-}Si$ fragment. In the second conformer, the phenyl groups at the silicon atoms in the Si–Si and $Si{-}C{\equiv}C{-}Si$ fragments are in the *trans*-positions. Its eight-membered ring is bent (the maximum deviation from the mean square plane is 0.27 Å).[81]

The macrocyclic molecules having the general formula $(Me_2SiC{\equiv}C)_n$ (n = 4–6) (compounds **1**–**3**) have different ring conformations.[57,102] The molecule of compound **1** (n = 4) consists of a 12-membered ring with a square plane structure (D_{4h} symmetry).[57] The C(sp^3)–(Si)–C(sp^3) angles are larger than the tetrahedral angle (110.7°, 112.6°), while the C(*sp*)–(Si)–C(*sp*) angles are smaller (102.96°, 103.77°). The triple bonds are bent to the outside owing to ring strain. Compound **2** (n = 5) consists of a nonplanar ring with the envelope conformation.[57] Its triple bonds are slightly bent into the interior of the ring. As in compound **1**, the C(sp^3)–(Si)–C(sp^3) bond angles are larger than the tetrahedral value (111.4–113.5°), while the C(*sp*)–(Si)–C(*sp*) angles are smaller (104.73–106.83°). The molecule of compound **3** (n = 6) has the 'chair' conformation.[102] The C(*sp*)–C(*sp*) bond lengths in compounds **1**–**3** are 1.205–1.209, 1.210–1.220, and 1.218–1.222 Å for n = 4, 5, and 6 respectively, i.e. they increase with increase in ring size and are larger than in their C-analogues (1.18–1.19 Å), which is evidently due to their electronic interaction with the silicon atom.

The Si–C(*sp*) bond lengths (1.808–1.829 and 1.818–1.847 Å) in compound **27** are shorter[103] than in 1,1,4,4,7,7,10,10-octamethyl-1,4,7,10-tetrasilacyclododeca-2,8-diyne **47**,[101] but are approximately the same as in compound **2**.[57]

The crystal of compound **56** has C_i symmetry, although its intrinsic symmetry is C_{2h}. This 18-membered macroheterocycle has an overall 'chair' conformation and is on the whole rigid. The average Si–C(*sp*) distance (1.850 Å) differs little from the average Si–C(sp^3) distance (1.857 Å), apparently owing to failure to take into account corrections for the thermal motions of the atoms (especially the methyl groups). The length of the triple bond (1.201–1.207 Å) has the usual value. The molecules of compound **56** form stacks in the crystal, the outer surfaces of which are made up of the $Si{-}C{\equiv}C{-}Si$ fragments.[75]

A characteristic feature of the macrocyclic silicohydrocarbons with endocyclic $Si{-}C{\equiv}C{-}Si$ and Si–CH=CH–Si groups is a tendency towards disorder in the crystal structure.[95,103,104] This is frequently caused by their great flexibility combined with an appreciable looseness of the crystal structure — which is a consequence of the noninvolvement of the endocyclic $-C{\equiv}C-$ and CH=CH– bonds in the intermolecular contacts, which leads to the coexistence in the crystal of two or more conformers with different orientations.[75,95]

The molecular structure of compound **85** with endocyclic Si–O–Si (two) and $Si{-}C{\equiv}C{-}Si$ (six) groups is ordered.[95] The molecule of compound **86** differs from the structurally similar molecule of compound **85** by the presence of the CH=CH groups instead of the two $C{\equiv}C$ groups.[96] The Si–O bond lengths (1.630 Å) in compound **85** are greater than in compound **86** (1.605 Å), which is due to the greater strain in compound **85**. The latter leads in its turn to a decrease in the Si–O–Si bond angle in compound **85** (148.9°) compared with compound **86** (156.9°). The remaining bond lengths and bond angles in compound **85** are close to those observed in compound **86** [the Si–C(*sp*) bond lengths are 1.839 and 1.834 Å respectively].

The overall configuration of the bicyclic molecule of compound **78** ('butterfly'), determined primarily by the tetrahedral valence environment of the 'bridging' Si atoms, is the most compact.[104] The *trans*-structure of the Si–CH=CH–Si bridge disturbs the symmetry of this molecule. The disorder is comparatively small and is associated with the presence of

Table 1. The bond lengths (Å) and bond angles (deg) in compounds **46** and **49**–**51**.[101]

Compound	n	Si–C(*sp*)	Si–C(sp^2)	Si–C(sp^3)	C≡C	Si–C(*sp*)–C(*sp*)
46	1	1.867	1.872	1.842	1.216	176.9
49	2	1.866	1.879	1.844	1.213	173.7
50	3	1.862	1.877	1.851	1.216	179.5
51	4	1.867	1.877	1.843	1.220	178.1

two enantiomers at each crystallographic site. In the ordered fragments of the molecule of compound **78**, the bond lengths and bond angles have the usual values. Thus the average Si–C(*sp*) distance is the same as the value observed in other silicohydrocarbons.[101] A similar type of disorder has been observed also in the crystals of the macrocyclic compounds **24**, **27**, **49**, and **54** with four silicon atoms in the ring and an asymmetric distribution of the C≡C, CH=CH, and CH_2-CH_2 groups.[103]

The structure of compound **31** can be regarded as the same as one of the condensed heterocycles in the molecule of compound **78**.[103] The macrocycle **31** with five silicon atoms exists in the crystal in the form of three conformers, which is manifested by a pronounced structural disorder. All three conformers of this heterocycle have virtually the same, almost symmetrical, 'large envelope' configuration.

2. Melting points

The melting points of the cyclodimethylsilethynes $(Me_2SiC{\equiv}C)_n$ (n = 3–10) exceed 140 °C and oscillate markedly as the ring size varies. The compounds with an even number n have higher melting points (the melting point is a maximum for n = 6). Among the compounds with an odd number n, the minimum melting point is observed for n = 3 (Fig. 1).[59,60,83] A similar behaviour is manifested by the first three known analogues of these compounds containing only one double bond, namely $(Me_2SiC{\equiv}C)_{n-1}(Me_2SiCH{=}CH)$, the melting points of which are 228, 198, and 257 °C for n = 4, 5, and 6 respectively;[64–66] this also applies to cyclodimethylsilethenes $(Me_2SiCH{=}CH)_n$, the melting points of which are 158, 110, and 230 °C for n = 4, 5, and 6 respectively.[71]

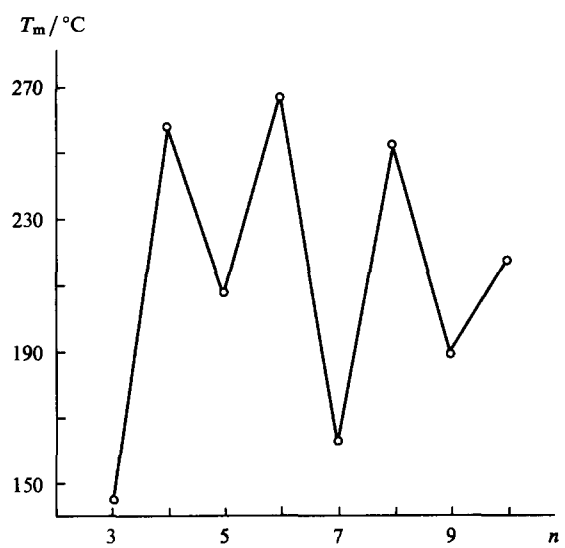

Figure 1. Melting points of the cyclodimethylsilethynes $(Me_2SiC{\equiv}C)_n$ (n = 3–10).[59,60,83]

The replacement of the methyl groups in the polyunsaturated macrocyclic silicohydrocarbons by substituents such as H, C_2H_5, $CH{=}CH_2$, C≡CH, $CH{=}CHSiMe_3$, and $C{\equiv}CSiMe_3$, leading to a decrease in ring symmetry, diminishes the melting point.[59–62] A decrease in the degree of unsaturation of the macrocycle also entails a decrease in the melting point.

The bicyclic and tricyclic as well as spirocyclic polyunsaturated silicohydrocarbons differ from the monocyclic ones by higher melting points (Table 2). A decrease in the melting point with decrease in the degree of unsaturation is also observed for these substances.

Table 2. The melting points of the bicyclic, tricyclic, and spirocyclic macrocycles.[61,65,66,90–92]

Compound	Cyclic system	T_m/°C	Compound	Cyclic system	T_m/°C
76	bicycle	277	**80**	bicycle	274
77	"	305	**81**	tricycle	269
78	"	280	**82**	spiran	293
79	"	255	**83**	"	299

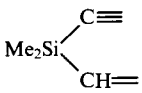
3. NMR spectra

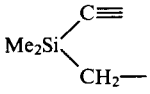
The chemical shifts of the protons in the methyl groups at the silicon atom in the polyunsaturated macrocyclic silicohydrocarbons are determined by the nature of the neighbouring endocyclic bonds and are almost independent of the size of the macroring (Table 3).

Table 3. The chemical shifts (δ) of the methyl protons in the ^{1}H NMR spectra of macrocyclic polyunsaturated silicohydrocarbons.

Fragment	δ/ppm	Ref.
$Me_2Si(C{\equiv})_2$	0.26–0.32	59–71
$Me_2Si(C{\equiv})(CH{=})$	0.23–0.24	74
$Me_2Si(CH{=})_2$	0.16–0.19	75
$Me_2Si(C{\equiv})(CH_2{-})$	0.15–0.16	90–93

The chemical shifts of the protons in the endocyclic CH=CH and CH_2-CH_2 groups have the usual values for the acyclic SiCH=CHSi and $SiCH_2CH_2Si$ groups (6.0–7.10 and 0.62 ppm respectively).





On the other hand, in the ^{13}C NMR spectra the chemical shifts of the carbon atoms of the methyl groups are determined both by the ring size and by the nature of the neighbouring bonds. With increase in the size of the macrocycle, the ^{13}C signal arising from Me_2Si undergoes a downfield shift. Thus the ^{13}C chemical shift of Me_2Si in the NMR spectra of the cyclodimethylsilethynes **1**, **2**, and **3** (n = 4–6) varies in the following sequence: −0.80 to −0.69, 0.12–0.15, and 0.62–0.87 ppm respectively.[59,60]

In the NMR spectrum of the $Me(CH_2{=}CH)Si(C{\equiv})_2$ fragment, the signal due to the methyl carbon atom undergoes an upfield shift (δ = −2.10 to −2.21 ppm).[59,60] The shift of the methyl carbon atom in the $Me(H)Si(C{\equiv})_2$ (δ = −3.89 ppm) [59,60] and $Me_2Si(CH{=})_2$ (δ = −3.37 to −3.80 ppm) fragments[63,65] is even more pronounced. The $^{13}C(sp^3)$ chemical shift is −2.43 to −2.57 ppm for the $Me_2Si(C{\equiv})(CH{=})$ fragment and −4.01 to −4.90 ppm for the $Me(HC{\equiv}C)Si(C{\equiv})(CH{=})$ fragment, depending on the ring size. The ^{13}C chemical shift of the ^{13}C atom in $-CH_2-$ in the endocyclic $Me_2Si(CH_2)(C{\equiv})$ fragment is 8.10 ppm.[63,75]

The chemical shifts of the C(sp) atoms in the endocyclic $SiC{\equiv}CSi$ fragment are in the range 105.1–117.2 ppm [$\delta(^{13}C)$ = 113.02 ppm for $Me_2SiC{\equiv}CSiMe_3$ [105]]. The ^{13}C chemical shifts for the exocyclic ethynyl groups linked to the silicon atom have the following values: 84.60–86.30 ppm (C≡) and 95.51–95.76 ppm (≡CH).

The ^{13}C signal for the endocyclic SiCH=CHSi fragment is at 146.15–150.45 ppm (for comparison, we may note that the signal for $Me_3SiCH{=}CHSiMe_3$ is at 150.0 ppm[106]). The ^{13}C chemical shifts for the exocyclic vinyl groups linked to the silicon atom are at 130.70–132.85 ppm (CH=) and 135.60–136.25 ppm ($=CH_2$).

Table 4. The chemical shifts of the silicon atoms (δ_{Si}) in the ^{29}Si NMR spectra of highly saturated macrocyclic silicohydrocarbons.

Fragment	δ_{Si}/ppm	Ref.
$Me_2Si(C\equiv)_2$	−40.1 to −42.7	59–71
	−26.1 to −27.6	74
$Me_2Si(CH=)_2$	−14.7 to −17.4	75
$Si(C\equiv)_4$	−66.9 (in spiran)	90–93
$MeSi(C\equiv)_3$	−69.0 to −70.0 (in monocycle)	
$Me(HC\equiv C)Si(CH=)_2$	−32.1	
	−14.5	
$Me(CH_2=CH)Si(C\equiv)_2$	−48.5 to −49.0	
$CH_3Si(C\equiv)_3$	−54.6 (in tricycle)	

The silicon chemical shifts in the ^{29}Si NMR spectra are independent of the size of the macrocycle and are determined exclusively by the nature of the endocyclic and exocyclic substituents (Table 4).

4. UV, Raman, and photoelectron spectra

The silicohydrocarbons containing the $SiC\equiv CSi$ fragment absorb in the near ultraviolet. A maximum at 215 nm and a shoulder at 228 nm are observed in the UV spectrum of $(Me_2SiC\equiv C)_4$ **1**, while the spectrum of $(Me_2SiC\equiv C)_5$ **2** has only a shoulder at 230 nm.[57] Quantum-chemical calculations by the semiempirical AM1 method for the molecule of compound **2** indicate a marked conjugation between the π MO of the $C(sp)-C(sp)$ bond and the π MO of the silicon atom, which leads to the splitting of the corresponding molecular orbitals to the extent of 1.73 eV. According to UV spectroscopic data, conjugation in the molecules increases from compound **24** to compound **21** and to compound **19**.[107] This is accompanied by a bathochromic shift of the bands (210, 217, and 223 nm respectively), compared with $(Me_2SiC\equiv CSiMe_2O)_2$ **88** (202, 207, and 215 nm).[101]

The linear (disilanylene)ethynylene polymers of the type $(SiR_2SiR_2C\equiv C)_n$ (R = alkyl) absorb in the range 241–244 nm with an extinction coefficient of 13 000–17 000 litre mol^{-1} cm^{-1} per unit.[49,82] An electron is transferred from the MO involving the Si–Si σ-bond. Quantum-chemical calculations (CNDO/2) show that the highest occupied and the lowest unoccupied MO are σ-type orbitals.[108] This agrees with the finding that the polymer of the type $(Et_2SiOSiEt_2C\equiv C)_n$, not containing the Si–Si group, absorbs at shorter wavelengths (at 216 nm).[82]

As a consequence of the symmetry of the triple bond in the $SiC\equiv CSi$ fragment in macrocyclic ethyne hydrocarbons, the stretching vibrations of the triple bond are inactive in the IR spectra, while the Raman spectra show an intense $C\equiv C$ stretching vibration band. The $\nu(C\equiv C)$ band in the Raman spectra of cyclodimethylsilethynes $(Me_2SiC\equiv C)_n$ with $n = 4-6$ undergoes a slight hypsochromic shift (2132, 2134, and 2137 cm^{-1} respectively).[57] The band due to the stretching vibration of the triple bond in the Raman spectra which we obtained for crystalline cyclodimethylsilethynes ($n = 4-10$) is located in the lower-frequency range 2110–2120 cm^{-1} and decreases slightly with increase in n from 5 to 10 (Table 5). The lower $\nu(C\equiv C)$ frequency for $n = 4$ (2113 cm^{-1}) is apparently due to the 'rigid' molecular structure (see above). The Raman spectra of the spirocyclic compounds **82** and **83** show two lines characteristic of the triple bond vibration (2116, 2122, and 2116, 2127 cm^{-1} respectively). The doublet nature of the lines is apparently associated with the resonance of the triple bonds in the orthogonal rings. The triple bond vibration appears in the Raman spectra of the model compounds $(Me_3SiC\equiv C)_4E$ (E = Si, Ge) by a single line (2114.5 and 2118.5 cm^{-1} respectively).

Table 5. The stretching vibration frequency of the triple bond in the Raman spectra of compounds of the type $(Me_2SiC\equiv C)_n$.

Compound	n	$\nu(C\equiv C)$/cm^{-1}	Compound	n	$\nu(C\equiv C)$/cm^{-1}
1	4	2113	**6**	7	2115
8	4	2118	**4**	8	2112.5
2	5	2119	**7**	9	2113, 2109 sh.
3	6	2118.5	**5**	10	2113

The He(I) photoelectron spectra of compounds **59**, **68** and **71** have been obtained. The interpretation of the first bands in these spectra is based on a comparison with the orbital energies calculated by the semiempirical MINDO/3 and MNDO methods.[109,110] The Si–Si bonds have very low ionisation energies and may therefore destabilise the π orbitals of the ethyne fragments.[109] An interaction via the σ-bonds between the out-of-plane π orbitals and the Si–Si σ-bonds, leading to a marked destabilisation of the $a_g(\pi)$ orbital (8.13 eV), has been observed in compound **59**. A similar interaction via σ-bonds has also been noted for compound **68**.

This review has been written with the financial support of the Russian Fundamental Research Fund (Project Code 18405).

IV.	The supermolecular level of the structural organisation of metallopolymers	870
V.	Conclusion	874

Abstract. The spatial organisation of metallopolymers (macromolecular metal chelates) is analysed on three levels; local, molecular, and supermolecular. The thermodynamic features of the formation of chelates with polymeric ligands are examined and data are presented concerning the dependence of the structure of the chelate units on various factors. The principal changes which the macrochain may undergo on formation of metal chelate centres are considered. The behaviour of the macromolecular ligands and their low-molecular-mass analogues is compared on the molecular level. The principal characteristics of the formation of intramolecular and intermolecular complexes are listed and the causes of their stability are examined. The bibliography includes 125 references.

I. Introduction

The problems of the chemistry of macromolecular metal chelates (MMC)† have attracted increased attention by investigators during recent years.[1–9] As a result of the efforts of specialists in various fields (polymer, coordination, bioinorganic, and analytical chemistry, catalysis, etc.), considerable advances have now been achieved in the MMC chemistry. Thus numerous MMC containing virtually any metals in the Periodic System have been obtained, their physicochemical properties have been investigated, and their principal structural characteristics have been elucidated. However, the quantitative parameters of the chelate formation process involving macromolecular ligands have so far been studied inadequately,[11] in contrast to the low-molecular-mass metal chelates‡ (LMC). This has been explained by the need to take into account a whole series of additional factors, in the first place those arising from the chain nature of the ligand. It is useful to examine three levels of the spatial organisation of the MMC:

1. the local level, which reflects the chemical structure of a single chelate unit in the chain molecule (the nature of the complex forming metal and of the electron-donating atoms, the ring size, the steric structure of the ring, etc.);
2. the molecular level, which is determined by the chemical structure of the polymer chain (the chain length, the elemental composition of the repeat units, the shape and conformation of the chain, etc.);
3. the supermolecular level, which reflects the nature of the intermolecular interaction of the macromolecules and the degree of their mutual order.

Taking these three levels of the spatial organisation of the MMC into account, the free energy of formation of the chelates involving macroligands can be represented (on the assumption that its components are additive) by the equation[12]

$$\Delta G = \Delta G_1 + \Delta G_2 + \Delta G_3 , \quad (1)$$

where ΔG_1, ΔG_2, and ΔG_3 are the free energy changes for the local, molecular, and supermolecular levels respectively. Under certain conditions, the free energy change for a particular level may be neglected, which makes it possible to analyse in detail the enthalpy (ΔH) and entropy ($T\Delta S$) contributions to ΔG for each level.

$$\Delta G = \Delta H - T\Delta S \quad (2)$$

Taking this into account, the characteristics of the steric structure of the MMC on each level are analysed in the present review.

II. The local level of the structural organisation of metallopolymers

Initially we shall consider dilute solutions of polymers, i.e. solutions in which chain association may be neglected. Then $\Delta G_3 \to 0$ and Eqn (1) can therefore be expressed in the form

$$\Delta G = \Delta G_1 + \Delta G_2 . \quad (3)$$

† A characteristic feature which makes it possible to identify fairly reliably chemical compounds of this class in the presence of a polymer chain and of metal chelate rings.

‡ The chelate effect in the LMC is one of the most interesting phenomena in the thermodynamics of intermolecular interactions.[10]

Received 13 April 1995
Uspekhi Khimii **64** (9) 913–934 (1995); translated by A K Grzybowski

In the case of infinitely long chains ($l \to \infty$) and low degrees of conversion§ with respect to the chain molecule ($\alpha \to 0$), the chelation process may not exert a significant influence on the form and conformation of the macromolecule, so that $\Delta G_2 \to 0$ and hence

$$\Delta G = \Delta G_1 \ . \qquad (4)$$

Thus, in the case of dilute solutions with $l \to \infty$ and $\alpha \to 0$ the chelating macroligand behaves similarly to its low-molecular-mass analogue and the familiar Flory principle then operates: when the components of the model reaction are chosen correctly, the reactivity of the binding centres is independent of whether they belong to the polymer chain or to the low-molecular-mass analogue. This makes it possible to exclude from consideration the molecular and supermolecular levels and to analyse only the local chelate units. The entropy and enthalpy components of ΔG in the case of MMC are determined mainly by the same contributions as in the case of LMC. Since the nature of the complex-forming metal and the electron-donating groups is the same in both cases, the enthalpy of chelate formation changes little on passing from LMC to MMC. For example, ΔH for the chelation of copper(II) ions by type **1** and **3** poly(amido-amines) and their type **2** and **4** low-level-mass analogues are similar (Table 1),[13] which indicates a similar steric structure of the chelate units in these compounds. Therefore, for both MMC and LMC ΔG is determined by the entropy component. This is indicated by the isotypical nature of the dependences of ΔG and ΔS in chelation processes on the degree of conversion (Fig. 1) and also by the independence of ΔH of α (Table 1).

Table 1. Thermodynamic functions for the formation of copper(II) complexes (in kJ mol^{-1} and J mol^{-1} K^{-1}).

Ligand	ΔG	$-\Delta H$	ΔS
 **1**	51.5–47.3[a]	30	72–58[a]
 **2**	57.0	30	90
 **3**	37.2–33.1[b]	16	71–58[b]
 **4**	34.5	17	58

[a] Degree of conversion $\alpha = 0.45-0.85$.
[b] Degree of conversion $\alpha = 0.18-0.88$.

Formally the chelation reaction can be divided into several hypothetical elementary stages and the entropy of the entire process can be expressed as follows:

$$\Delta S_1^0 = \Delta S_{solv} + \Delta S_4^0 = \Delta S_2^0 + \Delta S_3^0 + \Delta S_5^0 + \Delta S_4^0 \ ,$$

§ The degree of conversion α is defined as the ratio of the actual number of metal ions bound to one chain and the maximum possible number.

where ΔS_1^0 is the experimental entropy of the reaction in solution, ΔS_4^0 is the calculated theoretical entropy of the reaction in the gas phase, ΔS_{solv} is the entropy of solvation of the metal ion (ΔS_2^0), of the ligand (ΔS_3^0), and of the complex formed (ΔS_5^0), which is determined as the difference between the entropies in solution and in the gas phase.

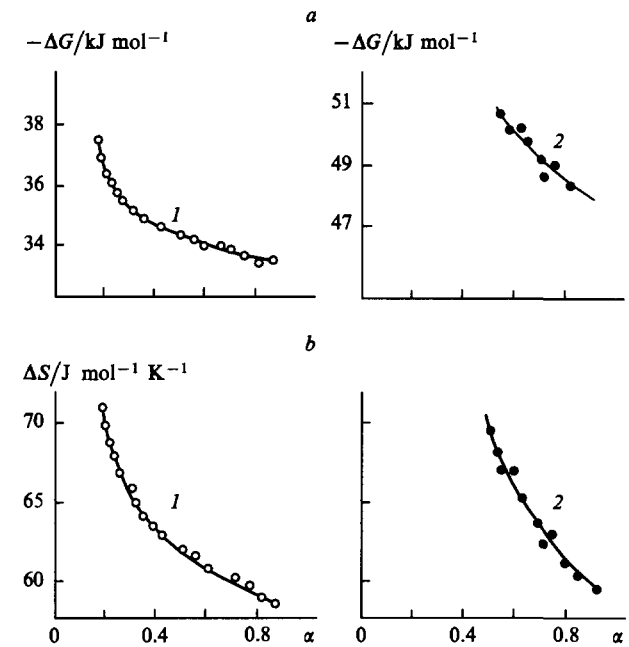

Figure 1. Dependence of ΔG (*a*) and ΔS (*b*) for the formation of copper(II) chelate complexes of poly(amidoamines) of types **1** (curve *1*) and **3** (curve *2*) on the degree of conversion.

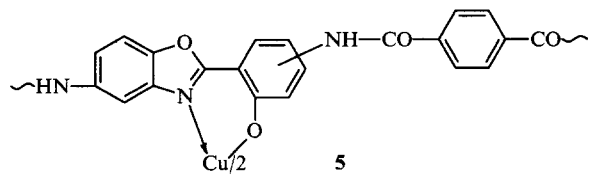
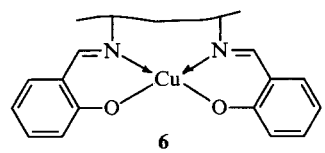


ΔS_4^0 represents in its turn the sum of the entropies of transfer (ΔS_t), internal rotation ($\Delta S_{int.rot}$), symmetry (ΔS_{sym}), isomerisation (ΔS_{isom}), vibration (ΔS_{vib}), and rotation (ΔS_{rot}).[14]

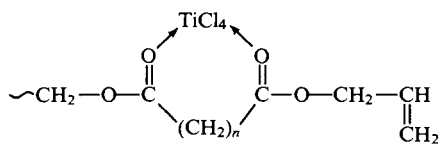
$$\Delta S_1^0 = \Delta S_{solv} + \Delta S_t + \Delta S_{int.rot} + \Delta S_{sym} + \Delta S_{isom} + \Delta S_{vib} + \Delta S_{rot} \ .$$



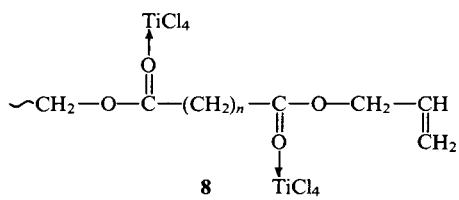
It is assumed[14] that the positive contributions to the entropy component of ΔG come from ΔS_t, ΔS_{rot}, ΔS_{sym}, and ΔS_{isom}. The contribution of ΔS_t, due to the change in the number of species on chelation, apparently changes little on passing from LMC to MMC. Consequently the entropies of chelation are similar in the two cases, since the contribution of the transfer process is the main one. ΔS_{rot} makes a definite contribution to the entropy component. It is smaller in the case of MMC than in the reaction with monodentate ligands because the initial macroligand and the MMC formed are nonrotating species. The symmetry groups for the low- and high-molecular-mass compounds are significantly different and the number of possible isomers of polymeric chelates may be smaller, so that the contribution of isomerisation is in this case reduced. Thus the nickel(II) chelate complexes with salicylaldimine ligands exist in two isomeric forms: planar (green) and tetrahedral (brown). Only a paramagnetic pseudo-tetrahedral form has been obtained on a polymer base[15] even under conditions where the diamagnetic isomer is formed preferentially in the low-molecular-mass system.[16]

ΔS_{vib}, $\Delta S_{int.rot}$, and ΔS_{solv} makes negative contributions to the entropy component.[14] It is postulated that the contributions by the vibration and internal rotation are much lower in the case of the high-molecular-mass system than in the case of the LMC. If the monomeric and polymeric chelating ligands form structurally identical chelate units, then the contribution of solvation is approximately the same in both cases. However, as a rule such cases are rare and the polymer chain exerts a significant influence

on the structure of the local chelate unit with the possibility of the formation of structures which are both less and more distorted than the LMC. As an example, one may quote the copper(II) chelate complex of poly(hydroxyphenylbenzoxazole-terephthalamide) **5**, which has a distorted tetrahedral structure like its low-molecular-mass analogue. However, a somewhat higher value of A and a lower value of g in the EPR spectra compared with the LMC are characteristic of the MMC, which indicates a smaller dihedral angle.[17] On the other hand, in the case of the salicylaldimine ligands the structures of the chelate units are different in the LMC and MMC: planar in the LMC and distorted tetrahedral in the MMC (complex **6**).[15] In conformity with the change in the stereochemistry of the chelate unit, an increase or a decrease in the contribution of solvation is observed.

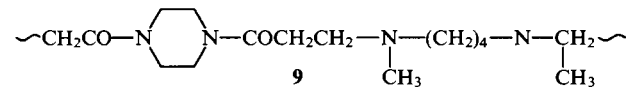


5

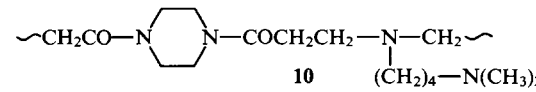


6

As for the LMC, the free energy ΔG in the case of polymeric ligands depends to a large extent on the size of the chelate ring. The familiar Chugaev ring rule holds for the MMC: five- and six-membered rings prove to be the most stable. The influence of ring size on the mechanism of the binding of metal ions by polymers can be illustrated in relation to the formation of complexes between $TiCl_4$ and the copolymers of styrene and the diallyl esters of dicarboxylic acids.[18] For n = 1 or 2, a mixture of complexes with the *cis*-disposition (complex **7**) or *trans*-disposition (complex **8**) of the carbonyl groups is formed. Both in the initial ligand and in the MMC, there are two nonequivalent carbonyl groups, but the difference between the vibrational frequencies $\Delta\nu$(C=O) for the *cis*- and *trans*-forms increases from 10–15 to 40–45 cm^{-1}. This indicates a more rigid fixation of the isomers on complex formation. The increase in the size of the separating bridge ($n > 3$) precludes the formation of chelates.



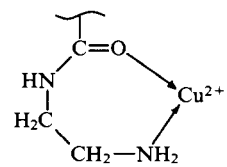
7



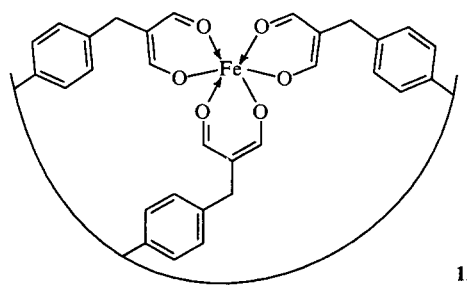
8

The study of copper(II) complexes of poly(amidoamines) showed that an increase in the chelate ring size from five-membered to six-membered entails a significant decrease in the stability constants or even precludes the chelation of copper(II) with formation of stable complexes. In this case, the decrease in stability is accounted for mainly by the decrease in enthalpy, since conformational freedom is reduced to a much greater extent in polymers than in low-molecular-mass compounds.[19,20]

The ligands **9** and **10**, which should form seven-membered chelate rings, do not give rise to stable complexes. Thus an increase in the length of the aliphatic chain, linking the nitrogen atoms of the monomer unit, greatly diminishes the complex forming capacity of poly(amidoamines)[19]



9



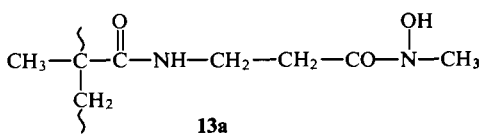
10

However, since the polymer chain determines the steric structure of the chelating fragment while the metal ion selects sections of the macromolecular chain with the preferred conformation, there is a possibility of the formation of analogues of metallocycles different from the low-molecular-mass ones. For example, the interaction of copper(II) ions with vinyl polymers containing aminoalkylamide units in the side chain results in the formation of the seven-membered chelate rings **11**, the amine nitrogen atom and the amide C=O groups participating in the coordination to the metal.[21] On the other hand, in the copper(II)–glycylglycine low-molecular-mass system, five-membered rings are formed.[22] Thus, knowing the conformation of the local chelating fragment, it is possible to predict the formation of MMC with metallocycles having a particular size.

11

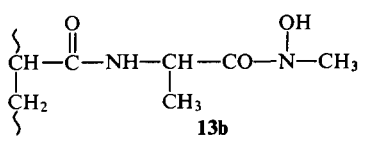
As well as the contributions from the entropy and enthalpy of chelating common to low- and high-molecular-mass metal chelates, a series of specific contributions are characteristic of the MMC. They include a contribution reflecting the 'adjustment' of the local chelating fragment because the interaction of metal ions with the chelating macroligand is accompanied not only by direct chemical steps (the formation of the metallocycle) but also by a change in the 'local rigidity' ¶ at the reaction site, which is determined by the change in the interaction of the valence-nonbonded chain atoms. The energy of this 'adjustment' is much smaller for soluble macroligands than the energy of chelation, so that the structure of the coordination centres is usually determined by the nature of the complex-forming metal. For example, in the interaction of an iron(III) salt with polystyrene, containing acetylacetone (acac) groups, the 'adjustment' of the polymer chain takes place in such a way that the octahedral structures **12** are formed without appreciable strain.[24]

12



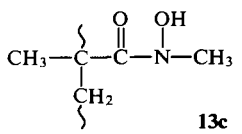
¶ In conformity with the definition given by Landau and Lifshitz,[23] the 'local rigidity' is understood as the resistance to bending of a uniform straight linear filament.

Table 2. Spectroscopic and magnetic characteristics of the monomeric and polymeric nickel and cobalt chelates with ligands of the Bipy and Phen types.



Complex	M	L	IR spectrum (principal frequencies)/cm^{-1}			Dq/cm^{-1}	B'/cm^{-1}	β	μ_{ef}/B.M.
			ν(C=C)	ν(heterocycle)	ν(COO$^-$)				
Monomer	Ni	Bipy	1635	1605	1565	1134	773	0.743	3.16
Polymer	Ni	Bipy	1639	1606	1560	1028	837	0.804	2.96
Monomer	Co	Bipy	1637	1610	1560	1152	834	0.859	4.53
Polymer	Co	Bipy	1638	1608	1560	1018	883	0.909	4.75
Monomer	Ni	Phen	1637	1600	1565	1166	830	0.797	3.17
Polymer	Ni	Phen	1640	1600	1560	990	857	0.823	2.95
Monomer	Co	Phen	1635	1605	1565	1163	849	0.874	4.75
Polymer	Co	Phen	1639	1608	1565	1016	884	0.911	4.87

The change in the 'local rigidity' can influence significantly the stereochemistry of the chelate unit formed. Thus the monomeric and polymeric nickel(II) and cobalt(II) chelates with ligands (L) of the type of 2,2'-bipyridyl (Bipy) and 1,10-phenanthroline (Phen) have similar spectroscopic and magnetic characteristics (Table 2), indicating the same steric structure of the chelate units.[25] On the other hand, a decrease in the splitting parameter Dq and an increase in the Racah interelectron repulsion parameter B' have been observed on passing from LMC to MMC. Bearing in mind[26] that $Dq \sim 1/a$,[6] one can assume that the decrease in the splitting parameter indicates an increase in the metal–ligand distance a in the given series. Furthermore, the nephelauxetic parameter β increases in the same series, which indicates a decrease in the degree of covalence in the metal–ligand bond. A consequence of this is, for example, a weakening of the exchange interactions on passing from low-molecular-mass dinuclear nickel(II) chelate complexes of *N*-acylsalicylamides[27] to their polymeric analogues.[28,29] It is known[30] that the bond lengths are altered less than the bond angles, so that a more pronounced distortion of the bond angles compared with the bond lengths can be expected in the MMC.

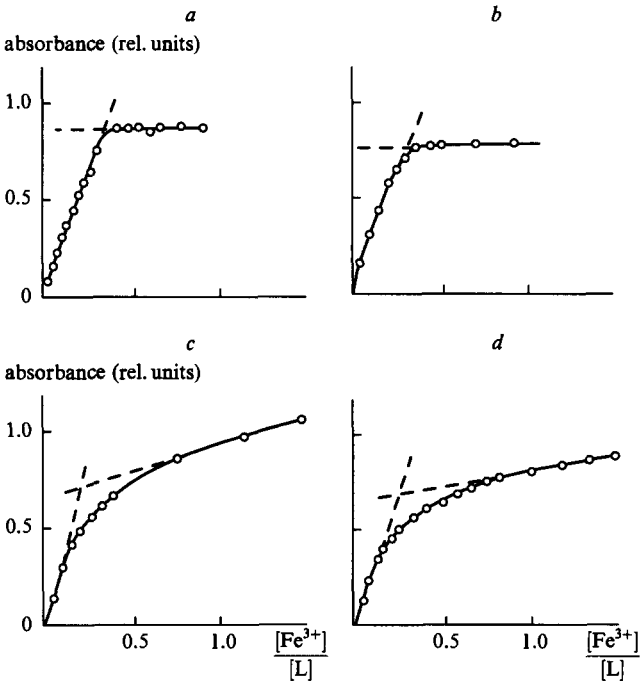


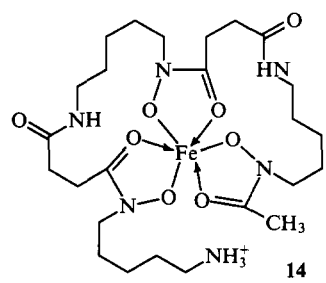
A contribution arising from the 'neighbouring groups' effect also appears in the case of the MMC. This contribution is associated with the influence of both reacted and unreacted units on the free energy of formation of the chelating fragment and hence on the structure of the chelate unit. This effect, which is explained mainly by steric factors, leads to the repulsion of the chelate units and their deformation, hindering chelate formation as the degree of conversion increases. For example, the octahedral iron(III) complexes of hydroxamic acid copolymers **13a–c** are formed without appreciable strain only when the chelating fragments are separated by 11 atoms (compounds **13a**).[31] When the number of atoms between the hydroxamic groups is $t = 7$, a slight strain arises, whereas in the case where $t = 1$ (compound **13c**) the complexes are not formed at all (Fig. 2).

13a

13b

13c





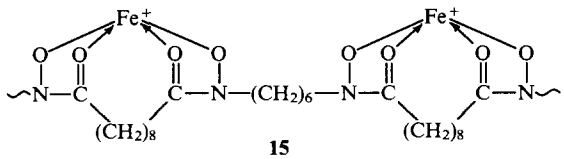


Figure 2. Determination of the composition (inflexion point) of the iron(III) complexes of deferrioxamine (*a*) and poly(hydroxamic acids) **13a** (*b*), **13b** (*c*), and **13c** (*d*).

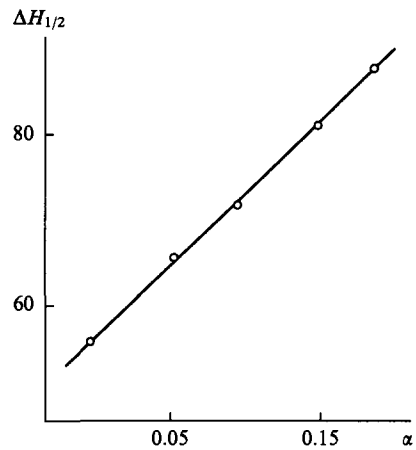
It is noteworthy that the hydroxamic groups in deferrioxamine **14** [a low-molecular-mass ligand with a high selectivity with respect to iron(III) ions] are separated by nine atoms.

14

In contrast to copolymers containing hydroxamic groups, the formation of complexes with [M]:[L] = 1:3 is not characteristic of the homopolymer — poly(hydroxamic acid).[32] In the presence of the $-(CH_2)_8-$ bridge, the 1:2 complexes **15** are formed preferentially, whereas in the case of the bridge having the composition $-(CH_2)_6-$ a considerable strain arises, as a consequence of which the formation of octahedral complexes becomes impossible.

15

Bulky chelating ligands arranged side by side in the polymer chain preclude exchange interactions between metal ions even at a high concentration of the latter. For example, an increase in the number of copper(II) ions bound to poly(hydroxyphenylbenzoxazole-terephthalamide) (complex **5**) leads to a broadening of the EPR spectral lines as a consequence of magnetic dipole–dipole interaction between the paramagnetic centres (Fig. 3) due to the decrease in the distance between them.[17]



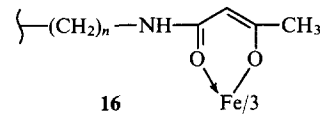


Figure 3. Dependence of the line half-width ($\Delta H_{1/2}$) on the degree of conversion for the copper(II) complex of poly(hydroxyphenylbenzoxazole-terephthalamide) **5**.

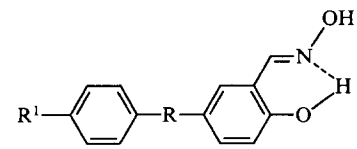
However, even for the minimum binding of copper(II) ions to the polymer, the spectrum is not fully converted into a singlet, which indicates the occurrence of exchange interactions between the metal ions. It is known[33] that cooperative effects begin to be manifested over distances of 6–9 Å; consequently the minimum distances between neighbouring copper(II) ions in such MMC exceed this quantity. This distinguishes such complexes from, for example, the copper complexes of linear polyethyleneimine (PEI), in which there is no steric hindrance to exchange interactions between the metal ions.[34] On the other hand, the uncoupling of the chelating fragments leads to the appearance of unfavourable entropy factors. In particular, a decrease in the stability constant ($\lg K$) is observed on passing from the picolinic acid-based LMC to its macromolecular analogue (the copolymer of styrene and vinylpicolinic acid [M = Cu, Ni, Co, Zn, or Mn (Table 3)].[35]

Table 3. The values of $\lg K$ for metal complexes of picolinic acid (A) and its polymeric analogue (B) (dioxane–water).



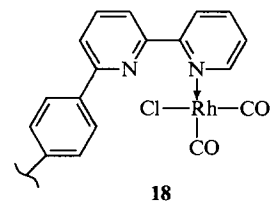
Ligand	Cu^{2+}	Ni^{2+}	Co^{2+}	Zn^{2+}	Mn^{2+}
A	12.80	12.70	12.50	12.72	9.50
B	9.88	9.56	8.28	8.44	8.44

If the chelating fragment is in a side chain, the influence of the main chain depends on the length of the connecting bridge and when the latter increases the difference between the LMC and the MMC vanishes. For example, for type **16** MMC, starting with $n = 2$, the stability of the complexes becomes virtually the same.[36]

16

The chelation process is greatly influenced also by the nature of the connecting bridge between the chelating fragment and the polymer chain. For example, the transfer of copper(II) ions from the aqueous to the organic phase (chloroform, toluene) in the formation of a complex with a hydrophobic low-molecular-mass ligand (compound **17a**) takes place very readily. On the other hand, chelation by its polymeric analogue **17b** takes place ineffectively and only the replacement of the short and hydrophobic methylene bridge in compound **17b** by the long hydrophilic ethylenediamine (compound **17c**) or methylamine (compound **17d**) unit imparts appreciable hydrophilicity and spatial mobility to the chelating fragments, which promotes the diffusion of ions in the polymeric medium and renders the ligands bound to the polymer more mobile.[37]

17a–d



R = CH_2, R^1 = CH_3 (**a**)

R = CH_2, R^1 = polystyrene (**b**)

R = $NHCH_2CH_2NH$, R^1 = polystyrene (**c**)

R = CH_2NH, R^1 = polystyrene (**d**)

On the other hand, if the polymer chain gives rise to hindrance to the formation of chelate complexes, as in the case of polystyrene with bipyridyl groups fixed in the 4-position in the benzene ring,[38] then monodentate binding of the metal with formation of compound **18** is observed.

18

In other words, the selection of the macroligand makes it possible to follow the multistage mechanism of the formation of the MMC, to isolate the intermediates, and to stabilise the unstable (in the case of low-molecular-mass analogues) complexes.

Thus on the local level the free energy changes are similar when the components of the model reaction involving the LMC and the MMC are chosen correctly. However, it is then necessary to take into account the polymeric nature of the chelating ligand and the contributions arising from this factor to the entropy of chelation. If one considers the reaction

$$[CuX]^+ + Y^- \rightleftharpoons [CuY]^+ + X^-, \quad (5)$$

where Y = poly(amidoamine) and X = its low-molecular-mass analogues, the contribution of the transfer process is zero (the number of species remains unchanged). The free energy change can then be found from the equation

$$\Delta G = -2.303\,RT \lg K = -A_{es} - TS_{st}\,, \quad (6)$$

where A_{es} is the loss of electrostatic energy when the positively charged cation moves away from the negatively charged heteroatom on the polymer to infinity, S_{st} is a statistical factor, and $\lg K$ is defined by the expression

$$\lg K = \lg K_{[CuY]^+} - \lg K_{[CuX]^+} \quad . \tag{7}$$

The enthalpy and entropy of the ligand exchange process (5) are estimated by means of the equations

$$\Delta H = -A_{es}\left[1 + \frac{T}{\varepsilon}\frac{\delta\varepsilon}{\delta T}\right] , \tag{8}$$

$$\Delta S = -A_{es}\left[\frac{1}{\varepsilon}\frac{\delta\varepsilon}{\delta T}\right] + S_{st} , \tag{9}$$

where ε is the effective relative permittivity. As was in fact to be expected, ΔH for this process is zero,[39,40] which indicates an isotypical ligand environment of the copper(II) ions in the LMC and the MMC. On the other hand, the entropy component varies with increasing degree of conversion from positive to negative values (Table 4). It attains zero (i.e. the ΔG for the LMC and the MMC are equal) when half of the negative charges on the polymer are bound to the copper(II) ions or, in other words, when the numbers of the positive and negative charges on the polymer are found to be equal. On the other hand, further addition of copper ions results in the preferential concentration of positive charges on the polymer.

Table 4. Thermodynamic functions of the ligand exchange reaction (5).

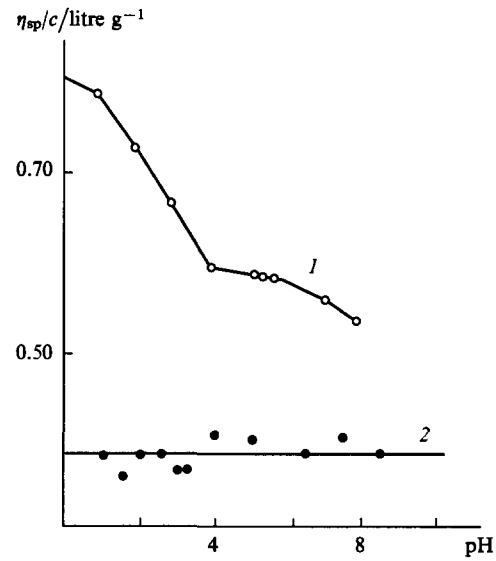
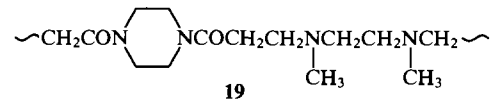
III. The molecular level of the structural organisation of metallopolymers

With increase in the degree of conversion and/or decrease in the length of the polymer chains, it is necessary to take into account the molecular level of the spatial organisation of the MMC. We shall analyse initially the influence of the degree of conversion on the chelation process for a fixed length of the polymer chains.

The effect consisting in the change of the chain conformation, which is observed after the attainment of a certain degree of conversion and involves different numbers of monomer units, is most frequently manifested. There is then a possibility of both a helix–coil transition, characteristic of charged chains, and of a change in the preferential conformation of the statistical coil.[41] Conformational transitions have been detected in linear poly(amidoamines) on protonation and complex formation.[19] Thus viscometric titration showed that the viscosity of the linear polymer **19** decreases monotonically with increase in the pH (Fig. 4). Analysis of the superposition of the distribution curve on the pH dependence of the viscosity shows that the ratio of the specific viscosity and the concentration (η_{sp}/c) decreases on completion of the formation of the complex CuL and then remains virtually constant until the deprotonation of the ligand is completed. The second small jump corresponds to the formation of HL_2^+ and can be explained by a conformational transition.[39]





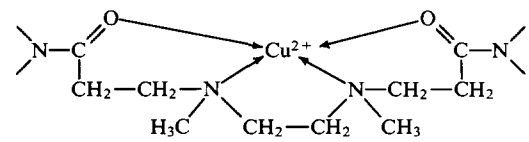


Figure 4. The viscosity and the distribution curves as a function of pH for the copper (II) complexes of linear (compound **19**, curve *1*) and branched (compound **21**, line *2*) poly(amidoamines).

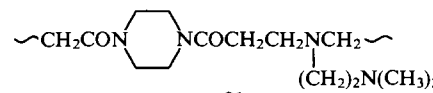
In other words, the involvement in the reactions of the nitrogen atoms of the main chain is accompanied by conformational transitions which influence the properties of the entire macromolecule, since the junctions between different monomer units (six-membered diacylpiperazine chelate rings in complex **20**) are very rigid.



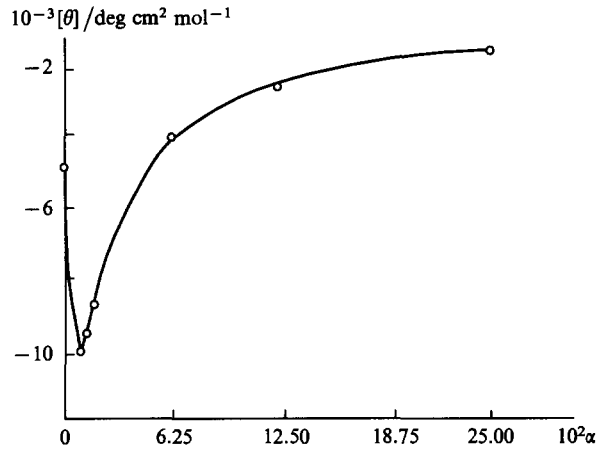
19

20

In the case of the branched polymer **21**, appreciable deviations of η_{sp}/c from a constant value are not observed over the entire pH range (Fig. 4).[40] The weak dependence of the viscosity on the pH and on the degree of conversion for this polymer is unusual and is probably due to the fact that the conformational transition associated with complex formation involves only the side substituents and does not affect significantly the characteristics of the main chain.

21

It has been established[42] that, for the poly-L-lysine.heme and poly-L-lysine.hemin complexes at low degrees of conversion, the fraction of the α-helical structure and the viscosity of the solution do not change. This result shows that the MMC obtained is intramolecular and that the helical structure can be represented schematically in the form of complex **22**. If the degree of conversion exceeds 0.1, then the fraction of the helical structure diminishes, which indicates the existence of steric hindrance to its establishment owing to the coordination of the bulky complexes **23**.



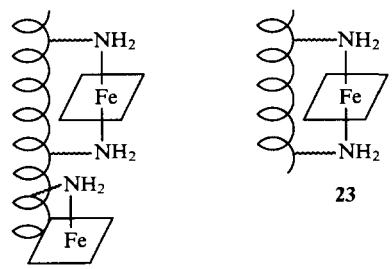


Figure 5. Dependence of the ellipticity θ of poly-*N*(5)-(3-hydroxypropyl)-L-glutamine on the degree of conversion of the Cu^{2+} ions.

In the interaction of copper(II) ions with poly-*N*(5)-(3-hydroxypropyl)-L-glutamine up to a degree of conversion of 6.25×10^{-2}, the α-helical conformation predominates, whilst above this conversion the chain conformation changes (Fig. 5).[43]

The helix – coil transition may be observed in the copper(II) – poly-L-glutamic acid system when a change takes place both in the ratio $[M^{2+}]/[L]$ (Fig.6) and in the pH of the solution for a fixed $[M^{2+}]/[L]$ ratio (Fig.7).[44] If the degree of neutralisation is

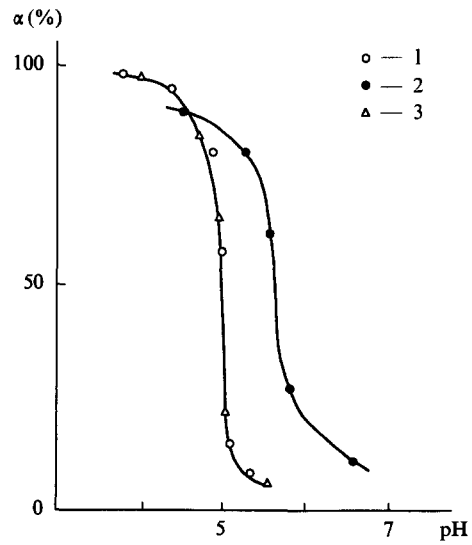

Figure 6. Dependence of the content of the α-helium (α) in poly-L-glutamic acid (*1*) and in its copper complex on pH for $[Cu^{2+}]/[L] = 0.1$ (*2*) and 0.02 (*3*).

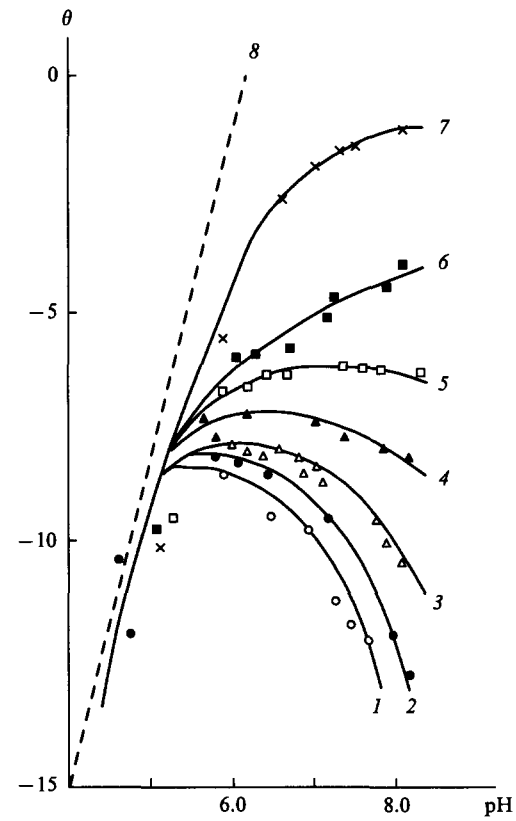

Figure 7. Relation between the molar ellipticity at 222 nm and the pH of Cd^{2+} – polyglutamic acid solutions for different ratios $[Cd^{2+}]/[L]$: (*1*) 1.5; (*2*) 1.0; (*3*) 0.77; (*4*) 0.5; (*5*) 0.4; (*6*) 0.3; (*7*) 0.15; (*8*) 0.0.

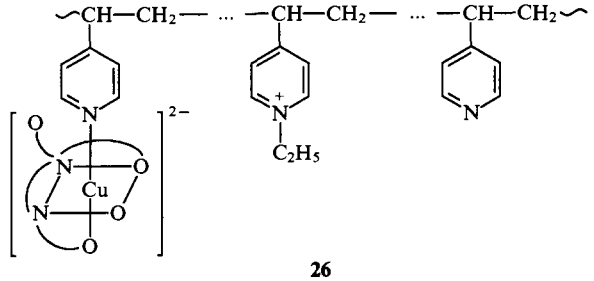
less than 0.2, i.e. the polyaminoacid has a helical structure, then the Cu^{2+} ions are hardly bound by the polymer. On the other hand, the interaction of these ions with poly-L-lysine leads to the formation of complexes containing a polymer in the α-helical conformation.[45,46] It is interesting to note that, when Cu^{2+} ions are added, poly-D-lysine undergoes a conformational transition, whereas the addition of other ions, for example, Zn^{2+}, Mg^{2+}, Mn^{2+}, or Ca^{2+}, has no effect whatever on the polymer conformation.[47]

Electrostatic, hydrophobic, or hydrophilic interactions between the components may exert an appreciable influence on the chelation of metal ions. On formation of charged chains, the macromolecules is stretched as a result of the reaction with the metal ion as the degree of conversion increases. Thus the introduction of metal cations into the cavity within the macrocycles of the homopolymers of vinylcrown-ethers may alter significantly the conformation of the polymer chain. In the initial state, such polymers are typical micelles, in which the nonpolar hydrocarbon 'tails' are collected in a coil, whilst the polar 'heads' (crown ethers) emerge into the solution surrounding the micelle. On complex formation, the polymeric crown-ethers are converted into polyelectrolytes, which leads to electrostatic repulsion of the monomer units. This interaction results in the uncoiling of the coil and the assumption by the polymer of the extended chain conformation.[48]

The formation of a complex between uncharged polyvinylpyrrolidinone and copper(II)-chlorophyllin is accompanied by the formation of hydrogen bonds, which leads to a sharp increase in the viscosity of the solution.[49]

The hydrophobic interaction of the LMC with the macroligand is also important. This has been clearly shown in relation to the formation of complexes between heme and water-soluble polmers — poly(ethylene oxide), poly(vinyl alcohol), and polyvinylpyrrolidinone.[50] It was found that the equilibrium between



the monomeric and dimeric forms of heme, which obtains in aqueous solution, is fully displaced towards the monomeric form at a high concentration of the polymeric ligand. This effect increases with increasing hydrophobicity of the polymer in the series polyvinylpyrrolidinone > poly(ethylene oxide) > poly-(vinyl alcohol), which led to the conclusion that there is a hydrophobic interaction between heme and the polymer.

Table 5. Stability constants of complexes **26**.

CuX^{n-}	Ligand				
	4-ethyl-pyridine	P4VP	QP4VP (20)[a]	QP4VP (25)[a]	QP4VP (61)[a]
24	72	60	123	–	240
25	70	48	–	870	1100

Note. Reaction conditions: aqueous methanol (1:1 by volume), ionic strength of solution 0.1 M, pH 8, T = 298 K.
[a] Here and in Table 6 the numerals in brackets denote the degree of quaternisation.

The macroligand may contain positively or negatively charged atoms, which either promote or interfere with its interaction with metal ions (although they do not in fact influence significantly the formation of a direct chemical bond involving them). This has been noted in a study of the interaction of CuX^{n-}, where X = ethylenediaminetetraacetate (complex **24**) or *N*-(2-hydroxyethyl)ethylenediamine-*N,N',N'*-triacetate (complex **25**), with quaternised poly-4-vinylpyridine (QP4VP) in the formation of type **26** complexes.[51] The stability constants of these complexes (Table 5) increase with increase in the degree of quaternisation despite the fact that steric hindrance should increase in this case. Evidently this is caused by an electrostatic effect; the local concentration of CuX^{n-} should increase with increasing degree of quaternisation by virtue of the Coulombic interaction between the polycation and CuX^{n-}. An increase in the charge on the initial LMC increases its affinity for the polycation and the stability constants also increase in the same sequence.

26

The degree of conversion of metallochlorophyllins (M = Co^{3+}, Fe^{3+}, Ni^{2+}, Cu^{2+}, or Zn^{2+}) in the interaction with QP4VP proved to be unity.[52] The stability constants of these complexes were $\sim 10^3$ litre kg mol^{-1}, i.e. were greater than for the low-molecular-mass analogues. In all probability, the stability of the complexes of the metallochlorophyllins with QP4VP is determined by the electrostatic binding of the carboxylate anion of the LMC to the quaternary pyridinium cation in the polymer chain.

Similar conclusions were reached[51] also in a study of the formation of complexes of methylaquocobaloxime† with pyridine-containing ligands [reaction (10)]. In this case, the stability constants decreases in the sequence 4-ethylpyridine > P4VP > QP4VP(25) > QP4VP(61). The steric hindrance exerted by the polymeric ligand and the positive charge density increase in the same sequence.

† MeCo(dimethylglyoxime monoanion)$_2H_2O$ (Ed. of Translation).

Table 6. The stability constants and rates of formation of complexes by reaction (10).

Constant (method of determination)	Ligand			
	4-ethyl-pyridine	P4VP	QP4VP (25)	QP4VP (61)
K/litre mol^{-1} (a)	3.5×10^3	1.7×10^3	5.3×10^2	95

k_{-1}/s^{-1} (b)	5.3×10^{-3}	1.0×10^{-2}	1.6×10^{-2}	2.6×10^{-2}
k_{-1}/s^{-1} (a)	6.0×10^{-3}	9.9×10^{-3}	1.7×10^{-2}	1.8×10^{-2}

Note. Method: (*a*) kinetic [aqueous methanol (3:7 by volume), ionic strength of solution 0.05 M, pH 8, T = 298 K]; (*b*) spectrophotometric.

$$CH_3Co(DH)_2H_2O + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CH_3Co(DH)_2L + H_2O \quad (10)$$

(DH = dimethylglyoxime)

Chelation makes it possible comparatively frequently to stabilise conformational and tautomeric forms uncharacteristic of the initial polymer. Thus the addition of the [(2,2',2'',2'''-tetrapyridyl)iron]$^{3+}$ ions to solutions of sodium poly(L-glutamate) increased the content of the α-helical form at pH values where the coil usually predominates.[53] In other words, the metal ion selects the polymer chain conformation which it prefers most.

The chain conformation is determined by many factors (for example, the nature of the solvent) which exerts a significant influence on the entire chelation process. Thus, in the interaction of poly(2-methyl-*N*-vinylimidazole) with the $CoCl_3(en)_2$ system, where en = ethylenediamine, in $H_2O-C_2H_5OH$ mixture, an increase in the ethanol content from 0 mass% to 10 mass% entails a decrease in thermodynamic parameters: from 46.5 to 43.6 kJ mol^{-1} in ΔG, from 97.2 to 41.5 kJ mol^{-1} in ΔH, and from 164.3 to 47.3 J K^{-1} mol^{-1} in ΔS.[50] The solvent also significantly influences the rate constants for forward (k_1) and reverse (k_{-1}) ligand exchange reactions [reactions (11)] (Fig. 8).[54] This can be accounted for by the variation of the conformation of the polymeric ligand as a function of the nature of the solvent; the rate of the ligand exchange reaction of cobaloximes with polymeric ligands, such as the styrene–4-vinylpyridine copolymer, may be controlled by varying the conformation of the macroligand.

$$K = \frac{[ClCo(DH)_2L][DMF]}{[ClCo(DH)_2DMF][L]}$$

$$ClCo(DH)_2DMF + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cl \cdot Co(DH)_2L + DMF \quad (11)$$

The rate constants for the chemical decomposition (k_{decomp}) of the complex between cobaloxime and the styrene–chloromethylstyrene copolymer proved to be smaller by a factor of 4 than the low-molecular-mass benzylcobaloxime (Table 7).[55] This can be explained by the fact that the diffusion of divalent cobalt complexes, formed in the homolytic photochemical decomposition, proceeds less easily as a consequence of steric hindrance by the polymer chain. Furthermore, the alkyl radicals formed are retained by the polymer; the probability of their recombination thus increases compared with the monomeric analogues. However, this type of effect has not been observed in dimethyl sulfoxide (Table 7), because in this solvent cobaloximes are

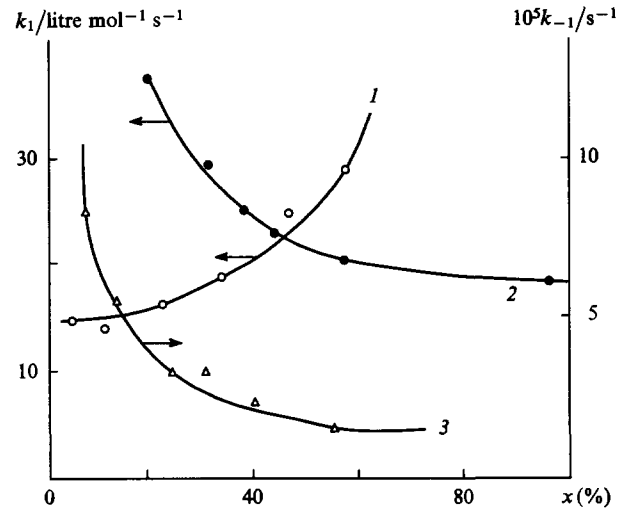

Figure 8. Dependence of the rate constants for the forward (k_1) and reverse (k_{-1}) reactions on the content (x) of 4-vinylpyridine units in the copolymer: (*1*) in benzene; (*2*) and (*3*) in DMF.

localised on the surface of the polymer coil and are not subjected to steric hindrance due to the polymer chain. In mixed solvents (DMSO–benzene), the ratio of the rate constants for the decomposition of the polymer (k^P) and the monomer (k^m) diminishes with increase in the benzene content (Fig. 9). It follows from measurements of the viscosity of the polymer to which cobaloxime is attached that the polymer chain becomes 'extended' with increase in the benzene content in the solvent. Thus the decrease in the rate constant for the photochemical decomposition of the polymer-bound cobaloxime with increase in the benzene content in the solvent is apparently caused by the extension of the polymer chain.

One of the characteristic features of the chelation reaction involving polymeric ligands on the molecular level is the 'neighbouring group' effect caused both by the interaction of the neighbouring chelating fragments and by the statistical nature of the entire chelation process.[56] If blocks containing a smaller number of active centres (functional groups) than required for

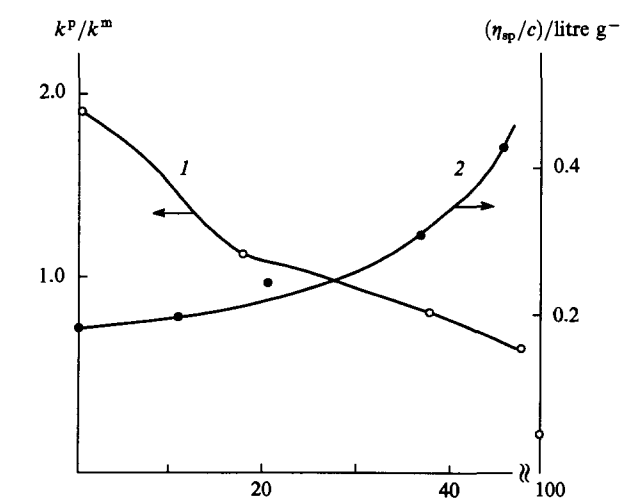

Figure 9. Variation of the relative rate constant (k^P/k^m) for the photochemical decomposition of alkylcobaloximes (curve *1*) and of the ratio η_{sp}/c (curve 2) for MMC as a function of the benzene content in the solvent.

chelation to the metal ion remain unreacted during the chelation process, then such blocks no longer participate in the coordination, i.e. the concentration of the unreacted centres is not equal to the active concentration of the reacting species. Here it is necessary to take into account the fact that the fraction of the monomer units capable of coordination, among all the unreacted monomer units, depends on the degree of conversion. Various ways of binding the metal to the macroligand are possible.[41] Thus, if there are q metal ions on the chain containing m active centres, then the number of complexes formed, having different structures, is c_m^q (the number of combinations of q molecules with m chain centres).

Low-molecular-mass cobalt(II) chelates, for example of ethylenediamine, have a fairly large volume (diameter about 10 Å), so that during their coordination, even when a close packing is produced, some P4VP units remain uncoordinated for steric reasons (complex **27**).

27

The calculated maximum degree of conversion of P4VP is in this case 0.63, which is close to the experimental values (Fig. 10, see over). A complex of this kind has a rigid rod-shaped structure, in which the mobility of the Co^{2+} chelate is much smaller than that of the monomeric analogues. The decrease in the g-factor in the EPR spectrum of the complex *cis*-$[Cr(en)_2(P4VP)Cl]Cl_2$ with increase in the degree of conversion indicates a decrease in the symmetry of the Cr^{3+} complex (D_{4h}).[8] Such disburbance of the anisotropy is caused by the steric hindrance generated both by the P4VP ligands and the fixed chelates.

For the vinyl imidazole copolymers, the number of ligands axially coordinated to heme is about two, decreasing with decrease in the 1-vinylimidazole content in the copolymer (Table 8, see over). A favourable contribution by the entropy factor, associated according to the authors[57] with the high apparent concentration of the functional groups in the polymer

Figure 10. Table 10. Thermodynamic parameters of the ligand exchange reaction (11).

Ligand	ΔG/kJ mol^{-1}	ΔH/kJ mol^{-1}	ΔS/J mol^{-1} K^{-1}
Pyridine	−27.2	−14.2	42
P4VP	−22.2	−8.0	50.4
Styrene–4-vinylpyridine copolymer[a]	−29.3	−6.3	79.8

Note. Solvent–DMF (at 20 ± 0.5 °C).
[a] Content of 4-vinylpyridine units 32%.

[Eqn (11)]: styrene–4-vinylpyridine copolymer (13%–53% of 4-vinylpyridine) > Py > styrene–4-vinylpyridine (10% of 4-vinylpyridine) copolymer > poly-4-vinylpyridine.[54] The distance between the pyridine fragments in P4VP is so short that not all the 4-vinylpyridine groups can function as ligands owing to the steric hindrance generated by the coordinated cobaloximes. In the case of the copolymer containing 13%–53% of 4-vinylpyridine fragments, where the steric hindrance between the cobaloxime moieties may be neglected, the equilibrium constant is higher than for the low-molecular-mass analogue (Py). This is also indicated by the calculated thermodynamic parameters of the ligand exchange reaction (Table 10).

The rate of formation of the cobalt chelates with the partly quaternised P4VP diminishes in the following sequence of groups R (the group in the quaternising agent): H > CH_3 > $CH_2C_6H_5$ (Fig. 10), which is due to the steric hindrance arising from the polymeric ligands.[58]

The use of polymeric crown-ethers for the formation of [L]:[M] = 2:1 complexes with a sandwich structure (Fig. 11), i.e. in those cases where the size of the cavity within the macrocycle is too small for the formation of 1:1 complexes, proved to be effective. This is clearly seen in relation to the interaction of the potassium ion with the 15-crown-5-ether (the constant for the extraction of potassium picrate is 0.42×10^3 mol^{-2}) and with its polymeric analogue (extraction constant 2.3×10^3 mol^{-2}). The greater effectiveness of the polymeric crown-ethers in the formation of the 2:1 complexes is caused by the high local concentration of the macrocycles in the polymer chain, which entails the single-stage binding of the metal ion by two neighbouring fragments (Fig. 11). However, one should note that the examination of the macromolecular models of the complexes indicates that the involvement in complex formation of, not neighbouring, but alternate monomer units is preferable.[59]

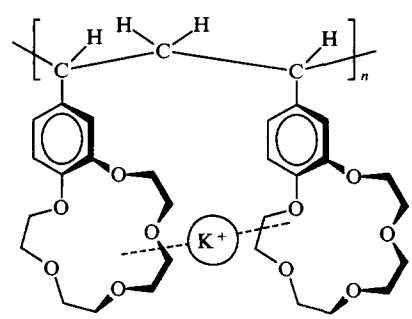

Figure 11. The structure of the sandwich type complex formed by the K^+ ion and the polyvinylbenzo-15-crown-5.

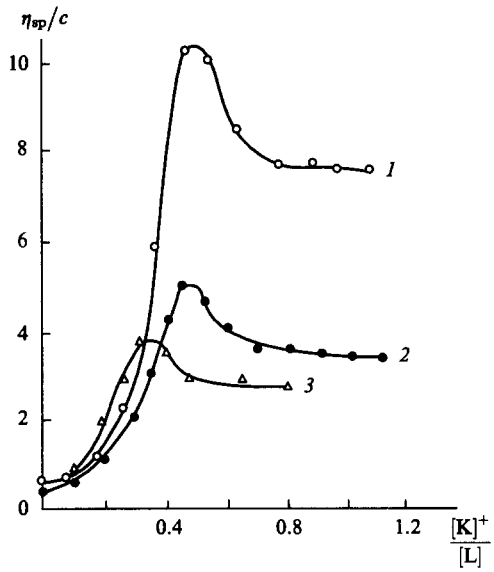

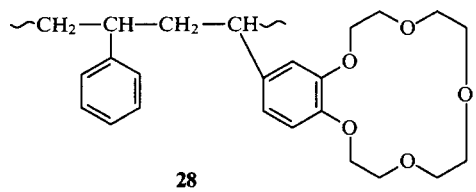

Figure 12. Dependence of the viscosity of the styrene–vinylbenzo-15-crown-5 copolymer on the ratio $[K^+]:[L]$ for different contents of the chelating fragments (%): (*1*) 18; (*2*) 11.8; (*3*) 5.8.

The results of viscometric measurements have shown (Fig. 12) that the maximum values of η_{sp}/c in the potassium ion–copolymers **28** system corresponds to the 2:1 complex and that the content of the crown-ether units does not exceed 20%. In other words, intramolecular metal chelates are formed only when the chelating fragments are separated by less than four (on average) styrene units.[60]

28

In the formation of the MMC, the first step may be regarded as a second-order reaction (first-order with respect to each component), while all the subsequent steps (with formation of the chelate rings) may be regarded as first-order reactions. The overall formation of metal chelates with a single chain is a second-order reaction. Since the rates of complex formation reactions are ususally high, it is difficult to distinguish experimentally the consecutive stages of the process. However, in those comparatively rare cases where this has been achieved the successive stability constants K_i as a rule increase with increase in the degree of conversion. Low-molecular-mass ligands behave differently. Thus, in the case of the low-molecular-mass pivaloylacetone and methacryloylacetone the ratio $K_1/K_2 = 1.08$ and 1.12 respectively (copper complexes are considered). On the other hand, the analogous ratio for polymethacryloylacetone[61] is 0.84, i.e. the stability constants increase with increase in the degree of conversion. This is a consequence of the cooperative 'chain effect', which involves a change in the shape of the macromolecule without change in the contour length on complex formation.[41,59] In particular, the interaction of metal ions with soluble polymers decreases the flexibility of the polymer chains with increase in the degree of conversion. This effect is manifested particularly clearly in the case of polymers containing biypyridyl units in the main chain.[62,63] Appreciable changes in the shape of the macromolecules of poly-2-vinylpyridine have been observed[64] in its interaction with cobalt acetylacetonate. The stability constant of the MMC in the case of polymeric ligands can be expressed in the form

$$K = \prod_{i=1}^{i=N} K_i = \sigma K_j ,$$

where $\sigma = K_i/K_{i-1}$ is the parameter of the cooperative effect, showing by what factor the stability constant increases as a result of each successive addition compared with the previous value. It has been postulated that all the consecutive stability constants, other than the first, are the same (since virtually the entire entropy is lost in the first step, the subsequent stages represent intramolecular cyclisation). The 'chain effect' is manifested by the high local concentration of the functional groups, so that the stability constant is not determined by the average concentrations of the components but by their local concentrations in the coils (as in microreactors).[65] After entering a region of a high local concentration of the functional groups, the metal ion immediately forms coordinatively saturated complexes, whilst the groups which remain free participate in the formation of a small number of coordinatively unsaturated structures.

The constancy of the composition of the complexes for different ratios of the reacting components (within wide limits) is a distinctive feature of the reactions of macroligands compared with their low-molecular-mass analogues: it is thermodynamically easier for a macromolecule to form coordinatively saturated complexes (even if their amount is smaller) than the unsaturated complexes. Thus a study of copper(II) complexes of a polymer aminated by ethylenediamine, diethylenetriamine, and trimethylenediamine demonstrated[66] small differences between the values of $A_{||}$ and $g_{||}$ as well as α^2 (the unpaired electron density on the coordination ion) for the LMC and the MMC (Table 11). These differences indicate the existence of some steric hindrance to the formation of the tetracoordinate complex CuN_4 in the case of the polymer. When the content of copper ions in the MMC is <0.05 mmol g^{-1}, the EPR spectrum is satisfactorily resolved and corresponds to isolated mononuclear complex species having the same composition. When the copper concentration increases, the EPR spectrum represents the superposition of an anisotropic multiplet (due to the isolated complexes) and a singlet with a g-factor of about 2.08–2.10. The amplitude of the latter increases with increase in the copper content in the MMC. The singlet is evidently due to the existence of regions with a higher local concentration of copper ions, where the distance between neighbouring ions does not exceed 7–9 Å and where there is a strong spin-exchange interaction between them. The composition of the copper complexes in such regions apparently correspond to the formulae CuN_4, CuN_3, CuN_2, or CuN—i.e. in the course of chelation coordinatively saturated complexes are formed initially as the degree of conversion increases and then coordinatively unsaturated complexes are produced.

In the case of an acrylic acid copolymer containing phenanthroline units, a 1:1 complex (this complex has the highest stability constant) and then a 1:2 complex are formed in succession with increase in the degree of conversion.[67] On passing from the

Table 11. Parameters of the EPR spectra of the copper complexes of a polymer aminated by polymethylene amines and of its low-molecular-mass analogues at 77 K.

first complex to the second, a slight increase in $A_{||}$ and an appreciable decrease in α^2 (by 0.05) are observed, which indicates slight tetrahedral distortions of the coordination unit. This can be explained by the steric hindrance arising when four coordinated nitrogen atoms are located in a single plane.

Together with the main peak at 613 nm due to the $^5D_0 \rightarrow {}^7F_2$ transition (as in the low-molecular-mass analogue dibenzoylmethane), an additional peak at 580 nm, corresponding to the forbidden $^5D_0 \rightarrow {}^7F_0$ transition,[68] appears in the emission spectrum of the Eu^{3+} complex of poly(*p*-benzoylacetylstyrene) **29** (Fig. 13). The appearance of this peak is associated with the decrease in symmetry around the Eu^{3+} ion (owing to the steric hindrance arising in the formation of the polycyclic complex). An increase in the degree of conversion in this instance leads to the formation of 1:2 and 1:1 complexes with the [M]:[L] = 1:3 complex. The fluorescence intensity remains almost constant until the attainment of the maximum at low Eu^{3+} concentrations (Fig. 14). In other words, the maximum intensity corresponds to the 1:3 complex. When the β-diketone fragment is introduced into the main chain (the ligand **30**), the formation of 1:3 complexes becomes more difficult and the 1:2 complex, characterised by a low fluorescence intensity, becomes the main product.

29

30

The reaction of iron(III) ions with the low-molecular-mass ligand bipyridyl produced an equilibrium mixture of 1:1, 1:2, and 1:3 complexes, whereas the formation of only 1:1 chelate is characteristic of poly(6-vinyl-2,2′-bipyridyl).[69] Thus the polymeric ligand makes it possible to stabilise complexes having a specified composition.

One of the manifestations of the chain effect in metallopolymer systems is also the independence of the thermodynamic parameters of the chelation process of the chain length (molecular mass) of the polymeric ligand.[70] Thus, in the formation of copper(II) complexes of poly(hydroxamic acids), the stability constants of the latter diminish with increase in the molecular mass of the polymer (from 3000 to 15 000).[71] Fig. 15 presents the spectra of the copper complexes of methylhydroxamic acid and its polymeric analogues in the far infrared. In this case, the absorption band at 550 cm^{-1} in the IR spectrum of the LMC refers to the Cu–O and C–N bond vibrations. This band undergoes a bathochromic shift with increase in the molecular mass of the polymer. The band at 516 cm^{-1}, assigned to the deformation vibration of the ring and the O=C–C– group, shifts in the same direction. Bearing in mind that the order in which the frequencies of the stretching vibrations and their force constants vary corresponds to the order of the variation of the stability constants of the complexes of β-diketones, one may postulate that the stability of the copper complexes of poly(hydroxamic acid) diminishes with increase in molecular mass.[72]

The formation of low-molecular-mass chelates involving cobalt(II) and P4VP with a lower degree of polymerisation also proceeds more readily.

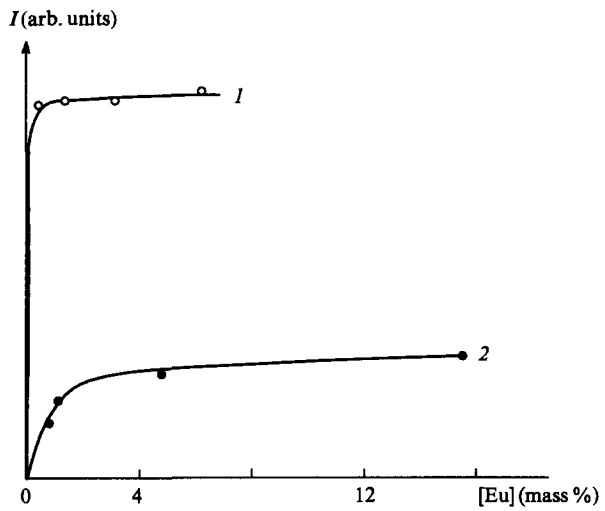

Figure 14. Dependence of fluorescence intensity at λ = 613 nm on the europium content in the macrocomplexes of **29** (curve *1*) and **30** (curve *2*).

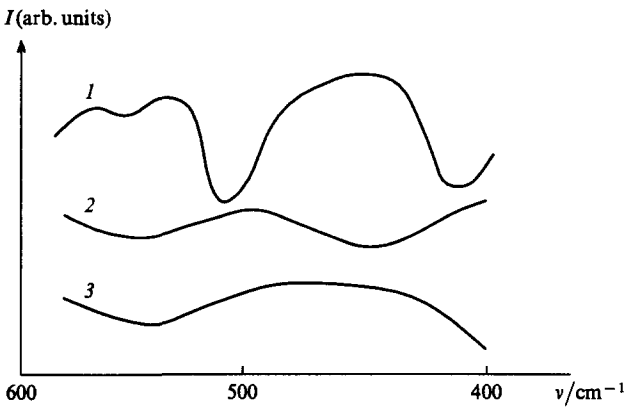

Figure 15. IR spectra of the copper(II) complexes of methylhydroxamic acid (curve *1*) and poly(hydroxamic acids) with M_n = 640 (curve *2*) and 17 000 (curve *3*).

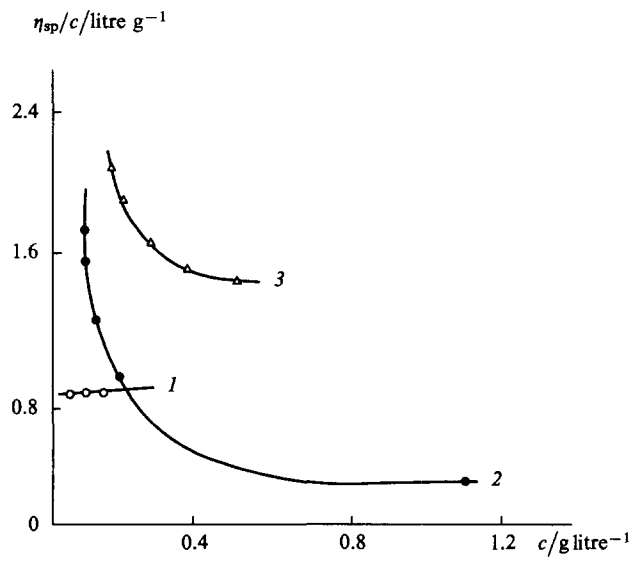
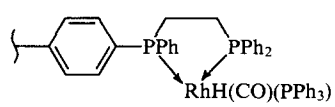
The chelating fragments of one (intramolecular metal chelates) or two polymer chains (intermolecular metal chelates) may participate in the formation of macromolecular metal chelates. A typical manifestation of the chain effect is intramolecular (and not intermolecular) cyclisation in dilute solutions. For example, the interaction of poly(6,6'-dimethyl-5-vinyl-2,2'-bipyridyl) with cobalt(II), copper(II), and zinc(II) chlorides in ethanol at 298 K results in the formation of 1:1 complexes with M←N bonds.[73] The decrease in the viscosity of the solutions of the MMC in dimethylformamide (DMF) on dilution (Fig. 16) indicates their polyelectrolyte nature. The solubility of these compounds indicates the absence of intermolecular cross-linking, i.e. the bipyridyl groups behave like the usual chelating ligands in the side chains of the polymer. Similar results have also been obtained for the VO^{2+} and Co^{2+} complexes of polyureas incorporating the bipyridyl group.[74]





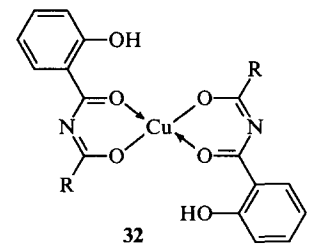


Figure 16. Concentration dependences of the ratio η_{sp}/c for poly-4-methyl-4'-vinyl-2,2'-bipyridyl (curve 1) and its complexes with $ZnCl_2$ for [Zn]:[L] = 0.3 (curve *2*) and 0.6 (curve *3*).

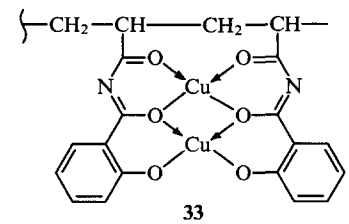
The features of the formation of chelates with participation of polymeric ligands noted above may lead both to the appearance of new reactions, uncharacteristic of the low-molecular-mass compounds,[75] and to a change in the mode of the complex formation reactions known for the LMC.[76] Thus it has been shown that the polymer modified by 1,2-bis(diphenylphosphino)ethane forms the mononuclear complex **31** on interaction with $RhH(CO)(PPh_3)_3$,[77] whereas the low-molecular-mass analogues — 1,3-bis(diphenylphosphino)propane and 1,4-bis(diphenylphosphino)butane — give rise to dimeric rhodium complexes.



31

The low-molecular-mass chelating ligands *N*-acylsalicylamides afford mononuclear metal chelates on interaction with copper(II) ions and, of the two possible coordination centres, the diacylamine fragment participates in the complex formation reaction (complex **32**).[27] However, the *N*-acylsalicylamide on the polymer base immediately gives rise to the dinuclear copper complexes **33**.[78]

32

33

Another characteristic example is the shift of the monomer ⇄ dimer equilibrium in solution of metallophthalocyanines towards the monomeric form on formation of complexes with polymeric ligands, which is indicated, for example, by the increase in the intensity of the monomer peak with a simultaneous decrease in the intensity of the dimer peak in the UV spectra of the metallophthalocyanines (Fig. 17).[79] This shows that the large size of the polymer chain prevents the aggregation of the metallophthalocyanine units. Evidently the dimer cannot arise if only one metal chelate molecule is present in each polymer coil. The mole fraction X_i of the metal chelate bound to the polymer chains, each of which contains k metal chelate molecules, may be calculated by the equation[79]

$$X_i = \frac{k(1-p^2)(p\alpha)^{k-1}}{(1-p+p\alpha)^{k+1}}, \qquad (12)$$

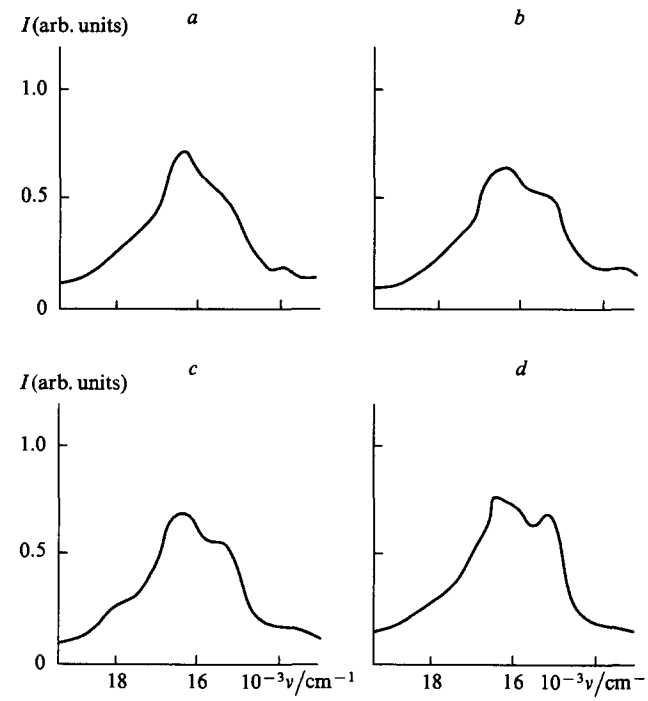


Figure 17. Absorption spectra in the visible region of complexes of cobalt-tetrasulfophthalocyanine (concentration 2.5 μM) with PVA at different concentrations of the latter (mM): (*a*) 2.5; (*b*) 5.9; (*c*) 10.0; (*d*) 25.0.

where $p = 1 - 1/P_n$ (P_n is the number-average degree of polymerisation). Calculations showed (Table 12) that, in the case of a polymer with a relatively low molecular mass (P_n = 50), X_i for isolated (k = 1) metal chelate molecules is extremely large and diminishes slowly with increase in α. On the other hand, in the case of a polymer with a high molecular mass (P_n = 1680), the fraction of polymer chains containing only one metal chelate molecule attains high values at low degrees of conversion.

Table 12. Calculated amounts (in mol%) of isolated molecules of metallophthalocyanines bound to polyvinylamine.

$10^2\alpha$	P_n = 50	P_n = 1680

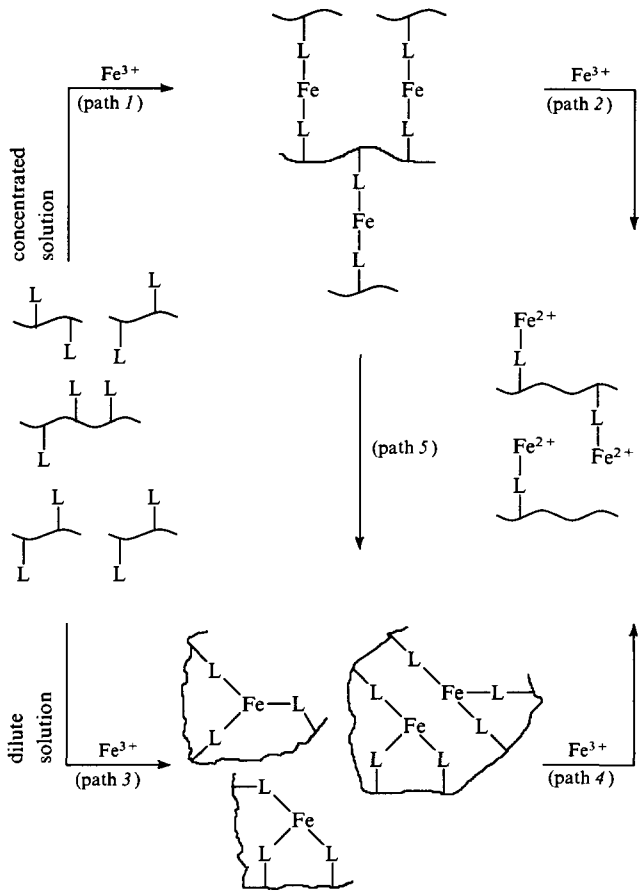
0.02	98.07	56.04
0.01	99.03	73.31



At the molecular level there are spatial organisation requirements which distingish macromolecular metal chelates from their low-molecular-mass analogues. The principal polymer chain effects are fully manifested on this level: the changes in the conformation of the chain, neighbouring groups, etc. In certain cases, these effects can be separated, which makes it possible to discover their characteristic features.

IV. The supermolecular level of the structural organisation of metallopolymers

On passing from a dilute to a concentrated solution and further to a massive specimen, there is a significant increase in the extent of the intermolecular interaction of both the initial polymers and of the metal chelates based on them, which makes it necessary to take into account a third (supermolecular) level of the spatial organisation of the MMC. Studies have shown that the reactions of metal ions with concentrated solutions of macroligands, cross-linked or graft polymers, are distinguished primarily by the greater free energy changes in the process. In concentrated solutions, the polymeric nature of the ligands considered should be manifested more strongly than in dilute solution and the characteristics of the chelation process associated with their polymeric character should be more pronounced. Therefore, in considering the kinetic and thermodynamic features of the chelation process on the supermolecular level, one has to take into account all the principal effects of the polymer chain.

With increase in the macroligand solution concentration, there is an appreciable increase in the probability of the formation of intermolecular (and not intramolecular) metal chelates.[80,81] By varying the degree of conversion, it is possible to observe the reversible transition between the intermolecular and intramolecular metal chelates. We shall demonstrate this with the aid of the scheme, presented below, for the formation of complexes between iron(III) ions and poly(hydroxamic acids) (Scheme 1).[82] At high polymer concentrations, the hydroxamic groups from different polymer chains are disposed closer to one another than the chelating fragments in the same chain. This increases the probability of the formation of intermolecular bonds (path *1* in Scheme 1), whereupon cross-linking becomes a significant feature of the process. The cross-linking of the polymer chain is accompanied by an increase in the viscosity of the solution (Fig. 18). Increase in viscosity by virtue of intermolecular cross-linking via the formation of metal chelates has been observed[60] after the addition of alkali metal salts to styrene–crown-ether copolymers. As a result of further addition of iron(III) ions, the cross-linked complexes with the composition [L]:[M] = 3:1 are converted into 1:1 complexes (path *2*) and, by virtue of the rupture of

Scheme 1

the cross-links, each iron ion is bound to only one hydroxamic group (path *4* also leads to the same products).

At low concentrations of the chelating macroligand, where the neighbouring hydroxamic acid groups in the same chain are disposed closer to one another than the groups from different polymer chains, the iron complex is formed intramolecularly (path *3*, Fig. 18), which diminishes the limiting size of the disordered polymer coil and hence diminishes the viscosity. With increase in polymer concentration, the change in viscosity becomes more appreciable, since the density of the cross-links

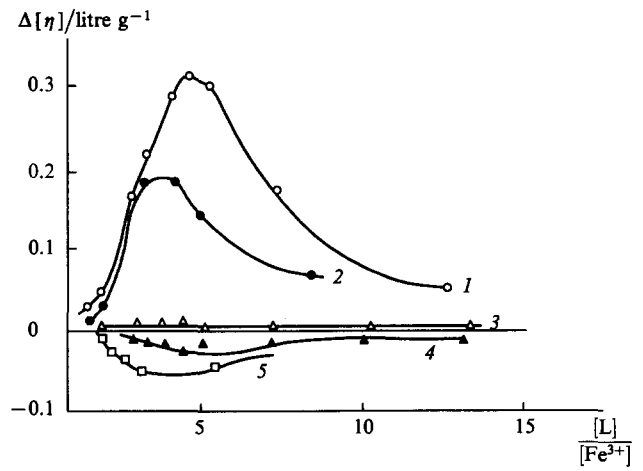


Figure 18. Dependence of the change in the intrinsic viscosity of the polymer containing 0.749 mol% of hydroxamic acid units on the ratio [L]:[Fe] for different concentrations of the polymer (g litre^{-1}): (*1*) 4.90; (*2*) 3.25; (*3*) 1.0; (*4*) 0.75; (*5*) 0.50.

increases. It is noteworthy that the molecular mass of the polymer has a greater influence on the viscosity than the content of the chelating fragments.[82]

The cross-linked polymers formed at high concentrations are 'kinetic' products, which after a time are converted into thermodynamically more stable intramolecular complexes (path *5*). The transition between the intramolecular and intermolecular complexes is reversible

Since the chemical bond is the same in both cases, the enthalpy of the transition ΔH should be zero and hence the transformation is determined by entropy factors. The conversion of intermolecular chelates into intramolecular ones is a first-order reaction, the rate constants for which are 5.21×10^{-6} s^{-1} at 303 K and 49.7×10^{-6} s^{-1} at 333 K. The activation energy and the entropy are 63.3 kJ mol^{-1} and 4.2 J mol^{-1} K^{-1} respectively.

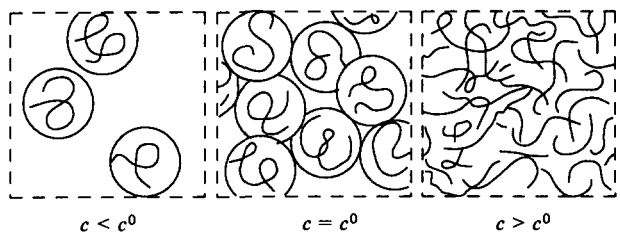

Figure 19. Schematic representation of the polymer at different concentrations of the latter.

The following two parameters are most important for the formation reactions of intermolecular metal chelates: the critical polymer concentration c^0 and the temperature T_t of the liquid ⇄ gel transition.

The quantity c^0 represents the concentration above which the intermolecular interaction becomes significant (Fig. 19).[83] It is noteworthy that the critical concentration of the polymer is inversely proportional to its molecular mass.[84] Above the critical concentration, the transition temperature T_t is almost independent of the concentration and molecular mass of the polymer (Fig. 20). It has been suggested that Eqn (13), obtained from the classical theory of gel formation, be used to calculate T_t.[85] This equation shows that T_t is determined mainly by the thermodynamic characteristics associated with the formation of metal–polymer bonds (i.e. ΔH and ΔS).

$$T_t = \frac{\Delta H}{\Delta S - R \ln[(c - c^0)/c^0]} \tag{13}$$

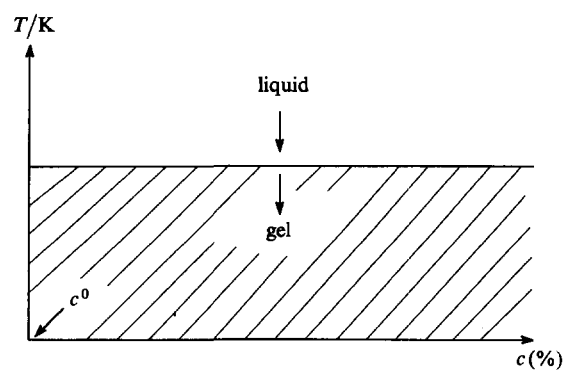

Figure 20. Liquid ⇄ gel phase diagram.

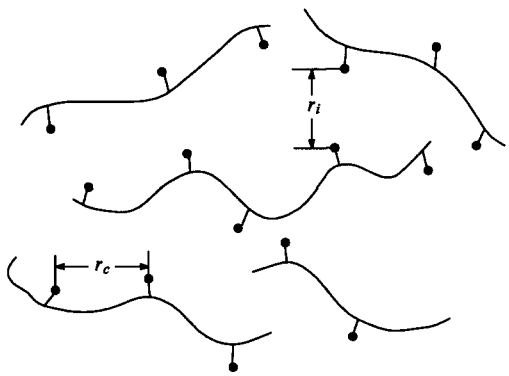

Figure 21. Schematic illustration of the formation of intramolecular (r_c) and intermolecular (r_i) chelates.

The distance between the chelating fragments on formation of the intramolecular (r_c) and intermolecular (r_i) metal chelates (Fig. 21) can be determined by means of statistical analysis, adopting the spheres in contact model. The distance r_i is determined from the equation

$$r_i = \frac{S}{(N_c/2)^{1/3}} , \tag{14}$$

where S is the length of the side of a box made up of close-packed spheres (1 cm) and N_c is the number of chelating fragments in 1 cm^3. The latter quantity is calculated as follows:

$$N_c = \frac{c_p}{100\, M_s} X N_A , \tag{15}$$

where c_p is the polymer concentration at the gel formation point (g litre^{-1}), M_s the average molecular mass of the elementary unit, X the mole fraction of the chelating fragments in the polymer, and N_A the Avogadro number.

The distance between the chelating fragments in one chain (r_c) is a function of the mole fraction of the chelating unit in the polymer and of the size of the polymer, which are determined by the solvent. Assuming that the polymer in solution consists of a disordered coil, r_c can be calculated by the equations

$$r_c = r_0 \beta , \tag{16}$$

$$r_0^2 = c_\infty t l^2 , \tag{17}$$

where r_0^2 is the mean square of the distance between neighbouring chelating fragments; t the average number of chemical bonds separating the chelating fragments, l the bond length (0.154 nm), c_∞ the characteristic ratio taking into account the increase in the size of the polymer as a result of short-range effects in the disordered coil model, and β the expansion factor taking into account the increase in the size of the polymer by virtue of its interaction with the solvent.

As an example, one may quote the results of the calculation of the quantities r_c and r_i for hydroxamic acid copolymers (Table 13).[82] Analysis of these data indicates that the hydroxamic acid groups of the polymer react in a 'disordered' fashion and

Table 13. Comparison of the values of r_c and r_i for hydroxamic acid copolymers.

Content of hydroxamic fragments in the copolymer (mol %)	r_c/nm	r_i/nm	Difference (%)
0.259	12.8	11.2	13
0.749	6.8	6.4	6
1.80	4.2	4.9	15

form infinite networks only when the probability of the intermolecular binding of the metal exceeds 50%.

In the analysis of the kinetics of reactions involving insoluble polymers, one must take into account both diffusional (transfer of the functional groups after the system has passed through the glass point) and topological (virtually complete absence of the translational diffusion of the functional groups grafted to the polymer skeleton) difficulties. In comparatively early studies,[86] it was shown that the rate-limiting stage of chelation by cross-linked macroligands is diffusion. Because of this, the surface chelating groups are the first to react and the access of metal ions to the interior of the block is restricted. In particular, the study of the kinetics of the chelation of metal ions by cross-linked polyamine ligands confirmed the appreciable influence of diffusion on this process: for polymer particles whose size is up to 0.1 mm, external diffusion is rate-limiting, whilst for particles with sizes in excess of 0.1 mm internal diffusion into the deep layers is rate-limiting.[87] In the case of linear polymers, the rate of complex formation is appreciably higher than for cross-linked polymers because it is determined by the rate of diffusion of the metal ions to the functional groups. The formation of chelates is preceded by the formation of outer-sphere complexes and their transformation into inner-sphere complexes with subsequent diffusion of the metal to the second ligand of the polymer, and so on. As a consequence of the lower metal concentrations at the reaction site, the overall composition of the complex may be different from that in the case of linear polymers and low-molecular-mass analogues. The significant difference in the binding of metal ions by the soluble and cross-linked macroligands also consists in the fact that in the latter the overall macroligand concentration is constant and independent of the dilution of the suspension by the solvent.

The small difference between the stability constants of the low-molecular-mass and high-molecular-mass hydroxyquinoline metal chelates indicates isotypical spatial environments of the metal ion in these compounds. Polymers with 8-hydroxyquinoline groups have been obtained by the polymerisation of[88] or polycondensation[89] method. The composition of the complexes corresponds in this case to the ratio [M] : [L] = 1 : (1.5 – 2.0), which is close to the ratio 1 : 2 corresponding to the stoichiometry of divalent metal complexes. On the other hand, the formation of 1 : 1 complexes is characteristic of cross-linked polymers.[90] Furthermore, the stability constants of complexes based on cross-linked polymers are lower than those of the low-molecular-mass analogues (Table 14).[91]

Table 14. *Stability constants of 8-hydroxyquinoline complexes.*

Metal	MMC			LMC		
	$\lg K_1$	$\lg K_2$	$\lg K_3$	$\lg K_1$	$\lg K_2$	$\lg K_3$
Cu	7.45	6.65	14.10	13.49	12.73	26.22
Ni	5.60	5.35	10.96	11.44	9.94	21.38
Mg	3.18	2.82	6.00	6.38	5.43	11.81

In terms of the stability of the complexes with 8-mercaptoquinoline polymer, divalent metals can be arranged in the sequence Hg > Cu > Ni > Co > Zn > Pb, which is the same as the stability series of the 8-mercaptoquinoline chelate complexes of these metals. However, in contrast to low-molecular-mass analogues, the macroligands form 1 : 1 complexes and the selectivity of 8-mercaptoquinoline in relation to certain metal ions is retained when this group is introduced into the polymer.[92]

The composition and stability of the MMC formed are also influenced by the physical state of the macroligand. As a result, their transition from the nonporous (gel) to porous structures is accompanied by a decrease in the overall stability constant of the complexes owing to the closer packing of the chains and the lower mobility of the functional groups, which leads to appreciable free energy losses on complex formation.

It is interesting to note that the time required for the saturation of the macroligand by the metal increases with increase in the size of grains in the latter.[93]

An increase in the degree of cross-linking leads, on the one hand, to a decrease in stability of the macrocomplexes as a consequence of the increase in strain in the twisted chain on formation of the second and subsequent coordination centres and, on the other, to a change in the nature of the intermolecular interaction. In particular, the rate of interaction of vanadyl acetylacetonate with the chloromethylated styrene–divinylbenzene copolymer modified by catechol groups is much lower when the degree of cross-linking of the polymer is 20% than when it is 2%. The rate increases if the polymer with a 20% degree of cross-linking is ground (Fig. 22).[94] The ratio of the initial rates of absorption of vanadyl ions from a solution of the polymers with 2% and 20% degrees of cross-linking is ~3.9.

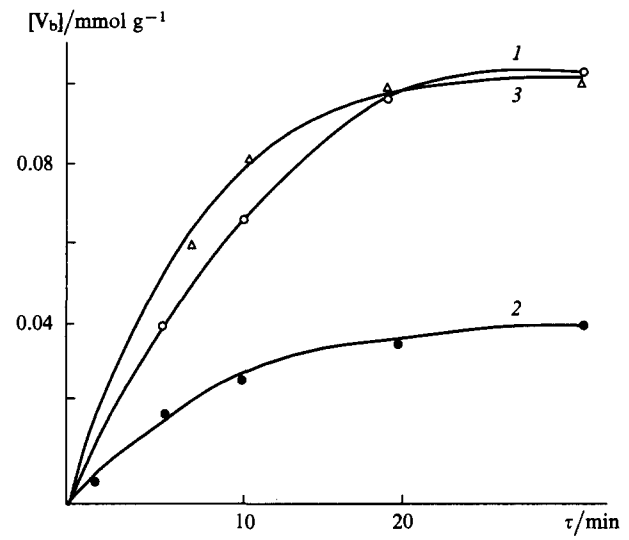

Figure 22. Absorption of vanadyl ions from a solution by a polymer containing catechol groups; (*1*) degree of cross-linking of the polymer 2%; (*2*) degree of cross-linking of the polymer 20%; (*3*) ground polymer with a degree of cross-linking of 20%.

An increase in the degree of cross-linking of the polymeric ligand may alter the steric configuration of the chelate unit: thus it changes from square planar to tetrahedral in the nickel complexes.[15]

The intermolecular interaction in a polymer is known[95] to be much more pronounced than in the analogous low-molecular-mass compounds. Apparently in the MMC it is still stronger than in the initial ligands. This happens both as a consequence of the decrease in chain flexibility on formation of the complex and as a result of the increase in the energy of the local intermolecular interaction. The parameters of the intermolecular interaction in the MMC are influenced by the electron-donating capacity of the functional groups, their distance from the main chain, and also the presence and size of other substituents which do not participate in the complex formation reaction. As a result of these factors, the polymeric complexes frequently give rise to more ideal morphological structures than the original macroligand. Thus the structural changes in the styrene–divinylbenzene copolymer during its alkylation by 5-chloromethyl-8-hydroxyquinoline in nitrobenzene in the presence of $AlCl_3$ have been elucidated in detail.[96] In the stage involving the attachment of the complex to the polymer, the latter undergoes a reorganisation — micronetwork rearrangements and twisting of

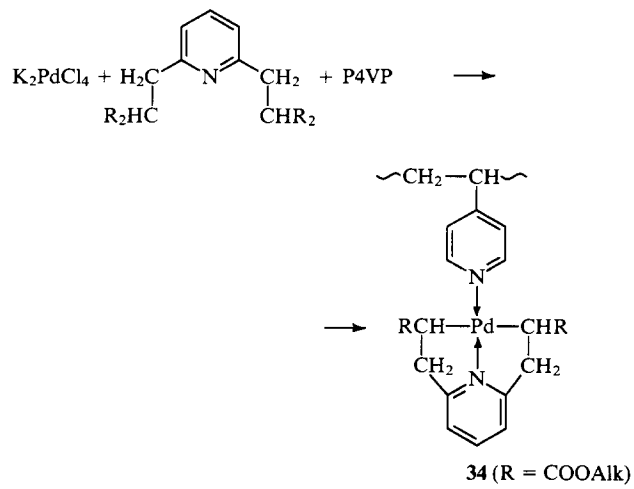
the polymer. The structural changes in the polymer obey the steric requirements of the complex-forming metal (minimum free energy loss) and in all cases the capacity of the chain molecules for twisting depends on the rigidity of the chain, the nature of the solvent, etc. By operating with these factors, it is possible to weaken or, conversely, to intensify the twisting or extension of the chain. It is then necessary to take into account the increase in the rigidity of the chain at the binding sites with increase in the degree of conversion.

In particular, the change in the chain rigidity, which depends on the number of bound functional groups, affects the stability of the complexes: the most stable complexes are formed for low degrees of conversion and the least stable are formed for higher conversions. With increase in the degree of conversion, the stability constants of the copper(II) chelate complexes of poly(acrylohydroxamic acid) pass through a maximum (Table 15): they increase with increase in η in the region of low conversions and diminish in the region of high values of η.[97]

Table 15. Stability constants of copper(II) chelate complexes of poly(acrylohydroxamic acid) {293 K, [$NaNO_3$] = 0.2 M}.

α	B_1	B_2	B
0.087	−1.9	−2.9	−4.8
0.26	−0.75	−1.85	−2.6
0.43	−1.1	−2.4	−3.5
0.69	−1.0	−2.8	−3.8

Note. $B_1 = K_1K_a$; $B_2 = K_2K_a$; $B = B_1B_2 = KK_a^2$.

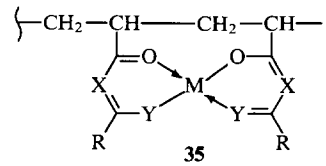


The stability of the MMC is influenced significantly also by the valence of the metal. Thus the stability of poly(enol-ketone) chelates based on oxidised poly(vinyl alcohol) films increases in the following sequence of ions: $M^+ > M^{2+} > M^{3+}$.[98] An important factor is that oxidation of the films promotes the permeation of the metal ions into their deep layers.

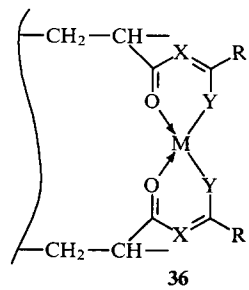
The dependence of the properties of the complexes formed and of the degree of conversion on the method of preparation of the complexes is characteristic of the MMC based on cross-linked macroligands.[99-101] As was to be expected, if the polymer does not swell in the given solvent, then the chelation reaction either does not occur or proceeds with a very low percentage binding of the metal.[102] This conclusion has been confirmed yet again by a study of the interaction of transition metal compounds with polymers based on 2,2′-dipyridylmethane.[103] The composition of the complexes formed with participation of this polymer also depends on the nature of the metal and the ligands bound to it.

The influence of temperature on the chelation process may be demonstrated in relation to the interaction of K_2PdCl_4 with 2,6-derivatives of pyridine[104] in the presence of P4VP or the styrene–4-vinylpyridine copolymer. The interaction results in the formation of complex **34** (Scheme 2).

Macromolecular metal chelates have been obtained at 298 and 360 K. It was found that the P4VP-based MMC, obtained at 298 K, are bright yellow in colour and dissolve readily in ethanol, while the polymer obtained at 360 K is dark yellow and is only slightly soluble in ethanol. This can be explained by the different conformations of P4VP in ethanol at different temperatures. On the other hand, the palladium chelate based on the styrene–4-vinylpyridine copolymer, the conformations of which are the same at these temperatures, dissolves readily both in ethanol and chloroform regardless of the temperature at which it is obtained. The degree of conversion, found from elemental analysis and NMR spectra, was 25% in all cases under these conditions. In other words, by varying the temperature, it is possible to obtain complexes having the same composition but with different steric structures.



Scheme 2



34 (R = COOAlk)

The structure of the complexes is in many respects determined by the conditions of their preparation. It is apparently necessary to take into account the relaxation time of the products formed, which are in a stationary state, and hence the dynamics of the variation of the required properties. The interchain cross-links arising in the rigid chain polymers alter appreciably their supermolecular organisation, which increases the rigidity of the chain. This should be manifested by a change in the relaxation transitions within the chains and the segments. Evidently, the α-relaxation, associated with the micro-Brownian motion of the long sections of the chains near the glass point, is more subject to such influences. For low degrees of saturation of the macroligand, the overall restriction of the chain mobility is slight. With increase in the degree of saturation, an ever increasing number of cross-links are formed between neighbouring chains, which should lead to an increase in the glass point T_g. In the region of β-relaxation, the glass point is almost independent of the metal content and intermolecular cross-linking leads to its increase. On cyclisation, T_g should increase with increasing metal content as a consequence of the increase in the rigidity of the individual sections and the decrease in the mobility of the entire chain.

Macroligands with chelating fragments grafted to the surface (the readily swelling functional group coating on an insoluble substrate) occupy an intermediate position between the soluble and cross-linked polymers.[1,65] The interaction of metal ions with such macroligands simulates to a large extent complex formation in solutions. As a rule, in both cases the free energy changes are similar.[105,106] Intramolecular cyclisation (complex **35**), and not intermolecular cyclisation (complex **36**), is characteristic of grafted macroligands, as for soluble polymers.[28,29,107]

35

36

In order to assess the interactions in transition metal ion–grafted macroligand systems, the modified Langmuir equation is usually employed:

$$\frac{c}{c_b} = \frac{1}{kf_{max}} + \frac{1}{f_{max}}, \quad (18)$$

in which c and c_b are the concentrations of the dissolved and bound metal, k is the stability constant, and f_{max} is a constant characterising the limiting degree of binding (limiting adsorption) of the metal to the functional groups of the polymer. This equation is valid only for low degrees of conversion when the concentration of the unreacted and unreactive centres may be neglected.

In particular, the adsorption of copper(II) ions on polymeric ligands with grafted iminodiacetic acid groups is described by the Langmuir equation (Fig. 23).[108] The parameters of the Langmuir equation, calculated from the relations presented in Fig. 23, are listed in Table 16. The constant f_{max} increases with increase in the degree of grafting to ~0.3. This quantity indicates that the number of centres capable of binding Cu^{2+} ions increases to 30% depending on the number of bis(carboxymethyl)amino-groups.

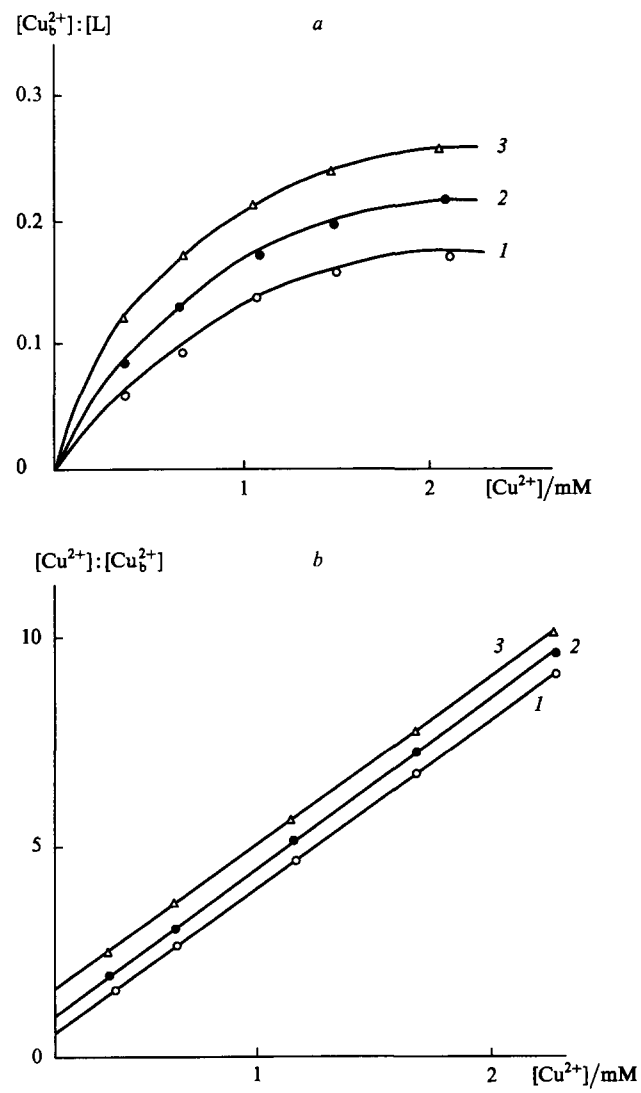


Figure 23. Relation between the amount of Cu^{2+} ions and their concentration in solution (*a*) and the corresponding Langmuir relation (*b*) for different degrees of grafting of the chelating fragments (%): (*1*) 24.4; (*2*) 31.8; (*3*) 40.5.

Table 16. Parameters of Eqn (18) for the chelation of copper(II) ions by polymers with grafted iminodiacetic acid groups.

Degree of grafting	$10^{-4}K$/litre mol^{-1}	f_{max}/mmol g^{-1}
24.0	1.8	0.24
31.8	2.2	0.26
40.5	3.1	0.29

The constant K also increases with increasing degree of grafting. These results show that the ability of the ligand groups of the grafted chains to chelate Cu^{2+} ions increases with increasing degree of grafting. The complexes formed become more stable apparently by virtue of the fact that, as soon as the Cu^{2+} ion has been coordinated to one ligand, other ligand groups coordinate to it more readily. On the other hand, the adsorption of Cu^{2+} by a polymer containing the same number of bis(carboxymethyl)-amino-groups bound directly to the main chain is described by the Langmuir equation with the parameters $K = 3.5 \times 10^3$ litre mol^{-1} and $f_{max} = 0.075$ mmol g^{-1} under the same conditions.[109] Thus the chelating capacity of the polymers improves after the introduction of a grafted chain as a bridge.

V. Conclusion

Analysis of the three levels of the structural organisation of the MMC shows that the characteristics of their formation differ significantly from those of the formation of the LMC. For the latter, the second and third levels are not as a rule considered. Therefore the methods for the estimation of the thermodynamic parameters of the MMC and the LMC should also differ. On the most thoroughly investigated local level, important information about the mechanism of the formation reaction can be obtained precisely by comparing the thermodynamic parameters.

Examination of the second level leads to the conclusion that, in the calculation of the thermodynamic parameters, account must be taken of the principal polymer effects, as for the kinetics of chemical reactions with participation of macromolecular reagents. Only this approach permits the quantitative estimation of the differences between the processes involving the formation of the LMC and of the complexes in the macrochain–MX_n systems. In ideal cases, it is possible to estimate the contribution of each effect (or at least to discover which is the dominant one) to the thermodynamics of the process, which helps in understanding the characteristic features of the formation and structure of the MMC.

The third, supermolecular level has been least investigated. This is associated, on the one hand, with the dependence of its parameters on the degree of conversion in the chelation process and, on the other, with the possibility of the occurrence of the so called 'stationary states' characteristic of long-chain molecules. The properties of the MMC obtained differ appreciably from the equilibrium ones. Unfortunately, not only the properties of the system in a specified 'stationary state' but also the very conditions of the appearance of such a state still remain uninvestigated.

In the general case, the observed equilibrium constant can be represented to a first approximation as the product of the equilibrium constants for different levels. Unfortunately, the number of kinetic studies on MMC is still insufficient for more specific generalisations.

Here we may also note that the importance of the problems under consideration is determined, firstly, by the need for a purposeful approach to the synthesis of MMC with specific homogeneous structures.[110] Secondly, there is a possibility of synthesising deliberately MMC designed for different practical applications (in the first place as metallopolymer composite materials in metal complex immobilised catalysts). Among comparatively new aspects, we may point out the use of

MMC in 'non silver' photographic processes,[111] as sensitisers of photodynamic cancer therapy,[112] and as high-temperature superconducting materials (ceramic material consisting of polymers with YBC-chelates‡).[113]

The structural organisation considered in the present review mainly in relation to polymerisation MMC is characteristic also of the MMC of the coordination and condensation types,[113-116] liquid-crystal polymeric chelates,[117-121] and also MMC obtained by methods involving the polymerisation and copolymerisation of the corresponding metal-containing monomers.[122] The formation of complexes between a metal-containing monomer of the chelate type and a template during radical copolymerisation and polymerisation makes it possible to regulate the position of the metal ion in the polymer matrix, while the high degree of cross-linking promotes the stabilisation of the functional group environment.[123] Such template polymerisation strategy is promising from the standpoint of the construction of highly specific catalysts, sorbents, and synthetic receptors for the recognition of complex biomolecules. In other words, the MMC, i.e. organised polymolecular *ensembles* (especially in thin Langmuir–Blodgett metallopolymer films),[124] are potential objects for the vigorously developing supramolecular chemistry[125]—the constructional chemistry of intermolecular bonds.

Abstract. The most important classes of heterogeneous catalytic reactions involving CO_2 are examined: the incorporation of CO_2 in the C–C, C–H, and C–N bonds with formation of carbonyl- and carboxyl-containing compounds and oxidation of other compounds by CO_2. Reactions of the second class are more promising from the standpoint of the utilisation of carbon dioxide as a chemical raw material and from the standpoint of the solution of the ecological problems involving its utilisation from the gaseous waste discharged into the atmosphere.

The reactions involving the oxidation of C_1-C_7 hydrocarbons and C_1-C_2 alcohols by carbon dioxide, which have been investigated by the authors of this review, are examined in detail. Catalysts based on manganese oxides are most effective in these reactions. The bibliography includes 231 references.

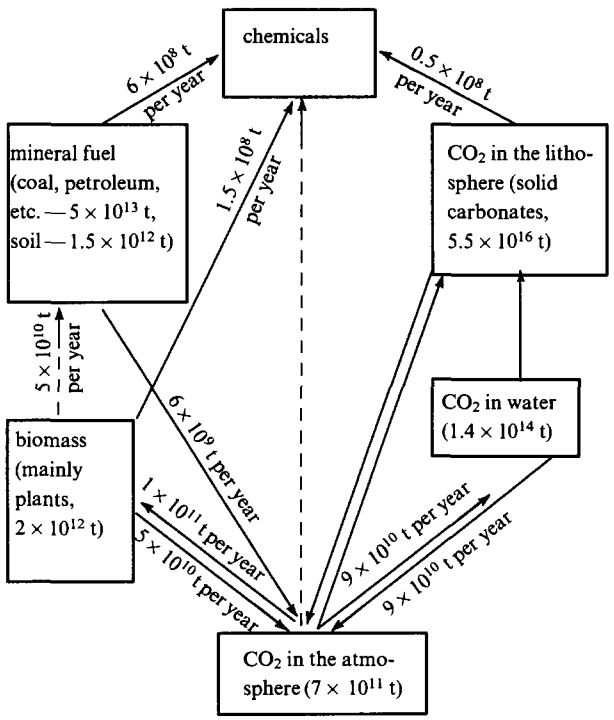
I. Introduction

Considerable interest in the heterogeneous catalytic reactions of CO_2 has been aroused by two factors: (1) the need to combat the greenhouse effect and (2) the exhaustion of the available resources of carbon-based raw materials. We shall examine both these factors.

1. The ecological importance of carbon dioxide

In May 1992, 143 countries signed in Rio de Janeiro an agreement concerning the control of global warming and the reduction of the carbon dioxide waste discharged into the atmosphere. The largest emitter of carbon dioxide is the USA, where 26.7% of the entire carbon dioxide waste or about 1.6 billion tonnes annually is discharged into the atmosphere.[1]

A series of communications concerning the possible consequences of global warming have been published recently. In particular, the influence of the CO_2 waste on changes in the climatic zones on the territory of the former USSR has been considered.[2,3] At first sight, the conclusions reached do not appear very alarming. In most regions, with the exception of highly mountainous ones and possibly the very centre of European Russia, an increase in temperature by several degrees is more likely to have favourable rather than negative consequences: the amount of atmospheric precipitation and ultimately the agricultural productivity will increase; the possible flooding of coastal regions does not appear quite so alarming either.



It has to be said that there exists also a different point of view on the consequences of the greenhouse effect. For example, it has been noted[4] that there have been periods during the Earth's history when the average content of CO_2 exceeded the current level by a factor of 5. The periods of the intense emission of CO_2 coincided with an intensification of volcanic activity and led to the rapid growth of numerous life forms. In discussions of this problem, Russian scientists have occupied a 'softer' position than foreign investigators. However, Russia cannot regard itself as an isolated society and if a decision has been reached at an international level (the Rio de Janeiro Conference) concerning the need to reduce the discharge of the greenhouse gases, then Russia — the third emitter of carbon dioxide after the USA and western Europe — must also inevitably participate in this process. We may likewise note that the CO_2 evolved will be partly absorbed by the hydrosphere, the lithosphere, and the biosphere (see the scheme overleaf). However, calculations have shown that such absorption will not compensate for the evolution. About 57% of the evolved CO_2 will remain in the atmosphere. A scheme illustrating the redistribution of carbon dioxide in natural objects is presented below (all the figures are quoted relative to carbon).

Carbon dioxide is not the only substance responsible for the greenhouse effect: the contribution of CO_2 is about 50%, 24% of the effect is due to the freons (chlorofluorocarbons) and N_2O, and 15% is due to methane. At the present time, vigorous research is being prosecuted throughout the world on the replacement of freons by other cooling agents, since freons decompose the ozone layer in the stratosphere. Since the methane molecule absorbs more solar radiation than the CO_2 molecule, the role of methane in the greenhouse effect may actually supercede that of CO_2 in the course of further development of industry and agriculture.

Considering the various methods for reducing the greenhouse effect, the well known Belgian scientist Delmon[5] noted that its

diminution by 3% requires either (1) the reduction of the felling of forests by 25%, or (2) the abolition of all rice plantations, or (3) the destruction of all ruminants, or (4) the reduction of the world consumption of energy by 7%. Out of the four procedures examined, only the first and the fourth are realistic, although both are very hard to achieve. It is of interest that if one follows the third procedure, then calculations show that the aim of reducing the emission of greenhouse gases by 3% will not be attained. The reduction of the felling of forests and the development of atomic power are extremely important in this connection. One must also not fail to note that from the environmental point of view atomic power is greatly preferable to thermal power.

The waste gases from industry, electric power stations, and transport are powerful contaminants of the atmosphere. In terms of the scale of their harmful effect on the atmosphere, the automobile exhaust gases occupy the first place.[6] The most undesirable components of the exhaust gases are hydrocarbons, CO, and NO and nowadays the efforts of many scientific teams are directed to the fight against these gases. The problem of reducing the amount of CO_2 in exhaust gases is hardly considered.

Naturally, a partial solution of a large number of ecological problems, including the problem of the greenhouse effect, might be to abandon automobile transport as a means of individual mobility and to go over to collective types of transport. However, the world community is not yet ready for such a solution. One cannot rule out the possibility that this question will arise in the XXIst century if the existing trend towards the growth of population and energy consumption and also the impairment of the environmental situation continues.

2. Carbon dioxide as a raw material

The second reason for the increased interest in the chemical processing of carbon dioxide is its utilisation as a raw material. Regardless of the problem of the greenhouse effect, carbon dioxide should be regarded as an important source of chemical raw material in the future. The resources of petroleum and coal are being rapidly exhausted. At the present time, they are estimated as $(5-10)\times10^{12}$ t in terms of carbon. After petroleum and coal, the resources of natural gas are coming to an end. On the other hand, the total amount of CO_2 in the atmosphere and in the ocean is $\sim 1.5 \times 10^{14}$ t (in terms of carbon), i.e. is greater by 1.5 orders of magnitude, while its amount in the lithosphere is greater still — by two orders of magnitude (see the Scheme).

Despite the enormous amounts available, the widescale application of CO_2 as a raw material is hindered by its low concentration in the atmosphere, which is only 0.03% in the present day 'pre-greenhouse' atmosphere (338.6 ppm in 1980). In the lithosphere, CO_2 exists in a concentrated state in the form of natural carbonates, but the decomposition of carbonates requires the expenditure of large amounts of energy. The most promising source of CO_2 as a raw material are probably the waste gases as well as natural gases. The CO_2 content in the natural gas from certain deposits reaches 30%.

In order to stimulate studies on the chemical utilisation of CO_2, it has been proposed in the USA to introduce a special tax on the consumption of fuel amounting to 13 dollars (at 1992 prices) per barrel of the petroleum equivalent (or 57 dollars per tonne of conventional fuel). If the aim is to achieve a 10% reduction of the discharge of CO_2 by 2010, then for a discharge amounting to 8.17 billion tonnes the tax will have to be increased to 44 – 155 dollars per barrel, which will impose a heavy burden on tax payers.[7]

At the end of September 1991, after two year discussions, the European Community adopted a differentiated tax on energy consumption, which will continuously increase from 1993 until 2000. The aim is to stabilise the discharge of CO_2 at the 1990 level.[8]

A major programme concerning the utilisation of CO_2 has been adopted in Japan.[9] Most attention is devoted to chemical methods for the processing of CO_2. The possibility of its being pumped into subterranean strata in order to increase the extraction of petroleum and also of its pumping into the ocean is considered. The latter variant can be achieved, in particular, with the aid of CO_2-fixing microorganisms. The majority of the projects presuppose the pumping of CO_2 into deep layers of the ocean (deeper than 1000 m). Under such conditions, the hydrates $CO_2.nH_2O$ ($n = 5 - 6$), which prevent the dissolution of carbon dioxide in water, are formed at the CO_2 – oceanic water interface.[10]

Thus the need both to combat the greenhouse effect and to employ new forms of raw material in industry requires the chemical processing of large amounts of CO_2. In pure form, carbon dioxide is so far little used. It is employed as a solvent, as an extractant, as a cooling agent, and also for the generaton of a carbon dioxide atmosphere in greenhouses.

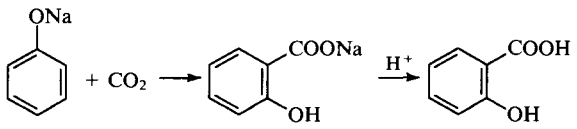
II. Utilisation of carbon dioxide

1. Carbon dioxide in the chemical industry

The largest industrial consumers of CO_2 are the producers of carbamide, calcined soda, and salicylic acid. In all these industries, CO_2 is obtained not from the atmosphere but from secondary industrial gases and from solid carbonates (mainly from limestone). The question of the utilisation of the CO_2 evolved on combustion of fuel has so far simply not been part of technological plans.

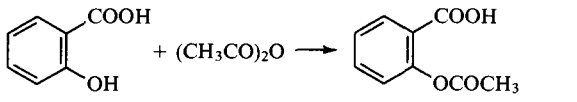
The world output in the production of carbamide (urea) is 110 million tonnes annually. Carbamide is formed when CO_2 reacts with ammonia under a pressure of 200 atm at 200 °C.

$$2NH_3 + CO_2 \rightleftharpoons NH_4COONH_2 \rightleftharpoons (NH_2)_2CO + H_2O$$



The production of carbamide is a good example of the employment of CO_2 not from an external source but from the resources of the same factory. After the conversion of CO by treatment with steam, hydrogen is used to synthesise ammonia, whilst CO_2 is directed to the manufacture of carbamide.

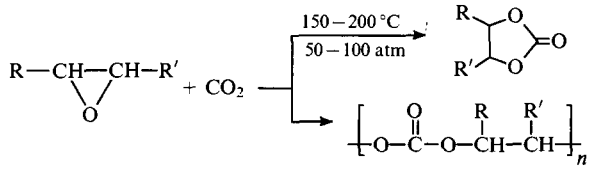
Another major industry involving the use of CO_2 as the raw material is the preparation of calcined soda by the Solvay method. The world production of cancined soda is about 30 million tonnes annually. Together with CO_2, the reactants are NaCl (in the form of a brine) and ammonia.



$$NaCl + NH_3 + CO_2 + H_2O = NaHCO_3 + NH_4Cl$$

Calcined soda is obtained by the heat treatment of $NaHCO_3$, whereupon CO_2 and H_2O are evolved.

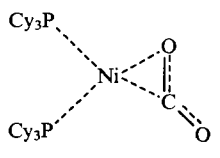
The manufacture of salicylic acid is not quite such a large scale process. It is synthesised by carboxylating phenol under pressure (the Kolbe–Schmitt reaction).



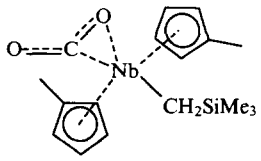
Aspirin (acetylsalicylic acid) is obtained from sallicylic acid.

In 1990, 25 000 tonnes of aspirin were produced in the USA.

A new rapidly developing field in which CO_2 is utilised involves the syntheses of organic carbonates. They are obtained by the interaction of oxiranes with CO_2 in the presence of inorganic and organic halides.



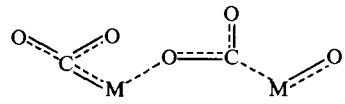
Organic carbonates are used as solvents and extractants, whilst polycarbonates are employed as constructional mateirals.



The examples quoted above virtually exhaust the applications of CO_2 in the chemical industry. On the other hand, scientific research has shown that carbon dioxide can enter into numerous reactions and can serve as the starting material for the synthesis of a series of useful chemical products. Disregarding the evident possibility of using CO_2 for the neutralisation of bases, we shall consider reactions involving the incorporation of CO_2 in transition metal complexes.

2. Carbon dioxide in transition metal complexes

Comnparatively few studies are known in which the binding of CO_2 as a ligand in transition metal complexes has been observed (see the relevant review[11]). Thus the stable nickel complex **1**[12] and the stable niobium complex **2**[13,14] have been described.

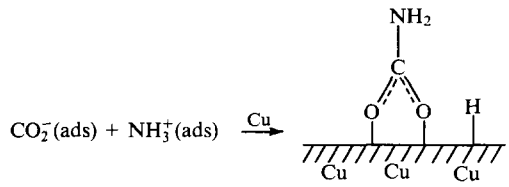


1

2

Cy = cyclo-C_6H_{11}.

Nonasssociative CO_2 complexes have also been found on the surfaces of transition metal.[15,16] For example, the study of the adsorption and desorption of CO_2 and $CO^{18}O$ on K/Ag(111) by Auger spectroscopy, electron energy loss spectroscopy (EELS), and other methods[15] made it possible to detect both associated and undissociated CO_2 complexes.

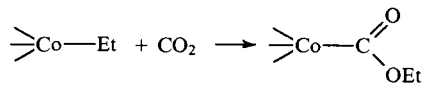


The energy of the bond between CO_2 and the metal in such complexes is low; for example, it is 34.3 kJ mol^{-1} in the complex $W(CO)_5CO_2$.[17] The study of the adsorption of CO_2 on crystalline potassium showed[18] that this entails the formation of oxalate ions $C_2O_4^{2-}$, which permeate under the potassium layer. They decompose into CO_3^{2-} and CO. Complexes similar to those indicated above have been found on potassium-promoted rhodium.[19]

It has been demonstrated by X-ray photoelectron spectroscopy (XPES) and EELS that CO_2 is not chemisorbed on the Cu(100) and Zn(0001) faces of metallic single crystals.[20] The coefficient of the adhesion of CO_2 to these faces is exceptionally low (their lifetime is $\sim 10^{-10}$ s at 20 °C). However, as a result of electron transfer, chemisorbed complexes are formed in the presence of ammonia.

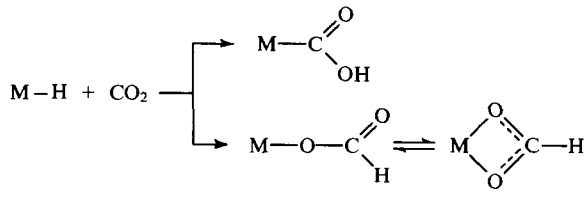
$$CO_2(gas) + e \rightleftharpoons CO_2^-(ads),$$

$$NH_3(gas) \rightleftharpoons NH_3^+(ads) + e,$$



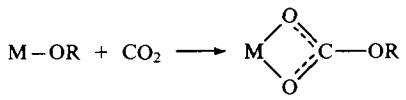
These interact with one another and give rise to adsorbed carbamate.

3

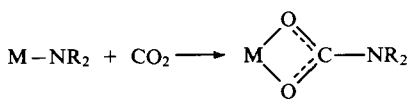


The bidentate carbamate **3** is inclined relative to the surface, so that the two O atoms are nonequivalent. It is of interest that the interaction of CO_2 with H_2O under these conditions does not lead to their joint adsorption.

There have been appreciably more studies on the incorporation of CO_2 in transition metal complexes (Co, Ni, Rh, Pd, Pt, Ir, Cu, etc.) in the M–C, M–H, M–O, and M–N bonds (where M = transition metal).[21,22] When CO_2 is inserted in the M–C bond, carboxylate complexes are formed. For example, the ethyl ester of the metalcarboxylic acid was obtained in the reaction of CO_2 with ethylcobalt.[23,24]



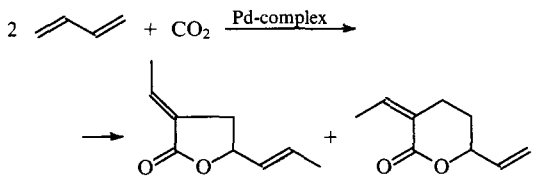
4



When the carboxylate complex **4** was treated with methyl iodide, ethyl acetate was obtained in a high yield. The carboxylate complexes of Cu, Zn, Ti, Zr, Mn, Fe, Co, Ni, and Rh have been synthesised similarly.[13] The insertion of CO_2 into the M–H bond leads to the formation of formate complexes and in certain cases of metalcarboxylic acids (see, for example, Kolomnikov et al.[24]).

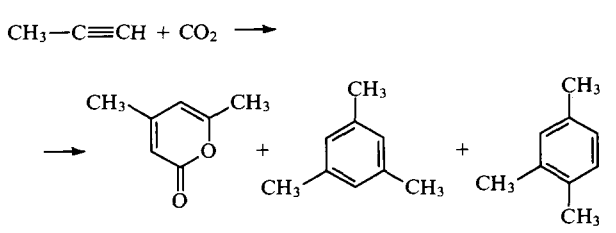
The insertion of CO_2 into the M–O bond results in the formation of complexes with carbonic acid monoesters.

Finally, the insertion of CO_2 in the M–N bond leads to the corresponding carbamate complexes.[14,21]



The interaction of CO_2 with organic compounds at the C–H bond constitutes the basis of the catalytic syntheses of carboxy-compounds: acids, esters, lactones, etc. For example, propionic acid and its ethyl ester have been obtained by carboxylating ethene at a high pressure and a temperature of 165 °C on a rhodium complex promoted by hydrogen halides.[25]

$$H_2C{=}CH_2 + CO_2 \xrightarrow[150-700\ atm]{\text{Rh-complex}} CH_3CH_2COOH + CH_3CH_2COOC_2H_5$$



The simultaneous coordination of CO_2 and C_2H_4 to the complex $PtCl(SnCl_3)(PPh_3)_2$ deposited on SiO_2 led to the formation of methyl 3-hydroxypropionate.[26]

The carboxylation of saturated hydrocarbons constitutes an attractive reaction, which, however, is not favoured energetically. The preparation of carboxylic acids in the cracking of $C_{12}-C_{40}$ hydrocarbons in the presence of CO_2 has been described.[9] The interaction of ethyne and diene hydrocarbons with CO_2 affords cyclic compounds.[27]

Cyclic carbonates are formed readily in the interaction of CO_2 with epoxides in the presence of Zn, Ni, Sn, Mg, Al, etc. compounds.

The interaction of CO_2 with methylethyne under a 60 atm pressure on Rh_4 and Fe_xRh_y clusters deposited on SiO_2 or Al_2O_3 leads to a mixture of cyclic compounds.[28]

A surface carbonate is an intermediate.

A number of examples of the use of CO_2 as a cocatalyst for the modification of homogeneous and heterogeneous catalysts are known. For example, CO_2 has been used effectively to regulate the catalytic activity and selectivity of zeolitic catalysts.[29] Carbon dioxide can alter appreciably the activity and selectivity of many catalysts for the oxidative condensation of methane.[30] In the presence of CO_2, oxygen alters the oxidative properties of Fe and Ru complexes.[31]

The examples presented above show that recently CO_2 has been used increasingly for the modification of homogeneous and heterogeneous catalysts. All the catalytic reactions with participation of these complexes which have been investigated belong to the class of reactions in which CO_2 is inserted into C–H, C–O, and C–N bonds. We shall not consider them in detail since they have been described in the reviews mentioned above.

Thus carbon dioxide can enter into numerous reactions and can serve as the starting material for the syntheses of a number of useful chemicals, i.e. the concept of the 'inertness' of CO_2, which existed for a long time, proved to be a myth. Nevertheless, the reactions listed above do not solve the problem of not only the reduction of the emissions of CO_2 but also of its large-scale employment as a raw material. In all these cases, the involvement of CO_2 in a reaction requires large amounts of another fairly expensive and environmentally unfriendly compound (ammonia, phenol, etc.).

The oxidation–reduction reactions in which CO_2 is used as the oxidant are more promising for large scale application. In this case, cheap reductants, mainly hydrocarbons found in natural raw materials (gas, petroleum) or which can be readily obtained from them (coal), could be involved in the reaction with CO_2.

III. Interaction of carbon dioxide with hydrogen

Hydrogen might become the best reductant for carbon dioxide. The most important reactions of CO_2 with hydrogen are the Sabatier reaction [reaction (1)], the Bosch reaction [reaction (2)], the reverse conversion of water gas [reaction (3)], and the syntheses of methanol [reaction (4)], dimethyl ether [reaction (5)], and formic acid [reaction (6)].

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O, \quad \Delta H_{298} = -164.1\ kJ\ mol^{-1}, \tag{1}$$

$$CO_2 + 2H_2 \rightleftharpoons C + 2H_2O, \quad \Delta H_{298} = -14.6\ kJ\ mol^{-1}, \tag{2}$$

$$CO_2 + H_2 \rightleftharpoons CO + H_2O, \quad \Delta H_{298} = 42.3\ kJ\ mol^{-1}, \tag{3}$$

$$CO_2 + 3H_2 \rightleftharpoons CH_3OH + H_2O, \quad \Delta H_{298} = -49.4\ kJ\ mol^{-1}, \tag{4}$$

$$2CO_2 + 6H_2 \rightleftharpoons CH_3OCH_3 + 3H_2O, \quad \Delta H_{298} = -112.2\ kJ\ mol^{-1}, \tag{5}$$

$$CO_2 + H_2 \rightleftharpoons HCOOH, \quad \Delta H_{298} = 16.7\ kJ\ mol^{-1}. \tag{6}$$

Reactions (1), (2), (4), and (5) are exothermic whilst reactions (3) and (6) are endothermic.[32] In all the reactions listed above, except reaction (6), between one and three water molecules correspond to one molecule of the target product (CH_4, C, CO, CH_3OH, CH_3OCH_3), i.e. a considerable proportion of the expensive hydrogen is consumed on the formation of the cheap and useless water.

1. Synthesis of hydrocarbons

Although the Sabatier reaction (1) leads to the formation of the cheap methane, it is nevertheless frequently used to remove CO_2 from technological gases ('methanation of CO_2').[33] This reaction proceeds at temperatures above 200 °C in the presence of various catalysts, the best of which are ruthenium or nickel on carriers. Depending on the design of the reactor, the process can take place in various regimes: from isothermal to autothermal with a large or small temperature drop across the catalyst bed.[34] Above 590 °C, the equilibrium in reaction (1) shifts to the left: the steam conversion of methane is observed.

A catalytic activity series has been obtained[35] for noble metals deposited on Al_2O_3 and used as catalysts in the reaction under consideration: Ru > Rh > Pt = Ir = Pd. Ruthenium also proved to be the most active of the metallic catalysts deposited on SiO_2: Ru > Co > Ni > Fe.[36] Ruthenium catalysts deposited on membranes are good methanation catalysts.[37] The study of nickel and cobalt catalysts deposited on carbon, Al_2O_3, and SiO_2 showed that the cobalt catalysts on carbon are the most active in

the methanation of CO_2.[38] The lanthanum–nickel alloys are also highly active.[39]

Oxide catalysts are less effective in this process. The spinels $La_{1-x}M_xCoO_3$ (M = Sr or Th) become active in the hydrogenation of CO_2 only after the formation of metallic cobalt.[40] Rhodium accelerates the hydrogenation of CO_2 in CH_4 on the Fe–Mn–O catalyst, while lanthanum slows down the process. In the presence of rhodium, CO_2 is apparently activated by the oxide component, while H_2 is activated by the metallic rhodium.[41]

A similar separation of functions is characteristic also of metals deposited on oxides. When the carrier in the Rh/CeO_2 [42,43] and Pd/CeO_2 [44] catalysts is reduced to Ce_2O_3, the latter acquires the ability to accept CO_2 as a result of the formation of vacancies in the oxide lattice. On the other hand, hydrogen dissociates on rhodium and further methanation takes place. Catalysts obtained by the 'reverse' method — the deposition of the oxides of Al, Zr, Nb, Ta, and W on rhodium foil — have been investigated.[45,46] It was found that AlO_x and FeO_x inhibit the hydrogenation of CO_2, whilst the remaining oxides accelerate it. The authors explain this acceleration by the formation of an anionic vacancy at the metal–oxide interface. The degree of reduction of the oxide in the hydrogenation of CO_2 is greater than in the hydrogenation of CO owing to the higher concentration of H on rhodium. The authors[46] observed a correlation between the acidity of the deposited oxide and the catalytic activity. This was explained by the fact that, in the adsorption of CO or CO_2 molecules on the metal–oxide interface, they are oriented with their oxygen atoms towards the acid Lewis centre. In the case of the Pt/CaO and Pt/MgO catalysts, the alkaline earth metal oxide accepts CO_2, affording CO_3^{2-}, while H_2 dissociates on Pt.[47]

When the hydrogenation of CO_2 is compared with that of CO on metallic catalysts, two interesting features are noted: (1) the rate of hydrogenation of CO_2 to methane appreciably exceeds the rate of methanation of CO; (2) whereas higher hydrocarbons are formed together with methane in the hydrogenation of CO, methane is formed with an almost 100% selectivity in the hydrogenation of CO_2.[48–55]

Only methane is obtained on an iron foil, CO_2 being hydrogenated seven times faster than CO.[52] The activation energy for the methanation of CO_2 on Ru/Al_2O_3 was appreciably lower than that for the methanation of CO.[53] The submonolayer deposition of TiO_2 on rhodium increases the rate of hydrogenation of CO_2 by a factor of 15 and that of CO only by a factor of 3.[48] The selectivity in the conversion of CO_2 into methane on a cobalt foil was 99%, while that in the conversion of CO into methane was only 80%.[54]

All these facts show that CO_2 is reduced to methane via the intermediate formation of CO.

$$CO_2 + H_2 \rightleftharpoons CO + H_2O$$

$$CO + 3\,H_2 \rightleftharpoons CH_4 + H_2O$$

The complete dissociation of CO and subsequent hydrogenation of C(ads) and O(ads) are necessary for the synthesis of methane and other hydrocarbons.[56]

According to Gupta et al.,[55] the lower temperatures of the methanation of CO_2 compared with CO on Ru/TiO_2 can be explained by the higher reactivity of the metal carbonyls formed initially, the latter being rapidly converted into reactive carbon atoms.

The rate of reduction of CO_2 on the reduced Fe/Al_2O_3 and Re/Al_2O_3 catalysts under thermoprogrammed conditions increases sharply after the addition of 1%–3% of H_2. For example, the interaction of CO_2 with 8% Fe/Al_2O_3 begins at 520 °C when 1%–3% of H_2 is added to the reaction mixture and not at 740 °C, as happens in the absence of H_2. Under these conditions, the rate of reaction increases by a factor of 20–25.

According to the data of Highfield at al.,[58] after the addition of H_2 a new path arises in the interaction of CO_2 and Fe, resembling a chain reaction and requiring a lower activation energy.

$$Fe + 0.5H_2 \rightarrow Fe(H) \quad (8)$$

$$Fe(H) + CO_2 \rightleftharpoons FeHCOO \quad (9)$$

$$FeHCOO + Fe \rightarrow FeO + Fe(H) + CO \quad (10)$$

$$CO_2 + Fe \rightarrow FeO + CO$$

Reaction (8) corresponds to the 'initiation', whilst reactions (9) and (10) correspond to the 'propagation' of the chain reaction. One hydrogen molecule can ensure the conversion of many CO_2 molecules. It is suggested that a surface formate is an intermediate. To test this hypothesis, formic acid was deposited on the surface of iron and rhenium, after which an increase in the rate of methanation was observed.

On the rhenium catalyst in the presence of hydrogen, the Boudouard reaction is also accelerated.

$$CO_2 + C \rightarrow 2CO$$

When 1%–3% of H_2 was added to the stream of CO_2, the rate of conversion of the latter increased by a factor of 20, while the coke oxidation temperature fell by 200 °C.

It is also possible to formulate a chain mechanism of the Boudouard reaction. For this purpose, stage (10) in Schemes (8)–(10) must be replaced by the stage

$$FeHCOO + FeC \rightarrow Fe + Fe(H) + 2CO. \quad (11)$$

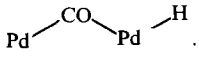
In this case, the 'initiation' is evidently again ensured by reaction (8), whilst 'chain propagation' is effected by reactions (9) and (11). At higher H_2 concentrations, reaction (3) takes place on Fe and Re.

The complexes Ru(H)CO, RuOCO, RuCO, and RuHCOO have been detected in an IR spectroscopic study of the $CO_2 + H_2$ reaction on Ru/TiO_2 [49] and Ru/Al_2O_3.[50] However, in most cases these complexes are present on the surfaces of the Al_2O_3, SiO_2, and TiO_2 carriers. In the most detailed studies, the rate of formation of CH_4 was compared with the rate of change in the intensities of the IR bands due to the intermediate adsorption complexes. For example a correlation between the concentration of adsorbed CO and $HCOO^-$ and the rate of methanation has been observed on Ru/TiO_2.[51,52] Hence it was concluded that the reaction has a dissociative mechanism (in the scheme below the symbol 'm' denotes the metal and the symbol 'c' denotes the carrier):

$$CO_2(gas) \rightleftharpoons CO_2(m),$$

$$H_2(gas) \rightleftharpoons 2H(m),$$

$$CO_2(m) + 2H(m) \rightleftharpoons HCOOH(c),$$



$$HCOOH(c) \rightleftharpoons H(m) + HCOO(c),$$

$$HCOOH(c) \rightleftharpoons CO(m) + H_2O,$$

$$CO(m) + 6H(m) \rightarrow CH_4 + H_2O.$$

On the Rh/Al_2O_3 catalyst, formates are intermediates in reaction (3) and the CO formed in this reaction undergoes methanation.[53] According to the data of Lahtinen et al.[54] and Gupta et al.,[55] the adsorption of H_2 on Rh/Al_2O_3 promotes the adsorption of CO_2, since this involves the formation of the formate, which may decompose into H_2O and CO on Rh or migrate on Al_2O_3, where it is more stable. On Rh/SiO_2, the formate is formed only in the presence of potassium.[56]

An increase in the degree of adsorption of CO_2 in the presence of H_2 has also been observed on deposited palladium,[57] where the complex

is formed. The formation of the formate, which occurs only in the presence of a carrier, is ensured by the spill-over of H atoms.

The formation of formate complexes has been observed by the IR spectroscopic method under the conditions of the interaction of H_2 and CO_2 on deposited ruthenium,[58,59] rhodium,[60-64] and palladium,[65] and nickel.[66]

The study of the interaction of H_2 with CO_2 on Ni(111) [67] and Cu(100) [68] single crystals and also on deposited nickel catalysts,[69,70] with the aid of various spectroscopic methods, showed that formate complexes are formed on their surfaces, their further reactions leading to the evolution of CO and H_2:

$$CO_2(ads) + H(ads) \rightleftharpoons HCOO(ads), \quad (12)$$

$$HCOO(ads) + H(ads) \rightleftharpoons H_2O + CO. \quad (13)$$

Reactions (12) and (13) apparently proceed simultaneously with the methane formation reaction, which require the complete dissociation of CO_2 and H_2 on adsorption.

The formation of higher hydrocarbons in the hydrogenation of CO_2 has been noted in comparatively few studies. For example, an increase in the heat treatment temperature of the Rh/Nb_2O_5 catalyst for the hydrogenation of carbon dioxide promotes an increase in the selectivity in the formation of C_2H_6 compared with CH_4.[71]

The carbides Mo_2C, Fe_3C, and VC proved to be active in the hydrogenation of CO_2;[72] the carbides TiC and SiC are inactive. C_1-C_3 hydrocarbons as well as CO and alcohols are formed in this process. Promotion with copper increases the selectivity in the formation of hydrocarbons.

When a mixture of iron and carbon powders is ground in a ball mill, a mixture of iron carbides is formed. The selectivity in the hydrogenation of CO_2 on this catalyst changes: instead of CO [reaction (3)], C_2-C_4 hydrocarbons and CH_4 are formed. With increase in the duration of grinding, the rate of reaction also increases and the alkanes : alkenes ratio diminishes from 0.37 to 0.16.[73]

On iron catalysts, higher hydrocarbons are formed apparently only in the presence of iron carbide.[74] On Fe-silicalite, higher hydrocarbons were not detected on hydrogenation of CO_2. This has been explained by the difficulty of reducing Fe, which hinders the formation of carbides.[75]

On polycrystalline cobalt, C_1-C_4 hydrocarbons were isolated on hydrogenation of CO, whilst methane and ethane were isolated on hydrogenation of CO_2.[54] The selectivity in the formation of CH_4 on the spinels $La_{1-x}M_xCoO_3$ (M = Sr or Th) increases with increasing degree of reduction, whilst the selectivity in the formation of C_2H_6 falls.[40]

2. The Bosch reaction

This reaction has been used in life support systems for the removal of CO_2 in the form of solid carbon.[34] It is employed also for the preparation of filamental carbon fibres.[76] Reaction (2) can be represented as the sum of reaction (1) and the catalytic cracking of methane:

$$CH_4 = C + 2H_2 \quad (14)$$

The dissociation of CH_4 on nickel proceeds rapidly even at 345 °C.

Reactions (1) and (14) can be carried out in a single reactor, where provision is made for the recirculation and isolation of water from the cycle. Depending on the nature of the catalyst (Ni, Co, Fe), pressure, and the number of times the recirculation has been carried out, the process is performed at temperatures ranging from 500 to 700 °C. There is also a possibility of another variant, where CH_4 is decomposed to C + $2H_2$ at 500 °C on Ni/SiO_2 in the first reactor, whilst in the second reactor CO_2 is methanated on the same catalyst at 300 °C, after which methane is returned to the first reactor. Filamental carbon is formed, in which Ni remains at the tip of the filament so that the activity is maintained at an unchanged level.[77]

CO_2 has also been reduced to carbon on iron, gallium, and zinc oxides and also on $LaFeO_3$.[78] The yield of carbon on WO_3 at 700 °C was 27%. Graphite was formed in the form of small isolated spots.

3. The reverse conversion of water gas

Reaction (3) proceeds on the same catalyst as the forward conversion of water gas but at a higher temperature (the equilibrium constant exceeds unity only above 530 °C).

The hydrogenation of CO_2 on oxide catalysts (in contrast to metallic catalysts) does not proceed as far as methane but only as far as CO. On oxides, the rate of hydrogenation of CO_2 is lower than the rate of hydrogenation of CO. Among the catalysts, mention should be made of the familiar iron–chromium oxide catalyst for the conversion of water gas. The selective reduction of CO_2 to CO has also been observed on Fe/MgO and Cu/ZnO [79] as well as Fe/C.[80] In addition, new active and selective catalysts for the reduction of CO_2 to CO, such as MoS_2 [81] and WS_2,[82] have been discovered.

Surface formates are produced as intermediates in reaction (3). However, there are data showing that the reaction proceeds via different surface compounds in the forward and reverse directions.[83]

In the hydrogenation of CO_2 on the chromium–manganese oxide catalyst, the only product is CO.[57] The formation of methane is observed only after the deposition of HCOOH on the surface. The mechanism of the reduction of CO_2 includes the interaction of H_2 with the carbonate structures formed initially:

$$H_2 + CO_3^{2-} \rightleftharpoons H_2O + CO + O^{2-}, \quad (15)$$

$$H_2 + O^{2-} \rightleftharpoons H_2O + [\ ], \quad (16)$$

where [ ] denotes a vacancy.

4. The synthesis of methanol and other oxygen-containing compounds

It is technologically inconvenient to synthesise methanol directly via reaction (4), since one third of hydrogen is consumed in the formation of water. The $CO + 3H_2$ mixture is therefore usually employed for the synthesis of methanol:

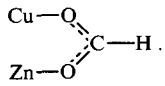
$$CO + 3H_2 = CH_3OH \quad (17)$$

For a long time, the zinc-chromium oxide catalyst, on which the process occurred with a high productivity at 320–400 °C and a pressure of 300 atm, was mainly used. In the 1960s–1970s new more active copper–zinc oxide catalysts, which made it possible to reduce the temperature to 250 °C and the pressure to 100 atm, were introduced into practical employment.

It was believed[84] that methanol is synthesised via the intermediate hydrogenation of CO. However, the use of the labelled $^{14}CO_2$ and ^{14}CO molecules showed[85] that in reality the species hydrogenated is not CO but the CO_2 formed from the latter. Careful elimination of CO from CO_2 and H_2O sharply reduced the rate of synthesis of methanol and only the formation of CO_2 via the water gas conversion reaction leads to the establishment of a stationary regime in the process. The rate of synthesis of methanol from CO_2 is many times higher than from CO.[86] This enabled the authors[87,88] to reach an unambiguous conclusion about the reaction paths of carbon oxides on oxide catalysts. According to their view, methanol is synthesised in two macroscopic stages. In the first stage, CO is converted by treatment with steam and this is followed by reaction (4).

It has been suggested that up to 5% of CO_2 be added to the synthesis gas in the industrial manufacture of methanol.[10]

The study of the kinetics and mechanism of the $CO_2 + H_2$ reaction on copper–zinc oxide catalysts permitted the conclusion that it proceeds via adsorption substitution stages.[89] Stable surface compounds participate in the reactions

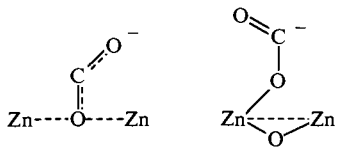


$$X \cdot H_2O + CO_2 \rightleftharpoons X \cdot CO_2 \cdot H_2O \rightleftharpoons X \cdot CO_2 + H_2O,$$

$$X \cdot CO_2 \cdot H_2O + CO \longrightarrow X \cdot CO_2 \cdot H_2 + CO_2,$$

$$X \cdot CO_2 + H_2 \longrightarrow X \cdot CO_2 \cdot H_2 \xrightarrow{2H_2} CH_3OH + X \cdot H_2O,$$

where X is a copper-containing surface centre, which is not part of the copper phase, for example a doublet of copper ions in the zinc oxide lattice.[88] The $X.H_2O.CO_2$ species may comprise the hydroxocarbonate and OH^- ions bound to a single X centre; this complex is hydrogenated to CH_3OH already at 120 °C. However, it is insufficiently stable above 200 °C and most probably does not participate in the synthesis of CH_3OH. The high-temperature chemisorption of CO_2 precedes the formation of CH_3OH and the only path leading to its formation is the adsorption substitution of H_2O.



According to the results of Jackson[90] and Walker et al.,[91] the adsorption of CO_2 is dissociative under the conditions of the synthesis of methanol. IR spectroscopy in situ[92–97] made it possible to detect the surface formates, bicarbonates. and carbonates on the surfaces of the $Cu-ZnO-Al_2O_3$ and $Cu-ZnO-SiO_2$ catalysts. $HCOO^-$ complexes have been detected on ZnO and Al_2O_3. There are also data indicating the formation of the bidentate formate

at the interface.

According to Amenomiya and Tagawa,[95] the activity of the catalyst in the synthesis of methanol from CO_2 and H_2 is proportional to the $HCOO^-$ concentration on copper. On the other hand, the $HCOO^-$ concentration on aluminium remains unchanged under the conditions of the catalytic reaction.

After the adsorption of CO_2 on ZnO/SiO_2 and $Cu-ZnO/SiO_2$, two complexes were detected,[94] one of which is bound to the polar surface (**A**) and the other to the nonpolar surface (**B**).

A **B**

Complex **B** is more readily hydrogenated to the formate. Further hydrogenation results in the formation of $CH_3O.Zn$ and CH_3OH. The function of the polar surface consists in the dissociation of H_2 and the supply of H atoms for the hydrogenation of complex **B**. The addition of CO to the $CO_2 + H_2$ mixture inhibits the formation of the formate as a result of the re-reduction of the surface.

Carbonates, bicarbonates, and the CH_3O and CH_2O groups have been detected by NMR on the surfaces of the catalysts under the conditions of the synthesis of methanol from CO_2 and H_2.[98]

Apart from $Cu-ZnO/Al_2O_3$, Cu/ZrO_2 and $Cu-ZnO/ZrO_2$,[99–101] as well as Cu/Ga_2O_3, Cu/Cr_2O_3, and $Cu-ZnO/Ga_2O_3$[95,102] are also active and selective catalysts for the hydrogenation of CO_2 to methanol. It has been shown[102] that Al_2O_3 and ZrO_2 are the true carriers: they increase the surface of the catalyst but do not affect the specific activity of copper. On the other hand, Ga_2O_3 increases the specific activity of copper by 40% and that of Cr_2O_3 by 30%.

Copper is stabilised on the surface of the carrier in the Cu^0 or Cu^+ state.[103,104] It may be that the stable active centre of $Cu^+-[\,]-Zn-O$, where [ ] is an oxygen vacancy, arises at the interface between Cu and ZnO.[100] The role of the reversible absorption of hydrogen by the lattice in the course of the stabilisation of the active centres of the copper catalysts has been noted.[105]

The discussion concerning the mechanism of the reaction and the nature of the intermediates and the active centres in the synthesis of methanol from CO_2 and H_2 is continuing. The vast majority of investigators accept nowadays[87] that methanol is not formed directly from the synthesis gas but via the intermediate formation of CO_2. As regards the active centres of the Cu–ZnO catalyst, it is claimed in some studies that the reaction proceeds only on copper in the Cu^0 state,[106] while in others (see, for example, Sizgek et al.[107]) it is stated that the active centres are both copper and zinc.

It has been shown in a theoretical study[108] that CO_2 is stabilised in a linear form, bound to the surface via an O atom, on Cu^+ and Zn^{2+}, whilst on Cu^0 coordination via the C atom is preferred. In the case of 'O-coordination', methanol may be formed on the Cu^+ and Zn^{2+} centres via the pathway

$$CO_2 + M \xrightarrow{H_2} HCOO-M \xrightarrow{H_2} H_2CO-M \xrightarrow{H_2}$$

$$\longrightarrow CH_3O-M \xrightarrow{H_2} CH_3OH + M,$$

whilst on 'C-coordination' it is produced on Cu^0 and Zn^{2+} centres via the pathway

$$CO_2 + M \xrightarrow{H_2} M-COOH \xrightarrow{H_2} M-CO \xrightarrow{H_2}$$

$$\longrightarrow M-CHO \xrightarrow{H_2} M-CHOH \xrightarrow{H_2}$$

$$\longrightarrow M-CH_2OH \xrightarrow{H_2} CH_3OH + M.$$

It is as yet difficult to say which path predominates. The first intermediate complex in the first path is the formate, which has been detected spectroscopically, whilst in the second it is a metal-carboxylic acid. The existence of active centres participating in the second reaction path appears preferable.

Copper analogues, namely silver[109] and gold,[110] deposited on oxides have also been investigated as catalysts for the synthesis of methanol from CO_2 and H_2. It was found[109] that the $Ag-ZnO-Ga_2O_3/Al_2O_3$ catalyst is more selective than $Cu-ZnO-Ga_2O_3/Al_2O_3$, but the yield of methanol on it is lower.

Carbonates, formates, bridging CO groups, and CH_2O have been detected on the Cu/ZrO_2, Hg/ZrO_2, and Au/ZrO_2 catalysts under the conditions of the synthesis of methanol from CO_2 and H_2.[111] On this basis, the following reaction mechanism has been proposed:

$$CO_2 + H_2 \longrightarrow HCOO^- + H^+ \underset{OH}{\overset{-OH}{\rightleftharpoons}} CO(ads) \xrightarrow{H_2}$$

$$\longrightarrow CH_2O \xrightarrow{H_2} CH_3OH$$

The formate is apparently formed on ZrO_2, whilst H_2 comes from the metal via the spill-over mechanism.

Palladium catalysts deposited on La_2O_3, CeO_2, and TiO_2 have also been used to synthesise methanol from CO_2 and H_2.[112,113] On Pd/CeO_2 at 230 °C and 30 atm, the selectivity in the formation of CH_3OH exceeded 90% for a 3% conversion. The authors[113] noted the role of the spill-over of H atoms from Pd to CeO_2 and observed the reduction of Ce^{4+} to Ce^{3+}.

The study of palladium catalysts on various carriers showed that they are more active in the synthesis of methanol than Cu/ZnO. Pd/Ga_2O_3 is especially active: at 250 °C and a pressure of 5 MPa and for the $H_2:CO_2 = 3:1$ ratio, the turnover number of the reaction on this catalyst is ten times greater than on Cu/ZnO.[114]

The liquid-phase synthesis of methanol from CO_2 and H_2 may be used to solve the technological problem of removal of the excess heat. This process has been achieved on a $Cu-Zn/Al_2O_3$ catalyst; the yield of CH_3OH was 93%.[115]

More reduced forms of the catalyst are apparently needed for the synthesis of higher alcohols from CO_2 and H_2. Ethanol, propanol, and butanol are formed on a bimetallic $Ir-Mo/SiO_2$ catalyst.[116] On a catalyst such as 5% $Rh-Ni-Mn-O/SiO_2$ at 220 °C, a pressure of 50 atm, and for the $H_2:CO_2=3:1$ ratio, the selectivities in the transformation of CO_2 into CH_3OH and C_2H_5OH reached 5.4% and 41.1% respectively for a degree of conversion of 1.6%.[117] Nickel- and ruthenium-containing zeolites with added copper are active in the synthesis of higher alcohols. The selective formation of C_2H_5OH from CO_2 and H_2 on the copper–chromium oxide catalyst is observed when an alkali or a lanthanide is added to it. This can be explained by the need for the presence of OH groups on the catalyst surface in order to activate CO_2.[118]

According to the data of Wang et al.,[119] mainly CO and hydrocarbons are formed on the $K-Cu-Co-Cr-O$ catalyst. The selectivity in the conversion into the C_1-C_6 alcohols is only 1.8%, the fraction of ethanol among the alcohols being 44.0%. The Cu–Ni alloy proved to be an active and selective catalyst for the hydrogenation of CO_2 to a mixture of alcohols. The Ni–Mn and Ni–Co alloys are less selective.[120] The conversion of methanol into a higher homologue has been observed[121] in a mixture with CO_2 and H_2 in contact with a suspension of $Cu_3Zr_2H_{11}$ in solution in an alcohol–benzene mixture. At 210 °C and 25 atm, small amounts of propanol, butanol, and the corresponding ethers were detected in the products.

Hydrocarbons may be synthesised from a mixture of CO_2 and H_2 on Cu–Zn catalysts, methanol being formed as an intermediate. This process is a modification of the familiar 'Mobil process'.

On the Cu–Zn–Cr oxide catalyst mixed with the HY zeolite at 400 °C, carbon dioxide is converted into C_2-C_6 hydrocarbons.[122,123] The conversion of CO_2 with formation of a mixture of methanol and hydrocarbons greatly exceeds the equilibrium yield of methanol under these conditions as a consequence of the shift of the equilibrium in reaction (4) to the right.

Liquid hydrocarbons (up to C_8) have been obtained on a catalyst of the Fischer–Tropsch type containing 95% Fe and 5% Cu at 400 °C and a pressure of 50 atm.[124,125]

It has been suggested[126] that a two-stage flow reactor be employed for the synthesis of petrol from a mixture of CO_2 and H_2. In the first stage (in the first part of the reactor), methanol is synthesised (250 °C, 50 atm) on the $Cu-Zn-Cr-Al-O$ catalyst modified with Ag and Pd. In the second stage, a mixture of C_1-C_6 hydrocarbons is formed on the H–Fe silicate, the structure of which is similar to that of the HZSM-5 zeolite. The overall selectivity in the conversion of CO_2 into petrol reaches 46% and the yield is 71 g litre^{-1} h^{-1}. The authors believe[126] that the CO_2-containing effluent gases from electric power stations may be used in this process.

5. Synthesis of dimethyl ether

It has been noted[127,128] that the best way of overcoming the thermodynamic limitations associated with the synthesis of methanol is the direct synthesis of CH_3OCH_3 from CO_2 and H_2. Dimethyl ether may be formed from the synthesis gas on a mixture of the catalyst for the synthesis of methanol and an acid dehydration catalyst.[129] The conversion of $CO_2 + H_2$ into CH_3OH and $(CH_3)_2O$ was achieved[130] on a mixture of the $Cu-ZnO-Al_2O_3$ catalyst with solid acid catalysts (zeolites, WO_3/SiO_2 silicalite). The use of a type Y zeolite afforded the best result: at 240 °C, the yield was 17% for a selectivity of 55.1% with respect to $(CH_3)_2O$ and of 13% with respect to CH_3OH. On the $Cu-Zn-Cr_2O_3-Al_2O_3$ catalyst mixed with a zeolite, the yield of oxygenated products reached 18.8%.

Another reaction which makes it possible to overcome the thermodynamic limitations involves the conversion of a mixture of CO_2 and H_2 into methyl formate by the carboxylation of the intermediate methanol:

$$2CO_2 + 4\,H_2 \rightleftharpoons HCOOCH_3 + 2H_2O.$$

This reaction has been achieved on a mixture of the methanol catalyst with the K–Fe/L zeolitic catalyst.[131]

6. Synthesis of formic acid

Under standard conditions reaction (6) is thermodynamically unfavourable. For this reason, only negligible yields of HCOOH are observed. In order to increase the yield under mild conditions, alkaline and alkylating agents are used, for example ruthenium and iridium complexes. Methyl formate has been obtained with their aid from the $CO_2 + H_2 + CH_3OH + H_2O$ mixture.[22]

CO_2 has been reduced[132,133] in aqueous solution by Na, Zn, and Al amalgams. Very small amounts of HCOOH were obtained. Triethylammonium formate was formed in the hydrogenation of CO_2 on the complex $[Rh(NBD)(PMe_2Ph)_3]BF_4$, where NBD = norbornadiene, in solution in tetrahydrofuran.[134]

On the whole, the data presented in this section demonstrate that, despite the high cost of hydrogen and the large amount of energy consumed in a series of CO_2 hydrogenation processes, many of them, especially those involving the syntheses of methanol and dimethyl ether, can already be regarded as a basis for large scale industries, serving as an alternative to the CO-based processes. Highly active low-temperature catalysts are necessary for this purpose. As regards scientific theory, the greatest advance achieved in the very recent years has been the detection with the aid of physical methods of intermediate compounds on the catalyst surfaces. Spectroscopic methods have still been inadequately employed in situ.

IV. Interaction of carbon dioxide with methane

The reduction of carbon dioxide by hydrocarbons, i.e. the employment of CO_2 an oxidant, is the most promising procedure for the establishment of large scale processes involving the utilisation of carbon dioxide.

1. Metallic catalysts

The direct interaction of methane with CO_2 on metallic catalysts has been investigated by many workers, starting with Fischer and Tropsch.[135] Kurganova et al.[136] studied the catalytic reactions of an equimolar mixture of methane and carbon dioxide on platinum deposited on various carriers. Platinum deposited on the BAU activated charcoal proved to be the most active. Reaction (18), involving the preparation of the synthesis gas, and to an even greater extent reaction (19), involving the formation of carbon, and reaction (20), in which methane is converted by steam, take place on this catalyst starting at a temperature as low as 350 °C:

$$CH_4 + CO_2 = 2CO + 2H_2, \quad \Delta H = 209.3 \text{ kJ mol}^{-1}, \tag{18}$$

$$CH_4 + 2CO_2 = C + 2CO + 2H_2, \quad \Delta H = 641.1 \text{ kJ mol}^{-1}, \tag{19}$$

$$CH_4 + H_2O = CO_2 + 3H_2, \quad \Delta H = 76.6 \text{ kJ mol}^{-1}. \tag{20}$$

The following reactions are also possible:

$$CH_4 + 3CO_2 = 4CO + 2H_2O, \quad \Delta H = 330.6 \text{ kJ mol}^{-1}, \tag{21}$$

$$2CH_4 + CO_2 = C_2H_6 + CO + H_2O, \quad \Delta H = 16.7 \text{ kJ mol}^{-1}. \tag{22}$$

All five reactions (18)–(22) are endothermic and take place at high temperatures (600–900 °C). At 800 °C, ΔG for the first four reactions is negative, whilst for reaction (22) it is positive but not very large. The equilibrium yield of C_2H_6 in reaction (22) at 800 °C is 13%, which is fairly large.

In the preparation of synthesis gas by reaction (18), $\Delta G = 0$ at 630 °C. Above this temperature, the equilibrium is displaced towards the formation of synthesis gas, while below it it is

displaced towards $CH_4 + CO_2$. The possibility of regulating the direction of the reversible reaction (18), i.e. the formation of synthesis gas at a high temperature and of methane at low temperatures, has been used to devise cells in which solar energy is employed: the endothermic reaction takes place on heating with sunlight, whilst the exothermic reaction is used to give up the energy.[137] The 1% Ru/Eu_2O_3 catalyst, containing 3 nm ruthenium particles having a hexagonal structure, is most suitable for the solution of the problem.[138]

Reaction (18) can be represented as a combination of the methane steam conversion reaction (20) and the reverse conversion of water gas [reaction (3)]. The study of the kinetics of reaction (18) on a nickel catalyst at 800–900 °C showed[139] that its rate is described by the same equation as the rate of the steam conversion:

$$r = \frac{k_1 P_{CH_4}}{1 + k_2(P_{H_2O}/P_{H_2}) + k_3 P_{CO}},$$

where k_1, k_2, and k_3 are constants and P_{CH_4}, P_{H_2O}, P_{H_2} and P_{CO} are the partial pressures of methane, water, hydrogen, and carbon monoxide respectively. The authors[139] explain this by the fact that CH_4 reacts initially not with CO_2 but with H_2O. Reaction (20) is rate-limiting. The hydrogen obtained in this reaction interacts rapidly with CO_2 via reaction (3) with reformation of H_2O.

The kinetics of all three reactions (18), (20), and (3) have been investigated[140] on eight different metallic catalysts deposited on MgO or Al_2O_3. It was found that the rate of reaction (3) exceeds slightly (in some cases by an order of magnitude) the rates of reactions (18) and (20). On the other hand, the rate of reaction (18) is lower than the rate of the steam conversion of methane with the exception of those cases where the latter is carried out on the Ni/MgO and Ni/Al_2O_3 nickel catalysts, where reactions (18) and (20) proceed at similar rates.

According to Blom et al.,[141] the reduced selectivity in the formation of H_2 compared with CO on Ni/Al_2O_3 at 600–800 °C can be explained by the fact that reaction (3) is much faster than the steam conversion of methane [reaction (20)]. Similar data have been obtained also on deposited cobalt catalysts.[142]

In conformity with Eqn (19), the interaction of CH_4 with CO_2 leads to the formation of carbon, which poisons the nickel catalyst. Carbon is formed both from methane on dissociation of the latter into carbon and hydrogen and from CO via the Boudouard reaction. Carbon is formed in the form of carbon filaments, probably on the Ni(111) face.[143]

Various procedures are used for the industrial preparation of synthesis gas from a mixture of CH_4 and CO_2. The so called 'Calcor' process involving the conversion of a natural or petroleum gas in the presence of CO_2, is available.[144,145] The Haldor Topsoe Company uses the $CH_4 + CO_2 + H_2O$ mixtures to reduce the poisoning of the nickel catalyst and the blocking of the tubes with carbon.[140,146–148] The same company has developed the SPARG (9 atm, 900 °C) process, where sulfur vapour, which passivates nickel and prevents the formation of carbon, is added to the active gas. Rostrup-Nielsen[146] believes that the formation of carbon requires an *ensemble* of several nickel atoms: the *ensemble* for the carbonic acid conversion of methane contains a smaller number of nickel atoms.

Inui et al.[149] suggested that joint $CH_4 + CO_2 + H_2O + O_2$ reforming be employed. This makes it possible to solve the problems of both coke formation and energy consumption. Whereas at 350 °C, the catalytic conversion of methane takes place, i.e.

$$CH_4 + 2O_2 = CO + 2H_2O, \quad \Delta H = 803.5 \text{ kJ mol}^{-1}, \qquad (23)$$

above 500 °C the weakly exothermic reaction involving the formation of the synthesis gas takes place:

$$2CH_4 + O_2 = 2CO + 4H_2, \quad \Delta H = -49.0 \text{ kJ mol}^{-1}. \qquad (24)$$

On the very active 6.6% Ni–3.9% CeO_2–2.2% Pt–0.02% Rh/Al_2O_3 catalyst, the degree of conversion of methane in a mixture with CO_2 and H_2O at a space velocity of 73 000 h^{-1} agrees with the equilibrium value, whereas at 358 000 h^{-1} (contact time 0.01 s) it is lower than the latter. However, if O_2 is added to this mixture, it is possible to achieve a yield of hydrogen of 2877 mol litre^{-1} h^{-1}.

The Ni/SiO_2 catalyst exhibits a much higher activity than the oxides CaO and Fe_2O_3. The temperature of the 50% conversion of CO_2 is 640 °C on Ni/SiO_2 and 900–1000 °C on the oxides.[150,151] The above oxides are coated by carbon faster than is nickel. At 800 °C, the degree of conversion of the $CH_4 + CO_2$ mixture into the synthesis gas was 83.1% on Ni/Al_2O_3, 74.2% on Co/Al_2O_3, and only 3.4% on Fe/Al_2O_3. On Ni/SiO_2, the rate of reaction is approximately 1.5 times lower than on Ni/Al_2O_3.[152,153] When the nickel content is less than 13%, the catalyst is fairly resistant to the deposition of coke. In the presence of a high nickel content, carbon filaments are formed.[154]

The use of MgO or CaO–MgO as carriers for nickel[155,156] and cobalt[156] catalysts greatly increases their activity and especially their stability. On interaction with CO_2, the alkaline carrier gives rise to a carbonate, which coats the surface and prevents coke formation.

A layer having the composition $CH_{0.08}$, i.e. close to pure carbon, is formed on nickel foil under the catalytic conditions. The layer has the composition $CH_{0.06}$ on Ni/SiO_2 and CH_2 on Ni/MgO. For this reason, less coke is formed on Ni/MgO. It has been postulated[157] that MgO acts as an electron-donating carrier and retards the dissociation of CH_x. The conversion of CH_x into C_{ads} leads subsequently to the formation of inactive graphite and the deactivation of nickel. It has been observed[159] that the composition of the CH_x fragment on nickel depends on the nature of the carrier: $x = 2.7$ on MgO, 2.5 on ZnO, 2.4 on Al_2O_3, 1.9 on TiO_2, and 1.0 on SiO_2. However, according to the data of Takeyasu et al.,[159] on the nickel catalysts Ni/MgO, Ni/SiO_2, and Ni/α-Al_2O_3 the ratios C:Ni are the same and equal to the corresponding ratio for metallic nickel.

Iron, cobalt, and nickel powders mixed with an ultradisperse ceramic material in proportions of 1:10 exhibit a high activity. At 740 °C, the yield of the reaction product was 94% at a space velocity of 4500 h^{-1} and 71% at 6100 h^{-1}. The catalysts retain their activity for 70 h.[160]

Nickel catalysts deposited on the nonacid MgY and NaY zeolites also exhibit a catalytic activity at 580 °C.[161] The maximum yield was observed in the presence of a 20% nickel content.

Nickel and cobalt metallic particles are probably formed also in the carbonic acid conversion of methane into the synthesis gas on the $Ca_{0.8}Sr_{0.2}Ti_{0.8}Co_{0.2}O_{3-\delta}$ and $Ca_{0.8}Sr_{0.2}Ti_{0.8}Ni_{0.2}O_{3-\delta}$ catalysts.[162] The nickel-containing catalyst is more active: at 755 °C, the degree of conversion of CO_2 was 64.6% and that of CH_4 was 89.6% on this catalyst. Under these conditions, the yield of CO reached 69.0% and that of H_2 54.8%, while the selectivity in the formation of H_2 was 84.8%. Reaction (18) is accompanied by the simultaneous deposition of coke via reaction (19). The basic properties of the surface may promote the occurrence of the oxidation-reduction process on the latter.

Platinum group metals are active catalysts for the carbonic acid conversion of methane.[138,140,151,163–180] The reaction already proceeds at an appreciable rate at 500 °C. It has been shown by the alternate pulse method that CO is formed when the CO_2 pulse is supplied. C_2H_6 and C_2H_4 are formed in the first pulses, i.e. the oxidative condensation of methane takes place. Carbon is less soluble in noble metals than in nickel, but after a time poisoning takes place — slow at 500 °C and rapid at 600 °C.

An evident disadvantage of noble metals is their high cost, while an advantage is their higher activity than that of nickel, cobalt, and iron and a smaller susceptibility to poisoning. Among the catalysts deposited on Al_2O_3, the most active at 500–700 °C is Rh/Al_2O_3[151,162–166] (Ru/Al_2O_3[171,175,178] and Ir/Al_2O_3[174] according to other data) and is followed by Pt/Al_2O_3 and

Pd/Al_2O_3. This series corresponds to the activity series of the catalysts for the dissociation reaction

$$CO_2 \rightleftharpoons CO + O(ads).$$

The activity series $Ru/MgO > Rh/MgO > Ni/MgO > Pt/MgO > Pd/MgO$ has been obtained for metals deposited on MgO.[153] Rhodium and palladium are poisoned to the least extent, but they are the most expensive.

When the same metal is deposited on different carriers, the latter form the following activity series:[171-173,179] $Al_2O_3 > TiO_2 > SiO_2 > MgO$. According to certain data,[165] acid carriers are more active because they promote the dispersion of the deposited metals. However, the formation of carbonates on basic carriers diminishes the deposition of coke.

The high activities of all the deposited noble metals investigated have been demonstrated.[161,168] It is also significant that in almost all cases the gas mixture had the $CO:H_2 = 1$ composition, i.e. virtually no side reactions were observed. Synthesis gas was formed from the initial $CH_4:CO_2 = 1$ mixture at 780 °C with the following yields: 1% on Al_2O_3, 85% on 1% Ni/Al_2O_3, 73% on 1% Pd/Al_2O_3, 89% on 1% Ru/Al_2O_3, 87% on 1% Rh/Al_2O_3, and 89% on 1% Ir/Al_2O_3. The Ni/Al_2O_3 and Pd/Al_2O_3 catalysts were saturated with coke faster than any others. The Ir/Al_2O_3 catalyst proved to be most resistant to coke formation: it retained its activity for 260 h. The yield of H_2 was found to exceed that of CO on Ru/Al_2O_3. When the $13CH_4 + O_2 + CO_2$ mixture is used, the yield of products on Ni/Al_2O_3 may reach 91% and the reaction becomes thermoneutral. The gas obtained from the $4CH_4 + O_2 + 9CO_2$ mixture contained exactly 50% of CO and H_2 and carbon was not formed on the surface.

The iridium and ruthenium catalysts obtained from the iridate ($Ln_2Ir_2O_7$) and ruthenate ($Ln_2Ru_2O_7$) pyrochlores (Ln = Nd, Sm, Eu, Gd) had a high activity.[169,170] These oxides are activated under the reaction conditions, being converted into the corresponding metals.

Mechanisms have been proposed for the reaction under consideration presupposing the dissociation of CH_4 and CO_2. The correlation between the activity series of the catalysts in the $CH_4 + CO_2$ reactions and in the dissociation reaction $CO_2 \rightleftharpoons CO + O$ suggested[158,180] the following mechanism:

$$CH_4 + S = [CH_{x,S}] + (4 - x)H_S = C_S + 2H_2,$$

$$CO_2 + 2S = CO_S + O_S,$$

$$CO_S = CO + S$$

(The symbol S denotes the catalyst surface).

Other investigators[168,173] also postulate the stepwise dissociation of the CH_4 molecule, but the process mechanism includes the Boudouard reaction.

$$CH_4 + O(ads) = CH_3(ads) + OH(ads),$$

$$CH_3(ads) = CH_x + H(ads),$$

$$CO_2 + H(ads) = CO(ads) + OH(ads),$$

$$CH_x + O(ads) = CO + xH(ads),$$

$$2OH(ads) = H_2O + O(ads),$$

$$CO_2 + C = 2CO,$$

$$C + H_2O = CO + H_2.$$

The study of the $CH_4 + CO_2$ interaction on the $Rh/\gamma\text{-}Al_2O_3$ catalyst with the aid of a TAP reactor[181] showed that the reverse Boudouard reaction proceeds exceptionally rapidly and the mechanism involving it is extremely likely.

Above 500 °C (on Rh), carbon forms a supersaturated solution which inhibits the reaction. The reactions

$$CH_2(ads) + CO_2 = CO + H_2O + C(ads),$$

$$CH(ads) + OH(ads) = CO + H_2$$

are also possible.

The ratio $CO:H_2 > 1$, frequently observed in the products, indicates the occurrence of a number of secondary reactions: the conversion of water gas, the hydrogenation of CO, CO_2, etc.

The study of pure metals by XPS and Auger spectroscopy[182] showed that the reactions

$$CH_4 + Z \rightarrow CH_3-Z \rightarrow CH_2-Z \rightarrow CH-Z \rightarrow C-Z,$$

$$CH_x-Z + O-Z = CO + \tfrac{1}{2}xH_2 + 2Z$$

and the equilibrium reaction

$$H_2O + Z = O-Z + H_2$$

(Z is a catalyst surface centre) occur on the surface.

According to this scheme, the carbonic acid conversion of CO_2 requires that the CH_x particles, formed on interaction between methane and the metal, do not last sufficient time to be fully dehydrogenated and that they should have reacted with O_2. In this case, the reaction

$$CO_2 + Z = O-Z + CO$$

is rate-limiting and the carbonic acid conversion of CH_4 is therefore slower than the steam conversion. It is also possible that the rate of the overall process depends on the CO concentration on the surface. Carbon monoxide participates in the reactions

$$CO + Z = CO-Z$$

and

$$CO-Z \rightarrow C-Z + O-Z.$$

C–Z is probably less reactive than O–Z. The metals on which the heat of adsorption of CO is high undergo a greater reduction in their activity following the replacement of H_2O by CO_2.

However, the study of the carbonic acid conversion of methane on Rh/Al_2O_3 and Ir/Al_2O_3 showed that the dissociation of CO_2 into $CO + O_{ads}$ is not observed under the catalytic conditions (700 °C).[183] On the other hand, methane decomposes quantitatively into $C + 2H_2$. There are no CH_x particles on the surface, since all the surface carbon is hydrogenated quantitatively to methane. The authors therefore propose the following reaction mechanism:

$$CH_4 + Rh_S \rightarrow C_S-Rh_S + 2H_2,$$

$$C_S-Rh_S + CO_2 \rightarrow 2CO + Rh_S.$$

Dissociative mechanisms have also been put forward. Analysis of the IR spectra in situ indicate the formation of formate species (apparently on the carrier),[171,184] linear and bridging carbonyls,[185] and CH_x groups.[173,174]

2. Oxide catalysts

A series of oxide catalysts for the oxidative condensation of methane have been investigated.[186-199] Their behaviour in two reactions was compared: (1) $CH_4 + O_2$ (100 : 1) and (2) $CH_4 + CO_2 + O_2$ (100 : 100 : 1). It was found that, on a catalyst with a moderate basicity, an even higher yield of C_2 hydrocarbons is achieved in the $CH_4 + CO_2 + O_2$ mixture than in the $CH_4 + O_2$ mixture. For example, on 50% PbO–MgO the yield of C_2 species was 3.28% in the first reaction and 4.37% in the second; on $CaO-BaO-CeO_2$, the yields were 2.2% and 3.5% respectively. These results led to the conclusion[188] that the oxygen atoms split off from CO_2 participate in the oxidative dehydrogenation of hydrocarbons:

$$CO_2 \rightarrow CO + O(ads), \quad (25)$$

$$2CH_4 + O(ads) \rightarrow C_2H_6 + H_2O, \quad (26)$$

$$C_2H_6 + O(ads) \rightarrow C_2H_4 + H_2O. \quad (27)$$

Experiments with labelled $^{13}CO_2$ and CD_4 molecules showed that ^{13}CO and C_2D_6 are formed in the reaction.[189] This means

that the CO is obtained only from CO_2 and not as a result of the further oxidation of the hydrocarbon. In the absence of the hydrocarbon, the CO_2 on the catalyst is absolutely unreactive. A certain initial amount of ethane is necessary to initiate the reaction. The conversion of CO_2 is apparently achieved via the reversible conversion of water gas [reaction (3)] by the hydrogen formed in the gas-phase dehydrogenation of ethane with the intermediate dissociative adsorption of CO_2 [reaction (25)]. Thus, in the oxidative dehydrogenation of CH_4 and C_2H_6, the mechanism of the activation of the hydrocarbon is the same regardless of whether O_2 or CO_2 is used as the oxidant.

On pure MgO, synthesis gas is formed via reaction (18), reactions (19) and (21) take place on PbO, while the oxidative condensation reactions (22) and (27) occur preferentially on PbO.MgO. Catalysts with strong basic centres, for example Li/MgO or Ni/ZnO, are less active in the $CH_4 + CO_2$ reaction than in the $CH_4 + O_2$ reaction and are rapidly deactivated.[189]

The carbonic acid conversion of methane has been achieved on vermiculite 22 $MgO.22SiO_2.5Al_2O_3.Fe_2O_3.40H_2O$ at 900–970 °C, for the ratio $CO_2 : CH_4 = 0.5 - 1.5$, and fairly long contact times (10.5–21 s). The degree of conversion of the $CH_4 + CO_2$ mixture into synthesis gas was 99.2%–99.7%. In the empty reactor at even lower rates of supply of the starting material at the same temperature, 62% of CH_4 and 40% of CO_2 were converted, the walls of the reactor becoming coated with a layer of carbon.[190]

The influence of various oxide additives (Cu, Mn, Fe, etc.) on the activity of the nickel catalyst for the carbonic acid conversion of CH_4 has been investigated.[191] Manganese oxides proved to be most effective. The formation of carbon was reduced in their presence, while the degree of conversion of CO_2 increased with increasing manganese content in the nickel catalyst.

Further studies showed that it is possible to do without nickel altogether in carrying out reaction (18). The characteristic features of the $CH_4 + CO_2$ reaction on manganese oxide catalysts have been investigated in detail.[192–203] Under stationary conditions the 5% Ca–12% $Mn-O/Al_2O_3$ catalyst proved to be the most effective. At 870 °C and a space velocity of 900 h^{-1}, the degree of conversion of CH_4 was 83.1%, that of CO_2 was 62.7%, and the selectivity with respect to H_2 was 76.5%. An equimolecular mixture of CO and H_2 was obtained. Extensive oxidation of methane by the catalyst oxygen occurred initially and the conversion of CO_2 did not take place. As the reaction proceeded and the catalyst was reduced, the activation of CO_2 began. The CO and H_2 concentrations then increased continuously. The complete conversion of CO_2 and CH_4 was achieved on the catalyst operating under stationary conditions at 930 °C (the selectivity was 99.7% in the formation of CO and 84.6% in the formation of H_2). The activity of the catalyst was retained for a long time (> 500 h) and carbon was not formed via reaction (19).

The study of the phase composition of the working Ca–MnO/SiO_2 catalyst showed[193] that the more oxidised Mn_2O_3 and Mn_3O_4 phases are reduced during the reaction and only the reduced MnO phase is retained in the catalyst. After the stabilisation of the composition of the catalyst, the formation of the manganese carbide and metallic magnesium phases was not observed.

After the initial treatment of the catalyst with carbon dioxide and subsequent exposure of the former to methane at 850 °C, ethane and ethene are formed, i.e. the oxidative dimerisation reactions (22) and (28) take place, possibly with participation of the carbonate phase.[196]

$$2CH_4 + CO_2 = C_2H_4 + CO + H_2O, \quad \Delta H = 176 \text{ kJ mol}^{-1}, \; T_{\Delta G=0} = 750 \text{ °C}. \qquad (28)$$

The yield of C_2 hydrocarbons is 9%.

A decrease in the temperature of the treatment of the catalyst with carbon dioxide raises the yield of C_2H_6 and C_2H_4 to 13%. When the reduction of Mn_2O_3 and Mn_3O_4 has been completed, the yield of C_2 hydrocarbons falls and only synthesis gas is formed in the stationary state. An increase in the degree of conversion of CH_4 hardly affects the selectivity. This may be associated with the establishment of equilibrium in the water gas conversion reaction (3).

The La–Na–$Mn-O/SiO_2$ catalyst exhibits a high selectivity in the conversion of CH_4 into C_2 hydrocarbons under non-stationary conditions.[197] After its treatment with carbon dioxide and subsequent admisison of methane at 800 °C, C_2 hydrocarbons are formed in almost 100% yield, whereas CO is not produced. Consequently the process takes place via the interaciton of CH_4 with the carbonate fragments of the catalysts and not via a multistage oxidation-reduction mechanism:

$$CO_3^{2-} + 2CH_4 \rightarrow C_2H_6 + CO + H_2O + O^{2-},$$

$$CO_3^{2-} + C_2H_6 \rightarrow C_2H_4 + CO + H_2O + O^{2-},$$

$$CO_3^{2-} \rightleftharpoons CO_2 + O^{2-}.$$

The selectivity of another catalyst investigated in the formation of C_2 hydrocarbons, namely La–Cu–O/SiO_2 was lower.[197,199] Under alternation conditions, the reaction of CO_2 with the catalyst produced CO, whilst the subsequent reaction with methane gave rise to C_2 hydrocarbons. The oxidation–reduction mechanism is more probable in this case. Under stationary conditions, synthesis gas, and not ethane and ethene, is formed on both catalysts.

The properties of the La–$Mn-O/Al_2O_3$ catalyst proved to be similar to those of La–$Mn-O/SiO_2$.[198,199] The selectivity in the formation of C_2 hydrocarbons in separate interactions did not exceed 5%. The constancy of the rate of reoxidation of the catalyst by carbon dioxide as a function of time can be explained by the occurrence of the reverse reaction involving the reduction of the catalyst by the carbon monoxide formed on reoxidation by reaction (24).

A similar equilibrium has been observed also in the oxidative condensation of methane on the familiar Li–MgO catalyst:[198,199]

$$Li^+[\,] + Li^+O^{2-} + CO_2 \rightleftharpoons 2Li^+O^- + CO \qquad (29)$$

[ ] = lattice defect.

The rate of formation of CO in such a process is 40 times lower than in the reoxidation of the manganese systems. Reaction (29) is accompanied by the reaction involving the formation of the stable lithium carbonate Li_2CO_3, which coats the surface and does not therefore participate in the stationary reaction. The selectivity in the formation of hydrocarbons on the Li–MgO catalyst by the $CH_4 + CO_2$ reaction was only several tenths per cent.

The rates of formation of hydrogen under the conditions of the stationary catalytic reaction on $Ca-MnO/Al_2O_3$ (3×10^{-3} mol g^{-1} h^{-1}) and in the reductive reaction between CH_4 and the catalyst (1.7×10^{-3} mol g^{-1} h^{-1}) are comparable. On the other hand, the rate of the interaction of CO_2 with the reduced catalyst (reoxidation of the catalyst) exceeds the rate of the reduction. Thus, in contrast to the metallic catalysts,[139,167] the rate-limiting stage on the magnesium oxide catalysts is apparently the cracking of methane with formation of surface carbon deposits, which are then rapidly oxidised. The presence of manganese oxide in the catalyst increases the rate of oxidation of carbon on the surface. Carbon dioxide interacts with MnO giving rise to a surface carbonate, which reacts with carbon.[191,196]

Scheme 1

$$CH_4 + MnO \xrightarrow{a} MnO...C + 2H_2,$$

$$CO_2 + MnO \overset{b}{\rightleftharpoons} MnCO_3,$$

$$MnCO_3 + MnO...C \xrightarrow{c} 2MnO + 2CO,$$

$$MnCO_3 + H_2 \xrightarrow{d} MnO + CO + H_2O,$$

$$MnO...C + H_2O \xrightarrow{e} MnO + CO + H_2.$$

According to X-ray diffraction data, the MnO and $MnCO_3$ phases are stationary under the catalytic conditions: appreciable oxidation and reduction is not observed and the catalysis does not take place via the mechanism involving the alternate oxidation and reduction of the catalyst. Nevertheless, one may postulate

that intermediate oxidised forms are produced in stage *c* after the decomposition of the carbonate:[199]

$$3MnCO_3 + H_2O \rightleftharpoons Mn_3O_4 + 2CO_2 + CO. \quad (30)$$

The possibility that the carbonates perform transport functions in relation to oxygen has been noted in a study[204] where the oxidative dimerisation of methane with the use of O_2 on $La_2O_3-BaCO_3$ was investigated. The following equation for the rate of reaction arises from Scheme 1:

$$r = \frac{k_1 P_{CH_4}}{1 + (1/k_2k_3)(P_{CO}^2/P_{CO_2}) + k_2 P_{CO_2}},$$

where P_{CH_4}, P_{CO} and P_{CO_2} are the partial pressures of CH_4, CO, and CO_2 respectively and k_1, k_2, and k_3 are the reaction rate constants (Scheme 1). This equation has been confirmed by experimental data.

The introduction of potassium and chromium into the catalyst alters the nature of the process and reaction (21) becomes dominant. On $K-Cr-Mn-O/SiO_2$, the reaction apparently proceeds via the oxidation-reduction mechanism. The second transition metal oxide (Cr_2O_3) participates in the reoxidation. It apparently forms an interface, which facilitates the oxidation-reduction process. When CO_2 is employed, the oxygenating capacity in the oxidative process on $K-Cr-Mn-O/SiO_2$ is much smaller (by a factor of 8) than in the case where O_2 is used.

The $CH_4 + CO_2$ reaction may serve as the first stage in the synthesis of higher hydrocarbons. A two-stage process has been proposed,[202] according to which in the first reactor at 950–970 °C methane undergoes the carbonic acid conversion on manganese silicate modified with 21.8%–2.4% of K_2O with complete conversion of the starting material. In the second reactor, the synthesis gas is converted into C_2-C_3 alkenes with a selectivity of 20%–26% on a catalyst containing 8.1%–9.4% of Fe and 2.2%–6.9% of K on Al_2O_3 at 415–425 °C.

The reverse reaction (18) may be employed in devices utilising solar energy the forward reaction proceeds under the influence of solar energy, whilst the reverse reaction takes place at a low temperature. Owing to the lower selectivity of the reverse reaction, the process efficiency is 54%.[205]

The results presented in this section show that recently there has been a considerable growth of interest by investigators in the interaction of methane with carbon dioxide. Both reaction components are cheap and one may hope to be able to devise large scale processes on their basis. In particular, this applies to the preparation of synthesis gas. As regards the final carbonic acid condensation of methane, the prospects for its industrial application are so far not quite so evident.

Nickel catalysts are most often employed to obtain synthesis gas, but they are poisoned by carbon. Iridium and ruthenium catalysts are active and are not poisoned by carbon, but they are expensive. Finally, the oxide catalysts based on MnO and the rare earths are not poisoned, but they operate at a high temperature and their productivity is inadequate. The mechanisms of the action of the metallic and oxide catalysts are apparently different. Methane is readily dissociated on the former, but the activation of CO_2 is difficult whilst the opposite situation obtains on the latter.

V. Interaction of carbon dioxide with other paraffins

1. Interaction with ethane

When CO_2 interacts with ethane, both the oxidative dehydrogenation of the latter to ethene [reaction (28)] and the formation of synthesis gas [reaction (31)] and carbon [reaction (32)] may take place.2).

$$C_2H_6 + 2CO_2 \rightarrow 4CO + 3H_2, \quad (31)$$
$$\Delta H_{298} = 247.9 \text{ kJ mol}^{-1},$$

$$C_2H_6 + 2CO_2 \rightarrow CO + 3H_2O + 3C. \quad (32)$$

The study of the oxidative dehydrogenation of ethane with the aid of CO_2 showed that manganese oxides serve as a base for the most active and stable systems for the activation of CO_2 and hydrocarbons.[191–193, 195, 196, 202, 204, 206–210] With increase in the manganese concentration in the $Mn-O/SiO_2$ system from 8% to 17%, the degree of conversion of C_2H_6 at 800 °C, a space velocity of 3600 h^{-1}, and for the ratio $CO_2 : C_2H_6 = 1.5$ increases from 65.1% to 73.1%, the degree of conversion of CO_2 rises from 42% to 46.2%, the selectivity with respect to C_2H_4 increases from 52.5% to 61.0%, while the yield of C_2H_4 increases from 34.3% to 44.5%. On the 17% MnO/Al_2O_3 catalyst, the degrees of conversion of C_2H_6 and CO_2 were approximately the same, but the selectivity in the formation of C_2H_4 was somewhat smaller (46.6%). Under the same conditions, reactions (31) and (32) occurred on the nickel catalyst, which was rapidly poisoned as a consequence of coke formation.

A number of oxides (of antimony, zinc, vanadium, and iron), used in the hydrocarbon dehydrogenation reactions, were tested as additives to manganese oxide. The degree of conversion of CO_2 on the $Mn-Sb-O$ and $Mn-Zn-O$ systems was low. A 58% conversion was observed on $MnO-V_2O_5$, but the selectivity in the formation of C_2H_4 was low. The $Mn-Fe-O/SiO_2$ system proved more active, but a high level of selectivity (67%) is attained on this catalyst only during the initial period of its operation (up to 3 h), after which the selectivity falls.

Comparison of data on the catalytic activity of the $Mn-Fe-O/SiO_2$ system and its phase composition under stationary conditions in situ and also under reduction and reoxidation conditions showed that manganese oxides are reduced to MnO during the reaction, while iron oxides are reduced to α-Fe and the carbide. This is apparently the cause of the decrease in selectivity with respect to C_2H_4, the increase in the degree of conversion in reactions (31) and (32), and the saturation of the surface by carbon. Hence it was concluded that the modifying additive to the base oxide should be sought among variable-valence metal oxides exhibiting a catalytic activity in the dehydrogenation reactions and not reduced to the metal under the reaction conditions. Chromium oxides possess such properties. On the 5% Cr–17% $Mn-O/SiO_2$ catalyst, the selectivity with respect to C_2H_4 reaches 70% at 800 °C. A further increase in selectivity is observed when the catalyst is modified by alkali and alkaline earth metal oxides. After the introduction of 1.5% of K into this catalyst, the reaction selectivity at 830 °C increased from 65.4% to 76.8% for ethane and CO_2 conversions of 82.6% and 52.3% respectively. The yield of C_2H_4 was 55.7% for $C_2H_4 : CO \approx 1$. Under these conditions, the degrees of conversion of C_2H_6 and CO_2 on the $Cr-O/SiO_2$ catalyst, which contains no manganese, are low.

The study of the degrees of conversion of C_2H_6 and CO_2 showed that the selectivity with respect to C_2H_4 initially increases with increase in the $CO_2 : C_2H_6$ ratio and then attains a plateau (for $CO_2 : C_2H_6 > 2.5$). This effect is probably associated with the increasing degree of oxidation of the surface and with decrease in the contribution of the extensive cracking of ethane. Such variation of the selectivity differs significantly from that observed in the oxidative dehydrogenation of C_2H_6 in the presence of oxygen, where the selectivity with respect to the alkene fell with increase in P_{O_2}.

Reaction (18) can be carried out also under conditions with separate oxidation and reduction steps. In this regime, C_2H_6 is converted into C_2H_4 on reduction of the catalyst, whilst the reoxidation of the later results in the reduction of CO_2 to CO.

Bearing in mind the data showing that the dehydrogenation and extensive conversion of ethane occur on different centres, one may put forward the following mechanism for the reactions of methane in a general form:

$$\begin{array}{l} C_2H_6 \xrightarrow{I} RO \longrightarrow C_2H_4, \\ \quad\quad\quad\quad\ \downarrow \\ C_2H_6 \xrightarrow{II} R \longrightarrow \text{extensive conversion products} \end{array} \qquad (33)$$

The mode of conversion of ethane is determined by the ratio of the oxidised and reduced centres (RO : R), an increase which results in an increase in selectivity with respect to ethene. As the degree of conversion of ethane increases and CO accumulates in the reaction medium, the catalyst surface is reduced by carbon monoxide and process II predominates. The rates of the parallel processes specified in reaction (33) may be described by the equations

$$r_I = k_1 P_{C_2H_6}[RO],$$

$$r_{II} = k_2 P_{C_2H_6}[R].$$

The RO and R centres are linked by the equilibrium reaction $R \leftrightharpoons RO$.

From the stationary condition [R] + [RO] = 1 and the equations for r_I and r_{II}, we obtain the expressions

$$r_I = \frac{k_1 k_3 P_{C_2H_6} P_{CO_2}}{k_3 P_{CO_2} + k_{-3} P_{CO}},$$

$$r_{II} = \frac{k_2 k_{-3} P_{C_2H_6} P_{CO}}{k_3 P_{CO_2} + k_{-3} P_{CO}}.$$

The following equation can be formulated for the process selectivity:

$$S = \frac{r_I - r_{II}}{r_I} = 1 - \frac{k_2 k_{-3} P_{CO}}{k_1 k_3 P_{CO_2}}.$$

It explains the decrease in selectivity with increasing degree of conversion. The concave form of the curve relating the rate of reaction to the degree of conversion in the temperature range 700–830 °C can be accounted for by the inhibition of the reaction by the CO formed.

The equations for r_I and r_{II} differ from the corresponding equation for the oxidation-reduction process involving the oxidation of alkanes by oxygen. In the latter case, the denominator represents the sum $k_{Ox}P_{CO_2} + k_{Red}P_{C_nH_m}$.[207] The inhibition by ethane is not observed in this case.

The rate of reoxidation of the catalyst by carbon dioxide (0.7×10^{-3} mol g^{-1} h^{-1}) is comparable to the rate of its reduction by ethane (0.6×10^{-3} mol g^{-1} h^{-1}). However, the activation energy for the reoxidation reaction (109 kJ mol^{-1}) is significantly lower than the activation energy for the reduction reaction (176 kJ mol^{-1}).

The study of the phase composition of the K–Cr–Mn–O/SiO_2 catalyst in situ showed[206] that the Mn_3O_4 phase, observed initially, is gradually reduced and is converted into the new phase MnO. The degree of dispersion of the manganese-containing phase increases as the reaction proceeds.

The following mechanism of the dehydrogenation of ethane in the presence of CO_2 on K–Cr–Mn–O/SiO_2 was proposed on the basis of all the results obtained:[168]

Scheme 2

$$C_2H_6 \xrightarrow{a} C_2H_4 + H_2 \text{ (thermal process)},$$

$$C_2H_6 + Cr^{3+}O^{2-} \xrightarrow{b} C_2H_5 + Cr^{2+}OH^-,$$

$$C_2H_5 + Cr^{3+}O^{2-} \xrightarrow{c} C_2H_4 + Cr^{2+}OH^-,$$

$$C_2H_6 + MnCO_3 \xrightarrow{d} C_2H_4 + MnO + CO + H_2O,$$

$$2Cr^{2+}OH^- \xrightarrow{e} Cr^{2+}O{-}Cr^{2+} + H_2O,$$

$$Cr^{2+}O{-}Cr^{2+} + MnCO_3 \xrightarrow{f} 2Cr^{3+}O^{2-} + MnO + CO,$$

$$MnO + CO_2 \xrightleftharpoons{g} MnCO_3.$$

In addition, one should include here the cracking reaction, which reduces the selectivity.

$$C_2H_6 + Cr^{2+} \xrightarrow{h} Cr^{2+}...CH_x + \tfrac{1}{2}(6-x)H_2.$$

$$Cr^{2+}...CH_x + Cr^{3+}O^{2-} \xrightarrow{i} 2\,Cr^{2+} + CO + \tfrac{1}{2}xH_2.$$

The Boudouard reaction

$$CO_2 + C \longrightarrow 2CO \qquad (34)$$

also takes place with an activation energy of 201 kJ mol^{-1}, but its contribution under stationary conditions is low.

Scheme 2 makes it possible to explain why the yield of CO greatly exceeds that of hydrogen: at 700 °C, the ratio $CO : H_2$ is between 5 and 8, whilst at 830 °C it is between 1.5 and 2. This means that the contribution of the thermal pyrolysis of methane (reaction *a* in Scheme 2) is relatively small.

The activation of the manganese catalyst by chromium and the distinctly observed synergism are probably due to the fact that, being mobile, the manganese containing phase (MnO) participates during reoxidation in transferring oxygen from CO_2.

$$\begin{array}{l} MnO...[\ ]_L Cr^{2+}O^{2-}Cr^{2+}O_L^{2-} + CO_2 \longrightarrow \\ \longrightarrow MnCO_3...[\ ]_L Cr^{2+}O^{2-}Cr^{2+}O_L^{2-} + CO_2 \longrightarrow \\ \longrightarrow MnO + CO + O_L^{2-}Cr^{3+}O^{2-}Cr^{3+}O^{2-} \end{array} \qquad (35)$$

The oxidation-reduction mechanism of the decomposition of manganese carbonate plays an important role under these conditions. The reduction of Cr^{3+} to Cr^{2+} during the reaction is indicated by the decrease in the magnetic susceptibility of chromium.

The above mechanism is supported by data on the thermal desorption of CO_2.[209] During the thermoprogrammed heating of the Mn–O/SiO_2 catalyst, pretreated with CO_2, the evolution of CO_2 is observed at three temperatures — 335, 425, and 750 °C — owing to the nonuniformity of the adsorption centres. The activation energies for desorption are 93 ± 8, 226 ± 8, and 293 ± 8 kJ mol^{-1} under these conditions. During the thermal desorption of CO_2 from a surface treated with hydrogen before adsorption (500 °C, 4 h), three types of centres are also observed, their capacity with respect to CO_2 being somewhat lower probably as a result of the removal of some of the oxygen centres during the reduction of the catalyst by hydrogen. The activation energies for desorption do not change under these conditions. The activation energies for the thermal desorption of CO_2 are close to those for the thermal desorption of oxygen under the same conditions. This may indicate the similarity of the nature of the centres for the activation of CO_2 and O_2 and identical principles governing the manganese catalysts in the carbonic acid and oxygen conversions.

On the other hand, in the thermal desorption of CO_2 from the Cr–Mn–O/SiO_2 catalyst, only one high-temperature peak is observed (the activation energy for desorption is 233 ± 8 kJ mol^{-1}). Such a change in the thermoprogramming diagram (TPD) on passing from Mn–O to Cr–Mn–O is evidently associated with the reoxidation of Cr^{2+} by the intermediate CO_2-accepting manganese-containing phase. The decrease in the degree of adsorption of CO_2 during the preliminary reduction of the catalyst by hydrogen indicates that the carbon dioxide adsorption centres are regular O^{2-} lattice ions on the basic surface. The strong CO_2-accepting centres in the high-temperature region are probably less reactive in the reoxidation of Cr^{2+}. Consequently the strength of the basic centres determines the stability of the carbonate structure and hence the degree of reoxidation of the oxidation-reduction centres. Centres with a moderate basicity are needed for the acceptance of CO_2 and the reoxidation of Cr^{2+}, which is in fact observed when the system

contains the weakly basic oxide MnO. The presence of an interface between MnO and CrO under these conditions probably facilitates the reoxidation of CrO.

The capacity with respect to oxygen of the catalytic system $Cr-O/SiO_2$, which contains no manganese oxide, is significantly lower after its reoxidation by CO_2 than the similar capacity of the $Cr-Mn-O/SiO_2$ system. From this standpoint, the $Cr-Mn-O$ composition can be regarded as bifunctional: on the one hand, it activates CO_2 on the basic centres and, on the other, it converts the hydrocarbon on the oxidation-reduction centres.

The oxygen capacity and the rate of oxidation of the catalyst can be altered by adding oxygen to the $C_2H_6 + CO_2$ mixture. For a particular $CO_2:O_2$ ratio, it is posisble to attain the optimum degree of oxidation of the surface, which ensures a high selectivity in the conversion of C_2H_6 into C_2H_4.[195] The reoxidation activation energy is significantly higher than the activation energy for the decomposition of the carbonate fragments. This is probably one of the reasons for the lower oxygen capacity of the catalysts reoxidised by carbon dioxide compared with their capacity when they are reoxidised by O_2.

The activation energies for the reoxidation of $Cr-Mn$ catalysts of different composition are the same (this also applies to the $V-Mn-O$ catalyst), although their oxygen capacities are different. This means that, although CO_2 is initially bound to Mn, the second element (Cr, V) determines the rate of reoxidation.

The centres on which oxygen is bound and the oxygen ions formed promote also the transition of CO_2 to the activated state. The mobile oxygen species pass from the manganese carbonate phase via spill-over to the chromium oxidation-reduction centres.

Another example of oxides with a moderate basicity having oxidation-reduction centres is provided by lanthanide oxides. Thus the oxidative dehydrogenation of ethane has been achieved on La_2O_3.[211] Under these conditions, La_2O_3 is converted into the hexagonal carbonate $La_2O_2CO_3$, which is in fact the active phase. Other lanthanide oxides do not form monocarbonates and are much less active than La_2O_3.

2. Interaction with propane

In the heterogeneous-catalytic conversion of propane by reaction with CO_2 on different catalytic systems, three reactions take place to different extents: oxidative dehydrogenation of propane to propene [reaction (36)], its degradative cleavage to C_2H_4 [reaction (37)], and its extensive conversion with formation of CO and H_2 [reaction (38)].

$$C_3H_8 + CO_2 \rightarrow C_3H_6 + CO + H_2O, \quad \Delta H_{298} = 165.3 \text{ kJ mol}^{-1}, \tag{36}$$

$$2C_3H_8 + 2CO_2 = 3C_2H_4 + 2CO + 2H_2O, \tag{37}$$

$$C_3H_8 + 3CO_2 = 6CO + 4H_2. \tag{38}$$

Like the interaction of ethane with CO_2 [reaction (31)], reaction (38) is of interest as a method of preparation of a synthesis gas with an increased CO content. According to the data of Mamedov et al.,[192] the degree of conversion of CO_2 in an equimolar mixture with propane is 80%–85% on a nickel catalyst at 750 °C. However, the process is accompanied by extensive coke deposition.

The $CO_2 + C_3H_8$ reaction has been investigated on the Ni/SiO_2, Rh/SiO_2, and Pd/SiO_2 catalysts at 600 °C. The Ni/SiO_2 catalyst proved to be the most active and selective: the degree of conversion reached 92% and the selectivity in the formation of $CO + H_2$ reached 70%–80%. According to the authors,[212] the rate-limiting stage is the dissociation of propane:

$$C_3H_8 + 2Ni \rightarrow 2NiCH_2 + CH_4.$$

This is followed by the reactions

$$CH_4 + Ni \rightleftharpoons NiCH_2 + H_2,$$

$$NiCH_2 + CO_2 \rightleftharpoons Ni + 2CO + H_2,$$

$$NiCH_2 + 2CO_2 \rightleftharpoons Ni + 3CO + H_2O,$$

$$Ni + CO_2 \rightleftharpoons NiO + CO,$$

$$NiCH_2 + NiO \rightleftharpoons 2Ni + CO + H_2,$$

$$NiO + H_2 \rightleftharpoons Ni + H_2O.$$

The manganese oxide systems proved to be active and stable catalysts for the oxidative-reductive dehydrogenation of propane via reactions (36) and (37) with formation of propene and ethene.[192, 196, 204, 213]

In the presence of $Mn-O/SiO_2$, the conversion of propane into C_2-C_3 alkenes proceeds more selectively than on the nickel catalyst. At 800 °C, the yield of C_2-C_3 alkenes is 47% relative to the propane passed through the system. With increase in temperature, their yield diminishes, but the yield of CO and H_2 increases. Preliminary treatment of the catalyst with carbon dioxide increases the selectivity for the formation of the C_2-C_3 compounds. After preliminary treatment with hydrogen, the overall degree of conversion of propane and CO_2 increases, but the selectivity for the formation of alkenes falls. Evidently the selective degradation of propane to ethene and methane and the oxidative dehydrogenation to propene take place on the oxidised surface, whereas on the reduced surface propane undergoes cracking with formation of carbon fragments, which are oxidised by carbon dioxide to CO. Thus the overall characteristics of the conversion of propane are similar to those of the conversion of ethane.

The best catalyst for the selective conversion of propane by CO_2 is, for ethane, the 1.5% K–5.5% Cr–17% $Mn-O/SiO_2$ system. At 830 °C, a space velocity of 3600 h^{-1}, and for $CO_2:C_3H_8 = 1.5$, a degree of conversion of C_3H_8 of 96.0%, a degree of conversion of CO_2 of 52.0%, a selectivity in the formation of the C_2H_4 and C_3H_6 hydrocarbons of 75% (80% in the case of C_2H_4), a yield of C_2-C_3 alkenes of 72%, and the $CO:(C_2H_4 + C_3H_6)$ ratio = 1.4 were attained on this catalyst. At 890 °C, the ratio $CO:(C_2H_4 + C_3H_6)$ increases to 4. The amount of hydrogen present in the reaction product is smaller by a factor of 5–8 than that of CO. With increase in the degree of conversion, there is a considerable fall in the selectivity in the formation of alkenes. This behaviour can probably be accounted for by the higher degrees of conversion of the hydrocarbon and the formation of a reaction mixture with more effective reducing properties than in the case of ethane.[196]

After the reduction of the catalyst by propane, the rate of formation of C_2-C_3 alkenes diminishes: the rate of formation of C_2H_4 on the oxidised surface is 2–3 times greater than on the reduced surface. It must be emphasised that, in the interaction of propane with a catalyst pretreated with air, the extensive oxidation products (CO and CO_2) are formed preferentially. This can apparently be explained by the fact that, when the catalyst is treated with air, chromium passes to a higher oxidation state (up to Cr^{6+}) than in Cr_2O_3. On the other hand, the intermediate state of chromium (Cr^{3+}) is responsible for the formation of C_2-C_3 alkenes. Manganese oxides are reduced in the stationary state to MnO (according to X-ray diffraction data obtained in situ). This phase participates in the oxygen transport and maintains chromium in the Cr^{3+} oxidation state [see reaction (35)].

The $Cr-O/SiO_2$ catalyst is less active and selective. Evidently without MnO it is impossible to maintain chromium in the oxidised state.

Under stationary conditions with $C_3H_8:CO_2 = 1-1.2$, the amount of coke formed does not exceed 3.6% relative to the weight of the catalyst. Electron microscopy shows that, after the treatment of the catalyst under nonstationary conditions, coke is present on the surface in two forms: as filamental carbon and in the form of flat scales Under stationary conditions, filamental carbon is not formed. This is associated either with the absence of metallic inclusions in the catalyst (Cr^0) or with the rapid interaction of the nuclei of the carbon phase with CO_2 in

accordance with the Boudouard reaction. Coke is removed from the $Mn-Cr-O/SiO_2$ catalyst at a much lower temperature (610 °C) than from $Mn-O/SiO_2$ (870 °C).

A scheme for the oxidative pyrolysis of propane in the presence of CO_2 (Scheme 3) has been proposed.[168] It is similar to the scheme for the $CO_2 + C_2H_6$ interaction on the $K-Cr-Mn-O/SiO_2$ catalyst (Scheme 2). According to Scheme 3, C_2H_4 is formed mainly on the Cr^{3+} centres, while CH_4, CO, and H_2 are formed on the Cr^{2+} centres; MnO ensures the activation of CO_2. The gas-phase reactions of the radicals are not included in the scheme.

Scheme 3

$$C_3H_8 + Cr^{3+}O^{2-} \xrightarrow{a} C_3H_7^{\cdot} + Cr^{2+}OH^-,$$

$$C_3H_7^{\cdot} + Cr^{3+}O^{2-} \xrightarrow{b} C_2H_4 + CH_3O^-...Cr^{2+},$$

$$CH_3O^-...Cr^{3+} \xrightarrow{c} Cr^{3+}O^{2-} + CH_3^{\cdot},$$

$$CH_3O^-...Cr^{2+} \xrightarrow{d} Cr^{2+}[\ ] + \text{extensive oxidation products}$$

$$C_3H_8 + 2[\ ]Cr^{2+} \xrightarrow{e} C_2H_4...Cr^{3+} + C...Cr^{2+} + 2H_2,$$

$$C_2H_4...Cr^{2+} \xrightarrow{f} CH_4 + C...Cr^{2+},$$

$$C_2H_4...Cr^{2+} + [\ ]Cr^{2+} \xrightarrow{g} 2C...Cr^{2+} + 2H_2,$$

$$2Cr^{2+}OH^- \xrightarrow{h} Cr^{2+}[\ ] + Cr^{2+}O^{2-} + H_2O,$$

$$Cr^{2+}[\ ] + Cr^{2+}O^{2-} + MnCO_3 \xrightleftharpoons{i} \rightleftharpoons 2Cr^{3+}O^{2-} + MnO + CO,$$

$$C...Cr^{2+} + Cr^{3+}O^{2-} \xrightarrow{j} 2Cr^{2+}[\ ] + CO,$$

$$MnO + CO_2 \xrightleftharpoons{k} MnCO_3.$$

The first two stages in Scheme 3 may be combined into one, i.e. the Scheme may be formulated also without the participation of free radicals, although their formation in the high-temperature interaction of alkanes with oxides is extremely probable. If it is postulated that, in the case where the process proceeds via a parallel reaction mechanism, the catalyst may be reduced both by the initial hydrocarbon and by CO, the rate of the selective formation of ethene from propane may be expressed by the equation

$$r_{C_2H_4} = \frac{k_1 P_{C_3H_8} k_2 P_{CO_2}}{k_1 P_{C_3H_8} + k_2 P_{CO_2} + k_3 P_{CO}}.$$

However, under real conditions the catalyst is reduced by the hydrocarbons 17 times more slowly than by carbon monoxide (the rate of oxidation of CO is 17 times higher than the rate of the extensive oxidation of propene). We then have $k_3 P_{CO} \gg k_1 P_{C_3H_8}$ and the rate equation is transformed into

$$r_{C_2H_4} = \frac{k_1 P_{C_3H_8} k_2 P_{CO_2}}{k_2 P_{CO_2} + k_3 P_{CO}}.$$

The activation energy for the formation of ethene from propane is 151 kJ mol^{-1}, which is close to the value obtained in the case of ethane (167 kJ mol^{-1}), confirming the similarity of the mechanisms of the primary activation of these hydrocarbons on the $K-Cr-Mn-O/SiO_2$ catalyst. The kinetic equations for the conversion of ethane and propane are also similar and differ from the corresponding equations describing the oxidation of alkanes by oxygen.

The chemistry of the interaction of propane with CO_2 on metals (Ni) and oxides (MnO_x) is different. On the former, synthesis gas is formed selectively, whilst on the latter C_2-C_3 alkenes are formed preferentially. On metals, propane dissociates into C(ads) or CH_x, whereas on oxides hydrogen is split off from propane or oxidative cracking takes place. On metals, CO_2 reacts with carbon via the reverse Boudouard reaction, whilst on oxides it interacts with hydrogen (the reverse water gas conversion).

On zeolitic catalysts, the oxidative dehydrogenation of propane in the presence of CO_2 takes place at lower temperatures and is directed towards aromatisation.

$$2C_3H_8 + 2CO_2 = C_6H_6 + 2H_2O + 3H_2 + 2CO$$

The interaction of propane with CO_2 on the Zn-HZSM-5 catalyst (10% of H atoms replaced by Zn) has been investigated.[214,215] It was observed that CO_2 greatly increases the conversion of C_3H_8, suppressing the formation of coke. The yield of CO exceeds the conversion of CO_2, which indicates the partial formation of CO from propane via coke. At 550 °C, the maximum degree of conversion of C_3H_8 was 68.4%, whilst that of CO_2 was 13.1%. A mixture of C_1 and C_4 hydrocarbons as well as aromatic hydrocarbons is also formed with a selectivity in the formation of the aromatic hydrocarbons of 50.8%. The first reaction stage is the dehydrogenation of propane, which is initially faster in the absence of CO_2, but the deactivation in the presenc e of CO_2 is very slow. This indicates a considerable role for the Boudouard reaction.

Among the zeolites investigated, the highest activity in the oxidative aromatisation of propane in the presence of CO_2 was shown by Zn-ZSM-5. On H-ZSM-5 and Na-ZSM-5, the yield of aromatic hydrocarbons from C_3H_8 in the presence of CO_2 was somewhat higher than in its absence, whilst on Pt-ZSM-5 it was lower. This can be explained by the higher cracking capacity of platinum in relation to propane. In the reaction involving the formation of synthesis gas, the zeolitic catalysts can be arranged in the following activity series: Pt > Zn > Ga > H-ZSM-5.[216]

We have already mentioned studies in which the influence of CO_2 on the reactions of hydrocarbons on zeolites was investigated. it may be that in these studies too the positive effects of CO_2 can be accounted for by its oxidising properties, for example by its interaction with the coke formed.

3. Interaction with n-butane

The conversion of n-butane by reaction with CO_2 also proceeds on manganese-containing oxide catalysts.[204,209] At 630-650 °C and for the ratio $n\text{-}C_4H_{10}:CO_2 = 1-1.2$ on the $Cr-Mn-La-V-O/SiO_2$ catalyst, the degree of conversion of n-butane reached 81%-84%, whilst the selectivity for the formation of C_2-C_4 alkenes reached 76%-78%. Oxidative cracking predominates over oxidative dehydrogenation: more C_2H_4 is formed than C_3H_6 and the amount of the latter is greater than that of C_4H_8. The selectivity with respect to synthesis gas reached 22%-24%, CO and H_2 being obtained in approximately equal amounts, in contrast to the reaction of CO_2 with ethane and propane.

Consequently, the simple catalytic or noncatalytic dehydrogenation

$$C_4H_{10} = C_4H_8 + H_2$$

and the oxidative dehydrogenation

$$C_4H_{10} + CO_2 = C_4H_8 + CO + H_2O$$

take place to only a limited extent. The principal reaction path is oxidative cracking with formation of alkenes and synthesis gas:

$$C_4H_{10} + CO_2 = 2C_2H_4 + CO + H_2O,$$

$$C_4H_{10} + CO_2 = C_3H_6 + 2CO + 2H_2,$$

$$C_4H_{10} + CO_2 = C_2H_4 + CH_4 + 2CO + H_2.$$

Direct cracking

$$C_4H_{10} \rightarrow C_3H_6 + CH_4,$$

apparently also makes a considerable contribution, which is indicated by the high CO_2 content in the final gas. However, it is not clear why this process proceeds to a very limited extent in the absence of CO_2.

It is of interest that the MnO/SiO_2 catalyst, which contains no vanadium and has more basic properties, exhibits a higher selectivity in relation to dehydrogenation. It may be that, as in the case of C_2-C_3 hydrocarbons (see above), oxidative dehydrogenation of n-butane with the aid of CO_2 proceeds via the formation of intermediate carbonates, while oxidative cracking (or simply cracking) takes place with participation of more reduced centres.

4. Interaction with isobutane

The dehydrogenation of isobutane with participation of carbon dioxide can be described by the equation

$$\text{iso-}C_4H_{10} + CO_2 = \text{iso-}C_4H_8 + CO + H_2O, \quad \Delta H = 195.4 \text{ kJ mol}^{-1}. \tag{39}$$

In the absence of the catalyst, the degree of conversion of isobutane in a mixture with CO_2 (or N_2) to isobutene at 665 °C is 19%; under these conditions, CO_2 does not react. In the presence of the $K-Cr-Mn-O/SiO_2$ catalyst at 670 °C, the degree of conversion of iso-C_4H_{10} is 35%–36%, whilst that of CO_2 is 5.8%; on the $K-Cr-Mn-O/Al_2O_3$ catalyst, the degree of conversion of iso-C_4H_{10} increases to 50% and that of CO_2 increases to 9%–10%; on $Cr-Mn-O/Al_2O_3$ (in the absence of potassium), the degree of conversion of iso-C_4H_{10} reaches 61%–66% and that of CO_2 reaches 20%–29.5%.[204, 209, 217] The selectivity with respect to the main product (iso-C_4H_8) on the last catalyst is 78%–81%. CO and H_2 are also formed in equal amounts. This distinguishes this process from those involving ethane and propane, where $CO : H_2 = 7$.

Preliminary treatment of the catalyst with hydrogen does not lead in this case, in contrast to the reactions of ethane and propane, to a decrease in the yield of the alkene, whilst preliminary treatment with CO_2 reduces both the yield and the selectivity. The selectivity in the cleavage of isobutane into propene and methane increases under these conditions. As the reaction proceeds, the selectivity and activity of the catalyst increase similarly: this also distinguishes the above process from reactions involving ethane and propane, where the selectivity with respect to the alkene increases as the surface is oxidised.

The reaction of CO_2 with isobutane has also been investigated under the conditions of their separate interaction with the catalyst. When isobutane came into contact with the surface at 670 °C in the absence of CO_2, iso-C_4H_8, CO, H_2, C_3H_6, and CH_4 were obtained. The rate of formation of CO in such interaction of iso-C_4H_{10} with the surface is significantly lower (by a factor of 12–30) than the rate of its formation under stationary conditions. Calculations showed that under stationary conditions only 3%–4% of CO is the result of the regeneration of the coke-saturated catalyst by the reaction

$$C + CO_2 \rightarrow 2\ CO.$$

However, this reaction ensures the activity of the catalyst for a long time.

The study of the oxidation of hydrogen by carbon dioxide on this catalyst showed that the rate of formation of CO under these conditions is comparable to the rate of its formation under stationary conditions. Consequently, the main path leading to the formation of CO under stationary conditions is reaction (3).

The rate of formation of CO in the interaction of CO_2 with the reduced catalyst is also appreciably lower (by a factor of 10 in the case of the $Cr-Mn-O/SiO_2$ catalyst) than the rate of formation of CO under stationary conditions at 670 °C [reaction (39)]. It is observed preferentially at temperatures above 700 °C.

Consequently, at 600–700 °C the interaction of isobutane with CO_2 represents mainly the sum of two consecutive reactions:

$$\text{iso-}C_4H_{10} \rightarrow \text{iso-}C_4H_8 + H_2, \qquad H_2 + CO_2 \rightarrow CO + H_2O. \tag{40}$$

The overall mechanism of the reactions of iso-C_4H_{10} on the Mn–Cr catalyst can be represented by Scheme 4.

Scheme 4

$$\text{iso-}C_4H_{10} + Cr^{3+}O^{2-} \xrightarrow{a} \text{iso-}C_4H_9 + Cr^{2+}OH^-,$$

$$\text{iso-}C_4H_9 + Cr^{3+}O^{2-} \xrightarrow{b} \text{iso-}C_4H_8 + Cr^{2+}OH^-,$$

$$2Cr^{2+}OH^- \xrightarrow{c} Cr^{2+}[\ ] + Cr^{2+}O^{2-} + H_2O,$$

$$MnO + CO_2 \overset{d}{\rightleftharpoons} MnCO_3,$$

$$H_2 + MnCO_3 \xrightarrow{e} H_2O + CO + MnO,$$

$$H_2 + Cr^{3+}O^{2-} \xrightarrow{f} H_2O + Cr^{2+}[\ ],$$

$$Cr^{2+}[\ ] + CO_2 \xrightarrow{g} Cr^{3+}O^{2-} + CO.$$

Dehydrogenation (in addition to the thermal dehydrogenation) takes place with participation of the reduced centres, probably chromium ions. The presence of hydrogen in the gas phase shows that oxidative dehydrogenation does not predominate over direct dehydrogenation. H_2 interacts with CO_2 apparently via the $MnCO_3$ carbonate fragments (reactions *d* and *e* in Scheme 4).

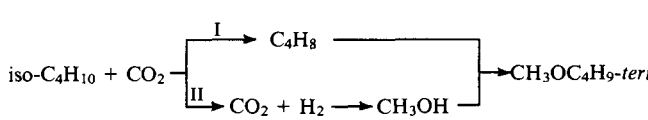
The kinetic equation for the process differs from the equation describing the interaction of ethane and propane with CO_2 and has the form of the Mars–Van Krevelen equation:

$$r_{\text{iso-}C_4H_8} = \frac{k_1 P_{\text{iso-}C_4H_{10}} k_2 P_{CO_2}}{k_1 P_{\text{iso-}C_4H_{10}} + k_2 P_{CO_2}}.$$

This shows that the role of the reduction of the catalyst by the carbon monoxide formed during the reaction is small. The change in the reaction kinetics on passing from C_2H_6 and C_3H_8 to iso-C_4H_{10} is probably caused by the lower energy of the C–H bonds in isobutane, which ensures their cleavage with participation of less oxidised or carbonate centres. In this case, hydrogen should be present in the reaction mixture.

At a high temperature (750–900 °C), the reaction does not proceed via carbonates but via the dissociative adsorption of CO_2 and subsequent oxidative dehydrogenation.

$$\text{iso-}C_4H_{10} + [O] \rightarrow \text{iso-}C_4H_8 + H_2O,$$



$$CO + H_2O \rightleftharpoons CO_2 + H_2.$$

In both cases, the last reaction is the equilibrium conversion of water gas, leading to an equilibrium mixture of H_2, CO, H_2O, and CO_2.

The hydrogen formed in the dehydrogenation of isobutane is not fully oxidised [only half of its participates in the subsequent reduction of CO_2 in accordance with the equilibrium reaction (3)]. This results in the formation of a mixture containing iso-C_4H_8, CO, and H_2 as the main products. The selectivity for the formation of the side products (C_3H_8 and CH_4) is about 10%.

The addition of n-butane to the reaction mixture does not alter the characteristics of the dehydrogenation of isobutane by carbon dioxide.[217]

The simultaneous formation of isobutene and synthesis gas in the reaction of isobutane with CO_2 makes it possible to propose a new process for the preparation of *tert*-butyl methyl ether — the high-octane component of nonethylated petrol.

Reaction I is endothermic (155 kJ mol^{-1}), whilst reaction II is exothermic (92 kJ mol^{-1}). The combination of these reactions makes it posisble to diminish by a factor of 2 the energy consumption in reaction I.

5. Interaction with n-heptane

Studies have shown[194,218] that, on interaction with CO_2 on manganese oxide catalysts, heavy alkanes undergo mainly oxidative cracking. Under stationary conditions, it proceeds without the accumulation of coke fragments and a high degree of conversion of the hydrocarbon is attained. By altering the nature of the hydrocarbon employed and the catalyst, it is possible to direct the process towards the formation of light alkenes, alkanes, and also isomeric paraffinic hydrocarbons.

On $K-Mn-O/Al_2O_3$, $La-Mn-O/Al_2O_3$, and La–Mn/NaY, the reaction takes place at 540–670 °C. Oxidative cracking with formation of H_2, CO, CH_4, C_2H_4, C_3H_6, and C_4H_8 is observed. The La–Mn/NaY catalyst is more active in cracking than $La-Mn-O/Al_2O_3$ and $K-Mn-O/Al_2O_3$. The degree of conversion of n-heptane on this catalyst at 670 °C reaches 100% for a low degree of conversion of CO_2 (4.2%). On $La-Mn-O/Al_2O_3$, the overall degree of conversion of n-heptane is lower (86.4% at 670 °C), but that of CO_2 is higher (30.2%). In addition, a low yield of H_2 ($CO:H_2 = 10$) was observed on La–Mn/NaY, whilst on $La-Mn-O/Al_2O_3$ and $K-Mn-O/Al_2O_3$ carbon monoxide and H_2 were formed in equal amounts. It follows from the foregoing that $La-Mn-O/Al_2O_3$ and $K-Mn-O/Al_2O_3$ are more active in the activation of CO_2.

The reduction of CO_2 with the formation of CO probably proceeds via several paths: as a result of the oxidation of H_2 (a cracking product) by carbon dioxide and via the gasification of the surface carbon fragments.

Experiments have been carried out on the reoxidation of the $La-Mn-O/Al_2O_3$ catalyst by treating it with CO_2 after the stationary oxidative cracking process. The rate of reoxidation at 620–670 °C is constant in time, i.e. the saturation of the surface is not observed. The interaction of H_2 with CO_2 has also been investigated. The rate of formation of CO in this reaction was somewhat lower than in the conversion of heptane by reaction with CO_2.

The rate of formation of CO under stationary conditions at 670 °C is 14 times higher than in the reoxidation of the catalyst. This shows tht the oxidation of the catalyst

$$MnO + CO \rightleftharpoons MnCO_3,$$

$$3MnCO_3 \rightleftharpoons Mn_3O_4 + CO + CO_2$$

is not the main path leading to the formation of CO under stationary conditions. Reaction (3) does not proceed via the direct alternate oxidation-reduction

$$H_2 + [O] \rightarrow [\ ] + H_2O,$$

$$[\ ] + CO_2 \rightarrow CO + [O],$$

but via the 'associative' interaction of H_2 with the surface carbonates:

$$H_2 + MnCO_3 \rightarrow CO + H_2O + MnO.$$

In the stationary state, an intermediate carbonate structure participates in the process.

Another source of CO is reaction (40), i.e. the interaction of CO_2 with carbon deposits. This ensures the selective oxidative (carbonic acid) cracking and a stable activity of the $La-Mn-O/Al_2O_3$ and $K-Mn-O/Al_2O_3$ catalysts without the accumulation of coke fragments on the surfaces.

The low rate of formation of CO on the La–Mn/NaY catalyst is apparently associated with the formation of stable carbonates. Presumably decationated zeolites modified with manganese should serve as a base for an effective catalyst for the cracking process in the presence of CO_2.

Thus the oxidative cracking of n-heptane with the aid of CO_2 may be described by the following equations:

$$C_7H_{16} \rightarrow C_4H_8 + C_3H_6 + H_2,$$

$$C_7H_{16} \rightarrow 3C_2H_4 + C^* + 2H_2,$$

$$H_2 + CO_2 \rightleftharpoons CO + H_2O,$$

$$C^* + CO_2 \rightleftharpoons 2CO.$$

Summarising the results of the study of the oxidative interaction of C_4-C_7 alkanes with CO_2, we may note that experiments have demonstrated the possibility of the simultaneous formation of alkenes and synthesis gas. In contrast to the familiar cracking and dehydrogenation processes, this path makes it possible to employ CO_2 as the starting material.

Nickel-containing compounds are known to be deposited from petroleum during catalytic cracking on zeolitic catalysts and to poison the latter as a consequence of the increased coke formation. CO_2 has been used to passivate this process.[219] The $C_7H_{16} + CO_2$ reaction has been investigated on the $Ni-La-8\%\ MnO/Al_2O_3$ catalysts containing between 0.5 mass% and 2.5 mass% of lanthanum and nickel. With increase in the nickel content, the degrees of conversion of C_7H_{16} and CO_2 at 670 °C increase. It is especially important that the presence of CO_2 in the mixture ensures the maintenance of the stable activity of the catalyst, whereas in the traditional catalytic cracking an increase in the CO_2 content entails an increase in coke formation and a decrease in the catalyst activity. If CO_2 is replaced in the reaction mixture by N_2, the overall activity falls and the yield of C_4 hydrocarbons diminishes, but that of C_2 hydrocarbons increases, i.e. the undesired extensive cracking takes place. In the absence of manganese, nickel is reduced to the metallic state even in the presence of CO_2, which also leads to deactivation. Evidently manganese promotes the binding and activation of CO_2 in accordance with the scheme

$$MnO + CO_2 \rightleftharpoons MnCO_3,$$

$$MnCO_3 + Ni \rightarrow MnO + NiO + CO.$$

In conclusion of this section about the reactions of hydrocarbons in the presence of CO_2, we may note certain general features. The mechanisms of the activating effect of CO_2 on the reactions of C_1-C_3 and C_4-C_7 hydrocarbons are different. In the case of the lower alkanes, CO_2 enters into an oxidation–reduction interaction with the catalyst, after which the surface O^{2-} ions oxidise the hydrocarbon. The reaction takes place at a high temperature (750–850 °C). The decrease in temperature to 550–650 °C in the oxidative aromatisation of propane on zeolitic catalysts can be accounted for by the greater role of the reverse Boudouard reaction [reaction (40)] in this process.

In the conversion of C_4 hydrocarbons (at 650–700 °C), the first stage is their direct dehydrogenation, after which hydrogen is oxidised by reaction with CO_3^{2-}. (We examined the accelerating effect of hydrogen on the reactions with participation of CO_2 in Section III).

The principal path in the interaction of higher hydrocarbons with CO_2 (at 650–750 °C) is oxidative cracking, the reverse Boudouard reaction [reaction (40)], i.e. the interaction of C* with CO_2, playing a major role in the reaction mechanism. The activation of carbon dioxide and not of the hydrocarbons is rate-limiting. The hydrogen evolved accelerates the Boudouard reaction.

Manganese-containing catalysts can be used to convert both groups of hydrocarbons. This can be explained, firstly, by the fact that manganese oxides gives rise to moderately stable carbonates, which are capable of decomposing under reaction conditions. Secondly, manganese affords oxides capable of being readily oxidised and reduced under the reaction conditions.

When alkaline (Na, K) oxides are added, the stability of these carbonates increases, while the addition of acid oxides (Mo, V) diminishes the stability. Alkaline oxides shift the process towards oxidative dehydrogenation, whilst acid ones shift it towards oxidative cracking. The surface carbonates participate in the oxidation-reduction reactions with the hydrocarbon or hydrogen.

VI. Oxidation reactions of carbon dioxide with other compounds

Transition metal and lanthanide oxides also catalyse the oxidative reaction of CO_2 with other organic compounds.

1. Interaction of carbon dioxide with the carbon fragments in cracking catalysts

The regeneration of the coke-saturated cracking catalyst is known to involve combustion processes entailing the development of high temperatures, which reduce the process efficiency. The use of CO_2 instead of O_2 for the regeneration makes it possible, in principle, to increase the process efficiency.[220-222]

In the interaction of the coke-saturated zeolite-containing KNTsU-B catalyst with CO_2 at 680 °C and a space velocity of the supply of CO_2 of 900 h^{-1}, the degree of conversion of CO_2 does not exceed 1%. The rate of regeneration of the catalyst modified by manganese acetate (5% Mn) after saturation with coke exceeds by a factor of 15 the rate of regeneration of the unmodified catalyst under similar conditions. Apart from CO, methane is also formed, the rate of its formation being greater by a factor of 1.3 than the rate of formation of CO. Hydrogen is detected only in trace amounts.

When the coke-saturated catalyst is modified with chromium, an increase in the rate of formation of CO is also observed. In this case, $CO:CH_4 = 4-5$. On regeneration of the coke-saturated catalyst modified by lanthanum carbonate with CO_2, the formation of CO has already begun at 400 °C.

The modifying additives can be introduced into the catalyst during its preparation, before its employment in cracking and its regeneration. When 5% of lanthanum is introduced into the zeolite-containing catalyst Tseokar-2, the regeneration with the aid of CO_2 begins at 400 °C. Under programmed heating conditions, the thermogram showed two maxima corresponding to the formation of CO ($E = 138$ and 226 kJ mol^{-1}) and a maximum corresponding to the evolution of CH_4 ($E =$ 201 kJ mol^{-1}). H_2 is also evolved during the heating process.

The stoichiometric equations for the formation of CO, H_2, and CH_4 can be expressed in the form

$$CH_x + CO_2 \rightarrow 2\ CO + \tfrac{1}{2}xH_2,$$

$$2CH_x \rightarrow CH_4 + C + (x - 2)H_2.$$

For $x = 2$, the overall equation assumes the following form:

$$2CH_2 + CO_2 \rightarrow CH_4 + 2CO,$$

whence it follows that methanation and the Boudouard reaction take place in the oxidation of CH_x fragments by CO_2.

Thus the effective acceptance of CO_2 by manganese or lanthanum oxides ensures a high rate of oxidation of the surface CH_x fragments.

The processing of heavy petroleums is greatly hindered by the presence of heavy metals (Ni and V) in them, mainly in the form of porphyrins, which are deposited on the surfaces of the catalyst. These metals greatly increase the poisoning and coke formation. In this case too, the addition of manganese proved useful. In the presence of manganese, nickel appreciably accelerates the regeneration of the catalyst by CO_2.[219] On the other hand, the oxidation of vanadium by carbon dioxide is retarded in the presence of MnO_x or La_2O. The positive effect of CO_2 reduces in this case to the stabilisation of the surface as a result of its being blocked by the lanthanum and manganese carbonate fragments, which prevents the deactivation of the catalyst by vanadium.[223]

It is well known that the gasification of coal by CO_2 or H_2O is accelerated by alkaline additives. Tunnels are formed in the layer of carbon beneath the alkalies (K, Na, Li, Ba, and Ca oxides) deposited on it. Evidently here too the carbon formed interacts with the carbonate ions.[224]

2. Interaction with other hydrocarbons

In the absence of a catalyst, ethene does not interact with CO_2 at temperatures below 750 °C. A low degree of conversion of C_2H_4 (up to 12%) is observed at 750-820 °C with formation of CH_4, C_4H_6, C_3H_6, and traces of C_2H_4. Mainly synthesis gas is obtained on the nickel catalyst under these conditions.

$$C_2H_4 + 2CO_2 = 4CO + 2H_2 \qquad (41)$$

Up to 2%-3% of butadiene is also evolved. The degree of conversion of ethene at 750 °C is 65%.

On Ru/Al_2O_3 and $Ru-Co/Al_2O_3$, carbon dioxide interacts with hex-1-ene at a low temperature (100 °C) and a pressure of 10-35 atm.[225] Alkenes, ethers, aldehydes, and ketones have been detected in the products; the degree of conversion has not been reported.

The use of the $Mn-O/SiO_2$ oxide catalyst (see Refs 200, 204, 226, and 227) in the reaction of ethene with CO_2 led to the formation of butadiene and propene. On the 17% $Mn-O/SiO_2$ catalyst at 820 °C, a degree of conversion of C_2H_4 of 22.3% was attained, that of CO_2 was 11.6%, and the selectivity was 25.0% with respect to C_4H_6 and 18.0% with respect to C_3H_6. We may note that the reaction involving oxidative dimerisation with the aid of CO_2, i.e.

$$2C_2H_4 + CO_2 \rightarrow C_4H_6 + CO + H_2O, \quad \Delta H = 243\ kJ\ mol^{-1} \qquad (42)$$

is highly endothermic and thermodynamically unfavourable ($\Delta G > 0$). However, CO, H_2, CH_4, C_3H_6, and C_4H_8 are also formed under the catalytic conditions, so that it is difficult to carry out an exact thermodynamic calculation for these conditions. Treatment of the $Mn-O/SiO_2$ catalyst with carbon dioxide reduces the selectivity with respect to C_4H_6 and C_3H_6, whilst treatment with hydrogen increases it. A different behaviour has been observed with alkanes. The process proceeds on the reduced catalyst.

On Cr_2O_3/SiO_2, the degree of conversion of C_2H_4 at 820 °C was 27.3%, that of CO_2 was 14.8%, and the selectivity was 39.0% with respect to C_4H_6 and 24.2% with respect to C_3H_6.[226] Surface carbonate fragments participate in the process. At low temperatures (400-600 °C), the oxidation of the CH_x fragments by CO_2 takes place in accordance with the scheme

$$CH_x + CO_3^{2-} \rightarrow CH_xO + CO + O^{2-},$$

$$CH_xO \rightarrow CO + \tfrac{1}{2}xH_2.$$

At high temperatures (600-750 °C), carbon monoxide is formed mainly from carbon:

$$CO_3^{2-} + C \rightarrow 2CO + O^{2-}.$$

We may note that the characteristics of the interaction of CO_2 with ethene are not the same as those of its interaction with alkanes. Thus, in the $C_2H_4 + CO_2$ reaction, the addition of the acid oxide WO_3, instead of a basic one, to Mn/SiO_2 increased the degree of conversion of C_2H_4 and the selectivity in the formation of C_3H_6 and C_4H_6.

On the 2% W-17% $Mn-O/SiO_3$ catalyst at 820 °C, a space velocity of 2700 h^{-1}, and for $C_2H_4:CO_2 = 1$, the degree of conversion of C_2H_4 was 30.1%, that of CO_2 was 12.4%, and the selectivity was 33.4% with respect to C_4H_6 and 20% with respect to C_3H_6.

On the 2% W-5.5% $Cr-O/SiO_2$ catalyst, the best parameters for the conversion of C_2H_4 and for the selectivity in the

formation of butadiene were attained; the catalyst was not saturated with coke under the reaction conditions. At 820 °C, the degree of conversion of C_2H_4 was 30.5%, that of CO_2 was 13.7%, and the selectivity was 50.2% with respect to C_4H_6 and 30.6% with respect to C_3H_6; CO, CH_4, C_3H_6, and C_4H_8 were also formed. The degree of conversion of CO_2 was 2–3 times smaller than that of ethene. This is apparently associated with the fact that CO_2 is consumed in the interaction with the coke deposits and the contribution of this reaction is small compared with the target reaction.

During the operation of the 2% W – 5.5% Cr – O/SiO_2 oxide catalyst, the WO_3 and Cr_2O_3 phases are detected in its composition. After the attainment of the stationary state, the WO_3 phase ceases to be detected, while a large proportion of Cr_2O_3 is reduced, which is indicated by the decrease in the intensity of the corresponding band in the spectrum by a factor of 15–20.

The study of the kinetics of the $C_2H_4 + CO_2$ reaction on the Cr – W – O/SiO_2 catalyst showed that the rate of formation of C_4H_6 and C_3H_6 increases with increase in the degree of conversion to 25%, after which it begins to fall. The activating effect of the reaction products, especially CO, is apparently due to the reduction of the surface, which promotes the activation of ethene. Extensive oxidation of the target product is not observed. When no account is taken of the homogeneous pyrolysis of ethene, the rate of accumulation of butadiene is expressed by the following equation according to Mirzabekova and Mamedov:[226]

$$r_{C_4H_6} = \frac{kP^2_{C_2H_4}k_{-r}P_{CO}}{k_rP_{CO_2} + k_{-r}P_{CO}},$$

where k is the reaction rate constant and k_r and k_{-r} are the rate constants for the reoxidation and reduction of the catalysts.

The rate of the overall catalytic conversion of ethene in the mixture with CO_2 into butadiene at 820 °C is greater by a factor of 5–6 than the rate of the thermal pyrolysis.

The rate equation for the accumulation of butadiene differs significantly from the rate equations for the carbonic acid converiso of alkanes (see above). This difference is caused by the nature of the tungsten – chromium catalyst. In contrast to the catalysts for the conversion of alkanes, it exhibits a high Lewis acidity, as a result of which its accepting capacity in relation to CO_2 is reduced and the CO formed during the reaction does not affect quite so much the state of the surface.

The study of the interaction of propene with CO_2 on the Mo – Mn – O/SiO_2 catalyst made it possible to observe the occurrence at 640 °C of partial oxidation with formation of formaldehyde (8% selectivity) and acrolein (32% selectivity) for degrees of conversion of C_3H_6 and CO_2 of 25.0% and 12.0% respectively.[227] Degradative decomposition with formation of products of the radical reactions (C_2H_4 and CH_4) predominates at higher temperatures.

On the K – Cr – Mn – O/SiO_2 catalyst, the process proceeds in the direction of the formation of the synthesis gas in accordance with Eqn (41). This is probably associated with the fact that the intermediates are oxidised to CO on the oxidised catalyst surface.

The possibility of the conversion of ethene into butadiene suggests a new scheme for its preparation from natural gas:

$$CH_4 \rightarrow C_2H_4 \rightarrow C_4H_6.$$

The interaction of toluene with CO_2 on a Pd/γ-Al_2O_3 catalyst promoted by Ce, Y, Sm, and La oxides has been investigated.[228]

$$C_6H_5CH_3 + CO_2 \rightarrow C_6H_6 + 2CO + 2H_2, \quad \Delta H = 209.7 \text{ kJ mol}^{-1}.$$

At 400 °C, the ratio C_6H_6 : CO was 0.41 on Pd(Ce)/γ-Al_2O_3 and 0.83 on Pd/γ-Al_2O_3. Lanthanide oxides retard the activation of the catalyst. When CO_2 is admitted, the catalyst is oxidised.

$$Pd + CO_2 \rightarrow PdO + CO.$$

When toluene is brought into contact with this catalyst, stoichiometric amounts of C_6H_6, CO_2, CH_4, CO, and H_2 with a small content of xylene are formed. The subsequent introduction of CO_2 leads to the appearance of slightly higher amounts of CO, evidently due to the coke formed from toluene. The overall process mechanism is

$$C_6H_5CH_3 \xrightarrow{Pd} [C_6H_5CH:] + H_2 \xrightarrow[CO_2]{PdO} C_6H_6 + CO + Pd(0).$$

The CeO_2 phase in contact with palladium gives rise to the Pd^{2+}/Pd^0 and Ce^{4+}/Ce^{3+} couples, facilitating thereby the oxidation of palladium.

3. Interaction with alcohols

The attempt to combine the dehydrogenation of methanol to formaldehyde with the reduction of carbon dioxide to CO is of considerable interest.

$$CH_3OH + CO_2 \rightarrow CH_2O + CO + H_2O, \quad \Delta H = 204.2 \text{ kJ mol}^{-1}. \tag{43}$$

This makes it possible to employ CO together with the unreacted methanol in the reaction involving carbonylation to methyl formate and the process can be carried out in accordance with a scheme balanced with respect to carbon.

The oxide compositions Mn – O, Mo – Mn – O, Fe – Mn – O, Cr – Mn – O, Cu – Mn – O, and Mo – Cr – Mn – O deposited on SiO_2 have been investigated in the reactions considered.[229] The catalysts without manganese were relatively inactive. The 10% Mn – 5.5% Cr – 5% Mo – O/SiO_2 catalyst showed the highest activity and selectivity at 560–750 °C (space velocity 900–7200 h^{-1}, $CH_3OH : C_2 = 1$). Under stationary conditions, reaction (43) was accompanied also by others:

$$CH_3OH + 2CO_2 \rightarrow 3CO + 2H_2O, \tag{44}$$

$$CH_3OH \rightarrow CH_2O + H_2, \tag{45}$$

$$H_2 + CO_2 \rightarrow CO + H_2O,$$
$$CH_3OH \rightarrow CO + 3H_2. \tag{46}$$

At 650 °C, the degree of conversion of CH_3OH was 30.2%, that of CO_2 was 14.6%, the selectivity with respect to CH_2O was 91%, and the yield of formaldehyde was 27.5%.

Under nonstationary conditions, the reduction of the catalyst by methanol or H_2 lowers the selectivity in the formation of CH_2O. The reoxidation of the catalyst by oxygen increases the selectivity. The reoxidation of the reduced Mn – O/SiO_2 catalyst by carbon dioxide takes place above 700 °C and is accompanied by the formation of CO. Consequently the low activity of the catalyst under stationary conditions is associated with the low rate of its reoxidation. It increases markedly in the case of the binary Cr – Mn, Mo – Mn, and Cu – Mn catalysts At the beginning of operation of the fresh catalyst, a high selectivity with respect to formaldehyde is observed, but, as the reaction proceeds, it falls, probably owing to the reduction of the catalysts by the reaction mixture.

Formaldehyde does not have an inhibiting effect on the conversion of methanol. Under the reaction conditions, it is converted into CO and CO_2 with a low degree of conversion. The rate of reaction is proportional to the CH_3OH pressure and, up to a certain surface coverage, the CO pressure. Subsequently it attains a constant value. The rate of formation of formaldehyde may be expressed by the kinetic equation

$$r_{CH_2O} = r'_{CH_2O} - r''_{CH_2O}$$

$$= \frac{k'P_{CH_3OH}P_{CO_2}}{k_rP_{CO_2} + k_rP_{CO}} - \frac{k''P_{CH_2O}P_{CO_2}}{k_rP_{CO_2} + k_{-r}P_{CO}},$$

where r'_{CH_2O} and r''_{CH_2O} are the rates of formation and decomposition of CH_2O.

The principal stages in the reaction on the Mn–Cr–Mo–O catalyst are presented in Scheme 5 below.[229]

Scheme 5

$$CH_3OH + Cr^{3+}O^{2-} \xrightarrow{a} CH_2O + Cr^{2+} + H_2O,$$

$$MnO + CO_2 \overset{b}{\rightleftharpoons} MnCO_3,$$

$$MnCO_3 + Cr^{2+} \overset{c}{\rightleftharpoons} Cr^{3+}O + MnO + CO,$$

$$CH_2O + Cr^{3+}O \xrightarrow{d} CHOCr^{2+}H,$$

$$CHOCr^{2+}H + Cr^{3+} \xrightarrow{e} CO + 2Cr^{2+}H,$$

$$2Cr^{2+}H \xrightarrow{f} 2Cr^{2+} + H_2.$$

The $Cr^{3+}O$ centres correspond to the Cr_2O_3 phase. The Mo_8O_{23} phase has also proved useful. Both phases have been detected by X-ray diffraction. Thus methanol is dehydrogenated with participation of the oxidised chromium and molybdenum phases, whilst the reduced manganese oxide phase participates in the activation of CO_2.

We may note that the Cr–Mo–Mn–O/SiO_2 catalyst has more acid properties than Cr–Mn–O/SiO_2. The presence of acid centres has been confirmed in a study of the desorption of ammonia. The acid centres apparently activate methanol, whilst the basic centres (MnO) activate CO_2. The reduction of the catalyst increases the rate of the extensive cleavage of CH_2O.

The data on the conversion of methanol in the absence of CO_2 show that a significant amount of formaldehyde is formed via the direct dehydrogenation [reaction (45)], but is obtained mainly via reaction (43). In the absence of the catalyst, the rate of conversion of methanol is insignificant.

The oxidation of methanol to formaldehyde by CO_2 or the $CO_2 + O_2$ mixture may prove convenient compared with the direct dehydrogenation or oxidation with O_2, since it makes it possible to carry out the process via a thermally neutral mechanism.

The interaction of ethanol with CO_2 on manganese oxide catalysts has been investigated. Mainly the same products as in the Lebedev reaction are obtained: thus butadiene is obtained from the alcohol.[230]

$$2\ C_2H_5OH = C_4H_6 + 2\ H_2O + H_2 \qquad (47)$$

For reasons which have not so far been explained, reaction (47) stops after the attainment of a certain limiting yield, which is appreciably lower than the yield allowed by thermodynamics. The use of CO_2 makes it possible to increase the yield of C_4H_6. The reaction was carried out at 500–600 °C and a space velocity of 1000–3600 h^{-1} in the presence of the Cu–Mn–O/Al_2O_3 catalyst. C_4H_6 and C_4H_8 predominate in the ethanol conversion products. C_2H_4, CH_4, and H_2 have also been obtained. When a $C_2H_5OH + N_2$ mixture is used at 550 °C, the selectivity in the formation of C_4H_6 is 43% for a degree of conversion of C_2H_5OH of 52%. The replacement of nitrogen by CO_2 increases the degree of conversion of C_2H_5OH to 63% and the selectivity with respect to C_4H_6 to 60%, the degree of conversion of CO_2 amounting to 16% under these conditions. The ratio $CO : H_2$ in the contact gas is close to unity, while the concentration of butadiene exceeds by a factor of 2–3 the concentrations of CO and H_2.

The overall stoichiometric equation can be expressed in the form

$$4\,C_2H_5OH + CO_2 \rightarrow 2\,C_4H_6 + CO + H_2 + 5\,H_2O. \qquad (48)$$

Bearing in mind that the generally accepted mechanism[230] of the Lebedev reaction [reaction (41)] presupposes the combination of the dehydrogenation, hydrogenation, condensation, and hydration stages, CO_2 probably prevents the extensive hydrogenation of the aldol condensation products by reacting with the hydrogen formed as an intermediate, increasing thereby the selectivity in the formation of C_4H_6.

The effectiveness of CO_2 as an oxidant in the presence of manganese oxide catalysts both in the conversion of methane[194] and in the condensation of ethanol to C_4H_6 may be important for the alternative synthesis of C_4H_6 from natural gas and CO_2 in accordance with the scheme

$$C_4H_6 + CO_2 \longrightarrow CO + H_2 \longrightarrow C_2H_5OH$$
$$\uparrow \qquad\qquad\qquad\qquad \downarrow$$
$$\longleftarrow C_4H_6 + CO + H_2$$

It follows from the foregoing that carbon dioxide may be used as an oxidant not only for alkanes but also for other organic substances, including alkenes and alcohols. Some of these reactions are of potential practical importance, but the number of investigations of this kind is so far small.

VII. Conclusion

The data presented show, contrary to widespread ideas, that carbon dioxide is capable of entering into a wide variety of reactions with other compounds. The most important classes of reactions involving CO_2 are as follows: (1) the incorporation of CO_2 in the C–C, C–H, and C–N bonds with formation of carboxy- and carbonyl compounds; (2) the oxidation of other compounds by CO_2. The reactions of the first class occur at low temperatures and are catalysed by homogeneous transition metal complexes, while those of the second class are as a rule carried out at a high temperature and are accelerated by metals or transition metal oxides.

Despite the numerous studies carried out, high yields of useful products and appreciable reaction rates have so far been achieved in only a few of them. This is associated with various thermodynamic and kinetic difficulties. One of the main causes of this for reactions of the first class is that the energy of the bond between CO_2 and the transition metal atom in the complex is low (20–60 kJ mol^{-1}) and there is insufficient time for the CO_2 molecule in the coordination sphere to react with another molecule: its lifetime is insufficient. The CO_2 molecule has a filled electron shell and its reactivity is therefore low. Hence it is necessary to increase its reactivity by using another, more effective catalyst or by introducing another ligand. Incidentally, this problem is outside the scope of the present review.

As regards reactions of the second class, in most cases thermodynamic limitations prohibit their occurrence at a low temperature, whilst at a high temperature not every catalyst is able to operate: problems of mechanical strength, resistance to sintering, etc. arise. The most important task is therefore to seek new reactions which do not occur at quite such high temperatures but are promising as regards their economic and environmental aspects and also to seek new catalysts. This requires in its turn the elucidation of the rules governing the selection of the catalysts and the kinetics and mechanisms of the reactions, in particular the paths in the surface reactions, with the aid of physical methods in situ. The application of the latter is difficult at high temepratures, although isolated examples exist, as shown above.

Numerous catalytic and noncatalytic reactions of the first class are known, in which carboxylic acids, esters, carbamates, etc. are formed. However, at present one can only speak of two processes achieved on a large scale — the syntheses of urea and salicylic acid. This does not of course mean that such processes will not develop extensivley in the future.

However, nowadays reactions of the second class — the employment of carbon dioxide as an oxidant — are more promising both from the standpoint of the use of CO_2 as the starting material and from the standpoint of the solution of the environmental problem of the utilisation of CO_2 from gaseous waste. The largest scale process in which CO_2 is used as an

oxidant is the synthesis of methanol. It has been discovered recently that the compound reacting with hydrogen is not CO, as thought previously, but the CO_2 obtained from CO. It would be attractive to synthesise CH_3OH directly by the $CO_2 + H_2$ reaction, although from the thermodynamic standpoint it is preferable to obtain dimethyl ether rather than methanol.[112,113] The synthesis of higher alcohols from CO_2 and H_2 also has apparently a number of advantages compared with the synthesis from CO and H_2.[85,231]

For so long as cheap methods for the preparation of hydrogen have not been found, the reactions of CO_2 with a cheap starting material — hydrocarbons and other organic compounds — are preferable. Such reactions can lead to large scale syntheses of C_2H_4, C_3H_6, C_4H_6, and CH_2O and also would make it possible to devise an alternative method of preparation of the $CO + H_2$ synthesis gas.

The catalytic reactions involving the reduction of C_1-C_7 hydrocarbons and C_1-C_2 alcohols in their interaction with CO_2 were examined above. A disadvantage of the highly active metallic catalysts (Ni, Co, and Fe) is their rapid poisoning by coke. Among the catalysts investigated, the manganese oxide systems proved to be the most effective. There are still many obscure questions concerning both the mechanism of the action of manganese and the kinetics of the above processes.

An essential condition for the correct selection of the catalyst is the selection of systems capable of accepting and activating CO_2. The acid nature of CO_2 necessitate the employment of a catalytic system with basic properties. However, alkali and alkaline earth metals, which form stable carbonates, are ineffective. Moderately strong bases forming carbonates with reduction of CO_2 are needed. Such requriements are met by manganese oxide and apparently certain lanthanide oxides. Their acid and oxidation-reduction properties may be altered by adding other oxides.

Abstract. The experimental and theoretical studies on the structure and properties of the simple stable proton hydrate are surveyed. It is shown that the hydrate is the ion $(H_2O\cdots H\cdots OH_2)^+$. The mechanism of the generation of the continuous absorption observed in the IR spectra of solutions of acids and strong bases is examined. It has been found that a common feature of the structures of all stable proton solvates — the ions $(A\cdots H\cdots A)^{\pm}$ — is the presence in the latter of a symmetrical hydrogen bridge, the properties of which hardly depend on the nature of the ligand A. The constancy of the parameters of the hydrogen bridge provided a basis for the creation of a unique quantitative theory of the catalytic action of acids and bases. The bibliography includes 103 references.

I. Introduction

The physicochemical and catalytic properties of solutions of acids are determined mainly by the presence in the latter of protons, which appear on dissociation of the acid. In solution the protons form stable solvates, the structure and principal properties of which do not change on further solvation.[1] The simplest stable proton solvates actually participate in the majority of the processes occurring in solutions of acids. Special mention should be made of the fact that they play a primary role in homogeneous acid catalysis. In the chemical reactions of organic and inorganic compounds, stable proton solvates act as reactants and ionising agents, forming various intermediate complexes. Thus they participate in the equilibrium and nonequilibrium stages of the acid-catalytic process.

The simplest stable proton solvate is the stable chemical species formed on interaction of the dissociated proton with a specific number of solvent molecules. The properties and structure of the 'excess' solvent molecules solvating it hardly differ from those of the molecules of the pure solvent (the 'free' molecules). The desolvation of the simplest stable proton solvate leads to a rearrangement of its structure and of the system of its chemical bonds, which is manifested by a marked alteration of its properties.

II. The origin of the hypothesis that the H_3O^+ ion is the simplest stable proton hydrate

The problem of the determination of the stoichiometric compositions and structures of the simplest stable proton solvates in solutions arose long before the appearance of the physical methods which make it possible to achieve this. As long ago as the past century it was known that, when salts and especially acids are dissolved in water, heat is evolved, indicating strong binding of the solute to water. In 1886, Arrhenius and van't Hoff showed that many salts and acids decompose into ions in an aqueous medium.[1,2] Hence it was possible to conclude that the high heats of solution of acids in water are due to the formation of stable proton hydrates.

On the basis of the above considerations and also data on the kinetics of esterification in aqueous alcoholic systems, Hantzch and Caldwell[3] and Goldschmidt and Ulby[4] postulated as early as 1907 that the dissociation of an acid in water results in the formation of the hydroxonium ion H_3O^+. The firm establishment of this view was in many respects promoted by the proton theory of acids established independently by Brønsted[5] and Lowry.[6] According to this theory, the interaction of an acid and water takes place as follows:

$$HA + H_2O \rightleftharpoons H_3O^+ + A^- .$$

At that time, there were no data whatsoever indicating the simultaneous addition of several molecules to the proton. This was also the reason why the vast majority of investigators had no doubt that the simplest proton hydrate was always the hydroxonium ion.

The concept of the H_3O^+ ion, which existed for decades, became generally accepted and the appearance in the literature of alternative hypotheses was entirely ignored. An extremely instructive situation arose as a result of this. In the 1950s, it was already possible to identify proton hydrates with the aid of physical methods and to estimate their geometrical parameters. Nevertheless, the efforts of all investigators were directed not to the establishment of the composition and structure of the simplest stable proton hydrate but to the search for H_3O^+ in the solid and liquid phases. Experimenters therefore made a special selection of the conditions under which only the hydroxonium ion could be formed (naturally the appearance of any other proton hydrates was impossible under these circumstances). Such conditions are fulfilled when there is not more than one water molecule for each dissociated proton.

III. The hydroxonium ion in the solid phase

The above approach was used in studies designed to detect and identify the H_3O^+ ion in the solid phase with the aid of resonance and diffraction methods. This made it possible to obtain data on its structure and properties. The first hypothesis of the existence of an ion with three equivalent O–H bonds was put forward in 1924 on the basis of the results of crystallographic studies on perchloric acid monohydrate and ammonium perchlorate, which demonstrated that these substances are fully isomorphous.[7] The structure of the hydroxonium ion in the solid phase (in crystalline strong acid hydrates) was established a quarter of a century later, after the NMR method had become available. It was shown that[8,9] the H_3O^+ ion in the crystalline monohydrates of perchloric, nitric, and sulfuric acids is a pyramid with three O–H bonds 0.98–1.02 Å long and apical angles of ~115° (Fig. 1*a*).

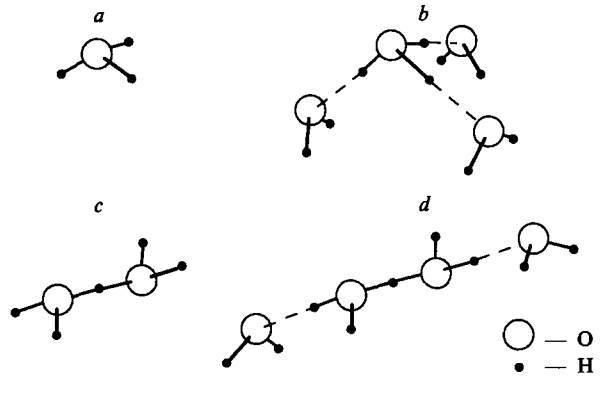

Figure 1. The structures of proton hydrates: (*a*) the hydroxonium ion H_3O^+; (*b*) the hydroxonium ion trihydrate $H_9O_4^+$; (*c*) the proton dihydrate $H_5O_2^+$; (*d*) the proton tetrahydrate $H_9O_4^+$.

The vibrational frequencies of the H_3O^+ ion in the crystalline monohydrates of hydrogen halides and also of nitric, perchloric, and sulfuric acids were measured by IR spectroscopy.[10–12] The frequencies for different crystals, assigned to the vibrations of the hydroxonium ion, differ significantly. The scatter of the deformation and stretching vibrational frequencies can reach several tens or hundreds of reciprocal centimetres respectively. Such a considerable difference between the frequencies does not conflict with the theory of vibrations because the influence on the H_3O^+ ion of the surrounding anions is different in different systems.[13] In individual cases, the influence of the anion is so strong that the hydroxonium ion loses its initial C_{3v} symmetry.

Evidently the distortion of the geometry of the H_3O^+ ion under the influence of the surrounding anions is smaller the lower the charge density on the latter, i.e. the larger their ionic radii. The frequencies observed in the $H_3O^+ \cdot ClO_4^-$ crystal (3220, 2820, 1670, and 1020 cm^{-1}), in which the charge density on the ClO_4^- anion and hence the distortion of the structure of the hydroxonium ion should be smallest, can therefore be most legitimately adopted as the vibrational frequencies of the H_3O^+ ion unperturbed by anions.[14] By analogy with the isoelectronic ammonia molecule and other molecules of the type XH_3, these vibrations were interpreted as follows:[10] $\nu_1 = 2820\ cm^{-1}$, $\nu_2 = 1020\ cm^{-1}$, $\nu_3 = 3220\ cm^{-1}$, and $\nu_4 = 1670\ cm^{-1}$.

Among the numerous studies on the Raman spectra of the hydroxonium ion in the solid state, mention should be made of the communications[15,16] in which the Raman spectra of the $H_3O^+ \cdot SbCl_4^-$, $H_3O^+ \cdot Cl^-$, and $H_3O^+ \cdot Br^-$ were published. The frequencies of the fundamental vibrations of the H_3O^+ ions in these crystals had the following values respectively: 3509, 3463, 1604, and 1095 cm^{-1}; 2900, 2700, 2570, 1605, and 970 cm^{-1}; 2895, 2630, 2525, 1650, 1615, and 970 cm^{-1}.

Since the $SbCl_4^-$ anion has the largest radius, the spectrum of the H_3O^+ ion in the $H_3O^+ \cdot SbCl_4^-$ crystal is closest to that of the unperturbed symmetrical hydroxonium ion. With decrease in the radius of the anion, the splitting of the second (2700 and 2570 cm^{-1}) and then also the third (1650 and 1615 cm^{-1}) vibrational frequencies of the H_3O^+ ion, associated with the loss of the C_{3v} symmetry by the latter, is observed. The occurrence of such splitting indicates unambiguously that, in frequency terms, the second and third vibrations of the unperturbed H_3O^+ ion (3463 and 1604 cm^{-1} for the $H_3O^+ \cdot SbCl_4^-$ crystal) are degenerate stretching (ν_3) and deformation (ν_4) vibrations respectively. This assignment agrees fully with results of measurements of the degree of depolarisation of the lines considered.[15,16]

Thus the interpretation of the vibrations of the H_3O^+ ion based on the Raman spectra is better founded that the assignment based solely on the isoelectronic nature of the H_3O^+ ion and the NH_3 molecule. In contrast to the free ammonia molecule,[17] the highest-frequency vibration of the hydroxonium ion proved to be the symmetrical stretching vibration (ν_1) and not the degenerate stretching vibration (ν_3). From the standpoint of the theory of vibrations, such inversion of the frequencies is possible. The ratio of the ν_1 and ν_3 frequencies depends on the angle between the X–H bonds and on the force constant for their interaction.[18]

Analysis of the literature data shows that towards the 1980s the structures and spectra of proton hydrates had been investigated in detail only in those cases where not more than one water molecule corresponded to each acid proton, i.e. when only the H_3O^+ ion could be formed in the system. The question of the composition and structure of the simplest stable proton hydrate in systems with a stoichiometric water : proton ratio greater than 1 : 1 was not considered at all. Investigators assumed that the simplest stable proton hydrate is always the hydroxonium ion even in the presence of an excess of water.

IV. The hydroxonium ion in the liquid phase

It is impossible to obtain quite such detailed data on the structure of the H_3O^+ ion in solution as in the solid phase. In the study of the structures of the molecular formations in a liquid, the X-ray and neutron diffraction methods as well as the NMR method yield little information (owing to the thermal motion of the molecules and ions). The conclusions reached concerning the structure of the simplest proton hydrate in aqueous solutions of acids were therefore based solely on the study of their IR spectra.

Three absorption bands with maxima near 2900, 1750, and 1205 cm^{-1} (2170, 1400, and 960 cm^{-1} in the case of the deuterio-analogues) have been recorded in the IR spectra of aqueous solutions of HCl, HBr, HNO_3, $HClO_4$, and H_2SO_4.[19–21] The observed bands were located near those of the H_3O^+ ion in the

solid phase. They were therefore assigned to the vibrations of the hydroxonium ion without additional studies. Here no account was taken of the fact that the vibrations of this ion, which according to the theory should be active simultaneously in the IR and Raman spectra,[18] were detected only in absorption spectra. All attempts to record hydroxonium lines in the Raman spectra of the above aqueous solutions were unsuccessful.[12,22]

However, on passing to liquid systems in which only the hydroxonium ion may be formed (with the ratio water : acid = 1 : 1) the picture changes sharply. Thus the Raman spectrum of a solution of the equimolar $H_2O-HSbCl_4$ mixture in dichloroethene exhibits all four lines of the H_3O^+ ion: 3560 (ν_1), 3510 (ν_3), 1600 (ν_4), and 1095 cm^{-1} (ν_2).[23] The reliability of the assignment of the observed lines to the corresponding vibrations of the H_3O^+ ion has been confirmed, as in the spectra of the crystalline monohydrates (see above), by the splitting of the degenerate vibrational frequencies (3510 and 1600 cm^{-1}) following the replacement of the $SbCl_4^-$ anion by smaller anions (Cl^- and Br^-).

Summarising the foregoing, it must be emphasised that the H_3O^+ ion has been detected only in those solid and liquid systems where only one water molecule corresponded to each acid proton. On the other hand, the conclusion that this ion is present in dilute aqueous solutions of acids clearly conflicted with the theory of vibrational spectra. Nevertheless, the concept of the H_3O^+ ion as the simplest stable proton hydrate in aqueous solutions of acids was not questioned.

Together with the experimental data listed above, the theoretical results conflicting with this idea also remained disregarded. Since the 1930s, the study by Hückel, who showed that the addition of a water molecule to the proton results in the formation of an ion with three equivalent O–H bonds the enthalpy of formation of which is ~170 kcal mol^{-1},[24] has been frequently quoted in the literature. On the other hand, nobody discussed the theoretical study by Huggins,[25] which was carried out at approximately the same time. On the basis of quantum-chemical estimates, the hypothesis was put forward in the latter study that in aqueous solutions of acids the dissociated proton can be strongly hydrated by two water molecules. This results in the formation of the symmetrical ion $H_5O_2^+$, in which the hydrogen bond is significantly shorter (2.55 Å) than in liquid water (Fig. 1*b*). According to Huggins' view, this ion is in fact the principal form of the hydrated proton.

V. The proton dihydrate $H_5O_2^+$

The first experimental results indicating that the simplest stable proton hydrate in aqueous solutions is not the hydroxonium ion were obtained by Eigen.[26,27] He estimated the kinetic diameter of the proton hydrate from measurements of the rate of recombination of the H^+ and OH^- ions in water and found it to be ~9 Å. This is very close to the size of the hydroxonium ion trihydrate $H_9O_4^+$, which has the C_{3v} symmetry like the H_3O^+ ion (Fig. 1*b*). The hypothesis that the simplest stable proton hydrate is the $H_9O_4^+$ ion, put forward on the basis of the above agreement, was confirmed also by certain indirect data. However, more careful measurements of the rate constants for the recombination of the H^+ and OH^- ions showed[28] that in reality they are almost twice as high as the values obtained by Eigen.[27] It followed from these data that the diameter of the proton hydrate should be ~5 Å and not 9 Å.[29] This value of the diameter of the simplest proton hydrate in aqueous solutions does not agree with the size of not only the H_3O^+ ion but also the $H_9O_4^+$ ion. Nevertheless the concept of the $H_9O_4^+$ ion, which was very popular in the 1950s and 1960s, can still be encountered in isolated communications even at the present time.

Since the beginning of the 1960s, experimental data began to appear in the literature from which it followed that in aqueous acid solutions the proton is bound firmly to two water molecules. The formation of the stable proton dihydrate was first established as a result of an analysis of the changes in the IR spectrum of a polymeric film of poly(styrenesulfonic acid) occurring when it is moistened.[30] In aqueous solutions of strong acids, such dihydrates were detected in a study of the kinetics and mechanisms of the hydrolytic reactions of organic compounds.[31] Later their presence in solutions was confirmed by IR spectroscopy.[32] The above data demonstrated incontrovertibly that the simplest stable proton hydrate in aqueous solutions has the composition $[H\cdot 2H_2O]^+$. However, there was no information about its molecular structure in solution, stability, and energetic stability.

Studies on the proton dihydrate in the crystalline phase proved more informative. Thus it followed from crystallographic data that, when a water molecule adds to the H_3O^+ ion, the structure of the entire hydrate undergoes a major rearrangement. This results in the formation of the $H_5O_2^+$ ion with a shortened symmetrical (or quasi-symmetrical) O···H···O bond. On further hydration of this ion, its structure hardly changes and the length of the hydrogen bridge always remains 2.4–2.5 Å.[26]

The IR and Raman spectra of the $H_5O_2^+$ ion in the solid phase have been investigated thoroughly.[33,34] The results obtained by Picotin et al.[33] are presented in Figs 2 and 3. Crystals of $H_5O_2^+\cdot SbCl_6^-$, $H_5O_2^+\cdot GaCl_4^-$, and $H_5O_2^+\cdot GaBr_4^-$, as well as their deuterio-derivatives were chosen as the objects of study. The selection of crystals with large anions ensured the least distortion of the geometry of the $H_5O_2^+$ ion, so that its spectra are fairly close to those of the free ion (Figs 2 and 3). Analysis of the vibrational frequencies of the initial and deuteriated crystals showed that only the vibrations of the proton dihydrates are manifested in the region above 500 cm^{-1}. We may note that the

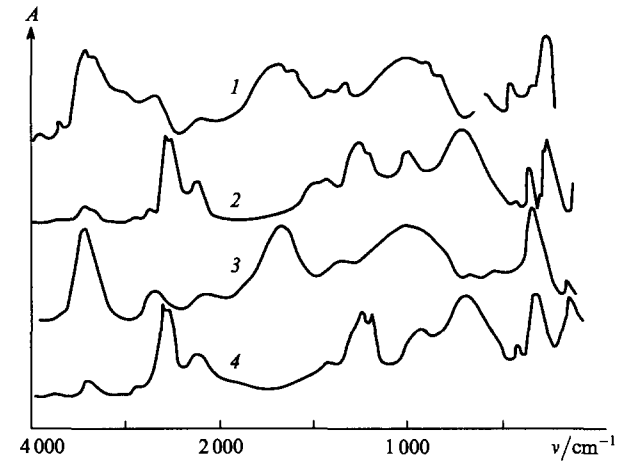

Figure 2. IR spectra of the crystals of $H_5O_2^+\cdot SbCl_6^-$ (curve *1*), $D_5O_2^+\cdot SbCl_6^-$ (curve *2*), $H_5O_2^+\cdot GaBr_4^-$ (curve *3*), and $D_5O_2^+\cdot GaBr_4^-$ (curve *4*) according to the data of Picotin et al.[33]

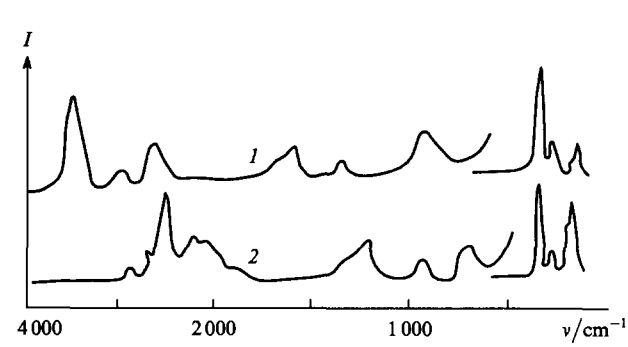

Figure 3. Raman spectra of the crystals of $H_5O_2^+\cdot SbCl_6^-$ (curve *1*) and $D_5O_2^+\cdot SbCl_6^-$ (curve *2*) according to the data of Picotin et al.[33]

IR spectrum of the $H_5O_2^+$ ion (Fig. 2) contains significantly more components than the Raman spectrum (Fig. 3). However, the marked overlap of the bands precludes the determination of not only their positions but also their total number.

The spectrum of the $H_5O_2^+$ ion has a much more elaborate structure and is better resolved when it is recorded by the inelastic neutron scattering method. Such a spectrum (Fig. 4) has in fact been obtained[35] for the ionic crystal of $(H_5O_2^+)_3(PW_{12}O_{40}^{3-})$. In the frequency range 350 – 1800 cm^{-1}, it is possible to note in this spectrum 28 vibrational bands in the form of inflections or distinct peaks. The selection rules for the absorption, Raman, and incoherent inelastic neutron scattering spectra are different, so that comparison of these spectra is legitimate only as regards the frequencies of their bands.

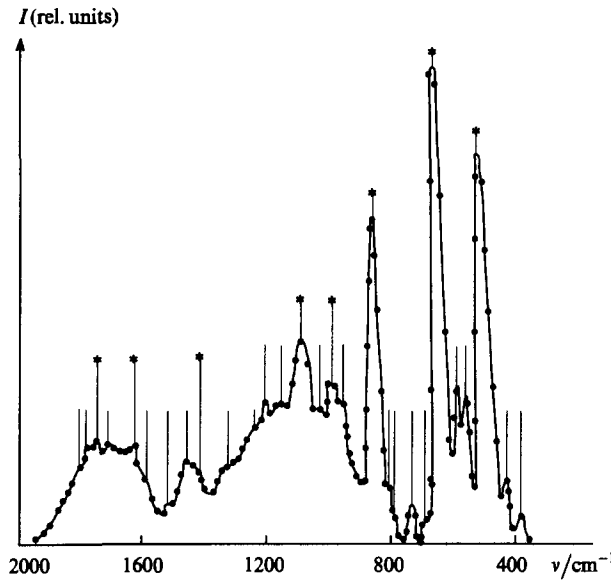

Figure 4. The spectrum of the incoherent inelastic neutron scattering by a crystal of $(H_5O_2^+)_3(PW_{12}O_4^{3-})$ according to the data of Kearley et al.[35]

Interesting results have been obtained in the study of proton hydration in the gas phase. Kebarle and coworkers performed a series of novel investigations[36,37] of gas-phase reactions of the type

$$H^+(H_2O)_{n+1} + H_2O \rightleftharpoons H^+(H_2O)_n .$$

It was shown that the heat of addition of a water molecule to the hydroxonium ion in the gas phase is 31.6 kcal mol^{-1}.[37] This greatly exceeds the energies of the strongest hydrogen bonds, indicating the stability of the $H_5O_2^+$ ion formed. The energy of the addition of the third and subsequent water molecules to the proton is significantly smaller, decreasing monotonically with increase in their number (Fig. 5).

The above investigations[36,37] stimulated a whole series of theoretical studies of the structure and the shape of the potential energy surface of the hydrated proton $H^+(H_2O)_n$. As a result, it was established that the energy of the addition of a H_2O molecule to the H_3O^+ ion is 32 kcal mol^{-1}.[38] This value agrees well with experimental data.[37] It has also been shown that a linear symmetrical hydrogen bond with an equilibrium O···O distance of 2.39 Å corresponds to the energy minimum of the $H_5O_2^+$ ion.[38] The potential energy curve for the central proton has a very flat minimum — when the proton is displaced by 0.3 Å, the potential energy hardly changes. For fixed O···O distances, significantly exceeding the equilibrium value, the cross-section through the potential energy surface along the O···H coordinate has two minima. The calculations of Kraemer and Diercksen[38] have been confirmed in other studies (see, for example, Kollman and Allen[39] and Yukhnevich et al.[40]).

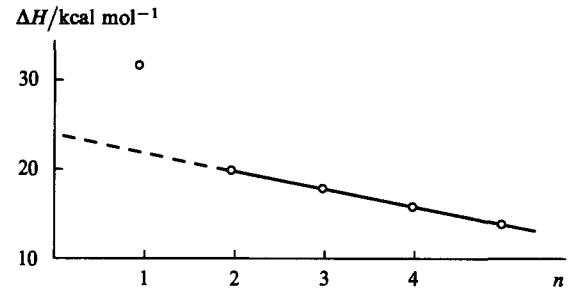

Figure 5. Variation of the heat of addition of a water molecule (ΔH) to the proton hydrate $H^+(H_2O)_n$ with the composition of the latter (n), according to the data of Kebarle et al.[36]

Nonempirical calculations for the hydrates $H_3O^+ \cdot (H_2O)_n$ with $n = 0-4$ showed[41] that the $H_9O_4^+$ ion has a stable chain structure with a central symmetrical hydrogen bond (Fig. 1*d*). The O···O distance (2.36 Å) then proves to be the same as in the $H_5O_2^+$ ion. This result was unexpected to Newton and Ehrenson,[41] who believed that the simplest stable proton hydrate is the hydroxonium ion and that $H_9O_4^+$ represents H_3O^+ hydrated by three water molecules, i.e. has the C_{3v} symmetry (Fig. 1*b*). Thus the results of quantum-chemical calculations led to the same conclusions as the results of the experimental studies examined above: first, the existence of the stable ion $(H_2O\cdots H\cdots OH_2)^+$ with a strong symmetrical hydrogen bond is energetically favoured and, second, the structure and properties of this ion are almost independent of the surrounding molecules.

VI. The $H_5O_2^+$ ion in solutions

The claim that the simplest stable proton hydrate in aqueous solutions is the symmetrical ion $(H_2O\cdots H\cdots OH_2)^+$ was first made on the basis of the analysis of the IR spectra of such solutions.[42] It was shown[42] that, despite the fact that the vibrational frequencies of the H_3O^+ and $H_5O_2^+$ ions are fairly similar (Table 1), these ions may be identified by comparing the IR and Raman spectra of the system investigated.

Table 1. The vibrational frequencies (cm^{-1}) of proton hydrates in IR (IRS) and Raman (RS) spectra.

H_3O^+ (C_{3v})		$H_5O_2^+$ (C_s)	
IRS	RS	IRS	RS
			460
1100	1100	1170	–
–	–	1370	–
1600	1600	1710	1710
2900	2900	2900	2900
3500	3500	3500	3500

The concept formulated by Librovich et al.[42] permitted an approach from a single standpoint, to the consideration of various physicochemical properties of aqueous solutions of acids. By employing it, it has been possible to account for the experimental hydration numbers of protons in aqueous solutions,[32] the kinetics and mechanisms of acid-catalytic hydrolytic reactions,[31,43] and a number of other features. It also made it possible to establish the ionic-molecular composition of the sulfuric acid – water system.[44]

The results of diffraction measurements on aqueous HCl solutions have been published,[45] showing that the O···O distance is shortened and equal to 2.52 Å. The authors attributed it to the complex $H_2O \cdot H_3O^+$. However, taking into account the data

considered above, one must recognise that such a short distance is more likely to be characteristic of the $H_5O_2^+$ ion.

The $H_5O_2^+$ ion has also been detected in the liquid phase by high-resolution NMR.[46] When an equimolar amount of water was added to a solution of octanesulfonic acid in a mixture of deuteriohalomethanes (Fig. 6, spectrum *1*), the bands of the H_3O^+ ion were recorded (Fig. 6, spectrum *2*). The addition of an excess of water to the solution led to a sharp weakening of these bands and the appearance of two new narrow lines with a 1:4 intensity ratio (Fig. 6, spectrum *3*). These lines are due to the central and terminal protons of the symmetrical ion $(H_2O\cdots H\cdots OH_2)^+$.

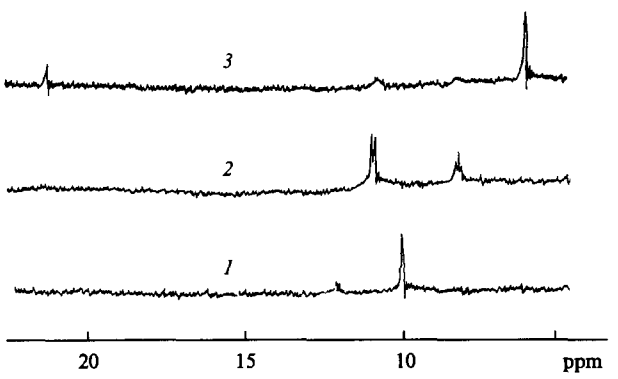

Figure 6. NMR spectra of dilute solutions of $H_2O-HSO_4C_8H_{17}$ mixtures in deuteriohalomethanes according to Golubev's data[46] for different $H_2O:HSO_4C_8H_{17}$ ratios: (*1*) 0:1; (*2*) 1:1; (*3*) 2:1.

Solutions of the $CF_3SO_3H-H_2O$ and $HI-H_2O$ mixtures in an inert solvent (CCl_4) diluted to 10^{-2} M have been investigated by IR spectroscopy.[47] For the acid : water = 1:1 ratio, the bands of the hydroxonium ion were observed in the spectrum of the solution (Fig. 7, spectrum *1*). Following an increase in the water concentration to give the ratio 1:2, the spectrum changed sharply (Fig. 7, spectrum *2*). Further addition of water to the system did not affect the IR absorption curve.

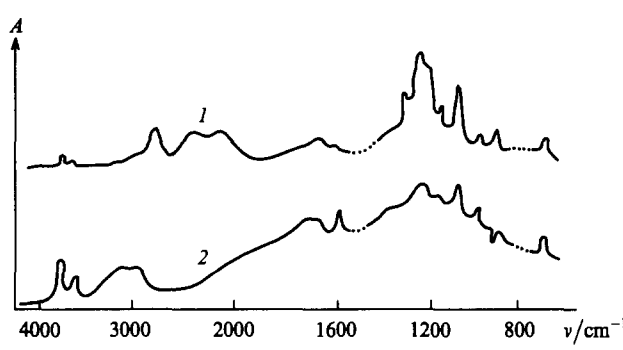

Figure 7. IR spectra of the $H_2O-HSO_3CF_3-CCl_4$ ternary system according to data of Dogonadze et al.[47] for different molar component ratios: (*1*) 1:1:50; (*2*) 2:1:50.

Artificially created systems, fairly remote from aqueous acid solutions, have been studied.[46,47] Nevertheless, the results obtained demonstrated unambiguously the following most important features of the interactions of the proton with water molecules in solution.

1. The hydroxonium ion exists in the liquid phase only when there is not more than one water molecule per acid molecule.

2. With increase in the water content in the system, a chemical reaction between H_3O^+ and H_2O and not simple hydration of the H_3O^+ ion takes place in the system. It is accompanied by a rearrangement of the bonds and the formation of the symmetrical ion $H_5O_2^+$.

3. The hydration of the $H_5O_2^+$ ion (to give a water : acid ratio in excess of 2:1) does not alter its structure.

VII. The continuous absorption in the IR spectra of solutions of acids. Initial interpretation

The determination of the molecular structure of the simple proton solvate in solutions is indissolubly linked to the study and interpretation of its vibrational spectra. Until recently, such interpretation involved considerable difficulties. The point is that the IR spectra of all systems in which proton dihydrates (as well as other proton disolvates formed via a strong symmetrical hydrogen bond) are present exhibit an intense continuous absorption (CA) in the range from ~3500 to 800 cm^{-1}. The positions and intensities of individual, usually indistinct, maxima on the contour of this continuum depend on the composition of the test solution. A significant factor proves to be not only which species, other than the proton disolvate $(A\cdots H\cdots A)^{\pm}$, are present in solution but also what molecules A solvate the proton.[48]

The continuous absorption in the spectra of solutions of acids and strong bases was first recorded in the near infrared (4300–6700 cm^{-1}) and it was immediately established that its optical density is proportional to the acid or alkali concentration in solution.[49,50] Much later a similar spectroscopic phenomenon was observed also in the region of the fundamental vibrational frequencies of the molecules.[51,52] Ackermann,[52] who was the first to detect a continuous absorption in this region, assumed that it is due to the delocalisation of the positive or negative charge in the solvate complex. Subsequently, the continuous absorption observed in the spectra of numerous aqueous and nonaqueous solutions was vigorously studied by various investigators.[53–57]

A large series of studies on the continuous absorption has been carried out by Zundel and coworkers.[30,57–60] Some of their results are extremely interesting. Thus it has been shown[30] with the aid of a novel experiment that the appearance of the continuous absorption requires that the solution contains a dissociated proton bound to two water molecules. On the other hand, it must be said that in his studies Zundel's aim was not to obtain the spectrum of the ion 'in a pure form'. He confined himself to the analysis of the spectra of mixtures in terms of the transmittance scale (see, for example, Fig. 8). This made it impossible for him to draw inferences about the details of the spectral absorption curve for the ion under consideration and hence about its molecular structure. We may also note that Zundel based his concept concerning the mechanism of proton hydration both on incontrovertible experimental data and on the results of studies[27,51,52] which proved subsequently to be erroneous. For this reason, the explanation which he proposed for the causes of the appearance of the continuous absorption[58] appears unconvincing. As a result of Zundel's many publications,

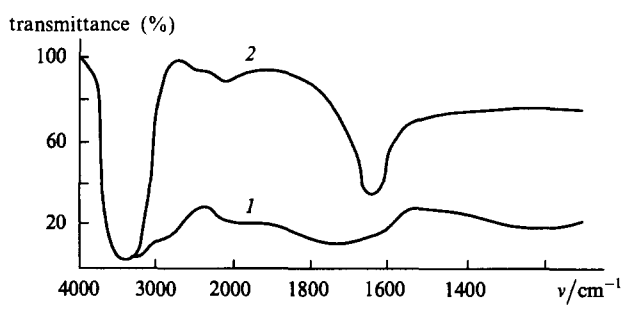

Figure 8. IR spectra of a 10 M HCl solution in H_2O (curve *1*) and of water (curve *2*) according to the data of Schioberg and Zundel.[57]

his view became well known and we shall therefore consider it in detail.

Zundel based his interpretation of the continuous absorption on the following assumptions:[58]

1. The spectra of aqueous solutions of acids and strong bases contain the same vibrational bands.

2. The lifetime of the H_3O^+ ion (which is the simplest proton hydrate in Zundel's view) is so short that its vibrations cannot be recorded by IR spectroscopy.

3. The most stable ion-molecule formation, the vibrations of which are manifested in the IR spectrum of the solution, is the $H_9O_4^+$ ion (Fig. 9).

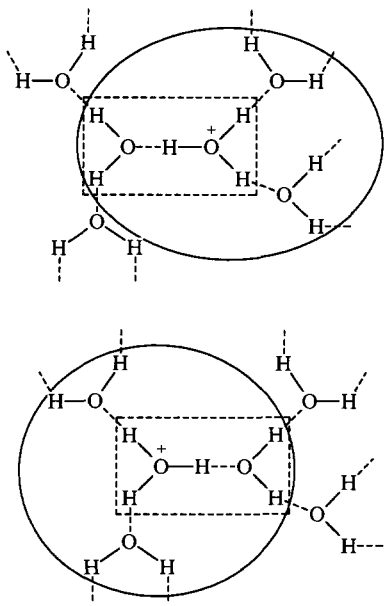

Figure 9. The molecular structure of the proton hydrate according to Zundel's data.[58] The $H_9O_4^+$ ion is shown within the circumscribed region.

On the basis of the assumptions listed,† Zundel proposed a model of the proton hydration in solution, the essential features of which reduce to the following. The $H_5O_2^+$ group (not the simplest stable ion but an unstable group which is incapable of entering into chemical reactions as an integral whole) exists in aqueous solutions of acids. The proton in this group is rapidly exchanged between the two water molecules, occupying one of the boundary positions:

$$(H_2OH^+\cdots OH_2) \rightleftharpoons (H_2O\cdots H^+OH_2).$$

The transfer of the proton, which is located in a potential well with two minima, takes place as a result of the fluctuations of the electric field generated by the environment of the $H_5O_2^+$ group. The ultrahigh polarisability of the hydrogen bond (this property of the O···H···O bond is simply postulated) plays a special role in this process. According to this model (which has not undergone significant changes since that time[59,60]), the continuous absorption arises by virtue of the appearance of additional transitions during the tunnelling of the proton through the central potential barrier.

Together with the explanation of the origin of the continuous absorption examined above, other treatments of this spectroscopic phenomenon have been proposed.[61-65] Like Zundel's hypothesis, they are all based on the hypothesis of a strong interaction between the bridging proton and the medium. For example, it has been shown[65] that the experimentally observed broad absorption region may arise as a result of the interaction of the vibrations of the central proton in the $H_5O_2^+$ ion with the low-frequency vibrations of the surrounding ligands (the proton–phonon theory). This approach made it possible to describe the isotope effects and to account for the presence of the continuous absorption in the IR spectra of solutions of strong bases. The simplest stable solvated ion in such solutions has the structure $(HO\cdots H\cdots OH)^-$.

However, in the studies by Golubev, Denisov,[47] and Pankov and coworkers[66] published at the beginning of the 1980s, it was shown that the initial postulate, on which all the proposed theories were based, conflicts with experiment. In these investigations, studies were made of the IR spectra of the ion $(H_2O\cdots O\cdots OH_2)^+$ in a water–acid–carbon tetrachloride ternary system[47] and of the complex $(RO_H\cdots H\cdots O_HR)^+$ in a alcohol–acid–aprotic solvent (CCl_4 and CH_2Cl_2) system.[66] It was established that, even when the solvation effects are reduced to a minimum, the shape of the contour and the intensity of the continuous absorption in the spectrum of the ion $(A\cdots H\cdots A)^{\pm}$ remain the same as in polar solvents. In other words, the continuous absorption is not caused by the influence of the medium but is due to the intrinsic internal properties of the ions with a symmetrical hydrogen bond.

The data obtained in the above studies[47,66] made a most important contribution to understanding the phenomenon under consideration, on the one hand, and posed a new major problem before investigators, on the other. It was now necessary to explain all the characteristics of the continuous absorption in the vibrational spectra of solutions of acids and strong bases listed above on the basis of the properties of a molecular system consisting of a small number of atoms (only five in the case of the $H_3O_2^-$ ion). The successful solution of this problem, i.e. the establishment of a quantitative relation between the properties of the individual structural elements of the proton disolvate and its vibrational spectrum, would make it possible not only to understand the mechanism of the appearance of the continuous absorption but also to determine the structure of the ion $(A\cdots H\cdots A)^{\pm}$.

Evidently, the solution of the problem formulated requires more accurate information about the nature of the vibrations of the proton disolvate, i.e. on the experimental side it was necessary to effect a transition from the spectra of mixtures to the individual spectra of ions, and on the theoretical side the consideration of the monocoordinate O···H···O bridge had to be replaced by allowance for all the degrees of freedom of the vibrational system investigated. A formulation of this kind was achieved by a number of investigators.[40,48,67-71]

VIII. Differentiation of the spectra of proton disolvates from the spectra of solutions

In practice, the structure of the simplest proton hydrate in solution may be established only by investigating its IR spectrum. It is therefore necessary to measure this spectrum as thoroughly as possible. Thus, in the case of strongly absorbing liquids, to which aqueous solutions also belong, the IR spectra must be measured not by the transmittance technique but by the multiple distorted total internal reflection (MDTIR) technique.[72] The high accuracy of the measurement of the spectrum is especially important in cases such as the resolution of the spectrum into components or the differentiation of the spectrum of a particular molecule from the spectrum of a mixture.

From the standpoint of the correctness of the primary spectroscopic measurements, mention may be made of the studies of Yukhnevich et al.[48] and Maiorov and Librovich.[71] Using the MDTIR method, these investigators obtained, with a highly satisfactory accuracy, the absolute spectroscopic absorption coefficients of aqueous and methanol solutions of hydrogen

† These postulates conflict with experimental data in Refs 11, 15, 19, 46, and 48, in Refs 15, 19, and 23, and in Refs 28, 29, and 42 respectively.

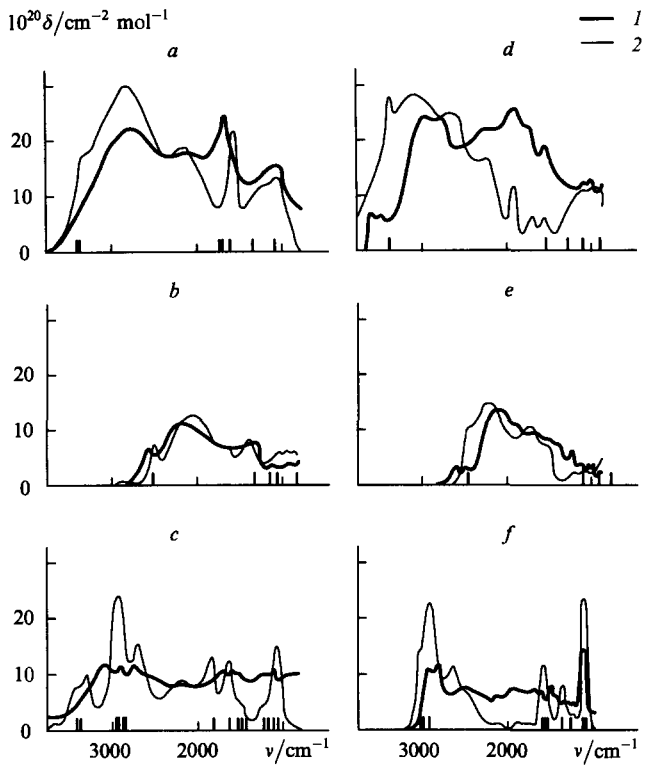

Figure 10. The measured (curves *1*) and calculated (curves *2*) IR spectra of proton disolvates according to the data of Yukhnevich et al.[48]: (*a*) $H_5O_2^+$, (*b*) $D_5O_2^+$; (*c*) $(CH_3OH)_2H^+$; (*d*) $H_3O_2^-$; (*e*) $D_3O_2^-$; (*f*) $(CH_3O)_2H^-$.

chloride and potassium hydroxide. This made it possible to differentiate for the first time the spectra of the ions $H_5O_2^+$, $D_5O_2^+$, $(CH_3OH)_2H^+$, $H_3O_2^-$, $D_3O_2^-$, and $(CH_3O)_2H^-$ 'in a pure form' by measuring the spectra of a series of auxiliary systems (Fig. 10).

In the differentiation of the spectra of positively charged ions, acid–solvent systems with known ion-molecular compositions and known molar absorption coefficients of the system were selected. The spectra of the ions $(A\cdots H\cdots A)^+$ were found directly by subtracting from the IR spectrum of the solution the absorptions due to the solvent molecules and the acid anions. The differentiation of the vibrational spectra of the negatively charged ions involved much greater difficulties. The point is that the spectrum of the solvent molecules (water and methanol respectively), which strongly solvate the $H_3O_2^-$ and $(CH_3O)_2H^-$ ions present in the solution, differs appreciably from the spectrum of the pure solvent.[73,74] Therefore, in determining the spectra, estimates were made of the position, width, and intensity of the ν_{OH} band of the H_2O and CH_3OH molecules solvating the ions $(A\cdots H\cdots A)^-$. As a result, the accuracy of the absorption cross-sections obtained for ions with a negative charge (~30%) proved to be significantly lower than for the positively charged ions (~15%).

IX. Calculation of the IR spectra of proton disolvates

Interpretation of the IR spectra of proton disolvates requires allowance for their highest-order vibrations.[47,66] In other words, the mechanism of the appearance of the continuous absorption must be analysed in terms of the anharmonic approximation of the theory of the vibrations of polyatomic molecules. This approach has been used in the calculation and analysis of the IR spectra of the ions $(A\cdots H\cdots A)^{\pm}$ in a number of studies.[40,48,67–70] Proton disolvates differing significantly in composition—$H_5O_2^+$, $D_5O_2^+$, $(CH_3OH)_2H^+$, $H_3O_2^-$, $D_3O_2^-$, and $(CH_3O)_2H^-$—were chosen as the objects of study. This made it possible to determine the influence of the ionic charge, of the nature of the ligand, and of deuteriation on the shape of the continuous absorption contour.

For the calculation of the spectra of the systems listed above, it was also necessary to know, together with the properties of the ligand molecules, also the geometrical, energetic, and electro-optical parameters of the O···H···O bridges. The authors of the studies under consideration based the determination of the above parameters on the data concerning the ions $(A\cdots H\cdots A)^{\pm}$ already available at the time. In view of the importance of the characteristic properties of these ions for the understanding of the nature of the continuous absorption, we shall consider them in detail.

The study of the kinetics of the gas-phase chemical reactions leading to the formation of the ions $(A\cdots H\cdots A)^{\pm}$ showed that the energy of the addition of the second solvating molecule to the proton is virtually unchanged (31 ± 2 kcal mol^{-1}) for several tens of compounds investigated, in which the molecule A is water, an alcohol, acid, ester, ketone, or aldehyde.[34,75–78] The invariance of the bond energy of the symmetrical hydrogen bridge in all the systems containing it was confirmed by the results of numerous quantum-chemical calculations.[76,79–82] All the available experimental data[83–88] as well as the results of calculations by various methods[79–82,89,90] showed that the length of the O···H···O bridge (2.4–2.55 Å) also depends little on the structure of the molecules solvating the proton. The results of quantum-chemical calculations[48,68] demonstrated that the force constants, the atomic charges, and the dipole moments of the bonds in the O···H···O fragment are independent of the nature of the ligand (Table 2). The last two of the characteristics indicated are determined by the ionic charge.

Table 2. Parameters of the symmetrical hydrogen bridge O···H···O (data of Yukhnevich et al.[48]).

Parameter	$H_3O_2^-$	$H_5O_2^+$	$(CH_3O)_2H^+$	$(CH_3OH)_2H^+$
$R_{O\cdots H}$/Å	1.207	1.197	1.212	1.203
$F_{O\cdots H}$/ mdyn Å^{-1}	2.35	2.0	2.62	2.48
$F_{O\cdots H,\ O\cdots H}$/ mdyn Å^{-1}	1.76	1.50	1.99	1.79
$F_{O\cdots H\cdots O}$/ mdyn Å^{-1}	0.16	0.13	0.16	0.10
Q_O/electric charge units	−0.84	−0.42	−0.67	−0.42
Q_H/electric charge units	0.36	0.41	0.36	0.40
$\mu_{O\cdots H}/\mu_{OH(H_2O)}$	1.33	0.63	1.30	0.75

There have been few experimental studies devoted to the nature of the potential energy surface of proton disolvates.[87,88] However, in the case of the ion $[(C_2H_5O)_2O\cdots H\cdots O(C_2H_5)_2]^+$, investigated for this purpose, as well as the ion $H_5O_2^+$,[38–40] the central proton is located in a symmetrical potential well with one minimum. This conclusion was reached on the basis of the results of studies of a single crystal of the etherate $(C_2H_5)_2O\cdot HZnCl_3$ by X-ray diffraction and ^1H NMR.[87,88]

The IR spectra of the ions $H_5O_2^+$, $D_5O_2^+$, $(CH_3OH)_2H^+$, $H_3O_2^-$, $D_3O_2^-$, and $(CH_3O)_2H^-$ have been calculated, taking into account the kinematic, dynamic, and electrooptical anharmonicities of the vibrations, by a variational method[91] in accordance with a general algorithm. No adjustment of the calculated frequencies and intensities of the absorption bands to achieve agreement with experimental spectra of specific ions was carried out. All the parameters of the O···H···O bridges needed to calculate the spectra of the test systems were found with the aid of

a semiempirical model for the description of the dynamic and electrooptical properties of the hydrogen bond[92] or by means of quantum-chemical calculations.[48,68]

The absorption spectra of the proton disolvates calculated in this way are presented in Fig. 10. The positions of the fundamental vibrational bands are designated by vertical lines. The complete set of the calculated frequencies of the $H_5O_2^+$ ion in the range 200–1800 cm^{-1} is presented in Table 3. The table shows that the average deviation of the calculated fundamental vibrational frequencies from the frequencies of the most intense lines in the inelastic neutron scattering spectrum[35] is ± 18 cm^{-1} (which corresponds to the accuracy achieved by a modern theory of the vibrations of polyatomic molecules[18]).

[a] The fundamental vibrational frequency.

Analysis of the calculated IR spectra of the ions investigated established two characteristic features. Firstly, the majority of the vibrations of the proton disolvates and primarily the vibrations of the hydrogen bridge are not localised in one coordinate. Their modes, determined by the structure of the ion, are individual.[48,69] Secondly, in the region where the continuous absorption is observed experimentally the spectra of all the ions considered contain tens (40–300) compound vibrational bands and overtones, the intensities of many of which (30%–60%) are comparable to those of the fundamental vibrational bands.[67–70]

Detailed study of the influence of various anharmonic parameters on the nature of the calculated spectra of the ions $(A\cdots H\cdots A)^{\pm}$ showed that the presence in the latter of a large number of intense combination bands is a consequence of the electrooptical anharmonicity of the vibrations of the O···H···O fragment. Furthermore, it has been possible to establish unambiguously that only two nonequivalent electrooptical parameters make a decisive contribution (~85%) to the overall intensity of the higher-order vibrational bands in the spectra of proton disolvates.[70] The causes of the appearance of intense overtone vibrational bands in the spectra of the ions $(A\cdots H\cdots A)^{\pm}$ were analysed by considering the modes and intensities of the vibrations of the hydrogen bridge O···H···O. Such analysis made it possible to establish that the vibrations of the O···H···O fragment, in which the central proton shifts simultaneously along and across the direction of the hydrogen bond, are anomalously intense and to understand why precisely these vibrations are so intense.[69]

Analysis of the coefficients in the expansion of the anharmonic eigenfunctions of the vibrational energy levels in terms of the harmonic basis functions made it possible to explain why the intense combination bands in the spectra of proton disolvates are so numerous. It was found that the strong kinematic interaction of the coordinates of the hydrogen bridge with other coordinates of the ions $(A\cdots H\cdots A)^{\pm}$ causes the displacement of the proton along or across the hydrogen bond to occur in more than half of their fundamental vibrations, while the simultaneous shift in both directions indicated occurs in virtually every third overtone vibration. These composite vibrations and overtones are in fact active in the absorption spectrum.[48,69]

Thus it follows from the calculations that the continuous absorption in the spectra of proton disolvates may be due to the presence in the range 800–3700 cm^{-1} of a large number of overlapping intense higher-order vibrational bands. The appearance of such bands is caused by the intrinsic properties of the ions $(A\cdots H\cdots A)^{\pm}$ and in the first place by the electrooptical anharmonicity of the O···H···O fragment and the strong interaction of the coordinates of the hydrogen bridge with the internal coordinates of the ligand.

X. Interpretation of the continuous absorption in the IR spectra of solutions of acids and strong bases

The results of the comparison of the calculated and measured absorption cross-sections of the ions $H_5O_2^+$, $D_5O_2^+$, $(CH_3OH)_2H^+$, $H_3O_2^-$, $D_3O_2^-$, and $(CH_3O)_2H^-$ (Fig. 10, Table 4) demonstrated the validity of the explanation of the nature of the continuous absorption proposed by Yukhnevich et al.[48] It is seen from the spectra presented in Fig. 10 and the data in Table 4 that the calculation made it possible to reproduce on the whole correctly the overall form of the spectral curves and the integral absorption of all the ions in the frequency range considered and also to reproduce correctly the changes in the spectra of the $H_5O_2^+$ and $H_3O_2^-$ ions occurring on isotopic substitution.

Table 4. The absolute absorption intensities of the proton disolvates (I) and their isotopic ratios (I_H/I_D) according to the data of Yukhnevich et al.[48]

Ion	Calculation		Experiment		Frequency range/cm^{-1}
	I/D^2 Å^{-1}	I_H/I_D	I/D^2 Å^{-1}	I_H/I_D	
$H_3O_2^-$	87	2.8	62 ± 13	2.6 ± 0.8	3700–900
$D_3O_2^-$	31		24 ± 5		2700–900
$H_5O_2^+$	96	2.5	130 ± 14	3.1 ± 0.5	3700–900
$D_5O_2^+$	38		42 ± 5		2700–800
$(CH_3O)_2H^-$	66		82 ± 17		3700–900
$(CH_3OH)_2H^+$	84		131 ± 14		3700–900

Yet another confirmation of the concept concerning the origin of the continuous absorption under discussion is the fact that, when the $H_5O_2^+$ and $H_3O_2^-$ ions are deuteriated, their integral absorption (the average for both ions) diminishes by a factor of 2.85 ± 0.5 (Table 4). This value agrees well with the calculated value 2.65 (Table 4). However, it can correspond neither to the isotopic ratio of the fundamental vibrational intensities of the O–H bond nor to the ratio of the intensities of the first overtone vibrations. According to the theory of vibrations,[18] in the former case the isotopic ratio should be 1.84, while in the latter it should be 3.39. The experimental

isotopic intensity ratio (2.85) can be explained by averaging the values (1.84 and 3.39) for several fundamental and first overtone vibrations.

Thus the published data show that the continuous absorption in the spectra of acids and strong bases is caused by the intrinsic vibrations of the simplest stable proton solvates. The solvates themselves are stable charged species with a symmetrical hydrogen bridge O···H···O, the properties of which are almost independent of the nature of the ligand.

XI. The structure of the solvated proton and the catalytic properties of acids

The equilibrium stage involving the protonation of the organic compound which subsequently undergoes chemical reaction plays an important role in homogeneous acid catalysis. The degree of protonation of the organic compound depends on the catalytic activity of the acid solution and primarily on the acidity function of the solution. It was assumed for a long time that the protonation of the organic molecule B involves the transfer to the latter of a proton from the acid medium and the formation of the protonated form BH^+. It was postulated that BH^+ is the simplest stable proton solvate, the addition to which of a second and subsequent solvent molecules does not alter its structure. However, as early as 1980 it was already established[93] that in many cases the protonation of the molecule of compound B is a reaction involving the substitution of a water molecule in the $H_5O_2^+$ ion by a molecule of B:

$$(H_2O\cdots H\cdots OH_2)^+ + B \rightleftharpoons (H_2O\cdots H\cdots B)^+ + H_2O. \qquad (1)$$

The radical revision of the ideas concerning the mechanism of the catalytic action of acids was caused by the finding that the protonated form of the organic molecule in solutions is usually not the BH^+ ion but the $(H_2O\cdots H\cdots B)^+$ ion.[94] The new concept, elucidating the characteristic features of this mechanism, was based on the constancy of the enthalpy of formation of proton disolvates[34,75-78] and the independence of the parameters of the symmetrical hydrogen bridge on the nature of the molecules solvating the proton.[48,68,79-90] Understanding the fact that the properties of the central ···H··· fragment, which is common to a wide range of compounds, determine not only the nature of their vibrational spectra but also their behaviour and chemical reactions made it possible to solve the following fundamental problem in homogeneous acid catalysis.

1. The physical significance of the Hammett acidity function H_0 was discovered and the limits of its applicability were established. Previously, the use of this function was based on the postulate that the mechanisms of the protonation in acid solutions of stable compounds (indicators) and of the reacting organic molecule are the same.[95] This postulate had no physical justification, since no common properties embracing indicators and organic compounds with different structures and chemical compositions were known.

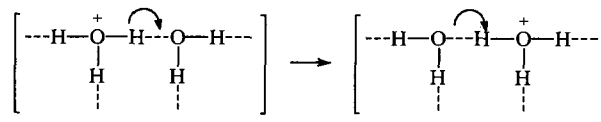
It has been shown[93] that Hammett's postulate holds only in those cases where the molecules of compound B are protonated via reaction (1). In other words, an obligatory condition for its validity is the presence in the proton solvate of a symmetrical hydrogen bridge with invariant parameters. A number of conditions must be fulfilled for the protonation of the molecule of compound B to occur in accordance with the scheme indicated.[96] Firstly, the acid–base interaction in the solution must go to completion, i.e. positively charged proton solvates must be formed in it. Secondly, the molecules solvating the proton must have lone pairs ensuring the formation of a symmetrical hydrogen bond. Thirdly, it is necessary that the heat of addition of a proton to a molecule of compound B (the proton affinity) should be greater than the proton affinity of the water molecule (i.e. >170 kcal mol^{-1}) but less than 197 kcal mol^{-1}.[96] For heats of addition of a proton to a molecule of compound B exceeding 197 kcal mol^{-1}, the preconditions for the fulfilment of Hammett's postulate vanish and protonation leads to the formation of the BH^+ ion.

2. Quantitative relations between the acidity functions of acid solutions and the thermodynamic activities of water have been obtained. It has been shown[94] that, when equilibrium (1) obtains in the solution of an acid, then the Hammett acidity function H_0 should be formulated as follows:

$$H_0 = -\lg\left(a_{H^+}\, a_{H_2O}\frac{f_B}{f_{BHOH_2^+}}\right), \qquad (2)$$

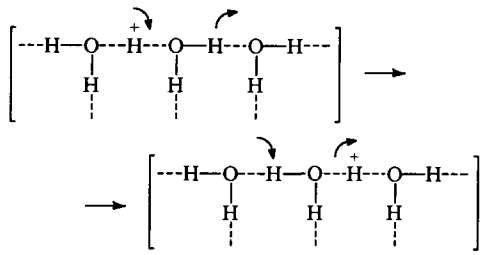
where a represents the thermodynamic activities of the corresponding species and f represents the activity coefficients.

The fundamental difference between Eqn (2) and the formulation adopted earlier for H_0 is the presence in the former of the activity of water. This made it possible to account for the long established fact[95,97] that the quantity $H_0 + \lg a_{H_2O}$ is independent of the activity of the anion in solution, while the ratio of the activity coefficients is the same for organic compounds having different structures, provided that Hammett's hypothesis holds. It has also been shown[94] that, in those cases where equilibrium (1) obtains, the degrees of protonation and the basicity constants $K_{BHOH_2^+}$ should be calculated in virtually the same way as for the previous ideas concerning the structure of the protonated form:



$$H_0 = pK_{BHOH_2^+} + \lg\left(\frac{c_B}{c_{BHOH_2^+}}\right),$$

$$K_{BHOH_2^+} = \frac{a_B a_{H_5O_2^+}}{a_{BHOH_2^+}\, a_{H_2O}}.$$



3. An explanation has been proposed for the difference between the gas-phase and liquid-phase acidities observed for many compounds. A large number of organic compounds, forming the $BHOH_2^+$ ion both in the gas and liquid phases, fall within the range of the energies for the addition of a proton to a molecule of compound B indicated above.[98] However, the mech-anisms of the protonation of a series of compounds in the gas and liquid phases are different (a substitution reaction with formation of the $BHOH_2^+$ ion takes place in the gas phase, while the BH^+ ion is formed in the liquid phase).[96] A difference between the gas-phase and liquid-phase acidities is observed in precisely such cases. Hence the above difference is caused not by the influence of the medium on the activity coefficients of the forms B and BH^+ but by the different mechanisms for the protonation of the organic molecule in the liquid and gas phases.[96]

4. The mechanism of the hydrolytic reactions of organic compounds was established. It has been shown[43] that ions with symmetrical hydrogen bonds may participate as the reactants in the rate-limiting stages of acid-catalytic processes. However, only the stoichiometric composition of the intermediate complexes could be inferred from the kinetic data. In order to establish the mechanism of the rate-limiting stage of the reaction, it was also necessary to know the structures of the reacting species. The information obtained about the structures of the simplest stable proton hydrates in aqueous solutions of strong acids made it possible to establish the structure of the intermediate complex in the hydrolytic reactions. This permitted the understanding of the detailed mechanism of the rate-limiting stage in these reactions.[99]

5. The mechanism of the proton conduction in aqueous solutions of acids was revised. On the basis of the concept of the H_3O^+ ion, it had been assumed previously that the anomalously high mobility of the proton in such cases can be explained by the Grotthus relay mechanism.[26,95]

However, in reality the simplest stable proton hydrate in aqueous solutions of acids is the $H_5O_2^+$ ion. In this case, charge transfer without disturbing the structure of the solution is possible only for a synchronous transfer of two protons in accordance with the mechanism:[100,101]

Such a transfer is equivalent to the migration of a proton from one potential well to another, overcoming a barrier of $\sim$2.4 kcal mol^{-1}.[102]

An analogous mechanism of the transfer of a negative charge (a proton defect) can be put forward for aqueous solutions or bases, where the simplest stable hydrate of the hydroxide ion is $(HO\cdots H\cdots OH)^-$.[65]

XII. Conclusion

The history of the development of ideas concerning the structure of the simplest stable proton hydrate shows how important is the correct understanding of the relation between the molecular structures of the test objects and their properties recorded experimentally.

The main outcome of studies carried out over many years, the different stages of which have been examined consecutively in the present review, is the establishment of the structures and properties of the simplest stable proton solvates in solutions of acids and strong bases. Such solvates are the ions $(A\cdots H\cdots A)^{\pm}$ with a symmetrical hydrogen bridge, the properties of which are almost independent of the nature of the ligand A. The broad region of continuous absorption observed in the IR spectra of proton disolvates is due to the electrooptical anharmonicity and the noncharacteristic nature of their vibrations.

The elucidation of the characteristic features of the mechanism of the vibrations of systems containing strong symmetrical hydrogen bonds led to a deeper understanding of the process involving the establishment of their IR spectra. Together with the interpretation of the continuous absorption, which has been confirmed experimentally, it also made it possible to achieve a simple explanation, having a clear physical significance, of the 'anomalous' dependence of the vibrational frequencies of such systems on the isotopic composition.[103]

The level of knowledge concerning the structures and properties of the simplest stable proton solvates achieved at the present time has made it possible to abandon the purely empirical relations in the determination of the mechanisms of acid–base catalytic reactions and to construct a unique quantitative theory of the catalytic action of acids and bases. The satisfactory foundations and the clear-cut definition of the limits of the applicability of this theory have made it possible to employ it successfully in order to account for the known experimental facts and to predict the conditions for the occurrence of various physicochemical processes in solutions.

This review has been written with the financial support of the Russian Fundamental Research Fund (project No. 93-03-18356).

VII.	Conclusion	925

Abstract. Problems concerning the structures of compounds of the series $M^IP(As)UO_6 \cdot nH_2O$ (M^I = H, Li, Na, K, Rb, Cs; n = 4 for M^I = H, Li and n = 3 for M^I = Na, K, Rb, Cs) are examined. The results of X-ray powder diffraction, thermographic, and IR spectroscopic studies on the above compounds are analysed. The experimental standard enthalpies of formation ($\Delta_f H^\circ$) of the compounds $M^IP(As)UO_6$ and their crystalline hydrates are discussed. The characteristic features of the variation of $\Delta_f H^\circ$ as a function of the structural characteristics of the compounds and of the physical properties of the Group I elements in the series of phosphorus and arsenic compounds are described. The enthalpies of dehydration and ion exchange involving the compounds investigated are presented. The bibliography includes 103 references.

I. Introduction

The compounds $M^IM^VUO_6 \cdot nH_2O$, where M^I = hydrogen or an alkali metal and M^V = phosphorus or arsenic, are of interest by virtue of a whole series of factors. The compounds include well-known, and fairly widely distributed in nature, uranium minerals with M^I = H, Na, or K, the rubidium compounds which have been much less investigated and are not encountered in nature, as well as the caesium compounds and natural uranium compounds with the same formula containing vanadium as the pentavalent element, which have not been investigated at all.

It is known that the compounds $HPUO_6 \cdot 4H_2O$ and $HAsUO_6 \cdot 4H_2O$ have a high proton conductivity and may be used in autonomous energy sources. The alkali metal derivatives are interesting from the standpoint of their electrophysical characteristics: for example, a high ionic conductivity is characteristic of these substances. Finally, the natural compounds $M^IP(As)UO_6 \cdot nH_2O$ are widely distributed objects of study in the geochemistry of uranium, in the development of processes for its extraction from natural raw material, and in the processing of uranium-containing waste.

N G Chernorukov, N V Karyakin Lobachevskii Nizhnii Novgorod State University, prosp. Gagarina 23, 603600 Nizhnii Novgorod, Russian Federation. Fax (7-831) 235 64 80. Tel. (7-831) 265 76 06 (N G Chernorukov)

Received 18 April 1995
Uspekhi Khimii **64** (10) 975–990 (1995); translated by A K Grzybowski

For the successful practical utilisation of the compounds $M^IP(As)UO_6 \cdot nH_2O$, it is necessary to have scientific information about the characteristics of their structure, their properties which depend on their physical state, and the energy characteristics of the chemical reactions and processes involving them. The foregoing suggests that a combined physicochemical study of the compounds $M^IP(As)UO_6 \cdot nH_2O$ is of current interest and desirable.

II. Discovery of the compounds $M^IP(As)UO_6 \cdot nH_2O$

The main element determining the nature of the structure of the compounds $M^IP(As)UO_6 \cdot nH_2O$ is uranium(VI). The crystal structures of compounds of uranium(VI) are on the whole determined by its pronounced tendency to form the O⩲U⩲O structural motif with two extremely strong and axially disposed uranium–oxygen bonds with increased [substantial? (Ed. of Translation)] multiplicity. This structural element is referred to as the uranyl group. The presence of the uranyl group in a compound usually gives rise to a layered structure.[1,2] The other elements — phosphorus, arsenic, and the alkali metal — have less influence on the overall structure. They perform a subsidiary function, 'building up' the structure of the compound and making it electrically neutral. The complex compounds containing uranium(VI) have therefore come to be referred to as the uranium compounds.

Information about the compounds $M^IPUO_6 \cdot nH_2O$ first appeared in the literature at the beginning of the XIXth century. The first studies have been reviewed in two publications.[3,4] These and other investigations (for example, those of Linau[5] and Rimbach[6]), carried out in France and Germany towards the beginning of the XXth century, were descriptive in character and contained no data about any kind of physicochemical measurements.

Scientific interest in the compound $M^IP(As)UO_6 \cdot nH_2O$ was not renewed until the 1930s–1940s in connection with the development of nuclear power. The enormous interest in uranium as a strategic raw material led to a vigorous search during these years for uranium deposits throughout the world. The study of uranium minerals showed that among them there are more than 20 varieties of the so-called phosphate and arsenate mica-like materials having the composition $M^m_{1/m}P(As)UO_6 \cdot nH_2O$, where $M^m_{1/m}$ are univalent or divalent elements.[2,7–14] $HPUO_6 \cdot 4H_2O$ (hydroautunite), $HAsUO_6 \cdot 4H_2O$

(hydrouranospinite), $NaPUO_6 \cdot 3H_2O$ (sodium autunite), $NaAsUO_6 \cdot 3H_2O$ (elvailerite), $KPUO_6 \cdot 3H_2O$ (metaankoleite), and $KAsUO_6 \cdot 3H_2O$ (abernathyite) have been found among the uranium mica-like materials. The corresponding rubidium and caesium compounds have not been found in nature. Naturally, the crude mineral material does not contain the pure individual phases but solid solutions, isomorphously substituted mixtures, and mechanical mixtures with other minerals, i.e. compositions with defective structures.

In order to determine the structure and to investigate the physicochemical characteristics, the compounds $M^IP(As)UO_6 \cdot nH_2O$ with M^I = H, Na, K, or NH_4 have been synthesised. The methods of synthesis, the conditions for isolation from solution, the solubilities, the dehydration conditions, and other properties of the compounds of the elements listed above have been discussed.[3,4,13,15-27] The studies published in the 1950s–1960s are extremely contradictory and approximate and refer solely to uranium(VI) phosphate derivatives.

The next period in the study of the properties of the compounds $M^IP(As)UO_6 \cdot nH_2O$ began in the 1970s and has continued to this day. It is difficult to establish who was the first to note the high proton conductivity of $HPUO_6 \cdot nH_2O$. Most probably this was done simultaneously by different investigators.[26,28,29] The conductivity of $HPUO_6 \cdot nH_2O$, which is 0.2 Ω^{-1} cm^{-1} at 90 °C, proved to be much higher than in the solid proton-containing materials known at the time.[26,29-31] The low solubility, corrosion stability, the ease of mechanical treatment, and the fairly high thermal stability, which are characteristic of crystalline $HPUO_6 \cdot 4H_2O$, make it an extremely promising electrolyte in autonomous electrochemical energy sources. These studies initiated more detailed structural investigations employing different physical methods and aroused interest in the arsenate derivatives of uranium(VI) and alkali metals having similar compositions and structures. In the 1980s, the number of studies devoted to the proton conductivity of $HP(As)UO_6 \cdot 4H_2O$ increased in an avalanche-like fashion. However, because this aspect is outside the scope of the problem with which we are concerned we shall confine ourselves here merely to presenting a brief bibliography[32-44] of the descriptions of the electrophysical properties of the compounds $M^IP(As)UO_6 \cdot nH_2O$. We shall note only that, together with the use in electrochemical energy sources,[44] reports have appeared on the employment of $HP(As)UO_6 \cdot 4H_2O$ as a sensor for the detection of protons,[38] in a solid-state electrochromic display,[40] and in luminescent materials.[45]

Towards the beginning of the 1990s, reports concerning the application of the compounds $M^IM^VUO_6 \cdot nH_2O$, where M^V = vanadium, niobium, tantalum, or antimony, for the fixation of ecologically dangerous radionuclides in order to immobilise them in the human habitat, began to appear.[35,36,46-50]

At the same time, studies were published[52,53] in which it was shown that neptunium(VI), plutonium(VI), and americium(VI) can replace uranium(VI),[51] whilst the lanthanides(III) and the actinides(III) can replace M^I in the compounds $M^IP(As)UO_6 \cdot nH_2O$. Natural and synthetic compounds having the composition $M^{II}_{0.5}P(As)UO_6 \cdot nH_2O$, where M^{II} = an alkaline earth metal or other divalent element, are also known.[54-57]

Comparison of the structural characteristics of the compounds $M^m_{1/m}P(As)UO_6 \cdot nH_2O$, where M^m represents univalent, divalent, or trivalent elements, on the one hand, and the compounds $M^n_{1/n}M^VM^{VI}O_6W \cdot nH_2O$, where M^V = vanadium, niobium, tantalum, or antimony and M^{VI} = neptunium, plutonium, or americium, on the other, showed that all the compounds have a layer structure and probably tend to form mixed crystals. This indicates the possibility of their employment for the retention of a wide range of radionuclides in different valence states in the form of a single thermally and chemically stable crystalline matrix.[52-57]

III. The structure of the compounds $M^IP(As)UO_6 \cdot nH_2O$

Numerous studies have been devoted to problems of the structure of the compounds $M^IP(As)UO_6 \cdot nH_2O$.[2,13,30,51,58-67] However, the functional composition of the compounds is treated in different ways by different investigators. In most reports, the phosphates and arsenates of uranium(VI) and univalent elements are regarded as double salts — disubstituted uranyl phosphates and arsenates having the compositions $UO_2M^IPO_4 \cdot nH_2O$ and $UO_2M^IAsO_4 \cdot nH_2O$. Such representation of the formula unit presupposes the existence of an anionic sublattice, made up of phosphate or arsenate tetrahedra, and a cationic sublattice, the sites of which contain the uranyl groups and the cations of the univalent element. However, such representation of the compounds is more a result of the tradition established by mineralogists in relation to uranium(VI) minerals[2] rather than reflecting the true situation corresponding to the experimental facts.

According to X-ray diffraction data, the uranium in the compound $UO_2HPO_4 \cdot 4H_2O$ [30] is in an octahedral environment comprising oxygen atoms, two of which actually form shortened O⋯U⋯O linkages with an increased multiplicity along one of the fourfold axes and these have in fact been interpreted as isolated uranyl groups UO_2^{2+}. However, the remaining four uranium–oxygen bonds in the octahedron are also distinguished by an appreciable strength and do not permit the isolation of the uranyl group without the disruption of the structure as a whole.

From our point of view, which is shared also by other investigators (see, for example, Weigel and Hoffman[51]), the compounds under consideration should be regarded as salts of phosphouranic and arsenouranic acids $M^IP(As)UO_6 \cdot nH_2O$. In these compounds, phosphorus and uranium or arsenic and uranium form a common anionic framework in the form of two-dimensional layers of the type $[P(As)UO_6]^{n-}_{2\infty}$ distinguished by an increased stability. The cations binding the layers play an appreciably smaller role in the formation of the crystal structure as a whole. They merely promote the imposition of a certain order in the interlayer space, ordering the disposition of the H_2O molecules and regulating their number.

The compounds $M^IP(As)UO_6 \cdot nH_2O$ can hardly be regarded as complex uranium(VI) oxides, because according to current ideas,[68] the cationic and anionic sublattices can be fairly readily isolated in their structures. Such separation is usually difficult in the structure of a complex oxide. Thus the most correct representation of the formula unit in the compounds under consideration is $M^IP(As)UO_6 \cdot nH_2O$, since it reflects most satisfactorily their functional properties and structural characteristics.

Direct structural studies on the compounds $M^IP(As)UO_6 \cdot nH_2O$ by X-ray diffraction and neutron diffractometric methods have been carried out in relation to the $HPUO_6 \cdot 4H_2O$,[30] $HAsUO_6 \cdot 4H_2O$,[60] $LiAsUO_6 \cdot 4H_2O$,[62] $KPUO_6 \cdot 3H_2O$,[61] and $KAsUO_6 \cdot 3H_2O$ [13] single crystals. Analysis of these data showed that the phosphouranic and arsenouranic acids are full structural analogues. As an illustration, Fig. 1 presents the crystal structure of $HPUO_6 \cdot 4H_2O$ in projection onto the 100 and 001 crystallographic planes.[30] According to these data, the structure is of the typical layered type. The uranium(VI) ions are located in an octahedral environment comprising oxygen atoms, two of which form shortened O⋯U⋯O linkages along an axis perpendicular to the $[P(As)UO_6]^{n-}_{2\infty}$ layer. The remaining four oxygen atoms belong to four different tetrahedral phosphate or arsenate groups. Water molecules, linked to one another by hydrogen bonds to form squares, the planes of which are parallel to the plane of the layer, are located between the layers. The centres of the squares are located on axes passing through the 'uranyl' groups. The protons compensating for the negative charge of the layer are located between two nearest water molecules belonging to neighbouring squares. Thus only two water molecules are linked

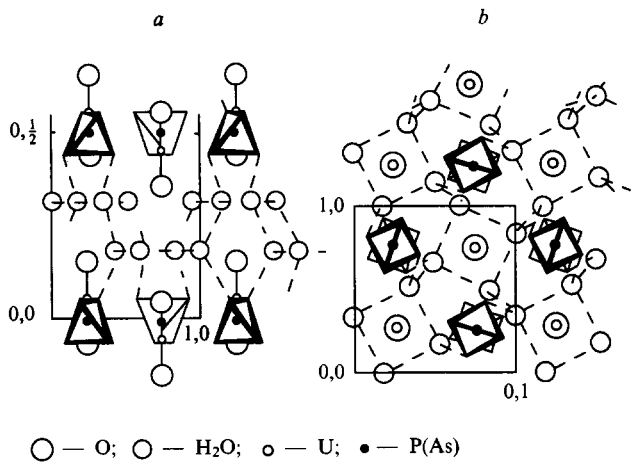

Figure 1. The crystal structure of the compound $HPUO_6 \cdot 4H_2O$ in projection onto the 100 (*a*) and 001 (*b*) planes.

to protons, forming the hydroxonium ions $H_5O_2^+$. Comparison of the crystal structures of the acids $HPUO_6 \cdot 4H_2O$ and $HAsUO_6 \cdot 4H_2O$ as well as the salts $LiAsUO_6 \cdot 4H_2O$, $KPUO_6 \cdot 3H_2O$, and $KAsUO_6 \cdot 3H_2O$ shows that both the hydrogen and salt forms have similar structures of the $[P(As)UO_6]^{n-}_{\infty\infty}$ two-dimensional layer. The differences are manifested only in the positions of the alkali metal cations and the proton. Thus, when the proton is replaced by a lithium ion, no changes are observed in the structure and the number of water molecules is also retained. However, in the case of the larger K^+ ions, the H^+ or Li^+ positions become inaccessible. Therefore, when H^+ is replaced by K^+, the hydroxonium ion H_3O^+ is displaced from the structure and the K^+ cation occupies the position of one of the water molecules. As a result, the potassium salt contains one H_2O molecule less. This substitution mechanism probably operates also in the case of the sodium and rubidium compounds. However, direct structural studies on the above crystal phases have not been carried out. There are only numerous results of X-ray phase analysis and of the indexing of the X-ray diffraction powder patterns comprising the phospho- and arseno-uranate derivatives of hydrogen, lithium, sodium, potassium, and rubidium. The contradictory and ambiguous nature of the available results may be judged by analysing the crystallographic characteristics presented in Table 1 and calculated by different workers. The uncertainty in the available information applies both to the choice of the crystal system and symmetry space group and to the determination of the number of water molecules per formula unit of the compound. There is no information whatever in the literature about the composition and structure of the caesium derivatives.

The X-ray diffraction studies carried out on the $HPUO_6 \cdot 4H_2O$ and $HAsUO_6 \cdot 4H_2O$ single crystals at the beginning of the 1980s elucidated to a large extent the nature and position of the water in the above compounds. During the preceding period, frequent attempts were made to investigate the nature of the water in $M^IP(As)UO_6 \cdot nH_2O$ by means of other methods. One of the early publications[69] describes a simplified treatment of the IR spectra of $HPUO_6 \cdot 4H_2O$, in which bands belonging to the 'uranyl' group were differentiated. Another communication[70] gives a fuller description of the state of water based on the analysis of the IR spectra and it is concluded that the hydroxonium ion $H_9O_4^+$ is present in the $HPUO_6 \cdot 4H_2O$ structure. Kobets et al.,[28] who noted that the proton is localised in the hydroxonium ion, arrived at the same conclusion. It is noteworthy that this was an incorrect conclusion, because the IR spectra quoted in the above communications contained the band due to the deformation vibrations of H_2O in the region of 1625 cm^{-1}. This band shows that a proportion of the water does not belong to hydroxonium ions. Subsequent direct structural studies showed that only two out of the four water molecules are involved in the interaction with the proton, affording a hydroxonium ion of the type $H_5O_2^+$.[60]

Thus one may conclude that the characteristics of the structure and the state of the water molecules in $M^IP(As)UO_6 \cdot nH_2O$ have been established reliably only for a small number of compounds, namely for $HPUO_6 \cdot 4H_2O$, $HAsUO_6 \cdot 4H_2O$, $LiAsUO_6 \cdot 4H_2O$, $KPUO_6 \cdot 3H_2O$, and $KAsUO_6 \cdot 3H_2O$. Only X-ray phase analysis has been carried out for the compounds $NaP(As)UO_6 \cdot 3H_2O$ and $RbP(As)UO_6 \cdot \cdot 3H_2O$, indicating that they may belong to a single structural type. The analogous caesium compounds have not been investigated and there are no reports in the literature about their structure.

Studies on the structures of the crystalline phases of $HPUO_6 \cdot 4H_2O$, $HAsUO_6 \cdot 4H_2O$, and their derivatives with all the alkali metals (including the caesium derivatives which we obtained), carried out at the beginning of the 1990s (Tables 2 and 3), indicate that the X-ray diffraction patterns of all the compounds contain similar sets of reflection maxima with similar p ɔsitions and relative intensities. Lower relative intensities of a series of diffraction peaks and a reduction in the number of the latter have been observed only in the case of $CsPUO_6 \cdot 3H_2O$ and $CsAsUO_6 \cdot 3H_2O$. These findings may be a consequence of the steric strain arising in the crystal lattices after the incorporation in the latter of the large caesium ions.

The analytical indexing of the X-ray powder diffraction patterns presented in Table 4 shows that all the compounds have similar structures and have close unit cell parameters. Analysis of the IR spectra permits a fuller interpretation of the structures of the test compounds. The number of absorption bands, their positions, and their relative intensities are similar in the spectra of all the compounds in each of the series of phosphates and arsenates of the uranium derivatives. They confirm not only the structural similarity but also the similar functional composition and the identical nature of the distortion in the compounds of the principal coordination tetrahedra of phosphorus and arsenic (tetrahedra), uranium(VI) (octahedron), and the alkali metal. The assignment of the absorption bands in the spectra of the compounds $M^IPUO_6 \cdot nH_2O$ and $M^IAsUO_6 \cdot nH_2O$ is presented in Tables 5 and 6. The partial superposition of the stretching vibrations of the arsenate tetrahedron and of the shortened U⋯O⋯U linkages of the UO_6 octahedron in the 800–900 cm^{-1} region does not hinder their assignment because of their highly characteristic nature.

Table 4. The tetragonal unit cell parameters of the compounds $M^IP(As)UO_6 \cdot nH_2O$ (space group $P4/ncc$, $Z = 4$).[71,72]

Compound	a/Å	c/Å
$HPUO_6 \cdot 4H_2O$	6.984 ± 0.001	17.440 ± 0.004
$LiPUO_6 \cdot 4H_2O$	6.945 ± 0.002	18.242 ± 0.013
$NaPUO_6 \cdot 3H_2O$	6.949 ± 0.001	17.154 ± 0.007

$RbPUO_6 \cdot 3H_2O$	6.994 ± 0.002	18.083 ± 0.011
$CsPUO_6 \cdot 3H_2O$	7.005 ± 0.003	17.629 ± 0.014
$HAsUO_6 \cdot 4H_2O$	7.140 ± 0.002	17.594 ± 0.007
$LiAsUO_6 \cdot 4H_2O$	7.149 ± 0.006	17.808 ± 0.012
$NaAsUO_6 \cdot 3H_2O$	7.142 ± 0.002	17.119 ± 0.009
$KAsUO_6 \cdot 3H_2O$	7.172 ± 0.008	18.138 ± 0.042
$RbAsUO_6 \cdot 3H_2O$	7.178 ± 0.005	17.594 ± 0.018
$CsAsUO_6 \cdot 3H_2O$	7.151 ± 0.031	18.374 ± 0.080

The characteristic vibrations of the water of crystallisation can be distinguished in the spectra. The most striking feature is the separation into components of the ν_2 deformation vibration bands of water in the $HPUO_6 \cdot 4H_2O$ and $HAsUO_6 \cdot 4H_2O$ spectra. The ν_2 vibration of water in the $HPUO_6 \cdot 4H_2O$ spectrum at 1637 cm^{-1} is accompanied by a band with an intensity equal to that of the band at 1737 cm^{-1} corresponding to the deformation vibrations of the hydroxonium ion.[74] A similar separation of the ν_2 vibrations into bands at 1626 and 1737 cm^{-1} occurs in the $HAsUO_6 \cdot 4H_2O$ spectrum. The ν_2 doublets with comparable relative intensities permit the assumption that two water molecules form the hydroxonium ion $H_5O_2^+$, while the remaining water molecules retain their molecular individuality.[73]

The ν_2 vibrations of water in the IR spectra of $LiPUO_6 \cdot 4H_2O$ and $LiAsUO_6 \cdot 4H_2O$ are also represented by doublets at 1635 and 1675 cm^{-1} for the first compound and at 1614 and 1659 cm^{-1} for the second. The appearance of the doublets is a consequence of the nonuniformity of the water molecules in the lithium compounds and indicates the isolation of part of the water in the form of complex ions of the type $(H_2OLiOH_2)^+$ owing to the formation of the familiar Li bond. Thus the small size of the H^+ and Li^+ ions and their high electrostatic fields are the cause of the increased content of water molecules in the $HP(As)UO_6 \cdot 4H_2O$ and $LiP(As)UO_6 \cdot 4H_2O$ crystal lattices and are responsible for the incorporation of water molecules in the hydroxonium and 'lyonium' ions. The ν_2 deformation vibration bands of H_2O at 1600 cm^{-1} in the sodium, potassium, rubidium, and caesium compounds indicate the typically molecular form of water.

The ν_1 and ν_3 stretching vibrations of water in the region of 3400 cm^{-1} are not resolved in the spectra of any of the test compounds. They are represented in a broad band due to the presence of branched hydrogen bonds between the molecules of water of crystallisation.

The Cs^+ ions, among alkali metals, are characterised by the highest crystal-chemical radius and an extremely weak force field. Because of this, the X-ray diffraction patterns of the compounds $CsPUO_6 \cdot 3H_2O$ and $CsAsUO_6 \cdot 3H_2O$ reveal the disappearance of a series of diffraction peaks due to steric causes, indicating a degree of structural disorder.

Thus all the compounds considered with the composition $M^IP(As)UO_6 \cdot nH_2O$, where $M^I = H^+$, Li^+, Na^+, K^+, Rb^+, or Cs^+, are individual crystalline phases belonging to a single structural type. The composition of the coordination polyhedra of their structural-forming elements is based on the same principle and they differ from one another only in the number of molecules of water of crystallisation.

IV. Thermographic study of the compounds $M^IP(As)UO_6 \cdot nH_2O$

The presence of water of crystallisation is responsible for important properties of the compounds $M^IP(As)UO_6 \cdot nH_2O$ with a layered structure. The capacity of compounds of this kind for hydration has two characteristic features: the unequal water contents for different alkali metals and the different nature of the water in the compounds under consideration. The same compound from the series considered can exist in states with different susceptibilities to hydration depending on the formation conditions. The number of water molecules changes stepwise on passing from one degree of hydration to another and the nature, location, and the role of water in the structure of each hydrate differ. The stability of a particular hydrate is determined by the size of the alkali metal cation. The removal of water from compounds with different cations under conditions where the water content is the same is accompanied by energy effects of different magnitude. This is associated with the nature of the ordered arrangement of the water molecules in the structure of the compound — their bonds both with the interlayer cation and the uranium phosphate (uranium arsenate) layer and with one another. Water determines in its turn the order in the packing of the anionic uranium layers and its removal leads to a shift of the layers relative to one another. The complete removal of water can lead to maximum disorder and hence to the retention of only two-dimensional order within the limits of the anionic uranium layer.

Despite the fact that the study of the dehydration of a number of the compounds $M^IP(As)UO_6 \cdot nH_2O$ has continued for more than 30 years, information about the temperature ranges in which water is removed is contradictory. Thus according to Karpov and Ambartsumyan,[75] 3.5 water molecules per formula unit are removed from $HPUO_6 \cdot 4H_2O$ in the temperature range 30–180 °C and four water molecules are removed at 230–250 °C. On the other hand, according to Weiss et al.,[76] three water molecules are removed from $HPUO_6 \cdot 4H_2O$ at 60 °C. The removal of 2.5 water molecules from the same compound at 60–70 °C and the removal of total water at 220 °C have been reported.[77] The most complete information about the dehydration of $HPUO_6 \cdot 4H_2O$ has been presented by Kobets and coworkers.[78,79] These results are presented in Table 7.

Table 7. Characteristics of the $HPUO_6 \cdot nH_2O$.[78,79]

Compound	Dehydration temperature range/K	Number of water molecules removed	$\Delta_r H°(T)$/ kJ mol^{-1}
$UO_2HPO_4 \cdot 4H_2O$	323–353	2	51.5 ± 2.5
$UO_2HPO_4 \cdot 2H_2O$	373–388	$\frac{1}{2}$	56.5 ± 3.3
$UO_2HPO_4 \cdot 1\frac{1}{2}H_2O$	443–463	$1\frac{1}{2}$	65.3 ± 2.9
$UO_2HPO_4 \cdot H_2O$	833–873	$\frac{1}{2}$	–

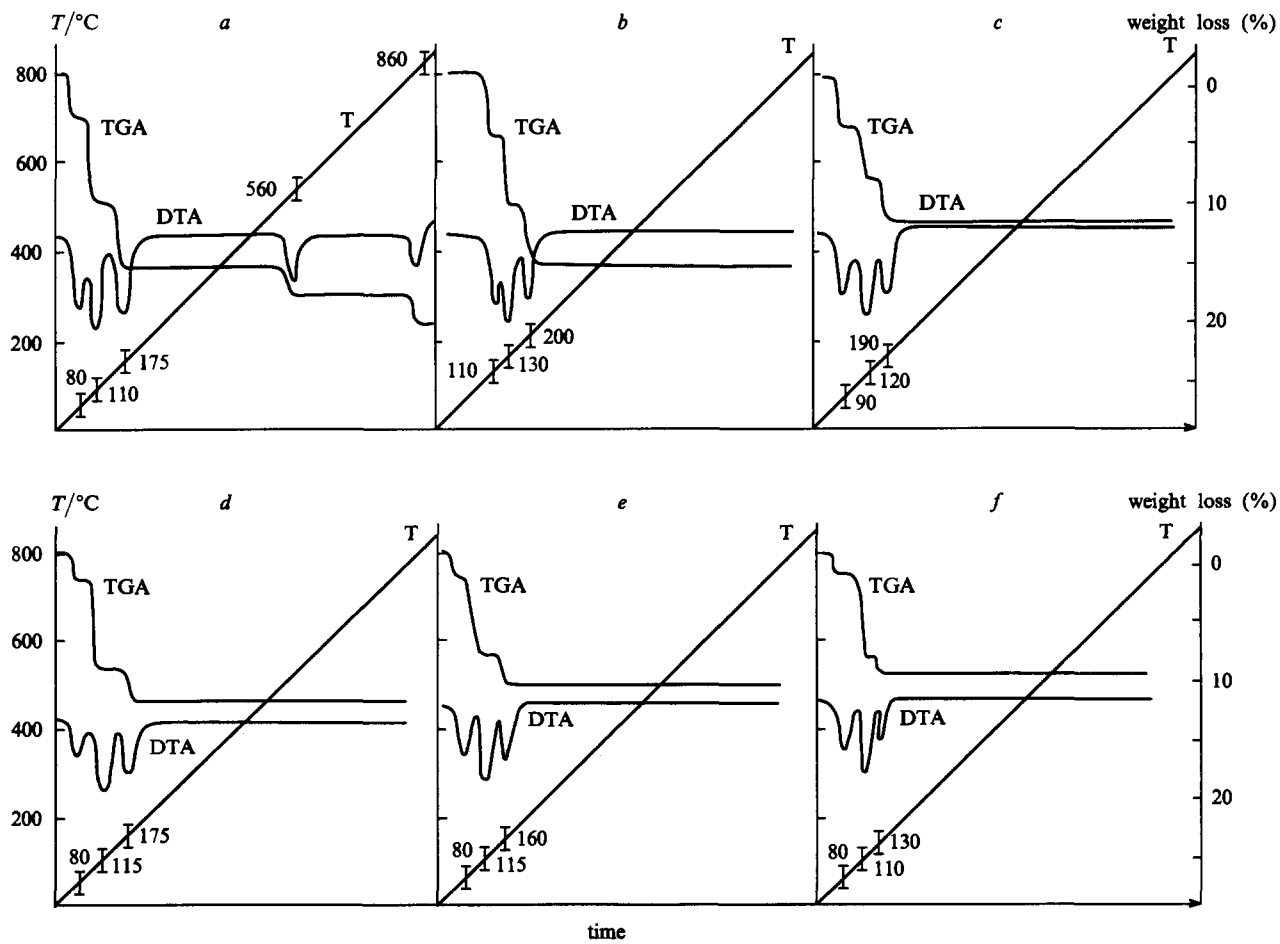

Figure 2. Derivatograms for the compounds $M^IPUO_6 \cdot nH_2O$: (*a*) $HPUO_6 \cdot 4H_2O$; (*b*) $LiPUO_6 \cdot 4H_2O$; (*c*) $NaPUO_6 \cdot 3H_2O$; (*d*) $KPUO_6 \cdot 3H_2O$; (*e*) $RbPUO_6 \cdot 3H_2O$; (*f*) $CsPUO_6 \cdot 3H_2O$.

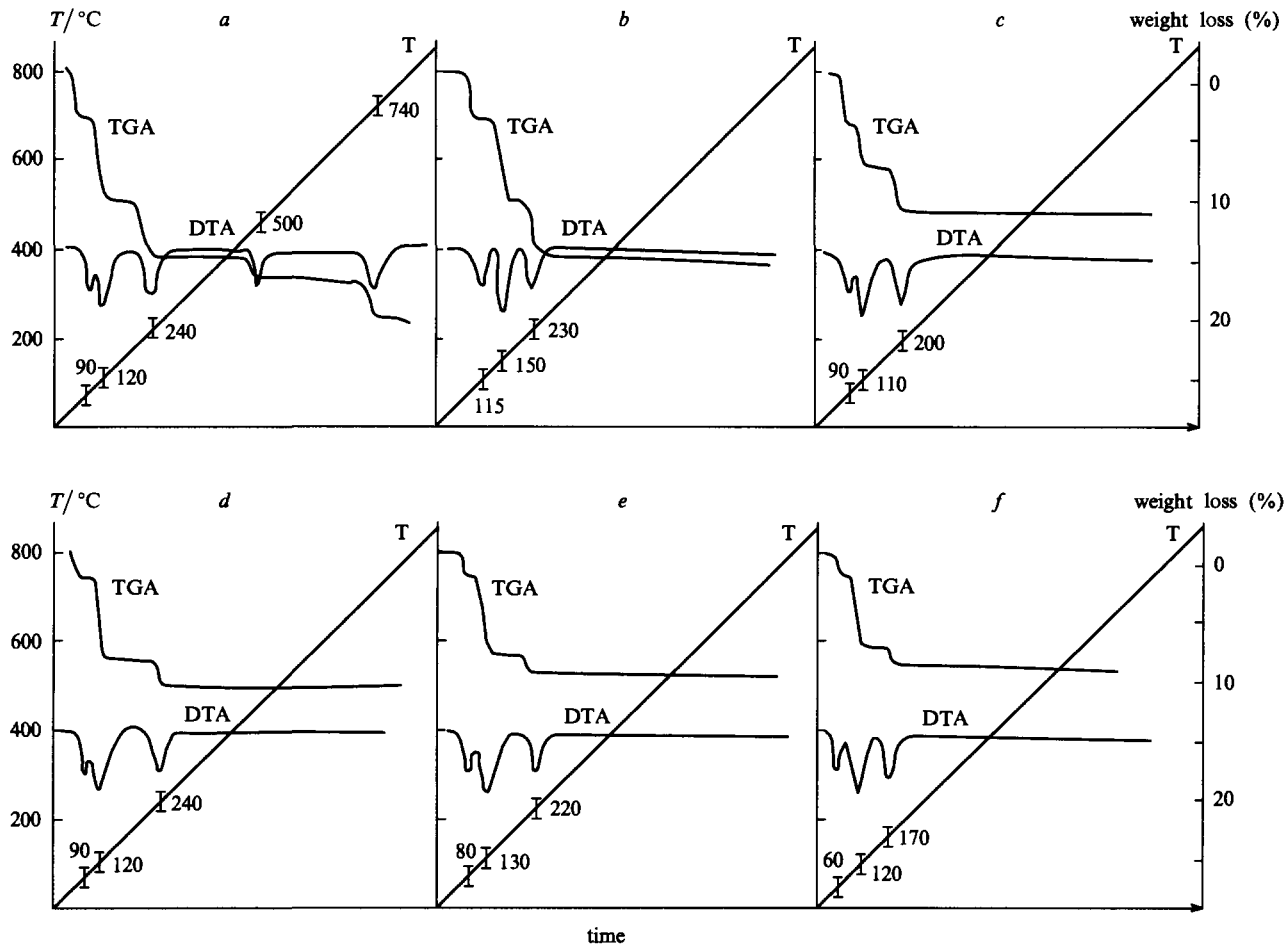

Figure 3. Derivatograms for the compounds $M^IAsUO_6 \cdot nH_2O$: (*a*) $HAsUO_6 \cdot 4H_2O$; (*b*) $LiAsUO_6 \cdot 4H_2O$; (*c*) $NaAsUO_6 \cdot 3H_2O$; (*d*) $KAsUO_6 \cdot nH_2O$; (*e*) $RbAsUO_6 \cdot 3H_2O$; (*f*) $CsAsUO_6 \cdot 3H_2O$.

The results quoted conflict with the data of other workers both as regards the temperature ranges and as regards the number of water molecules removed. However, they make it possible to estimate the enthalpy of the overall dehydration reaction of the crystalline compound $HPUO_6 \cdot 4H_2O$.

$$HPUO_6 \cdot 4H_2O \rightarrow HPUO_6(\text{solid}) + 4H_2O(\text{liq.}) \quad (1)$$

When account is taken of corrections for the enthalpy of vaporisation of water,[80] the enthalpy of the removal of four H_2O molecules calculated in terms of liquid water is $\Delta_r H^\circ_1(298) = 16.7$ kcal mol^{-1} [69.9 kJ mol^{-1}]. The soundest available information (from the scientific point of view) about the dehydration reactions of the compounds $M^IP(As)UO_6 \cdot nH_2O$ is in essence restricted to these results. One may note in addition only isolated studies, carried out at different times, on the dehydration of $LiPUO_6 \cdot 4H_2O$,[3] $NaPUO_6 \cdot 4H_2O$, $NaAsUO_6 \cdot 4H_2O$, $KPUO_6 \cdot 4H_2O$, and $KAsUO_6 \cdot 4H_2O$.[2] However, the different experimental conditions, the uncertainty in the determination of the number of water molecules in the formula units of the same compounds, and the limited number of representatives of the $M^IP(As)UO_6 \cdot nH_2O$ structural series investigated have led to the problem of their dehydration being little studied.

The thermal stability of the compounds $M^IP(As)UO_6 \cdot nH_2O$ has been studied to an even lesser extent. Identical decomposition mechanisms have been put forward only for the compound $HPUO_6 \cdot 4H_2O$ by virtually all the workers who have investigated it (see, for example, Refs 25, 59, 79, and 81). The thermal stabilities of other compounds $M^IP(As)UO_6 \cdot nH_2O$ have not been studied.

The thermographic study of the compounds $M^IP(As)UO_6 \cdot nH_2O$ which we carried out by the derivatographic method combined with X-ray phase analysis of the intermediate and final dehydration thermal decomposition products showed that the acids $HPUO_6 \cdot 4H_2O$ and $HAsUO_6 \cdot 4H_2O$ are thermally least stable.[71-73] In conformity with the derivatograms presented in Figs 2 and 3, their thermal decomposition can be represented by the following reaction:

$$HPUO_6 \cdot 4H_2O \xrightarrow[-H_2O]{80\ ^\circ C} HPUO_6 \cdot 3H_2O \xrightarrow[-2H_2O]{110\ ^\circ C}$$
$$\rightarrow HPUO_6 \cdot H_2O \xrightarrow[-H_2O]{175\ ^\circ C} HPUO_6 \xrightarrow[-\frac{1}{2}H_2O]{560\ ^\circ C}$$
$$\rightarrow \tfrac{1}{2}(UO_2)_2P_2O_7 \xrightarrow[-\frac{1}{2}O_2]{>\ 860\ ^\circ C} \tfrac{1}{2}U_2O_3P_2O_7,$$

$$HAsUO_6 \cdot 4H_2O \xrightarrow[-H_2O]{90\ ^\circ C} HAsUO_6 \cdot 3H_2O \xrightarrow[-2H_2O]{120\ ^\circ C}$$
$$\rightarrow HAsUO_6 \cdot H_2O \xrightarrow[-H_2O]{240\ ^\circ C} HAsUO_6 \xrightarrow[-\frac{1}{2}H_2O]{500\ ^\circ C}$$
$$\rightarrow \tfrac{1}{2}(UO_2)_2As_2O_7 \xrightarrow[-\frac{1}{2}O_2]{740\ ^\circ C} \tfrac{1}{2}U_2O_3As_2O_7.$$

Analysis of the above data shows that the mechanisms of the dehydration and thermal decomposition of both compounds are the same with the sole difference that water is removed from $HAsUO_6 \cdot 4H_2O$ at a higher temperature and requires a larger

energy expenditure. On the other hand, the condensation of the acid group in $HAsUO_6$ takes place with a smaller energy expenditure than in the case of $HPUO_6$. The higher temperature ranges corresponding to the dehydration of $HAsUO_6 \cdot 4H_2O$ compared with $HPUO_6 \cdot 4H_2O$, despite their analogous composition and total structural similarity, may be due to the coordinative unsaturation of the arsenic in the AsO_4 polyhedron, which results in a redistribution of the electron density in the As ← O ← H chains, strengthening the hydrogen bonds. This property of arsenic(V) is characteristic of many arsenates[82] and is manifested even in As_2O_5, in the crystal lattice of which 50% of the arsenic atoms are involved in tetrahedral coordination, whilst the remaining 50% are involved in octahedral coordination,[77] which is completely uncharacteristic of oxygen compounds of phosphorus.

The higher temperatures of the condensation of the acid phosphate groups with formation of pyrophosphates are entirely reasonable and are a consequence of the coordinative saturation of the phosphorus in the PO_4 tetrahedron, which is responsible for the stability of the latter.

The compounds $M^IP(As)UO_6 \cdot nH_2O$, where M^I = Li, Na, K, Rb, or Cs, are distinguished by a higher thermal stability compared with the corresponding acids. After the multistage removal of molecular water, they all have the composition $M^IP(As)UO_6$. However, the elimination of water molecules from the coordination environment of the alkali metal cation leads to the disruption of the coordination polyhedron of the latter and to the breakdown of the structure of the compounds as a whole. The dehydration reactions of $M^IPUO_6 \cdot nH_2O$ and $M^IAsUO_6 \cdot nH_2O$ are presented below (Scheme 1).

Several trends are manifested in the dehydration reactions of the compounds $M^I(P)AsUO_6 \cdot nH_2O$, where M^I = H, Li, Na, K, Rb, or Cs, presented in Scheme 1. Firstly, the dehydration reactions of the phosphouranate and arsenouranate compounds of the same univalent element have the same stages. Secondly, lower temperature ranges of the dehydration reaction are characteristic of the phosphouranate derivatives, which may be a consequence of the weaker binding of water in these compounds. Thirdly, the temperature ranges of the dehydration reactions decrease on passing from lithium to caesium derivatives of both phosphouranate and arsenouranate compounds. This effect corresponds to a decrease in the enthalpies of dehydration of the alkali metal ions with increase in their size and indicates the inclusion of water molecules in the coordination environment of the univalent elements. Fourthly, the condensation of the acid groups in $HAsUO_6$ takes place with smaller energy expenditures than happens in the case of $HPUO_6$. This difference may be due to the coordinative unsaturation of the arsenic in the AsO_4 tetrahedron, which is the reason for its lower stability.

In connection with the thermal decomposition, it is necessary to consider yet another feature mentioned above. The complete dehydration of the compounds $M^IP(As)UO_6 \cdot nH_2O$ leads to their conversion into an amorphous form, i.e. to the breakdown of the long-range order and hence to the appearance of disorder in the crystal lattice. This is an extremely important feature because it involves a change in the energy state of the compounds and should influence their standard enthalpies of formation. The question arises of the reason for such conversion into an amorphous form. Direct structural studies on $KAsUO_6 \cdot 3H_2O$,[13] $KPUO_6 \cdot 3H_2O$,[61] and $LiAsUO_6 \cdot 4H_2O$ [62] single crystals have shown that the coordination environment of the alkali metal atoms includes the oxygen of the water of crystallisation. Since the oxygen atoms of the molecular water occupy the so-called crystallographic sites in the structure of the compounds, the removal of water leads to the disruption of the coordination polyhedra of the univalent elements and to the disordering of the structure as a whole. The possibility of the appearance of a new coordination environment around the alkali metal atoms is significantly hindered because the oxygen atoms present in the compounds $M^IP(As)UO_6$ now belong to the uranium octahedra and the phosphorus (arsenic) tetrahedra and are very rigidly fixed in the structure. As a result of this, instead of the stable lattice of the crystalline hydrate $M^IP(As)UO_6 \cdot nH_2O$, the less stable structure of the anhydrous compound with a highly polarised $M^{\delta+}[P(As)UO_6]^{\delta-}$ bond, similar to that which occurs in ionic melts, appears.

Scheme 1

$$LiPUO_6 \cdot 4H_2O \xrightarrow[-H_2O]{110\ ^\circ C} LiPUO_6 \cdot 3H_2O \xrightarrow[-2H_2O]{130\ ^\circ C} LiPUO_6 \cdot H_2O \xrightarrow[-H_2O]{200\ ^\circ C} LiPUO_6,$$

$$NaPUO_6 \cdot 3H_2O \xrightarrow[-H_2O]{90\ ^\circ C} NaPUO_6 \cdot 2H_2O \xrightarrow[-2H_2O]{120\ ^\circ C} NaPUO_6 \cdot H_2O \xrightarrow[-H_2O]{190\ ^\circ C} NaPUO_6,$$

$$KAsUO_6 \cdot 3H_2O \xrightarrow[-\frac{1}{2}H_2O]{90\ ^\circ C} KAsUO_6 \cdot 2.5H_2O \xrightarrow[-2H_2O]{120\ ^\circ C} KAsUO_6 \cdot 0.5H_2O \xrightarrow[-\frac{1}{2}H_2O]{240\ ^\circ C} KAsUO_6,$$

$$RbAsUO_6 \cdot 3H_2O \xrightarrow[-\frac{1}{2}H_2O]{80\ ^\circ C} RbAsUO_6 \cdot 2.5H_2O \xrightarrow[-2H_2O]{130\ ^\circ C} RbAsUO_6 \cdot 0.5H_2O \xrightarrow[-\frac{1}{2}H_2O]{220\ ^\circ C} RbAsUO_6,$$

$$CsAsUO_6 \cdot 3H_2O \xrightarrow[-\frac{1}{2}H_2O]{60\ ^\circ C} CsAsUO_6 \cdot 2.5H_2O \xrightarrow[-2H_2O]{120\ ^\circ C} CsAsUO_6 \cdot 0.5H_2O \xrightarrow[-\frac{1}{2}H_2O]{170\ ^\circ C} CsAsUO_6.$$

V. Thermodynamic properties of the compounds $M^IP(As)UO_6 \cdot nH_2O$

Before our investigations, there were virtually no literature data concerning the determination of the standard thermodynamic functions of formation of the compounds $M^IP(As)UO_6 \cdot nH_2O$. Attempts have been made in a number of studies[5,16,17,75,83-85] to calculate the standard Gibbs free energies of formation of a series of compounds of this type at 298.15 K ($\Delta_fG°$, kJ mol^{-1}) from the solubility products (K_s) in aqueous solutions. The calculation was based on the idea that the following equilibria exist at the precipitate $\rightleftharpoons$ solution interface:

$$HP(As)UO_6 \cdot 4H_2O\,(cryst.) \rightleftharpoons UO_2^{2+}\,(soln) + HP(As)O_4^{2-}\,(soln) + 4H_2O, \quad (2)$$

$$M^IP(As)UO_6 \cdot nH_2O\,(cryst.) \rightleftharpoons M^+(soln) + UO^{2+}(soln) + P(As)O^{3-}(soln) + nH_2O, \quad (3)$$

where M^I are alkali metals.

Bearing in mind the low concentration of ions in solution and assuming that the activity of the solid phase is unity, one can postulate that the equilibrium constants of reactions (2) and (3) are equal to the solubility products of the corresponding compounds. Then we have

$$\Delta_rG^\circ_{2,3}(298) = 298.15 \times 8.314 \times \ln K_s/J.$$

The solubility products K_s of the compounds are listed in Table 8.

Table 8. The solubility products (K_s) of certain compounds $M^IP(As)UO_6 \cdot nH_2O$.

Compound	K_s	Ref.
$HPUO_6 \cdot 4H_2O$	2.14×10^{-11}	20, 23, 27
$HAsUO_6 \cdot 4H_2O$	3.17×10^{-11}	17
$LiPUO_6 \cdot 4H_2O$	2.4×10^{-26}	3, 21
$LiAsUO_6 \cdot 4H_2O$	1.5×10^{-19}	17
$NaPUO_6 \cdot 4H_2O$	6.4×10^{-24}	21, 27
$NaAsUO_6 \cdot 3H_2O$	1.35×10^{-22}	17
$KPUO_6 \cdot 3H_2O$	8×10^{-24}	21, 23, 27
$KAsUO_6 \cdot 3H_2O$	2.25×10^{-23}	17
$RbPUO_6 \cdot 3H_2O$	1×10^{-27}	21, 27

Table 9 presents the [standard] free energies [of formation] $\Delta_fG°(298)$ for a series of compounds calculated from the following relations:

$$\Delta_fG°[298,\ HP(As)UO_6 \cdot 4H_2O,\ cryst.] = \Delta_fG°(298, UO_2^{2+}, soln) + \Delta_fG°[298, HP(As)O_4^{2-}, soln] + 4\Delta_fG°(298,\ H_2O,\ liq.) + RT\ln K_s,$$

$$\Delta_fG°[298,\ M^IP(As)UO_6 \cdot nH_2O,\ cryst.] = \Delta_fG°(298, M^{I+}, soln) + \Delta_fG°(298, UO_2^{2+}, soln) + \Delta_fG°[298, P(As)O_4^{3-}, soln] + n\Delta_fG°(298, H_2O, liq.) + RT\ln K_s.$$

Langmuir[85] calculated the standard enthalpies of formation of $NaPUO_6$ (−2536 kJ mol^{-1}) and $KPUO_6$ (−2561 kJ mol^{-1}) from $\Delta_fG°(298)$ and the standard entropy of formation evaluated by the method of contributions. It is noteworthy that these values can be regarded as only estimates. For this reason, in the subsequent sections of the review we shall deal in greater detail with the determination of the standard enthalpies of formation of the compounds $M^IP(As)UO_6 \cdot nH_2O$ and their dehydration products.†

VI. Standard enthalpies of formation of the compounds $M^IP(As)UO_6$ and their crystalline hydrates

Detailed schemes for the determination of the standard enthalpies of formation of the compounds $M^IP(As)UO_6$, where M^I = H, Li, Na, K, Rb, or Cs, and their crystalline hydrates having the general formula $M^IP(As)UO_6 \cdot nH_2O$, where n = 4 for M^I = H or Li and n = 3 for M^I = Na, K, Rb, or Cs, have been put forward.[87-96] In the present review, we shall therefore consider only the general approach to the solution of the problem in relation to the calculation of the standard enthalpies of formation $\Delta_fH°(298)$ of the compounds $M^IP(As)UO_6$, where M^I = Li, Na, K, Rb, or Cs.

The standard enthalpies of the following processes were determined in an adiabatic calorimeter:

$$[KH_2P(As)O_4\,(cryst.) + UO_3\,(cryst.) + M^INO_3\,(cryst.)] + 4HF\,(soln) \rightarrow KF\,(soln) + UO_2F_2\,(soln) + M^IF\,(soln) + H_3PO_4\,(soln) + HNO_3\,(soln) + H_2O, \quad (4)$$

$$[M^IP(As)UO_6\,(solid) + KNO_3\,(cryst.)] + 4\,HF\,(soln) \rightarrow KF\,(soln) + M^IF\,(soln) + UO_2F_2\,(soln) + H_3PO_4\,(soln) + HNO_3\,(soln). \quad (5)$$

The design of the calorimeter and its use have been described in detail.[97] The standard enthalpies of reactions (4) and (5) are presented in Table 10.

The reactant ratios in reactions (4) and (5) were constant at 1 mol of the mixture: 260 mol of HF : 800 mol of H_2O.

† We carried out these investigations in 1990-1994, but unfortunately they cannot be compared with any other data because of the lack of the latter in the literature.

Cs	58.8 ± 2.4	107.0 ± 1.0	25.2 ± 1.0	89.5 ± 1.4

When Eqn (5) is subtracted from Eqn (4), we arrive at the following process:

$$KH_2P(As)O_4\,(cryst.) + UO_3\,(cryst.) + M^INO_3\,(cryst.) \rightarrow M^IP(As)UO_6\,(solid) + KNO_3 + H_2O\,(liq.), \quad (6)$$

the standard enthalpy of which is $\Delta_r H^\circ_6(298) = \Delta_f H^\circ_4(298) - \Delta_r H^\circ_5(298)$ according to Hess's law.

On the other hand, the quantity $\Delta_r H^\circ_6(298)$ is equal to the algebraic sum of the $\Delta_r H^\circ(298)$ of all the participants in reaction (6). The standard enthalpies of formation of the compounds investigated (Table 12) can then be calculated from the quantities $\Delta_r H^\circ_6(298)$ and the literature values of the standard enthalpies of formation of the corresponding reactants (Table 11).

Table 11. The standard enthalpies of formation of the reactants in reaction (6) at 298.15 K.

The following additional experiments were performed in order to test the results. Firstly, the enthalpies of reactions (4) and (5) were determined for two other reactant ratios (1 mol of mixture : 130 mol of HF and 1 mol of mixture : 520 mol of HF). It was established that the enthalpies $\Delta_r H^\circ_{4,5}(298)$ are independent of the molar reactant ratio within experimental error (1.5%–3.0%). Secondly, the enthalpies of reactions (4) and (5) were determined for two acids participating in the reaction — HF and HCl. It was established that the enthalpies of reaction (6) are identical within experimental error. This is in fact the reason why the products of reactions (4) and (5) are indicated as the most probable. Their chemical nature may be different but the important feature is that they are the same in the corresponding pairs of reactions.

Analysis of the results shows that reactions (4) and (5) are exothermic (Table 10); the absolute values of $\Delta_r H^\circ_4(298)$ for both phosphorus and arsenic compounds decrease on passing from lithium to caesium. Such variation of the enthalpies of the above processes in the series of alkali metals can be accounted for as follows.

Since the participants in reaction (4) — phosphorus or arsenic derivatives — differ only in the chemical nature of the alkali metal nitrate (M^INO_3) and the alkali metal ion in solution [$M^IF(soln) \rightleftharpoons M^+ + F^-$], the changes in the overall enthalpies $\Delta_r H^\circ_4(298)$ in the direction Li → Na → K → Rb → Cs are caused by the different crystal lattice energies of M^INO_3 and the different hydration energies of the M^+ ions in solution. The first term is always positive (endothermic process), diminishing on passing from lithium to caesium. Thus the endothermicity of this stage of the overall process (4) should decrease in the direction Li → Cs. On the other hand, the hydration of the M^+ ions in aqueous solutions is an exothermic process. With increase in the ionic radius of M^+, the hydration enthalpy diminishes (the exothermicity decreases in the direction Li → Cs). The experimental data therefore permit the following conclusions: the overall enthalpy $\Delta_r H^\circ_4(298)$ is negative, because the term associated with the enthalpy of hydration of the M^+ ions in aqueous solution exceeds the energy of the disruption of the M^INO_3 crystal lattice; the decrease in the absolute enthalpy of hydration of the M^+ on passing from lithium to caesium is the decisive factor governing the decrease in the exothermicity of the overall process (4) in the same direction.

The variation of the overall enthalpies $\Delta_r H^\circ(298)$ of reactions (5) can be accounted for similarly. The reactions differ only in the chemical nature of $M^IP(As)UO_6$ and the M^+ ion in aqueous solution.

The linear variation of the enthalpies of reactions (4) and (5) with increase in the ionic radius (r) of the alkali metal or with decrease in the hydration enthalpy [$\Delta_h H^\circ(298, M^+, soln)$] of the alkali metal ion in aqueous solution can be accounted for by the same causes. The corresponding relations assume the form

$$\Delta_r H^\circ(298) = a + b(X),$$

where X is a characteristic of the alkali metal or its ion (ionic radius, enthalpy of hydration). The quantities r and $\Delta_h H^\circ$ for alkali metals are presented in Table 13 and the coefficients a and b are listed in Table 14.

The significantly lower exothermicity of reactions (4) and (5) involving the same alkali metal in phosphorus compounds compared with arsenic compounds can be explained in the following manner. As a consequence of the greater, compared with arsenic, coordinative saturation of phosphorus in the oxygen compounds, the effective charge on the alkali metal atom is lower, which leads ultimately to an increase in the K–O bond energy in KH_2PO_4 [reaction (4)] or the M^I–O bond energy in M^IPUO_6 [reaction (5)] compared with the analogous arsenic compounds. On the other hand, the higher effective charge of the AsO_4^{3-} ion compared with PO_4^{3-} is responsible for the higher energy of dehydration of the AsO_4^{3-} ion in aqueous solution. Allowance for

Table 13. The characteristics X of the alkali metal according to Glushko and Pauling.[84,101]

M^I	r/Å	$\Delta_h H^\circ(M^+)$/ kJ mol^{-1}	$\Delta_f H^\circ(M^+)$/ kJ mol^{-1}	I_1/ eV[a]

Table 14. The coefficients a and b in the equations $\Delta_r H°(298) = a + bX$ for reactions (4) and (5).[103]

X	a		b	
	phosphates	arsenates	phosphates	arsenates
Reaction (4)				
r/Å	−122.8	−154.0	41.57	28.8
$\Delta_h H°(298, M^+, soln)$/ kJ mol^{-1}	−0.90	−71.12	0.188	0.126
Reaction (5)				
r/Å	−99.31	−152.3	47.32	38.16
$\Delta_h H°(298, M^+, soln)$/ kJ mol^{-1}	39.46	−43.53	0.214	0.165

these two factors actually makes it possible to understand the greater exothermicity of reactions (4) and (5) for the same alkali metal in the case of the arsenic compounds compared with the phosphorus compounds (Table 10).

The greater stability of the M^IPUO_6 structure compared with the M^IAsUO_6 structure is manifested by the fact that the absolute values of $\Delta_f H°(298)$ for the phosphorus compounds are higher than the corresponding values for the arsenic compounds. For all the alkali metals investigated (M^I = Li, Na, K, Rb, or Cs), the difference $\Delta_f H°(298, M^IAsUO_6) - \Delta_f H°(298, M^IPUO_6) = 400 \pm 5$ kJ mol^{-1} is virtually constant.

The absolute values of $\Delta_f H°(298)$ for the phosphorus and arsenic compounds exhibit a distinct tendency to increase in the direction Na → K → Rb → Cs. The linear relations $\Delta_f H°(298) = a + bX$, where X is a characteristic of the alkali metal, have been established. The corresponding coefficients a and b are presented in Table 15.

Table 15. The coefficients in the equation $\Delta_f H°(298) = a + bX$.

Analogous schemes have been used to calculate the standard enthalpies of formation of the crystalline compounds of the $M^IP(As)UO_6 \cdot nH_2O$ series (Table 16).

Table 16. The standard enthalpies of formation of the compounds $M^IP(As)UO_6 \cdot nH_2O$.[90,91]

Compound	$-\Delta_f H°(298)$/ kJ mol^{-1}	Compound	$-\Delta_f H°(298)$/ kJ mol^{-1}
$HPUO_6 \cdot 4H_2O$	3473 ± 8	$HAsUO_6 \cdot 4H_2O$	3086 ± 7
$LiPUO_6 \cdot 4H_2O$	3707 ± 9	$LiAsUO_6 \cdot 4H_2O$	3311 ± 8
$NaPUO_6 \cdot 3H_2O$	3392 ± 9	$NaAsUO_6 \cdot 3H_2O$	2998 ± 8
$KPUO_6 \cdot 3H_2O$	3413 ± 8	$KAsUO_6 \cdot 3H_2O$	3022 ± 8
$RbPUO_6 \cdot 3H_2O$	3412 ± 9	$RbAsUO_6 \cdot 3H_2O$	3023 ± 7
$CsPUO_6 \cdot 3H_2O$	3423 ± 11	$CsAsUO_6 \cdot 3H_2O$	3030 ± 7

For example, the enthalpies of the reactions of equimolecular mixtures of $M^IAsUO_6 \cdot nH_2O$ and potassium nitrate with an aqueous solution at HF at 298.15 K have been determined for the ratios 1 mol of the mixture : 260 mol of the HF : 800 mol of H_2O.[91]

$$[M^IAsUO_6 \cdot nH_2O(\text{cryst.}) + KNO_3(\text{cryst.})] + 4HF(\text{soln}) \rightarrow KF(\text{soln}) + M^IF(\text{soln}) + UO_2F_2(\text{soln}) + H_3P(As)O_4(\text{soln}) + HNO_3(\text{soln}) + nH_2O \quad (7)$$

Subtraction of Eqn (7) from Eqn (4) yields the process

$$KH_2AsO_4(\text{cryst.}) + UO_3(\text{cryst.}) + M^INO_3(\text{cryst.}) + (n-1)H_2O \rightarrow M^IAsUO_6 \cdot nH_2O(\text{cryst.}) + KNO_3(\text{cryst.}), \quad (8)$$

the enthalpy of which $\Delta_r H°_8(298) = \Delta_r H°_4(298) - \Delta_r H°_7(298)$. The enthalpies $\Delta_f H°(298)$ for the crystalline hydrates investigated can be calculated from the values of $\Delta_r H°_8(298)$ and the standard enthalpies of formation of the corresponding reactants (Table 10).

$$\Delta_f H°(298, M^IAsUO_6 \cdot nH_2O, \text{cryst.}) = +\Delta_r H°_8(298) + \Delta_f H°(298, KH_2AsO_4, \text{cryst.}) + \Delta_f H°(298, UO_3, \text{cryst}) + \Delta_f H°(298, M^INO_3, \text{cryst.}) + (n-1)\Delta_f H°(298, H_2O, \text{liq.}) - \Delta_f H°(298, KNO_3).$$

Analysis of the quantities presented in Table 16 permits the following conclusions: the enthalpies $\Delta_f H°(298)$ for the phosphorus derivatives are greater in absolute magnitude, as in the case of anhydrous compounds, than the corresponding values for the arsenic derivatives. For all the alkali metals investigated, the difference $\Delta_f H°[298, M^IAsUO_6(\text{cryst.})] - \Delta_f H°[298, M^IPUO_6(\text{cryst.})]$ is almost constant and equal to 393 ± 3 kJ mol^{-1}; in the series of phosphorus and arsenic derivatives, the absolute value of $\Delta_f H°$ increases in the direction Na → K → Rb → Cs; the linear relations $\Delta_f H°[298, M^IP(As)UO_6 \cdot nH_2O] = a + bX$ have been established (Table 17); in the series of the phosphorus and arsenic compounds (M^I = Na, K, Rb, Cs), the difference between the enthalpies $\Delta_f H°(298)$ for the anhydrous compounds and their crystalline hydrates $\Delta_f H°[298, M^IP(As)UO_6] - \Delta_f H°[298, M^IP(As)UO_6 \cdot 3H_2O]$ per mole of the water of crystallisation is virtually constant and equal to 293 ± 3 kJ (mol H_2O)$^{-1}$; the analogous difference in the case of the hydrogen and lithium compounds is also constant but it exceeds the above value, i.e. $\Delta_f H°[298, M^IP(As)UO_6] - \Delta_f H°[298, M^IP(As)UO_6 \cdot 4H_2O] = 300 \pm 4$ kJ (mol H_2O)$^{-1}$, which emphasises yet again the stronger binding of the water of crystallisation in the hydrogen and lithium derivatives compared with other Group I elements.

Table 17. The coefficients in the equations $\Delta_f H°[298, M^IP(As)UO_6 \cdot 3H_2O, \text{cryst.}] = a + bX$ (M^I = Na, K, Rb, Cs).

1. The enthalpies of the dehydration reactions of the compounds $M^IP(As)UO_6 \cdot nH_2O$

We shall examine the methods for the determination of the enthalpies of dehydration of the test compounds in relation to the phosphorus derivatives.

The enthalpies of the reactions of M^IPUO_6 or their crystalline hydrates with an aqueous solution of hydrofluoric acid have been determined calorimetrically.

$$M^IPUO_6(\text{solid}) + 3HF(\text{soln}) \rightarrow M^IF(\text{soln}) + UO_2F_2(\text{soln}) + H_3PO_4(\text{soln}), \quad (9)$$

$$M^{I}PUO_6 \cdot nH_2O\,(cryst.) + 3HF\,(soln) \rightarrow$$
$$\rightarrow M^{I}F\,(soln) + UO_2F_2\,(soln) + H_3PO_4\,(soln) \cdot nH_2O. \quad (10)$$

Subtraction of Eqn (9) from Eqn (10) yields the dehydration process [see Eqn (1)], the enthalpy of which is equal to the difference $\Delta_r H^\circ_{10}(298) - \Delta_r H^\circ_9(298)$ (Table 18).

Table 18. The standard enthalpies of reactions (1), (7), (9), and (10) (the $\Delta_r H^\circ$ are expressed in kJ mol^{-1}).[87,90]

M^I	$-\Delta_r H^\circ_9(298)$	$-\Delta_r H^\circ_{10}(298)$	$-\Delta_r H^\circ_1(298)$	$-\Delta_r H^\circ_7(298)$
H	65.5 ± 1.0	9.63 ± 0.08	53.8 ± 1.1	–

Na	77.9 ± 0.3	58.4 ± 0.6	19.5 ± 0.9	85.4 ± 1.4
K	59.7 ± 0.6	43.0 ± 0.1	16.7 ± 0.7	75.1 ± 1.2
Rb	57.8 ± 0.3	44.4 ± 0.3	13.4 ± 0.6	74.7 ± 0.5
Cs	55.8 ± 0.2	45.2 ± 0.2	10.6 ± 0.4	72.7 ± 0.5

Since all the crystalline hydrates investigated differ in the amount of water of crystallisation, Table 19 presents the enthalpies of the dehydration reactions per mole of water evolved.

The higher binding energy of the water of crystallisation in the $M^{I}AsUO_6 \cdot nH_2O$ structures compared with $M^{I}PUO_6 \cdot nH_2O$ is striking. This happens despite their analogous functional composition and complete structural similarity, including identical locations of the water molecules around the univalent element. These results are fully consistent with the thermographic determinations of the temperature ranges in the stage-by-stage and complete elimination of water from the phosphorus and arsenic compounds (see Section IV). The cause of these differences, which consists in the unequal coordination capacities of phosphorus(V) and arsenic(V), was investigated in detail by the present authors in an earlier study.

Table 19. The enthalpies of the dehydration reaction[103] $(1/n)M^{I}P(As)UO_6 \cdot nH_2O(cryst.) \rightarrow (1/n)M^{I}P(As)UO_6\,(solid) + H_2O\,(liq.)$.

Compound	$-\Delta_r H^\circ(298)$/ kJ mol^{-1}	Compound	$-\Delta_r H^\circ(298)$/ kJ mol^{-1}

$RbPUO_6 \cdot 3H_2O$	4.5	$RbAsUO_6 \cdot 3H_2O$	7.0
$CsPUO_6 \cdot 3H_2O$	3.5	$CsAsUO_6 \cdot 3H_2O$	5.5

The significantly higher energy of the dehydration of the hydrogen forms compared with their salt analogues confirms the nonequivalent nature of the water in compounds $HP(As)UO_6 \cdot 4H_2O$, which is indicated by the results of an IR spectroscopic study of these compounds (see Section III). It has also been established that the decrease in the enthalpy of dehydration of the crystalline hydrates $M^{I}P(As)UO_6 \cdot nH_2O$ in the series of alkali metal compounds is equivalent to the decrease in this series of the enthalpies of dehydration (in kJ mol^{-1}) of the ions of the corresponding elements in aqueous solution:

$$\Delta_r H^\circ(298) = [-3.5 + 0.0245\Delta_h H^\circ(298,\ M^+,\ soln) \pm 0.2];$$

for the phosphates;

$$\Delta_r H^\circ(298) = [-3.0 + 0.0305\Delta_h H^\circ(298,\ M^+,\ soln) \pm 0.2].$$

for the arsenates.

2. Enthalpies of ion-exchange reactions

The substitution of a proton in the compounds $HP(As)UO_6 \cdot 2H_2O$ by alkali metal ions constitutes the basis of the synthesis of the crystalline compounds $M^{I}P(As)UO_6 \cdot nH_2O$. Knowledge of the energy relations governing the ion-exchange reactions is therefore necessary.

The standard enthalpies of the exchange reactions

$$M^+(soln) + HP(As)UO_6 \cdot 4H_2O$$
$$\rightleftharpoons M^{I}P(As)UO_6 \cdot nH_2(cryst) + H^+(soln) + (4-n)H_2O, \quad (11)$$

were calculated from the standard enthalpies of formation of the crystalline hydrates (Table 6) and the literature values of the standard enthalpies of formation of alkali metal ions in aqueous solution. The results are presented in Table 20.

Table 20. The ionic radii and standard enthalpies of formation of alkali metal ions and the standard enthalpies of reaction (11).[96]

M^I	R/A	$-\Delta_r H^\circ(M^+)$/ kJ mol^{-1}	$\Delta_r H^\circ_{11}(298)$/kJ mol^{-1}	
			$M^{I}PUO_6 \cdot nH_2O$	$M^{I}AsUO_6 \cdot nH_2O$
Li^+	1.28	278.45 ± 0.21	44.5	54.5
Na^+	1.61	240.41 ± 0.13	35.5	42.5
K^+	2.01	252.25 ± 0.13	26.5	30.5
Rb^+	2.17	251.04 ± 0.13	26.0	28.5
Cs^+	2.42	255.56 ± 0.13	22.5	28.5

The standard enthalpies of the ion-exchange reactions presented are positive i.e. the above processes proceed with absorption of energy. The enthalpies $\Delta_r H^\circ(298)$ decrease on passing from lithium to caesium in the series of alkali metals. In order to establish the causes of such variation, we shall consider the energy relations for the ion-exchange reactions in greater detail.

The overall enthalpy of the ion-exchange reactions can be represented by the following terms:

$$\Delta_r H^\circ = \Delta H^\circ_{M^+} + \Delta \bar{H}^\circ_{M^+} + \Delta H^\circ_{H^+} + \Delta \bar{H}^\circ_{H^+} + \Delta H^\circ_{O-H}$$
$$+ \Delta H^\circ_{O-M} + \Delta H^\circ_{lat}, \quad (12)$$

where $\Delta H^\circ_{M^+}$ is the enthalpy of hydration of the M^+ ion in the crystalline $M^{I}P(As)UO_6 \cdot nH_2O$ phase, $\Delta \bar{H}^\circ_{M^+}$ is the enthalpy of dehydration of the M^+ ion in solution, $\Delta H^\circ_{H^+}$ is the enthalpy of hydration of the proton in solution, $\Delta \bar{H}^\circ_{H^+}$ is the enthalpy of dehydration of the proton in the crystalline $HP(As)UO_6 \cdot 4H_2O$ phase, ΔH°_{O-H} is the enthalpy of dissociation of the O–H bond in the crystalline $HP(As)UO_6 \cdot 4H_2O$, ΔH°_{O-M} is the enthalpy of formation of the O–M bond in the crystalline $M^{I}P(As)UO_6 \cdot nH_2O$ phase, and ΔH°_{lat} is the enthalpy of the disruption of the $HP(As)UO_6 \cdot 4H_2O$ crystal lattice and of the formation of the $M^{I}P(As)UO_6 \cdot nH_2O$ crystal lattice.

During the ion-exchange reaction, dehydration of the M^+ ion takes place before the transfer of the latter from solution to the crystalline $HP(As)UO_6 \cdot 4H_2O$ phase becomes possible. Such a process is associated with the expenditure of energy, so that $\Delta \bar{H}^\circ_{M^+} \gg 0$. In the series of alkali metal ions ranging from lithium to caesium, the enthalpy of dehydration diminishes from 534 kJ mol^{-1} for the lithium ion to 284 kJ mol^{-1} for the caesium ion.[101] A proportion of this energy expenditure is compensated by the energy of hydration of the corresponding M^+ ion in the crystalline $M^{I}P(As)UO_6 \cdot nH_2O$ phase ($n = 4$ in the case of M^I = Li and $n = 3$ in the case of all other alkali metals). In the stage involving the transfer of a proton from the crystalline $HP(As)UO_6 \cdot 4H_2O$ phase to the solution, the proton is hydrated with a considerable evolution of energy, amounting to $\Delta H^\circ_{H^+} = -1090$ kJ mol^{-1}.[84] Thus, from the standpoint of the ion hydration-dehydration processes, reaction (11) should be significantly exothermic. However, together with the energetic processes considered, other terms of Eqn (12) must also be taken into account.

As shown above, the four water molecules in $HP(As)UO_6 \cdot 4H_2O$ are not equivalent. Two of them form the hydroxonium ion $H_5O_2^+$, whilst the other two retain their molecular individuality. Whereas the removal of molecular water from $HP(As)UO_6 \cdot 4H_2O$ involves a considerable energy expenditure, at the level of the energy of hydrogen bonds, the decomposition of the hydroxonium ion into $2H_2O$ and H^+ is associated with an appreciable endothermic effect, i.e. $\Delta\overline{H}^\circ_{H^+} > 0$. An appreciable energy expenditure is also necessary for the dissociation of the P(As)O–H bond in the $HP(As)UO_6 \cdot 4H_2O$ crystals. Thus the average O–H bond dissociation energy is 463 kJ mol^{-1}. Finally, an energy expenditure is necessary to increase the interlayer distance on passing from the crystalline $HP(As)UO_6 \cdot 4H_2O$ phases to the crystalline $M^IP(As)UO_6 \cdot nH_2O$ phases. For example, this distance increases from 17.440 Å in the $HPUO_6 \cdot 4H_2O$ phase to 18.242 Å in the $LiPUO_6 \cdot 4H_2O$ phase. The analogous distances for the arsenic compounds are 17.594 and 17.808 Å (Table 4). Furthermore, it is necessary to take into account additional energy expenditures as a consequence of the structural rearrangement caused by the decrease in the number of water molecules from four to three in the $M^IP(As)UO_6 \cdot nH_2O$ formula unit on passing from lithium compounds to sodium, potassium, rubidium, and caesium compounds, i.e. $\Delta H^\circ_{lat} > 0$.

Thus the predominance of the energy expenditure over the exothermic effect, due to ion hydration processes ($\Delta H^\circ_{H^+} < 0$, $\Delta H^\circ_{M^+} < 0$) and the formation of new P(As)O–M bonds in the crystalline phase (ΔH°_{O-M}), is the cause of the endothermicity of the ion-exchange reactions (11). In this case, the quantities $\Delta_r H^\circ(298)$ decrease linearly with increase in the radius of the alkali metal ion (R) in aqueous solution (Table 20):

$$\Delta_r H^\circ(298) = [(67.5 - 19.35R) \pm 1.5]/\text{kJ}$$

for reactions involving $HPUO_6 \cdot 4H_2O$, and

$$\Delta_r H^\circ(298) = [(82.5 - 24.12R) \pm 3.0]/\text{kJ}$$

for reactions involving $HAsUO_6 \cdot 4H_2O$.

The observed greater endothermicity of the ion-exchange reactions (11) for arsenouranic acid compared with the analogous processes for phosphouranic acid is associated with the higher dehydration energy of $HAsUO_6 \cdot 4H_2O$ compared with that of $HPUO_6 \cdot 4H_2O$ and the lower packing density of the crystal lattice of the latter compound.

The considerable endothermicity of the reactions involving the exchange of hydrogen for alkali metal ions in the crystalline compounds $HP(As)UO_6 \cdot 4H_2O$ shows that the displacement of the equilibrium towards the formation of the exchange products requires that the entropy term $T\Delta_r S^\circ$ in the equation for the standard Gibbs free energy function $\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$ should be positive and should exceed the enthalpy term. However, an estimate of $\Delta_r G^\circ(298)$ for reactions (8) shows that the ion-exchange enthalpy makes the main contribution to the Gibbs free energy of the given process. For example, for the reaction

$$Li^+ \text{ (st. soln)} + HAsUO_6 \cdot 4H_2O \text{ (cryst.)} \rightleftharpoons LiAsUO_6 \cdot 4H_2O \text{ (cryst.)} + H^+ \text{ (st. soln)},$$

the free energy $\Delta_r G^\circ$ is given by

$$\Delta_r G^\circ(298) = \Delta_f G^\circ(298, LiAsUO_6 \cdot 4H_2O, \text{cryst.}) + \Delta_f G^\circ(298, H^+, \text{st. soln}) - \Delta_f G^\circ(298, HAsUO_6 \cdot 4H_2O, \text{cryst.}) - \Delta_f G^\circ(298, Li^+, \text{st. soln}).$$

If we employ the data presented in Table 18 and the quantity $\Delta_f G^\circ(298, Li^+, \text{st. soln}) = -292.29 \pm 0.46$ kJ mol^{-1},[84] we obtain $\Delta_r G^\circ(298) = 21$ kJ mol^{-1}. Consequently the equilibrium constant of the process, from the equation $\Delta_r G^\circ = -RT\ln K_e$, is $K_e(298) = 2 \times 10^{-4}$. The displacement of the equilibrium in reaction (11) towards the formation of the exchange products is possible either as a result of an increase in temperature or as a result of the employment of reactions occurring with liberation of energy. Table 21 presents the results of the calculation of the standard enthalpies of the reactions of $HP(As)UO_6 \cdot 4H_2O$ with aqueous solutions of alkali metal hydroxides and also the enthalpies of the ion-exchange reactions with participation of the anhydrous acids.[103]

$$M^IOH \text{ (st. soln)} + HPUO_6 \cdot 4H_2O \text{ (cryst.)} \rightarrow M^IPUO_6 \cdot nH_2O \text{ (cryst.)} + (n-1)H_2O \text{ (liq.)}. \quad (13)$$

$$M^+ \text{ (st. soln)} + HP(As)UO_6 \text{ (solid)} \rightleftharpoons M^IP(As)UO_6 \text{ (solid)} + H^+ \text{ (soln)}. \quad (14)$$

The reactions of $HP(As)UO_6 \cdot 4H_2O$ with solutions of alkali metal hydroxides are exothermic, which ultimately permits the quantitative formation of the crystalline compounds $M^IP(As)UO_6 \cdot nH_2O$. These results confirm the legitimacy of the use of ion-exchange reactions for the synthesis of the compounds $M^IP(As)UO_6 \cdot nH_2O$.

Table 21. The standard enthalpies of reaction (13) and (14).

M^I	$-\Delta_r H^\circ_{13}(298)$/kJ mol^{-1}		$\Delta_r H^\circ_{14}(298)$/kJ mol^{-1}	
	$HPUO_6 \cdot 4H_2O$	$HAsUO_6 \cdot 4H_2O$	$HPUO_6$	$HAsUO_6$
Li^+	11.5	2.5	29.5	21.5
Na^+	20.5	13.5	0.5	−1.5
K^+	29.0	25.5	−12.0	−19.5
Rb^+	29.5	27.0	−15.0	−26.0
Cs^+	33.5	27.5	−22.0	−30.0

It has been established on the basis of the results of X-ray phase analysis that the dehydration of the compounds $M^IP(As)UO_6 \cdot nH_2O$ leads to the disordering of their structures as a consequence of the disruption of the coordination environment of the ion of the univalent element. We used this finding to assess the role of structural factors from the standpoint of their contribution to the energy relations of the ion-exchange reactions.

The exclusion of contributions of the type ΔH°_{lat} from the energy relations of the ion-exchange reactions [see Eqn (12)] leads to a decrease in the overall energy expenditure in the processes under consideration and, in the case of the sodium, potassium, rubidium, and caesium compounds, the exchange reactions proceed with liberation of energy.

VII. Conclusion

The study of the crystalline compounds $HPUO_6 \cdot 4H_2O$ and $HAsUO_6 \cdot 4H_2O$ as well as their alkali metal derivatives by X-ray diffraction showed that the diffraction patterns of all the compounds have analogous sets of reflection maxima with similar positions and relative intensities. In terms of the results of the analytical indexing of the X-ray powder diffraction patterns, the compounds are structurally similar and have similar tetragonal unit cell parameters, which are virtually identical with the results of direct structural studies on $HPUO_6 \cdot 4H_2O$, $HAsUO_6 \cdot 4H_2O$, $LiAsUO_6 \cdot 4H_2O$, $KPUO_6 \cdot 3H_2O$, and $KAsUO_6 \cdot 3H_2O$ single crystals.

The numbers of bands, and their positions and relative intensities in the IR spectra of all the compounds in each of the series of phospho- and arseno-uranate derivatives are similar, which confirms not only the structural similarity of the compounds but also indicates their identical functional composition and the similar nature of the distortion of the principal coordination polyhedra: of phosphorus (tetrahedron), of arsenic (tetrahedron), and or uranium(VI) (octahedron).

A more detailed analysis of the IR spectra, especially in the region of the deformation vibrations of the so-called water of crystallisation, shows that its nature in the test compounds is not the same. In the compounds $HP(As)UO_6 \cdot 4H_2O$ and $LiP(As)UO_6 \cdot 4H_2O$, part of the water is present in the form of the complex hydroxonium ions $H_5O_2^+$ and the lyonium ions $(H_2OLiOH_2)^+$, whilst another part exists in the molecular form. In the compounds of other alkali metals, the entire water is molecularly homogeneous. The different nature of the water in the hydrogen and lithium derivatives, on the one hand, and the sodium, potassium, rubidium, and caesium derivatives, on the other, does not introduce fundamental differences into the structures of the principal coordination polyhedra of phosphorus, arsenic, and uranium or into the structures of the compounds as a whole.

The results of thermographic study of the compounds $M^IP(As)UO_6 \cdot nH_2O$ by the derivatographic method combined with X-ray phase analysis of the intermediate and final dehydration and thermal decomposition products showed that the temperature ranges corresponding to the dehydration of the $HAsUO_6 \cdot 4H_2O$ (363–513 K) are higher compared with $HPUO_6 \cdot 4H_2O$ (353–448 K), which is due to the excess force field of the arsenic in the coordinatively unsaturated AsO_4 polyhedron. On the other hand, the higher temperatures of the condensation of the phosphate groups in $HPUO_6$ with formation of pyrophosphates (833–1133 K) are a consequence of the coordinative saturation of the phosphorus in the PO_4 tetrahedron, which is responsible for the greater stability of the latter (the analogous condensation of the arsenic groups takes place in the range 773–1013 K). After the removal of water in stages, the alkali metal phospho- and arseno-uranate derivatives are converted into the compounds $M^IP(As)UO_6$. The elimination of water molecules from the coordination environment of the alkali metal cation leads in this instance to the conversion of the compound into an amorphous form, i.e. to the breakdown of the long-range order and hence to the disordering of the crystal lattices of the test compounds.

Higher dehydration temperature ranges are also characteristic of alkali metal arsenouranate derivatives compared with the corresponding phosphates, which is a consequence of the stronger binding of the water in $M^IAsUO_6 \cdot nH_2O$. A decrease in the dehydration temperature ranges is observed in both series of compounds on passing from lithium to caesium compounds. This effect is fully consistent with the decrease in the enthalpies of dehydration of alkali metal ions with increase in their size and indicates the incorporation of water molecules in the coordination environment of the univalent element.

The standard enthalpies of formation at 298.15 K of the compounds $M^IP(As)UO_6$ and their crystalline hydrates have been determined from calorimetric data. Quantitative rules governing the variation of the quantities $\Delta_fH°(298)$ for the compounds as a function of the physical characteristics of the alkali metal ions (ionic radius, enthalpy of formation of the ion in the gas phase, ionisation potential) have been established. The results have been compared with the structural characteristics of the same compounds. In particular, the structural similarity of the compounds is manifested by the fact that the standard enthalpies of formation of the phosphorus and arsenic derivatives obey the similarity principle proposed by M Kh Karapetyants.

$$\Delta_fH°(298, M^IPUO_6)$$

$$= \{[-463.5 + 0.97\Delta_fH°(298, M^IAsUO_6)] \pm 2\}/\text{kJ mol}^{-1}$$

$$\Delta_fH°(298, M^IPUO_6 \cdot nH_2O)$$

$$= \{[-351.5 + 1.01\Delta_fH°(298, M^IAsUO_6 \cdot nH_2O)] \pm 3\}/\text{kJ mol}^{-1}.$$

In the series of phosphates and arsenates with M^I = Na, K, Rb, or Cs, the difference between the $\Delta_fH°(298)$ for the anhydrous compounds and their crystalline hydrates per mole of water of crystallisation is virtually constant at 293 ± 3 kJ mol^{-1}. The analogous difference in the case of the hydrogen and lithium forms is also constant, but exceeds the above quantity and amounts to 300 ± 4 kJ mol^{-1}, which emphasises yet again the stronger binding of the water of crystallisation in the hydrogen and lithium derivatives compared with the derivatives of the other Group I elements. This is also indicated by the enthalpies of the dehydration reactions of the crystalline hydrates investigated.

The study of the energy relations of the ion-exchange processes showed that they are all endothermic. This is due to the predominance of the energy expenditure associated with the change in structure on passing from the compounds $HP(As)UO_6 \cdot 4H_2O$ to $M^IP(As)UO_6 \cdot nH_2O$ compared with the overall exothermic effect in the accompanying process involving the dehydration-hydration of the alkali metal ions and the proton in the aqueous phase. The enthalpies of the ion-exchange reactions decrease in this instance in the series of alkali metal derivatives from lithium to caesium for both $HPUO_6 \cdot 4H_2O$ and $HAsUO_6 \cdot 4H_2O$. The results lead to prospects for the practical use of the ion-exchange reactions in order to isolate the compounds and also to prevent the entry of the ecologically dangerous (including radioactive) elements into the human habitat.

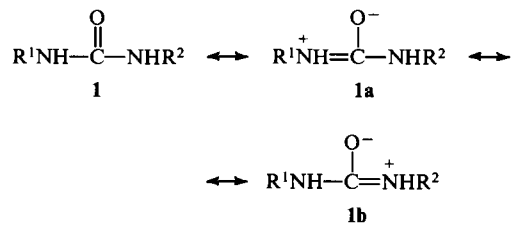
IV.	Applications of isoureas	937
V.	Conclusion	937

Abstract. Data on the methods of synthesis, chemical properties, and applications of isoureas are surveyed. Promising ways of using isoureas in organic synthesis are demonstrated. The bibliography includes 166 references.

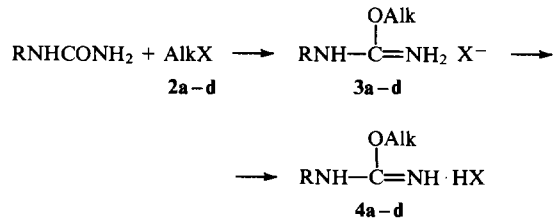
I. Introduction



Ureas and isoureas (urea derivatives with *O*-functional-group substituents) are genetically related classes of organic compounds. This claim is based on the fact that they can be obtained from the same starting materials (carbodiimides, cyanamides, and organic cyanates) and also on their ability to be interconverted.

One of the promising aspects of the chemistry of ureas is their synthesis from compounds of different classes with an amide group activated beforehand. A transition of this kind from the amide to the iminoester group has already yielded excellent results. Thus imidates have been obtained from amides,[1,2] while lactim esters have been obtained from lactams.[3] The lactim esters were subsequently used in new ways which had not been employed before. There are virtually no reviews on the chemistry of isoureas apart from Hegarty's paper,[4] but the description of the methods of synthesis of isoureas in the latter is more in the way of a summary. This led to the writing of the present review in which information about the methods of synthesis, chemical properties, and applications of isoureas is compiled.

II. Methods of synthesis of isoureas



1. Syntheses from ureas

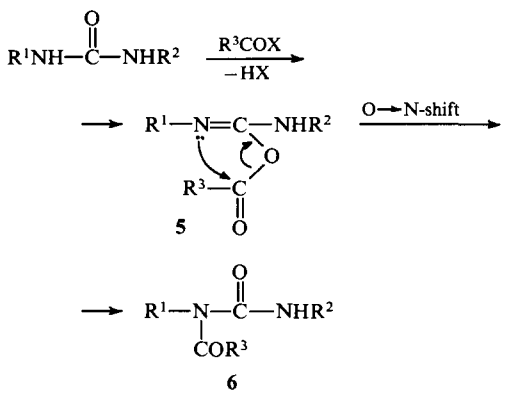
The delocalisation of π electrons in the R^1N-C-O and R^2N-C-O fragments in the ureas **1** is responsible for their weak basicity. The structure of the ground state of ureas can be expressed as a hybrid of the resonance forms **1**, **1a**, and **1b**.

1 **1a** **1b**

Nevertheless, among the multiplicity of the reactions which ureas tend to undergo, the most characteristic are those involving nucleophilic attack on the oxygen or nitrogen atom of the ureas **1** by electrophiles or neutral reagents, the resonance forms **1a** and **1b** being the most probable reactive species in these reactions. One of the specific examples of nucleophilic attack on the oxygen atom of ureas is provided by the direct *O*-alkylation of urea by various alkylating agents **2a–d**. The isoureas **4a–d** are apparently formed via the isouronium intermediates **3a–d**.

2a–d **3a–d** **4a–d**

R = H, Alk, Ar;



X = $AlkSO_4^-$ (**a**), $NaSO_3^-$ (**b**), I^- (**c**), $AlkSO_3^-$ (**d**).

The reaction involving the *O*-alkylation of ureas is carried out as a rule in neutral media at low temperatures (up to 100 °C), because the alkylating agents AlkX are extremely reactive. Alkyl sulfates **2a**,[5–7] alkanesulfonates **2b**,[5] alkyl iodides **2c**,[8] and aryl alkanesulfonates **2d**[5] are usually employed as the *O*-alkylating agents for ureas. *O*-Alkylisoureas **4a–d** are as a rule isolated as the corresponding salts, but in some cases the free bases can also be obtained by careful neutralisation. The isoureas **4** with easily removeable groups ($AlkO^-$) tend to undergo elimination readily in a basic medium.

Many investigators believe[9–13] that the *N*-acylation of ureas proceeds via the initial *O*-acylated intermediate **5**.

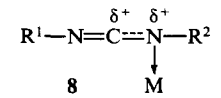
6

However, the kinetically controlled adduct **5** has not so far been isolated in the classical acylation reactions of ureas, only the *N*-acylureas **6** being found among the reaction products.[14-16] *N*-Acylureas **6** are formed as a result of the intramolecular thermodynamically more favourable O → N shift (migration) of the acyl group. For example, the acylation of *N*-methylurea by acetyl chloride affords *N*-acetyl-*N*-methylurea **6**,[13] which agrees with the formation of the *O*-acetyl intermediate **5**, although the secondary nitrogen atom should be more nucleophilic in the direct attack by the acylating agent.

2. Synthesis from carbodiimides

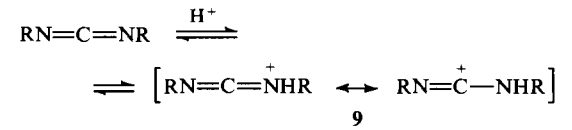
Carbodiimides (CDI) constitute one of the most important types of unsaturated compounds with a heterocumulated bond system. By virtue of thoroughly developed and reliable methods of synthesis, CDI have found extensive applications, mainly in peptide synthesis and for the immobilisation of biomolecules.[17,18] The close relationship between CDI and ureas is emphasised by the fact that ureas are one of the traditional sources of CDI[17-22] and the latter can be readily converted, in their turn, into ureas. CDI are obtained from 1,3-disubstituted ureas by dehydration with P_2O_5,[19] metal carbonyls [$Fe(CO)_5$, $Fe_2(CO)_4CNPh$, $Fe_2(CO)_9$, $W(CO)_6$, $Mo(CO)_6$],[20] triphenylphosphine dibromide,[21] or triphenylphosphine[22] in triethylamine and aromatic sulfonic acid chlorides under conditions of phase transfer catalysis,[23] or by the interaction of *N*-alkylideneureas with PCl_5.[24]



By virtue of their comparatively ready availability and high reactivity in reactions with nucleophiles, CDI have proved to be perhaps the principal synthons for the synthesis of *O*-alkyl(aryl)isoureas. The reactions of CDI with alcohols and certain phenols in the presence of specific catalysts or alkoxides in the synthesis of *O*-alkyl(aryl)isoureas do not even require heating.[25-32] The noncatalytic addition of alcohols and phenols to CDI is relatively ineffective because of the weak nucleophilic properties of these reagents.

7

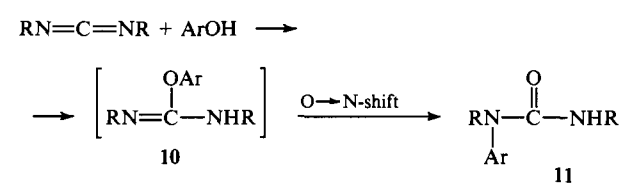
R^1, R^2 = Alk, Ar.



The relatively low nucleophilicity of alcohols (phenols), on the one hand, and the known tendency of CDI to undergo spontaneous or initiated polymerisation[33] during the synthesis of isoureas **7**, on the other, can be readily overcome by employing a series of synthetic procedures designed to increase the electrophilicity of the heterocumulene fragment of the CDI towards nucleophiles. In this part of the review, we shall quote only the studies which were published after the reviews of Bocharov[34] and Pankratov,[35] where reactions involving CDI, including the reactions of CDI with alcohols, were surveyed. The interaction of CDI with alcohols (phenols) is usually catalysed by copper salts (CuCl, $CuCl_2$, Cu_2O) or Zn^{2+}.[36-41] The catalytic action of metal ions apparently consists in the formation of a coordination complex between the CDI and the metal ion (via the imine nitrogen atom).

8

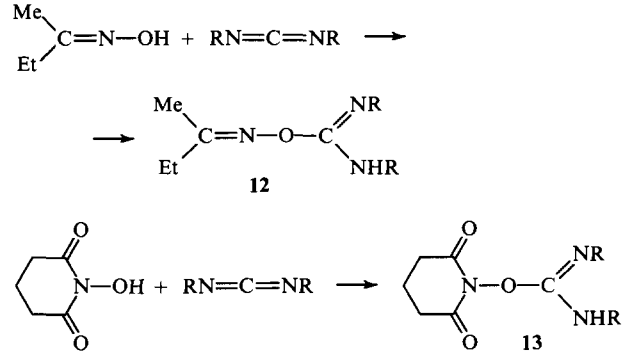
M = Cu(I), Cu(II), Zn(II).



The formation of the coordination complex **8** leads to an increase in the electrophilicity of the central carbon atom of the CDI. Another method for the activation of CDI in reactions with nucleophiles, including alcohols, involves the use of proton-donors.[42,43] The protonation of CDI results in the formation of the electrophilic species **9**.

9

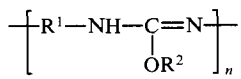
The preliminary *N*-functionalisation of the CDI by electron-accepting groups (acyl, sulfoxyl, and phosphoryl) significantly facilitates subsequent nucleophilic addition.[44]



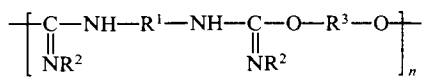
Proceeding now to certain characteristic features of the reactions of CDI with alcohols (phenols), we note in the first place that the interaction of CDI with alcohols affords the corresponding isoureas **7**, whilst the analogous reactions with phenols do not proceed unambiguously. The usual phenols react with CDI to form in most cases *N*-arylureas **11**[45-48] and many workers are inclined to assume that these reactions proceed via the *O*-aryl intermediate **10**, although there is no reliable evidence for this.

10 11

The fact that phenols with distinct acid properties react with CDI to form stable *O*-arylisoureas **10** may serve as indirect evidence in support of the existence of the intermediate **10**.[49-55] Such compounds have been isolated in the reactions of CDI with 2,6-dichloronitrophenol,[55] pentachlorophenol,[51,52] and 2-carboxy-4,6-dinitrophenol. It has been postulated that *ortho* substituents in the phenols mentioned above inhibit the usual O → N shift as a result of their steric influence on the reaction centre.



It has been shown in a number of studies[37,56-59] that the non-traditional isoureas **12** and **13** can be obtained from CDI and *N*-hydroxy-compounds.

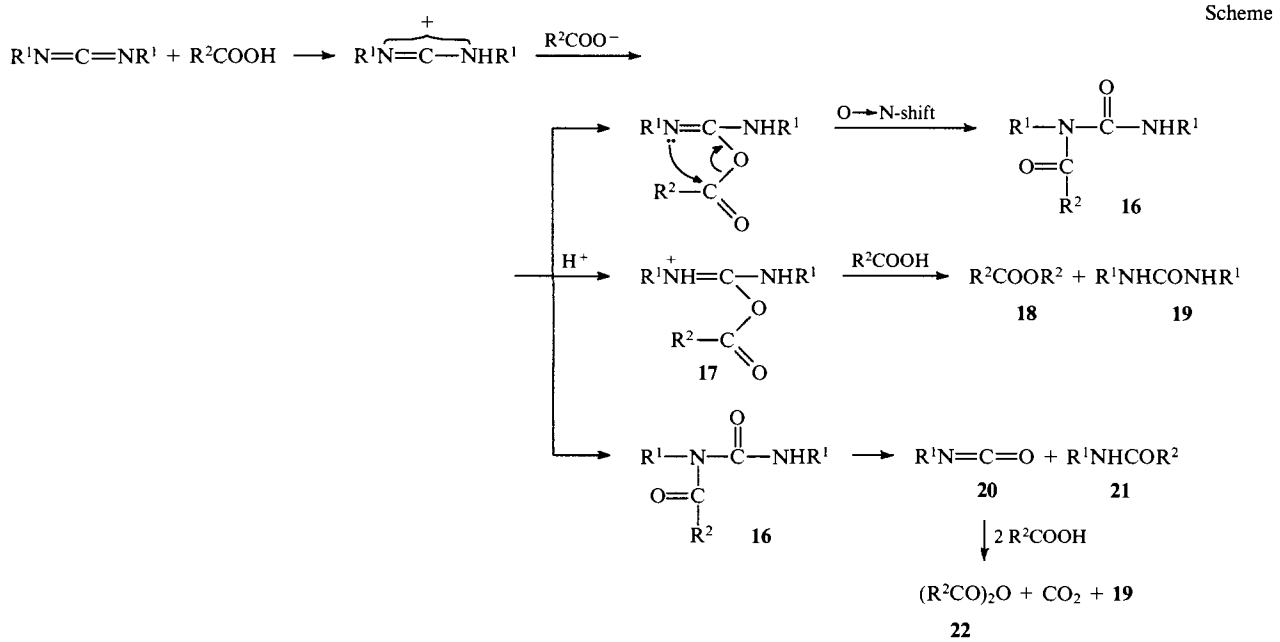


12 13

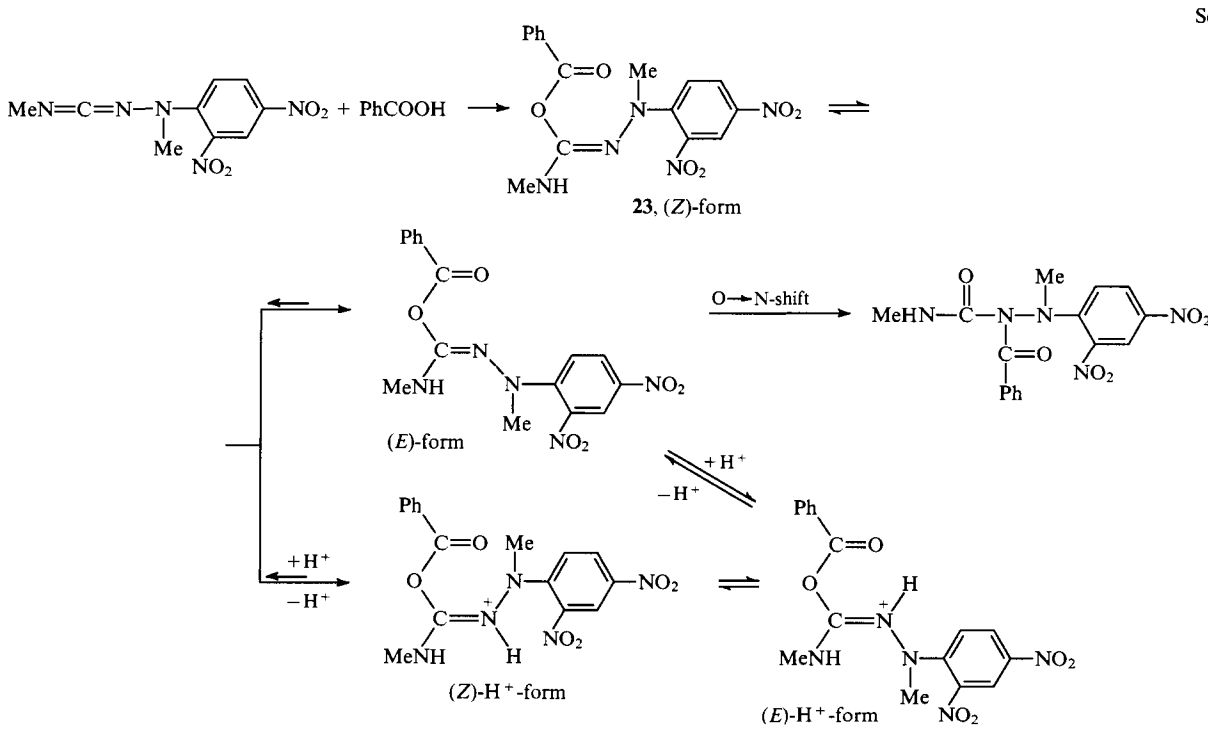
R = Alk, Ar.

Polycarbodiimides react with aliphatic alcohols to form the corresponding poly-*O*-alkylisoureas with structures **14** and **15**.[60–63]

14



15

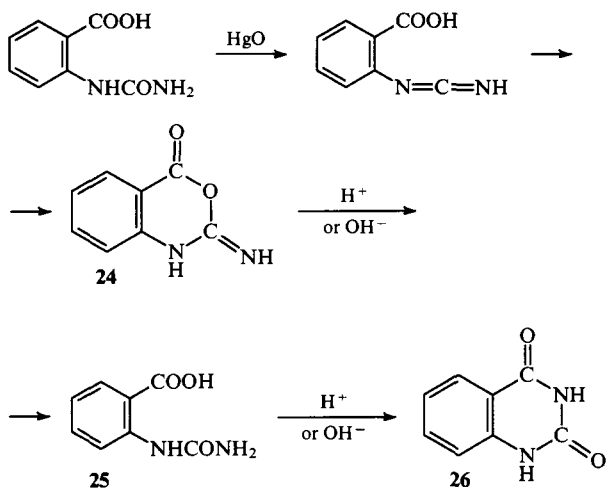


It is of interest that the polyisoureas **14** and **15** are more soluble and have lower melting points than the initial polycarbodiimides.

The attractive features of CDI in peptide synthesis stimulated detailed investigation of the reactions of CDI with carboxylic acids, including the kinetics of these processes.[18,64–70] The reactions of CDI with carboxylic acids (Scheme 1) are completed, depending on the acidity of the medium, temperature, and the amount of reactant, by the formation of either the *N*-acylurea **16**, or of the ester **18** and the urea **19**, or of the amide **21** and the anhydride **22** via the intermediate isocyanate **20**. The formation of the *N*-acylurea **16** is usually observed at elevated temperatures or when the reaction is carried out for a long time.[71] A highly acid medium promotes the formation of the esters **18** via the protonated intermediate **17**; sterically cumbersome groups R^1 or the use of a high temperature lead to decomposition of the *N*-acylurea **16** into the isocyanate **20** and the amide **21**, while the isocyanates **20** react with two molecules of a carboxylic acid to produce two molecules of the urea **19** and the anhydride **22** (Scheme 1).

Scheme 1

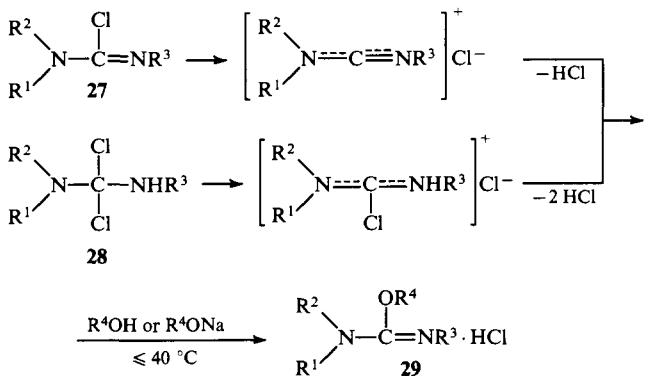
Scheme 2



In order to eliminate the racemisation of the acid substrate, which is undesirable in peptide synthesis, and the competing O → N shift in reactions with carboxylic acid, one may employ *N*-hydroxysuccinimide or 1-hydroxybenzotriazole.[72,73]

It is believed[74,75] that poly-*N*-acylureas are formed from polycarbodiimides and carboxylic acids via the corresponding poly-*O*-acylated intermediate.

Comparatively recently, it has been possible to synthesise and isolate the stable *O*-acylisourea **23** (Scheme 2).[76,77]

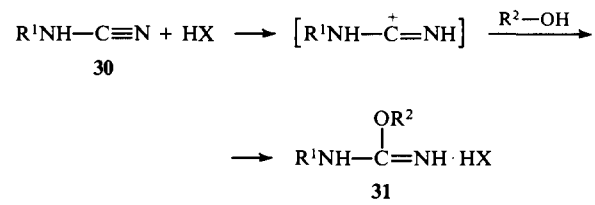


The stability of the *O*-acylisourea **23** is attributed to the (*Z*)-configuration relative to the C=N bond, while the (*E*)-isomer undergoes the spontaneous O → N shift of the acyl group.

The synthesis of 1,2-dihydro-2-imino-3,1,4-*H*-benzoxazolin-4-one **24**, which can be converted into the quinazolinedione **26** via the urea **25**, is a remarkable example of the intramolecular stabilisation of *O*-acylisoureas.[78]

3. Syntheses from chloroformamidines

Mono- and di-chloroformamidines **27** and **28** can be readily synthesised from the corresponding CDI and dry HCl.[17,18,33,34] They are sometimes obtained by treating *N,N,N'*-trisubstituted ureas with PCl_5.[4] Being highly reactive in dissociative reactions, the chloroformamidines **27** and **28** smoothly substitute the chloride anion by alkoxide anions, affording *O*-alkylisoureas **29** in a high yield.[79–82]

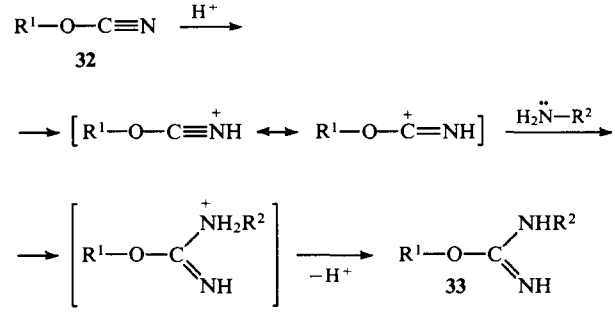


R^1–R^4 = Alk, Ar.

Despite the simplicity of the formation of the isoureas **29**, the methods of their synthesis based on chloroformamidines have not come to be widely used in preparative chemistry, which is evidently associated with the greater availability of CDI and ureas, although in certain cases (for trisubstituted isoureas) chloroformamidines are preferable.

4. Syntheses from cyanamides

The close relationship between ureas and cyanamides **30** can be seen on the basis of their interconversion: the dehydration of *N*-substituted ureas in basic media results in the formation of cyanamides **30**, whilst the reverse reaction affords ureas.[82] Cyanamides may be regarded also as a tautomeric form of CDI and the latter, as noted above, are 'genetically' close to ureas. Consequently cyanamides **30** tend to undergo the same addition reactions as CDI. As was in fact expected, cyanamides **30** react with alcohols in the presence of acids to form the isoureas **31** with a free imine group.[83–88]



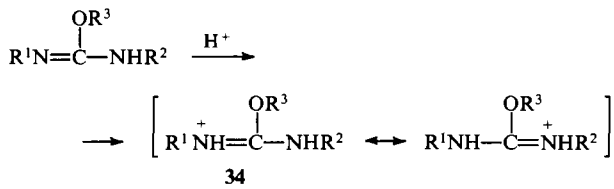
R^1, R^2 = Alk, Ar.

Both inorganic and organic acids are used as proton catalysts, whilst the isoureas **31** are isolated respectively as the halides and the sulfate, phosphate, carbonate, and nitrate salts or in the form of aliphatic and aromatic carboxylates.[83–88] ^{14}C-Labelled *O*-methylisourea has been obtained for biochemical research from the corresponding cyanamide and methanol in the presence of hydrogen chloride.[89]

5. Syntheses from organic cyanates

The methods of synthesis of isoureas examined above were based on the initial attack by nucleophilic alcohols (alkoxides) on the electrophilic carbon of the substrates, while the formation of isoureas from organic cyanates **32** is based on attack by a nucleophilic amine.

R^1, R^2 = Alk, Ar.



The reactions of organic cyanates **32** with amines or their salts are carried out as a rule in inert organic solvents at −50 to +150 °C, the best yields of the isoureas **33** being attained for equimolar proportions of the substrate and the reagent.[90–93]

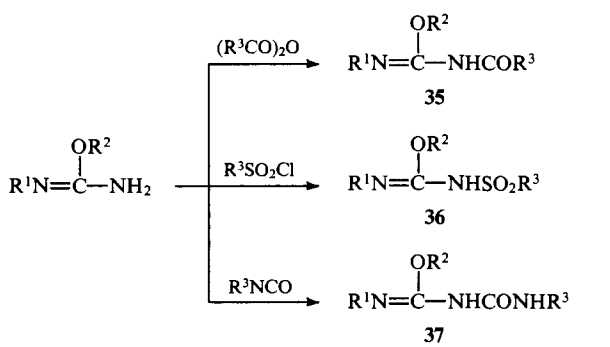
6. Other methods of synthesis of isoureas

A series of examples of the synthesis of isoureas, not related directly to the methods of synthesis examined above, have been described in the literature.[94–97] However, analysis of these methods showed[94–97] that they definitely imply the intermediate formation of species the conversion of which into isoureas was examined above. Bearing this factor in mind and taking into account the fact that these examples of the synthesis of isoureas[94–97] represent isolated instances, we believe that they do not require detailed comments.

III. Chemical properties

Isoureas, which contain the iminoester functional group, are stronger bases (the pK_a values for isoureas are from 6 to 10) than ureas. Thus pK_a for *O*-methylisourea is 9.80, while that for the isomeric *N*-methylurea is 0.82.[98,99] The increased basicity of isoureas can be accounted for by the higher stability of their conjugate acids as a result of the resonance of the isouronium cation **34**, which gives rise to a fundamental difference between isoureas and *N*-substituted ureas.

34



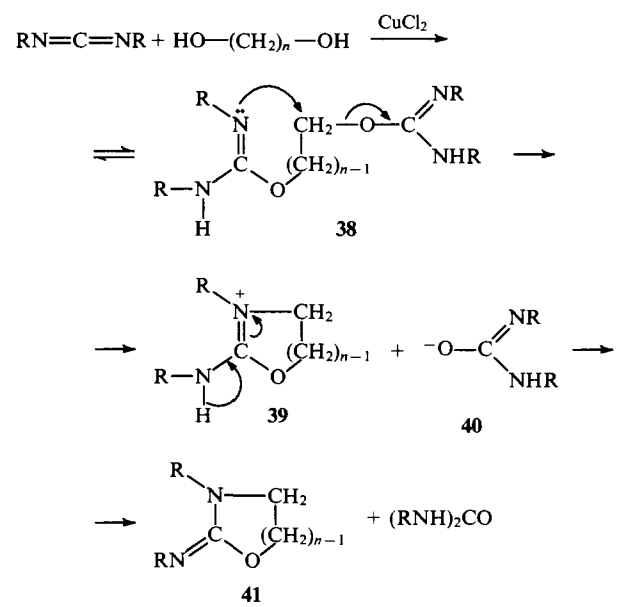
R^1-R^3 = Alk, Ar.

As was to be expected, isoureas are extremely reactive with respect to nucleophiles, but their free bases are themselves effective nucleophiles. The above general properties of isoureas make it possible to specify certain characteristic reactions which isoureas tend to undergo.

1. Reactions with participation of a nucleophilic nitrogen atom

In synthetic practice, *N*-acylation processes (Scheme 3) have been most widely investigated among the reactions of isoureas with widely the particpation of a nucleophilic nitrogen atom.[100-106]

Scheme 3

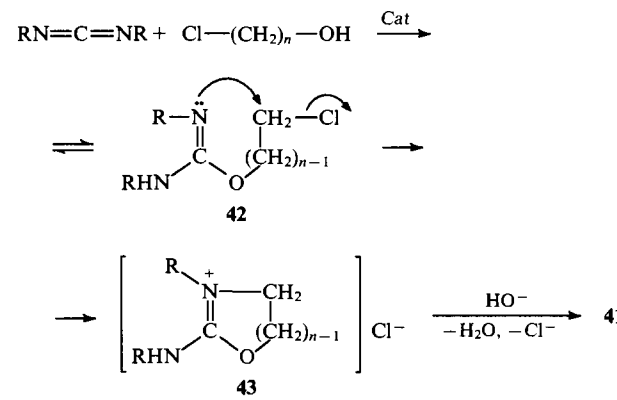


35 **36** **37**

R^1, R^3 = Alk, Ar; R^2 = Alk.

Examples of the synthesis of derivatives of bisisourea from phthalic acid dichloride and the corresponding isoureas are known.

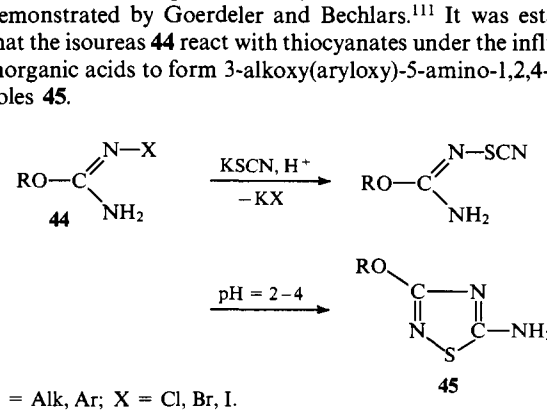
N-Acylisoureas **35-37** are as a rule formed smoothly and in high yields, the procedure for their isolation not requiring special conditions. The key stage in the formation of type **41** 1,3-oxazolidines involves nucleophilic attack by the imine nitrogen atom on the methylene group. Thus the interaction of glycols with CDI, catalysed by copper chloride,[107,108] is completed by the cyclisation of the intermediate bisisoureas **38** via intramolecular nucleophilic attack by the imine nitrogen atom on the terminal methylene group and the transfer of the proton in the cyclic isouronium ion **39** to the highly basic anion **40**.



The reactions of cyclohexanediols with CDI afford the corresponding oxazolidines with the *trans*-configuration.[109] It has been established that the type **41** oxazolidines are also formed in the reaction of CDI with certain haloalcohols.[103,105]

38 **39** **40** **41**

R = Alk, Ar; n = 2, 3.

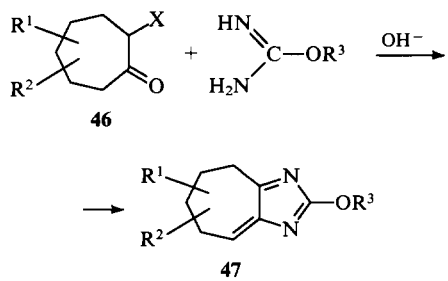


It has been suggested that the hydrochloride **43** is formed as a result of intramolecular nucleophilic substitution of the chlorine atom by the imine nitrogen in the isourea **42** and the subsequent dehydrochlorination in a basic medium leads to the oxazolidines **41**.[110]

42 **43**

R = Alk, Ar; n = 2,3; Cat = $CuCl_2$,[103] HBF_4.[105]

Another example of the cyclisation of isoureas has been demonstrated by Goerdeler and Bechlars.[111] It was established that the isoureas **44** react with thiocyanates under the influence of inorganic acids to form 3-alkoxy(aryloxy)-5-amino-1,2,4-thiadiazoles **45**.

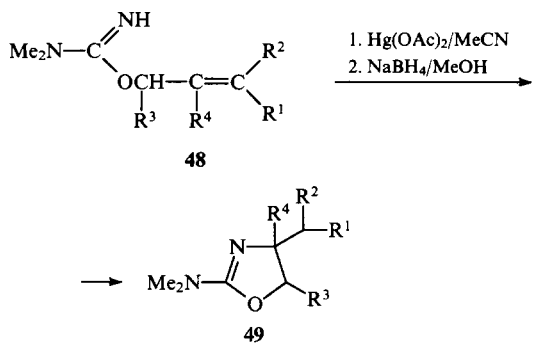


44 **45**

R = Alk, Ar; X = Cl, Br, I.

The thiadiazoles **45** proved to be extremely stable compounds, which are readily acylated and give rise to nitrosoamines capable of azo-coupling in an acid medium.[111]

The reactions of derivatives of the tropones **46** having functional-group substituents in the 2-position with isoureas or their salts in the presence of bases result in the formation of the cyclic 2-alkoxyimidazole derivatives **47**.[112]



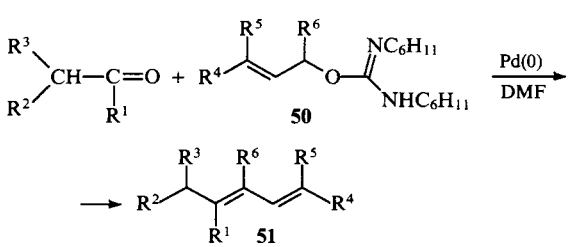
46 **47**

$R^1 = R^2$ = H, Alk, Ar, $PhCH_2$, Hal, OH, CN, NHY;

X = Br, Cl, AlkO, TsO; R^3 = Me, Et.

The intramolecular electrophilic cyclisation of alkyl-substituted 1,1-dimethylisoureas **48**, obtained from the corresponding alcohols and cyanamide, leads to the formation of the oxazole derivatives **49**.[113]

48 **49**



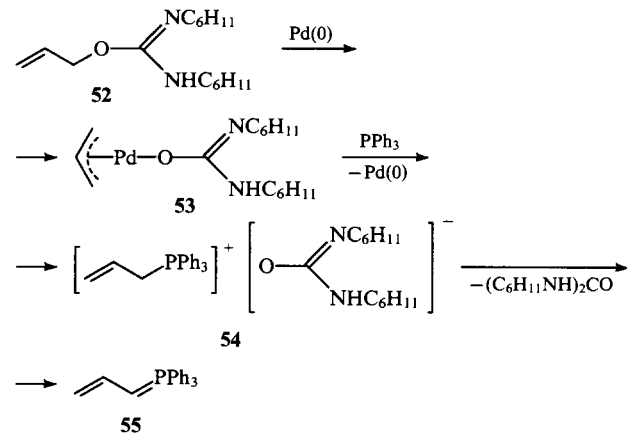
R^1–R^4 = H, Ar, Alk.

The relatively unstable *N*-haloisoureas RO–C(=NX)–NH_2 have been synthesised.[111] Their relative stability was found to depend on the nature of the substituent R (Me < Et < β-ClC_2H_4 < Ph < $PhCH_2$ ≪ cyclo-C_6H_{11}) and on the halogen X (I < Br < Cl). It was shown that the condensation of *O*-alkylisoureas with cyanamide gives rise to *O*-alkyl-*N*-cyanoisoureas and dicyandiamide.[114]

2. Reactions accompanied by the elimination of the *O*-alkyl(aryl) fragment

a. *C*-Alkylation

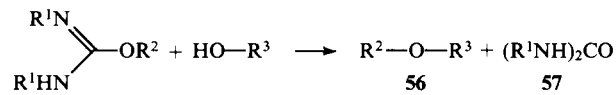
There are few examples of the *C*-alkylation of *O*-alkylisoureas in the literature. A convenient method of synthesis of alkenes employing 2-allyl-isoureas **50** as an effective agent for the direct α-allylation of ketones and aldehydes in the presence of zerovalent palladium or with added triphenylphosphine (for aldehydes) has been developed comparatively recently.[115,116]



50 **51**

R^1 = H, Alk, Ph; R^2, R^3 = H, Alk, Ph;

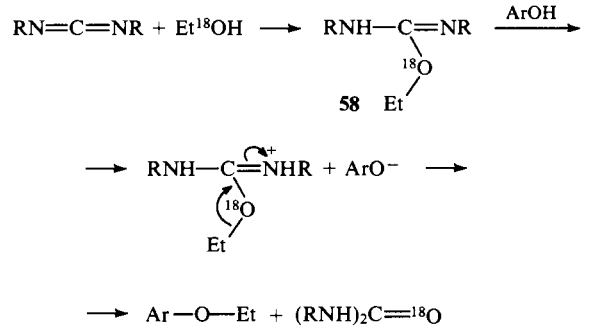
R^4–R^6 = H, Me, Pr, C_6H_{11}, Ph.



It has been suggested that the oxidative coupling of the isourea **52** with zerovalent palladium results in the formation of the π-allyl intermediate **53**. When triphenylphosphine is employed, the intermediate **53** reacts with the latter as a nucleophile, affording the phosphonium salt **54**. As a strong base, the isourea anion in compound **54** abstracts an α-proton, affording the allylidenetriphenylphosphorane **55** and the latter is then used as an agent for the introduction of the allylidene group into benzaldehydes via a Wittig type reaction.

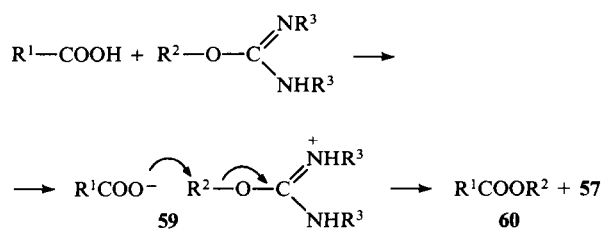
52 **53** **54** **55**

b. *O*-Alkylation (arylation)



Isoureas react smoothly with alcohols or phenols, giving rise to the ethers **56**; the leaving groups are the ureas **57**.[108, 117–119]

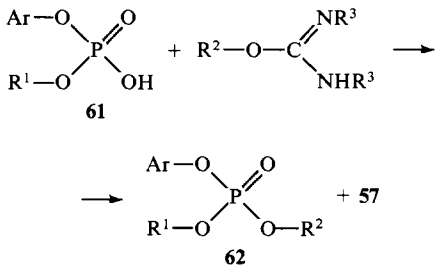
56 **57**



R^3 = Alk, Ar.

It has been established that type **56** ethers are formed in the interaction of ^{18}O-labelled ethanol with CDI by attack of the alkoxide or aryloxide anions on the alkyl group of the intermediate *O*-alkylisoureas **58**.[120]

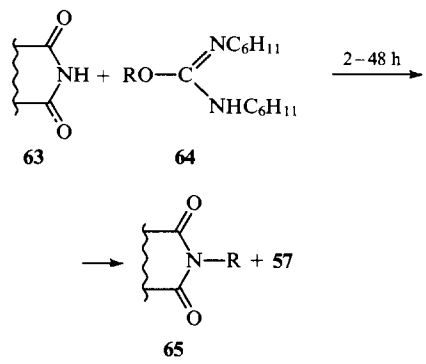
58



The esters **60** can be obtained in high yields by the reaction of *O*-alkylisoureas with carboxylic acids.[121,122]

59 **60**

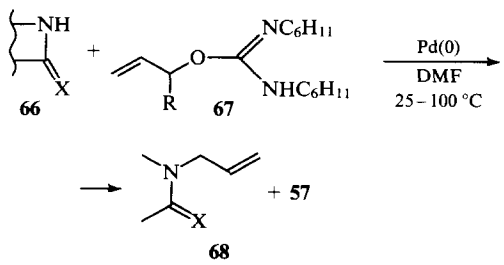
The existing ideas about the mechanisms of the reactions of isoureas with carboxylic acids are based on the fact that the isoureas are initially protonated to give the intermediate **59** and the latter is then attacked by the carboxylate anion at the alkoxy-group with formation of a tetrahedral intermediate.



The phosphates **61** react readily with *O*-alkylisoureas to form the corresponding esters **62**.[123]

R^1, R^2 = H, Alk.

c. *N*-Alkylation

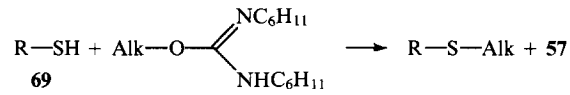


It has been found comparatively recently[124,125] that the refluxing of cyclic imides **63** with *O*-alkyldicyclohexylisoureas **64** in dimethylformamide (DMF) makes it possible to synthesise the *N*-alkylimides **65** in satisfactory yields.

R = Me, Bu, (±)-Bu^s, (±)-$C_6H_{13}CHMe$, $C_{12}H_{25}$.

According to the authors, the reaction proceeds via an S_N2 mechanism with 98% inversion of the configuration. This has been confirmed by the reaction of [(*R*)-(−)-1-methylheptyl]-isourea **64** with phthalimide, which leads to [(+)-1-methyl-heptyl]phthalimide. On treatment with hydrazine hydrate, the latter is converted into [(*S*)-(+)-1-methylheptyl]-amine.

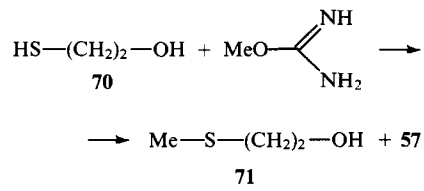
The zerovalent palladium-catalysed direct *N*-allylation of amides, thioamides, and certain lactams **66** by *O*-allylisoureas **67** has been achieved.[126]



X = O, S.

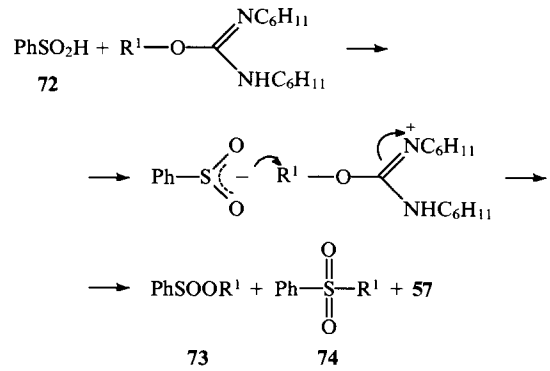
The yields of the *N*-allyl derivatives **68** are in the range 27%–87%.

In the allylation of certain heterocyclic bases (thymine, thymidine, uridine) by *O*-alkylisoureas, it was established that this entails the exclusive *N*-alkylation of the azaheterocycles, while the isomeric *O*-alkyl derivatives were not detected even in trace amounts.[127,128]



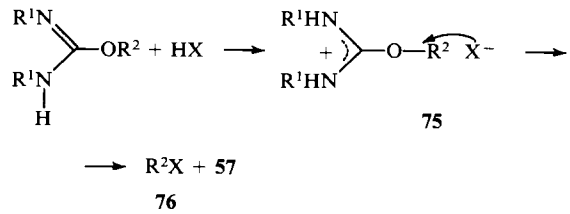
d. *S*-Alkylation

It has been shown in a number of studies[129,130] that *O*-alkyl-isoureas are excellent *S*-alkylating agents for mercaptans and thiophenols **69**.



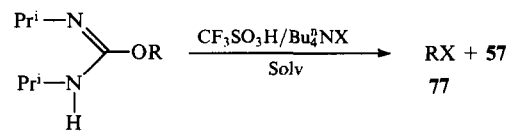
R = Alk, Ar.

It is remarkable that the reaction of *O*-methylisourea with 2-mercaptoethanol **70** affords selectively the *S*-methylated product **71**.[130]



The interaction of *O*-alkylcyclohexylisoureas with benzene-sulfinic acid **72** leads to the preferential formation of the sulfinates **73** (*O*-alkylation products), although the formation of appreciable amounts of the sulfones **74** (*S*-alkylation products) has also been observed.[131]

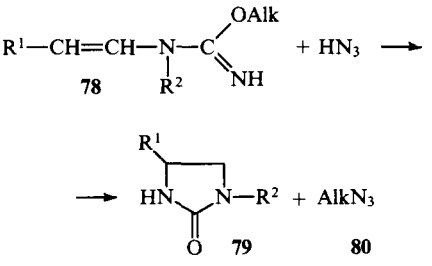
The overall yield of the alkylation products was 60%–90%. The ratio of the sulfinates **73** and the sulfones **74**, determined from ^{1}H NMR spectroscopic data, depends on the nature of the group R and the solvent employed, branched groups R inducing the virtually 100% formation of the sulfinates **73**.



e. Synthesis of alkyl halides

Nucleophilic substitution in the protonated urea **75** on heating with hydrogen halides, where the leaving groups are neutral ureas **57** and alkyl halides **76** are the products, has long been known.[132–135]

X = Cl, Br, I.



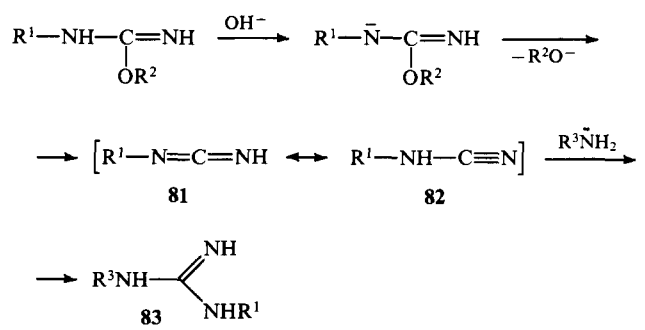
Since the traditional methods of synthesis of alkyl halides **76**, especially the bromides, frequently involve the formation of insufficiently pure target products, an effective modification of this reaction has been proposed,[136] permitting the synthesis, together with the usual alkyl halides, also of the unsaturated alkyl halides **77** in 57%–90% yields.

X = Br, I.

The use of trifluoromethanesulfonic acid instead of the traditional hydrogen halides made it possible to regulate accurately the amount of acid and to eliminate nucleophilic competition between the added halide and the acid residue. Kinetic study showed that this is a first-order reaction and that its rate depends on the concentration of the *O*-alkylisourea salt **75**. It has been established that, depending on the substituent, the reactivity of isoureas decreases in the following sequence: allyl = propargyl = benzyl > primary > secondary. Although the reaction involving nucleophilic substitution in solution in hexamethylphosphoramide and DMF proceeds more effectively, it is preparatively more convenient to employ dichloromethane or chloroform.

It has been shown[137] that the reaction of *O*-alkyl-*N*-alkenyl-isoureas **78** with hydrazoic acid does not lead to the expected aminotetrazoles, as in the case of iminoesters,[1] but affords *N*-alkylimidazolidin-2-ones **79** and alkyl azides **80**.

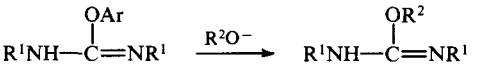
$R^1 = R^2$ = Alk, Ar.



It has been suggested[137] that the heterolytic dissociation of the O–Alk bond accompanied by nucleophilic substitution by the azide anion takes place in the hydrazoate salt of the isourea **78**. The isourea residue undergoes heterocyclisation to compound **79** apparently via intramolecular electrophilic addition to the double bond.

The formation of *N*-substituted ureas **57** has been observed in a number of instances on heating *O*-alkylisoureas.[125,136] Compounds **57** are obtained by elimination of an alkene from the *O*-alkylisoureas.

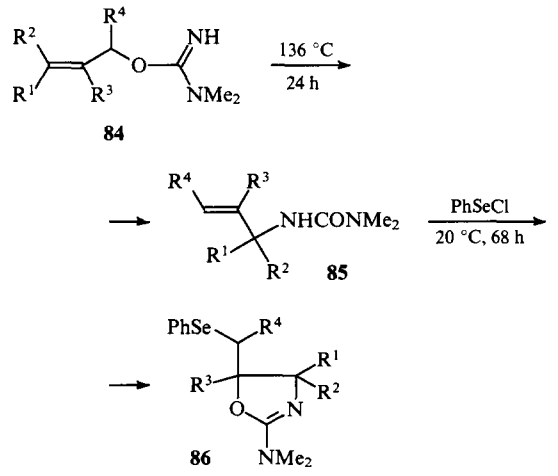
3. Reactions accompanied by the elimination of the alkoxy-fragment



Among reactions of this type, the reactions of isoureas with amines, leading to guanidines, are best known.[83,138]

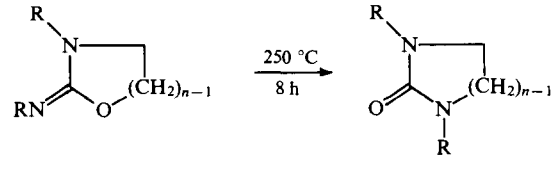
It has been suggested that the CDI **81** is formed initially via β-elimination and then undergoes a tautomeric transformation into the cyanamide **82**. The cyanamide undergoes nucleophilic attack by the amine.

R^1–R^3 = Alk, Ar.



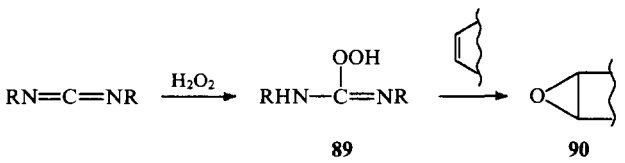
The exchange of the aryloxy-group for an alkoxy-group sometimes occurs in *O*-arylisoureas. It takes place on heating in the presence of the R^2O^- alkoxide ion via a mechanism involving a process similar to elimination-addition.[4]

It has been established that *N*-alkyl- and *O*-aryl-isoureas give rise to the corresponding alkanes and arenes on reduction with hydrogen over palladium.[139–141] Consequently, these reactions can be regarded as a general method for the reduction of alcohols and phenols to hydrocarbons. In a strongly basic medium, *N*-acylisoureas give rise to *N*-acylcyanamides,[142] whilst a high-temperature treatment of isoureas (250–300 °C) leads to the formation of isocyanates.[143]



4. Other reactions

The isomerisation of the isoureas **84** on refluxing in xylene leads to the formation of *N*-substituted ureas **85**, which are converted into the oxazolines **86** on treatment with PhSeCl in chloroform in the presence of silica gel.[113]



R^1–R^4 = H, Alk, Ar.

On heating to 250 °C, the isoureas **87** rearrange to the cyclic ureas **88**.[144]

n = 2, 3.

The interaction of CDI with hydrogen peroxide leads to the peroxycarboximidic acids **89**, which are effective agents for the oxidation of alkenes and especially arenes to the corresponding epoxides **90**.[145]

89 **90**

IV. Applications of isoureas

The principal fields in which isoureas are employed are agriculture, medicine, and biochemistry. Isoureas are used to a somewhat lesser extent in polymer and analytical chemistry.

Thus isoureas exhibit a high herbicidal activity,[146–148] are used as plant growth regulators,[146–153] and promote the acceleration of the growth of wool, improvement in the production of meat and milk from animals, and improvement in the assimilation of animal feed.[154]

The study of the biological activity of *O*-alkylisoureas established their stimulating effect on smooth muscles.[155] Certain isoureas are used as antiinflammatory medicinal drugs.[156] A few possess an anticancer activity.[157] Isoureas linked to purine or pyrimidine bases and containing fluorescent labels are used to detect deoxyribonucleic and ribonucleic acids and their fragments.[158]

Isoureas are employed in the synthesis of auxiliary agents for the dyeing of textiles and polymers[159] and for the synthesis of copolymers with a specified fibre shape.[60–63]

The pronounced basicity of isoureas made it possible to synthesise from them a large number of coloured coordination compounds and to investigate their properties.[160–166]

V. Conclusion

Unfortunately, new studies on the development of general methods of synthesis of isoureas have not been published recently. However, more vigorous investigation of the chemical properties of isoureas promises to yield important results both synthetically and theoretically. In this context, one of the promising procedures involves the study of the reactions of isoureas with various amino-derivatives which are potentially capable of giving rise to the synthesis of new heterocyclic systems. Analysis of literature data has shown that the reactions of isoureas with organometallic compounds, especially with Grignard reagents, have not been investigated. For example, the possibility of the addition of a Grignard reagent to the C=N bond and of the direct substitution of the alkoxy-group in isoureas by an alkyl residue may lead to interesting results, as has been shown for iminoesters.

The fairly large set and availability of the synthons for the preparation of a wide variety of isoureas have been by no means fully made use of, in our view, for the needs of medicine, biochemistry, and other purposes.

V.	Certain problems in the search for new effective ligands	947

Abstract. In the review, a systematic account is given of the methods of synthesis of bifunctional complexones and conjugates based on them, data on the physicochemical and biological properties of these compounds and their applications are analysed, and the prospects in the search for new ligands are examined. The bibliography includes 160 references.

I. Introduction

In the course of the development of the chemistry of complexones, attempts have been frequently made to construct molecules combining, together with the chelate fragment ensuring complex-forming properties, groups of atoms incapable of participating in the formation of complexes but imparting to the chelating agent new functions which were not previously characteristic of this compound.[1] The first 'hybrids' should legitimately include the analytical indicators synthesised at the beginning of the 1950s; Xylenol Orange **1**, phthalein complexone, alizarin complexone, thymolphthalexone, fluorexon, etc.[1,2] The chelating iminodiacetic acid (IDA or H_2ida) fragment and chromophoric groups are successfully combined in the molecules of these substances (Fig. 1, see over).

Later attempts were made to introduce into the complexone molecule a hydrophobic hydrocarbon group, imparting surface-active properties to the chelating agent,[3–6] paramagnetic spin labels,[7] etc.

However, complexones bound covalently to proteins, which appeared at the end of the 1970s, have aroused and continue to arouse the greatest interest.[8–12] This is associated with the fact that the products of the interaction of the protein of a bifunctional complexone and a cation — conjugates — have found extensive application in biology and medicine (see Fig. 2, p. 941).[1,8–13]

Despite the fact that all the 'hybrid compounds' mentioned above can perform simultaneously at least two fundamentally different functions, the term 'bifunctional complexones' became firmly established only after the introduction of the last variety of chelating agents.

At the present time, the term 'bifunctional complexones' embraces a range of substances containing, apart from the chelating fragment, a reactive group ensuring the covalent attachment of such a complexone to biological macromolecules (peptides, proteins).[1]

Various modifications of diethylenetriaminepentaacetic acid (DTPA or H_5dtpa), ethylenediaminetetraacetic acid (EDTA or H_4edta), and certain other complexones are usually employed to produce bifunctional complexones. Isothiocyanate, bromoacetamide, carboxymethoxy-, diazonium, or other similar groups are employed as groups with affinity for proteins.

So far as possible, the bifunctional complexones should satisfy the following requirements:

(i) To retain the ability to form thermodynamically highly stable complexes after immobilisation on the protein.

(ii) To become rapidly attached to the protein and to retain the cation in the chelating component for a sufficiently long time compared with the half-life of the radioactive label or the period required for natural elimination from the organism, which presupposes the existence also of kinetic stability (the lowest possible rates of dissociation of the complex in vivo), in addition to the thermodynamic stability.

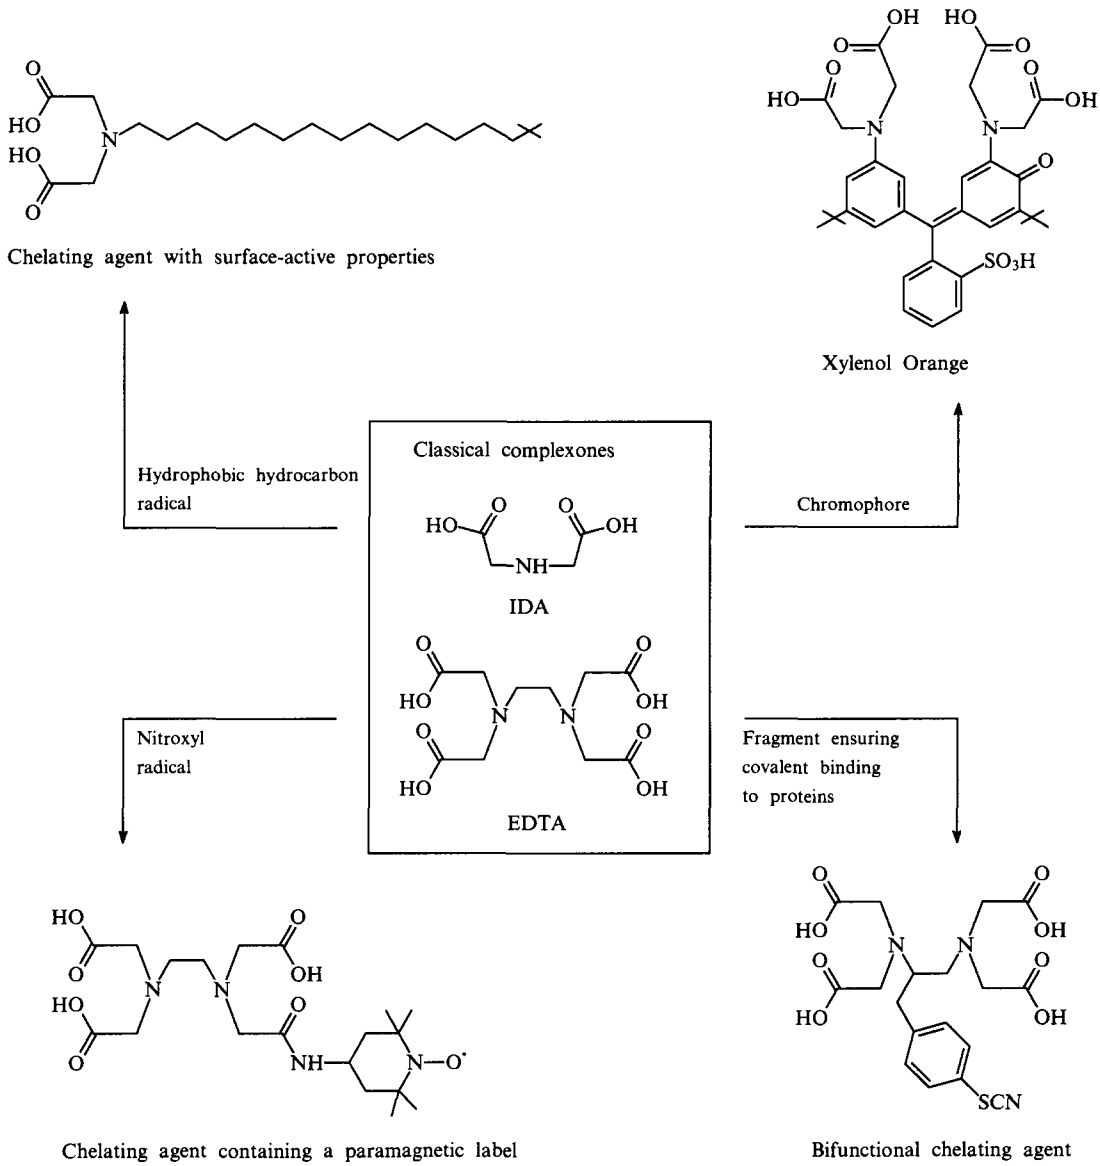
(iii) Not to exert a significant influence on the biological properties of the antigen.

Furthermore, the conjugate obtained must have a low toxicity and must not accumulate in the organism.

By virtue of the ability of the chelating fragment to bind cations into highly stable complexes, the conjugates acquire properties characteristic of the given metal: radioactivity, paramagnetism, the ability to absorb or emit photons, the ability to catalyse certain chemical reactions, etc.,[14,15] whilst variation of the protein component in the conjugate, for example the combination of the bifunctional complexone with various monoclonal antibodies, significantly increases selectivity in the accumulation of the cation-label or the cation-base of the therapeutic preparation in an in vivo situation.[16,17]

The bifunctional complexone not only ensures the attachment of the cation to the protein but frequently lowers, as a result of complex formation, the toxicity of the metal and increases its 'acceptability' to the organism.[18]

Studies in the field of the synthesis and application of bifunctional complexones have been prosecuted extremely



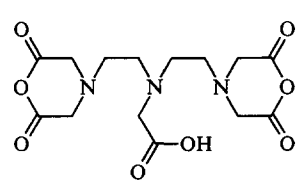


Figure 1. Different versions of the coupling of chelating and other functional fragments. IDA = iminodiacetic acid; EDTA = ethylenediaminetetraacetic acid.

vigorously. The possibility of the application of complexes of radioactive cations in the diagnosis and treatment of different forms of cancer,[19-24] in immunological research,[25-31] in the study of enzymes,[32-34] and in the study of various organs[35-37] has been discovered. Equally extensive prospects have arisen in connection with the complexes of paramagnetic (NMR tomography)[38-40] and fluorescent-active cations.[41-44]

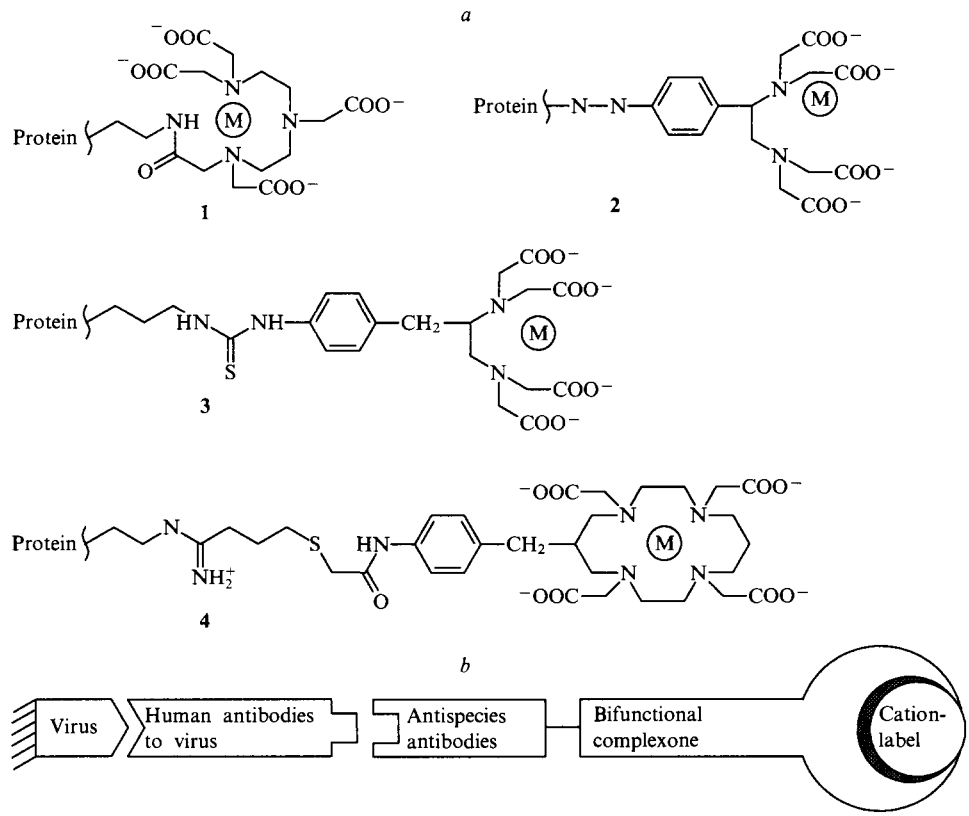
II. Methods of synthesis of bifunctional complexones

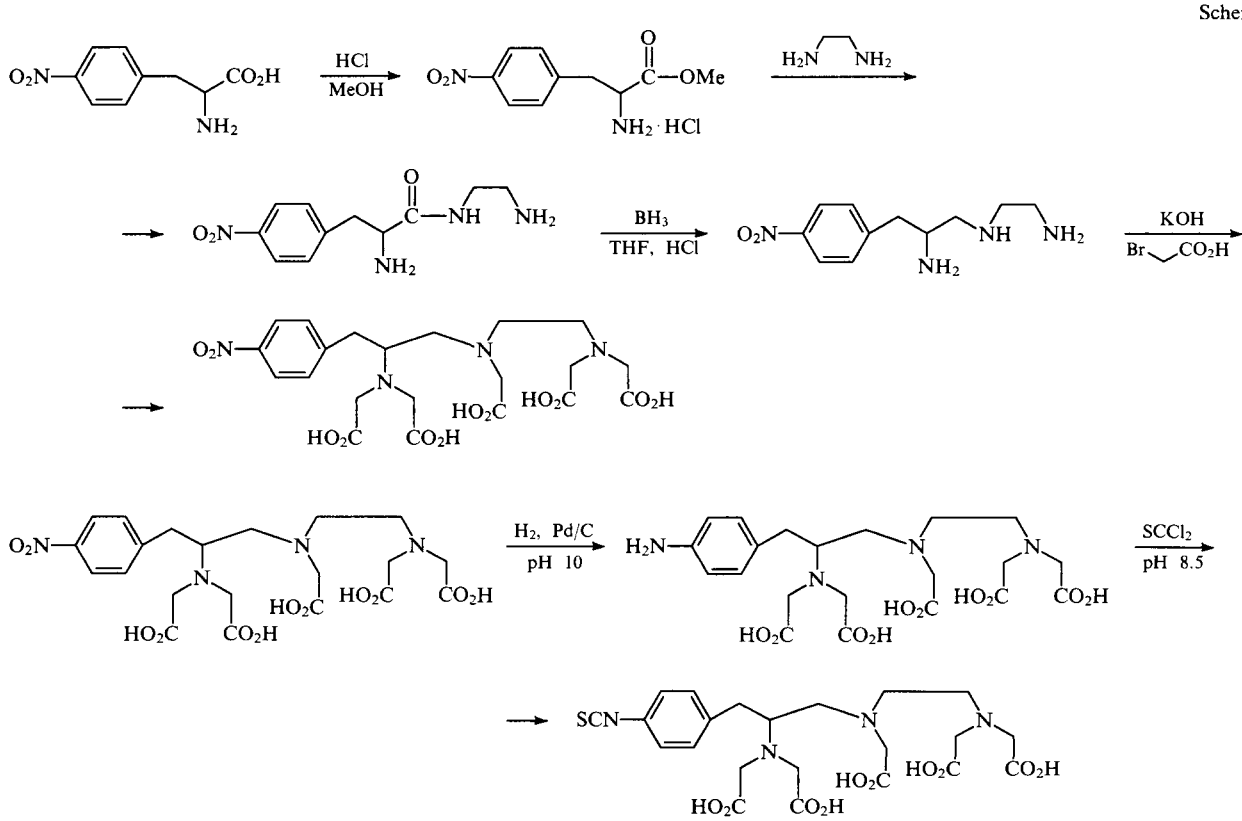
Nowadays it is possible to differentiate two approaches to the modification of complexone molecules. The first ensures the formation of a covalent antigen–complexone bond as a result of chemical reactions involving at least one of the acetate groups of the complexone (Fig. 2*a*, compound **1**). The potential denticity of the chelating component of the bifunctional complexone can then be reduced, since the complex-forming capacity of the oxygen atom, arising when the acetamide group is bound to the antigens, is lower than that of the analogous atoms in the ionised carboxy-group.

The starting materials for the preparation of bifunctional complexones are mixed (A-DTPA) and bicyclic (B-DTPA) anhydrides of DTPA, the bicyclic anhydride of EDTA, the *N*-hydroxysuccinimidic ester of DTPA (E-DTPA),[10,45-47] and certain other ligands.[10,46,48,49]

B-DTPA

The synthesis of such complexones is distinguished by its simplicity. Thus B-DTPA is obtained under heterogeneous conditions by heating DTPA in an excess of acetic anhydride and pyridine at 65 °C for 24 h with subsequent filtration of the reaction mass in order to separate the deposit of the target product.[50] Sometimes a mixture of pyridine and dioxane is used as the reaction medium.[45]





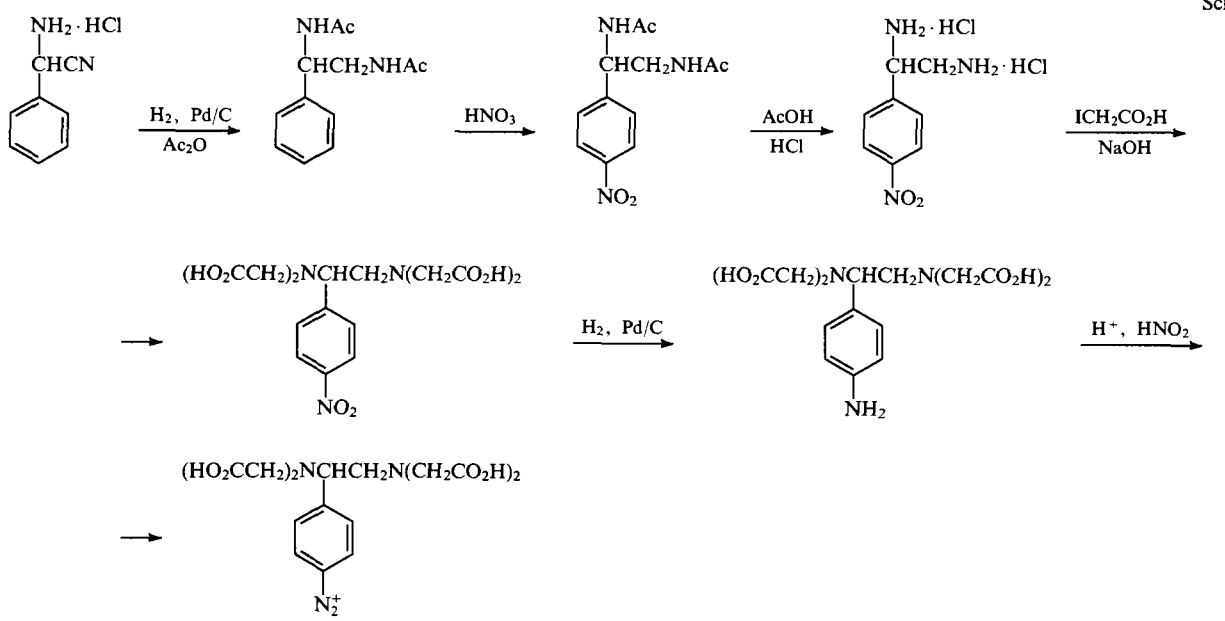


Figure 2. Conjugates formed by bifunctional complexones (*a*) and a general scheme for the diagnosis of viral diseases with the aid of bifunctional complexones (*b*).

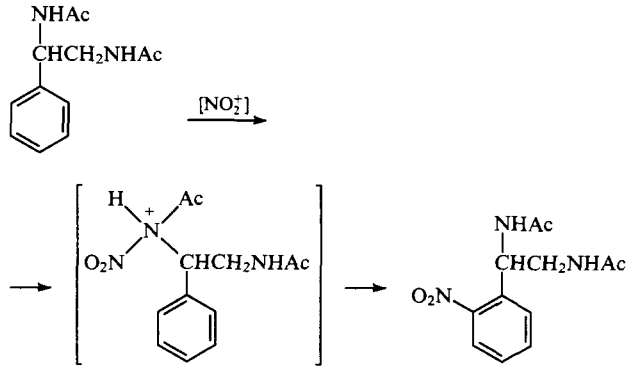
Scheme 1

Scheme 2

E-DTPA is also synthesised under mild conditions by the reaction of DTPA with *N*-hydroxysuccinimide in the presence of triethylamine and dicyclohexylcarbodiimide.[27,51]

The possibility of obtaining carboxyalkylated derivatives of ethylenediamine, diethylenetriamine, and their analogues containing secondary amino-groups by the interaction of the above amines with monochloroacetic acid in the presence of calcium oxide is extremely promising.[52-54] The presence of the 'free' amino-group in the structures of such ligands gives rise to hope for their employment in the synthesis of bifunctional complexones with a specified structure.

Another approach in the creation of bifunctional complexones is based on the incorporation in the hydrocarbon skeleton of the complexone of a centre reactive in relation to proteins (Fig. 2*a*, compounds **2**–**4**). In this case, the chelating capacity of the complexone is retained after its immobilisation on proteins, but the synthesis itself is made significantly more complex. As a rule, either a phenyl or an alkylphenyl group with an isothiocyanate fragment in the *para*-position relative to the chelating component is introduced into the hydrocarbon skeleton of the complexone (EDTA, DTPA).[55,56] On subsequent conjugation, the isothiocyanate (diazonium, azide, haloacetamide) group participates in the formation of a covalent bond with the protein.



The synthesis of 1-benzyl-substituted derivatives of DTPA and EDTA is a two-stage process. The nitrobenzyl derivatives of the complexones are obtained initially, after which the functional group of the benzyl substituent is converted into the fragment employed for coupling to proteins, for example via Scheme 1 (see previous page).[34]

Scheme 2 represents the process involving the formation of a modified EDTA containing a benzenediazonium group in the ethylene bridge.[34]

It is noteworthy that the nitration of the amine, obtained by the catalytic hydrogenation of the hydrochloride of 1-phenylglycine nitrile in acetic anhydride, leads, according to NMR spectroscopic data, to the formation of a mixture of *ortho*- and *para*-isomers in molar proportions of 2:3. The formation of the *ortho*-isomer is probably preceded by the formation of an intermediate in the nitration of the diamine—an unstable *N*-nitroamide (Scheme 3).

A disadvantage of the method described above is also the low yield (< 30%) of diaminotetraacetic acid in the stage involving alkylation of the corresponding diamine dihydrochloride with an

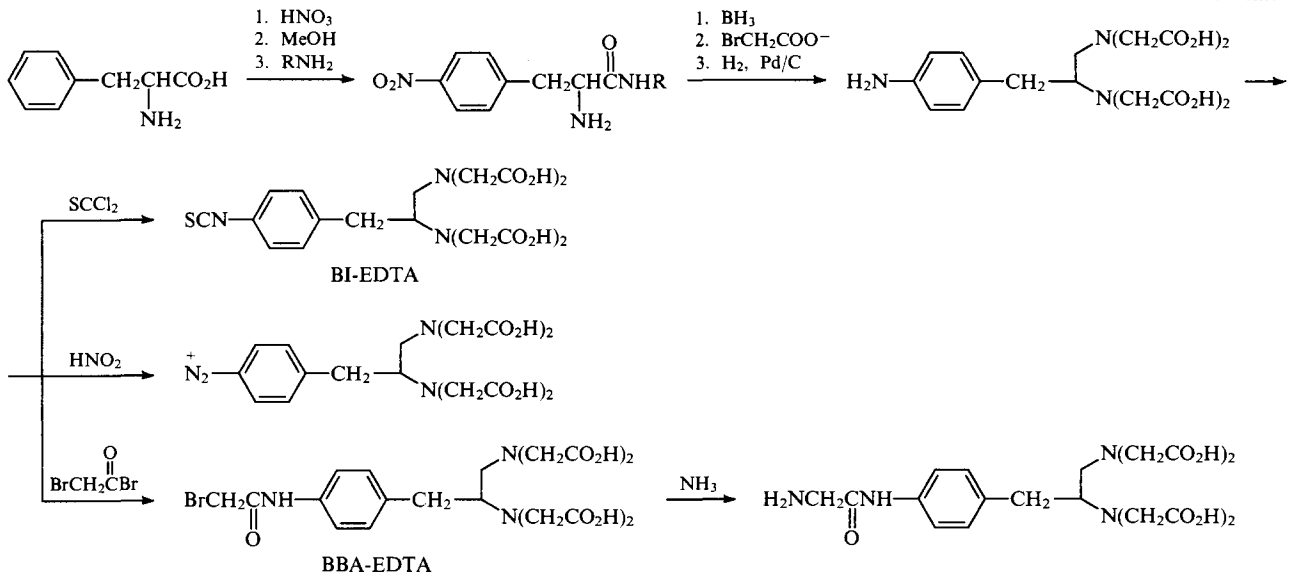
Scheme 3

excess of iodoacetate or bromoacetate.[57] The use of methyl 2-amino-4-phenylbutyrate as the initial compound[10] instead of the hydrochloride of 1-phenylglycine nitrile makes it possible to reduce to a considerable extent the amount of the *ortho*-isomer formed on nitration and to obtain the analogous bifunctional complexone in a high yield. The small amount of the *ortho*-isomer (~10%) is easily removed by crystallisation.

The reason for the appreciable decrease in the yield of the *ortho*-isomer in this case is the separation from the aromatic ring of the chelating group produced by a distance equivalent to two hydrocarbon units and the consequent decrease in the risk of β-elimination.

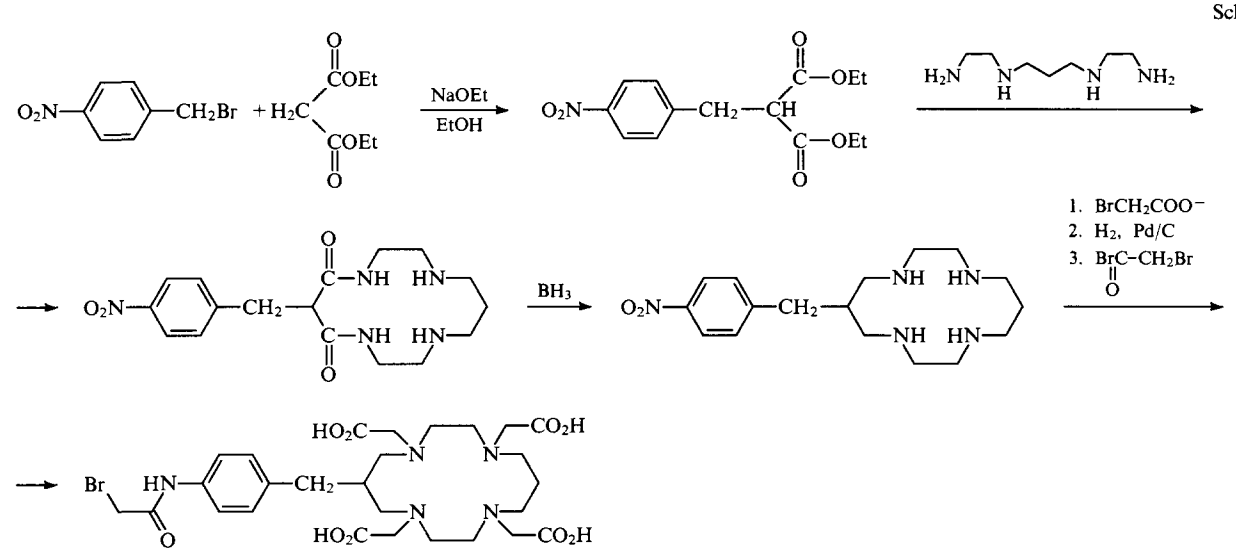
New possibilities in the synthesis of bifunctional complexones have arisen by virtue of the use of α-aminoacids (α-AA) as the initial compounds.[34]

α-AA → α-AA ester → α-AA amide → α-AA diamine



→ bifunctional complexone

By employing amines with different structures for the preparation of the amide, it is possible to vary widely the chelating properties of the target product.



Scheme 4 illustrates the synthesis of bifunctional reagents in which phenylalanine is employed as the initial compound.[27]

The only serious disadvantage of the above synthesis is the need to use the toxic thiophosgene in the stage where the amino-group is substituted by the isothiocyanate group.

Scheme 4

Scheme 5

The multistage nature of the process is to a large extent compensated by the virtually quantitative yield of (*S*)-*N*-4-{2,3-bis[bis(carboxymethyl)amino]propyl}phenylbromoacetamide (BBA-EDTA) and its phenyl isothiocyanate analogue (BI-EDTA).[55]

Derivatives of tetraazacyclotetradecanetetraacetic acid (TATA of H_4tata) (Scheme 5) have also been obtained in a high yield using a readily available starting material.[58]

III. Synthesis of conjugates based on bifunctional complexones

In the preparation of conjugates, the sequence of reactions in the synthesis of the final products can be various. For BBA-EDTA, BI-EDTA, and the anhydrides of DTPA and E-DTPA, it is recommended that the chelating agent is initially coupled to the protein and then the cation-label is introduced into the system. For TATA, the synthesis is usually carried out in the opposite sequence,[10] but the first version is also permissible.

The coupling of the anhydrides of TATA and DTPA to proteins proceeds as a rule readily and under mild conditions. For example, in order to obtain the conjugates based on B-DTPA, the dried and purified anhydride of DTPA is treated with a bicarbonate buffer solution of the protein (10–15 mg ml^{-1} in 0.05 M solution of sodium bicarbonate at pH 8.5). The free DTPA is removed from the bound protein with Sephadex-650 molecular sieve or by centrifugation.[59]

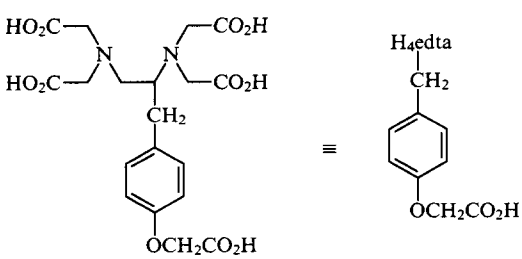
The combination of B-DTPA with proteins is statistical in character: some of the protein molecules always remain free, whilst others combine with several B-DTPA fragments at once. Calculation shows that, for the average ratio [protein]:[B-DTPA] = 1:3, only a small proportion of the macromolecules remain unbound to the complexone, whereas for the 2:1 ratio more than 60% of the protein reacts with B-DTPA.[59]

It is quite evident that the proteins can lose activity as a result of immobilisation, the degree of degradation increasing with increase in the number of attached complexone molecules. It has been noted that the probability of side reaction involving so called 'cross' binding to the antibodies i.e. the 'cross linking' of the protein molecules with one another, is relatively high for A-DTPA. The chelating capacity of the complexone then diminishes sharply and it becomes necessary to carry out an additional purification of the reaction mixture in order to remove such 'blank' conjugates with a double molecular mass.[33]

Comparison of the relative effectiveness of the conjugation of B- and A-DTPA showed that the latter reagent is unstable, hydrolysing at an elevated temperature, and it is therefore not

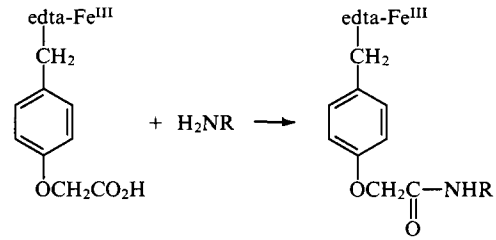
possible to isolate and analyse it. Accordingly, the determination of the protein : anhydride ratio involves significant difficulties. On the other hand, B-DTPA is stable and the synthesis involving it is to a large extent susceptible to monitoring. A satisfactory reproducibility of the coupling reaction is attained as a result.[59]

It has been established that the effectiveness of the incorporation of the radioactive indium-111 into systems obtained by treating various proteins with B-DTPA ranges from 30% to 60% of the indium-111 isotope introduced, depending on the nature of the antibodies.[32]



A minimal probability of cross-link formation has been noted for E-DTPA. For example, other conditions being equal, E-DTPA retains its antigen binding activity to a greater extent than B-DTPA — 100% and 70% respectively. Furthermore, the conditions needed to attain the maximum effectiveness of the coupling of E-DTPA to proteins are closer to the natural physiological conditions under which proteins exist than in the case of B-DTPA. In particular, maximum coupling efficiency has been noted for B-DTPA at pH 8.3, whereas in the case of E-DTPA it occurs in the region of pH 7.[60]

The number of variants of the coupling to proteins is much smaller for B-DTPA than for E-DTPA.[60] The bicyclic anhydride is capable of interacting mainly only with the accessible lysine residues, whereas E-DTPA adds also to the histidine and tyrosine fragments. Among the disadvantages of E-DTPA, one should include also its ability to form with proteins conjugates with a higher molecular mass and lower stability in vivo than the conjugates formed by B-DTPA. The practical consequences of this may be a higher degree of accumulation of the E–DTPA-labelled proteins in the liver and a considerable dose of the accumulated activity in the kidneys and in the bladder.[30]



The coupling to proteins of the bifunctional complexones formed as a result of the modification of the hydrocarbon 'skeleton' is usually carried out by simple mixing of the components at pH 8–9 whilst cooling the mixture. The complexone is as a rule taken in excess. At the end of the coupling reaction, lasting on average several hours, the conjugate is separated from the reaction mixture by dialysis. It has been noted that in certain cases, when the average number of chelating molecules bound to the protein is greater than 3, a loss of the immune activity of the antibodies is observed.[10,20,35,37]

It has been established that the haloacetamide groups are distinguished by a low selectivity in reactions with natural macromolecules. These groups interact effectively with a wide range of nucleophilic centres of proteins, including the sulfhydryl and amino-groups. The resistance of these groups to hydrolysis under the conjugation conditions (37 °C, pH 9.5) makes it possible to obtain the necessary number of protein-bound chelating groups ($c > 10^{-5}$ M), which ensures, in its turn, the rapid and quantitative binding of the metal cations in the next stage of the synthesis of the conjugate.[23] The immune activity of the complexone–protein conjugates is retained for the group of compounds under considerations at a level of 77%–84% relative to control antibody specimens.[61]

1-(*p*-Carboxymethoxybenzyl)-EDTA occupies a special place in the overall series of benzyl derivatives of EDTA.

A necessary condition for the formation of the imide bond between this compound and the protein molecule is the preliminary formation of a complex with a metal, which protects the chelating fragment from undergoing the analogous reaction. A cation-label, for example the radioactive indium(III) or iron(III) isotopes, is usually selected as the complex-forming agent. The iron complexonate is obtained by the interaction of the complexone with iron(II) at pH 2. The complexonate produced is rapidly oxidised by atmospheric oxygen to the corresponding iron(III) derivative [subsequently the iron(III) complexonate must be protected against photodegradation]. The iron(III) chelate, taken in excess, readily reacts with human serum albumin at 20 °C and pH 5.[62]

R = protein

If necessary, the iron(III) may be removed from the conjugate by reduction during dialysis, by employing a buffer solution containing ascorbate and citrate ions and EDTA at pH 5. In the absence of ascorbate ions, the iron(III) is not removed from the conjugate.[62]

Cations can be easily introduced into the system by simple mixing of the components (with some excess of the metal) at pH 6, established with the aid of an acetate buffer solution.[10,63] Depending on the nature of the cation and of the chelating component of the immobilised protein, the reaction lasts from several minutes (indium-111)[10] to several hours (yttrium-90).[64] The conjugate is separated by dialysis from the excess unreacted components. It has been shown[30,65] that the addition of EDTA is extremely effective in the stage involving the elimination of the free radioisotope from the conjugate.

IV. Physicochemical properties and structures of bifunctional complexones and the conjugates based on them

There are virtually no literature data on the most important physical, chemical, and biological properties of the bifunctional complexones. This can be accounted for to a large extent by the difficulty of isolating such complexones and of eliminating the impurities from the latter (this is needed for accurate potentiometric and spectroscopic studies) and also by the low yield of the final products. Therefore, in constructing the bifunctional complexone molecule, designed to chelate a specific cation, and also in the initial quantitative and qualitative assessment of its complex-forming properties, one has to be guided by the information accumulated for the usual complexones and complexonates, introducing appropriate corrections into the latter.

1. Thermodynamics of the complex formation reaction

Bifunctional complexones, which constitute a special case of classical complexones, are capable of chelating the vast majority of the cations derived from the metals in the Periodic System.[1,10] For biological and medical purposes, the cations of radioactive isotopes (^{111}In, ^{99}Tc, ^{90}Y, ^{67}Cu, ^{46}Sc, ^{67,68}Ga, ^{153}Gd, ^{109}Pd),[10,66–71] paramagnetic cations (Gd^{3+}, Mn^{2+}, Fe^{3+}),[72–76] and fluorescent cations (Eu^{3+}, Tb^{3+})[77,78] are of greatest interest. The thermodynamics of the complex formation reaction is then considered taking into account the presence of the background biometals, for example calcium, which are present in vivo in an excess relative to the cation-label and behave as a competitor capable of displacing the label from the conjugate, reducing thereby the specificity of the action of the preparation introduced.[1,79–81]

For the estimation of the ability of the bifunctional complexone H_nL to form complexes with the cation of the metal M in a preliminary stage, use is made of the concentration stability constant K_{ML} measured at a fixed ionic strength I and a fixed temperature, i.e.

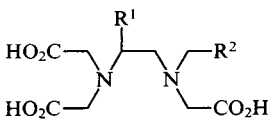
$$K_{ML} = \frac{[ML]}{[M][L]},$$

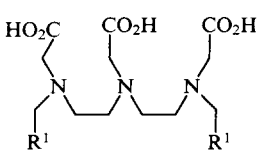
and also of the complex formation selectivity index — $K_{ML} : K_{CaL}$ (or $\Delta \lg K = \lg K_{ML} - \lg K_{CaL}$).

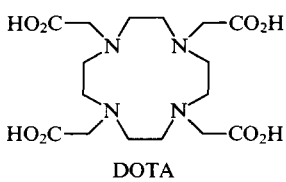
Our analysis of the literature values of the stability constants (see the stability constants handbooks[79-85] and the relevant reviews[86-88]) and inspection of the contents of the computer data bank produced for commercial use by the IUPAC Commission on Chemical Equilibria in 1993[89] revealed that the amount of thermodynamic data, permitting an indirect characterisation of the complex-forming capacities of the bifunctional complexones, is also extremely small. Direct thermodynamic studies on bifunctional complexones have been scarcely carried out. The first reports on this topic appeared comparatively recently.[90]

Table 1 presents certain data for EDTA and DTPA, which permit the qualitative estimation of the trends in the variation of the stabilities of the complexes on passing from classical complexones to their modifications modelling to some extent the bifunctional complexone.

The constants presented in Table 1 show that the introduction of aliphatic and aromatic groups into the ethylenediamine fragment of the complexone not only does not reduce the stability of the complexes but can actually tend to increase it. This effect is apparently associated with the stabilisation by the given group in solution of the ligand conformation most favourable for complex formation.







The replacement of one of the carboxy-groups by a hydrocarbon substituent leads unambiguously to a decrease in the overall stability of the complexes. However, there is then a possibility of an extremely significant increase in selectivity in complex formation by the typical cation-labels Cu^{2+} and Gd^{3+} relative to the endogenic background cations Zn^{2+} and Ca^{2+}.

It is remarkable that the replacement of the carboxylate fragment by the acetamide fragment also induces a sharp decrease in the stability constant. This suggests that in the case of gadolinium the decrease in the stability constant is associated with the decrease in the effective denticity of the ligand: the noninvolvement of the acetamide fragments in the formation of coordinate bonds with the lanthanide ion.

Ligands with 'built in' macrocycles are of considerable interest. Apart from the polychelating effect, the macrocyclic effect also makes an additional contribution in this case.[1,94-97] For example, the use of 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (DOTA or H_4dota) instead of EDTA makes it possible to increase the stability of the europium(III) complexonate by ten orders of magnitude. The selectivity in relation to calcium ion increases simultaneously.[1] At the same time, the differences between the stabilities of the copper, calcium, and zinc complexes are abolished to a significant extent.

The next stage in the approach to a real system involves the consideration of the effective (and not concentration) stability constants K_{ef}, in which account is taken of the hydrolysis of the complexonate. The need for such allowance is due to the tendency of polyaminopolycarboxylic acids to be protonated at the physiological pH (7.2). For example, EDTA is present in the equilibrium mixture under such conditions both in the form of the complex and in the form of the anions $Hedta^{3-}$ and H_2edta^{2-}. This reduces significantly the fraction of the complex proper. Furthermore, the aquometal ions are also partly hydrolysed at the above pH and are present in solution in the form of monomeric and polymeric hydroxy-complexes. The constants K_{ef} make it possible to estimate the pH values most favourable for the complex formation reaction between the given ligand and the given cation.[1,98,99]

Table 1. Stability constants of the complexes formed by EDTA, DTPA, DOTA, and their derivatives (I = 0.1; 20–25 °C).

Ligand (H_nL)	R^1	R^2	$\lg K_{ML}$				Ref.
			Ca^{2+}	Zn^{2+}	Cu^{2+}	Gd^{3+}	
	H (EDTA)	COOH	10.79	16.68	18.86	17.27	88
	Et	COOH	11.75	18.23	20.6	18.6	85
	Ph	COOH	11.25	17.05	19.4	17.4	85
	H	Pr	16.1	–	12.7	13.07[a]	85, 91
	H	Ph	6.7	–	16.8	–	85
	COOH (DTPA)		10.89	18.55	21.53	22.56	88
	C(O)NHMe		7.17	12.04	13.03	16.85	18
	Py		7.97	14.02	17.50	16.83	18
 DOTA			15.85	18.90	19.06	28.21	92, 93

[a] Data for europium(III) (I = 1) are presented.

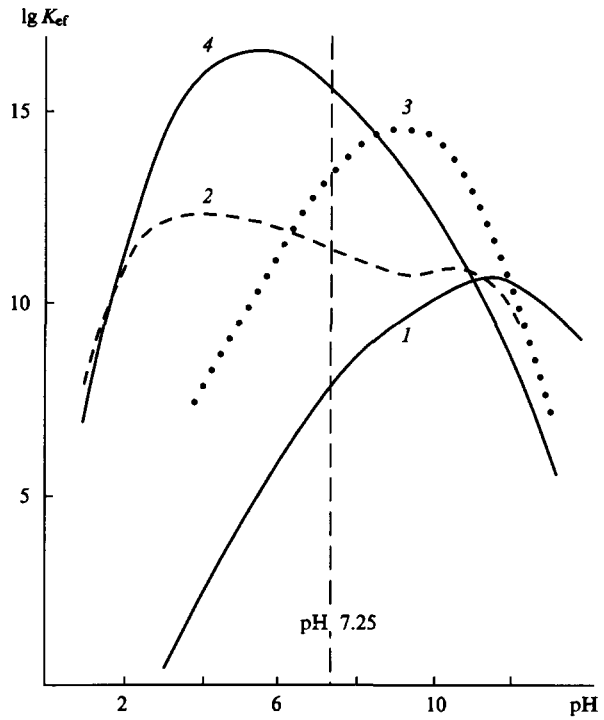


Figure 3. pH dependence of the effective stability constants of the complexes of EDTA with different ions: (*1*) Ca^{2+}; (*2*) Fe^{3+}; (*3*) Sm^{3+}; (*4*) In^{3+}.[100]

Fig. 3 presents the dependence of the logarithms of K_{ef} on pH for the complexes of EDTA with typical cation-labels: Fe^{3+}, Sm^{3+}, and In^{3+} (curves *2–4*). The corresponding values for the background element (calcium — curve *1*) are presented for comparison. The figure shows that in the alkaline region the complex formation reaction between EDTA and calcium becomes preferable to the reaction with indium or samarium.[100]

A clear idea about the ratio of the concentration and effective constants is provided by the following example. Despite the fact that the concentration stability constant of the iron(III) complex of EDTA is 10^6 times greater than that of the copper(II) complex of EDTA, at pH 7 the chelate $[Cuedta]^{2-}$ is 10^2 times more stable than $[Feedta]^-$ according to the calculations of the effective constants.[101]

It is also noteworthy that the calculations of the effective constants performed by different workers using different initial postulates can differ significantly[100,101] and as a rule require a critical analysis.

The problem of predicting the interaction between the complex-forming agent and the ligand in vitro in multicomponent systems, incorporating, apart from the bifunctional complexone, a series of bioligands and a wide range of background cations is much more complex.[79–81,101] Calculations have shown that the introduction of only one additional component into the In^{3+}–EDTA system reduces the K_{ef} at pH 7.4 by six orders of magnitude.[101]

Finally, difficulties which are truly impossible to overcome are faced by the experimenter when an attempt is made to assess quantitatively the thermodynamics of the complex formation reaction in vivo.[101,102] Nevertheless, on the whole knowledge of the thermodynamic stability constants makes it possible to predict fairly successfully the stability of the conjugate.[68,103]

2. Kinetic stability of the conjugates

Apart from the thermodynamic stability of the conjugates, when the latter are modified it is necessary to take into account also their kinetic stability: the rate of loss by the conjugate of the cation as a result of the dissociation of the complex or the substitution reaction between its 'own' cation-label and the competing biometals. Therefore, together with the problem of creating a complex with the bifunctional complexone which is thermodynamically as stable as possible, the problem of retarding the decomposition of the coordination compound appears no less important.

The rates of formation of the complexonates from the aquometal ions and also of the reverse process involving their dissociation are comparable to the rate of exchange of the water molecules in the aquo-ion, i.e. are determined to a first approximation by the properties of the aquo-ions.[1,104]

The introduction of an element of rigidity into the structure of the complexone molecule, in particular the introduction of macrocycles, makes it possible to retard significantly the dissociation of the complex formed by the complexone. For example, while the electrostatic charge on the anion is the same, the rate of dissociation diminishes sharply in the series EDTA–CDTA–DOTA (CDTA or H_4cdta = cyclohexanediaminetetraacetic acid).[1,104] It has been suggested that the kinetic features established in vitro for the classical complexones are also valid for their bifunctional analogues in vivo.

The kinetics of the loss of the metal atom by chelate complexes under the conditions of the living organism have been investigated.[10,34,105] The decomposition of the complex is a consequence of the operation of several factors at once, both kinetic and thermodynamic. In particular, it has been shown that the copper(II) complexes in human blood serum lose the metal in conformity with the prediction based on the analysis of the properties of simpler compounds. Thus the macrocyclic complexonate formed by TATA loses copper at a rate of 1%–3% in 24 h, the chelate based on the DTPA monoamide loses it at a rate of ~50% in 24 h, while the complex based on benzyl-EDTA loses the metal faster still.

The rate of loss of the metal by indium(III) complexonate has been investigated (Table 2).[105] It follows from the data presented that the coupling of the bifunctional complexone to albumin does not influence significantly the rate of biodegradation of the complex. At the same time, it is necessary to note that the ratio of the rate of degradation of the butylamides of EDTA and DTPA is directly opposite to that for EDTA and DTPA. Nevertheless, on the basis of the coordination possibilities of the modified ligands, the tendency in the variation of the rate of degradation of the modified ligands should be of the same type as for the rates of degradation of the corresponding unmodified ligands. The significant scatter of data between different series of experiments indicates the existence of a poorly monitored error.

Table 2. Kinetics of the in vitro loss of indium(III) by complexones, bifunctional complexones, and their conjugates with albumin.[105]

Ligand	Rate of loss of indium by the complexonate ML(%) in 24 h
1-(*p*-Carboxymethoxybenzyl)-EDTA	0.028 (0.041)
1-Methyl-EDTA	0.060 (0.052)
Albumin-phenyl-EDTA	0.060
Albumin-benzyl-EDTA	0.11
EDTA	0.53 (0.67)
EDTA mono-n-butylamide	29.0
DTPA mono-n-butylamide	0.93
Albumin-DTPA	1.6
	2.5[b]
DTPA	2.3 (2.6)

[a] The transfer of indium from the initial chelate complex ML to the complex with transferrin was investigated in human blood serum at pH 7.3 and 37 °C; the data for a repeated series of experiments are presented in brackets.

[b] A 0.01 M glycine solution was additionally introduced into the system.

3. The structure of the complexonates

Together with the thermodynamic, kinetic, and biological properties of the bifunctional complexones, their structure is an extremely important practical characteristic: the real denticity of the ligand and the coordination number of the cation. This is particularly important for the NMR-contrasted substances, since their capacity for paramagnetic interaction with the substrate is higher, other conditions being equal, the greater the number of water molecules retained in the coordination sphere of the paramagnetic cation incorporated in the conjugate.[106,107]

The structures of the metal complexonates have been examined in brilliant reviews.[108-110] Here we shall dwell only on two most important features discovered by analysing the results of more than 300 X-ray diffraction studies:

(i) The coordination number of the cation coordinated by the complexones frequently proves to be higher than those observed for the same ions in complexes with simple monodentate ligands. For example, manganese(II), cobalt(II), magnesium(II), and iron(III) in their EDTA and DTPA complexes exhibit a coordination number of 7, which is unusual for these metals. Because of this factor, the hexadentate EDTA ligand does not displace the entire water from the inner coordination sphere of iron(III), while the anion $[Fe(H_2O)edta]^-$ is a more effective relaxant than might have been expected. Indium(III) has a coordination number of 7 in its EDTA complex[108] and 8 in its DTPA complex.[111]

(ii) For all the structurally investigated crystalline normal complexonates ML and ML_2 with a coordination number greater than or equal to the denticity of the ligand, all the electron-donating ligand atoms are coordinated to the cation. Not a single case has been found in which the water molecule competed with the deprotonated carboxy-group for a site in the coordination sphere of the cation, i.e. a situation where the water molecule would have entered into the composition of the coordination sphere of the metal while one of the deprotonated carboxylate groups remained 'free'. On the basis of these data, one may predict, with a high degree of probability, the degree of shielding of the cation by the ligand on the basis of the structure of the molecule of the chelating agent itself.

Here it is appropriate to mention the lively discussion concerning the possibility of the retention of the structure of the complexonate when it passes from the crystalline phase to an aqueous solution.[112-118] Systematic radiospectroscopic[107,119-122] and EXAFS studies[123] in recent years have shown that the principal features of the structures of the complexonates, in particular the denticity of the ligand, are retained on dissolution. Thus the prediction of the structures of both simple complexonates and of the chelating component of the conjugates of bifunctional complexones in solution, based on X-ray diffraction structural data, is entirely correct.

V. Certain problems in the search for new effective ligands

In the general case, the isolation and analysis in a 'pure form' of any factors influencing the stability constants K_{ML} of polydentate, including bifunctional, complexones are extremely difficult. Thus any variation of the denticity of the ligand is as a rule coupled with the simultaneous variation of several parameters: the electrostatic charge, the size of the chelate ring, the ratios of the numbers of electron-donating atoms of different nature, etc.

Procedures such as variation of the denticity and of the dimensions of the rings potentially capable of being formed and the introduction into the structure of the chelating agents of elements of rigidity as well as heteroatoms, which ensure the selectivity of action in relation to the cation under consideration, are most widely used.[1]

For example, the introduction of the phosphonate group instead of the carboxylate group sharply increases the selectivity of the chelating agent in relation to copper(II) ions (Fig. 4). The tropicity (selectivity) in relation to bone tissue frequently

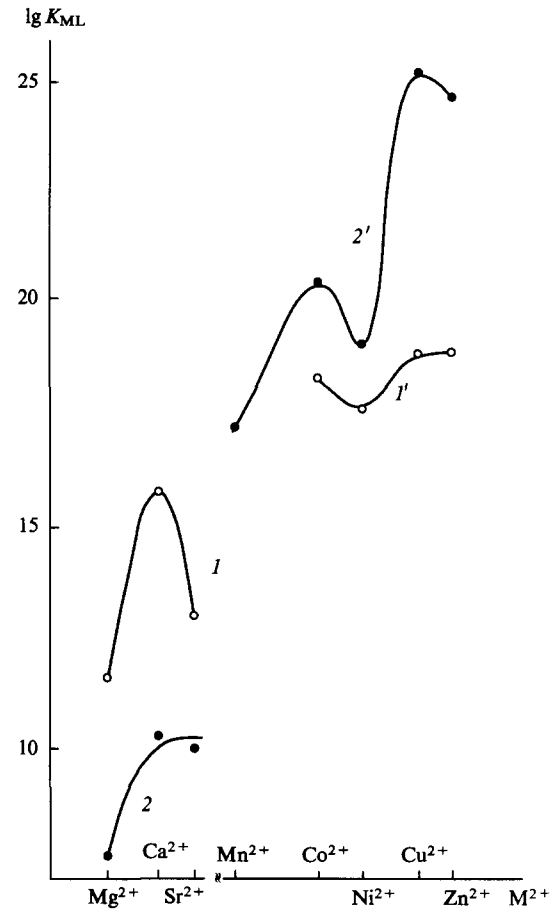

Figure 4. Relative changes in the stability constants in the series of alkaline earth (curves *1* and *2*) and 3*d* cations (curves *1'* and *2'*) for DOTA (curves *1* and *1'*) and its methylenephosphono-analogue (curves *2* and *2'*).[1,89,92,93]

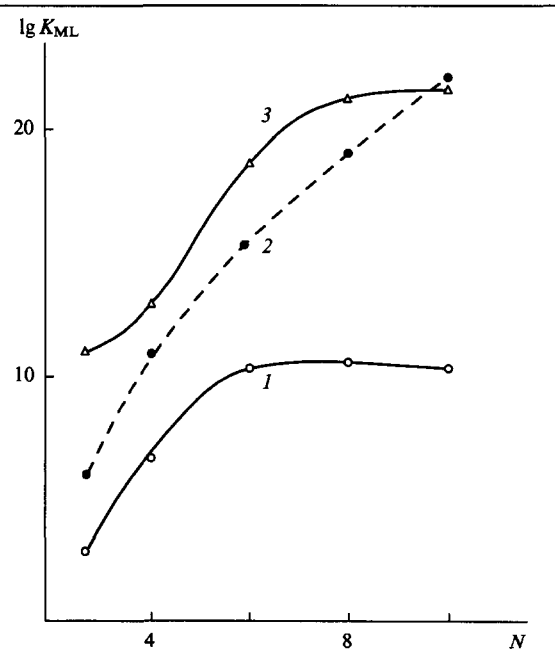

Figure 5. Dependence of the stability constants of the M^{n+} complexonates on the potential denticity of the ligand (*N*); M = Ca (curve *1*), La (curve *2*), or Cu (curve *3*). Data[85] for IDA, NTA (NTA or H_3nta = nitrilotriacetic acid), EDTA, DTPA, and TTHA (TTHA or H_6ttha = triethylenetetraminehexaacetic acid), considered as models of tri-, tetra-, hexa-, octa-, and deca-dentate chelating agents, were employed.

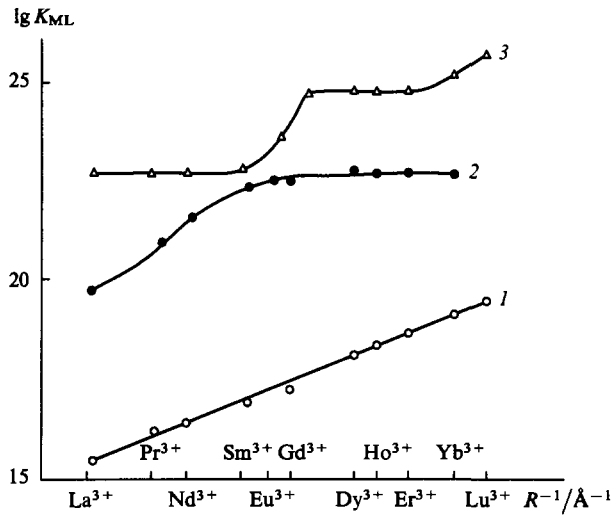
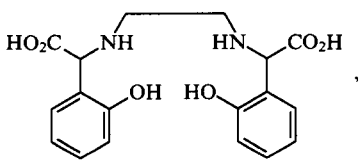
increases under these conditions in the complex formed.[124,125] An increase in the denticity and the charge of the ligand (Figs 5 and 6) as a rule renders this ligand more selective in relation to lanthanides, which have large coordination numbers.[126-129]

At the same time effects which are difficult to explain are also observed. For example, there is no equivalent increase in the stability of the complexes of the barium ion on passing from the hexadentate EDTA to the octadentate DTPA, although the size of the ion is not less than that of the lanthanide ions.

The creation of a chelating agent for a specific cation frequently extends over many decades. As an example, we may consider the development of events in the construction of the molecule of the optimum chelating agent for the iron(III), gallium(III) and indium(III) ions.





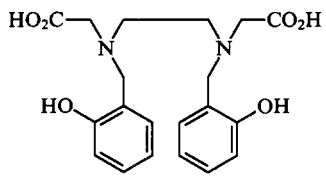


Figure 6. Dependence of the stability constant of the chelating agent on the ionic radius of the lanthanide (R):[85,88,89,93] (*1*) EDTA; (*2*) DTPA; (*3*) DOTA.

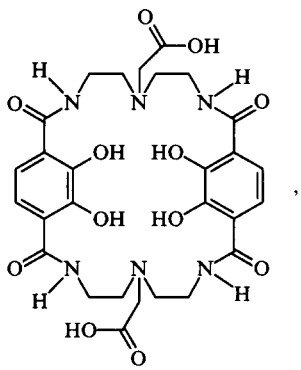
At the end of the 1950s and the beginning of the 1960s, it was found that the combination in the complexone molecule of fragments of ethylenediamine-*N,N'*-diaacetic acid and phenol, which happens in *N,N'*-ethylenebis[2-(*o*-hydroxyphenyl)glycine] (H_2ehpg),



increases sharply the stability of the iron(III) complex ($\lg K_{ML}$ = 33.9) compared with the universal chelating agents such as EDTA ($\lg K_{ML}$ = 25.0).[130,131] The success achieved initiated the synthesis of a series of preparations with contrasting properties.[132-137] However, according to L'Eplattenier et al.,[138] the relative positions of the donor atoms in the ligand considered generated a steric hindrance to their simultaneous involvement in coordination. Later X-ray diffraction studies on the complexes $[Mg(H_2O)_6][Gaehpg]_2 \cdot 3H_2O$, $[Co(H_2O)_6][Coehpg]_2 \cdot 4H_2O$, $Na_2[Cuehpg] \cdot 5.5H_2O$, as well as the iron(III) complex[139-140] showed that these fears were groundless: in all the complexes investigated, the ligand exhibits the maximum possible denticity of six by coordination of both nitrogen atoms, the two oxygen atoms from each carboxylate group, and the two oxygen atoms of the deprotonated hydroxy-groups. Nevertheless, the sterically free complexone ethylenediamine-*N,N'*-di(2-hydroxybenzyl-*N,N'*-diaacetic acid (H_2hbed),

made it possible to achieve the highest attained stability for an iron(III) complex: $\lg K_{ML}$ = 39.68.[138] The corresponding constants for indium(III) and gallium(III) also proved to be some of the highest (39.66 and 39.57).[141] These studies stimulated in their turn the synthesis of a series of bifunctional ligands based on H_2hbed.[68,142]

Subsequent experiments on the modification of similar structures led to the following results. The replacement of the carboxy-groups in H_2hbed by phosphono-groups made it possible to increase the selectivity of the complexone in relation to the copper(II) ions in the series of 3*d* elements.[143] Although another modification of H_2hbed, involving the replacement of the phenol moiety by a pyridine group, led to the formation of iron(III) complexes less stable than the corresponding compound derived from H_2hbed ($\lg K_{ML}$ = 36.91), it made it possible to increase its solubility and also its acceptability to the human organism.[143,144]

Contrary to expectations, attempts to synthesise on the basis of H_2hbed the macrocyclic complexone 4,17-bis(carboxymethyl)-10,11,23,24-tetrahydroxy-8,13,21,26-tetraoxo-9,10,11,12 : 22,23, 24,25-dibenzo-1,4,7,14,17,20-hexaazacyclohexacosane,[145]

did not lead to a further increase in the stability of the iron(III) complexes, although the stability constant proved to be extremely high — $\lg K_{ML}$ = 37.6 (25 °C, I = 0.1).

It is noteworthy that a high stability of the complex is by no means always the main aim. The structure of the chelating agents is frequently dictated by purely biological or methodological features. For example, as a consequence of the low stoichiometric chelate : protein ratios, the cyclic dianhydride of DTPA proved to be entirely effective for the creation of bifunctional conjugates with radioactive cations.[34] However, magnetic-resonance contrasting requires complexes with a high chelating agent : protein ratio. Under these conditions, the given chelating agent is less suitable,[146] since an increase in the relative content of the dianhydride of DTPA entails a sharp increase in the number of intermolecular covalent bonds involving it and in the number of heterogeneous products formed on conjugation; under these conditions, the reproducibility and technological applicability of the synthesis fell.

This obstacle can apparently be overcome by varying the macromolecular component of the conjugate. For example, when albumin was replaced by polysaccharides, it was possible to obtain conjugates with DTPA and gadolinium(III) virtually without intermolecular cross links.[147]

Another problem is the permeability of the cell membrane to the conjugate. Its solution requires the optimisation of a large

number of parameters. It has been shown[148,149] that the membranes are satisfactorily permeable to electrically neutral complexes. Electrical neutrality also reduces the osmotic pressure. However, this is accompanied by a decrease in the solubility of the complexonate itself[1] and also in the effective denticity of the complexone, which leads as a rule to a decrease in the thermodynamic stability of the complex and hence to an increase in its toxicity owing to the removal from the complex of a large amount of the cation-label in a 'free' state.

For example, the gadolinium complex of DTPA proved to be an extremely effective contrasting agent in NMR tomography by virtue of its high stability constant.[150] However, as a consequence of the high negative charge of $[Gddtpa]^{2-}$, this preparation is poorly assimilated through the gastrointestinal track[151] and can be used only in the form of injections. The replacement of DTPA by its dimethylamide derivative made it possible to obtain an electrically neutral gadolinium complex with a significantly higher permeating capacity but a lower thermodynamic stability in relation to dissociation into the 'free' ligand and the metal ion. However, subsequent studies showed that the toxicity of the complex not only did not increase but actually fell (Table 3). This is due to the fact that the stability of the complexes of the dimethylamide of DTPA with ions competing with gadolinium (calcium, zinc) diminishes to an even greater extent and under in vivo conditions the selectivity in the binding of gadolinium and the lethal dose increase.[18]

Table 3. Results of toxicological studies on gadolinium complexes (intravenous administration to mice).[18,151]

Ion investigated, complex	$\Delta \lg K_{ef}$ [a]	LD_{50}/ mmol kg^{-1}
$[Gd^{3+}aq]$	–	0.4 [b]
Na_2Hdtpa - BMA [c]	–	0.16
Na[Cadtpa - BMA]	–	16.6
[Gddtpa - BMA]	9.04	14.8 (0.7)
Na_2[Gddtpa]	7.04	5.6 (0.2)
	–	10.0 [b]
[Gddtpa - BP] [d]	5.32	2.8 (0.1)
Na_2[Gdedta]	4.23	0.3 (0.1)

[a] The difference between the logarithms of the effective stability constants of the gadolinium and zinc complexes with the given ligand at pH 7.4 was adopted as $\Delta \lg K_{ef}$.
[b] Intravenous administration to rats.
[c] dtpa - BMA = DTPA *N,N″*-bis(methylamide).
[d] dtpa - BP = *N,N″*-bis-(2-pyridylmethyl)-DTPA.

It is remarkable that an X-ray diffraction study of the gadolinium(III) complex of the dialkylamide of DTPA[152] did not reveal a decrease in the denticity of the complexone compared with the DTPA itself;[153] a coordination number of 9 in the case of gadolinium is achieved as a result of the presence of the octadentate ligand and one water molecule. Admittedly, the average metal - oxygen distances in the amide fragments proved to be greater than in the acetate fragments. The problem whether this structure is retained on dissolution of the complex still remains open.

* * *

On the whole one may conclude that the predictions of the thermodynamic and kinetic stabilities of the conjugate based on estimates of the properties of simple model chelates have proved to be fairly reliable. In particular, the high stability constants ($\lg K_{ML} > 20$) of the indium(III) complex of EDTA and the gadolinium(III) complex of DTPA make it possible to obtain effective indium- and gadolinium-containing diagnostic and therapeutic preparations, in which the chelating fragment is based on EDTA and DTPA derivatives.[154-157] The approach based on the kinetic stability of CDTA and DOTA complexonates proved no less fruitful. Thus the conjugates based on the CDTA and DOTA ligands retain the kinetic features characteristic of their classical analogues.[158,159]

On the other hand, successful bioconjugates could not be created on the basis of complexones such as IDA and NTA, which form complexes with low and moderate stabilities ($\lg K_{ML} < 17$).

However, one should note that, even in the case of the classical chelating compunds, it is not always possible to predict the optimum effect in vivo. For example, in selecting the ligand for the extraction of plutonium from the human organism it was found that the DTPA-based preparation was just as effective as the tetracarboxycatecholate ligand, which forms with plutonium complexes more stable by a factor of 10^{10} than those formed by DTPA.[160]

Bifunctional complexones constitute a vigorously developing field in the chemistry of chelate compounds. It may be expected that in the immediate future the search for chelating agents and conjugates with a specific tropicity in relation to particular organs and tissues will assume a greater importance.

This review was written thanks to the partial financial support by the Russian Fundamental Research Fund (Grant No. 94-03-09113) and the 'Creation of New Medicinal Agents by Chemical and Biological Synthetic Methods' Program.

Abstract. The results of kinetic studies on the thermal decomposition of alkyl derivatives of Group III and V elements, used to obtain semiconducting epitaxial structures, are surveyed. Their reaction paths in the gas phase and on the surface of epitaxial layers as well as the factors influencing the mode of decomposition are analysed. The possibility of the formation of complexes between the components of the organoelement mixture during their joint pyrolysis is demonstrated. The bibliography includes 128 references.

I. Introduction

Organometallic compounds (OMC) and hydrides are used as a source of the metal in the formation of epitaxial layers of semiconducting materials.[1–3] The decomposition of the OMC and hydrides on the surface, known as the OMC method or as the metal organic chemical vapour deposition (MOCVD) or the metal organic vapour phase epitaxy (MOVPE) method, is undoubtedly an effective technological process, which makes it possible to achieve the selective growth of epitaxial layers with the required composition and thickness and the necessary set of properties.[4,5] Manasevit was the first to propose the use of the reaction of trimethylgallium with arsine in order to obtain epitaxial gallium arsenide layers.[6,7] This reaction can be formulated by means of the following overall expression:

$$(CH_3)_3Ga + AsH_3 = GaAs + 3CH_4.$$

In subsequent studies,[8,9] the method was used to grow films of organoelement compounds (OEC) of Group III–V elements. This procedure was used to obtain GaP films from $(CH_3)_3Ga$ and PH_3, GaAsP films from $(CH_3)_3Ga$, PH_3, and AsH_3, GaAsSb films from $(CH_3)_3Ga$, SbH_3, and AsH_3, etc. AlAs, GaN, AlN, $GaAs_xP_{1-x}$, $GaAs_xSb_{1-x}$, InAs, GaInAs, InAsP, InP, etc. films, based on the alkyl derivatives of Group III elements and nitrogen, phosphorus, arsenic, and antimony hydrides, have been grown similarly.[8,9]

Initially the investigators were interested exclusively in the technological problems associated with the construction of the reactors, the behaviour of the carrier gas, and the selection of the substances required, problems of mass transfer and hydrodynamic aspects being discussed.[9–11] At the present time, serious attention has been devoted to the fundamental principles of these technological processes: the mechanisms of the chemical reactions occurring in the gas phase and on the surface.[12–14] In his review,[5] Shaw distinguishes the following stages in the MOCVD process: (1) the supply of the reactants to the film growth region; (2) diffusion of the reactants to the surface of the support; (3) adsorption of the reactants on the surface; (4) surface processes involving chemical reactions, surface diffusion, and the binding of deposited materials to the support; (5) desorption of the gaseous chemical reaction products; (6) diffusional transport of the products in the stream of carrier gas; (7) removal of the reaction products from the growth region.

Stages 3–5 generally determine the rate of the deposition process and its principal physicochemical characteristics. In the chain of problems comprising the synthesis, purification, and stabilisation of the OEC, the kinetics, thermodynamics, and mass transfer of the OEC, and the design features of the reactors for the growing of epitaxial layers, each has independent importance. However, it is recognised that the factor inhibiting the development of the chemical gas-phase deposition is primarily the difficulties of understanding the mechanism of the pyrolysis of the OEC.[12–14]

In the present review, attention is concentrated on the consideration of the mechanisms and rates of the thermal decomposition reactions of the OEC of Group III and V elements in the gas phase and under the real conditions in the growth of films as a result of chemical deposition from the gas phase. The study of the kinetics of the thermal decomposition of the above classes of compounds is of theoretical interest for the development of the OEC chemistry and ensures the solution of the technological problems in the preparation of Group III–V semiconducting materials.

The pyrolysis of the OEC to the element and hydrocarbons is a complex chemical process. The multistage nature of the homolytic reactions involving the abstraction of alkyl groups from the initial and intermediate OEC is combined with molecular decomposition reactions (β-elimination). The homogeneous and heterogeneous stages are manifested in different ways

in the pyrolytic reactions. As a consequence of the dual action of the wall, which is involved in the initiation and the destruction of the active centres on the surface, cases are possible where, despite the presence of heterogeneous stages, the rate of the overall process is independent of the ratio of the surface area of the walls (S) to the volume (V) of the reactor.

The homogeneous-heterogeneous character of the pyrolysis of the OEC and the involvement of these compounds in radical and molecular consecutive-parallel elementary reactions is the principal reason why it is impossible to establish a chemical mechanism which corresponds to the experimentally established macrokinetic law. Nevertheless, the knowledge of the macrokinetic laws makes it possible to solve a series of general and specific problems — in the first place, to test the validity of the hypotheses concerning the reaction mechanisms. The postulated mechanism is tested by comparing the experimental and theoretical and kinetic laws. The discrepancy between experiment and theory is a reliable sign that the proposed mechanism is erroneous. On the other hand, consistency between theory and experiment is not a sufficient basis for the adoption of the postulated mechanism.

Furthermore, the knowledge of the macrokinetics makes it possible to distinguish certain characteristic features of the reaction investigated. Thus a fractional order with respect to the OEC concentration and the independence of the rate of reaction of the concentration of one of the reactants yield reliable information about the involvement of free radicals in the reaction and about the role of the reactants in the rate-limiting stage of the process. Here one should also include the determination of the heterogeneity factor (S/V). The variation of the rate of the overall reaction as a function of S/V indicates an appreciable contribution of the desorption process (the fifth stage) and of the reactions at the interface.

There have been fairly numerous kinetic measurements on the pyrolysis of OEC of Group III and V elements, but they are frequently contradictory. Systematic treatment and discovery of the general features of the variation of the reactivity of individual OEC and their mixtures in the gas state and under the conditions of the growth of epitaxial layers will make it possible to select keys to the regulation of these processes.

II. Kinetics of the thermal decomposition of alkyl derivatives of Group III elements

The most 'puzzling' OEC among the compounds of Group III elements are probably organoaluminium compounds and particularly $(CH_3)_3Al$. The formal kinetics of its thermal decomposition were investigated for the first time by Yeddanapalli et al.[15] In the temperature range 570–610 K, the rate of thermal decomposition of $(CH_3)_3Al$ is described by the equation for a reaction the order of which is 3/2. The rate constant can be expressed as follows:

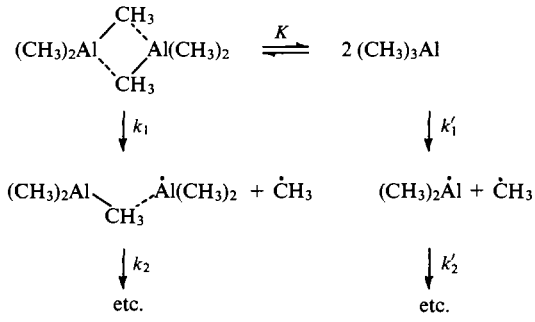
$$k = 8.1 \times 10^{15} \exp\left(-\frac{188.3}{RT}\right).$$

It is independent of the initial pressure of the gaseous $(CH_3)_3Al$ in the pressure range $(0.2-1.14) \times 10^4$ Pa. The variation of S/V hardly affects the constant k. The principal gaseous reaction product is methane (91 vol.%–98 vol.%). In the presence of hydrogen, the activation energy (here and henceforth E is expressed in kJ mol^{-1}) for the $(CH_3)_3Al$ decomposition reaction decreases from 188.3 to 127.6 kJ mol^{-1}. The numerical values of the rate constants decrease under these conditions, while the reaction order remains 3/2.

In later studies,[12,16] it was reported that the pyrolysis of $(CH_3)_3Al$ is first order with respect to the organoaluminium compound.

The reaction was carried out under a hydrogen atmosphere (10^5 Pa), where the partial pressure of $(CH_3)_3Al$ was ~200 Pa. The pressure was sufficiently low to allow the virtual exclusion of the sensitised decomposition of the OEC.

$$(CH_3)_3Al + \dot{C}H_3 \longrightarrow (CH_3)_2Al\dot{C}H_2 + CH_4$$



A distinctive feature of the pyrolysis of $(CH_3)_3Al$ at 200 Pa is the existence of 'high-temperature' (450–550 K)[12] and 'low-temperature' (290–320 K)[16] reaction regions. Activation energies for pyrolysis of 158.6 and 37.6 kJ mol^{-1} correspond respectively to these regions. In a general form, the 'low-temperature' pyrolysis is considered as a system of consecutive parallel reactions, where the first stage is the thermal decomposition of the trimethylaluminium dimer.[16]

$$[(CH_3)_3Al]_2 \xrightarrow{k_1} 2\,\dot{C}H_3 + [(CH_3)_2Al]_2$$

The low activation energy for the 'low-temperature' pyrolysis can be explained[16] by the fact that the bonds between the bridging methyl groups of the dimeric compound and the aluminium atom are weaker than the bonds in the monomeric molecule: the bond strength in the latter has been estimated, according to the data in Tel'noi's book,[17] as 278 ± 4 kJ mol^{-1}. The concentration of dimeric trimethylaluminium at 290–425 K is known[18] to exceed or be comparable to the concentration of the monomer, so that the dimers may play a significant role in the 'low-temperature' macrokinetics. However, this is not the only possible explanation of the characteristic features of the 'low-temperature' pyrolysis. Studies on the kinetics of the decomposition of trimethylaluminium on hot solid surfaces of copper and aluminium at 295–880 K demonstrated that methyl radicals are predominantly formed during the reaction.[19] The energy for the generation of methyl radicals in the interaction of $(CH_3)_3Al$ with the aluminium surface is 46 ± 8 kJ mol^{-1}. Within the limits of the error of the measurement, this quantity agrees with the activation energy for the 'low-temperature' pyrolysis (37.6 kJ mol^{-1}) quoted by Suzuki et al.[16] It is entirely probable that at 290–425 K the source of methyl radicals may be the dimeric trimethylaluminium, which decomposes heterogeneously at the surface.

With increase in temperature, the fraction of trimethylaluminium dimers diminishes as a result of dissociation. Therefore, over a wide temperature range it is necessary to take into account the contributions to the overall process by both the dimeric and monomeric forms (Scheme 1).

Scheme 1

T/K	E/kJ mol^{-1}	Ref.
290–450	37.6	16
450–565	158.6	12
570–610	188.3	15

The role of each of the competing paths in the pyrolysis is determined by two temperature-dependent factors: the shift of the dimer ⇌ monomer equilibrium (K) and the change in the rate constants for the abstraction of the methyl groups from the dimer (k_1) and the monomer (k_1'). The higher the reaction temperature, the higher the activation energy for the pyrolysis of $(CH_3)_3Al$.

This type of variation of E is consistent with the concept of competing reactions occurring with rate constants k_i and k_i', where $i = 1, 2$ (see Scheme 1).

The monomer concentration increases with increasing temperature. The rate constant for the decomposition of the monomer (k_1') increases with temperature faster than the rate constant for the composition of the dimer (k_1). In the ideal case, the complete conversion of the dimer into the monomer can be achieved by raising the temperature. If the rate-limiting stage is the abstraction of the first methyl group from the $(CH_3)_3Al$ molecule, then the value of E at temperatures above 600 K should approach the average bond dissociation energy $D_{Al-CH_3} = 278$ kJ mol^{-1}. An increase in the length of the hydrocarbon group virtually rules out the possibility of the existence of the dimeric form of the organoaluminium compound in the gas phase.[18,20] The nature of the pyrolysis products then changes. The contribution of the molecular β-elimination reaction increases. With increase in the length of the hydrocarbon group R, the thermal stability of the organoaluminium compounds falls.

$$R_3Al \begin{cases} \longrightarrow R_2AlH + R'CH{=}CH_2 & (1) \\ \longrightarrow R_2\dot{A}l + \dot{R} & (2) \end{cases}$$

For example, the rate of the gas-phase decomposition of $(C_2H_5)_3Al$ ($P_0 = 6.7 \times 10^3$ Pa, T = 435 – 465 K) is appreciably higher than the rate of decomposition of $(CH_3)_3Al$.[21] The temperature dependence of the effective rate constant for the overall $(C_2H_5)_3Al$ reaction is given by the equation[21]

$$k = 10^{8.2} \exp\left(-\frac{121.3}{RT}\right).$$

The attainment of a limiting value of the rate constant for the gas-phase decomposition of the organoaluminium compounds R_3Al on passing from $R = C_2H_5$ to $R = n-C_8H_{17}$ is indicated indirectly by data on the liquid-phase thermal decomposition of R_3Al.[22] The rate constants for the liquid-phase thermal decomposition of $(n\text{-}C_4H_9)_3Al$ and $(n\text{-}C_8H_{17})_3Al$ differ only slightly (1.5×10^{-4} s^{-1} and 1.7×10^{-4} s^{-1} respectively).

The thermal decomposition of the gaseous alkylgallium compound R_3Ga ($R = CH_3$, C_2H_5, $n\text{-}C_3H_7$, $n\text{-}C_4H_9$) obeys the kinetic equation for a first-order reaction.[13,14,23–32] Trimethylgallium exhibits the highest thermal stability. The homolysis of the Ga–C bond with a fairly ready loss of two methyl groups is characteristic of this compound.[23,26,28] The rate-limiting stage of the process is the abstraction of the first methyl group.

$$(CH_3)_3Ga \longrightarrow (CH_3)_2\dot{G}a + \dot{C}H_3$$

The subsequent fate of the methyl radicals depends on the composition of the gas phase. The reaction

$$C_6H_5CH_3 + \dot{C}H_3 \longrightarrow C_6H_5\dot{C}H_2 + CH_4,$$

is observed in a stream of toluene. The bibenzyl formed confirms the radical mechanism of the decomposition of $(CH_3)_3Ga$ in a toluene atmosphere.[23]

Mass-spectrometric analysis of the gas phase[14] confirms the occurrence of the following reactions of the methyl radicals:[14]

$$\dot{C}H_3 + \dot{C}H_3 + M \longrightarrow C_2H_6 + M^*$$

$$\dot{C}H_3 + H_2(D_2) \longrightarrow CH_4(CH_3D) + \dot{H}(\dot{D})$$

$$\dot{C}H_3 + (CH_3)_3Ga \longrightarrow CH_4 + (CH_3)_2Ga\dot{C}H_2$$

M= reactor wall or any molecule.

In a stream of hydrogen, the decomposition is faster than in a stream of helium, which suggests the possibility of the occurrence of the reaction

$$(CH_3)_3Ga + \dot{H} \longrightarrow (CH_3)_2\dot{G}a + CH_4.$$

At a temperature below 720 K, the polymer $(GaCH_x)_n$ is formed.[26] Above 770 K, it decomposes with liberation of metallic gallium.

One may agree with the claim that hydrogen reduces the activation energy by the abstraction of the last methyl group in the final stage of the pyrolysis.[13] The dissociation of the bond in monomethylgallium requires an energy of approximately 343 kJ mol^{-1}.[33] The overall activation energy for the decomposition of $(CH_3)_3Ga$ in a stream of hydrogen is in the range 184–260 kJ mol^{-1} according to the data of different workers.[25,26] The concluding stage of the decomposition of $(CH_3)_3Ga$ in the gas phase should therefore be a reaction favoured energetically.[34]

$$CH_3Ga{:} + H_2 (\text{or } \dot{H}) \longrightarrow Ga + CH_4 + \dot{H}$$

An attempt to detect the presence of gallium atoms in the vapour-phase decomposition of $(CH_3)_3Ga$ by IR spectroscopy was unsuccessful.[35] At any rate the pyrolytic reactions catalysed by the surface or occurring on the surface do not limit the rate of the process,[26,36] since an increase in the surface area does not accelerate the pyrolysis of $(CH_3)_3Ga$.

The homogeneous-heterogeneous mechanism of the decomposition of $(CH_3)_3Ga$, examined in detail by Masi et al.,[36] has been proposed on the basis of studies of the decomposition of this compound under the conditions of the formation of epitaxial layer by the MOCVD method,[23,28–30] while a model mechanism has been proposed on the basis of data on the pyrolysis of $(CH_3)_3Ga$ at different temperatures and the involvement of H_2 in the decomposition processes and in the processes leading to the formation of the decomposition products in the gas phase and on the GaAs surface. It was established that, in the gas-phase decomposition of $(CH_3)_3Ga$ in a stream of hydrogen, the gallium hydrides $[H_xGa(CH_3)_{3-x}]$ are not formed, especially under the conditions for the growth of GaAs films. The absence of the dissociation of $(CH_3)_3Ga$ in the gas phase to metallic gallium has been confirmed by spectroscopic data, according to which the concentration of gallium atoms in the gas phase is several orders of magnitude lower than the concentration of the intermediate species $CH_3Ga{:}$. Spectroscopic studies[37,38] made it possible to consider in detail the surface reactions of $(CH_3)_3Ga$, which include the dissociation of $(CH_3)_3Ga$ and of the intermediate species $(CH_3)_2Ga^*$ and $CH_3Ga{:}$ on the surface adsorption centres (s).[36] The activation parameters were estimated for each of the reactions presented below, which makes it possible to predict their occurrence in the real MOCVD process (Scheme 2).

Reactions (3)–(6) take place in the gas phase, whilst reactions (7)–(13) occur on the surface. The activation energies E are given in kJ mol^{-1} and the rate constants k in (mol cm^{-3})$^{1-n}$s^{-1}, where n is the reaction order.

The epitaxial GaAs layers were grown by the MOCVD method on a base comprising $(CH_3)_3Ga$ and metallic arsenic using hydrogen as the carrier gas.[39] Methane molecules are obtained in this process via two paths: via the direct gas-phase interaction of two methyl radicals [see Eqn (44) below], formed on decomposition of $(CH_3)_3Ga$, and via the reaction of the $\dot{C}H_3$ radical with the carrier gas. The activation energies for these processes were estimated as 23 and 39 kJ mol^{-1} respectively.

The reaction involving the abstraction of alkyl radicals, typical for $(CH_3)_3Ga$, is also characteristic of $(C_2H_5)_3Ga$ with the sole difference that in the case of the latter β-elimination takes place as a parallel reaction. The probable mechanism of

Scheme 2

$$(CH_3)_3Ga \longrightarrow (CH_3)_2\dot{G}a + \dot{C}H_3, \qquad k = 3.5 \times 10^5 \exp\left(-\frac{249}{RT}\right); \tag{3}$$

$$(CH_3)_2\dot{G}a \longrightarrow CH_3Ga{:} + \dot{C}H_3, \qquad k = 8.7 \times 10^7 \exp\left(-\frac{148}{RT}\right); \tag{4}$$

$$(CH_3)_3Ga + \dot{H} \longrightarrow (CH_3)_2\dot{G}a + CH_4, \qquad k = 5 \times 10^{13} \exp\left(-\frac{41.9}{RT}\right); \tag{5}$$

$$(CH_3)_2\dot{G}a + \dot{H} \longrightarrow CH_3Ga{:} + CH_4, \qquad k = 5 \times 10^{13} \exp\left(-\frac{41.9}{RT}\right); \tag{6}$$

$$CH_3Ga{:} + Ga\,(s) \longrightarrow CH_3Ga\,(s), \qquad k = 5.4 \times 10^{11} T^{0.5}; \tag{7}$$

$$CH_3Ga\,(s) \longrightarrow CH_3Ga{:} + Ga\,(s), \qquad k = 10^{14} \exp\left(-\frac{188}{RT}\right); \tag{8}$$

$$CH_3Ga\,(s) \longrightarrow Ga\,(s) + \dot{C}H_3, \qquad k = 2.6 \times 10^{13} \exp\left(-\frac{159}{RT}\right); \tag{9}$$

$$Ga\,(s) + \dot{C}H_3 \longrightarrow CH_3Ga\,(s), \qquad k = 1.3 \times 10^{12} T^{0.5} \tag{10}$$

$$Ga\,(s) + \dot{C}H_3\,(s) \longrightarrow GaCH_3\,(s) + s, \qquad k = 10^{17} \exp\left(-\frac{41.9}{RT}\right); \tag{11}$$

$$(CH_3)_2\dot{G}a + s \longrightarrow CH_3Ga\,(s) + \dot{C}H_3, \qquad k = 5 \times 10^{11} T^{0.5}; \tag{12}$$

$$(CH_3)_3Ga + s \longrightarrow CH_3Ga\,(s) + 2\dot{C}H_3 \qquad k = 4.6 \times 10^{11} T^{0.5} \exp\left(-\frac{41.9}{RT}\right). \tag{13}$$

the decomposition of $(C_2H_5)_3Ga$, investigated by the mass-spectrometric method in a stream of He and H_2,[14] may be represented by the reactions

$$(C_2H_5)_3Ga \longrightarrow (C_2H_5)_2\dot{G}a + CH_3\dot{C}H_2 \tag{14}$$

$$(C_2H_5)_3Ga \longrightarrow (C_2H_5)_2GaH + C_2H_4 \tag{15}$$

$$2CH_3\dot{C}H_2 + M \longrightarrow C_4H_{10} + M^*, \tag{16}$$

$$CH_3\dot{C}H_2 + H_2 \longrightarrow C_2H_6 + \dot{H}, \tag{17}$$

$$CH_3\dot{C}H_2 + (C_2H_5)_3Ga \longrightarrow C_2H_6 + (C_2H_5)_2Ga\dot{C}HCH_3 \tag{18}$$

M = reactor wall or any molecule.

The radical recombination reaction (16) proceeds virtually with zero activation energy. Reaction (17) has an activation energy of 55 kJ mol^{-1}.[40] With increase in temperature, the fraction of ethene in the reaction products increases and above 600 K the elimination reaction (15) becomes the dominant path.

Quantum-mechanical calculations[41] demonstrated that the β-elimination reaction is favoured energetically for $(C_2H_5)_3Ga$ compared with the homolysis of the Ga–C bond, which agrees with the results of experimental measurements at temperatures above 600 K.

The kinetics of the pyrolysis of the alkylindium derivatives R_3In, where $R = C_2H_5$, n-C_4H_9, n-C_5H_{11}, or n-C_6H_{13}, have been investigated.[42–45] Analysis of the literature data permits the conclusion that the pyrolysis of the alkylindium derivatives in the gas phase in the temperature range 473–780 K is described by the kinetic equation for a first-order reaction. The apparent activation energy for the process decreases on passing from the methyl derivative (197.5 kJ mol^{-1}) to the hexyl derivative (63.2 kJ mol^{-1}). It was established that the pyrolysis of trialkylindium is a complex homogeneous-heterogeneous process, which proceeds simultaneously via radical and olefinic-hydride mechanisms, the radical reaction paths predominating. The formal process mechanism can be represented as follows:

$$R_3In \longrightarrow R_2\dot{I}n + \dot{R}$$

$$\downarrow$$

$$In + 2\dot{R}$$

$$2\dot{R} \longrightarrow RH + R_{(-H)}$$

$$2\dot{R} \longrightarrow R_2$$

$$\dot{R} + R_3In \longrightarrow RH + RIn\dot{R}_{(-H)}$$

$$\dot{R} \xrightarrow{In} R_{(-H)} + \dot{H}$$

$$R_3In \longrightarrow R_2InH + R_{(-H)}$$

$$2R_2\dot{I}n \longrightarrow R_2InInR_2 \longrightarrow R_2In\dot{I}nR + \dot{R}.$$

The pyrolysis $(CH_3)_3In$ at atmospheric pressure in a stream of helium or hydrogen (deuterium) has been studied in detail by the mass-spectrometric method.[45] The rate constant for the pyrolysis of $(CH_3)_3In$ in a stream of helium is comparable to the rate constants published recently and obtained in the presence of a radical trapping agent (toluene).[44]

$$\lg k = 17.9 - \frac{226}{2.3RT}$$

Trimethylindium decomposes predominantly homolytically in a stream of helium and does not undergo radical attack by methyl radicals. The pyrolysis is accelerated slightly in a stream of H_2 or D_2.

$$\lg k = 13.4 - \frac{167}{2.3RT} \qquad \text{(in a stream of } D_2\text{)},$$

$$\lg k = 15.0 - \frac{178}{2.3RT} \qquad \text{(in a stream of } H_2\text{)}.$$

The principal pyrolysis products are CH_3D and C_2H_6 in a stream of D_2 and CH_4 and C_2H_6 in a stream of H_2. The ratio CH_3D/C_2H_6 decreases monotonically with increase in temperature. In the study of the mechanism of the decomposition of $(CH_3)_3In$ in a stream of D_2, the authors[45] used a modelling procedure. It was postulated that the hypervalent short-lived

intermediate $[D(CH_3)_3In]^*$ is formed initially.

$$\dot{D} + (CH_3)_3In \longrightarrow [D(CH_3)_3In]^*$$

$$\dot{C}H_3 + [D(CH_3)_3In]^* \longrightarrow CH_3D + (CH_3)_3In$$

$$\dot{D} + [D(CH_3)_3In]^* \longrightarrow D_2 + (CH_3)_3In$$

$$[D(CH_3)_3In]^* \longrightarrow CH_3D + 2\dot{C}H_3 + In$$

This model explains the increase in the rate of pyrolysis of $(CH_3)_3In$ in a D_2 atmosphere. A similar decomposition mechanism has also been proposed for a H_2 atmosphere.

New organometallic sources of metallic indium have been investigated—$C_2H_5(CH_3)_2In$ and $(CH_3)_2N(CH_2)_3In(CH_3)_2$. These are potential substitutes for $(CH_3)_3In$.[46,47] In contrast to $(CH_3)_3In$, these compounds are liquid at room temperature with relatively high vapour pressures. It is particularly effective to employ them in combination with *tert*-$C_4H_9PH_2$ for the preparation of high-quality InP films. $(C_2H_5)_2InCl$, which is converted into InCl on decomposition, is very effective in organometallic gas-phase epitaxy. When PH_3 and *tert*-$C_4H_9PH_2$ are used, phosphorus is incorporated during the growth of InP films.

The pyrolysis of $(CH_3)_3Tl$ has been investigated in a flow system in a stream of toluene in the temperature range 452–536 K.[48] The CH_4, C_2H_6, and $C_6H_5C_2H_5$ found in the reaction products are formed from the methyl radicals abstracted from $(CH_3)_3Tl$.

$$(CH_3)_3Tl \longrightarrow (CH_3)_2\dot{T}l + \dot{C}H_3$$

$$\downarrow$$

$$Tl + 2\dot{C}H_3$$

The apparent activation energy of 152.3 kJ mol^{-1} corresponds to the Tl–C bond dissociation energy.[48]

The kinetic parameters of the thermal decomposition of the alkyl derivatives of Group III elements are presented in Table 1. There is no unanimity as regards the estimation of the effective rate constants for the overall reactions. The constants k based on the data of different workers differ significantly for the same compound. The studies of Price and coworkers,[23,44,48,49] where the thermal stabilities of the compounds $(CH_3)_3E$ (E = Ga, In, Tl) were investigated under comparable conditions, merit special attention. The reactivities of such organometallic compounds increase in the sequence $(CH_3)_3Ga < (CH_3)_3In < (CH_3)_3Tl$. $(CH_3)_3Al$ 'deviates' from this series. Relatively low activation energies[12,15,16] and a low thermal stability, consistent with the hypothesis that its dimeric form is involved in the process kinetics, are characteristic of this compound.

The causes of the variation of the reactivity of the compounds R_3Ga in the sequence $CH_3 < C_2H_5 <$ n-$C_4H_9 <$ n-C_3H_7 [13,24,49] and of R_3In in the sequence $CH_3 <$ n-$C_4H_9 < C_2H_5 \approx$ n-$C_5H_{11} \ll$ n-C_6H_{13} [43,44] so far remain unelucidated.

It has been shown comparatively recently[50–54,55] that high-quality thin aluminium and gallium films may be obtained when complexes of aluminium and gallium hydrides with the tertiary amines $EH_3 \cdot NR_3$, where E = Al or Ga and R = CH_3 or C_2H_5, are used as the organometallic sources.[55] Such adducts do not contain an E–C bond, are less combustible and toxic than the compounds R_3E, and their vapour pressures are sufficient to employ them in the MOCVD processes at relatively low temperatures.

The thermal decomposition of the complexes $AlH_3 \cdot NR_3$, where R = CH_3 or C_2H_5, has been investigated.[56] The gas-phase decomposition leads to the formation of hydrogen, metallic aluminium, and the corresponding amine. In the condensed phase, the thermal decomposition in the temperature range 353–393 K is accompanied by the formation of the amine and a solvated polymeric form of aluminium hydride. The decomposition mechanism can be expressed as follows:

$$AlH_3 \cdot NR_3\,(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} AlH_3\,(g) + NR_3\,(g), \qquad (19)$$

$$AlH_3\,(g) \xrightarrow{k_2} Al\,(s) + 1\tfrac{1}{2}H_2\,(g), \qquad (20)$$

$$AlH_3 \cdot NR_3\,(l) \longrightarrow \frac{n-1}{n} NR_3\,(g) + \frac{1}{n}[(AlH_3)_n \cdot NR_3]\,(s), \qquad (21)$$

$$\frac{1}{n}[(AlH_3)_n \cdot NR_3]\,(s) \longrightarrow Al\,(s) + 1\tfrac{1}{2}H_2\,(g) + \frac{1}{n}NR_3\,(g). \qquad (22)$$

The abbreviations g, l, and s correspond to the gas, liquid, and solid phases.

The following expressions were obtained for k_1 and k_2 (s^{-1}):

$$k_1 = 1.6 \times 10^{12} \exp\left(-\frac{117.2}{RT}\right) \quad \text{for } AlH_3 \cdot N(CH_3)_3,$$

$$k_1 = 5.3 \times 10^{12} \exp\left(-\frac{113}{RT}\right) \quad \text{for } AlH_3 \cdot N(C_2H_5)_3,$$

$$k_2 = 4.2 \times 10^{20} \exp\left(-\frac{175.8}{RT}\right).$$

Table 1. Parameters of the thermal decomposition of the alkyl derivatives of Group III elements.

Compound	T/K	$\ln k_0$	E/kJ mol^{-1}	Experimental conditions	Ref.
$(CH_3)_3Al$	571–607	36.63	188.3	Static system	15
$(C_2H_5)_3Al$	435–465	18.88	121.3	"	21
$(CH_3)_3Ga$	686–983	35.7	249	Flow system, toluene carrier	23
	683–703	29.3	184	Flow system, hydrogen atmosphere	25
$(C_2H_5)_3Ga$	610–749	36.1	197.5	Flow system, toluene carrier	49
	543–1023	18.2	95	Flow system, hydrogen atmosphere	24
	573–653	11.3	95.8	Static system	27
(n-$C_3H_7)_3Ga$	473–553	13.1	76.5	"	27
(n-$C_4H_9)_3Ga$	473–553	5.8	49.8	"	27
$(CH_3)_3In$	550–781	36.2	197.5	Flow system, toluene carrier	44
$(C_2H_5)_3In$	453–523	28.3	144	Static system	42
(n-$C_4H_9)_3In$	473–553	17.7	110.8	"	43
(n-$C_5H_{11})_3In$	473–553	14.5	86.2	"	43
(n-$C_6H_{13})_3In$	473–553	13.8	63.2	"	43
$(CH_3)_3Tl$	452–536	34.7	152.3	Flow system, toluene carrier	48

Note. The parameters of the Arrhenius equation which correspond to a first-order rate constant are quoted with the exception of the parameters for $(CH_3)_3Al$, the order of the reaction of which is 3/2 and the dimensions of k are s^{-1} mol$^{-0.5}$ litre$^{0.5}$.

The enthalpy of reaction (19) is 113 ± 4 kJ mol^{-1}, which virtually agrees with the activation energy for this process and is close to the Al–N bond dissociation energy. The constant k_2 is the effective rate constant for the decomposition of AlH_3 in the gas phase.

The mechanism of the growth of a thin aluminium film on the crystalline surface of aluminium (111) has been investigated by a method involving the decomposition of the complexes of aluminium hydride with trimethylamine[52] and triethylamine.[57] The process occurring on the surface can be represented in a simplified form by the following reactions:

$$AlH_3 \cdot NR_3\,(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} AlH_3 \cdot NR_3\,(s), \quad (23)$$

$$AlH_3 \cdot NR_3\,(s) \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} AlH_3\,(s) + NR_3\,(s), \quad (24)$$

$$AlH_3\,(s) \xrightarrow{k_3} Al\,(s) + 3H\,(s), \quad (25)$$

$$NR_3\,(s) \xrightarrow{k_4} NR_3\,(g), \quad (26)$$

$$3H\,(s) \xrightarrow{k_5} \tfrac{3}{2}H\,(g, s). \quad (27)$$

It was shown[52] that reaction (24)—the dissociation of the Al–N bond in the complex adsorbed on the surface—is the rate-limiting stage in the deposition of the aluminium film in the aluminium hydride–trimethylamine system, while in the aluminium hydride–triethylamine system the rate-limiting stage in the growth of the film is reaction (27)—the desorption of hydrogen atoms from the surface.[57] The activation energy for bond dissociation in $AlH_3 \cdot N(C_2H_5)_3$ on the surface has been estimated as 65–80 kJ mol^{-1}, which is less than the activation energy for the desorption of hydrogen from the surface. Epitaxial aluminium layers without an admixture of carbon were obtained at 310 K and above.[52, 57]

The complexes between aluminium hydride and tertiary amines, such as $AlH_3 \cdot N(C_2H_5)_3$, $AlH_3 \cdot N(n\text{-}C_3H_7)_3$, and $AlH_3 \cdot N(n\text{-}C_4H_9)_3$, are liquids at room temperature, but their thermal stability diminishes with increase in the bulk of the substituents in the amine. Among the liquid aluminium hydride complexes, the most stable is that with ethyldimethylamine,[54] which has been used to obtain ultrapure aluminium in the construction of lasers. It has been suggested that the adduct decomposes via reactions (23)–(27).[54]

The gallium complexes $GaH_3 \cdot NR_3$ are hardly used in the formation of epitaxial layers, since, for example, $GaH_3 \cdot N(CH_3)_3$ is unstable and decomposes even at room temperature. The more stable adduct $GaH_3 \cdot NH(CH_3)_2$ has been described. It has been used in combination with AlH_3 and *tert*-$C_4H_9AsH_2$ for the formation of (AlGa)As/GaAs heterostructures.[58]

The adduct $(CH_3)_3In \cdot N(CH_3)_3$ has been synthesised in a satisfactory yield and with adequate purity from metallic indium, NMe_3, and methyl iodide in the presence of magnesium and diethyl ether.[59] The vapour pressure of the adduct was determined: 7.42 × 10^6 Pa at 323 K and 0.97 × 10^6 Pa at 293 K. For comparison, we may note that the vapour pressure of $(CH_3)_3In$ at 293 K is 1.41 × 10^6 Pa. The complex $(CH_3)_3In \cdot N(CH_3)_3$ and PH_3 have been used to prepare InP films.

III. Kinetics of the thermal decomposition of alkyl derivatives of Group V elements

The rate of thermal decomposition of gaseous alkyl derivatives of Group V elements is described by the equation for a first-order reaction regardless of the nature of the heteroatom or the alkyl group R in R_3E^V, where E^V = P, As, Sb, or Bi and R = CH_3, C_2H_5, or n-C_3H_7 (Table 2).

The kinetic parameters of the thermal decomposition of $(CH_3)_3As$ have been published[60–62] for both dynamic and static conditions. The decomposition in a closed quartz reactor[60] at 673–733 K leads to the formation of methane (~90 vol.%), ethane (4%), ethene (2.5%), hydrogen (1%), and higher hydrocarbons. Approximately the same proportions of the gaseous products have been observed in a flow reactor.[61] The solid phase contains 98.4% of metallic arsenic. An increase in the length of the hydrocarbon group diminishes the thermal stability of alkylarsines.[62, 63] The reactivities of trialkylarsines increase in the sequence $(CH_3)_3As < (C_2H_5)_3As < (n\text{-}C_3H_7)_3As$. Thus, at 679 K the rate constants for the decomposition of trimethyl-, triethyl- and tri-n-propyl-arsines are 9 × 10^{-5}, 193 × 10^{-5}, and 257 × 10^{-5} s^{-1} respectively. The composition of the gaseous products indicates an increase in the contribution of the β-elimination to the overall process on passing from the ethyl to the propyl derivatives.

Systematic studies of the influence of the central heteroatom on the rate of thermal decomposition of the methyl[61, 64–66] and ethyl,[62, 67–70] derivatives of Group V elements showed that the reactivities of $(CH_3)_3E^V$ and $(C_2H_5)_3E^V$ increase from phosphorus to bismuth: P < As < Sb < Bi.

Comparison of the temperatures at which the effective rate constants for the pyrolysis of the ethyl derivatives of Group V elements are the same and equal to 10^{-5} s^{-1} shows that this temperature is 653 K for $(C_2H_5)_3P$, whereas the significantly lower temperature of 433 K corresponds to $(C_2H_5)_3Bi$.[67, 69–71]

The composition of the products of the decomposition reaction (Table 3) indicates a radical mechanism for the decomposition of $(CH_3)_3E^V$ and the occurrence of the competing radical and molecular reactions of the corresponding ethyl derivatives $(C_2H_5)_3E^V$. Unsaturated compounds are formed via the β-elimination reactions and also as a result of the disproportionation of the alkyl radicals.

Table 2. Kinetic parameters of the decomposition of the alkyl derivatives of Group V elements.

Compound	T/K	$\ln k_0$	E/kJ mol^{-1}	Experimental conditions	Ref.
$(C_2H_5)_3P$	693–753	34.7	251.8	Static system	69, 70
	850–1050	36.8	263.6	Flow system	71

Table 3. Composition of the gaseous products of the decomposition of the methyl and ethyl derivatives of Group V elements.[62,67]

Compound	T/K	Composition (mol.%)								
		H_2	CH_4	C_2H_6	C_2H_4	C_3H_8	C_3H_6	C_4H_{10}	C_4H_8	Unidentified compounds
$(CH_3)_3As$	688–731	0.4–0.27	88.1–90.4	4.9–1.5	1.1	1.9–3.5	3.6–1.3	–	–	–
$(C_2H_5)_3As$	642–693	–	5.1	77.0	8.4	2.5	5.0	2.0	–	–
$(C_2H_5)_3Sb$	578–613	–	0.5	65.3	3.3	1.9	4.0	16.4	8.3	0.7
$(C_2H_5)_3Bi$	465–497	–	–	45.5	7.3	–	–	28.8	6.3	12.0

The consecutive-parallel thermal decomposition reactions of the ethyl derivatives of Group V elements can be represented in the following way in a general form (Scheme 3):

Scheme 3

$$(C_2H_5)_3E \longrightarrow \begin{cases} (C_2H_5)_2\dot{E} + CH_3\dot{C}H_2, \\ (C_2H_5)_2EH + C_2H_4, \end{cases}$$

$$(C_2H_5)_2\dot{E} \longrightarrow C_2H_5E: + CH_3\dot{C}H_2,$$

$$(C_2H_5)_2EH \longrightarrow C_2H_5E: + C_2H_6,$$

$$C_2H_5E: \longrightarrow E + CH_3\dot{C}H_2,$$

$$2CH_3\dot{C}H_2 \longrightarrow \begin{cases} C_2H_6 + C_2H_4, \\ C_4H_{10}. \end{cases}$$

The decomposition mechanism was devised on the basis of the analysis of the composition of the stable gaseous products and does not provide, for example, for the successive transformation of $(C_2H_5)_3E^V$ into E^VH_3, because molecular hydrogen, the formation of which would have been expected in the pyrolysis of E^VH_3, is not detected in the products at fairly low temperatures. At high temperatures, the role of secondary processes involving the reactions of the ethyl radicals increases. This is the reason for the presence of methane and higher hydrocarbons in the products of the thermal decomposition of $(C_2H_5)_3As$ and $(C_2H_5)_3Sb$.[72]

The radical reactions in the pyrolysis of $(C_2H_5)_3As$ and $(C_2H_5)_2AsH$ in a stream of hydrogen and deuterium have been investigated in detail by the mass-spectrometric method.[73] Tetraethylhydrazine was used as the source of ethyl radicals. Ethyl radicals accelerated the pyrolysis of $(C_2H_5)_2AsH$ but did not affect the pyrolysis of $(C_2H_5)_3As$. Isotopic analysis of the reaction products showed that β-elimination hardly occurs in the pyrolysis of these compounds under the conditions of the given experiment and that the radical reactions predominate. It has been established by computer modelling that the proposed reaction mechanism is consistent with experimental data.

Since the hydrides of Group V elements (PH_3, AsH_3, SbH_3) are toxic, it has been suggested in recent years that somewhat less toxic compounds such as *tert*-$C_4H_9PH_2$ or *tert*-$C_4H_9AsH_2$ be used for the MOCVD processes.[74–76]

The mechanisms of the thermal decomposition of *tert*-$C_4H_9PH_2$ and *tert*-$C_4H_9AsH_2$ have been discussed.[77–83] It was shown that the molecular processes leading to the formation of $\dot{A}sH_2$ and isobutane should be regarded as dominant in the decomposition of *tert*-$C_4H_9AsH_2$ in a D_2 atmosphere when the gas phase comes into contact with a SiO_2 or GaP surface.[78] β-Elimination, accompanied by the formation of AsH_3 and isobutene, becomes appreciable at high temperatures.

In contrast to *tert*-$C_4H_9AsH_2$, the decomposition of *tert*-$C_4H_9PH_2$ is a multistage process where free-radical reactions predominate according to Li and coworkers[81,82] and Fan et al.[83]

$$tert\text{-}C_4H_9PH_2 \longrightarrow (CH_3)_3\dot{C} + H_2\dot{P} \quad (28)$$

$$tert\text{-}C_4H_9PH_2 + (CH_3)_3\dot{C} \longrightarrow (CH_3)_3CH + tert\text{-}C_4H_9\dot{P}H \quad (29)$$

$$tert\text{-}C_4H_9\dot{P}H \longrightarrow (CH_3)_3\dot{C} + HP: \quad (30)$$

$$(CH_3)_3\dot{C} \longrightarrow (CH_3)_2C{=}CH_2 + \dot{H} \quad (31)$$

The *tert*-butyl radicals are destroyed by reactions (29) and (31), while the :PH and $\dot{P}H_2$ radicals are adsorbed on the surface and interact with one another. A change in the SiO_2 surface area does not influence significantly the rate of thermal decomposition of *tert*-$C_4H_9PH_2$, whereas the GaP surface has a catalytic effect on the decomposition of phosphine.[81] Gallium atoms play the role of catalytic centres. The adsorbed species located on the neighbouring Ga atoms participate in the reaction

$$tert\text{-}C_4H_9PH_2\,(s) + PH\,(s) \longrightarrow \quad (32)$$

$$\longrightarrow (CH_3)_3CH\,(g) + PH_{x-1}\,(s) + PH_2\,(s);$$

$x = 1–2$.

At high temperatures, the intramolecular β-elimination reaction cannot be ruled out for *tert*-$C_4H_9PH_2$.[83]

$$tert\text{-}C_4H_9PH_2 \longrightarrow (CH_3)_2C{=}CH_2 + PH_3 \quad (33)$$

In contrast to *tert*-$C_4H_9PH_2$, PH_3 decomposes under the conditions of the MOCVD process at temperatures higher by ~300 °C. The mechanism of the pyrolysis of PH_3 on the surface includes the following reactions:[84]

$$PH_3\,(g) \rightleftharpoons PH_3\,(s) \quad (34)$$

$$PH_3\,(s) \rightleftharpoons PH\,(s) + H_2\,(s) \quad (35)$$

$$2PH\,(s) \longrightarrow P_2\,(s) + H_2\,(g) \quad (36)$$

$$PH_3\,(s) + PH\,(s) \longrightarrow P_2\,(s) + 2H_2\,(g) \quad (37)$$

$$2P_2\,(s) \longrightarrow 2P_2\,(g) \quad (38)$$

$$PH_3\,(s) + PH\,(s) \longrightarrow 2PH_2\,(s) \quad (39)$$

Comparison of the mechanisms of the decomposition of *tert*-$C_4H_9PH_2$ and PH_3 shows that the reactions of the radicals: PH and $\dot{P}H_2$, which generally occur on the surface, are common to them. The difference is determined by the nature of the rate-limiting stages for the processes: reaction (28) or (32) is such a stage for *tert*-$C_4H_9PH_2$, while for PH_3 it is reaction (35), which can occur both homogeneously and heterogeneously.

The study of the kinetics of the thermal decomposition of *tert*-$C_4H_9PH_2$ (22 experiments)[85] showed that the reaction is pseudo-first-order with respect to the substrate. The kinetic parameters of the pyrolytic reaction were determined in the temperature range 593–626 K at an initial pressure $P_0 = (2.2 - 2.7) \times 10^4$ Pa. The rate constant varies from 2.39 [2.39×10^{-4}? (translator)] to 12.5×10^{-4} s^{-1} and the process activation energy is 159 ± 5 kJ mol^{-1}. The composition of the gaseous decomposition products (in mol.%), determined by gas–liquid chromatography, is as follows: CH_4 (0.2), iso-C_4H_{10} (99.3), and iso-C_4H_8 (0.5). At temperatures above 780 K, the gaseous products of the

hydrolysis of *tert*-$C_4H_9PH_2$ undergo further decomposition.[85] According to the data of Li et al.,[81] further decomposition does not occur in a flow system in a D_2 atmosphere. Under static conditions in the temperature range 780–840 K, the thermal decomposition of isobutane takes place at an appreciable rate with formation of CH_4, C_2H_6, C_2H_4, C_3H_8, C_3H_6, and iso-C_4H_8.

The high pyrolysis temperature and the toxicity of the hydrides of Group V elements forced investigators to turn to the alkyl derivatives of Group V elements capable of generating hydrides at fairly low temperatures directly in the hot zone of the reactor. The possibility of using the compounds $As(R_r)(R_\beta)_{3-n}$ for the preparation of semiconducting layers, where R_r is the alkyl group participating in the free-radical decomposition at the $As-R_r$ bond, and R_β is the alkyl group (usually iso-C_3H_7 or *tert*-C_4H_9) undergoing β-elimination with formation of $As(R_r)_nH_{3-n}$, has been analysed.[86] A model compound of this kind is *tert*-$C_4H_9(C_2H_5)_2As$.[86] The decomposition of this compound in the temperature range 373–725 K was investigated by the mass-spectrometric method. It was established that at 373–573 K the free-radical decomposition of this compound predominates over β-elimination (in proportions of 2:1). At a temperature above 620 K, β-elimination is the main process leading to the formation of $(C_2H_5)_2AsH$.

$$tert\text{-}C_4H_9(C_2H_5)_2As \longrightarrow (C_2H_5)_2AsH + \text{iso-}C_4H_8$$

The hydride $(C_2H_5)_2AsH$ is a source of arsenic in the preparation of epitaxial III–V layers.

Similarly it has been suggested that *tert*-$C_4H_9(CH_3)_2Sb$ be employed to prepare InSb layers. The temperature at which the epitaxial layers are grown is then reduced by about 100 °C compared with the process employing $(CH_3)_3Sb$ and by about 50 °C compared with (iso-$C_3H_7)_3Sb$.[87,88]

Comparison of the reactivities of alkyl derivatives of Group III and V elements (Tables 1 and 2) indicates a higher thermal stability of $(CH_3)_3E^V$ compared with $(CH_3)_3E^{III}$ (E^{III} and E^V are Group III and V elements in the same Period). Price and coworkers[23,44,48,49,61,65,66] carried out systematic studies on the kinetics of the thermal decomposition of the methyl derivatives of the above elements in a flow system, using toluene as the carrier gas. We used these data to compare the reactivities of the alkyl derivatives of Group III and V elements. The linear plots of $\ln k_{R_3E^{III}}$ against $\ln k_{R_3E^V}$ presented in Fig. 1 (lines *1* and *2*) confirm the existence of a correlation between the rate constants for the pyrolysis of the methyl derivatives of Group III elements and the rate constants for the pyrolysis of the methyl derivatives (line *1*) and ethyl derivatives (line *2*) of Group V elements. This finding confirms that the mechanisms of the pyrolysis of the compounds R_3E of Group III and V elements are of the same type. A certain scatter of the points about line *1* is associated with the fact that constants obtained by extrapolation were compared. The relations presented permit an estimate of the rate constant for the thermal decomposition of the monomeric compound $(CH_3)_3Al$, which proved to be 10^{-8} s^{-1} at 688 K. Hence it follows that the monomeric trimethylaluminium is a very stable compound. The rate constant for the pyrolysis of $(CH_3)_3Al$ obtained experimentally[15] at this temperature proved to be significantly higher than the value quoted. This is associated with the fact that the kinetically active species in the thermolysis is the dimer, its presence in the vapour phase reducing the thermal stability of the monomer in equilibrium with it.

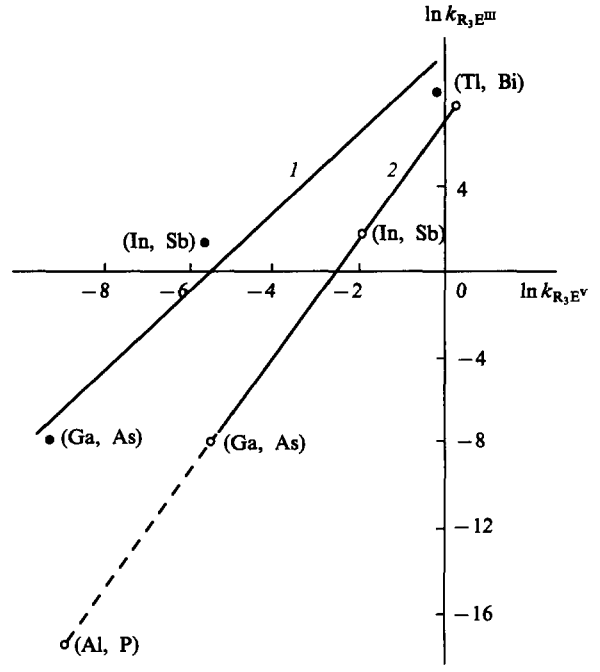

Figure 1. Relation between the rate constants for the pyrolysis of the methyl derivatives of Group III elements and the rate constants for the pyrolysis of the methyl (line *1*) and ethyl (line *2*) derivatives of Group V elements ($T = 488$ K).

IV. Joint decomposition of the organoelement compounds and hydrides of Group III and V elements in the gas phase and under the conditions for the formation of epitaxial layers

It follows from the data presented in Tables 1 and 2 that the majority of organometallic alkyl derivatives of Group III elements decompose in the temperature range 450–650 K, whereas the analogous compounds of Group V elements decompose at higher temperatures (600–850 K). The 'gap' between the temperature ranges of the decomposition reactions complicates the preparation of high-quality epitaxial III–V layers and heterostructures. As a rule, it is necessary to introduce the Group V compound into the reaction system in a large excess (by a factor of 10–100). However, the 'gap' is only apparent, since during their joint decomposition the compounds of Group III and V elements influence one another and the difference between their thermal stabilities is eliminated. The change in thermal stability may be associated with the possibility of the formation of adducts between the mixture components.

$$R_3M^{III} + R_3E^V = R_3M^{III} \cdot E^VR_3$$

The formation of such complexes follows from the acid–base properties of the reactants, since the organoelement compounds of Group III elements, having an unoccupied orbital, behave as Lewis acids, while the compounds of Group V elements, containing a lone pair, behave as Lewis bases.

The formation of adducts promotes the polarisation of the M–C bonds and changes in the steric configuration of the molecules, in the interatomic distances, and in the bond angles.[89] For example, the study of the NMR spectra of $(C_2H_5)_3Al$, $(C_2H_5)_3Ga$, and their etherates led to the conclusion that the element–carbon bonds in the complexes with ether are 'loosened' to a greater extent than the E–C bonds in the initial alkyl complexes.[90]

In the series of alkyl derivatives of Group V elements, the electron-donating properties are weakened in the following

sequence: N > P > As > Sb > Bi.[91-93] Among the compounds of Group III elements, the most pronounced electron-accepting properties are those of R_3Al.[91]

The thermal stability of the mixture of organoelement compounds is determined by the stabilities of kinetically independent species of different types: the molecules of individual compounds, their adducts, dimers, and the intermediates of the decomposition reaction formed in the mixture. The alkyl derivatives of Group III and V elements are known[91] to form fairly stable complexes $R_3M^{III}.E^VR_3$. The possibility of the existence of these complexes under the conditions of the thermal decomposition of the $(CH_3)_3Ga$ + $(CH_3)_3As$ and $(CH_3)_3Al$ + $(CH_3)_3As$ mixtures has been investigated.[94-97] The vapour pressure of the complex $(CH_3)_3Ga\cdot As(CH_3)_3$ was investigated at different temperatures and it was shown that the complex is fully dissociated in the gas phase at 470 K.[94] Under the severe conditions of the thermal decomposition of $(CH_3)_3Ga$ and $(CH_3)_3As$, one can therefore consider only the probability of the existence of the adduct $(CH_3)_3Ga\cdot As(CH_3)_3$,[96] which could not be detected with the aid of Raman spectroscopy.[98]

The rates and mechanisms of the thermochemical, photochemical, and plasmochemical decomposition of the mixture of organoelement compounds depend on the contribution by the decomposition of the complex to the effective pyrolysis rate constant. Thus, when $(CH_3)_3Ga$ and $(CH_3)_3As$ are mixed, the rate of their joint thermal decomposition increases by a factor of ~1.5–2 compared with the individual organoelement compounds.[95] Therefore knowledge of the thermodynamic and kinetic characteristics of the complexes formed becomes useful for the understanding of the kinetics of the joint decomposition of the organoelement compounds. The complexes $(CH_3)_3E\cdot As(CH_3)_3$ (E = Al, Ga, In) were synthesised in vacuo (P = 1–2 Pa) by mixing the initial organoelement compounds. $(CH_3)_3As$ was taken in excess and was then removed from the reactor by freezing out in a trap cooled with liquid nitrogen. By repeated sublimation, the complexes may be freed from the possible impurities comprising the individual organoelement compounds. The melting points (T_m) of the complexes $(CH_3)_3E\cdot As(CH_3)_3$ are given below.

E	T_m/K	Ref.
Al	304.2	96
Ga	296.6	91
	296.4–296.7	91
In	297.6	96
	297.2–297.8	91

The change in the Gibbs free energy or the dissociation constant K_e serves as a measure of the thermal dissociation of the complexes. The capacity of the test complexes[96,97] for thermal dissociation increases in the sequence

$$(CH_3)_3Al\cdot As(CH_3)_3 < (CH_3)_3In\cdot As(CH_3)_3 < (CH_3)_3Ga\cdot As(CH_3)_3.$$

For example, at 430 K the dissociation constants K_e for the above series of compounds are respectively 0.21, 1.005, and 3.51 atm.[97]

The temperature dependence of K_e suggests that the concentrations of the complexes are very low in the processes involving the high-temperature (~800 K) deposition of epitaxial layers. However, one cannot rule out the possibility that the role of such complexes in the kinetics of the pyrolysis is the same as that of free radicals and other active intermediate species. At lower temperatures (~350 K), the saturated vapour is a mixture of the gaseous complex and its dissociation products. The degree of dissociation of the complexes in equilibrium with the liquid phase at any temperature can be readily determined from K_e and the pressure P.

The rate of thermal decomposition of a mixture of $(CH_3)_3Al$ and $(CH_3)_3As$ has been investigated and the kinetic data obtained have been compared with the results for the thermal decomposition of the individual aluminium and arsenic compounds.[96] When gaseous $(CH_3)_3Al$ and $(CH_3)_3As$ are mixed at room temperature, the crystalline complex $(CH_3)_3Al\cdot As(CH_3)_3$ is formed. It was established that the arsine decomposes in the mixture independently of $(CH_3)_3Al$. On the other hand, the presence of $(CH_3)_3As$ influences the nature of the thermal decomposition of $(CH_3)_3Al$: firstly, its thermal stability increases (the temperature range of the decomposition reaction shifts from 590–650 K to 670–720 K) and, secondly, its decomposition is described by the kinetic equation for a first-order reaction. The results led to the following hypothesis concerning the mechanism of the joint decomposition of the above organoelement compounds: at 420–470 K, the saturated vapour obtained on evaporation of the complex $(CH_3)_3Al\cdot As(CH_3)_3$ is an equilibrium mixture of the individual OEC, the complex, and dimeric trimethylaluminium.

$$(CH_3)_3Al\cdot As(CH_3)_3 \rightleftharpoons (CH_3)_3Al + (CH_3)_3As$$
$$\Downarrow\Uparrow$$
$$[(CH_3)_3Al]_2$$

With increase in temperature, the complex and the dimer dissociate. Under the conditions of the thermal decomposition (670–720 K), the equilibrium concentrations of the dimer and the complex become insignificant. This may be inferred from results on the thermodynamic measurements of the degree of dissociation of dimeric trimethylaluminium.[18] However, even small amounts of the dimer and the complex may prove to be kinetically active in the thermal decomposition process. Therefore, under the pyrolysis conditions, it is essential to take into account the following paths in the reaction of the OEC:

$$\dot{C}H_3 + (CH_3)_2\dot{A}l + As(CH_3)_3 \qquad \dot{C}H_3 + (CH_3)_2\dot{A}s$$
$$\uparrow k_1' \qquad \uparrow k_2$$
$$(CH_3)_3Al\cdot As(CH_3)_3 \rightleftharpoons (CH_3)_3Al + As(CH_3)_3$$
$$\swarrow \quad \searrow k_1''$$
$$[(CH_3)_2Al]_2 \qquad \dot{C}H_3 + (CH_3)_2\dot{A}l$$
$$\downarrow k_1'''$$
$$2\dot{C}H_3 + \text{polymer}.$$

The experimentally determined constant k_1 (see below) is an effective quantity and includes the constants for the primary elementary stages k_1', k_1'', and k_1'''.

The Arrhenius relations for the temperature variation of the rate constants for the decomposition of $(CH_3)_3Al$ and $(CH_3)_3As$ in the mixture can be represented by the equations

$$\ln k_1 = (14.8 \pm 4.4) - \frac{123 \pm 10}{RT} \quad \text{for } (CH_3)_3Al,$$

$$\ln k_2 = (33.1 \pm 1.5) - \frac{240 \pm 9}{RT} \quad \text{for } (CH_3)_3As.$$

The formation of a 1 : 1 adduct of trimethylgallium and arsine has been demonstrated by the matrix isolation method in an argon matrix at 77 K.[99] Its spectroscopic characteristics have been published. The thermal stability of $(CH_3)_3Ga$ decreases on mixing with the arsine. The decomposition is observed already at 476 K.[92] The degree of decomposition increases with increase in temperature.[100]

$$Me_3Ga \cdot AsH_3 \longrightarrow Me_2Ga{-}AsH_2 + CH_4$$
$$Me_2Ga{-}AsH_2 \longrightarrow \text{-[MeGa-AsH]-}_n + CH_4$$
$$\text{-[MeGa-AsH]-}_n \longrightarrow GaAs + CH_4$$

The indium-containing adducts $R_3In \cdot AsH_3$, which are formed even at room temperature, are still more reactive.[101,102]

The formation of the adducts $R_3M^{III} \cdot E^V R'_3$ or the dimers $(R_3M)_2$ must be taken into account in describing the kinetics and mechanism of their decomposition. They influence significantly the mass transfer conditions in the chemical gas-phase deposition. The rate of thermal decomposition of arsine[26,104,106] increases significantly in the presence of $(CH_3)_3Ga$ and arsine itself reduces the thermal stability of $(C_2H_5)_3Ga$.[100,106-108]

An important factor in the variation of the thermal stability of the mixture of OMC is the exchange interaction between them. The exchange of radicals between $(CH_3)_3Ga$ and $(CH_3)_3Al$ [109] and also between $(iso\text{-}C_4H_9)_3Al$ and $(CH_3)_3Al$ [110] has been established by NMR spectroscopy. Such exchange alters the reactivities of the mixture components as a consequence of the change in the composition of the OEC.

The pyrolysis of $(C_2H_5)_3Ga$ in the presence of AsH_3 and $(CH_3)_3Al$ in a stream of H_2 has been investigated mass-spectrometrically.[107] It was established that the decomposition of $(C_2H_5)_3Ga$ is influenced by the components of the gas mixture: arsine diminishes the temperature of the pyrolysis of $(C_2H_5)_3Ga$ approximately by 20 °C, while $(CH_3)_3Al$ increases it by 25 °C. This is associated with the different mechanisms of the decomposition of $(C_2H_5)_3Ga$ in the presence of the above components. The rate-limiting stages of the processes differ significantly.

In a mixture of $(C_2H_5)_3Ga$ and AsH_3 in a stream of hydrogen, the main reactions are

$$(C_2H_5)_3Ga \longrightarrow CH_3\dot{C}H_2 + (C_2H_5)_2\dot{G}a,$$
$$CH_3\dot{C}H_2 + AsH_3 \longrightarrow C_2H_6 + \dot{A}sH_2,$$
$$CH_3\dot{C}H_2 + \dot{A}sH_2 \longrightarrow C_2H_5AsH_2,$$

while in a mixture of $(C_2H_5)_3Ga$ and $(CH_3)_3Al$ exchange reactions take place and mixed alkyl derivatives are formed.

$$2(CH_3)_3Al \rightleftharpoons (CH_3)_2Al(\mu\text{-}CH_3)_2Al(CH_3)_2$$

$$(C_2H_5)_3Ga + (CH_3)_2Al(\mu\text{-}CH_3)_2Al(CH_3)_2 \rightleftharpoons \quad (40)$$

$$\rightleftharpoons (CH_3)_2Al(\mu\text{-}CH_3)(\mu\text{-}C_2H_5)Ga(C_2H_5)_2 + (CH_3)_3Al$$
$$\Downarrow$$
$$(CH_3)_2C_2H_5Al + CH_3(C_2H_5)_2Ga$$

$$(CH_3)_3Al + CH_3(C_2H_5)_2Ga \longrightarrow \quad (41)$$
$$\longrightarrow (CH_3)_2C_2H_5Al + (CH_3)_2C_2H_5Ga$$

The compounds $CH_3(C_2H_5)_2Ga$ and $(CH_3)_2C_2H_5Ga$ formed in the exchange reactions (40) and (41) are thermally more stable than $(C_2H_5)_3Ga$. This explains the increase in the temperature of the pyrolysis of the mixture of $(C_2H_5)_3Ga$, $(CH_3)_3Al$, and H_2. As a result of the occurrence of the equilibrium reactions (40) and (41), the pyrolysis is undergone virtually not by the two individual OEC but by a mixture with a complex chemical composition.

It has been noted that the bimolecular reaction between $(CH_3)_3Ga$ and arsine alters the thermal stability of this mixture.[111-114]

Direct measurements of the concentration of the methyl radicals by means of laser IR spectroscopy made it possible to estimate the relative contributions of certain reactions to the joint decomposition of AsH_3 with $(CH_3)_3Ga$ or $(CH_3)_3In$ in a hydrogen atmosphere.[115]

$$\dot{C}H_3 + H_2 \longrightarrow CH_4 + \dot{H} \quad (42)$$
$$\dot{C}H_3 + \dot{C}H_3 \longrightarrow C_2H_6 \quad (43)$$
$$\longrightarrow CH_4 + {:}CH_2 \quad (44)$$
$$\longrightarrow C_2H_4 + H_2 \quad (45)$$
$$\dot{C}H_3 + AsH_m \longrightarrow CH_4 + \dot{A}sH_{m-1} \quad (46)$$
$$\dot{C}H_3 + (CH_3)_nM \longrightarrow CH_4 + (CH_3)_{n-1}M\dot{C}H_2 \quad (47)$$
$$\longrightarrow C_2H_6 + (CH_3)_{n-1}\dot{M} \quad (48)$$
$$(CH_3)_nM \longrightarrow \dot{C}H_3 + (CH_3)_{n-1}\dot{M} \quad (49)$$
$$(CH_3)_nM + AsH_m \longrightarrow (CH_3)_nM \cdot AsH_m \quad (50)$$

$n, m = 1-3$; M = Ga, In.

One cannot exclude from consideration reactions (42), (44), and (47) as potential sources of methane. The main supplier of methyl radicals in these processes is reaction (49). Reactions (43) and (48) are insignificant at low concentrations of the OEC, so that ethane is virtually absent from the reaction products. The formation of ethene has been observed only at temperatures above 870 K [reaction (45)]. The concerted variation of the concentrations of methyl radicals and methane has been noted when AsH_3 was introduced into the $(CH_3)_3M$ undergoing decomposition, which confirms the important role of reaction (46) in the chemical gas-phase deposition of epitaxial GaAs or InAs layers.

Within the framework of the classical Langmuir–Hinshelwood theory of the growth of layers, it has been possible to differentiate the kinetic and diffusional temperature ranges corresponding to the development of the MOCVD process.[116-120] For example, in a stream of hydrogen the kinetic region corresponding to the growth of the GaAs layer from $(CH_3)_3Ga$ and AsH_3 occurs in the temperature range 720–870 K. According to the results of Reep and Chandhi,[117] the effective process activation energy is 92 kJ mol^{-1}, which differs little from the activation energy for the heterogeneous decomposition of AsH_3.[108] It has been suggested that the adsorption of AsH_3 and its subsequent decomposition are the rate-limiting stages in the deposition of GaAs. The temperature range 870–1120 K corresponds to the diffusional region of the growth of the GaAs film. In this range, the rate of growth is almost independent of temperature. The apparent activation energy is only ~8.4 kJ mol^{-1}. A further increase in temperature leads to the 'etching' of the epitaxial layer.

Evidence for the formation of the intermediates CH_3AsH_2 and $(CH_3)_2AsH$ in the pyrolysis of a mixture of $(CH_3)_3Ga$ and AsH_3 and also of $C_2H_5AsH_2$ in the decomposition of $(C_2H_5)_3Ga$ in the presence of AsH_3 has been obtained by IR spectroscopy.[121] The formation of a complex between R_3Ga and AsH_3 and the surface reactions are not then taken into account, the radical gas-phase reactions being considered in detail (Scheme 4). A characteristic feature of this scheme is the hypothesis of the formation as intermediates of complexes of the alkyl radicals produced on decomposition of R_3Ga in the presence of arsenic hydrides with different degrees of substitution, i.e. $R_{4-m}\dot{A}sH_m$, where $m = 1-3$.

$R_3Ga \longrightarrow \dot{R} + R_2\dot{G}a$

$R_2\dot{G}a \longrightarrow \dot{R} + RGa$

$RGa \longrightarrow \dot{R} + Ga$

$\dot{R} + AsH_3 \longrightarrow RH + \dot{A}sH_2$

$\dot{R} + \dot{A}sH_2 \longrightarrow RAsH_2$

$\dot{R} + AsH_3 \longrightarrow R\dot{A}sH_3 \longrightarrow RAsH_2 + \dot{H}$

$\dot{R} + RAsH_2 \longrightarrow RH + R\dot{A}sH$

$\dot{R} + R\dot{A}sH \longrightarrow R_2AsH$

$\dot{R} + RAsH_2 \longrightarrow R_2\dot{A}sH_2 \longrightarrow R_2AsH + \dot{H}$

$\dot{R} + R_2AsH \longrightarrow RH + R_2\dot{A}s$

$\dot{R} + R_2\dot{A}s \longrightarrow R_3As$

$\dot{R} + R_2AsH \longrightarrow R_3\dot{A}sH \longrightarrow R_3As + \dot{H}$

The decomposition of $(CH_3)_3As$ and $(C_2H_5)_3Ga$ on the GaAs surface has been investigated mass-spectrometrically.[122] The rate constant found for the decomposition of $(CH_3)_3As$ (231.5) is much higher than the values obtained in a toluene atmosphere[61] and in the absence of a carrier gas.[60] The difference is associated not only with the influence of the carrier gas and with the catalysis by the GaAs surface, but apparently also with the formation of an adduct between the mixture components. The simplified model of the decomposition process then assumes the following form:

$(C_2H_5)_3\dot{G}a \longrightarrow (C_2H_5)_{3-x}Ga + x\,CH_3\dot{C}H_2,$

$(C_2H_5)_{3-x}Ga + (CH_3)_3As \longrightarrow (C_2H_5)_{3-x}Ga\cdot As(CH_3)_3,$

$(C_2H_5)_{3-x}Ga\cdot As(CH_3)_3 \longrightarrow GaAs(CH_3)_3 + (3-x)CH_3\dot{C}H_2,$

$(C_2H_5)_3Ga + (CH_3)_3As \rightleftharpoons (C_2H_5)_3Ga\cdot As(CH_3)_3,$

$(C_2H_5)_3Ga\cdot As(CH_3)_3 \rightleftharpoons GaAs(CH_3)_3 + 3CH_3\dot{C}H_2,$

$x = 1-3.$

The kinetics and mechanism of the joint pyrolysis of $(CH_3)_3Ga$ and AsH_3 on the growing GaAs surface have been investigated at low pressures of the initial reactants (1.3×10^{-2} Pa).[31] The primary stages in this case are the adsorption of $(CH_3)_3Ga$ on the surface (on Ga or As centres) and the subsequent removal of the methyl group from the surface [reactions (51) and (52)].

$(CH_3)_3Ga\,(g) \rightleftharpoons (CH_3)_3Ga\,(s)$ (51)

$(CH_3)_3Ga\,(s) \longrightarrow (CH_3)_xGa\,(s) + (3-x)CH_3\,(s)$ (52)

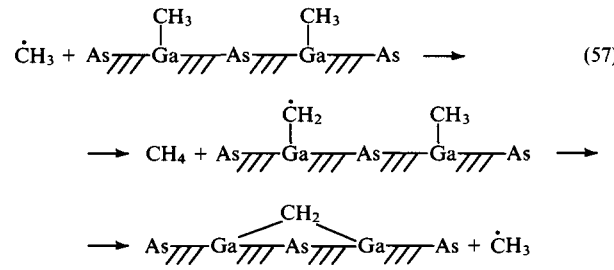
$x = 0-2.$

Methyl radicals are adsorbed on the Ga and As centres and are then desorbed into the gas phase.

$CH_3E\,(s) \longrightarrow \dot{C}H_3\,(g) + E\,(s)$ (53)

E = Ga, As.

Reactions (54) and (55) reflect the different paths to the formation of ethane.



$\dot{C}H_3\,(g) + CH_3Ga\,(s) \longrightarrow C_2H_6 + Ga\,(s)$ (54)

$\dot{C}H_3\,(s) + \dot{C}H_3\,(s) \longrightarrow C_2H_6\,(g)$ (55)

The process becomes important only at temperatures above 850 K.

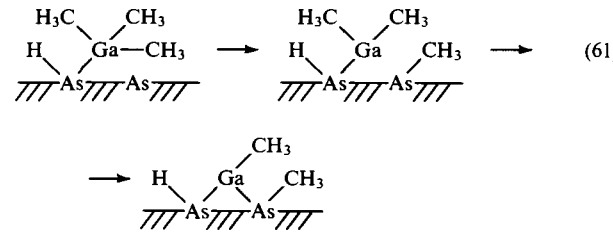
$(CH_3)_xGa\,(s) \rightleftharpoons (CH_3)_xGa\,(g)$ (56)

Reaction (57) demonstrates the possible ways in which carbon can be inserted in the growing epitaxial layer.

(57)

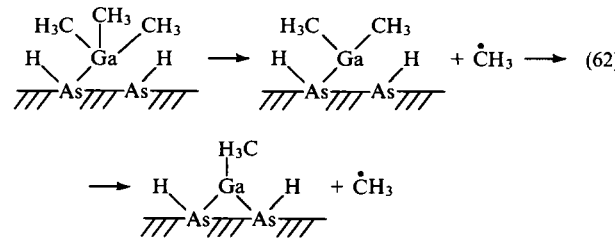
A methyl radical from the gas phase attacks the methyl group of the CH_3Ga fragment on the surface and abstracts a hydrogen atom. The resulting $\dot{C}H_2Ga$ fragment displaces a methyl radical from a neighbouring surface centre, forming a CH_2 bridge.

The products of the decomposition of AsH_3 were not detected in the gas phase (low pressure of the initial reactants). Reactions (58) and (60) reflect the AsH_3 decomposition processes on the surface.



$AsH_3\,(g) \rightleftharpoons AsH_3\,(s)$ (58)

$AsH_3\,(s) \longrightarrow AsH_y\,(s) + (3-y)\dot{H}\,(s)$ (59)



$H_yAsGa(CH_3)_x\,(s) \longrightarrow GaAs\,(s) + y\dot{H}\,(g) + x\dot{C}H_3\,(g)$ (60)

$y = 0-2.$

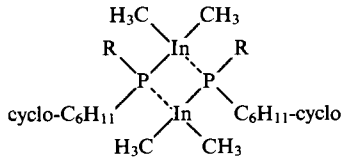
At low pressures of the reactants, the reactions occurring on the surface can probably be represented in the following way:

(61)

(62)

Reactions (61) and (62) correspond to the concerted processes occurring on the growing GaAs surface. The activation energy for the pyrolysis of $(CH_3)_3Ga$ on the surface is 108.8 kJ mol^{-1} and the pre-exponential factor is $10^{13.3}$ s^{-1}. The presence of arsine increases the rate of decomposition of $(CH_3)_3Ga$, whereupon E diminishes to ~84 kJ mol^{-1}.

A complex of the donor–acceptor type has been obtained in the reaction of $(CH_3)_3Ga$ with *tert*-$C_4H_9PH_2$. When the components are mixed in 1 : 1 molar proportions at room temperature, a liquid with a low vapour pressure is produced.[85]



On the basis of the results of a study[81] in which it had been established that *tert*-$C_4H_9PH_2$ accelerates the decomposition of $(CH_3)_3Ga$, remaining insensitive to its presence, Yablokov et al.[85] expected to observe two different temperature ranges for the decomposition of this mixture. One should have corresponded to the decomposition of *tert*-$C_4H_9PH_2$ and the other to the

decomposition of $(CH_3)_3Ga$. In reality, the process proved to be more complex. In the temperature range 513–520 K, the rate of thermal decomposition of the mixture is described by the kinetic equation for a first order reaction and assumes the following numerical form for the rate constant (in s^{-1}):

$$\lg k = (17.2 \pm 0.8) - \frac{(125 \pm 6)}{8.314T} .$$

The mixture of gaseous decomposition products consists of CH_4 (73.4 mol.%), C_2H_6 (0.21 mol.%), iso-C_4H_{10} (17.4 mol.%), and iso-C_4H_8 (9 mol.%). This product composition differs from that in the decomposition of the individual *tert*-$C_4H_9PH_2$ (where the amount of isobutane is 99.3 mol.%) and the authors[85] therefore postulated that the complex $(CH_3)_3Ga.$*tert*-$C_4H_9PH_2$ decomposes in the temperature range 513–520 K. CH_4 and the condensation products $[(CH_3)_2Ga-PHC_4H_9$-*tert*$]$ and $[CH_3Ga-PC_4H_9$-*tert*$]_n$ are formed. Their decomposition temperature is above 680 K. The probable mechanism of the joint decomposition of *tert*-$C_4H_9PH_2$ and $(CH_3)_3Ga$ has been put forward,[85] but it requires further confirmation.

Similar phenomena have been observed on mixing *tert*-$C_4H_9PH_2$ or $C_6H_{11}PH_2$ with $(CH_3)_3In$.[83] The adduct obtained on interaction of $C_6H_{11}PH_2$ with $(CH_3)_3In$ and deposited at room temperature on the walls of the reactor and of the measuring spectroscopic cell has the following structure:

The processes involving the pyrolysis of $(CH_3)_3Ga$ and R_3As on the GaAs(001) surface have been investigated[123] by the surface photoabsorption method[124] under the conditions of the MOCVD process. In the pyrolysis of $(CH_3)_3Ga$ on the GaAs surface, the rate-determining stage in the growth of the film is the desorption of methyl radicals from the surface. In the study of the pyrolysis of $(CH_3)_3As$, $(C_2H_5)_3As$, $(C_2H_5)_2AsH$, and *tert*-$C_4H_9AsH_2$, process activation energies of 2.93, 1.58, 0.82, and 0.82 eV respectively were determined (for comparison, we may note that the activation energy for the pyrolysis of AsH_3 is 0.74 eV). The authors postulate that $(C_2H_5)_2AsH$ and *tert*-$C_4H_9AsH_2$ are possible sources of hydrogen, alternative to AsH_3, in the MOCVD processes, since the activation energy for their pyrolysis is relatively low.

Fundamental advances have been made in the modelling of processes occurring in the complex $(CH_3)_3Ga-(CH_3)_3As-AsH_3-H_2$ multicomponent system in the gas phase and on the surface of GaAs epitaxial layers.[36] The authors were interested in the mechanism of the incorporation of carbon atoms in the epitaxial layers. The proposed mechanisms of the formation of such layers include 23 gas-phase and 64 surface reactions, in which 20 gaseous compounds and 14 compounds adsorbed on the surface participate. Fig. 2 illustrates schematically the principal reaction paths of these compounds in the MOCVD process. The communication cited[36] presents the kinetic and activation parameters for all the gas-phase and surface reactions calculated from literature sources and the author's own data.

Preliminary analysis of the kinetic model showed that contamination of the epitaxial layers by carbon takes place as a result of surface reactions in which the $GaCH_3$ intermediate species is most important. The gas-phase reactions do not affect the contamination of the surface layers by carbon.

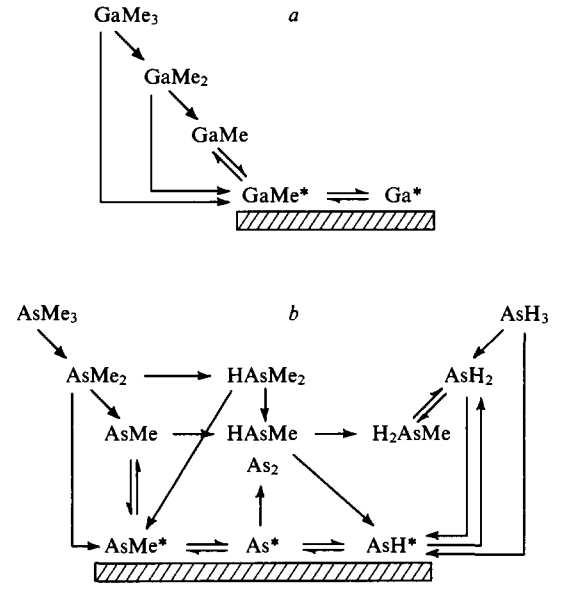


Figure 2. Schematic representation of gas-phase and surface paths of decomposition of OEC in the system $(CH_3)_3Ga-(CH_3)_3As-AsH_3$ in a stream of hydrogen (after Masi et al.[36]): (*a*) decomposition of $(CH_3)_3Ga$; (*b*) decomposition of $(CH_3)_3As$ and AsH_3.

V. Conclusion

Investigators have now come closer to understanding the detailed mechanism of the pyrolysis of the OEC of Group III and V elements in the gas phase and on the surface to such an extent that they are able to obtain excellent epitaxial layers, finding their way successfully through the labyrinth of incompatible, as regards thermal stability, explosive and toxic OEC.

The set of alternative organoelement sources in the MOCVD technology has expanded. The causes of the decrease in the rate of pyrolysis of both individual OEC and their mixtures have become understood. Ideas have been formulated concerning the combined study of the stability of OEC from the standpoint of the stability of an isolated molecule, the thermodynamic and kinetic stabilities, and also the dynamic stability of thermodynamically irreversible systems consisting of the OEC and the products of their decomposition in specific states of aggregation in the presence of mass and energy fluxes under conditions close to and remote from thermodynamic equilibrium.[125–128]

It is likely that these aspects of the investigations will in fact permit the development not only of the MOCVD technology for optoelectronics and semiconductor techniques but also for the solution of theoretical problems concerning the reactivity in the macro- and micro-processes occurring with participation of the OEC.

Abstract. The catalytic and certain physicochemical properties of low-percentage palladium and bimetallic (Pd–Re, Pd–Co, and Pd–lanthanide oxides) supported catalysts have been examined in the dehydrogenation reactions of cyclanes, cyclenes, cyclohexadienes, their functional derivatives, and heterocyclic compounds and also in the aromatisation of petrol fractions at elevated temperatures and at hydrogen pressures ranging from atmospheric upwards. The influence of thermodynamic factors on the dehydrogenation reaction is discussed and the mechanism of this reaction is considered. The bibliography includes 160 references.

I. Introduction

During the 1950s–1960s, the catalytic reactions of C_6–C_8 hydrocarbons designed to obtain aromatic hydrocarbons were vigorously investigated both in our country and abroad. In particular, the dehydrogenation reaction of cyclanes served as a model for the selection of active metal oxide catalysts. This reaction is also of practical interest, since the aromatisation of cyclanes makes it possible to increase the octane number of the petrols obtained in the catalytic reforming process.

Mainly platinum is mentioned in the extensive patent literature of those years devoted to catalytic aromatisation in the presence of Group VIII metals. Active studies in this field were performed in the USA.[1,2] Together with the platinum catalysts, certain patents mentioned palladium catalysts on various carriers.[3–9] However, there is no information in these patents about the methods for the preparation of the catalysts, their activation, stability, etc.

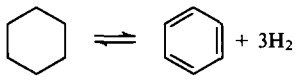
Studies on the selection of effective low-percentage supported metal oxide catalysts, including those containing palladium, for the dehydrogenation of cyclanes and the aromatisation of petrol fractions under reforming conditions at elevated temperatures and hydrogen pressures have been carried out since the 1950s at the Zelinskii Institute of Organic Chemistry under the supervision of N I Shuikin and Kh M Minachev.[10]

The fundamental and applied aspects of the use of palladium-containing catalysts on the sibunit carbon carrier (a highly porous graphite-like material) in the reverse hydrogenation reaction and also in oxidation, carbonylation, etc. reactions have been widely discussed in recent years.[11–15] The palladium–carbon catalysts also exhibit an activity in the dehydrogenation reaction of cyclanes.[16] However, whereas the palladium catalysts are widely used in the hydrogenation reaction, they have not found so far a large-scale use in the dehydrogenation reaction. Nevertheless, the problem of the replacement in supported catalysts of platinum, which is active in the dehydrogenation of cyclanes and in the aromatisation of petrol and other fractions resulting from the processing of petroleum, by the less scarce palladium is of current interest.



Supported palladium catalysts are also used in fine organic synthesis, which leads to new simpler procedures for the synthesis of valuable products. Heterocyclic rings constitute the structural basis of a large number of medicinal substances both of natural and of synthetic origin. The molecules of these compounds also contain various aliphatic and aromatic substituents. Derivatives of five- and six-membered heterocycles and their condensed systems constitute a class of medicinal heterocyclic compounds of practical importance.[17] Dehydrogenation reactions in the presence of supported palladium catalysts are employed to obtain some of them.

Studies designed to develop effective dehydrogenating supported palladium catalysts (monometallic and bimetallic) for the conversion of cyclanes, cyclenes, cyclohexadienes, and their derivatives and for the aromatisation of petrol fractions and the synthesis of indole, coumarin, papaverine and their derivatives, will be examined in the present review.

II. Thermodynamics of the dehydrogenation reactions of naphthenes

1. The influence of pressure

The dehydrogenation of six-membered naphthene hydrocarbons involve an appreciable increase in volume, so that an increase in pressure hinders their occurrence.

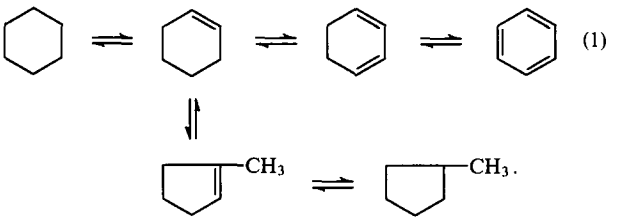
Calculations have shown[18] that the influence of pressure is particularly marked at temperatures below 500 °C. An increase in temperature from 400 to 600 °C at the same pressure shifts the equilibrium towards the formation of aromatic hydrocarbons. An increase in pressure from 14 to 56 atm at 510 °C has a negative effect on the formation of aromatic hydrocarbons, in particular on the conversion into benzene of cyclohexane and methylcyclopentane after the isomerisation of the latter to cyclohexane. The influence of pressure in this reaction is greater than in the conversion of methylcyclohexane into toluene.[19] An increase in pressure from 21 to 42 atm at 444 °C leads to a decrease in the yield of benzene obtained from cyclohexane from 70% to 33%.[20] In the presence of the Pd/Al_2O_3 catalyst at 460 °C, a space velocity (v) of 1.0 h^{-1}, and for the ratio H_2:HC = 5:1 (HC = hydrocarbon), an increase in pressure from 35 to 65 atm reduces the yield of aromatic hydrocarbons derived from ethylcyclohexane from 57.7% to 44.7%.[21]

2. The influence of temperature

In the presence of supported catalysts containing Group VIII metals, an increase in temperature from 440 °C to 510 °C (P_{H_2} = 21 atm, v = 3.0 h^{-1}, H_2:HC = 4:1) increases the yield of aromatic hydrocarbons derived from cyclohexane, methylcyclohexane, and methylcyclopentane from 70% to 93%, from 83% to 92%, and from 56% to 72% respectively.[20] In reactions involving cyclohexane and methylcyclohexane, the content of aromatic hydrocarbons in the catalytic reaction mixture reaches the equilibrium value.[22] An increase in temperature from 426 to 540 °C promotes the dehydrocyclisation of n-heptane; the yield of aromatic hydrocarbons increases from 2% to 25%.[20]

Thus, in conformity with thermodynamic postulates, an increase in hydrogen pressure inhibits the dehydrogenation reactions of six-membered cyclanes but at a higher temperature this influence becomes less marked. For example, at 510 °C the yield of benzene from cyclohexane is almost independent of pressure.[20] An increase in pressure from 10.5 to 35 atm at 496 °C also has an insignificant influence on the dehydrogenation of methylcyclohexane.[19]

Nevertheless, the reforming process is carried out in industry under a hydrogen pressure in order to suppress reactions leading to the formation of a 'carbonaceous film' on the catalysts,[23,24] which reduce their activity.[25-28]



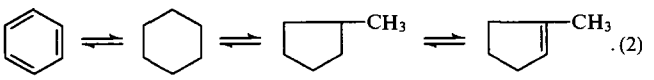
3. The influence of other factors

Apart from temperature and pressure, the aromatisation reaction is also influenced by the space velocity at which the starting material is supplied and by the starting material: hydrogen ratio.[19,29,30] As a rule, an increase in space velocity diminishes the yield of aromatic hydrocarbons. The change in the molar ratio of the circulating hydrogen and the starting material in the range (4–11):1 has little effect on the yield of the aromatisation product.[29] However, under platforming conditions, where the effluent gas consists mainly of hydrogen, the recirculating gas hinders the formation of the 'carbonaceous film' on the catalyst[24] and increases the lifetime of the latter, and thereby eliminates the need for frequent regeneration.

III. The mechanism of the dehydrogenation of cyclanes and cyclenes

At one time the sextet[31-41] and doublet[32,37,42-44] mechanisms of the dehydrogenation reaction as well as the mechanism postulating the initial formation of cyclohexene with subsequent disproportionation to cyclohexane and benzene[45-47] were widely discussed in the literature.

On metal oxide catalysts operating at an elevated pressure, the dehydrogenation of six-membered cyclanes[48,49] is to a large extent accompanied by their isomerisation with formation of five-membered cyclanes. A number of workers[50-52] considered the following scheme [scheme (1)] for the conversion of cyclohexane on metal oxide catalysts:



(1)

The isomerisation reaction proceeds via the carbonium ion mechanism.[53,54]

The reactions of radioactive cyclohexane have been investigated on the 1% $Pd-HF-Al_2O_3$ catalyst under reforming conditions (T = 480 °C, P_{H_2} = 21 atm, v = 1–2.5 h^{-1}, H_2:HC = 5:1).[55] In the presence of this catalyst, cyclohexane is converted into benzene (59%–63%) and methylcyclopentane (19%–23%), cyclohexene also undergoing dehydrogenation and isomerisation. However, cyclohexene, which is more reactive than cyclohexane, reacts almost completely. The specific radioactivity of the initial cyclohexene was zero and it might have been expected that it would increase with increasing degree of conversion. However, the results of the analysis of the reaction products showed that cyclohexene is almost nonradioactive, whereas benzene and methylcyclopentane are radioactive. Hence it follows that cyclohexane is not converted into cyclohexene. Thus the result failed to confirm the hypothesis that cyclohexene is an intermediate in the dehydrogenation of cyclohexane to benzene and in its isomerisation to methylcyclopentane. On a bifunctional catalyst, benzene and methylcyclopentane can apparently be obtained from cyclohexane without the intermediate formation of cyclohexene or at least without its desorption from the catalyst surface.[55]

In view of the results presented above, the role of methylcyclopentene in the expansion of the methylcyclopentane ring was investigated under the same conditions (T = 480 °C, P_{H_2} = 20 atm, v = 2.5 h^{-1}, H_2:HC = 5).[56,57] The reactions of a mixture of [6-^{14}C]methylcyclopent-1-ene and methylcyclopentane were investigated on the 1% Pd/Al_2O_3 catalyst. It was shown that the specific radioactivities of cyclohexane and benzene and also methylcyclopentane in the reaction products are similar and are in the range 2.0%–3.6% of the specific radioactivity of the initial [6-^{14}C]methylcyclopent-1-ene, whereas the specific radioactivity of the latter in the catalytic reaction mixture is much higher (12.1%–36.8%). Hence it follows that cyclohexane and benzene are obtained from methylcyclopentane without the intermediate formation of methylcyclopent-1-ene.

Scheme (2) therefore characterises the interconversions of the cyclanes more accurately than scheme (1):

(2)

But at the same time, it is necessary to take into account the possible conversion of methylcyclopent-1-ene into cyclohexane and benzene via scheme (1) as well, since the specific

radioactivities of cyclohexane and benzene exceed somewhat that of methylcyclopentane, which would be impossible for a strictly consecutive mechanism.

Thus cyclohexene is not an essential intermediate in the formation of benzene and methylcyclopentane from cyclohexane[55,57] and methylcyclopentene is likewise not an obligatory intermediate in the formation of benzene from methylcyclopentane.[56,58] This is confirmed by the experimental data for the reactions of cyclohexane and cyclohexene under reforming conditions (T = 450 °C, P_{H_2} = 21 atm, v = 10 h^{-1}, H_2 : HC = 5) where the 0.5% Pt–0.3% F–Al_2O_3 catalyst was poisoned with thiophene.[59] When mixtures of cyclohexane or cyclohexene with thiophene were passed through the system, a sharp decrease in the dehydrogenating capacity of the catalyst was observed, while the benzene content in the catalytic reaction mixtures diminished respectively from 74.2% and 90% to 15.4% and 46.6%. Thus the addition of thiophene to cyclohexane and cyclohexene diminishes the yield of benzene almost by a factor of 5 and only by a factor of 2 respectively.

The hypothesis[60] that thiophene acts predominantly on the cyclohexene dehydrogenation centres conflicts with the above results, so that the data of Hensel et al.[60] are inconsistent with scheme (1). The ratio of the concentrations of cyclohexane and methylcyclopentane in the catalytic mixtures obtained from cyclohexane is much closer to the equilibrium ratio than in the catalytic reaction mixture obtained from cyclohexene. These data also indicate that cyclohexene cannot be regarded as an essential intermediate in the isomerisation of cyclohexane to methylcyclopentane under reforming conditions.

In order to test scheme (1) and the data of Hensel et. al.,[60] a study was made of the reactions of cyclohexane and cyclohexene on the 1% Pd/AlO_3 and 1% $Pd/Al_2O_3 \cdot HF$ catalysts. The dehydrogenating functions of these catalysts were poisoned by thiophene, after which they were restored by treatment with a hydrocarbon. In contrast to the experimental conditions in the study of Isagulyants and Ryashentseva,[59] a much lower rate of supply of the hydrocarbons (5.5 h^{-1}) at 460 °C, P_{H_2} = 20 atm, and H_2 : HC = 5 was chosen to make sure that the catalytic reaction products contained also methylcyclopentene in addition to benzene and methylcyclopentane. For comparison, a study was also made of the reactions of cyclohexane and cyclohexene under the same conditions on the industrial AP-56 aluminoplatinum catalyst. On the palladium catalysts, the yield of methylcyclopentene was found to be higher by 2%–5%, whilst that of benzene was lower by 12%–16%, than on the platinum catalyst. This shows that the palladium catalysts are less active in the dehydrogenation reaction and are more active in the isomerisation process. After a mixture of cyclohexane with 1% of thiophene was passed through the system, the degree of activity of the aluminopalladium catalysts fell sharply (almost by a factor of 12), in contrast to the aluminoplatinum catalyst, while its isomerising activity remained almost unchanged. The dehydrogenating activity of the aluminopalladium catalyst was restored to the extent of 55%, while that of the fluorinated catalyst was restored to the extent of 50% relative to the initial activity after regeneration with cyclohexane for 6.5 and 8 h respectively. On the other hand, the activity of the platinum catalyst was 94% restored after passing cyclohexane for 4 h. Hence it follows that the dehydrogenating centres on the aluminopalladium catalyst are more sensitive to thiophene than the corresponding centres on the aluminoplatinum catalyst. In contrast to the platinum catalysts, the palladium catalysts convert cyclohexene into methylcyclopentenes to the extent of 12%–27%, which indicates their higher isomerising activity.[61,62] The dehydrogenating activity of the aluminopalladium catalyst fell from 13.7% to 6.9% and that of the similar fluorinated catalyst fell from 21.7% to 13.9% when cyclohexene was passed (T = 460 °C, P_{H_2} = 20 atm, v = 5.5 atm, and H_2 : HC = 5) through the system after the latter had operated for 3 h. At the same time, their isomerising activity increased: the yield of methylcyclopentenes rose from 18% to 44% and from 10% to 17.5% respectively. Up to 0.5% of cyclohexadiene was detected in the catalytic reaction mixtures. Under the same conditions, the isomerising and dehydrogenating activities of the aluminoplatinum catalyst remained unchanged.

After cyclohexene mixed with thiophene was passed over the palladium catalysts, the degree of formation of benzene fell by a factor of 2.3. Their isomerising activity (the yield of methylcyclopentenes) decreased only insignificantly under these conditions, which is inconsistent with the hypothesis[50] that dehydrogenating centres of two types are present on the catalyst surface and that cyclohexane is converted into cyclohexene on sections of the first type, while benzene is formed from cyclohexene on those of the second type. On further passage of cyclohexene, the dehydrogenating functions of the palladium catalyst are not restored, in contrast to the platinum catalysts, and the catalyst is irreversibly poisoned. The yield of benzene obtained from cyclohexene is much lower than that of the benzene obtained from cyclohexane. On the aluminoplatinum catalyst, this difference is difficult to observe owing to the high degrees of conversion. On the aluminopalladium catalysts, the yield of the benzene derived from cyclohexane was 54%–58%, whilst that of the benzene derived from cyclohexene was 18%–22%.

According to the results of Ryashentseva et al.,[61] only the centres for the dehydrogenation of cyclohexane to benzene should be poisoned. Consequently, according to scheme (1), the yields of methylcyclopentane derived from cyclohexane and cyclohexene should be similar. The experimental yield of benzene under the conditions of the conversion of cyclohexane mixed with thiophene was 3%, which indicates the inhibition of the benzene formation centres. The yield of methylcyclopentane proved to be 4%, i.e. the hydrogenation centres were also inhibited, which conflicts with the results of Isagulyants and Ryashentseva.[59] When a mixture of cyclohexane with thiophene was allowed to react, the yield of methycyclopentane did not diminish.

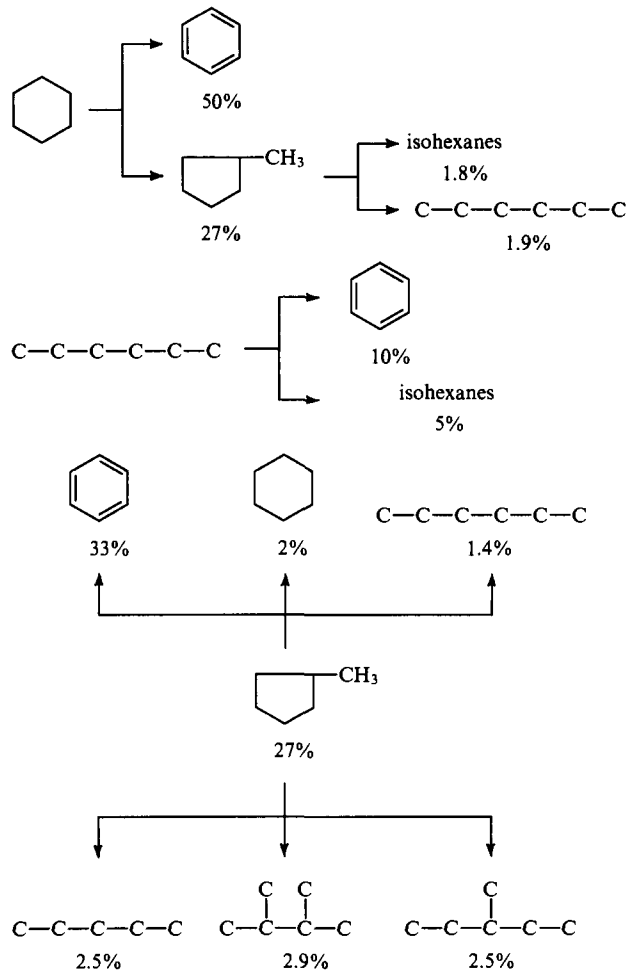
It follows from these data that the reactions involving the isomerisation of cyclohexane and cyclohexene proceed independently and probably on different isomerising centres.[62] This has been confirmed by the results obtained on the fluorinated aluminopalladium catalyst. In the presence of the latter, the yield of methylcyclopentane derived from cyclohexane increases, compared with the yield on the aluminopalladium catalyst, from 9.8% to 12.8% after 1 h, whereas the yield of methylcyclopentenes obtained from cyclohexene diminishes from 27.2% to 12.1%.[61] After the passage of the cyclohexene–thiophene mixture over the palladium catalysts, the content of methylcyclopentene was ten times greater than the content of methylcyclopentane. The absence of cyclenes from the products of the catalytic reaction involving cyclohexane and the presence in the latter of methylcyclopentane also cannot be accounted for by scheme (1).

All these findings confirmed the conclusion[55,59] that cyclohexene is not an essential intermediate in the conversion of cyclohexane into methylcyclopentane and benzene. On the aluminopalladium catalyst, the reactions of cyclohexane and cyclohexene proceed by independent paths, probably via different intermediates.[61] However, these is also evidence in support of the conversion of cyclohexane into benzene on metals to a large extent via the intermediate formation of cycloalkenes.[63] The difficulty of detecting the intermediate cycloalkenes is associated with the fact that their reactivity increases greatly in the sequence cyclohexane < cyclohexene < cyclohexadiene and hence cycloalkenes are present in the products in appreciable amounts only for very low degrees of conversion.

Apart from the consecutive path leading to the dehydrogenation of cyclohexane, which includes the desorption of cyclohexene, another path may also exist where cyclohexane is converted directly into benzene via a stage involving the formation of surface cyclohexene or bypassing it. The choice between these paths is apparently determined by the nature of the

chemical bond between the adsorbed hydrocarbon molecule and the catalyst surface.[63] According to the data of Tetenyi et al.,[64] the contribution of the path involving the direct hydrogenation of cyclohexane to benzene increases, while that of the dehydrogenation via the intermediate cyclohexene diminishes in the sequence

Co > Ni > Rh > Ir > Re > Pd > Pt.



IV. Palladium-containing supported catalysts in the dehydrogenation reactions of cyclanes and their functional derivatives

According to Balandin's multiplet theory,[65] there should be a structural correspondence between the catalyst multiplet and the part of the reactant molecule oriented on it which is altered in the reaction. The hexagonal symmetry of the multiplet necessary for the hydrogenation of benzene and the reverse cyclohexane dehydrogenation reaction is achieved only on cubic face-centred and hexagonal (but not cubic) body-centred crystal lattices. Although platinum and palladium both have type *A* face-centred cubic lattices with constants of 0.27746 and 0.27511 nm respectively, their activities differ appreciably in the reactions considered.

Palladium is used widely in laboratory practice as a dehydrogenation and especially hydrogenation catalyst.[66] In Zelinskii's early studies,[66,67] palladium black without a carrier was used as the catalyst for the reactions of hydrocarbons. In subsequent investigations, palladium black was deposited on various carriers (asbestos, activated charcoal, etc.) in order to obtain catalysts with a maximum surface area. However, the concentration of the active metal was fairly high even in such cases and varied in the range 30%–40%,[68,69] sometimes attaining even 70%.[70] Such catalysts were characterised by a high activity in the hydrogenation of benzene and only a satisfactory activity in the dehydrogenation of cyclohexane. Their low dehydrogenating activity and low stability were explained by the fact that, after deposition on activated charcoal, palladium black exists in the form of a hydride (with a crystal lattice parameter of 4.04 Å instead of the normal parameter of 3.88 Å).[71] It was established that, during prolonged operation of the catalyst, this parameter remains almost unchanged. The X-ray diffraction patterns taken after prolonged operation of the catalyst were found to contain, apart from the lines due to palladium, also secondary lines which did not refer to either palladium or its hydride. The appearance of a new finely dispersed palladium phase was explained by the low stability of the palladium catalysts.[72] A phase of this kind did not appear during the employment of platinum catalysts.

The low-percentage palladium catalysts containing from 2.0% to 0.5% of Pd/C exhibit a high dehydrogenating activity.[73,74] Their X-ray diffraction study before and after use showed that they contain only one crystalline palladium phase and X-ray diffraction patterns did not reveal the appearance of any new lines after the participation of the catalyst in the reaction. The low-percentage catalysts are apparently more active and stable because their palladium lattice has favourable parameters. However, even these palladium catalysts lose their activity comparatively rapidly under the conditions of prolonged operation, especially with petrol fractions containing, in addition to the six-membered cyclanes, also five-membered cyclanes, aromatic hydrocarbons, and alkanes.

Systematic studies led to the development of a 0.5% Pd/Al_2O_3 catalyst treated with hydrofluoric acid and hydrogen sulfide,[10] which is capable of operating at an elevated H_2 pressure and a high temperature. The reactions of cyclohexane, n-hexane, and methylcyclopentane,[48] which constitute the basis of the reforming of petrol fractions, were investigated on this catalyst at $T = 480$ °C, $P_{H_2} = 20$ atm, $v = 1.0\ h^{-1}$, and $H_2:HC = 5$.

It was shown that, together with the dehydrogenation of cyclohexane, the dehydroisomerisation of methylcyclopentane and the skeletal isomerisation and dehydrogenation of n-hexane take place on this catalyst. When gumbrin (a natural aluminosilicate containing 86.89% of SiO_2 or 4.14% of Al_2O_3 and having a specific surface of 260 $m^2\ g^{-1}$) is used as the carrier, methylcyclopentane is also formed from cyclohexane together with benzene on a 0.5% palladium catalyst under reforming conditions ($T = 475–480$ °C, $P_{H_2} = 20$ atm, $v = 1.0\ h^{-1}$, and $H_2:HC = 5:1$). Under these conditions, the carrier itself (gumbrin) exhibits pronounced isomerising properties — 19.2% of methylcyclopentane is formed on this carrier from cyclohexane, the reaction being accompanied by slight cracking.[75] Treatment of the catalyst with hydrogen sulfide enhances its dehydrogenating and isomerising properties: the benzene content in the catalytic reaction mixture increases from 28.5% to 40.2%, while that of methylcyclopentane increases from 19.2% to 22.7%. This bifunctional catalyst may be useful for refining low-octane petrols.

The 0.5% Pd/Al_2O_3 and 0.5% Pd/SiO_2 catalysts have been investigated in the conversion of methylcyclohexane.[76] The experiments were performed under the following conditions: $T = 460$ °C, $P_{H_2} = 20$ atm, $v = 1.1\ h^{-1}$, and $H_2:HC = 5:1$. The toluene contents in the products when the above catalysts were used amounted to 82% and 93% respectively. Under similar conditions, ethylcyclohexane underwent various reactions on the 0.5% Pd/Al_2O_3 catalyst: dehydrogenation, hydrogenolysis of the side chain, and isomerisation with ring contraction and subsequent opening of the five-membered ring.[77] The increase in pressure from 35 to 65 atm increases the degree of conversion of ethylcyclohexane from 61.4% to 84.8%. The introduction of fluorine into the catalyst lowers its dehydrogenating activity and increases its isomerising activity. It has been suggested that

fluorine in the form of PdF_2 partially shields the catalyst active centres, diminishing thereby its dehydrogenating activity.

The kinetics of the dehydrogenation of cyclohexane have been investigated on palladium-containing supported catalysts treated with hydrofluoric acid or hydrogen sulfide.[78] The apparent activation energies and pre-exponential factors in the Arrhenius equation for the reactions on the 0.5% Pd/Al_2O_3 and 0.5% $Pd/Al_2O_3 \cdot HF$ catalysts, calculated from the initial activity, hardly differed. After the treatment of the 0.5% $Pd/Al_2O_3 \cdot HF$ catalyst with hydrogen sulfide, the activation energy increased appreciably, while the pre-exponential factor changed by several orders of magnitude.

On the most active hydrogen sulfide-treated 0.5% $Pd/Al_2O_3 \cdot \cdot HF$ catalyst at atmospheric pressure, $T = 450$ °C, and $v = 0.3$ h^{-1}, cyclohexane is 94% dehydrogenated to benzene.[79]

New palladium-containing catalysts, obtained by depositing the metal on $AlPO_4$ and $AlPO_4 \cdot SiO_2$ colloidal systems, have been used successfully for the reduction of nitrobenzene.[80] Similar modified catalysts, containing 0.5% of palladium on the SiO_2, $AlPO_4$, and $SiO_2 \cdot AlPO_4$ carriers, have been investigated in the cyclohexane and methylcyclohexane dehydrogenation reactions under pulsed conditions.[81] In terms of dehydrogenating capacity, the platinum-containing catalysts proved to be much more active than the palladium-containing ones. Table 1 presents the results of experiments on the dehydrogenation of cyclohexane on these catalysts.

Table 1. Dehydrogenation of cyclohexane on various metal-containing catalysts[81] (atmospheric pressure, $T = 425$ °C, pulse size 8.34×10^{-5} moles).

Metal	Carrier	Yield of C_6H_6(%)	Activity[a]
Pd	SiO_2	13.6	9.00
Pt	SiO_2	82.3	3.90
Pd	$AlPO_4$	5.2	2.87
Pt	$AlPO_4$	25.5	1.45
Pd	$SiO_2 \cdot AlPO_4$	13.8	4.01
Pt	$SiO_2 \cdot AlPO_4$	72.0	3.73

[a] The number of moles of cyclohexane converted per m^2 of the metal multiplied by 10^3.

During the last decades, physical methods permitting the study of highly dispersed metal particles distributed on the surface of the carrier have developed vigorously. New approaches to the selection of metal-containing supported catalysts have appeared.[82-87] The state of palladium on aluminium oxide has been investigated by the XPS method and its strong interaction with the carrier has been demonstrated.[88] The interaction of the metal with the carrier is influenced by the ligand environment. For example, impregnation catalysts obtained with the aid of $PdCl_2$ or $Pd(NO_3)_2$ solutions have different properties. The state of palladium also changes during the reduction of the catalyst. The aluminium oxide carrier is capable of retaining chlorine.

The strong interaction of $PdCl_4^{2-}$ with the acceptor centres of γ-Al_2O_3 has been observed.[89] On the other hand, palladium interacts weakly with the carrier of the Pd/SiO_2 catalyst. Zerovalent palladium is formed already at 100 °C, but the metal is not fully reduced, the most dispersed zerovalent palladium particles interacting with the carrier. According to the results obtained by transmission electron microscopy, the average Pd(0) particle size is 4.5 nm in the 1% Pd/Al_2O_3 catalyst at 300 °C and 8.5 nm in the 1% Pd/SiO_2 catalyst.

Current ideas about the interaction of the metal with the carrier were taken into account[90] when the properties of the 0.5% Pd/γ-Al_2O_3 and 0.5% Pd/sibunit catalysts were investigated in the dehydrogenation of cyclohexane. A strong interaction of the carrier with the metal is manifest in the first catalyst, while the sibunit carbon carrier hardly undergoes such interaction.[91] The specific surface of the active alumina was 225 m^2 g^{-1} for an overall pore volume of 0.68 cm^3 g^{-1}, while the specific surface of sibunit (granulated carbon) was 590 m^2 g^{-1} for a particle size of 2–2.5 mm.[91] The data concerning the dehydrogenation of cyclohexane on these catalysts are presented in Table 2.

Table 2. Dehydrogenation of cyclohexane (atmospheric pressure, $t = 1$ h, H_2 stream).[16]

Catalyst	Reaction conditions		Yield[a]	Content of C_6H_6 (%)
	T/°C	v/h^{-1}		
0.5% Pd/γ-Al_2O_3	425	0.75	51.0	87
	450	0.75	89.4	47
	480	0.75	63.7	98
0.5% Pd/γ-Al_2O_3	440	1.5	83.6	81
(treated with	440	0.7	81.2	85
H_2S)	450	1.5	91.8	85
	455	0.6	95.2	90
	460	0.5	56.6	95
	470	0.5	66.7	100
0.5% Pd/sibunit	430	1.2	75.3	83
	440	1.2	80.0	89

[a] Yield of the catalytic reaction mixture.

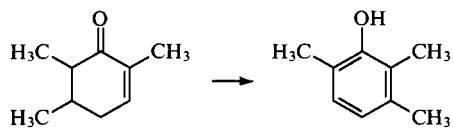
Cyclohexane is dehydrogenated in the temperature range 430–480 °C. Treatment of the catalyst with hydrogen sulfide increases the benzene content in the catalytic reaction mixture almost by a factor of 2 ($T = 440-450$ °C, $v = 0.75$ h^{-1}). A high yield of benzene is retained also following an increase in the space velocity at which cyclohexane is supplied by a factor of 2. The Pd/sibunit catalyst likewise exhibits a high dehydrogenating activity under similar conditions.

The dehydrogenating activity in this reaction is apparently influenced more by factors such as the porosity of the carrier, the catalyst grain size, the methods used to activate the catalyst, the composition of the reaction mixture, and other factors (which in fact determine the rate of reaction) than by the metal–carrier interaction.

Ethylcyclohexane was dehydrogenated in the liquid phase under a nitrogen atmosphere at 132 °C on suspended Pd/C and Pd/Al_2O_3 catalysts.[92] The activity of the catalyst was determined from the amount of hydrogen evolved. The results are presented in Table 3.

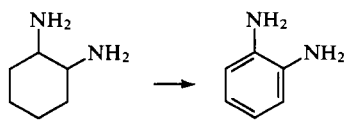
Table 3. Liquid-phase dehydrogenation of ethylcyclohexane (0.02 mmol per 100 ml of the catalyst) in the presence of supported catalysts containing 0.5% of the metal.[92]

Catalyst	H_2/mmol	Yield of ethylbenzene/mmol
Pd/C	9.22	3.18
Pd/Al_2O_3	3.67	1.25
Pt/C	23.93	7.75
Pt/Al_2O_3	13.04	4.15



The Pd/C catalyst has a dehydrogenating activity higher by a factor of 3 than Pd/Al_2O_3. However, Table 3 shows that both catalysts are appreciably inferior to the supported platinum catalyst. Under the conditions of liquid-phase dehydrogenation with the recondensation of the ebullition products, the Pd/C and Pd/Al_2O_3 catalysts exhibit a higher activity in the preparation of cyclooctene from cyclooctane than do supported rhodium and ruthenium catalysts.[93] The activity was determined from the degree of desorption of hydrogen.

The use of the Pd/C catalyst leads to new possibilities for the preparation of silicon-containing compounds by the hydrosilylation of cyclohexadiene with subsequent dehydrogenation. Phenylsilicones can be synthesised by this procedure in one stage, in which the liquid silicon hydride and cyclohexadiene react on refluxing in the presence of the Pd/C catalyst and $C_6H_5NO_2$ as the acceptor.[94]

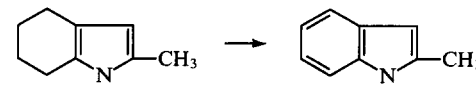


There are data concerning the use of supported palladium catalysts in the dehydrogenation reactions also of other organic compounds.[95-97] The synthesis of 8-hydroxycymene by the dehydrogenation of 8-hydroxymenthene in the presence of a palladium-containing catalyst has been described.[95]

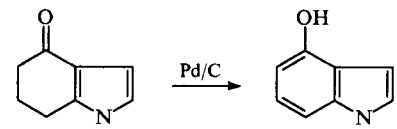
A mixture containing 78% of α-terpineol and 10% of γ-terpineol was passed at 190–200 °C at a rate of 0.4 kg h^{-1} for 588 h over the 0.2% Pd/Al_2O_3 catalyst treated beforehand with a NaOH solution, partly dried, and reduced.[95] This yielded 231.3 kg of product, which contained 154.78 kg of 8-hydroxycymene, 49.40 kg of the dihydroterpineol isomers, 11.98 kg of *p*-cymene and 10.2 kg of the initial terpineol. The degree of conversion was 98.2%. During the tests, the catalyst did not lose its activity.

Phenol and phenol derivatives can be obtained by dehydrogenating a cyclic ketone in the gas phase in the presence of the Pd/Al_2O_3 catalyst.[96] For example, 2,3,6-trimethylphenol has been obtained in 100% yield on passing 2,5,6-trimethylcyclohex-2-en-1-one in a stream of hydrogen at 300 °C at a rate of 0.25 litre per litre of the 0.5% Pd/Al_2O_3 catalyst (the specific surface of the carrier was 4 m^2 g^{-1}). The catalyst was prepared by impregnating the carrier with an aqueous $PdCl_2$ solution and was then dried and reduced with hydrogen at 300 °C. The degree of conversion was 82.6%. The selectivity of the catalyst decreased with increase in the specific surface of Al_2O_3. The selectivity was zero for a specific surface of 170 m^2 g^{-1}.

o-Phenylenediamine has been obtained in a yield of 69% at 200 °C by the dehydrogenation of 1,2-diaminocyclohexane in the gas phase at 175–225 °C, a pressure of 0.1–10 atm, and a supply rate of 0.25 ml min^{-1} over the 5% Pd/Al_2O_3 catalyst containing 0.61% of LiOH under a nitrogen atmosphere.[97]

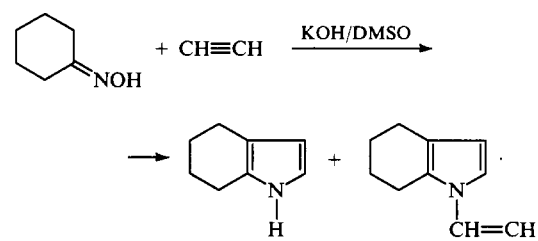


V. Palladium catalysts in the dehydrogenation reactions of heterocyclic compounds



1. Dehydrogenation of tetrahydroindole and its derivatives

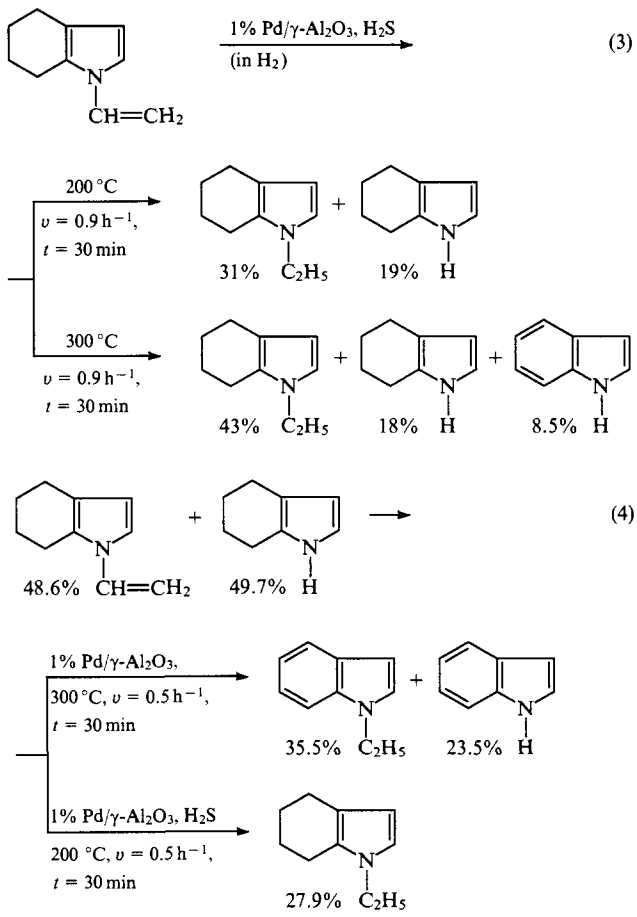
The selection of a catalyst for the dehydrogenation of heterocyclic compounds with a pyrrole ring is complicated by the fact that they poison catalysts containing noble metals. Indole and its derivatives were synthesised in the presence of palladium-containing supported catalysts in both liquid and gas phases. Indole and its homologues are important intermediates in fine organic synthesis. They are used as plant growth stimulators, especially β-indolylacetic acid (heteroauxin) and 3-(γ-indolyl)butyric acid.[98] Numerous medicinal preparations used in neurophysiology and psychopharmacology have been obtained from indole derivatives.[99] The principal source of indole is coal tar, which contains 2%–3% of this substance.[100]



Tetrahydroindole and its derivatives are promising sources for the preparation of pure indole by dehydrogenation. 1-Methylindole has been obtained in 67% yield from 1-methyl-4,5,6,7-tetrahydroindole in the presence of the 10% Pd/C catalyst in the xylene liquid phase under a stream of nitrogen after refluxing for 18 h.[101,102]

4-Hydroxyindole can be obtained in 94% yield by the liquid-phase dehydrogenation of 4-oxo-4,5,6,7-tetrahydroindole in 2-ethylhexyl acetate in the presence of a Pd/C catalyst at 192 °C.[103] The reaction is carried out by refluxing for 7 h.

The possibility of the dehydrogenation of the cyclohexene fragment of 1-vinyl-4,5,6,7-tetrahydroindole (VTHI) and in its mixture with 4,5,6,7-tetrahydroindole (THI) under the conditions of heterogeneous catalysis on low-percentage palladium-containing supported catalysts has been demonstrated.[104] The compounds VTHI and THI became available as a result of the development of a simple method of their synthesis from ketoximes and ethyne by the Trofimov reaction.[105] In the case of cyclohexanone oxime, the process proceeds in accordance with the following mechanism:



Depending on the medium in which the reaction is carried out, it is possible to obtain high yields (up to 83%–92%) of THI or VTHI.[106] The compounds THI and VTHI are promising indole synthons,[105-108] and are used, in particular, to synthesise α-substituted indoles which are otherwise difficult to obtain.[101,102]

The reactions of VTHI and its mixtures with THI in a solvent were achieved in a flow-type apparatus at atmospheric pressure in the temperature range from 100 to 525 °C, at $v = 0.3-1.2$ h^{-1}, and for a duration of the experiment ranging from 30 min to 3 h. Aluminopalladium catalysts containing 1% and 1.5% of the metal were used. The carriers were industrial γ-Al_2O_3 specimens.

A mixture of 48.6% of VTHI and 49.7% of THI (the remainder comprised cyclohexanone oxime) was obtained in a pilot plant from cyclohexanone oxime and ethyne. It was used without separation into components as the technically most readily available starting material.[109] The results are illustrated in schemes (3) and (4).

On the sulfided 1% Pd/γ-Al_2O_3 catalyst at 200 °C and $v = 1.0$ h^{-1}, 31% of 1-ethyltetrahydroindole (1-ETHI) and 19% of THI (relative to the VTHI passed through the system) are obtained from VTHI in 30 min in a hydrogen stream (3.6 litre h^{-1}), i.e. reactions involving the hydrogenation of the double bond and the cracking of VTHI, accompanied by the hydrogenolysis of the N–C bond, take place. The yield of the remaining cracking products ranges from 5% to 20%. On raising the reaction temperature to 300 °C, the yield of 1-VTHI increases to 42.7%. The six-membered ring is also dehydrogenated with formation of indole (yield 8.5%). The increase in the palladium concentration to 1.5% enhances the hydrogenating properties and weakens the cracking properties of the catalyst. The yield of 1-ETHI reaches 37%.

The principal products of the conversion of the VTHI – THI mixture are 1-ETHI, indole, and 2-ethylindole (2-EI), whose ratios depend on the composition of the catalyst. Indole is formed from VTHI in 47.2% yield on the 1% $Pd/\gamma\text{-}Al_2O_3$ catalyst at 350 °C and $\upsilon = 0.5\ h^{-1}$; the content of 2-ethylindole is 23.7%, while 1-ethylindole is virtually absent. The formation of 2-ethylindole is probably associated with the acid functions of the $\gamma\text{-}Al_2O_3$ carrier, which intensify the migration of the ethyl group to the α-position in the pyrrole ring (the thermal isomerisation of 1-alkylpyrroles to the 2-alkyl derivatives is well known).[110] The principal factor influencing the course of the above reactions on the aluminopalladium catalyst is the temperature, while the space velocity at which the mixture is supplied and the reaction time have little effect on the yield of indole and 2-ethylindole.

The selectivity of the sulfided aluminopalladium catalyst differs appreciably from that of the initial aluminopalladium catalyst. Only 1-ETHI is formed from the 1:1 mixture of VTHI and THI on the sulfided 1% $Pd/\gamma\text{-}Al_2O_3$ catalyst, i.e. the vinyl group is hydrogenated. At 250 °C, $\upsilon = 0.8\ h^{-1}$, and $\tau = 60$ min, the yield of 1-ETHI is 33.8% relative to the mixture passed over the catalyst or 72.9% relative to the reacted VTHI. The increase in temperature to 350 °C does not lead to an appreciable increase in the yield of 1-ETHI, which conflicts with data obtained using pure VTHI. These results indicate that the THI present in the initial mixture influences the reaction. The nature of the solvent (toluene or benzene) and dilution of the mixture have hardly any effect on the catalyst selectivity during the 3 h operation of the latter.[111]

By selecting the catalyst, it is possible to obtain 1-ETHI, indole, or a mixture of indole and 2-ethylindole from VTHI or its mixture with THI. On the sulfided 1.5% $Pd/\gamma\text{-}Al_2O_3$ catalyst, 47.9% of 1-ETHI is formed from VTHI ($T = 250$ °C, $\upsilon = 1.0\ h^{-1}$) and 37.6% of 1-ETHI is formed from the 1:1 mixture of VTHI and THI ($T = 250$ °C, $\upsilon = 0.5\ h^{-1}$). On the 1% Pd/Al_2O_3 catalyst ($T = 350$ °C, $\upsilon = 0.5\ h^{-1}$), 47.2% of indole and 23.7% of 2-ethylindole are formed from the same mixture. The yields of indole from the mixture of VTHI and THI show that the six-membered ring in both VTHI and THI is dehydrogenated.

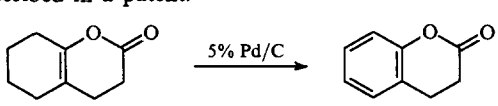
The reaction of the 1:1 mixture of VTHI and THI on $Pd/\gamma\text{-}Al_2O_3$ involves, together with the reactions indicated above, the dehydrogenation of the six-membered fragment of VTHI with formation of 1-ethylindole, which isomerises to 2-ethylindole. Indole is formed mainly as a result of the dehydrogenation of THI, which reacts more readily than VTHI with the active centres on the catalyst surface. The C=C bond is reduced selectively on the sulfided $Pd/\gamma\text{-}Al_2O_3$ catalyst and 1-ETHI is obtained, while in VTHI the C–N bond undergoes hydrogenation with formation of THI.[104] Hence one may conclude that the hydrogenation and dehydrogenation reactions proceed on different active centres of $Pd/\gamma\text{-}Al_2O_3$ and the sulfided catalyst.

A study has been made of the dehydrogenation of THI on the sulfided aluminopalladium catalysts containing 0.15%, 0.2%, and 0.25% of palladium, on the 0.15% Pb/sibunit and 0.5% Pd/sibunit catalysts, and also on the mixed (0.1% Pd, 0.1% Re)/$\gamma\text{-}Al_2O_3$ catalyst.[111] The results are presented in Table 4.

The hydrogen sulfide-treated 0.5% $Pd/\gamma\text{-}Al_2O_3$ catalyst operated for 30 min at 300 °C and $\upsilon = 1.1\ h^{-1}$, exhibiting an appreciable dehydrogenating activity (the catalytic reaction mixture contained 31% of indole). Other conditions being equal, on raising the temperature to 370 and 400 °C complete conversion of THI into indole takes place. The treatment of this catalyst with hydrogen at a high temperature (650 – 700 °C) enhances its cracking properties, which is indicated by the decrease in the yield of the catalytic reaction mixture from 98% to 87%. Indole is formed already at 300 °C in 100% yield relative to the THI passed over the sulfided 0.25% $Pd/\gamma\text{-}Al_2O_3$ catalyst and the space velocity is reduced by a factor of 2 compared with the value indicated above. During the 48 – 50 min operation of this catalyst, its high activity did not change on varying the temperature from 300 to 400 °C, υ from 0.5 to 0.75 h^{-1}, and the THI content in toluene from 14.5% to 20.8%. The yield of the catalytic reaction mixture was 96% – 100% on the (0.15% – 0.2%) $Pd/\gamma\text{-}Al_2O_3(H_2S)$ catalyst at 350 – 360 °C and $\upsilon = 0.33 - 0.57\ h^{-1}$. When benzene is used as the solvent, the yield diminishes slightly. On the 0.15% $Pd/\gamma\text{-}Al_2O_3(H_2S)$ catalyst, the six-membered fragment of THI is wholly dehydrogenated, but the reaction temperature is somewhat higher compared with the catalyst containing 0.2% of Pd. On the mixed (0.1% Pd, 0.1% Re)/$\gamma\text{-}Al_2O_3(H_2S)$ catalyst, this reaction occurs only when the starting material is supplied at a low space velocity $\upsilon = 0.3 - 0.35\ h^{-1}$. Under these conditions only indole accumulates in the catalytic reaction mixture during the first 40 min, and after 115 – 126 min of operation of the catalyst up to 5% of the unreacted THI remains. The six-membered fragment of THI is fully dehydrogenated after 60 min on the 0.5% Pd/sibunit catalyst at 364 – 370 °C and $\upsilon = 0.7\ h^{-1}$; after this, the activity of the catalyst decreases somewhat. Thus, after the catalyst has been used for 186 min, 6.5% of the unreacted THI remains in the catalytic reaction mixture. Indole has been obtained in a quantitative yield on the 0.5% Pd/sibunit catalyst at 400 °C and $\upsilon = 0.85\ h^{-1}$. The decrease in the palladium concentration in the Pd/sibunit catalyst from 0.5% to 0.15% also made it possible to obtain indole in a quantitative yield during the first 73 min of the operation of the catalyst at 365 °C and $\upsilon = 0.3\ h^{-1}$. However, subsequently its dehydrogenating activity fell. The hydrogen sulfide-treated specimen containing 0.15% of palladium on $\gamma\text{-}Al_2O_3$ has a dehydrogenating activity superior to that of the analogous catalyst on sibunit after being used for 100 min.

Thus the low-percentage catalysts containing 0.15% – 0.2% of palladium, which have been developed, ensure the selective dehydrogenation of the six-membered fragment of THI. Indole is formed quantitatively at 355 – 365 °C and $\upsilon = 0.3 - 0.6\ h^{-1}$.[111]

Table 4. Dehydrogenation of 4,5,6,7-tetrahydroindole on various palladium catalysts (atmospheric pressure, toluene, H_2 flow rate 0.6 litre h^{-1}).[111]



Catalyst	THI content (%)	Experimental conditions			Yield (%)

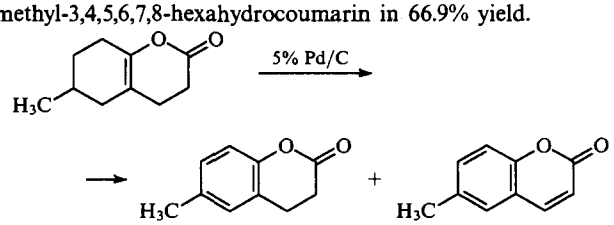
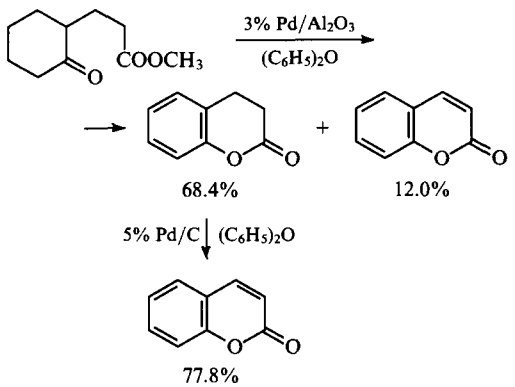
[a] On the same portion of the catalyst.
[b] Treated with hydrogen at 650–700 °C for 15 min.
[c] After the periodic operation of the same portion of the catalyst for 6 h.
[d] After the periodic operation of the same portion of the catalyst for 7 h.
[e] After the periodic operation of the same portion of the catalyst for 3.5 h.
[f] The specimen remaining after the experiments on the dehydrogenation of the cyclohexane for 9 h at 350–450 °C.



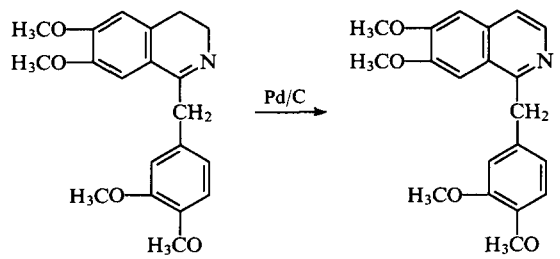
The six-membered fragment of THI is dehydrogenated on the 0.5% Pd/γ-Al_2O_3 catalyst at v = 0.75–1.2 h^{-1} and temperatures lower by 100 °C than in the dehydrogenation of cyclohexane, which makes it possible to employ catalysts with a low palladium content (0.15%–0.2%). The palladium catalyst on sibunit is also promising.

2. Dehydrogenation of dihydrocoumarins



A method of synthesis of coumarin and alkylcoumarins together with the corresponding dihydrocoumarins by liquid-phase dehydrogenation in the presence of Pd/C at 260 °C has been described in a patent.[112]

For the 100% degree of conversion of 3,4,5,6,7,8-hexahydrocoumarin, the yield of 3,4-dihydrocoumarin was 70%. For a degree of conversion of 98.5%, a mixture of 6-methylcoumarin and 6-methyl-3,4-dihydrocoumarin was obtained from 6-methyl-3,4,5,6,7,8-hexahydrocoumarin in 66.9% yield.



Coumarin has been obtained by the dehydrogenation of oxocyclohexanepropionic acid (OCPA) over Pd/Al_2O_3 in the liquid phase.[113]

For this purpose, OCPA in $(C_6H_5)_2O$ was heated at 250–260 °C in the presence of 3% Pd/Al_2O_3. A mixture of dihydrocoumarin (yield 68.4 mol%) and coumarin (yield 12 mol%) was obtained. Dihydrocoumarin in $(C_6H_5)_2O$ was dehydrogenated in the presence of 5% Pd/C for 14 h, which gave a mixture of 77.8% of coumarin and 22.1% of the unreacted dihydrocoumarin. After the carrier had been changed (5% Pd/Al_2O_3), the courmarin content fell to 50.8%, while that of the unreacted dihydrocoumarin rose to 49.1%.

3. Dehydrogenation of dihydropapaverine

Synthetic 1-benzyl-6,7,3',4'-tetramethoxyquinoline is identical with the natural alkaloid papaverine, which belongs to the class of opiate alkaloids and is widely used as a medicinal preparation. One of the last stages in the preparation of the synthetic papaverine is the dehydrogenation of dihydropapaverine at 200–250 °C in solution in tetralin in the presence of Pd/C under an inert gas (N_2, CO_2) stream.[17]

Dihydropapaverine was dehydrogenated on a catalyst containing 5% of palladium and deposited on an unwoven graphite material (UGM) with a volume concentration of 9.11 g cm^{-3} and a filtration coefficient of 5.3 × 10^{-2} cm s^{-1}.[114] The activity of the catalyst, determined from the evolution of hydrogen, increased after the introduction of CH_2O (to give a 1:1 mixture). The 5% Pd/UGM catalyst had the same activity as the industrial $Pd/BaSO_4$ (volume concentration 1.21 g cm^{-3}, filtration coefficient 3.5 × 10^{-5} cm s^{-1}), but a disadvantage of the latter is high hydrodynamic resistance. Papaverine can be obtained on the 5% Pd/UGM catalyst under both periodic and continuous conditions.[114]

VI. Palladium catalysts for the aromatisation of petrol fractions

The aromatisation of petrol fractions, carried out in catalytic reforming, ensures an increase in the octane number, such increase including the effect due to the dehydrogenation of naphthalenes. Aromatisation under platforming conditions is promoted by a high temperature and a low hydrogen pressure. However, when the pressure is too low, the catalyst activity falls rapidly owing to the deposition of carbon residues on its surface. The selectivity of the reaction on supported metallic catalysts is a complex function of the catalyst composition, pressure, temperature, the composition of the gas phase, etc.

The reforming catalysts possess a bifunctional activity because, together with the main reaction involving the dehydrogenation of six-membered cyclanes, reactions also occur in which five-membered cyclanes isomerise to six-membered ones with subsequent dehydrogenation, dehydrocyclisation reactions, alkane isomerisation reactions, and cracking. The presence on the catalyst surface of both the metal and of acid centres is therefore required. The platforming processes were carried out on platinum deposited on alumina, which possesses acid properties.[115-117]

Palladium, the crystal lattice of which has the same structure as that of platinum, is appreciably inferior to the latter as regards activity in reactions of both individual hydrocarbons and their mixtures.

The 0.5% $Pd/\gamma\text{-}Al_2O_3 \cdot HF$ catalyst treated with hydrogen sulfide exhibited an appreciable activity in the dehydrogenation of cyclohexane to aromatic hydrocarbons and retained its stability during operation of 262 h under the conditions of the reforming of the petrol fraction, with a boiling point of 96–114 °C, from the Il'sko-Khadyzhensk deposit (n_D^{20} = 1.4155, d_4^{20} = 0.7493, content of aromatic hydrocarbons 7.5%, sulfur content 0.0025%) at 450–460 °C, P_{H_2} = 20 atm, v = 1 h^{-1}, and H_2:HC = 5:1.[74,79] As a result of the dehydrogenation, the content of aromatic hydrocarbons rose to 36%–40%. Despite the high reaction temperature, the catalyst hardly induced any cleavage of the hydrocarbons to C_1–C_4 compounds and the effluent gas consisted of 98%–99% of hydrogen.[79]

The influence of hydrofluoric acid and of the treatment with hydrogen sulfide on the 0.5% $Pd/\gamma\text{-}Al_2O_3$ catalyst has been investigated under conditions of the reforming of the 89.5–125 °C petrol fraction containing 0.017% of sulfur compounds (calculated relative to sulfur).[118,119] The data on the composition of the fraction before and after reforming are presented in Table 5.

In the presence of the hydrofluoric acid-treated 0.5% $Pd/\gamma\text{-}Al_2O_3$ catalyst and in contrast to the initial 0.5% $Pd/\gamma\text{-}Al_2O_3$ catalyst, aromatic hydrocarbons are formed not only from six-membered cyclanes but also from five-membered cyclanes and alkenes. All the specimens also exhibit a desulfurising activity — the sulfur content decreases from 0.017% to 0.001%. The sulfided specimen is more resistant under these conditions to the action of sulfur compounds. However, when petrols containing sulfur compounds are used, the stability of the catalyst decreases with time and its aromatising capacity diminishes after 60 h of continuous operation.[119] The yield of

Table 5. Group composition of the petrol fraction with b.p. 89.5–126 °C (reforming conditions: T = 470–480 °C, P_{H_2} = 20 atm, v = 1.0 h^{-1}, H_2:HC = 12.5).[118,119]

Hydrocarbons	Content (mass %)			
	before reforming	after reforming on catalysts containing 0.5% Pd on

Cyclohexanes	18.5	1.0	0.8	1.0
Aromatic hydrocarbons	5.6	20.3	26.4	24.8

aromatic hydrocarbons decreases to 12%–12.5% after 27 h on the 0.5% Pd/γ-Al_2O_3 catalyst, after 46 h on the 0.5% Pd/γ-$Al_2O_3 \cdot HF$ catalyst, and after 13 h of reforming the petrol fraction on the sulfided 0.5% Pd/γ-$Al_2O_3 \cdot HF$ specimen. It is appropriate to mention that the sulfur content in the reformates proved to be identical in all cases. It is extremely likely that the decrease in the aromatising capacity of the most active 0.5% Pd/γ-$Al_2O_3 \cdot HF(H_2S)$ catalyst is associated with the removal from the latter of part of the chemisorbed sulfur, i.e. with the decomposition of PdS at a high temperature and a hydrogen pressure of 20 atm. The specific surface of the sulfided palladium catalyst is smaller by a factor of 1.5, whilst the temperature coefficient of the rate of dehydrogenation of cyclohexane to benzene is much higher than on the other two catalysts.[78] It may be that this explains why the sulfided specimen has the highest activity under the conditions of the reforming of the petrol fraction.

Thus the introduction of hydrofluoric acid into the aluminopalladium catalyst increases its isomerising capacity, whilst treatment with hydrogen sulfide increases its resistance to the sulfur compounds present in the petrol fraction.

The reforming of the petrol fraction with a boiling point of 89.5–126 °C and containing 0.017% of sulfur has also been investigated on palladium/aluminosilicate catalysts (containing 85.35% of SiO_2 and 11.91% of Al_2O_3) with different specific surfaces (S = 263, 240, 204, 180, and 93 $m^2 g^{-1}$).[120] The aluminosilicate catalysts, which are used extensively in the petroleum processing industry for cracking, are known to possess acid properties and hence to exhibit not only a cracking activity but also an extremely high isomerising activity. The deposition on the aluminosilicate of finely disperse palladium, which possesses dehydrogenating and hydrogenating properties, made it possible to create active aromatisation catalysts. An appreciably greater increment in the content of aromatic hydrocarbons (24%–33% instead of 17%–22%) is observed on these catalysts than on the 0.5% Pd/γ-Al_2O_3 catalyst. Aluminosilicate catalysts containing 0.5% of palladium also ensure the desulfurisation of the fraction: the sulfur content falls from 0.017% to 0.001%.[121] During the first hours of the operation, these catalysts exhibit an appreciable cracking activity and therefore it is more convenient to employ them in the reforming of higher-boiling petroleum fractions. In contrast to the catalyst deposited on alumina, on the palladium/aluminosilicate catalyst five-membered cyclanes and n-alkanes are involved in the aromatisation process in addition to the six-membered cyclanes.

VII. Bimetallic supported catalysts for the dehydrogenation of cyclanes and the aromatisation of petrol fractions

Low-percentage bimetallic supported catalysts, containing palladium and rhenium, were first developed at the Institute of Organic Chemistry of the USSR Academy of Sciences in the 1960s — several years earlier than the Pt–Re reforming catalyst (see below). The behaviour of the Pd–Re catalysts in the reactions of C_6 hydrocarbons, including the dehydrogenation of cyclohexane and methylcyclohexane at elevated temperatures and hydrogen pressures, has been widely investigated.[121–123]

Table 6 presents data on the reactions of cyclohexane and methylcyclohexane on catalysts containing 1% of Pd and 1% of Re and deposited on γ-Al_2O_3 and $Al_2O_3 \cdot SiO_2$.[122,123]

Together with benzene, methylcyclopentane is also formed. Table 6 shows that the (Pd, Re)/$Al_2O_3 \cdot HF$ catalyst treated with hydrogen sulfide exhibits the highest dehydrogenating activity. When it is employed, the benzene content in the catalytic reaction mixture increases from 67% to 87% and toluene is formed from methylcyclohexane in 90% yield. The use of aluminosilicate as the carrier instead of the hydrogen fluoride-treated alumina decreases the dehydrogenating activity of the catalyst.[123] The decrease in the specific surface of the aluminosilicate from 350 to 108 $m^2 g^{-1}$ also weakens the dehydrogenating activity of the catalyst. The introduction of hydrofluoric acid (0.5% or 1.5%) enhances the acid properties of the catalyst and increases the contribution of the reactions involving the hydrocracking of n-hexane and the hydrogenolysis and dehydroisomerisation of methylcyclopentane. When the aluminosilicate carrier was used, the highest dehydrogenating activity was shown by the (1% Pd, 1% Re)/$Al_2O_3 \cdot SiO_2$ 0.5%HF catalyst treated with hydrogen sulfide. The use of active bimetallic catalysts for the reforming of petrol fractions has also been studied (see below).

The dehydrogenation of cyclohexane has been investigated on the (1% Pd, 1% Re)/Al_2O_3 catalyst containing 0.3% of fluorine and treated with hydrogen sulfide in the temperature range from 370 to 420 °C, for the molar ratio hydrogen : cyclohexane = 3 : 1, at rates of supply of cyclohexane from 0.012 to 0.04 mol $g^{-1} h^{-1}$, and at a hydrogen pressure of 10 atm.[124] At 370, 400, and 425 °C, the equilibrium yields of the benzene obtained by the dehydrogenation of cyclohexane are respectively 65%, 83.3%, and 95.2%. The kinetics of the dehydrogenation reaction were investigated in a flow type apparatus. The quantities calculated by the kinetic equation

Note. The numerals in brackets indicate the degree of conversion of methylcyclohexane.
[a] The specific surfaces of the catalysts were 350 $m^2 g^{-1}$ (A), 160 $m^2 g^{-1}$ (B), and 108 $m^2 g^{-1}$ (C).

agreed with experimental data. The apparent activation energy for the dehydrogenation of cyclohexane was found to be 74.5 kJ mol^{-1}. The apparent activation energies for the isomerisation of cyclohexane and for the reverse reaction (the isomerisation of methylcyclopentane) in the temperature range 370–390 °C amounted to 72.0 and 48.5 kJ mol^{-1} respectively.

The properties of the sulfided 0.5% palladium catalysts deposited on alumina and of bimetallic catalysts containing 0.5% of palladium and 0.5% of rhenium were compared in the dehydrogenation of cyclohexane at atmospheric pressure (450 °C, v = 1.4–1.5 h^{-1}).[16]

The introduction of rhenium increased the yield of the catalytic reaction mixture from 91.8% to 94.2% and the benzene content from 85% to 91% and also made it possible to reduce the reaction temperature to 400 °C. At this temperature, the benzene content was 81% for a 92.4% yield of the liquid catalytic reaction mixture. Hence it follows that the palladium–rhenium bimetallic catalyst is more active than the pure palladium catalyst.

The nature of the promoting activity of rhenium both in aluminopalladium and aluminoplatinum catalysts[125–128] is not totally clear. It has been shown[129] that, in the absence of the second metal, rhenium deposited on Al_2O_3 is reduced to the metallic state almost completely at a concentration of 4%–5% and with greater difficulty at a concentration of 0.5%. This can be explained by the fact that, on low-percentage catalysts, rhenium and its oxides are in a highly disperse state and interact strongly with the acceptor sections of the carrier surface, which hinders reduction. The addition of rhenium does not affect the mechanism of the action of the bifunctional catalyst but reduces appreciably the rate of its deactivation.[121] It may be that, in contrast to palladium, rhenium promotes the removal of the coke-formation products from the catalyst surface.

The well known ability of rhenium to increase the stability of the catalyst can be explained by the fact that rhenium oxides hydrogenate the products preceding the formation of coke during catalytic reforming.[116,117]

An attempt has been made to discover a relation between the adsorption of hydrogen on promoted palladium-containing catalysts, on the one hand, and the state of the metals and their activity in the dehydrogenation of cyclohexane, on the other.[130] For this purpose, a detailed study was made of the overall content of hydrogen on the catalyst surface, the number of forms of chemisorption, and the temperature at which the maximum rate of desorption is attained and the activation energy for desorption and its kinetic order were calculated. The state of the active phase in both one-component and modified palladium catalysts was investigated by means of a series of physicochemical methods (thermoprogrammed desorption, diffuse reflection spectroscopy, X-ray phase analysis). The palladium catalysts deposited on alumina contained 0.02 mass%–0.35 mass% of the metal and were promoted with 0.1 mass%–6.3 mass% Co, Ce, or In. It was shown that the catalysts for the dehydrogenation of cyclohexane to benzene must be capable of activating hydrogen in both weakly and strongly bound forms. Since the centres for the chemisorption of hydrogen in the weakly bound forms are unoccupied during the reaction, they can serve as the sites for the formation of the intermediate adsorption complex in the dehydrogenation of cyclohexane. The adsorption of hydrogen in the weakly bound form is characteristic of palladium catalysts modified by non-noble metals, which contain the most reduced forms of both palladium and of the promoting Ce and Co additives and also incorporate mixed centres formed as a result of their interaction.

The introduction of neodymium oxide into the aluminopalladium catalyst increases appreciably its dehydrogenating activity.[131] The dehydrogenating activity of such catalysts was investigated at atmospheric and elevated hydrogen pressures. The results are presented in Table 7.

It follows from the data presented that the 1% Pd/Al_2O_3 catalyst containing 10% of Nd_2O_3 has the maximum dehydrogenating activity. An increase in pressure increases the yield of the product on the aluminopalladium catalysts containing 4.5% and 10% of Nd_2O_3. The stability of all the specimens was tested. After 18 h operation of the first catalyst, the benzene content fell from 91.8% to 48%. The same decrease in activity on the (1% Pd, 10% Nd_2O_3)/Al_2O_3 catalyst was reached after 40 h.

Table 8 presents data concerning the influence of other cerium- and yttrium-subgroup lanthanide oxides on the dehydrogenating activity of aluminopalladium catalysts.[132]

Evidently the lanthanide oxides increase appreciably the dehydrogenating activity of the aluminopalladium catalysts. The introduction of 10% of the lanthanide oxide lowers the specific surface of the alumina slightly (in the range 15–25 m^2 g^{-1}). The catalysts prepared were characterised by similar pH values with the sole exception of the catalysts containing neodymium oxide. The introduction of the lanthanide oxide diminished slightly the acidity of the aluminopalladium catalysts virtually regardless of the nature of the lanthanide oxide. Since all nine lanthanide oxides exert almost the same influence on the activity of the catalyst, in the preparation of such catalytic systems one can employ the most readily available and cheapest lanthanides and their mixtures.

Bimetallic catalysts containing palladium and rhenium on alumina were first developed in our country.[121] The use of these catalysts in the reforming of petrol fractions was investigated in 1962.[122] Later the properties of the platinum-rhenium supported catalysts designed for reforming began to be studied in Germany and the USA.[133,134] Platinum-rhenium/carbon catalysts were described in 1965[133] and the (Pt, Re)/Al_2O_3 catalyst

Table 7. Reactions of cyclohexane on the (1% Pd, Nd_2O_3)/Al_2O_3 catalysts (atmospheric pressure, T = 480 °C, v = 1.0 h^{-1}).[131]

Catalyst	s/m^2 g^{-1}	pH[a] of catalyst	Composition of catalytic reaction mixture (mass%)

was described in 1968.[134] The latter catalyst was prepared by the method described previously.[121] The 'rheniforming' process for improving the quality of petrol fractions was introduced in the USA in 1970.

The introduction of bimetallic catalysts is regarded as the greatest achievement in petroleum processing after the development in 1949 of the aluminoplatinum platforming catalyst. The advantage of the process on the bimetallic catalysts has been examined in detail in a monograph.[135] We shall note some of them. Rheniforming in the presence of the (Pt, Re)/Al_2O_3 bimetallic catalyst yields a reformed product with a higher octane number than that obtained in platforming on Pt/Al_2O_3. As a consequence of the high volume flow rates of the starting material, the productivity increases. The yield of the reforming product, hydrogen, and aromatic hydrocarbons rises, the useful lifetime of the catalyst increases, and the cracking of alkanes and naphthenes is reduced to a minimum. The employment of a lower pressure becomes possible, which promotes the occurrence of dehydrocyclisation and makes it possible to reduce the molar ratio of the circulating hydrogen and the starting material (H_2 : HC).[135] Preliminary purification of the petrol fractions to remove sulfur compounds is essential in rheniforming processes. The introduction of rhenium into the aluminoplatinum catalyst increases the lifetime of the latter, according to American workers, by a factor of 2–4 compared with that of the aluminoplatinum catalyst; the regeneration of the catalyst after three months' use ensures the complete restoration of its high initial activity.[135]

The influence of rhenium on the activity and stability of the aluminopalladium catalyst has been investigated under the conditions of the reforming of petrol fractions containing sulfur compounds (0.0123% of sulfur).[122] In the products obtained by reforming the Baku petrol B-70, the content of aromatic hydrocarbons increased from 5.5% to 57% after treatment for 25 h, while the concentration of sulfur compounds diminished from 0.0123% to 0.009%, i.e. by a factor of 1.4. During the initial period of the operation of the catalyst, the content of aromatic hydrocarbons reached 80%. The introduction of 1% of Re into the 1% Pd/Al_2O_3 · HF(H_2S) catalyst increased its stability almost by a factor of 4. However, after 111 h of continuous operation, the content of aromatic hydrocarbons fell to 14%.

The reforming of the 71–102 °C fraction of the Karadag petrol was investigated on the most active catalyst (1% Pd, 1% Re)/Al_2O_3 · HF(H_2S) in stationary and fluidised beds.[136] The results are presented in Table 9.

Table 9. Characteristics of the initial fraction with b. p. 71–102 °C of the Karadag petrol and the reforming products obtained with the process carried out in stationary and fluidised catalyst beds (T = 480 °C, v = 0.8–3.5 h^{-1}, P_{H_2} = 10 atm, H_2 : HC = 5–20).[136]

Component	Composition of fraction (mass %)	Composition of reforming products (mass %)		
		after treatment in a stationary bed for 25 h	after treatment in a fluidised bed for	
			25 h	100 h
Isopentane	1.4	1.2	1.1	0.9
n-Pentane	2.7	2.1	2.5	1.9
2,2-Dimethyl-butane	0.3	0.4	0.7	0.5
2-Methylpentane and 2,3-dimethyl-butane	5.9	6.3	6.1	5.8
3-Methyl-pentane	4.8	3.9	4.6	4.5
n-Hexane	12.4	10.9	11.6	10.3
n-Isoheptanes + dimethylcyclo-pentanes + cyclohexane + methylcyclo-pentane	48.9	36.7	30.7	37.4
Methylcyclo-hexane	15.4	1.1	0.8	2.8
Benzene	3.7	15.1	18.7	12.9
Toluene	4.5	21.3	23.2	23.0

It follows from Table 9 that, after 25 h of the operation of the catalyst, the content of aromatic hydrocarbons in the reforming products in the stationary and fluidised beds is 36%–42%. The content of benzene has then been increased by a factor of almost 4, whilst that of toluene increased by a factor of 5. The contents of the C_5 and C_6 alkanes remained almost unchanged. The fraction of isomeric hexanes (total hexanes) is ~50% in the initial petrol fraction. Approximately the same fraction of hexanes was attained earlier[121] on the same catalyst in the isomerisation of n-hexane in a stationary bed. Thus aromatic hydrocarbons are mainly formed as a result of the dehydrogenation of

six-membered cyclanes and to a slight extent as a result of the dehydroisomerisation of alkylcyclopentanes. The activity of the stationary catalyst bed gradually diminishes and, after it has worked for 40 h, the content of aromatic hydrocarbons in the reforming products falls to 29%, whilst in the fluidised bed their content after the catalyst has worked for 100 h diminishes only to ~36%. Hence it follows that the stability of the catalyst in the fluidised bed is 4 times greater than in the stationary bed. This can apparently be accounted for by the fact that in the fluidised bed the catalyst has a much larger macrosurface than in the stationary bed.

After 100 h of operation, the catalyst was regenerated with air in the fluidised bed at atmospheric pressure and 400 °C, was treated with hydrogen, and the experiment was again carried out at a pressure of 10 atm, a space velocity of 1.5–2.0 h^{-1}, and H_2 : HC = 10. The content of aromatic hydrocarbons in the reformate increased by a factor of 5, as before. Consequently, the hydrogen sulfide-treated rhenium–aluminopalladium catalyst fully recovers its activity as a result of regeneration.

VIII. Certain characteristic features of the catalytic and physical properties of palladium-containing supported catalysts

The available information about the physicochemical properties of supported palladium and palladium-rhenium catalysts for the dehydrogenation of cyclanes in the reforming of petrol fractions is extremely limited.[137–139] X-Ray diffraction analysis of the 0.5% Pd/Al_2O_3 catalyst, the same catalyst containing 0.5% of fluorine, and the fluorinated specimen subjected to an additional treatment with hydrogen sulfide showed that the palladium in all the specimens and the aluminium oxide in the first two specimens are in a crystalline state. The lattice constant of the aluminium oxide in these two cases is virtually the same, amounting to 7.91 and 7.90 Å respectively. The crystal dimensions are in the range 50–100 Å. The absence of Al_2O_3 reflections not coinciding with the palladium reflections (d = 2.349 and 1.384) is characteristic of the X-ray diffraction patterns of the sulfided specimen. It is therefore impossible to regard it as strictly demonstrated that the aluminium oxide in this specimen is in the crystalline state (lattice constant 7.86 Å).[78] The chemical treatment with hydrofluoric acid and hydrogen sulfide probably alters markedly the size and shape of the crystals and leads to the dispersion of the aluminium oxide. The palladium in the sulfided specimen is less saturated by hydrogen than in the first specimen. The rate of conversion of cyclohexane into benzene increases most markedly (by a factor of 4) with increase in temperature from 300 to 350 °C at atmospheric pressure in a flow system on the sulfided palladium-containing catalyst. The results obtained in tests of the activities and stabilities of these specimens under the conditions of the reforming of petrol fractions (see above) are related to the temperature coefficients of the rate of reaction.

Since the specific surfaces of the test specimens hardly changed during the dehydrogenation of cyclohexane, it follows that the differences between the activities and stabilities are induced by the chemical composition of the catalyst and not by structural features. It follows from data on the phase composition[78] that the impurities which are bound to be present in the specimens by virtue of the characteristics of the method of preparation can exist only in the form of surface compounds (AlF_3 or $HAlF_4$ and also PdS) or, which is less probable, in the form of an amorphous phase. Even at low concentrations, these compounds can influence significantly the activities and stabilities of the catalyst. It may be that the high activity and stability of the sulfided palladium specimen is due to the presence of PdS on the latter. The partial or complete sulfiding of the palladium surface apparently increases the temperature coefficient of the rate of dehydrogenation. This appears entirely probable, because sulfides are known to be active at higher temperatures than the metals forming part of their composition. For example, nickel sulfide hydrogenates the carbon–carbon bond at temperatures above 150 °C, whereas metallic nickel in the active form hydrogenates it already at room temperature.

Table 10. The contents of sulfur and carbon in the catalysts after prolonged operation under the conditions of the reforming of the petrol fraction with b.p. 89.5–124 °C (sulfur content in the fraction 0.017%).[78]

Catalyst	Duration of operation of catalyst/h	Content (%)	
		S	C
0.5% Pd/Al_2O_3	27	0.040	0.25
0.5% $Pd/Al_2O_3 \cdot HF$	46	0.035	0.28
0.5% $Pd/Al_2O_3 \cdot HF(H_2S)$	73	0.039[a]	0.27

[a] The initial reduced catalyst contained 0.125% of sulfur.

Data on the contents of sulfur and carbon in palladium-containing catalysts are noteworthy (Table 10).[78]

Regardless of the duration of the operation under the conditions of the reforming of petrol, the contents of sulfur and carbon remain almost unchanged in all the catalysts. If the accumulation of carbon had been limited by the coke saturation of the cracking surface centres, it would have been difficult to expect identical amounts of it on catalysts to have different properties. Therefore the data in Table 10 concerning the content of carbon are more likely to indicate that, after the formation of the 'carbonaceous film', the rate of hydrogenation of the film becomes equal to the rate of its formation on the catalyst surface, i.e. a certain equilibrium is established. Since the sulfur content in the catalyst does not increase with increase in the productivity in the operation of the latter, one may reach the unambiguous conclusion that the rupture of the sulfur compounds in petrol with formation of elemental sulfur on the catalyst does not occur and that sulfur is evolved in the form of hydrogen sulfide. The sulfur content in the initial sulfided catalyst was 0.125%. After the transition of the catalyst to the deactivated state as a result of performing the petrol reforming process on the latter, the sulfur content fell to 0.04%. Under these conditions, the sulfur content could have decreased only as a result of the formation and removal of H_2S.

It is appropriate to note that, when the activity fell to the same value, the sulfur contents in all the catalysts were also identical. It is extremely likely that the decrease in the activity of the sulfided catalyst is associated with the removal from the latter of part of the chemisorbed sulfur (the decomposition of PdS at a high temperature and hydrogen pressure).

The catalytic properties of metal oxide supported catalysts are known to be greatly influenced by the recrystallisation of the active phase. The specific surface of the metal in the alumino-palladium and aluminopalladium-rhenium catalysts has been estimated by a modified method involving the gas titration of the chemisorbed hydrogen by ethene[140,141] and also by the oxygen chemisorption method. Heat treatment of the Pd/Al_2O_3 catalyst at 640 °C increases the specific surface of palladium from 106 to 446 $m^2\ g^{-1}$.[137] The high H : Pd = 0.95 ratio shows that palladium is present on the carrier in a virtually atomic state. Oxygen titration yields lower specific surfaces (S increases on heat treament from 91 to 360 m^2 per gramme of palladium).

The specific surface of the metal (52 $m^2\ g^{-1}$) on the (Pd, Re)/Al_2O_3 catalyst is smaller than on Pd/Al_2O_3. Heat treatment of the catalyst increases the overall specific surface of palladium and rhenium. The specific surface of palladium in the bimetallic specimen is four times greater than in the palladium specimen. Thus in air rhenium does not inhibit the recrystallisation of palladium on the carrier but increases the thermal stability of the catalyst.

The effect of coke on the crystallisation of palladium and rhenium on different carriers has been examined.[138] X-Ray

diffraction study of palladium-rhenium catalysts on silica before and after saturation with coke (4%–5% of coke) under the conditions of the aromatisation of hydrocarbons at atmospheric pressure and 500 °C led to the identification only of lines corresponding to palladium. The introduction of rhenium into the Pd/SiO_2 catalyst retards the crystallisation of palladium on saturation with coke.

The relation between the activity of the $(Pd, Co)/Al_2O_3$ bimetallic catalyst in the dehydrogenation of cyclohexane and its adsorption capacity with respect to hydrogen has been investigated.[139] The dehydrogenation was carried out at 300–480 °C and atmospheric pressure under pulsed conditions. The specimen was subjected to a preliminary treatment in a stream of hydrogen at 520 °C for 15 min. The adsorption properties of the catalyst in relation to hydrogen (adsorption capacity, number of chemisorbed forms of hydrogen, the strength of the bond between hydrogen and the metallic catalyst surface) were determined by the thermoprogrammed desorption method. The conversion of cyclohexane on the 0.1% Pd/Al_2O_3 catalyst began at 340 °C and the maximum yield of benzene, equal to 38%, was attained at 480 °C. The Co/Al_2O_3 systems containing 1.66%, 3.0%, and 4.28% of the metal proved to be inactive. The activity of the $(Pd, Co)/Al_2O_3$ bimetallic catalyst is determined to a large extent by the concentration of the non-noble metal in the latter. The dehydrogenating activity of the palladium catalyst increases sharply after the introduction of 1% and 1.66% of cobalt: the yield of benzene at 480 °C reaches 83.4% and 68.4% respectively. At lower (0.1% and 0.5%) and higher (3.0% and 4.28%) cobalt concentrations, the degrees of conversion of cyclohexane into benzene are appreciably lower. C_1-C_6 hydrocarbons—cyclohexane cracking products—are formed on the bimetallic catalyst, in contrast to Pd/Al_2O_3.

The spectrum of the desorption of hydrogen from the Pd/Al_2O_3 catalyst contains one temperature range (600 to 700 °C) with a temperature of the maximum rate of adsorption of 660 °C. Kinetic calculations showed that hydrogen is desorbed in accordance with a second-order equation ($n = 2$) and that the activation energy for desorption is $E_{des} = 480$ kJ mol^{-1}. This indicates the atomic nature of the chemisorbed hydrogen and a high strength of the hydrogen–metal bond. The adsorption capacity of palladium in Pd/Al_2O_3 is low (0.1 ml per gramme of the catalyst), which corresponds to the ratio H:M = 0.54. Data have been obtained also for the Co/Al_2O_3 catalyst. On thermal desorption of hydrogen from the (0.1% Pd, 1.66% Co)$/Al_2O_3$ catalyst (the most effective in the dehydrogenation of cyclohexane), two forms of chemisorbed hydrogen (I and II) were detected. Hydrogen begins to be evolved at a lower temperature (300 °C) and the evolution takes place over a much wider temperature range (300 to 700 °C) than on the one-component palladium and cobalt catalysts. These results indicate a greater energy nonuniformity of atomic hydrogen and a weaker hydrogen–metal bond in the $(Pd, Co)/Al_2O_3$ catalyst. The strongly bound hydrogen (form II) is desorbed with $E_{des} = 280.5$ kJ ml^{-1}, whilst the weakly bound hydrogen (form I) is desorbed with $E_{des} = 118.5$ kJ mol^{-1}. The centres which bind hydrogen more strongly ($T_{des} > T_{reaction}$) are coated by adsorbed hydrogen on the catalysts showing a lower activity in the dehydrogenation of cyclohexane, whilst the centres for the weak chemisorption of hydrogen are virtually absent and their surface is coated only by the strongly bound forms.

The modifying effect of rhenium in the platinum-rhenium supported catalyst can be accounted for by the formation of bimetallic (alloyed) Re–Pt particles on the catalyst surface[125,126] or by the localisation of the platinum clusters on the low-valence rhenium ions bound to the carrier surface.[127] It is also possible to create catalysts containing transition metal complexes fixed on the carrier surface.

Bimetallic catalysts containing discrete surface structures of predominantly one composition can be obtained by the thermal decomposition of fixed surface complexes incorporating the atoms of the active metal and of the modifying element. Organic ligands are easily removed on reduction of the catalyst, which makes it possible to investigate the influence of the modifying element under conditions which rule out the uncontrollable modification of the deposited metal and of the carrier surface by the decomposition products. In the case of platinum-containing catalysts, the low-valence Group IV–VIII elements bound to the SiO_2 surface can serve as centres for the stabilisation of the reduced platinum atom or clusters.[128] By virtue of the formation of a chemical bond with the element of the additive, the deposited platinum is not sintered over a wide range of reduction temperatures.

The formation of zerovalent compositions[142] on the surface of the (0.5% Pd, 1.2% Si, 1.2% Cr)$/Al_2O_3$ specimen obtained by the method of Ermakov and coworkers[127,128] has been demonstrated by laser micromass spectrometry. Peaks corresponding to Cr_2O^+, $Cr_2O_3^+$, and SiO^+ are absent from the mass spectrum, which indicates the absence of chromium and silicon oxides. The presence of zerovalent silicon has been confirmed by XPS data. The presence of zerovalent chromium and silicon under the conditions of the preparation of the specimens favoured the formation on the surface of intermetallic compounds of the type of Pd_3Cr and Pd_2Si, which should promote an increase in the selectivity and stability of the catalyst in the dehydrogenation and aromatisation reactions as a result of the suppression of side processes involving the cleavage of the C–C bonds and saturation by coke.[142] On the Pd/Al_2O_3 catalyst modified by chromium and silicon compounds, it is possible to aromatise unsaturated cracking petrols containing alkenes and alkadienes without the preliminary hydropurification of the starting material.[142]

The formation of the alloy may improve the properties the platinum–rhenium catalyst compared with the platinum reforming catalyst usually employed.[143] The palladium–rhenium alloy was first investigated in the 1950s.[144] The limit of the solubility of rhenium in palladium corresponds to a ~20% rhenium content. The alloys remain single-phase up to a rhenium concentration of 7.4 mass% (12.8 at.%). When small amounts of rhenium (0.35 mass% and 2.24 mass%) are introduced into palladium, the electrical resistance of the specimen increases. Palladium and rhenium are transition metals with incomplete *d* shells. The valence of palladium is higher than that of rhenium, since the number of electrons in the $d+s$ levels in it is greater. The phase diagram for the palladium–rhenium system, like that for the platinum–rhenium system, belong to the peritectic type and reveals the presence of two limited solid solutions and no chemical compounds. The principal factors determining the nature of the interaction of the elements according to Tylkina et al.[145] are their position in the Periodic System, the isomorphous nature of the crystal structures, and the difference between the atomic dimensions and electronegativities. According to the Hume–Rothery rule, the formation of a continuous series of solid solutions requires that the difference between the atomic radii does not exceed 7%–8%, while the appearance of limited miscibility requires that the difference should not be greater than 15%. The platinum group metals and rhenium have virtually identical atomic radii. The size factor does not exceed 3%.

Another condition for miscibility is the similarity of the crystal lattices. This is why palladium, which has a face-centred cubic lattice, forms only limited solid solutions with rhenium, which has a hexagonal close-packed lattice. A significant characteristic of the elements is their electronegativity[146] because it is a function of the atomic radius and valence and may serve as a measure of the electron binding energy in the atom. It is known that, for a difference between the electronegativities of 0.2 e.u., one should expect continuous miscibility, while for a difference of 0.4 e.u. limited miscibility is to be expected. The electronegativities of rhenium and palladium are identical and equal to 2.08 e.u.

In the interaction of metals, the difference between their melting points plays a significant role. When the difference between the melting points is small (up to ~20 °C), there is a continuous miscibility, whereas in the case where it is considerable (up to ~50 °C) limited miscibility obtains. The difference between the melting points and the peritectic transformation temperature are also related. The greater the difference between the melting points of the two metals, the lower the peritectic transformation temperature, and the greater the extent of the two-phase region. The difference between the melting points of rhenium and palladium is 51 °C and that between the melting points of rhenium and platinum is 44 °C. For other platinum group metals, this difference is much smaller.

The above considerations suggest that the high effectiveness of the palladium–rhenium catalyst is associated with the formation on its surface of a palladium–rhenium alloy.

The formation of the surfaces of bimetallic catalysts is complex and takes place in several stages. It depends both on the carrier and on the conditions in the preparation of the catalyst. Furthermore, as a consequence of the specificity of the interaction of the components in small clusters, the composition of the catalyst surface may differ from that of the bulk-phase of the alloys.

The reasons for the promoting effect of the second metal in bimetallic supported catalysts have not been ultimately elucidated. There is a possibility of the interaction of the carrier with rhenium, the stabilisation of some kind of intermediate oxidation states by alumina, fusion, or the formation of metal clusters. However, one must assume that, since the coke deposition process is very slow, it is a consequence of side reactions. The second metal may more effectively catalyse the removal of the corresponding intermediates than palladium.

The prediction of the catalytic effect and selection of catalysts with specified properties is still one of the current problems in hetereogeneous catalysis.[147–153] Studies carried out by Boreskov's school[149–151] and other investigators have shown that, for a constant chemical composition of the catalyst, the specific catalytic activity depends slightly on the dispersity of the active component, the degree of its crystallinity, and the method of preparation. A stationary composition of the catalyst is established under the influence of the reaction mixture and its catalytic activity is independent of its initial state. For the majority of reactions, the postulate of the approximate constancy of the specific activity of the catalyst holds. These reactions belong to the class of the so called structure-insensitive reactions. On the other hand, the reactions for which appreciable deviations are observed are structure-sensitive.[154, 155]

Together with nickel, palladium is one of the most active hydrogenation catalysts. The advantage of palladium over nickel consists in the fact that it readily dissolves hydrogen, which diffuses through the metal.[148] The hydrogenation reaction is structure-insensitive.

Analysis of the data presented in the review suggests that dehydrogenation on palladium-containing supported catalysts belongs to the class of structure-sensitive reactions, the rate of which depends on the accessibility and structure of the active centres. For such a reaction, the method of preparation of the catalyst is much more important than for the structure-insensitive reverse hydrogenation reaction. In particular, much attention must be devoted to the selection of the carrier, the regulation of its porosity, the preliminary treatment, the determination of the depth of impregnation, and other similar factors.[153]

Sulfur- and nitrogen-containing heterocyclic compounds are known to be catalytic poisons for platinum group metals. The catalyst is poisoned as a result of the stable chemisorption of such compounds on the surface of the deposited metal. Apparently, more strongly chemisorbed sulfur- and nitrogen-containing intermediates are formed on palladium catalysts than on sulfided palladium-containing catalysts and the higher activity and stability of the latter in the aromatisation reactions of petrol fractions containing sulfur compounds and in the dehydrogenation of heterocyclic molcules are associated with this factor. The greater stability of the hydrogen sulfide-treated palladium-containing catalysts compared with the untreated catalysts may also be associated with the formation on the surface of palladium sulfide, which, like other metal sulfides, is more resistant to the poisoning effect of sulfur and nitrogen compounds. Furthermore, metal sulfides are much less subject to saturation by coke than the metals themselves, as a result of which, nickel sulfide may prove to be more active, for example in the hydrocarbon hydrogenation reaction, than metallic nickel. Sulfide catalysts are bifunctional in their nature. They exhibit both hydrogenating-dehydrogenating and acid properties.[149] The great interest in sulfide catalysts is associated with their wide-scale application in hydropurification processes. The nature of the active component in metal sulfide supported catalysts and the mechanism of the activation of the C–S bond and of the hydrogen molecule in the hydropurification process still remain obscure.[156] A certain amount of attention has also been devoted to problems of the catalytic elimination of nitrogen-containing compounds, but their content, for example, in petroleums, is much lower than the content of sulfur compounds and the number of obscure and unsolved problems in that field remains even greater.

The modification of palladium supported catalysts with rhenium may induce an increase in the activity of palladium as regards reduction and promotes the attainment of a higher dispersity of the metal particles than in the Pd/Al_2O_3 catalyst.[135] Rhenium ensures a high thermal stability of alumino-palladium–rhenium catalysts, diminishes coke deposition, and can be more effective than palladium in removing the sulfur- and nitrogen-containing intermediates from the catalyst surface.[137, 157]

Sulfided palladium and palladium-containing bimetallic supported systems are active catalysts for the dehydrogenation of cyclanes, cyclenes, cyclohexadienes, and their functional derivatives and may be used both for the synthesis of aromatic hydrocarbons and for the refinement of petrol fractions. Severe requirements as regards the content of aromatic hydrocarbons in the fuel have now begun to be imposed in certain developed countries.[158, 159] One of the methods for the reduction of the concentration of such hydrocarbons may involve the use of sulfided palladium — rhenium supported catalysts for the hydrogenation of petroleum fractions.[160] Palladium-containing supported catalysts exhibit a high activity and selectivity in the dehydrogenation reactions of nitrogen- and oxygen-containing compounds in processes involving the preparation of valuable products of fine organic synthesis, such as indole, coumarin, their derivatives, and papaverine. The heterocyclic nuclei of the above compounds are known to serve as the structural basis for a large number of medicinal compounds, perfumes, dyes, etc.

The search for new ways of preparing supported catalysts containing a metal in a highly disperse state, modification, the synthesis of new carriers, the discovery of a relation beween the catalytic activity and the adsorption properties of the deposited metal and its valence state on the carrier, and other similar studies will promote the development of the scientific foundations for the selection of catalysts with specified properties in particular reactions. Further continuation of these researches by application of the latest physicochemical methods is one of the most important problems in heterogeneous catalysis.

Abstract. The results of studies on the mechanism of the adsorption of water molecules by nonporous and microporous carbon adsorbents carried out using various physicochemical methods are surveyed. The influence of the chemical state of the surface and of the porous structure of adsorbents on the heat of adsorption and the mechanism of filling of the carbon surfaces of micro- and mesopores of carbon adsorbents are analysed. The nature of the primary adsorption sites and the influence of the adsorption of water molecules on the X-ray diffraction parameters (microcrystalline structure) of carbon adsorbents are studied. The methods of investigation of the porous structure and chemical state of the surface of carbon adsorbents based on the analysis of water vapour adsorption isotherms are considered. The bibliography includes 80 references.

I. Introduction

The adsorption of nonpolar molecules, in particular argon, krypton, nitrogen, oxygen, carbon dioxide, and various hydrocarbons on carbon adsorbents (CA) has been studied rather extensively. These adsorbable substances are widely used to determine the parameters of the porous structures and adsorption properties of CA.[1] For example, argon is used for determining the specific surfaces of solids having low specific surfaces; carbon dioxide is used to characterise ultramicroporous adsorbents, including coal. The 'subtraction' method developed in recent years, which is based on the simultaneous analysis of adsorption isotherms of carbon dioxide and nitrogen, is employed for the determination of the structural parameters of micropores of various types.[2] Benzene has been accepted as a standard vapour for characterising CA in the former USSR countries. In European countries, Japan, and USA, nitrogen and carbon tetrachloride are usually employed for this purpose.

The methods for the determination of the porous structure parameters from the adsorption isotherms of the above compounds are based on the use of physical adsorption equations. These are primarily the well-known Dubinin–Radushkevich, Dubinin–Astakhov, and Dubinin–Stoeckli equations of the theory of volume filling of micropores (TVFM), developed by the school of Academician Dubinin,[3–5] and also various equations of polymolecular adsorption theory, in particular, the Brunauer–Emmett–Teller (BET) equation,[1,5] and the Mikhail–Brunauer–Bodor (MP) equation, etc.[1]

The adsorption of water on carbon adsorbents has some peculiarities, compared with the adsorption of nonpolar substances. The characteristic features and peculiarities of the adsorption of water vapour on CA are primarily caused by the tendency of polar water molecules to form hydrogen bonds, the dispersion interactions with the carbon surface being relatively weak.

The attempts to develop methods for the analysis of the porous structures of CA using the water vapour adsorption isotherms published in the literature are based on various, sometimes mutually exclusive, views on the adsorption mechanism.

A distinctive feature of carbon adsorbents, which determines to a substantial degree the fields of their application, is their relative hydrophobicity. However, depending on the porosity and the chemical state of the surface, which can vary on prolonged storage or prolonged use of an adsorbent, the humidity of the medium may noticeably influence the adsorption capacity of CA toward substances of various types.[6,7] Therefore, the study of the general rules and peculiarities of the adsorption of water vapour on CA has acquired practical significance.

The study of the mechanism of the adsorption of water vapour on CA is supposed to answer the following questions: what is the role of the primary adsorption sites of CA in the adsorption of water molecules, what are these sites from a chemical viewpoint, where are they located, how do the molecules being sorbed interact with these sites, in what manner are the surface and the micropore volume of CA filled, and what changes in the adsorbent itself accompany the adsorption process?

Although a large number of studies dealing with the adsorption of water vapour on CA have appeared in the literature,[8–22] at present there are no unanimous views on the mechanism of the adsorption, the role of the chemical state of the surface, or the nature of the adsorption sites. The initial views on the mechanism of adsorption of water vapour can be divided into two main groups: (1) the concept of the capillary condensation mechanism of the filling of micropores (Juhola[11–13] is the most consistent adherent of this theory) and (2) the concept of primary adsorption sites and the specific interaction of water with the carbon surface (Pierce and Smith[14] and Dubinin[15] have

developed this concept independently of one another). Dubinin and coworkers[15] have reported on the surface oxides of CA, which play an important role in the adsorption of water molecules. In addition, it has been suggested[16,17] that the specific features of the adsorption of water vapour on CA are due to changes in the properties of the adsorbate caused by an increase in the average number of hydrogen bonds. It has also been noted[18] that the peculiarity of the adsorption of water is due to the fact that the carbon networks move apart and water molecules penetrate into the interlattice space of the CA by the 'collective' adsorption mechanism.

Within the framework of the concept of primary adsorption sites (PAS), there are also several views on the mechanism of further filling of the adsorption space: (1) the 'island' mechanism, according to which the PAS serve as nuclei for the formation of micro-drops, whose coalescence results in the formation of the bulk phase[14,19,20] and (2) the monomolecular-layer mechanism, according to which hydrogen bonds play a prominent role in the formation of a monomolecular layer.[21,22]

The studies published in recent years also did not completely clarify the problem of the mechanism of the adsorption of water vapour on carbon adsorbents, in particular on activated carbon (AC). Some authors apply widely the Kelvin[13] and Sircar[23] equations, based on the capillary condensation mechanism of adsorption, while other workers draw attention to the fact that the presence of acidic oxygen-containing complexes in the CA increases the adsorption of water vapour and facilitates the filling of micropores.[24-27] At the same time, the presence of non-acidic oxygen complexes does not influence the polarity of the CA surface and does not increase the adsorption of water vapour.[28]

In the present review, attention is concentrated on the role of the chemical state of the surface and of the microporous structure of the CA in the adsorption of water vapour, the nature of the PAS, the character of the interaction of the adsorbed molecules with the PAS, and the mechanism of the filling of the pore volume. Therefore, we carried out a systematic analysis of experimental data on the adsorption of water vapour on CA differing in porosity and chemical state of the surface, as well as adsorption on identical CA studied by various physicochemical methods. A total of about 300 samples of CA obtained from various materials by a variety of procedures were studied.

All the CA studied were characterised in terms of the adsorption of nitrogen vapour at 77 K. The specific surfaces (S_{sp}) of nonporous CA were calculated by the BET equation or determined from comparative plots, which have been surveyed and described by Greg and Sing.[1] The so-called 'absolute' adsorption isotherm on the surface of graphitised thermal carbon black was adopted as the 'reference' isotherm in the analysis of graphitised CA samples,[29] while in the analysis of other CA, the averaged adsorption isotherm for nonporous technical carbon black samples[30] was used.

The parameters of the porous structures of microporous AC (the limiting volume of the adsorption space of micropores W_o and the characteristic adsorption energy E_o) were calculated from the equations of the theory of the volume filling of micropores[5] using the comparative γ/F method of determining the surface area of mesopores.[30,31] The width of the micropores ($2x$) for the slit model was determined from the generalised Stoeckli equation,[32] which relates $2x$ (nm) to the characteristic adsorption energy E_o (kJ mol^{-1}).

$$2x = \frac{10.8}{E_o - 11.4}$$

From the W_o/x relationship, the geometric surface area of the slit-shaped micropores (S_g) was found.[4]

The parameters of mesoporous AC were determined by the MP method.[1,33]

Water vapour adsorption isotherms on technical carbon blacks and also on some AC (especially in the region of small relative pressures) were obtained in a vacuum adsorption unit using a beam microbalance having a sensitivity of 1.0 μg with weighed portions of about 2 g; adsorption on the other AC was measured using a McBain-type quartz spring balance having a sensitivity of about 3 μg with weighed portions of 100 mg. Low adsorbate pressures (less than 1.3 Pa) were measured by a capacitance membrane manometer with a sensitivity of 0.013 Pa.

Most of the experimental data on the adsorption of water vapour have been analysed by a comparative method,[34] which is widely used to determine the parameters of the porous structures of adsorbents from the adsorption isotherms of nonpolar substances.[1] In this case, the water vapour adsorption isotherm on nonporous graphitised carbon black was adopted as the 'reference' (standard) isotherm.[34]

II. Adsorption of water molecules on the surface of nonporous carbon adsorbents

1. Adsorbents with low concentrations of primary adsorption sites

In conformity with the concept of primary adsorption sites, when water molecules are sorbed on a nonporous carbon surface, they initially form hydrogen bonds with the PAS and, as the relative vapour pressure p/p_s (p_s is the saturated vapour pressure) increases, they form hydrogen bonds with one another too. Consequently, clusters of associated water molecules are formed around the PAS.[14] Kiselev and Kovaleva[35] have noted that the adsorption of water vapour on graphitised carbon black over the whole region of relative pressures remains insufficient for covering the entire surface with a continuous monomolecular layer. Apparently, the formation of 'islands' or clusters can account for the fact, observed by these authors, that the limiting adsorption at saturation of water molecules on surfaces of various carbon black samples, pretreated in a stream of hydrogen at 1973 K, is about 8 μmol m^{-2}, which is equivalent to approximately 50% of the surface being covered by a continuous water monolayer.[36] This value was obtained by plotting the absolute water vapour adsorption isotherms on various carbon black samples.[36]

Analysis of the data obtained by Golovko et al.[37], who studied the adsorption of water vapour on the surface of highly dispersed graphite, indicates that in this case too no continuous monomolecular layer is formed. One may suggest that, depending on the surface concentration of the PAS, the adsorption of water vapour may end in the formation of either separated clusters, existing in equilibrium with the saturated vapour, or of a continuous adsorption film on the surface. In the former case, the distance between the PAS (l_m) should be larger than a certain limiting size of the water clusters formed on the carbon surface, and the limiting adsorption at saturation (a_s) should be proportional to the number of PAS rather than to the surface

Table 1. The specific surfaces (S_{sp}), the numbers of primary adsorption sites (a_m), the distances between them (l_m), the total amounts adsorbed at saturation (a_s), and the numbers of statistical monomolecular layers (N_s) for the graphitised CA studied (samples *1–8*).

Sample	S_{sp}/m^2 g^{-1}	a_m/μmol g^{-1}	l_m/nm	a_s/μmol g^{-1}	N_s[a]
1	47	0.5	12.5	240	0.32

5	63	15.0	2.65	1790	1.80
6	50	2.5	5.76	390	0.49
7	33	1.6	5.85	250	0.48
8	100	4.0	6.44	590	0.37

[a] The N_s value was calculated for the area of the water molecule (0.105 nm^2) determined from the bulk density of water.

area of the CA. In the latter case, l_m should be smaller than the limiting size of the clusters and a_s should be proportional to the surface area of the CA.

A number of adsorbents prepared from ultradisperse technical carbon[38] with subsequent graphitisation at a temperature of 3073 K have been used as CA with low surface concentrations of PAS. As shown by mercury porosimetry, the initial sample *1* (Table 1) possessed a pore volume of 0.425 $cm^3\ g^{-1}$ with a narrow pore size distribution having a maximum near 25 nm. In order to deposit OH groups, sample *1* was chlorinated and then hydrolysed (samples *2* and *3*) by the procedure reported for a diamond surface.[39] Samples *4* and *5* were prepared by the oxidation of sample *1* in concentrated HNO_3 at 298 K and 373 K, respectively. In addition, sample *6*, prepared by treating the CA with phenol, was studied. Sample *7* differed from the initial sample *1* only by a lower specific surface and a higher PAS concentration. For comparison, Vulkan-7H carbon black graphitised at 3073 K (sample *8*), adopted as the 'reference' sample, was also studied.

Fig. 1 presents comparative plots for the adsorption of nitrogen vapour on samples *1–7* at 77 K. In these plots, the 'absolute' isotherm for adsorption on the surface of graphitised thermal carbon black was adopted as the reference isotherm.[29] For all the samples *1–7* studied, these plots are straight lines passing through the origin of coordinates. This indicates that the mechanisms of nitrogen adsorption on the samples studied and on the standard nonporous carbon surface are identical and that the surfaces of the adsorbents studied are energetically and structurally uniform. From the slopes of the comparative plots for the adsorption of nitrogen, the specific surfaces of the adsorbents (S_{sp}) may be determined.[29,30] Fig. 2 shows water vapour adsorption isotherms on some of these samples at 293 K, and Fig. 3 presents the comparative plots for the adsorption of water vapour. In this case, the water vapour adsorption isotherm on sample *8* was adopted as the standard. The slopes of the comparative plots for the adsorption of water are proportional to the concentration of the PAS (a_m).[34] The distance between the PAS (l_m) was calculated on the assumption that they are uniformly distributed over the surface.

From Table 1, one can see that the number of PAS on the initial sample *1* is significantly smaller than that on the 'reference' graphitised carbon black and that this number increases sharply when the CA is oxidised. The S_{sp} values for samples *1–4* and *6* are virtually identical, while S_{sp} for sample *5*, obtained by boiling sample *1* in concentrated HNO_3, is somewhat higher. The values of a_s for samples *1*, *4*, *6*, *7*, and *8* correspond to the fractions of the close packed monolayer.

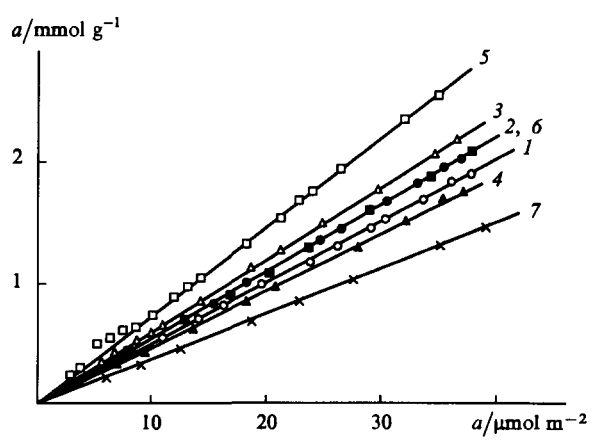

Figure 1. Comparative plots for the adsorption of nitrogen vapour on graphitised CA samples (*1–7*) at 77 K. The numbering of the samples in Figs 1–4 corresponds to that in Table 1.

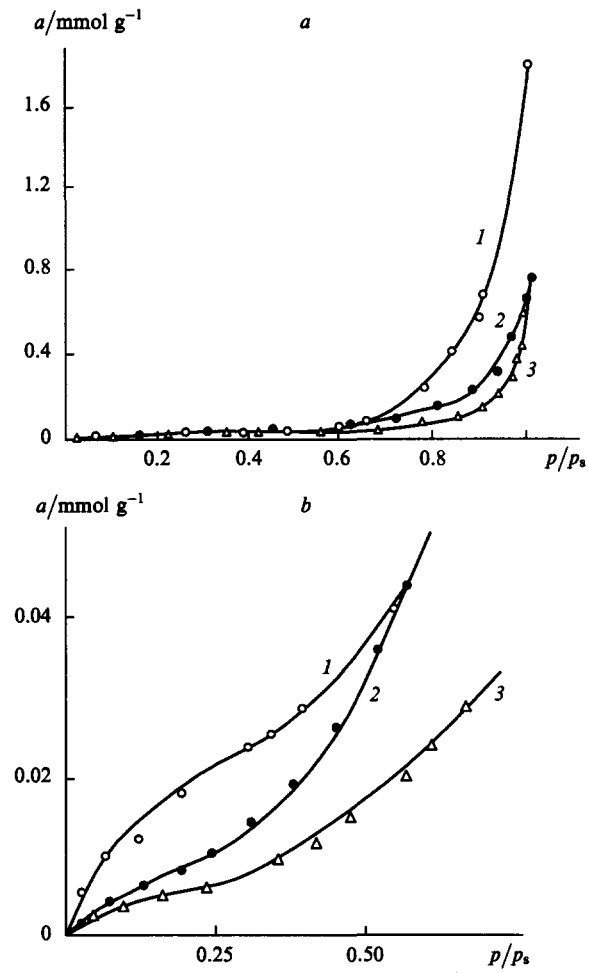

Figure 2. Water vapour adsorption isotherms at 293 K on the graphitised samples *3* (curve *1*), *4* (curve *2*), and *8* (curve *3*). The overall form of the isotherms (*a*) and the isotherms at low coverages (*b*).

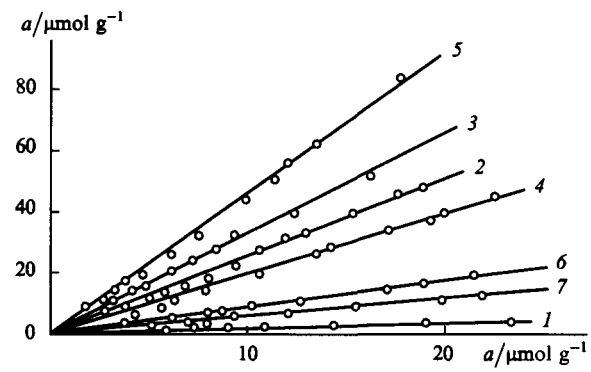

Figure 3. Comparative plots for the adsorption of water vapour on the graphitised samples *1–7* at 293 K.

The dependence of the total amount adsorbed at saturation a_s on the concentration of PAS a_m on graphitised CA is shown in Fig. 4. It is a straight line starting from the origin of coordinates. The slope of this straight line corresponds to the average number of water molecules in a cluster formed around a PAS at $p/p_s = 1$, which is approximately 150 molecules per site. The size of such a cluster can be evaluated from data on the numerical modelling of the adsorption of water molecules on a carbon surface.[40] If one assumes that the adsorbed water clusters are geometrically similar (a cluster consisting of 19 water molecules is a hemisphere 1.4–1.5 nm in diameter and 0.7 nm high[40]), a

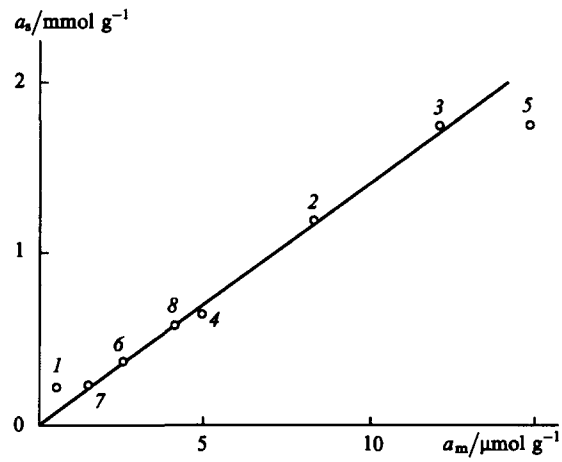

Figure 4. Dependence of the total amount of water vapour adsorbed at saturation on the number of primary adsorption sites (a_m) on graphitised CA samples.

cluster on a surface incorporating 150 water molecules should be about 3.0 nm in diameter and 1.5 nm high.

Thus, if the distance between the PAS l_m is larger than 3 nm, no continuous adsorption layer is formed on the surface of the graphitised CA. This result is supported by independent calorimetric measurements of the heats of immersion in water of sample *7* containing various quantities of preadsorbed water (Fig. 5).[41] From Fig. 5, one can see that the heats of immersion increase continuously as the quantity of preadsorbed water increases up to the total uptake at saturation, and reach 1.5 J g^{-1}. This means that the differential heats of adsorption calculated from the heats of immersion are lower than the heat of condensation over the whole range of coverages (curve *2* in Fig. 5). At low coverages, the differential heats agree with the isosteric heats calculated from the water vapour adsorption isotherms on this sample at 298, 293, and 273 K (curve *3*).

Taking into account the surface energy of normal water (118 mJ m^{-2}), one can infer that the heat of immersion equal to 1.5 J g^{-1} corresponds to the disappearance of 12.7 m^2 g^{-1} of the water surface, i.e. if the limiting quantity of water has been preadsorbed, the water molecules occupy about 40% of the whole surface of the graphitised sample, which amounts to 33 m^2 g^{-1} (see Table 1).

Thus, if the distance between the PAS is greater than the critical size of the clusters formed from water molecules adsorbed on the carbon surface, the clusters grow independently of one another until the amount adsorbed at saturation is achieved. By determining the amount of water vapour adsorbed at saturation, one can evaluate the number of PAS on the carbon surface.

It is noteworthy that the correct determination of the number of PAS for water molecules is very important in the approach outlined. The number of PAS on the CA can be calculated from the Langmuir equation for localised adsorption:

$$a = \frac{a_m bp}{1 + bp},$$

where p is the equilibrium pressure and b the energetic factor. This equation describes experimental adsorption isotherms in the region of low relative pressures where adsorption is mainly caused by the interaction of water molecules with PAS. The resulting number is identical with the number of acidic surface functional groups, which is determined by an independent method involving the neutralisation of these groups with a solution of Na_2CO_3. Determination of the number of PAS using the Dubinin–Serpinskii equations yields, as a rule, higher values of a_m,[42] which finally results in smaller distances between the PAS and, consequently, in lower values of the critical size of a cluster on the carbon surface.

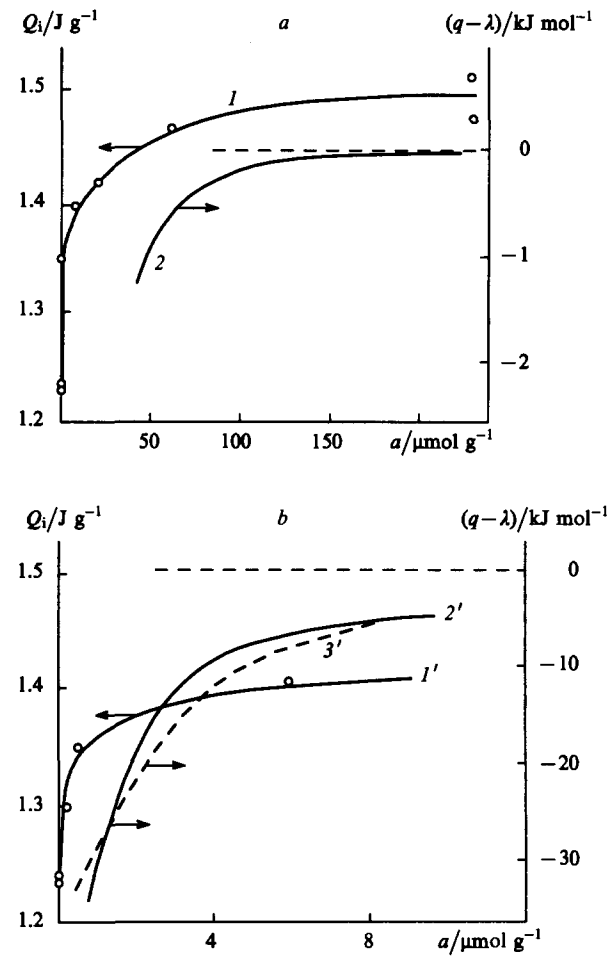

Figure 5. Dependence of the heat of immersion of sample *7* in water (Q_i) at 298 K on the quantity of preadsorbed water (curves *1* and *1′*) over the entire range of coverages (*a*) and in the initial section (*b*). The 'pure' differential heats of adsorption of water vapour ($q - \lambda$) were calculated from the Q_i values (curves *2* and *2′*). The isosteric heats of adsorption of water vapour on the same sample (curve *3′*) were calculated from the adsorption isotherms measured at 273, 293, and 298 K.

The first Dubinin–Serpinskii equation (DS-1) can be written as follows:

$$a = \frac{a_m ch}{1 - ch},$$

where c is a constant equal to the ratio between the adsorption and desorption rate constants and h the equilibrium relative pressure (p/p_s).

Allowance for the variation of the number of PAS present as new water molecules are adsorbed results in the second Dubinin–Serpinskii equation (DS-2):

$$h = \frac{a}{c(a_o + a)(1 - ka)},$$

where k is determined from the condition $a = a_s$ at $h = 1$, i.e.

$$k = \frac{1}{a_s} - \frac{1}{c(a_o + a_s)}.$$

Here a is the amount adsorbed at the relative pressure h, and a_s the amount adsorbed at $h = 1$.

2. Adsorbents with a relatively high concentration of primary adsorption sites

The adsorption of water vapour on CA with relatively high concentrations of PAS may result in the formation of a continuous adsorption layer. In this case, the total amount adsorbed at saturation should be proportional to the specific surface of the CA.

Table 2 presents the values of S_{sp}, a_s, l_s, and a_s as well as the number of statistical monomolecular layers N_s for such carbon black samples. The designations of the samples and the specific surfaces of the majority of carbon blacks studied were taken from two papers[29,30] (the values of S_y are given as the S_{sp}). In addition, samples of technical carbon PM-75, Ukhta channel carbon black (UKhT-K), and C-7 type acetylenic carbon black[29] with 5.5% of deposited pyrocarbon (AC-5.5) were studied. All the samples were subjected to preliminary heat treatment at 1273 K. As can be seen from Table 2, the l_m values for these samples are smaller than the critical cluster size, which indicates that the formation of a continuous adsorption film is possible. The a_s values for these carbon blacks correspond to the formation of 1.7 ± 0.3 statistical close-packed monolayers.

The plot of a_s against S_{sp} for the CA listed in Table 2 is shown in Fig. 6. This plot is linear and starts from the origin of coordinates. In this case, the slope of the straight line makes it possible to determine the amount of water vapour adsorbed at saturation per unit carbon surface: it is equal to approximately 26 μmol m^{-2}.

Table 2. The specific surfaces, the numbers of PAS, the distances between them, the total amounts adsorbed at saturation, and the numbers of statistical monomolecular layers for carbon blacks with high concentrations of PAS.

Sample	Carbon black	S_{sp}/ $m^2\ g^{-1}$	a_m/ μmol g^{-1}	l_m/ nm	a_s/ μmol g^{-1}	N_s
1	S-3	31	0.013	1.99	0.85	1.75
2	PM-75	68	0.061	1.36	1.85	1.74

10	UKhT-K	120	0.311	0.80	2.90	1.54
11	ST-10	126	0.068	1.75	2.95	1.49
12	S-9	126	0.132	1.26	2.50	1.27

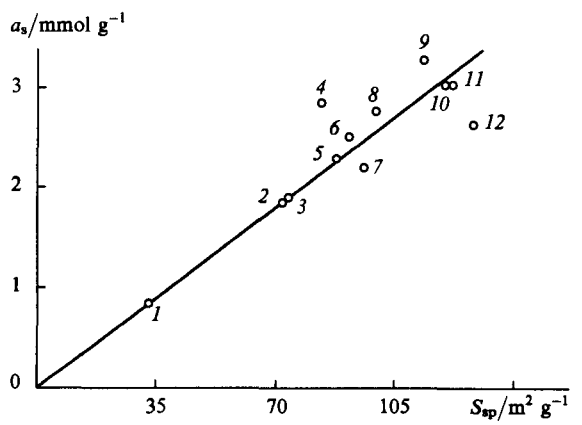

Figure 6. Dependence of the total amount of water vapour adsorbed at saturation on the specific surfaces of nonporous CA. The numbering of the samples corresponds to that in Table 2.

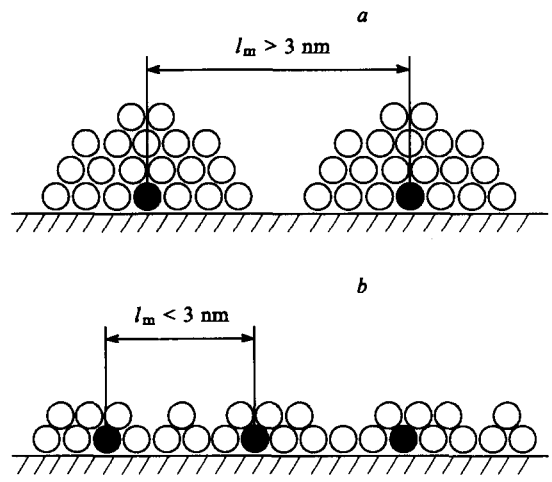

Figure 7. Schematic illustration of the coverage of the surfaces of nonporous CA with different surface concentrations of PAS: (*a*) l_m > 3 nm; (*b*) l_m < 3 nm.

The linear relationship between the amount of water vapour adsorbed at saturation and the S_{sp} of nonporous carbon adsorbents makes it possible to determine the surface areas of nonporous and mesoporous carbon adsorbents. This method has also been used[43] to evaluate the surface area of the mesopores of AC containing micro- and mesopores.

Thus, depending on the surface concentration of PAS on nonporous CA, two schemes for the filling of the surface can be suggested (Fig. 7). The first scheme (Fig. 7*a*) corresponds to a concentration of PAS below the critical concentration, when clusters of adsorbed molecules are formed and grow independently of one another until a limiting value of approximately 150 molecules per site is reached. The second scheme (Fig. 7*b*) corresponds to a rather high surface concentration of PAS, when a continuous adsorption layer is formed.

III. Adsorption of water molecules on activated carbons

The parameters of the porous structures of some typical representatives of the AC studied are listed in Table 3. The AC-1 and AC-5 samples were prepared from coal by steam activation, and their properties are close to those of industrial AC samples of AG-3 and AG-5 types. The peat-based AC-2 and AC-3 samples are similar in their properties to industrial recovered AC of the ART type. The AC-6, AC-7, and AC-8 samples were prepared under laboratory conditions from furfural. AC-4 is an industrial AC of the MSC-5 type (Japan), and AC-10 and AC-11 are industrial AC of the SKT-6A and SKT types, respectively. AC-9, AC-Ts, and AC-U-3 were obtained under laboratory conditions; the former two samples were prepared by the carbonisation of silicon and zirconium carbides respectively, while the latter (AC-U-3) was prepared from polyacrylonitrile.

Apart from the microporous AC listed in Table 3, ultramicroporous AC-U-1 (based on polyacrylonitrile) and AC-U-2 (an AC with MSC-4A molecular-sieve properties) samples, a supermicroporous coal-based AC-U sample, and a mesoporous AC-M (from molybdenum carbide) sample have also been studied. The specific surfaces of AC-M and AC-U are 470 and 1870 $m^2\ g^{-1}$ respectively. The total amounts of nitrogen adsorbed at saturation W_s on these samples are 0.85 and 1.44 $cm^3\ g^{-1}$, and the average pore sizes (the half-widths x) calculated from these values for the slit model are 1.8 and 0.77 nm, respectively. AC-U-1 and AC-U-2 virtually do not adsorb benzene.

Table 3. Porous structure parameters of typical representatives of the activated carbons studied.

Sample	S_m /m^2 g^{-1}	W_o /cm^3 g^{-1}	E_o /kJ mol^{-1}	x/nm
AC-1	100	0.28	19.0	0.71
AC-2	35	0.40	24.4	0.42
AC-3	140	0.26	19.5	0.67
AC-4	18	0.20	32.4	0.28
AC-5[a]	–	0.18	23.6	0.85
		0.38	10.4	
AC-6	30	0.32	34.0	0.24
AC-7	120	0.60	19.8	0.64
AC-8	300	0.67	17.6	0.87
AC-9	30	0.47	21.8	0.52
AC-10	–	0.55	21.4	0.54
AC-11	20	0.49	21.5	0.53
AC-Ts	25	0.82	17.8	0.84
AC-U-3	~0	0.10	29.2	0.30

[a] The calculation was carried out using the two-term equation of the theory of volume filling for a bidisperse porous structure; the x values have been averaged.[4] The calculation by the Dubinin – Stoeckli equation yields S_m = 300 m^2 g^{-1}, W_o = 0.38 cm^3 g^{-1}, x = 0.73 nm.

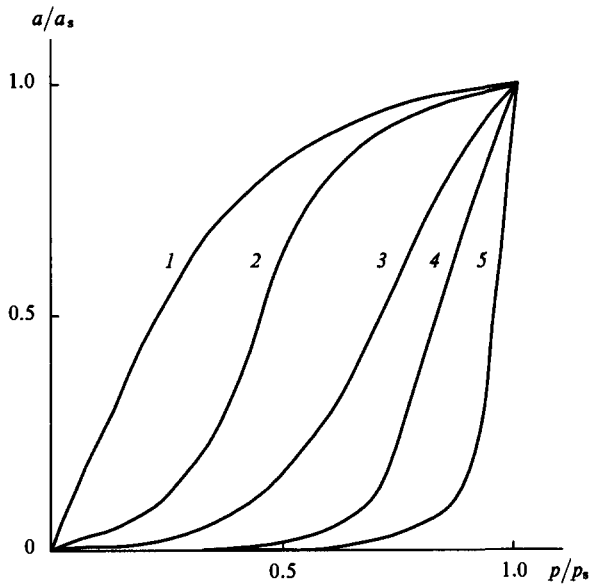

Figure 8. Water vapour adsorption isotherms in relative coordinates for typical AC: AC-U-1 (*1*), AC-2 (*2*), AC-1 (*3*), AC-7 (*4*), AC-M (*5*).

The parameters of the porous structures of other AC will be presented as required.

The adsorption isotherms for water vapour on the AC studied cover almost the whole range of known adsorption isotherms. Fig. 8 shows adsorption isotherms on typical AC in relative coordinates, a/a_s against p/p_s. The shapes of these adsorption isotherms vary from the atypical curve for the ultramicroporous AC-U-1, which is convex over the whole pressure range, to the concave curve for the mesoporous AC-M.

1. Adsorption isotherms at low coverages

While studying the adsorption of water vapour on AC, particular attention was concentrated on the initial sections of the adsorption isotherms, since this region had scarcely been investigated before, though it may provide valuable information concerning the number and nature of PAS and the mechanism of the interaction of water molecules with PAS.

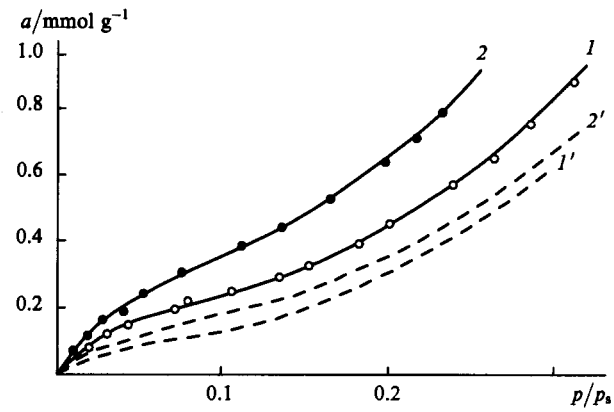

Figure 9. Initial sections of water vapour adsorption isotherms at 293 K on AC-1 and AC-2 evacuated at 293 K (curves *1* and *2*) and 673 K (curves *1'* and *2'*). The circles represent the adsorption isotherms for samples containing 0.6 and 1.8 mmol g^{-1} of firmly bound water respectively.

In Fig. 9, the initial sections of the isotherms for the adsorption of water vapour on two AC evacuated at 293 and 673 K are shown as examples. It can be seen that they have noticeable convex sections at relative pressures below 0.05 – 0.10. The presence of the convex sections indicates that, in the region of low relative pressures, the adsorption occurs predominantly on PAS. The number of PAS can be determined from the known Langmuir equation for localised adsorption. It is equal to the parameter a_m of the Langmuir equation. As a rule, the numbers of PAS for various AC are close to the amounts adsorbed at $p/p_s = 0.1$.

The numbers of PAS found from the Langmuir equation have been compared with those determined using the Dubinin – Serpinskii equation.[42] It was shown that a_m calculated from the Langmuir equation differs appreciably from and is virtually always lower than the number of PAS (a_o) found from the Dubinin – Serpinskii equation. In our opinion, a_m has a more clear physical meaning than a_o, since it is determined from the initial section of the adsorption isotherm, whose character is governed by the interaction of adsorbed molecules with PAS. This is also supported by the data reported[44-46] for oxidised AC for which the degree of adsorption of water vapour at $p/p_s = 0.1$ is practically identical with the number of acidic functional groups determined using the Boehm method, by neutralising these groups with bases of various strengths.[47]

Fig. 9 indicates that, when the temperature of preliminary evacuation is increased from 293 to 673 K, the water vapour adsorption isotherm is located in a lower position, which is associated with the decrease in the number of PAS on heating an AC.

In order to study the influence of the conditions in the preparation of the samples in more detail, AC-1 was evacuated at 673 K at a pressure of 10^{-2} Pa to constant weight, and, after cooling the sample to 293 K, three adsorption (to $p/p_s = 0.2$) and desorption cycles were carried out successively. The results of these experiments are shown in Fig. 10. In the fourth cycle, measurements were continued until the saturated vapour pressure was achieved, and, starting from the fifth cycle, a reproducible curve was obtained. As a result, the full adsorption isotherm (Fig. 11) was obtained, characterised by the so called 'open' hysteresis in which the desorption branch lies above the adsorption branch over the whole range of relative pressures (curve *1* in Fig. 11). The next adsorption-desorption cycle (curve *2* in Fig. 10) virtually did not lead to an increase in the quantity of firmly bound water, and the adsorption isotherm became reversible at low p/p_s with 'closed' hysteresis in the region $p/p_s = 0.3 - 1.0$.

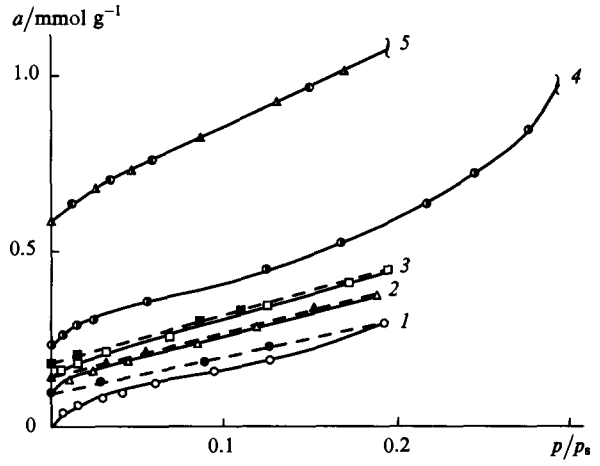

Figure 10. Water vapour adsorption (open symbols) and desorption (filled symbols) isotherms at 293 K on a AC-1 sample evacuated at 673 K. The numbers denote the numbers of adsorption-desorption cycles.

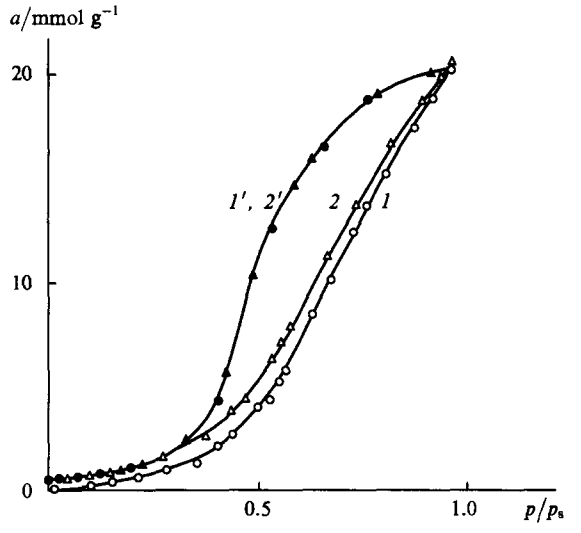

Figure 11. Full isotherms for the first (curves *1* and *1'*) and second (curves *2* and *2'*) adsorption (*1* and *2*) and desorption (*1'* and *2'*) cycles on AC-1 at 293 K.

The results presented in Figs 9 and 10 indicate that, after the thermal desorption of a sample at an elevated temperature (600–700 K), irreversible sorption (chemisorption) of water occurs synchronously with physical adsorption. Chemisorption also takes place at pressures of $10^{-1}-10^{-2}$ Pa during intervals between adsorption measurements. Therefore, each subsequent adsorption-desorption cycle occurs with a larger initial mass of the sample than the previous one. This chemisorption process causes the 'open' hysteresis on the water vapour adsorption isotherm on an AC subjected to preliminary evacuation at an elevated temperature.

The increase in the number of PAS with increase in the quantity of firmly bound water indicates that the firmly bound water acts as PAS. Irreversible adsorption of water vapour on AC was observed previously;[9,48,49] it has also been observed in a study of the interaction of an atomically pure graphite surface with water.[50]

Apart from the initial sections of the water vapour adsorption isotherms on AC-1 and AC-2 evacuated at 293 and 673 K, Fig. 9 also shows the adsorption isotherms on samples that have been evacuated at 673 K and then rehydrated. As one can see, preliminary heating of the samples results in a decrease in the amount of water adsorbed in the region of low p/p_s. After the rehydration of AC, the adsorption isotherms obtained for unheated and rehydrated samples coincide. Thus, a substantial proportion of the PAS are destroyed when the sample is heated to 673 K, and are almost entirely restored when the sample is rehydrated.

The numbers of PAS for some AC evacuated at 293 and 673 K and also for a number of AC, modified through oxidation in moist air at 623 K, deashing in HCl, successive deashing in HF and HCl, and heat treatment in an argon atmosphere at temperatures between 1273 and 2073 K, are presented in Table 4. It can be seen from this table that preliminary heating results in a decrease in the number of PAS for all the initial AC, except AC-9. In the case of AC-9, the number of PAS does not change on preliminary heating.

Table 4. The numbers of PAS (a_m/mmol g^{-1}) on the initial and modified AC at various evacuation temperatures (T_{evac}).

Sample	Method of pretreatment	The number of PAS after evacuation at	
		293 K	637 K
AC-1	None	0.30	0.16
	Oxidation	0.32	0.43
	Deashing with HCl + HF	0.40	–
	Heat treatment at		
	1273 K	0.10	0.10
	1473 K	0.08	0.08
	1673 K	0.07	0.07
	1773 K	0.06	0.06
	1873 K	0.05	0.05
	2073 K	0.03	0.03
AC-2	None	0.41	0.21
	Oxidation	0.44	0.44
AC-6	None	0.60	0.20
AC-7	"	0.41	0.08
AC-8	"	0.21	0.05
AC-9	"	0.20	0.20
AC-10	"	0.53	0.20
AC-U-1	"	1.24	0.34
AC-S	"	0.19	0.16
AC-M	"	0.70	0.20

The role of oxidation in air at 623 K does not reduce merely to an increase in the number of PAS. In fact, when the preliminary evacuation of AC-1 and AC-2 is carried out at 293 K, the numbers of PAS on the initial and oxidised samples are close, while in the case of evacuation at 673 K, the a_m values for oxidised samples are much larger than those for the initial ones. The major distinction in the adsorption behaviour of the initial and oxidised AC is that for samples oxidised in moist air, the change in the number of PAS on heating the AC from 293 to 673 K is substantially less pronounced. The oxidation not only leads to a change in the total concentration of PAS, but results in an increase in the ratio between the relatively unstable oxygen-containing surface compounds that are removed by moderate heating (in particular, chemisorbed water) and more thermally stable surface groups.

As can be seen from Table 4, heat treatment of AC in an argon atmosphere at 1273–2273 K leads to a continuous decrease in a_m.[42] When the treatment temperature is higher than 1273 K, the adsorption isotherms do not depend on the

conditions in which the sample is prepared for the experiment, i.e. the numbers of PAS on the heated and unheated samples are identical.

Extensive deashing by successive treatment with HCl and HF of the compounds evacuated at 293 K results in an increase in the number of PAS; i.e. the adsorption properties of the AC during their deashing are mostly influenced by the chemical modification of the surface, leading to an increase in the number of surface functional groups acting as PAS, rather than by the removal of oxygen-containing ash elements.

2. Heats of adsorption of water vapour at low coverages

The results obtained in studies of the adsorption of water vapour on CA in the region of low relative pressures attest to a substantial role of PAS in the adsorption. Useful information about the character of the interaction of adsorbed water molecules with PAS can be gained from the heats of adsorption of water vapour. Fig. 12 presents the dependences of isosteric heats (q_{st}) on the amount of adsorbed water vapour for some AC.[51] They all have a characteristic shape: in the range of low coverages, the q_{st} values are lower than the heats of condensation, but they increase with increase in coverage, and for high degrees of adsorption the q_{st} are constant and somewhat higher than the heats of condensation. For some AC, the $q_{st}(a)$ dependence goes through a maximum. A similar form of the dependence of the heat of adsorption on the amount adsorbed has been previously postulated in a study of the characteristic features of water vapour adsorption on CA.[17] We may note that our data are supported qualitatively by a calorimetric measurement of the heat of adsorption of water vapour on an AC previously evacuated at 298 K.[52]

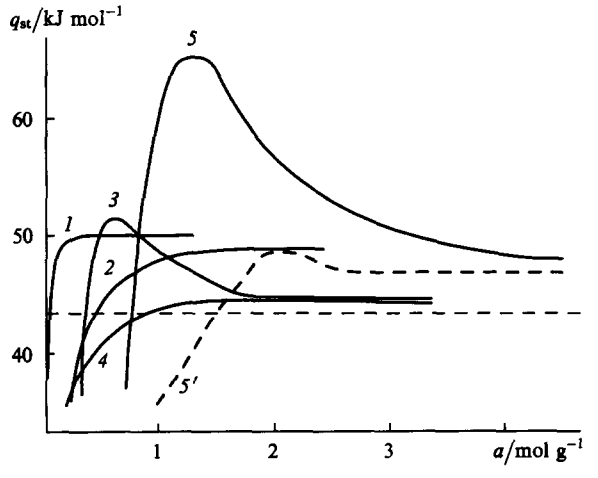

Figure 12. Dependence of isosteric heats of adsorption on the amount of adsorbed water for AC-1 (*1*), AC-2 (*2*), AC-N (*3*), AC-U-2 (*4*), and AC-U-3 (*5* and *5′*). Here and in Fig. 13, the dashed line represents the heat of condensation of water vapour.

It should be noted that the relationships for differential and isosteric heats of adsorption are applicable only to reversible adsorption cycles. As was shown above, the adsorption of water may be complicated by chemisorption, which distorts the results obtained in calculations of heats of adsorption. Strictly speaking, samples of a particular AC evacuated at different temperatures differ from one another in the chemical state of the surface and the concentration of PAS. For example, for AC-U-3, the variation of the temperature of experiments from 283 to 303 K leads to a substantial loss of the firmly bound water, and, as this takes place, the number of PAS considerably decreases. Therefore, two dependences of q_{st} against the amount adsorbed are shown in Fig. 12 for the AC-U-3 sample. One of them corresponds to the temperature range 283–293 K (curve *5*) and the other is for 293–303 K (curve *5′*). It has been shown[51] that the nonlinearity of adsorption isosteres, typical for most AC, hampers a precise quantitative determination of the isosteric heat of adsorption (q_{st}); however, the situation remains qualitatively the same.

In the region of low coverages, water molecules are mainly adsorbed on PAS, and the number of PAS is not invariable for a particular AC but depends on the temperature.

In this respect, it is expedient to refer the quantity of adsorbed water (a) to the number of PAS (a_m), which should be found separately for each temperature. This approach to the determination of heats of adsorption is equivalent to allowance for the temperature dependence of the adsorption-active surface of an adsorbent. The quantity a/a_m characterises the average number of water molecules adsorbed on one PAS.

To determine q_{st}, adsorption isotherms are plotted in terms of the a/a_m–p coordinates. The differential heats of adsorption q_Θ determined from these relationships for small a/a_m are given in Fig. 13. From this figure, one can see that in the region of small a/a_m the heats of adsorption virtually do not depend on the amount adsorbed within the limits of experimental error and are lower than the heat of condensation of water vapour. The method of determining heats of adsorption described can be used only in the region of low coverages, when there is less than one adsorbed water molecule per single PAS and the assumption that adsorption mostly occurs on PAS is obeyed sufficiently rigorously. When more than two or three water molecules are adsorbed on each PAS, the q_Θ values are also invariable and are somewhat higher than the heat of condensation of water vapour.

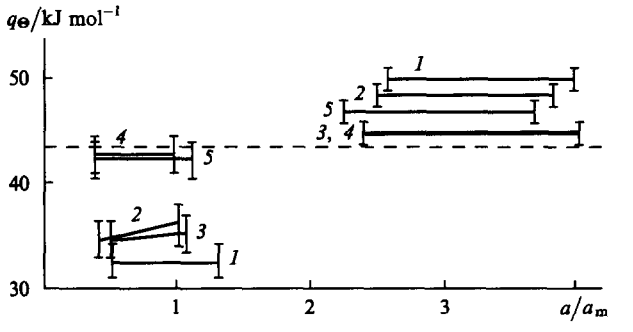

Figure 13. Dependence of the heats of adsorption of water vapour q_Θ on a/a_m for AC-1 (*1*), AC-2 (*2*), AC-N (*3*), AC-U-2 (*4*), and AC-U-3 (*5*).

From our viewpoint, the general character of the dependence of the heats of adsorption on the amount adsorbed agrees well with the mechanism of the adsorption of water vapour on CA considered above. Since the heat of adsorption on a PAS is related to the energy of formation of a hydrogen bond, the heat of adsorption should be equal to the energy of one hydrogen bond plus the energy of dispersion interaction. The energy of interaction of water molecules with a model PAS (a carbonyl group), found by numerical modelling,[40] is ~ 32 kJ mol^{-1} for the optimum arrangement of water molecules. Thus, it is reasonable to expect that in the region of low coverages the heat of adsorption should be smaller than the heat of condensation (~ 44 kJ mol^{-1}), which is itself somewhat greater that the energy of formation of two hydrogen bonds.

The fact that the heats of adsorption of water vapour at low coverages are lower than the heat of condensation implies that adsorbed molecules do not interact with one another and, in this sense, water molecules are adsorbed like the molecules of a gas. A similar suggestion was made previously[48] judging from kinetic data. However, some authors including those just cited[48] have obtained heats of adsorption at low coverages, larger than the heat of condensation. Among other reasons, this may be due to

the fact that, in most of these studies, measurements were carried out with CA evacuated at elevated temperatures. As has already been noted, in this case, apart from physical adsorption, chemisorption of water molecules takes place. It is this effect that has most probably been observed in the above studies.[48,53,54] The substantial energy evolved during chemisorption (the possibility of a chemical reaction also cannot be ruled out)[49,55] results in high calorimetric heats of adsorption in the region of low coverages. For high coverages, all the authors have obtained nearly constant heats of adsorption, which are somewhat higher than the heat of condensation of water vapour. This is explained by the fact that, as the clusters around the PAS grow, the average number of hydrogen bonds per molecule increases, and, consequently, the heat of adsorption also increases and can exceed the heat of condensation, owing to the contribution of the dispersion interactions of water molecules with the adsorbent.

The results obtained in another study[53] agree qualitatively with the scheme considered. It was found that, for relatively low temperatures (243–293 K), the heat of adsorption is nearly equal to the heat of condensation over the whole range of coverages studied; when the temperature is increased to 333–491 K, the quantity of firmly bound water acting as PAS decreases noticeably. In addition, when the temperature of the experiments is increased, one can study the region of low coverages at normal water vapour pressures. Under these conditions, the q_{st} values for small amounts adsorbed are much smaller than the heat of condensation, and grow rapidly as the degree of adsorption increases.[53]

3. Adsorption in the region of moderate and high coverages

The influence of the concentration of PAS on the full adsorption isotherm can be demonstrated by studying the adsorption of water vapour on various AC with similar microporous structures but different concentrations of PAS. The different types of interaction of the nonpolar nitrogen molecules and the polar water molecules with CA should lead to dissimilar mechanisms of adsorption on the surface and also to dissimilar mechanisms of the filling of the pore volume of a CA. Adsorbents that adsorb nitrogen in like manner can be essentially dissimilar towards the adsorption of water vapour. Fig. 14 shows relative isotherms for the adsorption of water vapour and nitrogen on two AC samples (AC-3 and AC-1). It can be seen that the degrees of adsorption of nitrogen on these two samples are close to one another over the whole p/p_s range (i.e. the samples possess similar porous structures). However, the amounts of water vapour adsorbed are significantly different, and only at $p/p_s \approx 1$ do they converge. These distinctions are due to the fact that the number of PAS on AC-3 is smaller than that on AC-1 by a factor of approximately six.

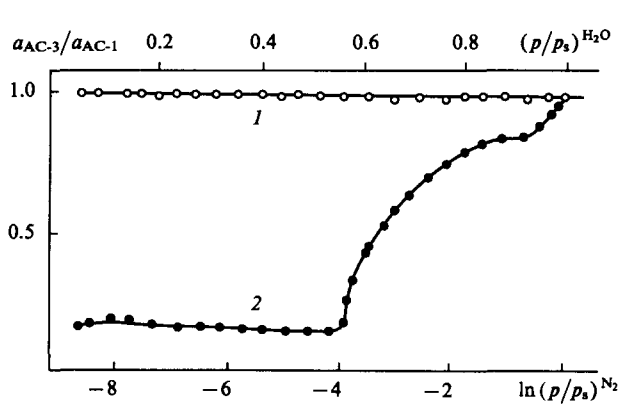

Figure 14. The ratios of the amount of nitrogen vapour adsorbed at 77 K (curve *1*) and the amount of water vapour adsorbed at 293 K (curve *2*) on AC-3 to the corresponding amounts adsorbed on AC-1.

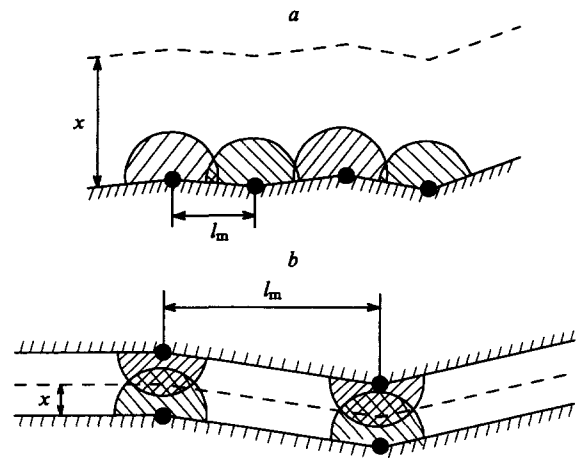

Figure 15. Schematic illustration of the filling of the pore volume of AC with various ratios of the average distance between the PAS (l_m) to the half-width of slit-like pores (x).

Thus, in the initial range of p/p_s, the adsorption of water on AC, similarly to that on nonporous CA, occurs on PAS, around which clusters of adsorbed water molecules can in principle form and grow. Generally, two schemes can be suggested to describe how the pore volume is filled as the clusters around PAS grow (Fig. 15). If the distance between the PAS is smaller than the width of a pore and smaller than the critical size of a cluster on a carbon surface, the clusters can coalesce as they grow to give a continuous adsorption layer on the surface of pores (Fig. 15*a*). For relatively narrow pores and a low concentration of PAS, one should expect that water molecules adsorbed on opposite walls of a pore would interact, forming bridge bonds (Fig. 15*b*).

The schemes presented indicate that the manner in which pores are filled depends both on the structure and on the chemical nature of the surface. At the same time, for low coverages, the mechanisms of the adsorption of water molecules on nonporous, mesoporous, and microporous CA are identical and are governed by the interaction with PAS. Fig. 16 shows isotherms for the adsorption of water vapour (referred to the numbers of PAS) on Vulkan-7H carbon black graphitised at 3073 K, mesoporous AC-M, ultramicroporous AC-U-3, and microporous AC-1, AC-2, AC-5, and AC-N. The data reported for some nonporous carbon blacks of the Graphon type[19,56] are also shown in this figure.

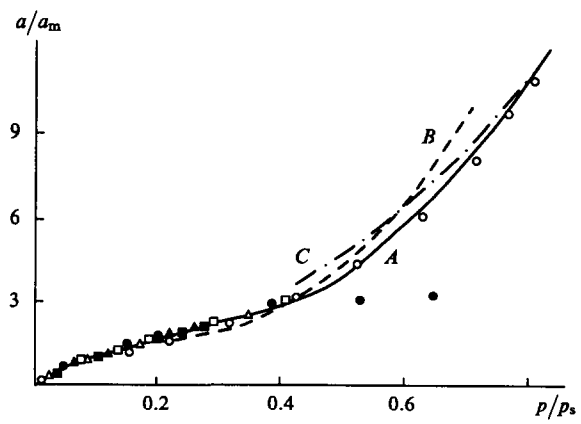

Figure 16. Water vapour adsorption isotherms in terms of the $(a/a_m) - (p/p_s)$ plots on Vulkan-7H carbon black (curve *A*), the mesoporous AC-M (*1*), the ultramicroporous AC-U-3 (*2*), the microporous AC-1 (*3*), AC-2 (*4*), AC-5 (*5*), AC-N (*6*), and also on Graphon carbon blacks (curves *B* and *C*).

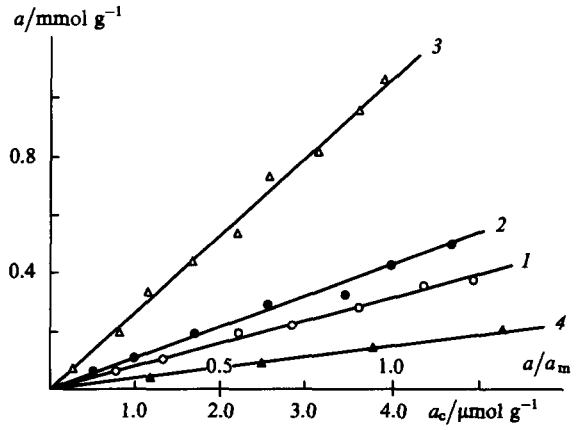

Figure 17. Comparative plots for the adsorption of water vapour in the region of low coverages for AC-1 (*1*), AC-2 (*2*), AC-U-1 (*3*), and AC-5 (*4*).

The similarity of the mechanisms by which water molecules are adsorbed on all CA in the range of small p/p_s is manifested, in particular, as follows. If the adsorption isotherm on separate PAS (or, to a first approximation, on a graphitised carbon black) is adopted as the reference isotherm, the comparative plots obtained for low coverages are straight lines starting from the origin of coordinates. The slopes of these straight lines are proportional to the concentrations of PAS. The initial sections of the comparative plots for some AC are shown in Fig. 17. Deviations of these plots from linearity should be expected in those cases where the mechanism of adsorption on a particular sample departs from independent cluster formation.

The coalescence of clusters yielding a continuous film should be shown on the comparative plots by a sharp downward deviation from the linear dependence. Among all the AC studied, these deviations from linearity were observed only for two adsorbents with relatively wide pores. Comparative plots for mesoporous AC-M and for AC, prepared by heat treatment of AC-1 at 2073 K [AC-1(2073)], with a specific surface of 110 $m^2\ g^{-1}$ are shown in Fig. 18. Adsorption on a continuous adsorption film apparently occurs less effectively than on free clusters. The abscissae of the break points allow one, in principle, to calculate the specific surfaces of adsorbents from the relationship $S = L^2 a_m N$, where L is the diameter of clusters at the instant they coalesce, a_m concentration of the clusters, and N the Avogadro number.

The validity of the adsorption scheme considered can be more clearly demonstrated by determining the amount adsorbed at the instant the clusters coalesce from the concentration of the PAS,

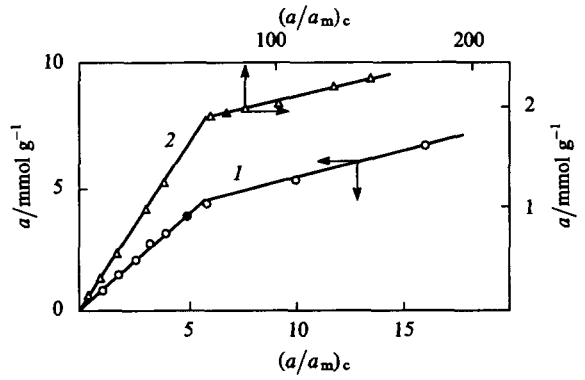

Figure 18. Comparative plots for the adsorption of water vapour on the mesoporous AC-M (*1*) and AC-1 (at 2073 K) (*2*).

from the specific surface of the sample (found by using nitrogen adsorption), and from the cluster sizes calculated by numerical modelling,[40] and by comparing the result with the ordinate of the break on the comparative plot. The adsorbed amounts calculated by this procedure for the AC-M and AC-1(2073) samples are 3.6 and 1.9 mmol g^{-1}. These values are close to the ordinates of the break points in Fig. 18, which confirms the validity of the adsorption mechanism suggested.

For adsorption on microporous AC, deviations from linearity (breaks) are seen on comparative plots even for low coverage, and they are directed upwards (Fig. 19*a*). This shape of comparative plots shows that interaction between water molecules adsorbed on the opposite walls of pores (i.e. the formation of bridging bonds) results in an increase in adsorption compared with that on separate sites. In addition, the narrower the micropores, the smaller is the abscissa of the break point. This is more clearly seen in Fig. 19*b*, where the comparative plots are given in reduced coordinates: the amounts adsorbed, expressed as numbers of molecules per adsorption site for the AC studied, are plotted as the ordinate, and the corresponding values for the reference carbon black Vulkan-7H(3073) are plotted as the abscissa.

Fig. 20 presents the correlation between the abscissa of the break point and the cube of the average size, x, of the micropores, calculated from the nitrogen vapour adsorption isotherms.

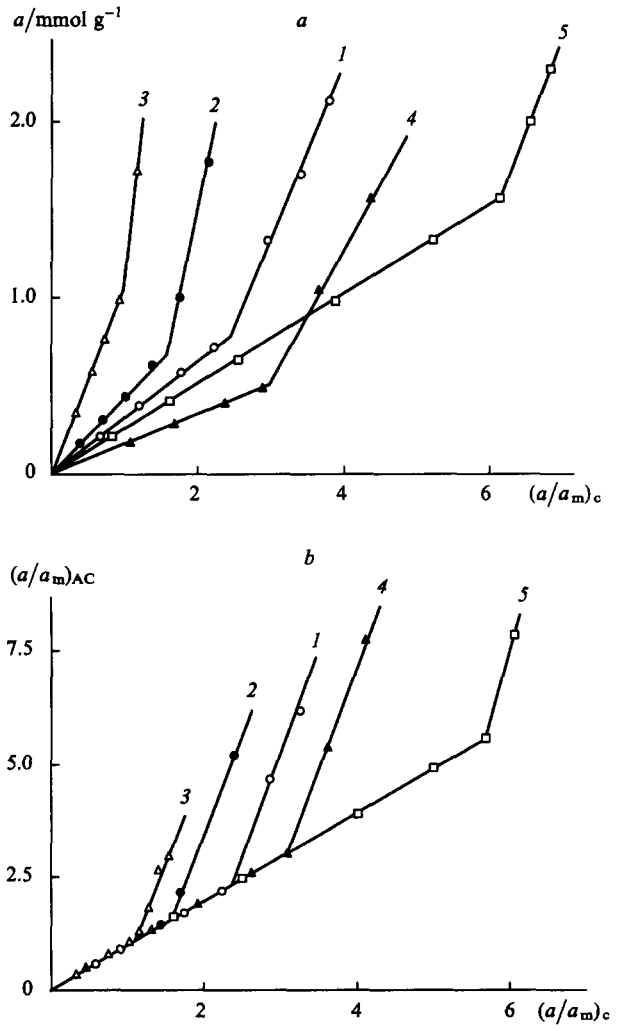

Figure 19. Comparative plots for the adsorption of water vapour on the microporous AC-1 (*1*), AC-2 (*2*), AC-U-1 (*3*), AC-5 (*4*), and AC-8 (*5*) in terms of the normal (*a*) and reduced (*b*) coordinates.

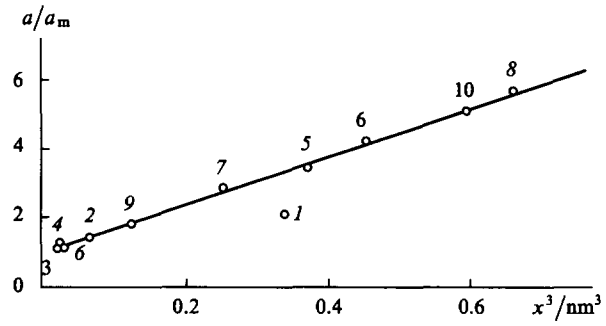

Figure 20. Correlation between the abscissa of the break point on comparative plots and the cube of the average size of micropores in AC-1 (*1*), AC-2 (*2*), AC-U-1 (*3*), AC-4 (*4*), AC-5 (*5*), AC-S (*6*), AC-7 (*7*), AC-8 (*8*), AC-9 (*9*), and AC-N (*10*).

The value of x can be found from the initial and middle sections of the water vapour adsorption isotherms on microporous AC.

The results obtained show that, when the micropores of the AC are filled with water, bridge bonds are formed. As this takes place, a relatively loose openwork structure, a 'lace', is produced in which the density of water is lower than that in the bulk phase. This can account for the fact that calculations of the limiting sorption volumes of AC from water vapour adsorption isotherms using the density of bulk-phase water usually afford smaller micropore volumes than calculations from the adsorption isotherms for other substances.[57] In principle, if the density of the adsorbed water is known, one can evaluate the size of the micropores by the foregoing procedure.[57]

Another method of evaluating the sizes of micropores of AC from adsorption and desorption isotherms for water vapour has also been reported.[58] The method is based on determining the width of the hysteresis loop between particular points on the adsorption and desorption isotherm branches. All the adsorption isotherms considered in this study have saturation sections, and the sharp rise of these isotherms ends at relative pressures of 0.8–0.9, and this limits the field of application of this method. In addition, it is known[59] that water vapour adsorption isotherms on ultramicroporous AC exhibit no hysteresis at all. One should also take into account the fact that repetition of the adsorption-desorption cycle for the same AC increases the amount of water adsorbed at saturation and diminishes the hysteresis loop,[60] which also hampers the use of this method.

The method of determining a porous structure from water vapour adsorption isotherms based on the formation of a monomolecular layer[4,22] at relative pressures of about 0.6 has been advantageously used for some AC. A common drawback of all the methods of calculation of specific surfaces based on the adsorption of water molecules is that for these calculations one must know the cross-sectional area of a water molecule; this value in its turn depends substantially on the oxidation state of the surface. It is likely that, for AC having typical micropores with diameters of the order of 4–5 water molecules, the overall adsorbed amounts are identical, whether a dense monomolecular layer or a loose 'openwork' packing is formed. In other words, the density of adsorbed water forming bridge bonds is approximately half that of liquid water. Hence, about two loose layers of the openwork packing are equivalent to a continuous monomolecular layer.[22] This is indirectly supported by the fact that the cross-sectional areas of water molecules differ by a factor of almost two: calculations give 0.06–0.08 to 0.13 nm^2 depending on the method, while the experimental results are 0.128 ± 0.54 nm^2.[61] A value of 0.148 nm^2 has been adopted as the cross-sectional area for a water molecule on carbon black.[20] Data on the linear dimensions of various molecules including water, obtained by various authors who have used different computational methods, have been analysed and systematised.[62] For a water molecule, values ranging from 0.276 to 0.348 nm were reported.

Dubinin and coworkers[63,64] later restricted the field of application of the previously suggested method[4,22] to activated carbons with a 'normally' oxidised surface and a narrow size distribution of micropores, while for a broader region of micropore sizes they suggested a calculation for a monomolecular layer from the point of inflection, determined with the aid of the Weibull equation,[63] which is used to describe experimental water vapour adsorption isotherms. The authors[63] showed that the inflection points, indicating, in their opinion, the formation of monomolecular layers on various AC, lie at p/p_s from 0.5 to 0.75, which expands significantly the applicability of this method of determining the porous structure of an AC. However, it should be noted that, since the experimental water vapour adsorption isotherms on ultramicroporous and mesoporous AC (see Fig. 7) have no normal inflection points, the approach suggested can scarcely be applied to these materials. For the same reason, this method cannot in principle be applied to nonporous CA.

Methods of determining the porous structure parameters based on the formation of a monomolecular water layer in the micropores of an AC are also not general, as the amounts of water adsorbed on various AC at the same relative pressure can differ appreciably, depending on the chemical state of the surface. For example, it has been shown[65] that the proportion of the surface of carbon blacks occupied by water at a relative pressure of 0.6 can vary from 10% to 450%, that is, 0.1 to 4.5 monomolecular layers are formed. Some authors dispute altogether the possibility of formation of a monomolecular layer on the surface of nonporous CA during adsorption of water vapour.[26,43]

As regards the above result,[65] it should be noted that the amount of water vapour adsorbed at saturation, which corresponds to the formation of more than two monomolecular layers, is associated, in our opinion, with the filling of the surface ultramicropores formed on oxidation of carbon blacks. Oxidation can not only be carried out by special treatment, but can also occur during storage in air, and may be accompanied by the formation of surface ultramicropores.[65] The presence of these surface ultramicropores can be demonstrated by a joint analysis of water vapour adsorption isotherms on ultramicroporous AC and Spheron-6 carbon black.[59]

It should be noted that the determination of the parameters of the microporous structure from water vapour adsorption isotherms by any method, including that suggested by us, is somewhat conventional, because the results obtained are compared with data on the adsorption of other substances (nitrogen or benzene), and for this purpose a particular model of the porous structure is introduced. Unfortunately, up to now, there are no other direct and reliable methods of studying the microporous structures of CA. The use of tunnelling electron microscopy may prove to be promising in this field; however, no systematic studies of CA by this method have yet been carried out.

IV. The nature of the primary adsorption sites

The nature of the PAS has been studied by temperature-programmed desorption with mass spectrometric analysis of substances being evolved, by neutralising surface oxides with bases of various strengths, and by X-ray photoelectron spectroscopy.

1. Temperature-programmed desorption

The substances evolved during the heating of AC have been analysed using mass spectrometry with a linear variation of the temperature of samples (a MAT-311A spectrometer, Varian, USA). Prior to heating, the samples were evacuated at 293 K and a pressure of 10^{-5} Pa for 12 h. Figs 21 and 22 show the temperature dependences of the rate of H_2O, CO_2, and CO evolution at heating rates of 5 K min^{-1} for initial and rehydrated

AC-U-1. As can be seen, the H_2O/CO_2 ratio depends on the type of AC. Some overlapping peaks on the curves correspond to various functional groups and their fragments. Joint desorption of H_2O and CO_2 is typical of AC-1. Analogous spectra were obtained for AC-2. It may be assumed that water is chemisorbed on these AC via lactone type groups, which accounts for the joint desorption of H_2O and CO_2.[67] Actually the groups being desorbed can be regarded as a complex carbonic acid $H_2O:CO_2$. In our opinion, the presence of an H_2O peak and a low-temperature CO_2 peak in the spectrum of the rehydrated substance is evidence in support of the chemisorption of water. The evolution of CO at high temperatures may occur either via the decomposition of the corresponding groups or via the chemical reaction with the lattice carbon of CO_2, formed on decomposition of carboxylic or lactone groups.

The spectrum recorded for the polymer-based AC-U-1 differs essentially from those for AC-1 or AC-2. The CO_2 band contains two peaks, one of which (in the high-temperature region) is close to the CO peak. Therefore, the following scheme can be proposed. Water is evolved due to decomposition of two carboxy-groups, yielding an anhydride structure. The low-temperature CO_2 peak results from decomposition of separate carboxy-groups, and the joint desorption of CO and CO_2 is associated with the decomposition of the anhydride structures at high temperatures. This scheme is in full agreement with the results of a study of IR spectra of Saran-type AC,[68] which are similar to the AC-U-1 studied by us.

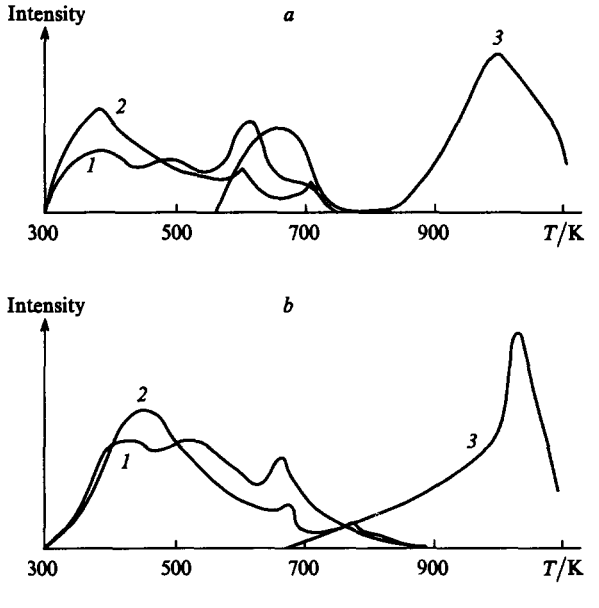

Figure 21. Temperature dependence of the rate of H_2O (*1*), CO_2 (*2*), and CO (*3*) evolution during the heating of the initial AC-1 (*a*) and the AC-1 rehydrated in water vapour after preliminary evacuation at 673 K (*b*) at a rate of 5 K min^{-1}.

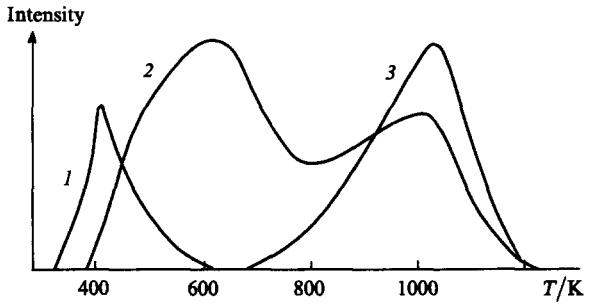

Figure 22. Temperature dependence of the rate of H_2O (*1*), CO_2 (*2*), and CO (*3*) evolution during the heating of AC-U-1 at a rate of 5 K min^{-1}.

Oxidation of these AC yields initially anhydride groups, which undergo hydrolysis by atmospheric moisture to give acid groups. These COOH groups are linked in pairs by hydrogen bonds.

A study on the nature of oxygen-containing functional groups in oxidised AC carried out recently by temperature-programmed desorption[69] has confirmed the existence of acidic carboxy-groups yielding a CO_2 peak at 600 K, and of anhydride groups with a CO_2 peak at 900 K. A significant role in the formation of 'CO_2 complexes' is played by the temperature of the oxidation of the AC in air or in nitric acid.[69] It has been found[44,70] that the quantity of CO_2 evolved is usually equivalent to the amount of alkali required to neutralise the acidic groups of AC.

From the adsorption results and data derived from temperature-programmed desorption, one may conclude that a part of the PAS (as a rule, the smaller one) are acidic carboxy-groups, thermally stable below 673 K. Adsorption on heated AC at low p/p_s occurs predominantly on these sites. The majority of the PAS on the AC prepared from natural raw materials (peat, coal, or wood) are chemisorbed water molecules, which are removed during heating simultaneously with CO_2. In this case, water molecules are apparently chemisorbed on lactone type groups, which can be regarded as complex carbonic acid adsorbed on the AC surface.

Water molecules chemisorbed on anhydride groups (carboxy-groups linked in pairs via hydrogen bonds) and individual carboxy-groups act as the PAS on Saran and other polymer-based AC.

2. Neutralisation of surface groups with bases of various strengths

The nature of the PAS has also been studied by the familiar Boehm[47] procedure, consisting in the neutralisation of the acidic groups with bases of various strengths. This procedure is being advantageously used to analyse the composition of acidic surface groups on oxidised AC, carbon blacks, and graphites. When the acidic groups being neutralised are weak, the interpretation of the titration data is more complicated, since neutralisation may be accompanied by the simultaneous ion exchange and direct hydrolysis of nonprotonated surface groups. We have carried out potentiometric titrations with a 0.05 N HCl solution of 0.05 N solutions of $NaHCO_3$, Na_2CO_3, NaOH, and C_2H_5ONa after they had been shaken with samples of AC.

Fig. 23 shows the potentiometric titration curves for the titration of solutions of NaOH (*a*) and Na_2CO_3 (*b*) with 0.05 M HCl after 20 ml of this NaOH or Na_2CO_3 solution had been shaken with 1 g of AC-1, AC-2, or AC-9 for two days. From Fig. 23*a*, one can see that in the case of AC-1 and AC-2, the titration curves for NaOH are similar to those for Na_2CO_3. One may assume that the surfaces of AC-1 and AC-2 contain the chemisorbed complex carbonic acid, $H_2O:CO_2$, which passes into the alkaline solution as Na_2CO_3 during interaction with water. This agrees with the data obtained by temperature-programmed desorption.

This characteristic of the titration of an NaOH solution, after shaking it with some of the AC, hampers a quantitative determination of the concentration of acidic groups of different strengths on the AC surface. In addition, it is known that inert electrolytes, for example KCl, added to a KOH solution substantially influence the results of the titration carried out after shaking the AC with this alkaline solution.[71] Since the mechanism of the action of inert electrolytes remains unclear, the authors[71] mostly used the data obtained on neutralisation of relatively strong acidic groups with a solution of Na_2CO_3.

Table 5 presents the concentrations of acidic surface groups neutralised by a solution of Na_2CO_3 (a_N), together with the number of PAS determined from water vapour adsorption isotherms on AC preliminarily heated at 673 K. One can see that these values are rather close, and it is quite probable that the convex section of the water vapour adsorption isotherm on the AC evacuated at 673 K is caused by the adsorption of water

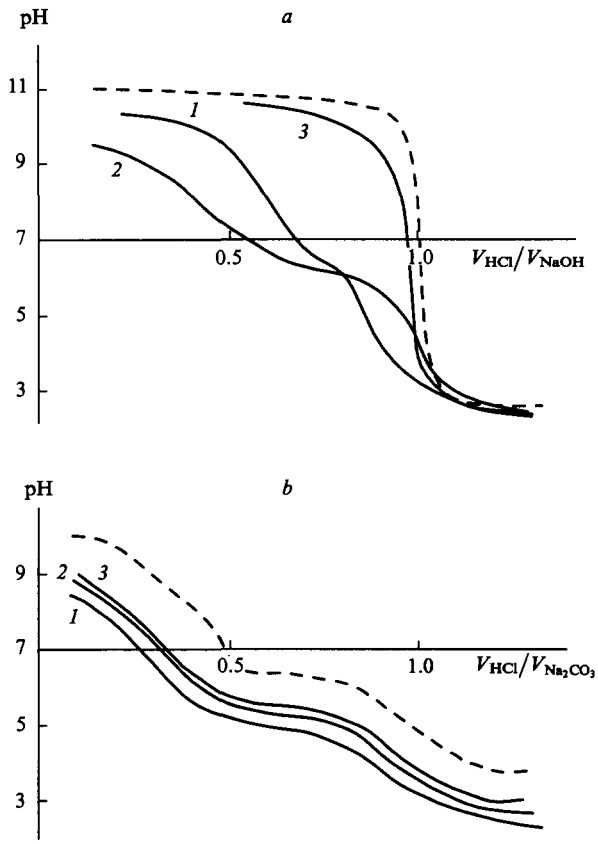

Figure 23. Curves for potentiometric titration with 0.05 N HCl of the NaOH (*a*) and Na_2CO_3 (*b*) solutions resulting from shaking 20 ml of 0.05 N NaOH and Na_2CO_3 respectively with 1 g of AC-1 (*1*), AC-2 (*2*), and AC-9 (*3*). The titration curves for the initial solutions of NaOH and Na_2CO_3 are shown by dashed lines.

molecules on relatively strong acidic carboxy-groups, which are not destroyed on heating to 673 K, as the PAS.[47] For nonporous graphitised Vulkan-7H carbon black, the number of surface groups neutralised with a Na_2CO_3 solution is 0.005 ± 0.002 mequiv. g^{-1}, which agrees with the data on the adsorption of water vapour ($a_m = 0.004$ mmol g^{-1}).

A correlation between the number of acidic groups determined by conductimetric titration and the amount adsorbed at point *b* (according to the BET equation) on the convex section of the water vapour adsorption isotherm has also been noted in a study[45] of the heats of immersion of a polymeric AC in water.

Despite the fact that quantitative analysis of the results of the titration of weakly acidic groups is difficult, one can make some qualitative conclusions. The titration curves for AC-9 have the normal shapes typical for the titration of a strong base with a strong acid. The numbers of acidic groups, neutralised with NaOH and Na_2CO_3, are close, i.e. the surface of AC-9 mostly contains strongly acidic groups, which are not removed on heating to 673 K. The adsorption properties of AC-9 with respect to water vapour almost do not depend on the evacuation temperature, i.e. adsorption occurs on thermally stable strongly acidic groups.

Table 5. The number of acidic surface groups neutralised by a solution of Na_2CO_3 (a_N) and the number of PAS (a_m) on the AC samples evacuated at 673 K.

Sample	a_N/mequiv. g^{-1}	a_m/mmol g^{-1}
AC-1	0.12	0.16
AC-2	0.16	0.21
AC-2 (oxidised)	0.50	0.44
AC-6	0.18	0.20
AC-7	0.09	0.08
AC-8	0.04	0.05
AC-9	0.18	0.20

It was shown previously that evacuation of AC-1 at 673 K leads to an appreciable decrease in the number of PAS, and the chemisorption of water molecules virtually restores the number of the PAS. In our opinion, the results obtained by the neutralisation of acidic groups are consistent with this assumption. When AC-1 is shaken with NaOH, some of the surface groups pass to the solution as Na_2CO_3. This results from the interaction of NaOH with weakly acidic groups on the surface of AC-1 (the complex carbonic acid, $H_2O:CO_2$). A relationship between the quantity of water, irreversibly adsorbed by the AC, and the number of oxygen-containing surface groups that decompose on heating to evolve CO_2 has also been observed in a study of the adsorption of water on AC modified with potassium permanganate and nitric acid.[44]

3. X-Ray photoelectron spectroscopy

The adsorption properties of AC with respect to water vapour are determined by an active part of the oxygen present, rather than by its total amount. The proportion of active oxygen can be evaluated by X-ray photoelectron spectroscopy. For this purpose, an AC sample was ground in an agate mortar and deposited as a suspension in water or ethanol on a support. After the evaporation of the liquid, the supported sample was introduced into the sluice compartment of an ESCA-3 MARK-2 spectrometer (VG, UK). The analysis was carried out after evacuation of the AC to a pressure of 10^{-9} Pa. X-Rays (magnesium K_α line) with $h\nu = 1253$ eV served as the ionisation source. The spectra were calibrated against an external standard [C 1*s* peak (285.0 eV) from a hydrocarbon layer on a gold support]. The O 1*s* spectra were recorded prior to and after heating the supported sample in the spectrometer compartment to 650 K. The O/C relative concentration was determined from the ratio between peak surface areas with allowance for the corresponding ionisation cross-sections. Simultaneously with the O 1*s* spectrum, the mass spectra of the desorbed substances were recorded using a built-in mass spectrometer. The oxygen spectrum is complex. Its detailed interpretation is complicated by difficulties associated with the calibration of the peak components; however, it may be noted that when the sample is heated, the spectrum component with a higher bond energy diminishes sharply [72] and evolution of H_2O and CO_2 occurs. The quantity of oxygen removed is estimated from the O : C ratios in the initial and heated AC.

Table 6 presents the O : C ratios for some AC as examples and also these ratios for AC-1 heat treated in argon at 1273 to 2273 K, oxidised in moist air at 623 K, and deashed with HCl or with HCl and HF in succession. As can be seen from the table, when the initial AC-1 is heated to 673 K, most of the oxygen remains in the AC, whereas the number of PAS is almost halved, as was shown above from the adsorption data (see Table 4). This indicates that most of the PAS on this AC are unstable oxygen-containing groups removed during heating to 673 K, in particular chemisorbed water. The overall amount of oxygen in AC-1 ensures a number of PAS a_m of 0.30 mmol g^{-1}. When 14% of the oxygen is removed, the number of PAS diminishes to 0.16 mmol g^{-1}, i.e. the adsorption-active oxygen comprises about a quarter of its overall content, which agrees with the data obtained by Boehm.[47]

Treatment of the AC in a moist air flow at 623 K does not result in an increase in the overall oxygen content (see Table 6); it actually decreases somewhat, due to the removal of some of the surface oxygen-containing groups on heating the sample. However, the relative change in the O/C concentration caused by heating decreases from 0.14 to 0.11 under these conditions.

Table 6. The O:C ratios calculated for some AC from X-ray photoelectron spectra prior to and after heating of the AC.

Sample	Method of treatment	O:C ratio (%)	
		before heating	after heating
AC-1	None	13.7	11.8
	Heat treatment at		
	1773 K	8.0	8.0
	2073 K	3.0	3.0
	Oxidation	12.3	10.9
	Deashing with		
	HCl	12.5	10.5
	HCl + HF	7.4	5.1
AC-2	None	20.0	–
AC-U-1	"	15.0	–
AC-10	"	39.0	–

Thus, oxidation in a moist air flow at 623 K results in an increase in the proportion of thermally stable oxygen-containing groups, rather than in the overall amount of oxygen on the AC. It is this effect that stabilises the number of PAS on the oxidised AC when it is heated from 293 to 673 K (see Table 4).

V. The influence of the adsorption of water vapour on the parameters of the microcrystalline structure of activated carbons

Valuable information about the mechanism of the adsorption of water molecules, the location of the PAS, and also the relationship between microporous and microcrystalline structures of adsorbents can be obtained from X-ray diffraction studies of AC adsorbing water vapour.

Carbon adsorbents normally consist of amorphous carbon and crystalline areas (crystallites), whose faces can form the walls of micropores. In X-ray diffraction patterns, the amorphous part is manifested as background scattering, while the structure of crystallites is characterised by two reflections: a more intense (002) reflection, the angle of which allows one to determine the distance between the graphite-like layers (d), and a weak (10) reflection corresponding to the ordering of atoms in the graphite-like layers.[73] The (10) reflection is actually a band that usually incorporates several unresolved lines — (100), (004), and (110). From the width of the (002) reflection, the X-ray diffraction parameter L_c characterising the 'height' of crystallites, i.e. the dimensions of the prismatic faces of the crystallites, can be estimated, while the width of the (10) band makes it possible to find the L_a parameter characterising the dimensions of the basal faces of crystallites. The relative intensity of the reflection provides information about the degree of crystallinity of the carbon material.[73, 74]

Since the X-ray diffraction patterns of the AC do not change when the surface is covered with oxides, it has been assumed[75] that oxygen is located at the corners of hexagons made up of carbon atoms. If we accept this assumption and take into account the fact that a proportion of the oxygen must be incorporated in the PAS, we find that the distances (l_m) between them should be of the same order of magnitude as the sizes of the crystallites L_a. To a first approximation, l_m can be estimated on the assumption that the PAS are uniformly distributed over the total surface of the AC ($S_g + S_m$).

The total surfaces ($S_g + S_m$) of AC found from nitrogen adsorption isotherms at 77 K, the numbers of the PAS (a_m) determined from water vapour adsorption isotherms at 293 K, and the distances between them (l_m) are listed as examples in Table 7. The L_a parameters and half-widths (x) for the slit model of pores are presented for comparison. One can see that the average distances between PAS for the majority of AC vary over a rather narrow range and are close, on average, to the sizes L_a of the crystallites forming the structure of the AC. The L_a parameters of the AC studied are consistent with the values reported[76] for various AC.

Table 7. The total specific surfaces ($S_g + S_m$), the numbers of PAS (a_m), the distances between them (l_m), the X-ray diffraction parameters L_a, and average half-widths x for some of the CA studied.

CA	(S_g+S_m)/ $m^2\ g^{-1}$	a_m/ mmol g^{-1}	l_m/nm	x/nm	L_a/nm
1	494	0.30	1.65	0.71	2.10
2	987	0.41	2.00	0.42	2.20
4	435	0.48	1.23	10.28	1.86
5[a]	820	0.16	2.92	0.73	–
6	1363	0.60	1.94	0.24	2.20
7	1058	0.41	2.07	0.64	3.30
8	1070	0.21	2.90	0.87	3.70
9	934	0.20	2.79	0.52	–
10	1019	0.53	1.79	0.54	2.36

[a] The calculations were carried out using the Dubinin – Stoeckli equation. Calculation by the two-term equation of the theory of volume filling yields a total specific surface of 713 $m^2\ g^{-1}$ and $x = 0.85$ nm.

A comparative X-ray diffraction study of various CA adsorbing water vapour makes it possible to identify the changes in adsorbents caused by the adsorption of water molecules. The adsorption of water vapour on some of the AC leads to a decrease in the interplanar spacing;[77] however, it is not clear whether this is a common characteristic feature of all AC and what is the physical meaning of these changes.

The results of a comparative X-ray diffraction analysis of CA are presented in Figs 24 and 25. The X-ray diffraction patterns were obtained on a DRON-3M diffractometer using CuK_α radiation (a Ni filter) by reflection from a flat sample, ground up beforehand and rubbed into a round cell. The measurements were carried out at room temperature; prior to the measurements, the samples were dried at 373 K and saturated with water vapour for 48 h. The interplanar spacings d and the intensities I of the (10) band, relative to the background, were determined for samples dried at 373 K and for samples saturated with water vapour.

Figs 24 and 25 present, among other data, the results of X-ray diffraction studies for those CA which are not listed in Tables 2 or 3. The d parameters for the dried samples studied varied from 0.355 nm for the P267-E carbon black to 0.462 nm for supermicroporous AC-S.

These figures indicate that the changes in the interplanar spacings (Δd) and intensities (ΔI) of the (10) band occurring after saturation of various AC with water vapour have some features in common. The average interplanar spacing d always decreases on adsorption of water molecules, and moist samples have closer d values than the dry ones. It is likely that water molecules, whose size is only slightly smaller than the distance between the graphite-like layers, influence the arrangement of the edge carbon atoms, located on the defective surfaces of crystallites, which makes a contribution to the change in the average interplanar spacing.

The Δd values increase as d increases up to a certain limiting value, after which they diminish (Fig. 24). At the same time, the intensity of the (10) band referred to the background increases for some of the samples (ΔI is positive) and decreases for others (ΔI is negative) (Fig. 25). The dependence of ΔI on d for moist samples of most of the AC studied is nearly linear (the samples with the maximum d value deviate from the general relation). This type of variation of Δd and ΔI with d can be explained in terms of the following scheme (Fig. 26). In the case of samples with small d values, the adsorption of water molecules on the edge dislocations of the graphite-like layers leads to a decrease in

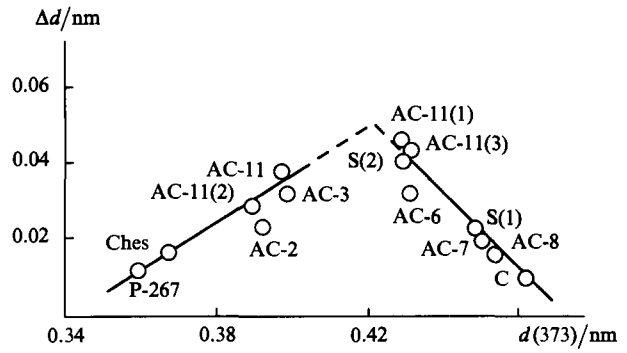

Figure 24. Dependence of $\Delta d = d(373) - d(H_2O)$ for samples dried at 373 K [$d(373)$] and samples saturated with water vapour [$d(H_2O)$] on $d(373)$. The points are labelled in conformity with the designations of the CA used in Tables 2 and 3. Additional designations are as follows: P is an industrial carbon black of the type P267-E, 'Ches' is a 'Chesacarb' type carbon black produced in the Czech Republic, S(1) is a modification of the supermicroporous AC-S, S(2) is AC-S treated with concentrated HNO_3, AC-11(1) and AC-11(2) are samples of AC-11 treated at 1173 K in an Ar or NH_3 atmosphere respectively, and AC-11(3) is AC-11 treated with concentrated HNO_3.

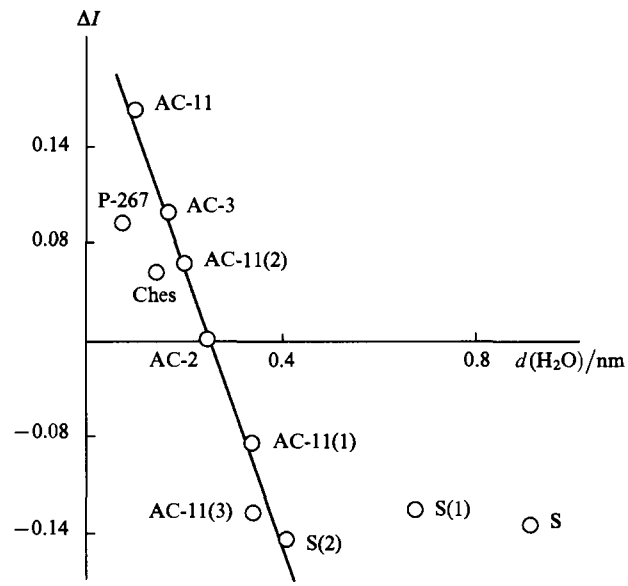

Figure 25. Dependence of the intensity difference $\Delta I = I(H_2O) - I(373)$ for samples saturated with water vapour [$I(H_2O)$] and those dried at 373 K [$I(373)$] on $d(H_2O)$ for moist samples. The designations are the same as in Fig. 24.

the interplanar spacing and simultaneously makes the mutual arrangement of the layers more ordered (Fig. 26*a*). For samples with medium d values, a decrease in d, virtually unaccompanied by an ordering of the networks, is possible (Fig. 26*b*). For samples with large d values, the adsorption of water molecules may result in a decrease in the interplanar spacing with a simultaneous distortion of the mutual arrangement of the layers (Fig. 26*c*). When d is further increased, the adsorption of water molecules does not influence it.

Thus, the character of the variation of the interplanar spacing d and of the relative intensity I of the (10) band after the adsorption of water vapour confirms the hypothesis that the adsorption occurs from the sides of the prismatic faces of the crystallites, where edge defects are located. This conclusion is also supported by the data on the influence of the adsorption of water

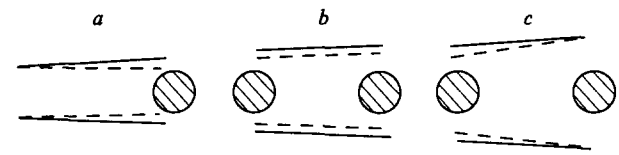

Figure 26. Schematic arrangement of water molecules near graphite-like layers at the edges of crystallites. The solid and dashed lines show the corresponding arrangement of the graphite-like layers prior to and after the adsorption of water molecules.

molecules on the L_a parameter characterising the size of the basal faces of the crystallites. Table 8 presents the L_a and L_c parameters for some AC dried at 373 K and saturated with water. One can see that L_a increases due to the adsorption of water vapour in all cases, and the larger the value of L_a, the larger the relative increase in $\Delta L/L_a$. At the same time, L_c varies slightly and irregularly. These results indicate that the adsorption of water molecules leads to the elongation of the carbon layers, and improvement of the latter.

Table 8. X-Ray diffraction parameters L_a and L_c for samples dried at 373 K and saturated with water.

Sample	L_a/nm		L_c/nm	
	373 K	H_2O	373 K	H_2O
AC-1	2.10	2.55	1.82	1.79
AC-6	2.20	3.10	0.98	1.02
AC-7	3.30	4.39	0.89	0.94
AC-8	3.70	5.00	0.75	0.94
AC-10	2.36	2.64	1.02	1.02
AC-S	2.14	3.67	0.89	0.86
AC-U-2	1.78	2.34	1.64	1.58

The combination of X-ray diffraction analysis in the study of the adsorption of water vapour with the determination of adsorption isotherms in the study of the formation of the porous structure of the AC in the carbonisation and activation stages makes it possible to demonstrate in some cases a bimodal size distribution of the micropores of some AC, associated with the presence of two independent structures.[78] Apart from the normal micropores, revealed by nitrogen vapour adsorption isotherms, some AC can contain ultramicropores revealed by water vapour adsorption isotherms.[78] This is due to the sensitivity of the adsorption of water vapour at low relative pressures to the size of very small micropores. The water vapour adsorption isotherm on these AC has a typical 'wave-like' shape, whereas the nitrogen vapour adsorption isotherm at 77 K has the normal shape.[78,79]

Thus, it may be stated that the water vapour adsorption isotherms are more sensitive in a certain sense to the features of the porous structure than adsorption isotherms for other adsorbable substances; this allows one to identify fine details of CA structures. Later, Naono and Hakuman[80] arrived at the same conclusion while studying the porous structures of silica gels and also iron and titanium oxides.

In general, one may conclude that the differences between the mechanisms of the adsorption of nitrogen and water vapours on CA are manifested by different effects of the chemical state of the surface and the porous structure of the CA on the form of the nitrogen and water vapour adsorption isotherms. Therefore, experimental data concerning adsorption of nitrogen and water vapour complement each other and provide more comprehensive and detailed characteristics of the porous structure of the CA.

The data obtained by X-ray diffraction agree with the previously suggested schemes for the filling of the micropore volume with water. The similarity of the L_a and l_m values, on the one hand, and their comparison with the x values, on the other hand, imply (see Tables 7 and 8) that for the majority of AC the distances between the PAS are larger than the half-widths of the micropores, so that the filling of the micropore volume with water molecules involves the formation of bridge bonds between the PAS located on the opposite walls of micropores. Thus, the character of the filling of the pore volume with water depends on the ratio between the widths of slit-like pores and the surface concentration of the PAS, which is determined, in its turn, by the average size of the crystallites forming the porous structure of the activated carbons.

Organic reactions on the surface of silicon dioxide: synthetic applications

V A Basiuk

Contents

I. Introduction 1003
II. Organic reactions carried out in the presence of silicon dioxide 1004
III. Conclusion 1016

Abstract. The literature data on the specific features of organic reactions in the presence of silicon dioxide (predominantly in the unmodified form) and its use for synthetic purposes are analysed. Oxidation (including dry ozonisation), reduction, alkylation and acylation, halogenation, elimination, hydrolytic and dehydration reactions, intermolecular cycloaddition and other cyclisation reactions, three-membered ring opening reactions, and peroxide decomposition reactions, as well as certain photochemical reactions are considered. In the processes investigated, the surface of silicon dioxide can function as a catalyst, as a solid medium for the occurrence of reactions, and/or as a matrix influencing the stereospecificity. The bibliography includes 214 references.

I. Introduction

Silicon dioxide is one of the most important inorganic compounds used in catalytic organic synthesis. In industrial catalysis, it is employed in the vast majority of cases as a carrier for substances with more pronounced catalytic properties.[1] However, in contrast to industrial organic synthesis, in organic synthesis as a whole the role of silicon dioxide is by no means restricted to its use as a simple more or less inert carrier. Like other generally known inorganic oxides (for example, Al_2O_3), it can be used not only in industrial processes such as hydrocarbon cracking but also in many heterogeneous reactions at the laboratory scale. Such reactions frequently take place under mild conditions (< 100 °C) and their characteristic features are more selective transformations (chemo-, regio-, and stereoselective) and simplified (compared with homogeneous analogues) methods for the isolation of the final products.[2] Many specialists in the field of laboratory fine organic synthesis are known to prefer commercially available silicon dioxide (usually silica gel) to catalytic systems with a platinum metal deposited on the oxide.

Many publications describe comparative studies on series of inorganic oxides in order to find optimum conditions for reactions and the optimum yield of their products. In some cases, the composition of the oxide may not affect the process or may affect it insignificantly, i.e. the oxides (for example, silicon and aluminium oxides, pure or mixed) are 'mutually replaceable'. Here it is appropriate to refer to certain studies involving the use of aluminium oxide (pure or with deposited reagents),[3-16] silicon–aluminium oxides,[17] zeolites,[18-23] and clays[24,25] in fine organic synthesis. A number of reviews[26-33] deal with processes with participation of various oxides. However, none of them presents complete information either about the employment of SiO_2 or about other oxides (for example, in the latest review[33] devoted to silicon and aluminium oxides, only about 50 publications were covered); furthermore, the data in the majority of these studies have become obsolete.

Bearing in mind the foregoing considerations, it appears entirely justified and timely to analyse in greater detail the role of silicon dioxide in fine organic synthesis. Attention is concentrated here on reactions involving the use of unmodified commercially available silicon dioxide (as a rule silica gel), in which its surface actually exhibits a catalytic effect (or other useful properties). Examples of the employment of SiO_2 as a carrier for any other catalyst (see, for example, Refs 34–39) are not considered in detail. However, sometimes it is extremely difficult to classify silica gel as a catalyst or as an inert carrier. Furthermore, in the literature considered certain terminological inaccuracies are encountered. In particular, it has been reported[40] that iron(III) chloride deposited on silica gel is an effective 'reagent' for the rapid and selective dehydration of alcohols and also for rearrangements of the pinacol and acyloin types. The use of the term 'reagent' is apparently illegitimate because a typical case of catalysis is considered. A still more striking example of a nonrigorous terminology is provided by the title of the book[41] *Catalysis of Organic Reactions by Supported Inorganic Reagents*. Nevertheless, these terms have become established and continue to be used, sometimes admittedly with the stipulation that the expression 'supported reagent' is understood both as a reagent, i.e. a stoichiometric agent, and as a catalyst.[42]

The classification of organic reactions used below (like virtually any classification) involves an arbitrary feature, reflecting synthetic aspects which are discussed in the literature analysed. For example, although dry ozonisation reactions formally belong to oxidation processes, they have been segregated in an independent section because they are of great synthetic value and are based on an unusual experimental approach.

Finally, a characteristic feature of the vast majority of publications on this topic is a purely practical approach, in which the main task (although not the only one) is to obtain the maximum yields of the target products, and is in no way concerned with the elucidation of the mechanism of the catalytic (or any other) action of silicon dioxide in the reactions employed.

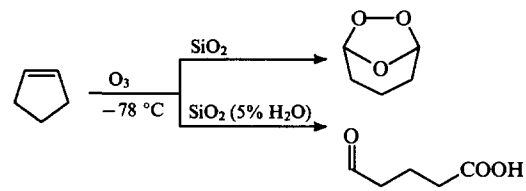
Because of this, the present review is inevitably one-sided in a certain sense: whilst there are numerous examples of synthetic applications of organic reactions on the surface of silicon dioxide, it is at present impossible to make serious generalisations about the characteristic features of their occurrence. Thus the data presented in this review will be more useful to specialists in synthetic organic chemistry rather than those engaged in catalysis and in the chemistry of the surfaces of inorganic oxides.

II. Organic reactions carried out in the presence of silicon dioxide

1. Dry ozonisation



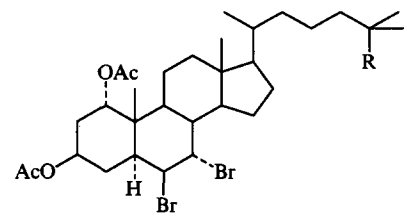
Dry ozonisation is one of the most important processes carried out in the presence of silicon dioxide and has great synthetic value because it makes it possible to introduce oxygen atoms into nonactivated C–H bonds.[43,44] Ozone is known to react slowly with saturated hydrocarbons at the C–H bonds, oxidising them to hydroxy- and keto-groups. Such insertion of oxygen takes place predominantly at tertiary carbon atoms with retention of the configuration of the substrate. However, the potential synthetic possibilities of these reactions are restricted by a number of factors, the most important of which is the low solubility of ozone in organic solvents and its high reactivity with respect to them.

These limitations can be removed by employing silica gel as the adsorbent and as the solid medium for the reaction.[45,46] The typical method proposed involves the preliminary deposition of the substrate (~1 mass%) on silica gel and the passage of a stream of ozone at −78 °C until saturation. A virtually quantitative conversion of the hydrocarbons (methyl- and dimethyl-cyclohexanes, decalins, adamantane, etc.) into the corresponding tertiary alcohols is achieved under these conditions with a virtually complete retention of the configuration of the *cis–trans* isomers and the absence of polyoxygenated products. Yet another important advantage of this method is the possibility of further stepwise oxidation of the product by repeating the ozonisation procedure. This has been demonstrated in relation to the introduction of a second hydroxy-group into monohydroxylated products (or their acyl derivatives) or in their oxidation to ketones.

According to the data of Proksch and de Meijere,[47–49] in the dry ozonisation of substituted cyclopropanes the attack by ozone is directed predominantly to the C–H groups in the α-position in the three-membered ring. This made it possible to develop a new approach to the α-functionalisation of the hydrocarbons indicated. The strained bicycloalkanes, containing a cyclopropane fragment, behaved differently under these conditions.[50] For example, the ozonisation of bicyclo[2.1.0]-pentane results in the formation of a 2 : 5 mixture of cyclopropylacetic acid and succinic dialdehyde. Comparison of the behaviour of aliphatic hydrocarbons and their cyclic analogues, led Tal et al.[51] to the conclusion that the degradation of the C–C bonds in the first case is more appreciable and the oxidative abstraction of alkyl groups results in the yields of the tertiary alcohols being lower and those of the ketones being higher.

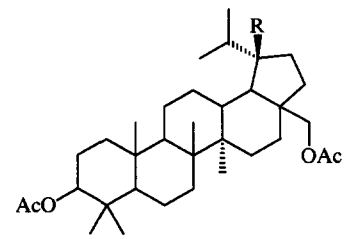
The dry ozonisation of mono-, di-, and tri-alkyl-substituted alkenes leads to the formation of a mixture of ozonides (or polymeric peroxides) and carbonyl compounds.[52] Phenylethyl-alkenes afford almost exclusively aromatic aldehydes and ketones under these conditions, while alkynes give rise to a mixture of carbonyl and carboxy-compounds.

It has been shown in relative to the dry ozonisation of a series of alkenes adsorbed on silica gel[53] that the composition of the reaction products depends greatly on the presence of water in the system. In particular, the oxidation of cyclopentene on silica gel dehydrated beforehand affords the normal monomeric ozonide, which can be isolated in 80% yield whereas after the addition of 5% of water oxidative cleavage of the double bond takes place with formation of 5-oxopentoic acid in approximately the same yield.



We may mention for comparison that, when the ozonisation is carried out in the usual way, the main product is a polymer.

Aromatic compounds without strong electron-accepting groups also undergo oxidative degradation under the conditions indicated.[54] For example, phenyl- and mesityl-cyclohexanes give rise to cyclohexanecarboxylic in 90% and 70% yields respectively (degrees of conversion of 95% and 90%), while tetralin affords adipic acid in 50% yield (degree of conversion 95%). The addition of 25% of water to the silica gel in the last case leads to an increase in the yield of adipic acid to 75%.



The possibility of the wide-scale employment of dry ozonisation on the silica gel surface for hydroxylation at tertiary aliphatic carbon atoms (which is particularly important in the chemistry of natural products) is limited by the reactivity to ozone of the double bond present in the molecule.

Since C–H bonds interact with ozone more slowly than C=C bonds, the latter must be protected by readily removable groups. It has been shown[55] that C–Br groups are less reactive to ozone than tertiary C–H groups, so that the bromination of the C=C bonds may be employed for protection.

Subsequently the dry ozonisation method was applied by the same investigators in the synthesis of the 1α,25-dihydroxy-derivative of vitamin D_3, for the oxidation of the dibromo-derivative **1** to the hydroxy-derivative **2** (yield 11%),[56] and also for the introduction of a functional group at the C(25) atom in other cholestane derivatives.[57] The dry ozonisation of 3β,28-diacetoxy-lupane **3** led to the 19-hydroxy-derivative **4**;[58] a mixture of 18β,19β-epoxyfriedelane **6** and the products of the oxidation of the CH_2 groups in the 19-position (compound **7**), the 15-position (compound **8**), and the 16-position (compound **9**) to the keto-groups (in 48%, 2%, 11%, and 11% yields respectively) was obtained from friedelane **5**.[59]

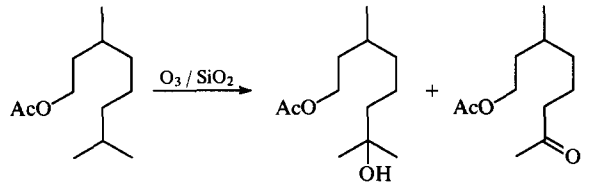
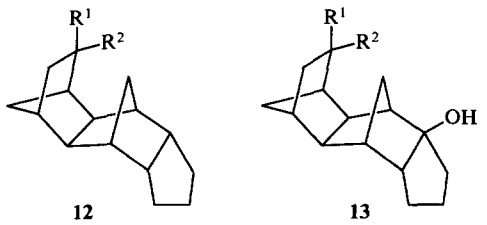
8: $R^1 = O$, $R^2 = R^3 = H_2$; 9: $R^1 = R^3 = H_2$, $R^2 = O$.



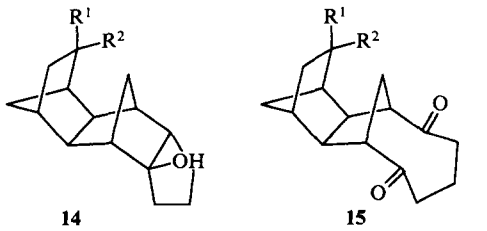
The dry ozonisation of friedelin (3-oxofriedelane) afforded analogous derivatives.[60]

This method has also been used to synthesise the hydroxy-derivative of cedrol acetate **10** and other sesquiterpenes.[61,62]



10 **11**

In contrast to ozonisation in solution, in the dry ozonisation of 3,7-dimethyloctyl acetate adsorbed in silica gel, the carboxy- or oxo-group is introduced predominantly in the 7-position, which is at a considerable distance from the functional group already present,[63,64] while oxidation in the 3-position is suppressed.



41%–69% 18%–31%

The maximum regioselectivity is attained when the initial compound is deposited on silica gel as a coating resembling a close-packed monomolecular layer. These results confirm the hypothesis that, by carrying out the reaction in adsorption layers, it is possible to increase the regioselectivity as a result of the mutual orienting effect of the substrate molecules. The ozonisation of cyclododecyl acetate under these conditions led to the formation of a mixture of its 5-, 6-, and 7-oxo-derivatives in 15%, 27%, 9% yields respectively.[65] The oxidation of the substituted cyclopentadiene trimers **12** led to the formation of the alcohols **13** and **14** and of the diketone **15**.

12 **13**

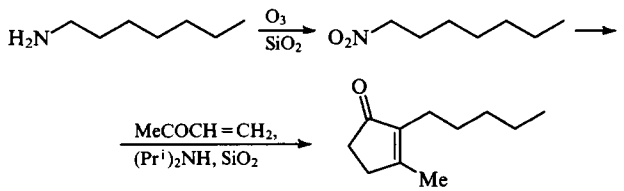
Substituents	(Yield %)		
	13	**14**	**15**
$R^1 = OAc$, $R^2 = H$	35	25	20
$R^1 + R^2 = O$	18	12	18

However, the authors[65] concluded that the proposed method of synthesis suffers from a series of disadvantages (difficulty of monitoring the course of the reactions, poor reproducibility, etc.) and subsequently modified it by introducing Freon 11 [trichlorofluoromethane (Ed. of Translation)] into the reaction medium and also by depositing the substrates on silica gel in the form of succinates to ensure their firmer fixation.[66] The advantages of the new approach were demonstrated by the authors in the ozonisation of the succinates of 6-methylheptan-2-ol, 3,7-dimethyloctanol, adamantan-2-ol, and two hydroxydecalins.

Among other reactions which take place effectively on treatment with ozone in the presence of silica gel, mention should be made of the oxidation of primary aliphatic amines to the corresponding nitro-compounds.[67] The synthesis lasts from several minutes to tens of minutes and the yields of the nitro-compounds reach 70%. The formation of more far-reaching oxidation products—ketones and carboxylic acids—is also possible, but their yields do not exceed 6%.

2. Other oxidation reactions

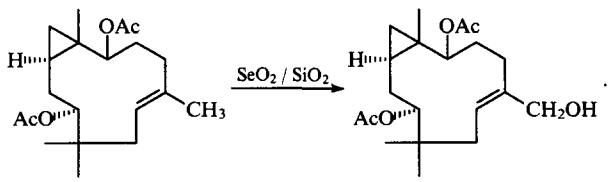
The use of solid inorganic oxidants in organic synthesis is limited by their insolubility in weakly polar media. This limitation can be overcome by the preliminary deposition of the oxidant on inert solid carriers, for which silica gel has been recommended among other substances. The first example of the use of SiO_2 in such reactions was the oxidation of a substituted benzyltetrahydroisoquinoline **16** by deposited manganese dioxide[68] with formation of isosalutaridine **17** (yield 4%).



16 **17**

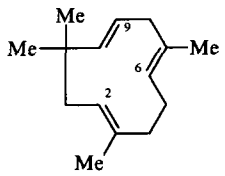
The oxidation of alcohols to aldehydes and ketones by potassium permanganate is a typical example.[69] The oxidation of benzyl alcohol to benzaldehyde,[70] of alkynes to diketones, of cyclic ketones to dicarboxylic acids, of acylated amines to acylimides, and of sulfides to sulfones,[71] as well as the conversion of ethers into lactones, of cyclic ketals into ketones, and of nitro-groups into carbonyl groups[72] on treatment with potassium and zinc permanganates have been investigated.

Chromic acid adsorbed on silica gel can also serve as a convenient reagent for the oxidation of alcohols to aldehydes and ketones in high yields (68%–90%).[73] Deposited potassium dichromate oxidises selectively benzyl alcohols and halo-derivatives to the corresponding ketones, the reactions being carried out in a neutral medium.[74] Chromic acid adsorbed on silica gel can be employed also for the synthesis of menthone from menthol (yield 96%). It has also been reported that deposited pyridinium chromate is suitable for the effective oxidation of a wide variety of secondary and primary alcohols containing labile acid groups.[75]



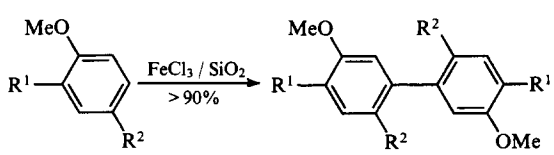
A mild method of synthesis of quinones from hydroquinones and catechols with the aid of deposited cerium(IV) and chromium(VI) salts has been described.[76] The homogeneous oxidation of 1-naphthol by cerium(IV) ammonium nitrate leads to 2,4- and 4,6-dinitro-derivatives.[77] However, the above reaction on silica gel leads to the formation of 2- and 4-nitro-1-naphthols in 42% and 38% yields respectively. Polynuclear arenes afford under these conditions the mononitro-derivatives and not quinones; for example, phenanthrene is converted into 2- and 3-nitrophenanthrenes (45% and 28%).

It is believed[78] that sodium methoxide deposited on silica gel is an ideal medium for the Nef reaction. Aldehydes and ketones may be obtained from primary and secondary nitro-compounds in yields exceeding 60%. The method has been used in the last stage of the synthesis of dihydrojasmone **18** from n-heptylamine and for the conversion of 1-(nitromethyl)cyclohexene into the corresponding aldehyde in 82% yield.[79]



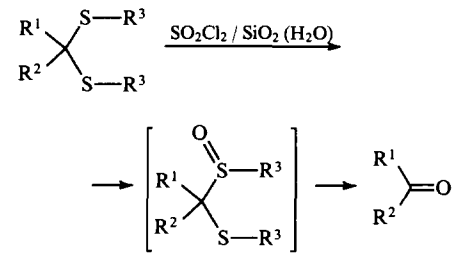
18

Among other inorganic oxidants deposited on silica gel and used in similar syntheses, mention should be made of sodium metaperiodate ($NaIO_4$, see, for example, the synthesis of quinones from hydroquinones[80]), potassium dimesoperiodate ($K_4I_2O_9$), and paraperiodic acid (H_5IO_6),[81] as well as selenium dioxide, which oxidises selectively allylmethyl groups to the corresponding primary alcohols and aldehydes.[82]



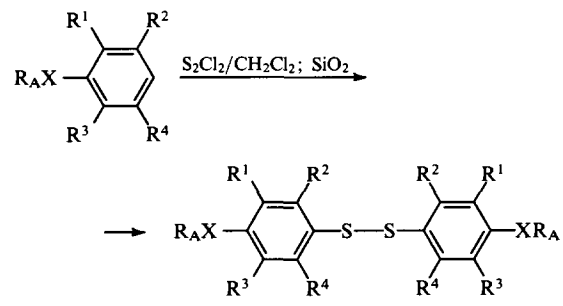
The oxidation of humulene (a sesquiterpene)

by perbenzoic acid and silver nitrate on silica gel[83] leads to the epoxidation of the double bonds in the 2,3-positions (the main product), the 6,7-positions, and the 9,10-positions; the $\Delta^{2,3},\Delta^{6,7}$-diepoxide is formed simultaneously. On the other hand, the dominant product in the homogeneous oxidation of this sesquiterpene is the $\Delta^{6,7}$-epoxide.



Iron(III) chloride deposited on silica gel can be used as the carrier for methoxy-substituted aromatic compounds.[84]

R^1, R^2 = Me, OMe.

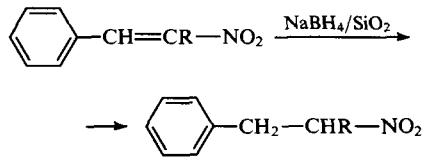


The rate of reaction increases after the complete removal of the solvent.

In a number of studies,[85-89] silica gel was regarded not as the reaction medium but as a catalyst of oxidation processes. Sulfuryl chloride is known to interact with methyl phenyl sulfide to form chloromethyl phenyl sulfide. It was found that, when reactions of this type are carried out in the presence of small amounts of moist silica gel, the corresponding sulfoxides are formed exclusively, while the chlorination of the alkyl groups is fully suppressed under these conditions.[85] The oxidation reaction takes place at room temperature in methylene dichloride; the yields of the sulfoxides exceed 80% (up to the quantitative yields for the unpurified products). When thioacetals are treated with sulfuryl chloride, the oxidative elimination of the thioacetal group takes place, the corresponding carbonyl derivatives being formed in almost quantitative yields at room temperature.[86,87]

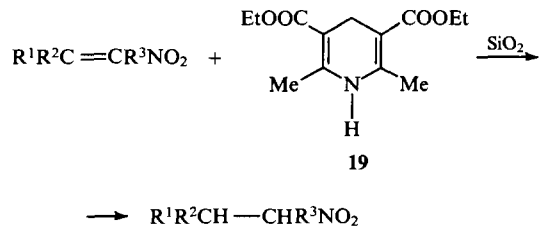
These results[86,87] have been used to develop a convenient method of synthesis of sulfoxides and carbonyl compounds labelled with the ^{18}O isotope.[88] The source of the isotope was the water $H_2{}^{18}O$ deposited on silica gel.

The interaction of adsorbed reagents of the type RSCl, $RSCH_2Cl$, and S_2Cl_2 with aromatic compounds has been investigated.[89] For example, when durene is acted upon by chloromethyl phenyl sulfide, a ring-substitution product — phenylthiomethyldurene — is formed (28%). The reaction of S_2Cl_2 with mesitylene leads to a mixture of dimesityl sulfide (29%) and dimesityl disulfide (52%). In the analogous method of synthesis of aryl disulfides, patented by Japanese investigators,[90] the formation of sulfides is suppressed.



R^1, R^2, R^3, R^4 = H, Alk, AlkO; R_A = 4-BrC_6H_4; X = O, S.

For example, when X = O and $R^1 = R^2 = R^3 = R^4$ = H, the yield of the disulfide reaches 61% (25 °C, 20 h).

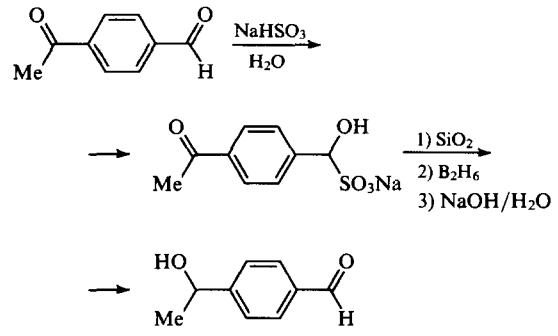


3. Reduction

The use of inorganic reagents for the reduction of organic compounds is not always possible, as in the case of solid oxidants, owing to their poor solubility in weakly polar solvents. One of the first reductants employed in the form deposited on silica gel was sodium tetrahydroborate.[91,92] Being commercially available, it proved to be extremely convenient for a wide variety of selective reactions involving the reduction of functional groups of one kind in the presence of others. However, a significant disadvantage of this reagent is its sensitivity to the presence of adsorbed water on silica gel — up to complete deactivation. An alternative stable and effective reductant proved to be tetrabutylammonium tetrahydroborate deposited on silica gel from solution in tetrahydrofuran.[93] The following reaction may serve as an example of selective reduction by tetrahydroborates on the surface of silica gel:[94]

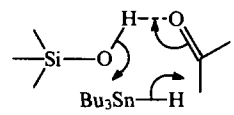
In contrast to the analogous homogeneous reaction, the formation of dimeric reduction products is almost fully suppressed under these conditions and high yields of nitroalkanes (92%–98%) are attained.

Another approach to the synthesis of nitroalkanes from nitroalkenes involves the interaction of the latter with the Hantzsch ester **19** in benzene in the presence of silica gel.[95]



19

The reduction of aliphatic and aromatic nitroalkenes proceeds smoothly and is not accompanied by the reduction of the nitro-groups and the dimerisation of the olefinic groups. Other groups, such as the ester groups, are inert under the given conditions; only the C=C bonds conjugated with the nitro-group are reduced.

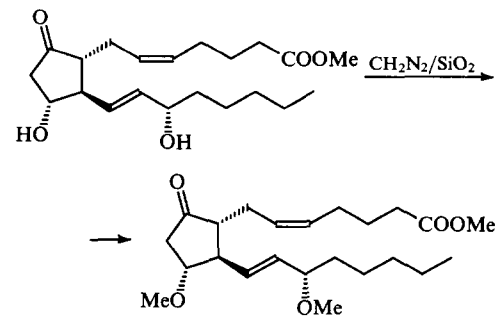


The deposition of the pyridine–borane complex on silica gel makes it possible to carry out the reduction of aldehydes and ketones under milder conditions.[96] For example, the heterogeneous reduction of benzaldehyde to benzyl alcohol in cyclohexane takes place at room temperature and is completed after 45 min with a yield in excess of 95%, whereas in the homogeneous system is takes place on refluxing in toluene or benzene and the yields are by no means always satisfactory.

The use of sodium bisulfite as the protecting agent for aldehyde groups and of silica gel as a solid matrix made it possible to carry out the selective reduction of 4-acetylbenzaldehyde.[97,98]

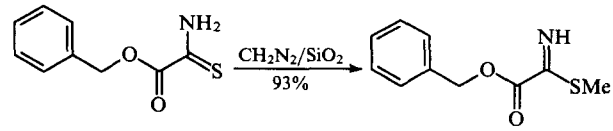
4-(1-Hydroxyethyl)benzaldehyde is formed with a selectivity of 70%–93% [4-acetylbenzyl alcohol and 1-(4-hydroxymethylphenyl)ethanol are minor products]. Positive results were also achieved when Al_2O_3 was used as the carrier. 4-Acetylbenzophenone was reduced in accordance with a similar scheme to 4-acetyl-α-phenylbenzyl alcohol with a selectivity of 80%.[99,100] (Carboxymethyl)trimethylammonium chloride hydrazide (the Girard reagent T) and lithium tri(*tert*-butoxy)hydroaluminate served as the protecting and reducing agents respectively.

The silica gel-catalysed reduction of aldehydes and ketones by tributyltin hydride is characterised by a high selectivity, but the yields of the corresponding alcohols vary from 69% to 94% under these conditions.[101] According to the authors,[101] the advantages of this method are simplicity, relatively mild conditions, and the absence of the need to neutralise the alkoxide salts, as well as the possibility of the selective reduction of aldehydes in the presence of ketones. One of the most probable mechanisms of the process involves the formation of a six-centre transition state:



The cyano- and nitro-groups are not reduced by lithium tetrahydroaluminate on silica gel, in contrast to the reaction in the homogeneous system. This feature has been used[102] for the selective reduction of ketones and esters containing the above groups to the corresponding cyano- and nitro-alcohols, which were obtained in 54%–82% yields. Methyl *p*-nitrophenyl sulfoxide was reduced similarly to the nitrosulfide (yield 73%).

The use of lithium tetrahydroaluminate deposited on silica gel for the reduction of aldehydes, ketones, and carboxylic acid chlorides and esters in nonpolar solvents (hexane, benzene) has been considered.[103,104] For the compounds of the first three classes, the process is rapid at room temperature, whereas esters are more inert and their reduction requires the heating of the reaction mixture. Because of these differences in the reactivities, the selective reduction of ketoesters to hydroxyesters is possible (the yields in different syntheses vary from 62% to 100%).



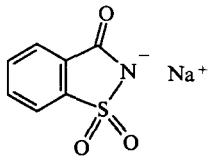
Silica gel treated beforehand with thionyl chloride has been used to reduce sulfoxides to sulfides.[105] The reaction occurred at room temperature for 10 min in CCl_4 or CH_2Cl_2.

4. Alkylation and acylation

In contrast to carboxylic acids, alcohols and phenols are difficult to methylate by diazomethane because of the low acidity of the OH groups. However, following adsorption on inorganic oxides, the acidity of these groups increases appreciably. Because of this, it has been possible to obtain ethers in quantitative yields from aliphatic alcohols and phenols adsorbed on silica gel by treatment of the latter with gaseous diazomethane.[106] The authors showed that, in the methylation of 1-decanol, Al_2O_3, a type NaY zeolite, and other similar carriers exhibit a comparatively weak catalytic effect. Polyhydric alcohols, including prostaglandins and carbohydrates, can also be used as the substrates.[107] For example, treatment of prostaglandins with a large excess of diazomethane makes it possible to obtain the corresponding diesters in quantitative yields.

The methylation of lactams and acyclic amides by diazomethane in the presence of silica gel also proceeds effectively.[108] The thioamide groups are methylated more readily than the amide groups, which may be used to carry out a selective reaction of the type

A simpler procedure has been used for the acetylation of phenols[109] and aliphatic (including secondary and tertiary) alcohols by ketene.[110] Apart from silica gel, aluminium, zinc, and magnesium oxides exhibited a high catalytic activity (the yields of the esters were 70%–91%).



Adsorption on silica gel (and also on aluminium oxide) makes it possible to carry out selectively the monoalkylation of malonic ester anions by 1,5-dibromopentane in the presence of sodium methoxide.[111]

$$CH_2(COOMe)_2 + Br(CH_2)_5Br \xrightarrow{MeONa/SiO_2} Br(CH_2)_5CH(COOMe)_2$$

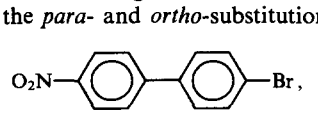
The reaction takes place at room temperature, but is fairly slow: the attainment of a satisfactory (28%–52%) yield of the product requires up to 13 days.

It has been shown[112] that silica gel is an effective catalyst for the alkylation of phenols by *tert*-butyl bromide. 2-*tert*-Butyl-, 2,6-di-*tert*-butyl-, and 2,4,6-tri-*tert*-butyl-phenols, which are difficult to obtain directly by the Friedel–Crafts reaction, can be synthesised readily by this procedure. $Et(Me_2)CBr$, *p*-$TolCH_2Cl$, $H_2C{=}CH-CHMeCl$, and $MeOCH_2Cl$ can also be used as the alkyl halides; thiophene, benzothiophene, furan, and 1-methylindole can serve as the aromatic substrates. The yields of the alkylation products vary in the range 6%–98% under these conditions.

The alkylation of saccharin

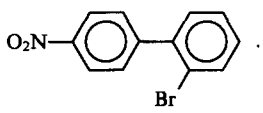
by benzyl, allyl, and hexadecyl bromides, benzyl chloride, and similar reagents has been carried out on silica gel (and also on aluminium oxide) in a microwave oven.[113] Depending on the nature of the alkylating agent, the reaction terminated after 1–10 min and the yields were 21%–91%.

The *N*-alkylation of pyrazoles by alcohols or ethers proceeds effectively on silicon, aluminium, titanium, and zirconium oxides at 200–500 °C.[114] For example, the interaction of 3,5-diphenylpyrazole and methanol results in the formation of 1-methyl-3,5-diphenylpyrazole in 96% yield.



5. Halogenation

According to the results of Stoldt and Turk,[115] when cyclohexene is brominated on silica gel in the absence of solvents, the formation of only *trans*-1,2-dibromocyclohexane is observed. Diethyl fumarate, in which the olefinic function is deactivated, is also effectively brominated under these conditions, the reaction being fully stereospecific and leading exclusively to the *trans*-adduct—*meso*-diethyl 2,3-dibromosuccinate.



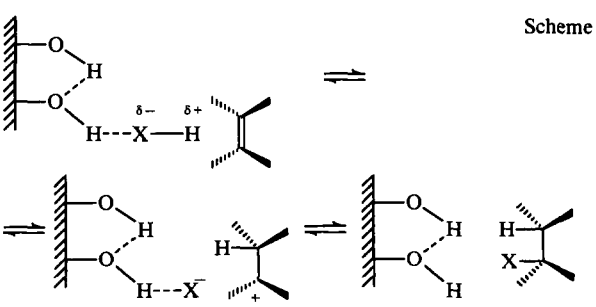
The chlorination of adamantane and other hydrocarbons adsorbed on silica gel by molecular chlorine and sulfuryl chloride has also been studied.[116] In all cases, products involving bridgehead chlorination were obtained in high yields.[116]

Under 'dry' conditions, the process takes place more effectively and selectively than, for example, in the presence of dichloromethane or under homogeneous conditions.

The bromination of biphenyl, 4-bromobiphenyl, and 4-nitrobiphenyl deposited on silica gel by gaseous bromine has been investigated.[117] The ratios of the yields of the products of the *para*- and *ortho*-substitution, for example

and

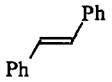
proved close to those obtained for the reaction carried out in a homogeneous system (~4:1). A control experiment involving biphenyl showed that the reaction does not occur in CCl_4 in the absence of silica gel.

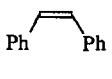


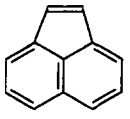
When alkylbenzenes are treated with sulfuryl chloride in the presence of silica gel, preferential substitution in the aromatic ring is observed (whereas in the absence of the catalyst, the chlorination takes place either in the alkyl substituents or does not occur at all).[118] Similar results have been obtained by Yaroslavksy.[119]

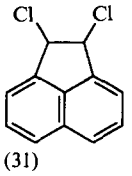
A series of studies[120–123] have been devoted to the catalytic introduction of halogen atoms into an aromatic ring. In particular, it has been established[120] that the chlorination of toluene by dichloramine T in the presence of silica gel takes place under very mild conditions (CCl_4, 25 °C) with formation of a mixture of the *o*- and *p*-isomers (65% and 35% respectively). Only fairly acid forms of silicon dioxide, for which the pH of a 10% aqueous suspension did not exceed 5, exhibited catalytic properties in these reactions. The activity increased after preliminary dehydration.[121]

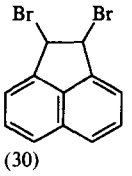
The chlorination of naphthalene by *tert*-butyl hypochlorite (CCl_4, room temperature) leads preferentially to 1-chloronaphthalene (93%), while the chlorination of alkylbenzenes and anisole affords a mixture of the *o*- and *p*-isomers in proportions typical for the usual homogeneous methods of synthesis. Depending on the amount of the brominating agent, the bromination of scatole by *N*-bromosuccinimide (CH_2Cl_2, 30 min) leads to the formation of 2-bromo- or 2,6-dibromoscatole (the substitution in the ring of 2-methyl- and 3-cyanomethylindoles takes place in the same way); the analogous reaction with benzimidazole affords 2-bromo- or 2,5-dibromo-benzimidazole, while the reaction with 2-methylbenzimidazole gives rise to only the 5-bromo-substituted product.[122] The same method has been used to brominate carbazole, where it is possible to introduce up to four bromine atoms into the ring.[123] It is of interest that in the case of *N*-ethylcarbazole the process stops at the stage involving the formation of the tribromo-derivative.

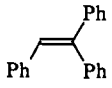


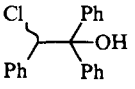


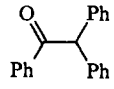


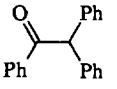


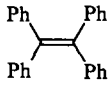


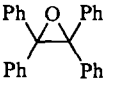


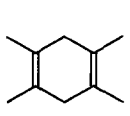


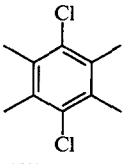


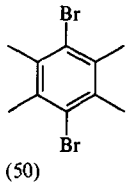


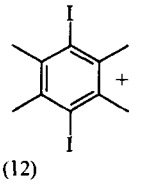


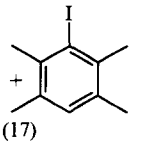










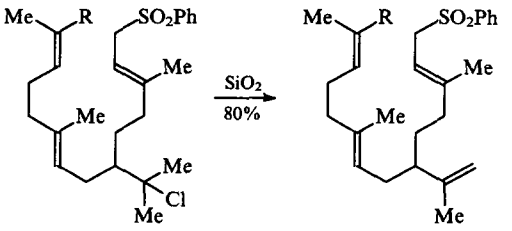


The addition of the hydrogen halides (HCl, HBr, and HI) to alkenes (cycloheptene, oct-1-ene, pinene, etc.), catalysed by silicon and aluminium oxides, has been investigated in detail.[124,125] The best medium for the reactions proved to be methylene dichloride and diethyl ether, the catalysts exhibiting the maximum activity after preliminary exposure to air at 120 °C until the attainment of equilibrium with atmospheric moisture, promoting more complete hydroxylation of the surface. Bearing in mind that the addition reaction results as a rule in the formation of products with the *cis*-configuration, the authors[124,125] proposed the most probable mechanism of the catalytic reaction, according to which the adsorption of the molecules of the hydrogen halide on the acid hydroxy-groups of the surface results in the polarisation of the X–H bond and in the protonation of the alkene with subsequent rapid transfer of the anion X^- (Scheme 1).

Scheme 1

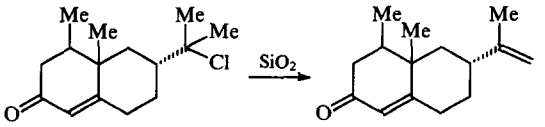
An interesting example of solid-phase tribochemical reactions is the interaction of aryl-substituted alkenes and alkynes with iodosobenzene described by Sohmiya et al.[126] The silica gel with the adsorbed hydrogen halide (HCl, HBr, or HI), the alkene (or alkyne), and iodosobenzene were placed in a mortar and ground with a pestle at room temperature for 5 min. The substrates employed, the products and their yields, are presented in Table 1.

Table 1. The products of the tribochemical reactions of solid alkenes and diphenylethyne with adsorbed hydrogen halides and iodosobenzene (according to the data of Sohmiya et al.[126])



Substrate	Products [yield (%)]		
	HCl	HBr	HI
	 (65)	 (39)	 (>5)
	 (58)	 (58)	[a]
	 (31)	 (30)	[a]
	 (74)	 (51)	 (<6)
	 (66)	 (47)	 (58)
	 (82)	[a]	[a]
	 (60)	 (50)	 (12)
			 (17)

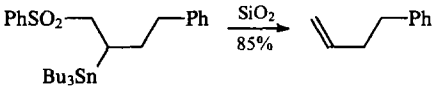
[a] The adducts were absent or their composition had not been established.



Attempts to carry out the reaction without the mechanochemical treatment were unsuccessful. Having established (for the reaction of *trans*-1,2-diphenyl- and 1,2,3,4-tetraphenylethene with adsorbed HCl) that the presence (absence) of water on the surface hardly affects the halogenation reaction, the authors[126] concluded that the reaction medium is provided directly by the silica gel surface.

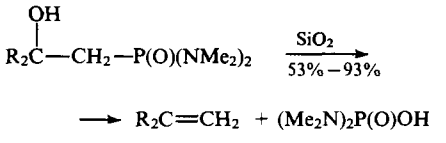
6. Elimination

When the chloro-derivatives **20** and **22** are kept in the presence of silica gel, selective dehydrochlorination to give the isopropenyl derivatives **21** and **23** respectively takes place.[127,128]



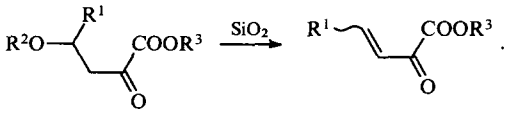
20 **21**

22 **23**



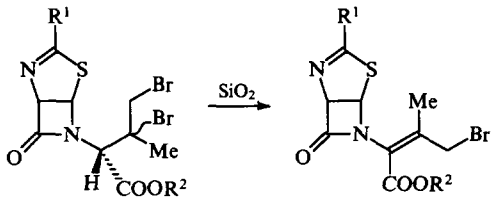
When the elimination reaction is carried out using other reagents, products containing admixtures of the isopropylidene isomers are formed.

The use of silica gel for the removal of trialkylstannyl groups in the last stage of the synthesis of alkenes by the desulfonylation of α,β-unsaturated sulfones has been reported.[129-132]



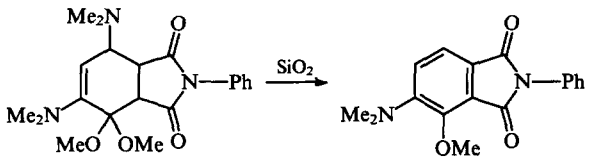
The β-elimination reaction,[129] the vinyl cyclisation of enynes,[130,131] and the methylenation of ketones[132] may serve as examples.

The phosphonamide approach to the synthesis of alkenes[133] includes as the final stage the elimination of phosphoric acid bisdimethylamide from the corresponding amides of β-hydroxyalkylphosphonic acids on refluxing their benzene or toluene solutions in the presence of silica gel.



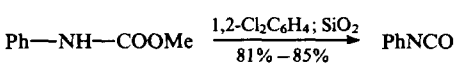
According to the authors,[133] this method is general.

A procedure for the synthesis of β,γ-unsaturated α-ketoesters in accordance with the following scheme has been patented:[134]



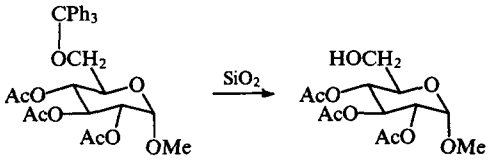
For example, when R^1 = Ph, R^2 = Me, and R^3 = Et, refluxing in benzene for 1 h leads to the corresponding α-ketoester in 92% yield.

The dehydrobromination of the intermediates in the synthesis of derivatives of antibiotics of the cephem group by chromatography on a silica gel column has been reported.[135]

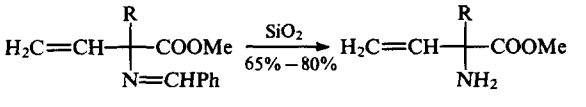


R^1 = $PhOCH_2$, Ph, Bu^t, p-$BrC_6H_4OCH_2$;
R^2 = Me, Ph_2CH.

The silica gel-catalysed elimination of Me_2N and MeO groups described by Gompper and Sobotta[136] required more severe conditions — heating to a temperature >110 °C (the yield was quantitative).

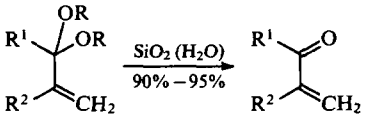


Finally, mention should be made of the synthesis of phenyl isocyanate by the thermal decomposition of methyl *N*-phenylcarbamate (elimination of MeOH).[137]



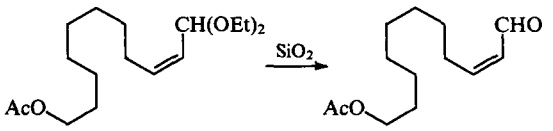
7. Hydrolysis and dehydration

The removal of the trityl protecting group in the synthesis of carbohydrates, reported by Lehrfeld,[138] is virtually the first example of the use of silica gel as a catalyst for hydrolytic processes.

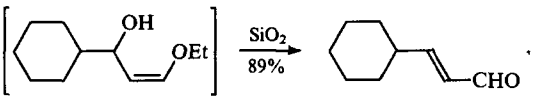


The hydrolysis was carried out by keeping a benzene solution of the initial compound on the chromatographic column for 16 h at room temperature. The yield of the purified detritylated product was 81%.

The hydrolysis of Schiff bases by chromatography on silica gel has been used in the synthesis of α-vinyl-substituted derivatives of valine, serine, histidine, tyrosine, and other aminoacids.[139]

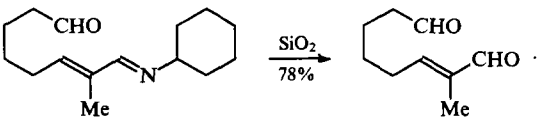


Moist silica gel has been used in the synthesis of alkenes for the removal of the ketal protecting group from the products of the reactions of α-ketoketals with Wittig reagents.[140]

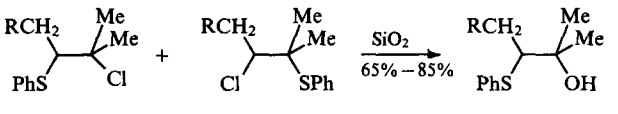


α-Cyclopropylideneketones can be obtained by the same procedure.[141]

The hydrolysis of the diethyl acetals of (*Z*)-α,β-unsaturated aldehydes in the presence of moist silica gel as the catalyst (two days at 23 °C) affords the corresponding (*Z*)-unsaturated aldehydes[142] in 47%–98% yields.

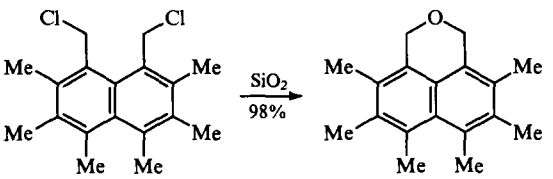


The product usually contains an admixture of the (*E*)-isomer (4%–14%) formed as a result of isomerisation. Other examples of the silica gel-catalysed hydrolysis of acetals have also been described.[143]



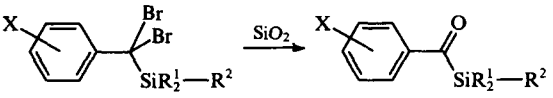
α,β-Unsaturated aldehydes are likewise formed when enol ethers — labile products of the reactions of aldehydes and ketones with (*Z*)-2-ethoxyvinyllithium — are chromatographed on silica gel,[144,145] i.e.

and also when the corresponding aldimines are passed through moist silica gel:[146]



The addition of benzenesulfenyl chloride to isoprenoid compounds at the terminal isopropylidene groups can be used, for example, for the hydroxylation of these substrates. The mixtures of the regioisomers **24** and **25**, formed as intermediates, do not require separation when they are converted into the β-hydroxysulfide **26** in the presence of silica gel.[147]

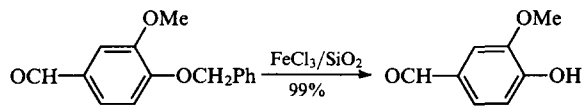
24 **25** **26**



The chromatography of 1,8-di(chloromethyl)-2,3,4,5,6,7-hexamethylnaphthalene **27** on silica gel affords the ether **28** in an almost quantitative yield.[148]

27 **28**

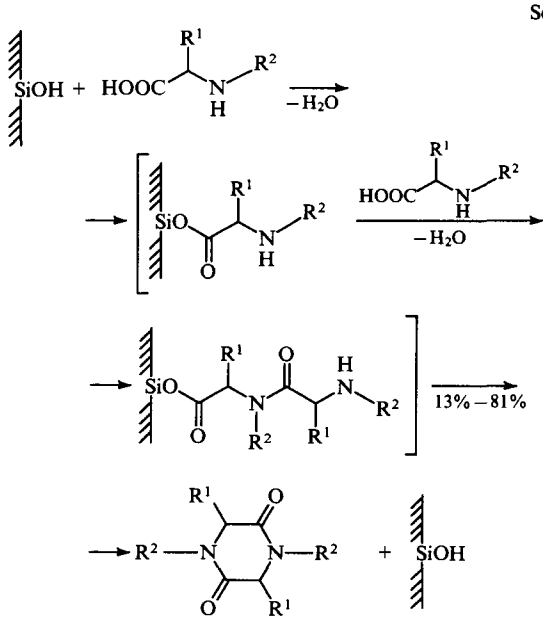
The diether is formed similarly in 84% yield from 1,4,5,8-tetra(chloromethyl)-2,3,6,7-tetramethylnaphthalene.



Acylsilanes may be synthesised in high yields by moderate heating (50 °C) of substituted α,α-dibromobenzylsilanes with silica gel in the absence of solvents.[149]

X = H, p-Cl, m-Cl; R^1, R^2 = Me, Ph, m-ClC_6H_4.

The authors[149] noted the importance of the degree of hydration of the silica gel; for example, the reaction was appreciably retarded when the silica gel had been dehydrated beforehand for 48 h at 200 °C. When aluminium oxide was employed, the rate of reaction was also comparatively low.

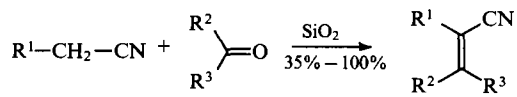


Iron(III) colloids deposited on silica gel can likewise catalyse certain hydrolytic reactions.[84]

The conversion of acetic acid into the amide by treatment with gaseous n-butylamine (200 °C in a stream of nitrogen) may be quoted as the simplest example of SiO_2-catalysed nucleophilic substitution,[150] but the yield of the amide in the presence of silica gel (87%) is lower than in the case where zirconium, titanium, and tin oxides are employed.

It has been established that carboxylic γ-, δ-, and ε-aminoacids are readily cyclodehydrated to the corresponding lactams on refluxing in toluene in the presence of silica gel or aluminium oxide.[151] In most cases their yields exceed 70%, quantitative yields being attained sometimes. For the optically active aminoacids (glutamic acid, lysine, and ornithine), appreciable racemisation is observed. The 'gas–solid phase' synthesis of 2,5-dioxopiperazines from aminoacids is similar in its essential chemical features.[153,152] It has been shown that aliphatic bifunctional aminoacids and proline undergo cyclodimerisation on sublimation in the presence of SiO_2 (170–220 °C) to cyclic dipeptides in 13%–81% yields (silochrome—a silica gel analogue obtained by the hydrothermal treatment of pyrogenic silicon dioxide—was used in the above studies). It has been suggested that the process mechanism involves the condensation of the carboxy-groups of the substrate and the surface silanol groups; the ester-type activated intermediate arising under these conditions is capable of condensing with the next aminoacid molecule attacking from the gas phase. The resulting dipeptide, chemically bound to the silicon dioxide, is readily split off from the surface, affording the corresponding symmetrical 2,5-diketopiperazine (Scheme 2).

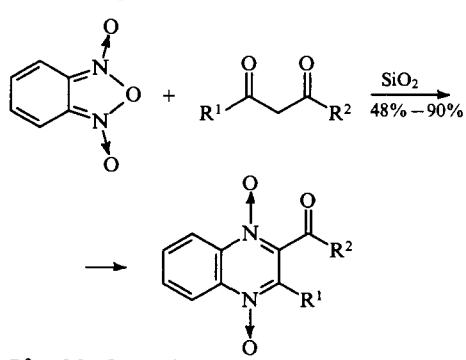
Scheme 2



R^1 = H, Me, Bu^s, Pr^i; R^2 = H;
R^1, R^2 = $-(CH_2)_3-$

It is of interest that, despite the fairly severe thermal conditions, appreciable racemisation of the aminoacid residues is not observed. On the grounds that the intermediates are surface-bound dipeptides (see Scheme 2), the authors[154] suggested that simple linear dipeptides can also be used as the initial reactants. Such modification of the 'gas–solid phase' method makes it possible to synthesise both symmetrical and asymmetric diketopeperazines in 40%–82% yields.

The synthesis of lactones with different ring sizes by the intramolecular cyclisation of carboxylic hydroxyacids has been patented.[155]

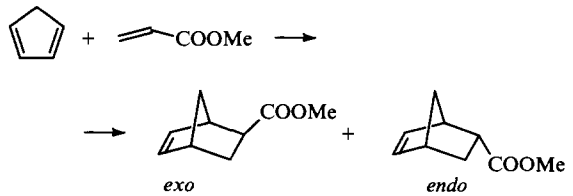


The reactions of carbonyl compounds with substrates containing an activated methylene unit (the Knoevenagel condensation) is accelerated in the presence of silica gel.[156]

R^1 = NC, O_2N, PhCO, *N*-Ac-L-Phe, *N*-Ac-L-Leu-L-Phe, *N*-Ac-L-Leu-D-Phe;
R^2 = H, Me; R^3 = Me, $HOCH_2$, HO(Me)CH, Ph, 4-$MeOC_6H_4$, 4-$Me_2NC_6H_4$, 4-$O_2NC_6H_4$, 2-$HOOCC_6H_4$, 3-MeO(4-HO)C_6H_3;
R^2, R^3 = $-(CH_2)_4-$, $-(CH_2)_5-$.

The interaction takes place when the reactants and the catalyst are mixed in methylene dichloride and lasts from 13 to 72 h. A necessary condition for the success of the synthesis is the presence of two strongly electron-accepting substituents in the methylene component.

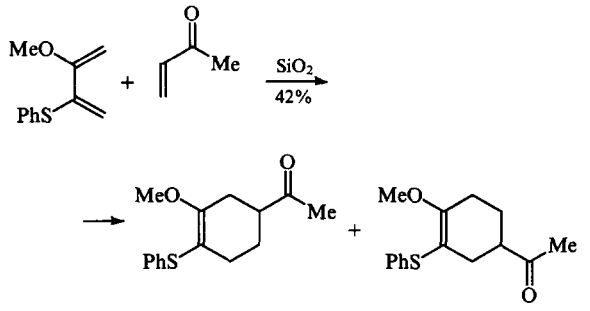
The reaction of benzofuroxan with 1,3-dicarbonyl compounds on the silica gel surface leads to the formation of 2,3-disubstituted quinoxaline 1,4-bisoxides.[157]



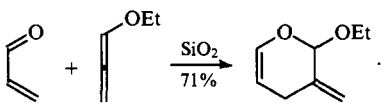
R^1, R^2 = Me, OMe, Ph, etc.

The reaction takes place in the absence of solvents for 1–2 weeks at room temperature. Its effectiveness depends on the acidity of the silica gel: more acid forms have better catalytic properties. The use of aluminium oxide gives rise to less satisfactory results, in particular, the formation of side products is observed.

8. Intermolecular cycloaddition reactions



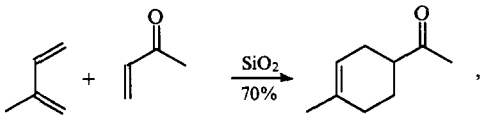
The Diels–Alder addition of the type



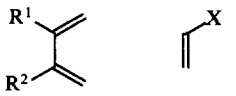
in the absence of a catalyst leads to a ~1 : 3 mixture of the *exo*- and *endo*-adducts. The adsorption of the dienophile on the SiO_2 surface makes it possible to alter their relative yields (10.5% and 87.5%); even better results are achieved when aluminium oxide is employed (2.9% and 93.7%).[158]

The Diels–Alder reaction between 1-acetoxybuta-1,3-diene and tetrafluoro-*p*-benzoquinone with formation of 5-acetoxy-2,3,4a,8a-tetrafluoro-4a,5,8,8a-tetrahydro-1,4-naphthoquinone on a silica gel column takes place at room temperature and is completed after 60 h,[159] whereas in the absence of a catalyst refluxing of the reactants in benzene is needed. The addition of *p*-benzoquinone as the dienophile takes place similarly, but the adduct eliminates acetic acid and the resulting dihydro-intermediate is dehydrogenated by the benzoquinone to 1,4-naphthoquinone (yield 87%).

The adsorption of a mixture of 2-methoxy-3-phenylthiobuta-1,3-diene and methyl vinyl ketone on the silica gel surface without a solvent and subsequent maintenance of the reactants for 24 h at room temperature lead to the formation of a mixture of adducts.[160]



The Diels–Alder cycloaddition of 1-ethoxypropa-1,2-diene to α,β-unsaturated carbonyl compounds proceeds especially effectively on the silica gel surface in the absence of solvents.[161] High yields are attained under relatively mild conditions (50–70 °C, 1–15 h). The following reaction may be quoted as an example:

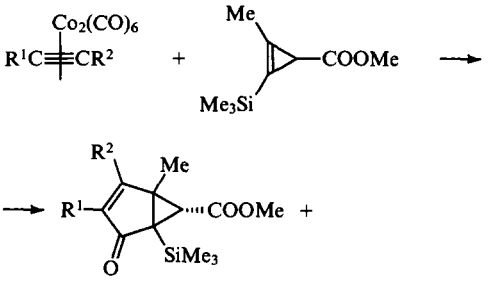


Since the dihydropyrans formed tend to polymerise on the acid centres of the surface of silicon dioxide, the latter was deactivated beforehand by treatment with triethylamine.

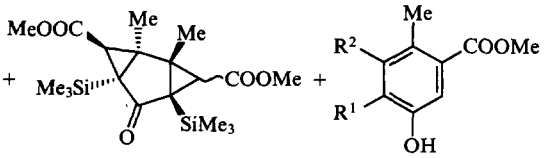
A similar approach in carrying out the [4+2]-cycloaddition reaction has been used by Vesselovskii and coworkers.[162,163] Depending on the nature of the diene component (butadienes, cyclopentadiene, furan, etc.) and the dienophile (methyl vinyl ketone, acrolein, methacrolein, crotonaldehyde, and ethyl vinyl ether), the synthesis was carried out at temperatures from −20 to 100 °C and lasted 0.5–14 h. For example, the cycloaddition

took place at room temperature. In an attempt to account for the mechanism of the promotion of the reaction, the authors postulated that adsorption may facilitate the formation (and possibly the stabilisation) of the prereaction complexes between the functional groups firmly fixed on the active surface centres; under these conditions, the absence of a solvent is a favourable factor.

Vesselovskii et al.[164] used chromatographic silica gel, dried beforehand at 200 °C, as the catalyst of the Diels–Alder reactions and other [4+2]-cycloaddition reactions involving substituted butadienes **29**, cyclopentadiene, and cyclohexadiene, as well as the dienophiles **30**.



29 **30**

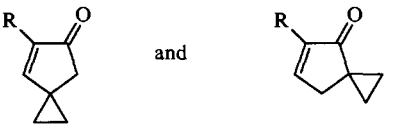


$R^1 = R^2 = H$, Me;
$R^1 = H$, R^2 = Me, $Me_2C{=}CH(CH_2)_2$;
X = CHO, COMe, COOMe.

The adducts were formed stereoselectively with yields up to 92%.

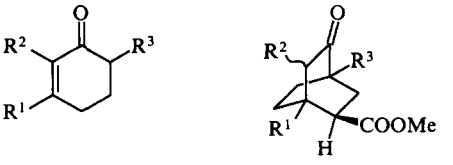
The [2+2+1]-cycloaddition reactions involving cyclopropenes and ethynecobalt hexacarbonyl complexes, described by Kireev et al.,[165] lead to a mixture of three products.

31



32

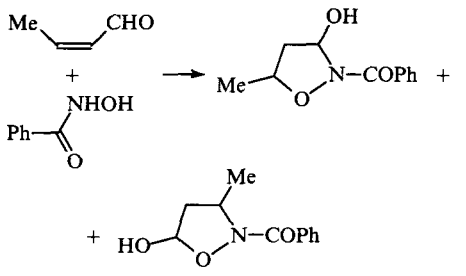
$R^1 = R^2 = H$, Me;
R^1 = Ph, R^2 = H.



When silica gel was used as the catalyst of this reaction, the product **31** was found to predominate, whereas in the presence of the NaX zeolite mainly compound **32** was formed.

The silicon dioxide-catalysed Khand–Pauson addition[166] of methylenecyclopropane to ethyne and its methyl-, phenyl-, and cyclopropyl-substituted derivatives leads to a mixture of two products, *viz.*

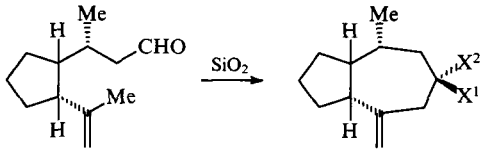
in proportions of (4.4.–6):1. The addition of methylenecyclobutane proceeds similarly.[167]



The regio- and stereo-selective Michael addition of methyl acrylate to the cyclohexenone derivatives **33** with subsequent silylation in situ and cyclocondensation in the presence of silica gel at room temperature results in the formation of the bicyclooctanone derivatives **34**.[168,169]

33 **34**

R^1 = H, Me, OMe, Bu, $CH{=}CH_2$;
R^2, R^3 = H, Me.

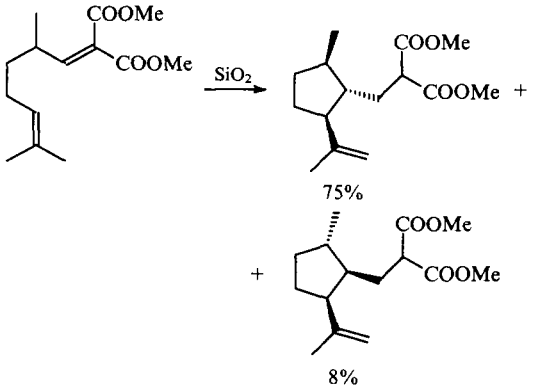


The reaction of phenylhydroxamic acid with crotonaldehyde in methanol leads to a mixture of *N*-substituted 3- and 5-hydroxyisoxazolidines.

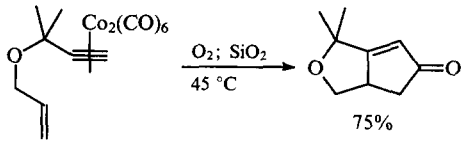
The dominant product is the first isomer. The rate of this reaction increases significantly when it is carried out on an adsorbent without a solvent.[170] Best results were obtained when silica gel was employed: the reaction was completed in 30–40 min with the exclusive formation of the 3-hydroxy-derivative (yield 80%–90%).

9. Other cyclisation reactions

Silica gel may serve as an effective catalyst of the cyclisation of unsaturated carbonyl compounds. The cyclisation at atmospheric pressure was investigated in early studies.[171–173] For example, chromatography on a silica gel column proved to be the simplest procedure for the cyclisation of the aldehyde **35** and its stereoisomers to the epimeric bicyclic alcohols **36**,[173] whereas the analogous reaction in a homogeneous system required the treatment of the aldehydes with tin(IV) chloride in benzene.



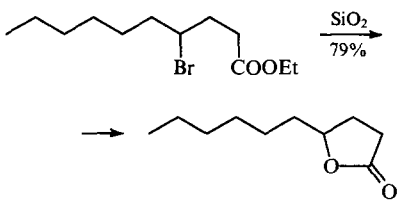
35 **36**



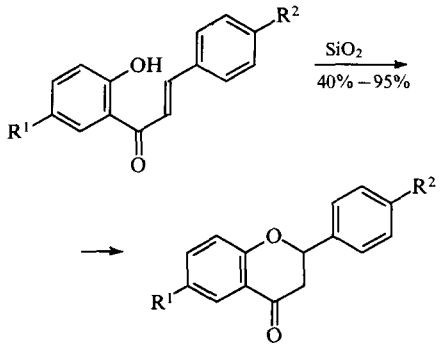
X^1 = H, X^2 = OH (86%);
X^1 = OH, X^2 = H (2%).

It has been shown in the syntheses of a series of five- and six-membered carbocycles that the effectiveness of the process increases significantly when it is carried out under a pressure of 15 kbar (solutions in methylene dichloride, 1.5–53 h, 25–60 °C). In individual instances, a fairly high stereoselectivity was noted.

The thermolysis of the adsorbed substrate in a stream of

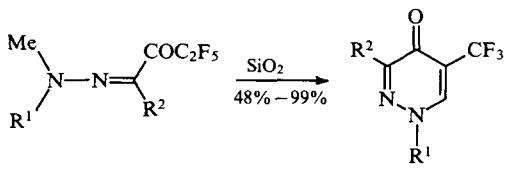


oxygen has been proposed as a general method for the promotion of the Khand–Pauson cyclisation of dicobalt hexacarbonyl complexes of allyl propargyl ethers to derivatives of 3-oxabicyclo[3.3.0]oct-5-en-7-one.[175–177]



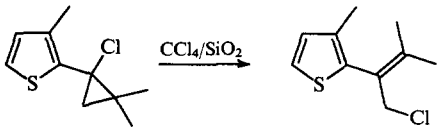
The reactions were completed in 30 min and the yields of the products were 46%–92%. Apart from silica gel, aluminium oxide may be used with different degrees of success and it has therefore been concluded[175–177] that the promoting effect should not be attributed to the specific surface properties of the oxides. The adsorption process itself probably influences the conformation of the initial compound: the attraction of the ether groups to the polar surface centres and the simultaneous repulsion from them of the hydrophobic fragments promote the mutual approach of the latter and a lowering of the entropy barrier.

The lactonisation of γ-haloethers on refluxing them in xylene for 3–15 h has been described (yields greater than 60%).[178]



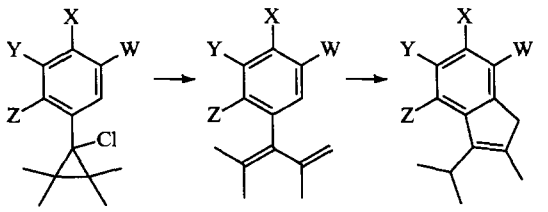
Bis-γ-butyrolactones can also be obtained by this procedure.

The intramolecular cyclisation of 2′-hydroxychalcones in the presence of silica gel (and also of ethylenediamine or the hydrochloride of hydroxylamine) affords flavones.[179]



R^1 = H, Me, Cl; R^2 = H, MeO.

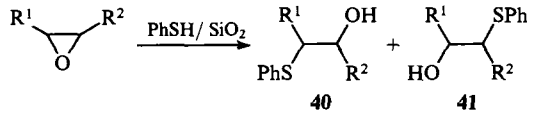
The cyclisation of 1,1,1,2,2-pentafluoroalkane-3,4-dione 4-dialkylhydrazones on silica gel (70–90 °C, 6–48 h) is a convenient method of synthesis for 5-(trifluoromethyl)-4-pyridazinones.[180]



10. The opening of three-membered rings

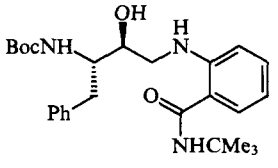
The opening of the ring in chlorocyclopropanes in the presence of silicon dioxide, leading to the formation of dienes or allyl halides, has been investigated.[181–183]

On the other hand, in the case of 1-aryl-1-chloro-2-methylcyclopropanes **37**, silica gel in carbon tetrachloride catalyses the tandem opening of the three-membered ring accompanied by cyclisation to the indenes **39**.[184]



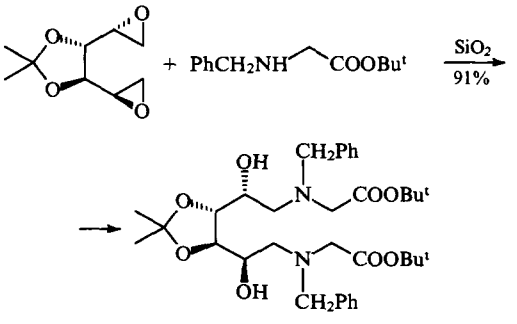
37 **38** **39**

W, X, Y, Z = H, OMe, etc.



The reaction proceeds at room temperature for 18 h (yields 63%–100%) and in some cases stops at the stage involving the formation of the intermediate dienes **38**, which may be isolated in 33%–90% yields.

The opening of epoxide rings on treatment with thiophenol in the presence of silica gel leads to the α- and β-adducts **40** and **41**.[185–187] In the case of α,β-epoxysilanes, the reaction takes place regioselectively and the isomers **40** are formed in 72%–98% yields.

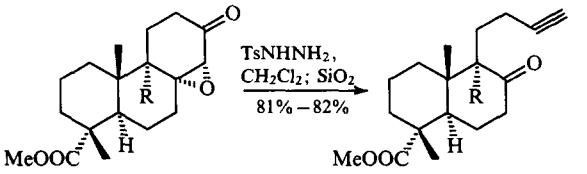


40 **41**

The formation of intermediates of the type

via the silica gel catalysed aminolysis of epoxides by anthranilic acid derivatives was the key stage in the synthesis of new inhibitors of HIV proteases.[188]

The aminolysis of certain epoxides by *tert*-butyl *N*-benzylglycinate in the presence of silica gel as the acid catalyst has been used as a convenient method of synthesis of the corresponding *N*-(β-hydroxyalkyl)glycine esters (in the absence of silica gel, a mixture of regioisomers was isolated).[189]

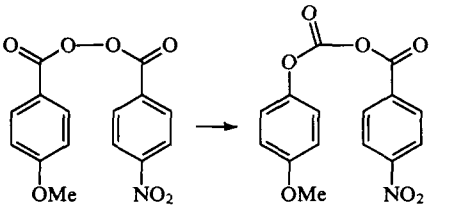


The synthesis was carried out in two ways:

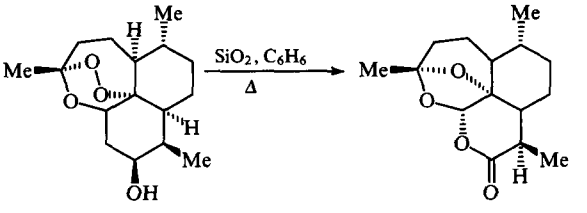
(1) the reactants and the catalyst were kept in methylene dichloride for 1–1½ days under a pressure of 10 kbar and a temperature ranging from room to 65 °C

(2) the reactants were deposited on silica gel and allowed to stand at room temperature for 1–6 days.

Best results were obtained in the second case. According to preliminary data, aliphatic amines may be used as the nucleophiles.

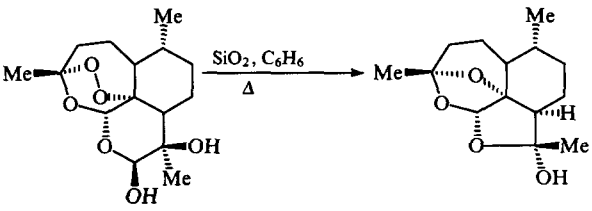


It has been shown that silica gel is an effective catalyst for the opening of the ring in α,β-epoxycycloalkanones by tosylhydrazine (the Eschenmoser reaction).[190] The reaction takes place under fairly mild conditions (at a temperature not exceeding room temperature), high yields (up to 96%) of the products [hept-6-yn-2-ones and 2-(3-butynyl)cycloalkanones] being attained even for relatively unreactive substrates of the type of podocarpanones (R = H, OH).



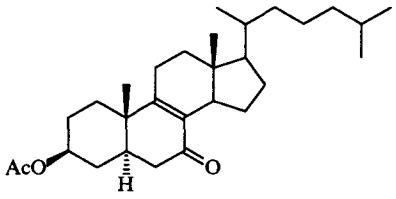
It has been noted that the catalytic effect of silicon dioxide is manifested not only in the formation of the intermediate tosylhydrazone but also in the course of its fragmentation to give the final acetylenic ketone.

11. The decomposition of peroxides

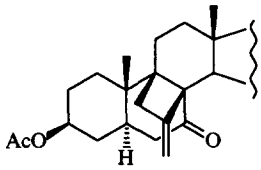


Silica gel is known to catalyse the decomposition of organic peroxides.[191–193] The reaction accelerating factor in the decomposition of di(β-phenylpropionyl), di(β-phenylisovaleroyl), and *p*-nitrobenzoyl β-phenylisovaleroyl peroxides on the silica gel surface reaches 160 relative to the analogous reactions in homogeneous systems. The rate of decomposition of *p*-methoxybenzoyl *p*-nitrobenzoyl peroxide increases by five orders of magnitude in the presence of silica gel.

Interesting reactions of dihydroartemisin **42** and 11β-hydroxy-11-epidihydroartemisinin **44**, leading to the formation of compounds **43** and **45** respectively, have been described.[194] The reactions take place on refluxing in benzene (6 h and 10 min respectively) in the presence of silica gel.

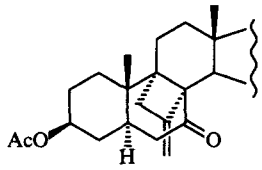


42 **43**

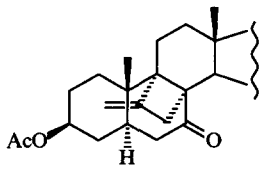


44 **45**

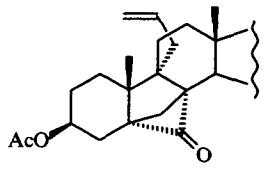
12. Photochemical reactions



The specific features of the photochemical cycloaddition of enones to allene have been investigated.[195] It was established that, in the case of the steroid enone **46** adsorbed on silica gel, the process is partly displaced towards the more sterically hindered β-addition, leading to the derivative **47**, together with the formation of the α-adducts **48** and **49** and the rearrangement product **50**.



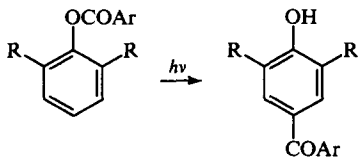
46



47

48

49



50

For the series of other, simpler examples of the enone – allene photocycloaddition, it was shown that the formation of the β,γ-adducts, which is preferred to homogeneous systems, becomes a minor process on the silica gel surface and the main products are the γ,δ-regioisomers.

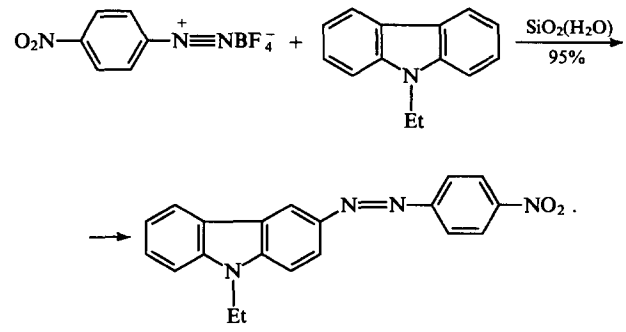
The reactions involving the photocycloaddition of alkenes and allene to α,β-unsaturated steroid ketones have been investigated similarly.[196,197] In this case, the adsorption of the ketone on silica gel or aluminium oxide promotes the occurrence of the more sterically hindered β-addition, while α-addition is characteristic of the reaction in homogeneous systems.

The yield of the products of the Fries photorearrangement

R = Me, Pr^i; Ar = Ph, 2,4,6-$Me_3C_6H_2$.

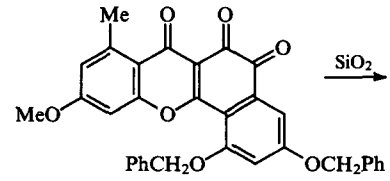
increases from 5%–9% to 23%–70% after the introduction of silica gel into the reaction mixture, best results being attained in the absence of solvents.[198]

Like ozone, the forms of oxygen generated by microwave discharge in oxygen and carbon dioxide atmospheres are effective oxidants for organic compounds.[199,200] At 0 °C, the oxidation of alkenes adsorbed on silica gel affords mainly epoxides and carbonyl compounds, as in homogeneous systems; at temperatures below −60 °C, ozonolysis products are formed. Consequently the microwave discharge in an oxygen atmosphere at low temperatures can be regarded as an oxidation method which is an alternative to dry ozonisation; the comparatively slow formation of ozone, ensuring more selective oxidation, may be included among the advantages of the first method.



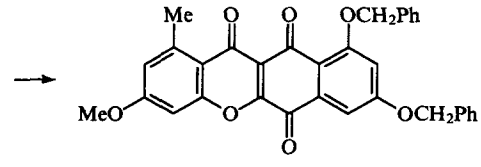
UV irradiation (λ = 350 nm) in the presence of molecular oxygen is also an effective oxidation method. Substituted phenylethenes adsorbed on silica gel are selectively cleaved to ketones or aldehydes under these conditions.[201]

Overall, despite the fact that extensive information has accumulated on the photochemistry of adsorbed molecules (see, for example, the review of de Mayo and Johnston[202]), the experimental data obtained are rarely employed for synthetic purposes.



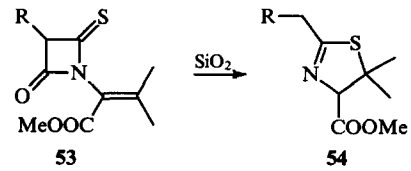
13. Various reactions

The oximes of toluene *p*-sulfonates may be converted into the corresponding amides (the Beckmann rearrangement) by stirring with silica gel at room temperature (yields 45%–90%).[203] The isomerisation of nontosylated aldoximes[204] on silica gel takes place on refluxing in xylene for 52–73 h, the yields amounting to 61%–93% for acetaldehyde derivatives and substituted benzaldehydes.



Silica gel facilitates azocoupling,[205] especially in the presence of small amounts of water (4%). The following reaction may serve as an example:

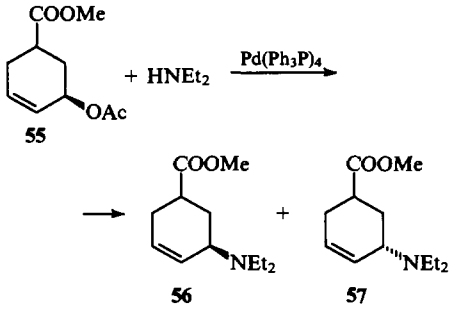
The unusual rearrangement of compound **51** to compound **52**, which takes place almost quantitatively, has been reported.[206]



51

52

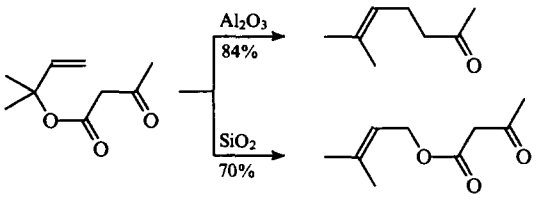
Treatment of the thiomalonimide **53** with a suspension of silica gel in chloroform gives rise to the thiazoline **54** also in an almost quantitative yield.[207]



53 **54**

It has been suggested that the first stage of the rearrangement is the hydrolysis of the lactam **53** by the water adsorbed on silica gel.

The instance where silica gel functioning as the carrier for another catalyst nevertheless influences the stereospecificity of the process must be mentioned.[208] The homogeneous reaction of



diethylamine with 5-methoxycarbonylcyclohex-3-enyl acetate **55** in the presence of tetrakis(triphenylphosphine)palladium gives a 67 : 33 mixture of the stereoisomers **56** and **57** in 85% yield. On the other hand, when the palladium catalyst is immobilised on silica gel, the only product is compound **56** (yield 72%).

An interesting approach to the creation of stereospecific catalysts has been proposed.[209,210] Chiral cavities, capable of catalysing enantioselective solvolysis (for example, 2,4-dinitrophenolysis) of the mixed anhydride of *N*-benzyloxycarbonyl-L-alanine and benzoic acid, were produced on the silica gel surface with the aid of the optically active *N*-benzoyl-(*N*-α-benzoyloxycarbonyl)-L-alanine amide. This series of studies will not be discussed in detail here because the chiral cavities possess catalytic properties only after the silica gel has been doped with aluminium ions in order to create active Lewis acid centres. Nevertheless, one may expect that this approach may prove applicable to other types of organic reactions catalysed by unmodified silicon dioxide.

Silica gel pretreated with thionyl chloride has been used as an effective catalyst of the thioacetalisation of aldehydes to give 1,3-dithiiranes and 1,3-dithianes (unmodified silica gel did not exhibit an appreciable activity).[211] On treatment with thionyl chloride, the adsorbed water is apparently removed and some of the surface silanol groups are converted into chlorosilyl groups.

In contrast to those cases where the behaviour of silicon and aluminium oxides is in general similar, chromatographic aluminium oxide catalyses the Carroll rearrangement, while the use of silica gel as the catalyst leads to the isomerisation of the alcoholic component of the initial acetoacetic ester.[212]

The last reaction proceeds on heating (60 °C) for 2–5 h.

Silica gel catalyses nucleophilic substitutions with thiocyanates.[213] For example, 1,2-epoxydecane cannot be converted into the corresponding epithio-derivative by treatment with finely ground potassium thiocyanate in toluene at 90 °C, whereas the introduction of silica gel into the reaction mixture ensures a quantitative yield of the thiirane. Best results are achieved in the presence of a small amount of water. Alkyl thiocyanates can be obtained similarly from haloalkanes, but this time preferably in the absence of organic solvents.[214] Silica gel proved to be the most active catalyst among the inorganic oxides investigated by the author.

III. Conclusion

The data examined in the present review show that the presence of chemically unmodified silicon dioxide (usually silica gel) can influence significantly the occurrence of a wide variety of organic reactions. Because of this, it has been frequently used for synthetic purposes in the oxidation (including dry ozonisation), reduction, alkylation and acylation, halogenation, elimination, hydrolytic and dehydration reactions of organic compounds, intermolecular cycloaddition reactions, and other reactions involving the formation of cyclic products as well as the opening of three-membered rings, the decomposition of peroxides, certain photochemical reactions, rearrangements, etc. The studies which have been carried out are largely phenomenological in character; in most cases, the principal or in general the only task was the attainment of the maximum yields of the target products. On the other hand, detailed information on the mechanism of the majority of the heterogeneous processes is not as yet available. Because of this, serious generalisations concerning the characteristic features of the influence of silicon dioxide on the reactions are at present impossible. On the basis of the available data, one can only reach the general conclusion that the silicon dioxide surface can function as a catalyst, as a solid medium for reactions (solid solvent), and/or as a matrix influencing the stereospecificity. In many cases, it is impossible to define clearly the role which the surface plays.

On the other hand, an unambiguous interpretation of the role of silicon dioxide as the catalyst can be found in by no means all publications describing clearly catalytic processes. It has been stated that silicon dioxide exhibits a catalytic activity in the reactions involving the oxidation of organic sulfides by sulfuryl chloride, the formation of sulfides and disulfides on treatment of aromatic compounds with RSCl, $RSCH_2Cl$, and S_2Cl_2, the reduction of aldehydes and ketones by tributyltin hydride, the alkylation and acylation of aromatic alcohols and phenols, the introduction of halogen atoms into an aromatic ring and the addition of hydrogen halides to alkenes, the dehydration of aminoacids, the Knoevenagel condensation, the Diels–Alder addition, cycloaddition and cyclisation, the opening of three-membered rings, the decomposition of peroxides, and certain other reactions.

Attempts to explain the mechanisms of the catalytic processes have been undertaken only for reactions involving the reduction of aldehydes and ketones by tributyltin hydride, the addition of hydrogen halides to double bonds, the cyclodimerisation of aminoacids to cyclic dipeptides, the Diels–Alder addition, and the Khand–Pauson cyclisation. In a number of instances, it has been stated that the degree of hydration of the silicon dioxide influences significantly the effectiveness of the process {for example, the introduction of halogen atoms into an aromatic ring, the addition of hydrogen halides to alkenes, the deketalisation of the products of the reactions of α-ketoketals with Wittig reagents, the hydrolysis of the diethyl acetals of (*Z*)-α,β-unsaturated aldehydes, the synthesis of acylsilanes by heating α,α-dibromobenzylsilanes, and the Diels–Alder reactions [(4 + 2)-cycloaddition], as well as nucleophilic substitution with participation of thiocyanates}. However, no general rules can be traced, since, overall, the state of the surface has different effects on different reactions. Only for the hydrolytic and hydration processes can one reach the unambiguous conclusion that the addition of water to the system should have a positive influence on the hydrolysis and conversely.

In the second case (silicon dioxide as a solid solvent), one may restate briefly that the chemistry of the silicon dioxide surface does not itself exert a significant influence on the course of organic reactions; the decisive factor is that the reactants become concentrated on the adsorbent surface and not the nature of the latter. This has been confirmed by instances of the successful employment of other inorganic oxides (for example Al_2O_3) together with silica gel. Adsorption can apparently facilitate the formation and/or stabilisation of the prereaction complexes between the functional groups of the reactants strongly fixed on the active surface centre; a favourable factor under these conditions is the absence of a liquid solvent.

Similar general considerations may prove legitimate also in the explanation of the role of silicon dioxide as a matrix

influencing stereospecificity. The results of various studies (in particular, on dry ozonisation) make it possible to claim that, by carrying out the reactions in adsorbed monolayers, it is possible in certain cases to increase the regioselectivity by means of the mutual orienting influence of the substrate molecules. Other carriers can apparently be used with equal success; however, unfortunately the limited number of literature data available at present makes it impossible to either confirm or reject the latter hypothesis.

The author expresses his indebtedness to the National Council on Science and Technology of Mexico (CONACyT) for the financial support in the writing of this review (Research Grant 4282-E and Individual Grant 930021).

Abstract. The interactions of organic nitriles with various electrophiles are analysed. It is shown that the numerous processes observed in such reactions are fairly general and are largely controlled by the nucleophilic properties of the nitrile. The bibliography includes 99 references.

I. Introduction

The nucleophilic properties of nitriles are due to the lone pair of the nitrogen atom and the π-electron system of the C≡N triple bond:

This leads to two possible directions of electrophilic attack and the formation of either the *n*-complexes **1** or the π-complexes **2** as the primary products.[1–3] The direction of the primary attack by the electrophile depends on its nature, the structure of the nitrile, and the reaction conditions. For example, quantum-chemical calculations and experimental data obtained by photoelectron and X-ray electronic spectroscopy constitute evidence that the highest occupied orbital of acetonitrile is a molecular π orbital, whilst the orbital occupied by the lone pair is located in a lower position.

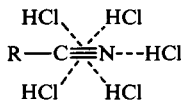
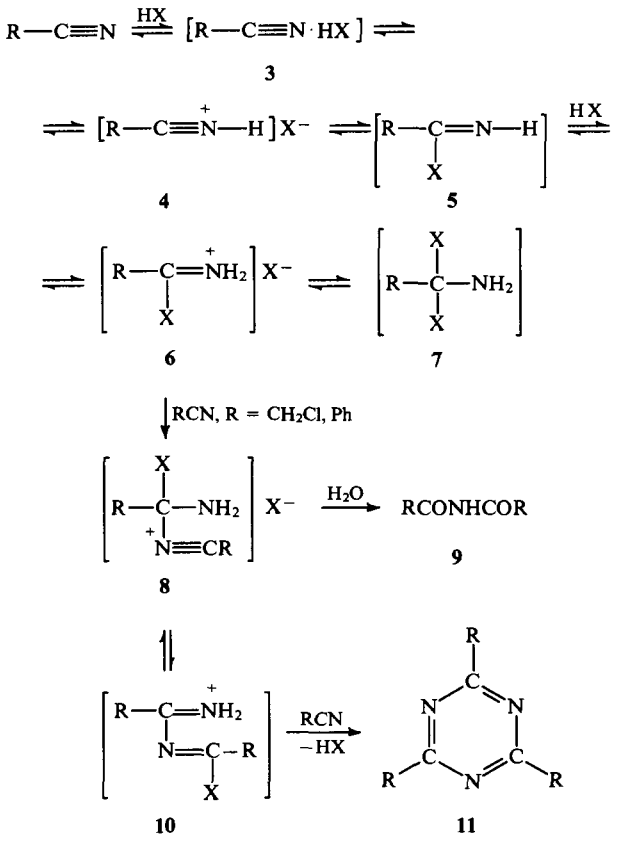
In the case of benzonitrile, the π orbitals of the benzene ring have the highest energies.[4]

Hence it follows that the primary product of the charge-controlled reaction of acetonitrile with an electrophile should be a π-complex.[5] However, as a result of the influence of a whole series of factors on the populations of the orbitals, such considerations are difficult to generalise and their value is therefore small. Furthermore, only one π-complex of a nitrile with an accurately established structure is known at the present time.[3] Nevertheless, we shall see below that the wide variety of primary products, observed in the interaction of nitriles with electrophiles, can be accounted for only by resorting to the concept of the formation of π-complexes.



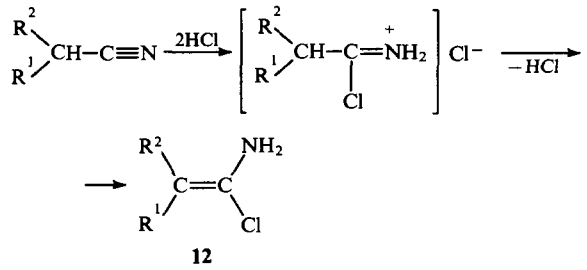
II. Interaction of nitriles with protic acids

Since protic acids catalyse a whole series of reactions of nitriles, the question of the structure of the primary products of the interaction of the latter with protic acids has been widely discussed in the literature.[1–3,6–21] Although it is regarded as generally accepted that nitriles can react with acids to form molecular π-complexes in which the proton retains its linkage with the acid anion, we are aware of only one study in which such interaction has been discussed in detail.[6]



As a result of the study of the fusion diagrams for binary mixtures of hydrogen chloride with acetonitrile, propionitrile, and benzonitrile, it has been shown[6] that these nitriles can form readily fusible molecular compounds RCN·HCl. The authors[6] suggest that the lone pair of the nitrogen atom of the nitrile group participates in the formation of these compounds. The same nitriles can form the molecular compounds RCN·5HCl, RCN·7HCl, and 2RCN·3HCl with lower melting points than the compounds RCN·HCl.

Compound	T_m/°C	Compound	T_m/°C
MeCH·HCl	−63.2	2EtCH·3HCl	−117.0
2MeCN·3HCl	−88.0	EtCN·5HCl	−129.0
MeCN·5HCl	−123.6	PhCN·HCl	−80.6
MeCN·7HCl	−125.0	PhCN·5HCl	−130.0
EtCN·HCl	−97.2	2PhCN·3HCl	−109.0



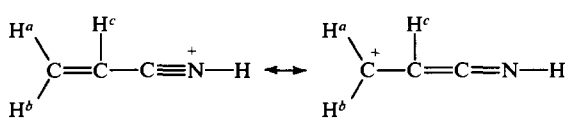
It has been suggested that these compounds are formed as a result of the interaction of HCl with the π-electron system of the nitrile, i.e. they are π-complexes.

At room and higher temperatures, nitriles react with protic acids to form salt-like compounds capable of dissociating in solution into ions, which is indicated by the results of conductimetric measurements[1,7,8] and cryoscopic studies.[9] The information accumulated hitherto makes it possible to represent all the possible products formed in the interaction of nitriles with acids in terms of the following scheme:

Although, as already noted, the formation of type **3** molecular complexes has been discussed in detail only by Murray and Schneider,[6] it is believed that this is the first stage of the interaction of nitriles with any protic acid. The formation of NH-nitrilium salts **4** has been postulated in the study of a series of acid-catalysed reactions of nitriles.[1,10,11] Indeed, in the hydrolysis of nitriles to amides or in the Hoesch reaction (acylation of phenols by nitriles), the intermediate formation of NH-nitrilium salts appears essential. However, low equilibrium concentrations of the salts **4** are sufficient for this purpose and it appears that in the case of nucleophilic anions (Hal^-, OSO_3H^-, $H_2P_2O_7^-$) the anion adds to the nitrile carbon atom with formation of type **5** compounds.[9,12] However, they are extremely unstable and the reports about the synthesis of imidoyl chloride **5** (X = Cl^-) were found to be erroneous.[1,13] The halo- and polyhalo-derivatives of immonium halides **6** (X = Hal^-, Hal_2H^-) have been isolated in a pure state and their structure has been confirmed by elemental analysis and IR spectroscopic data.[12,14,15] The same workers note that the isomeric aminochloro-derivatives **7**, the formation of which has been postulated,[13] cannot be isolated when nitriles interact with HCl. The formation of the neutral compounds **12** in the case where nitriles containing α-protons were introduced into the reaction with HCl [16] showed that the main product present in the mixture of the nitrile and HCl is the immonium halide salt.

12

The reaction of α-halonitriles with acids does not stop at the immonium salt **6** stage. It has been shown[9,11,17–20] that a second nitrile molecule is added with formation of the dimer salts **8** or **10**. A choice between these two structures cannot at present be made, but the formation of the dimer salts has been confirmed by the hydrolysis to the diacylamides **9**. The trimerisation of nitriles with electron-accepting substituents is also possible, leading to the formation of the triazines **11**. However, under the conditions of the interaction of nitriles with protic acids, this reaction proceeds to only an insignificant extent.



It has been observed in the reaction of fluoro- and bromo-acetonitriles with HCl [21] that, depending on the temperature, both the halo-derivatives of the immonium halides **6** and the dimer salts **8** can be obtained from the same nitriles. The former are formed at temperatures from −50 to −5 °C and the latter at room temperature. Unstable complex compounds are apparently formed initially. At a low temperature, these compounds are stabilised by the addition of a hydrogen halide molecule with formation of a halo-derivative of the immonium halide **6**. At a higher temperature, the unstable molecular complexes decompose, which increases the concentration of the free nitrile and ultimately leads to dimerisation to type **8** salts.[1]

The formation of type **4** NH-nitrilium salts can be observed in superacid media. Olah and Kiovsky[22] investigated protonated nitriles by ^1H, ^{13}C, ^{15}N NMR spectroscopy in solution in $FSO_3H-SbF_5-SO_2$ at lowered temperatures.

The presence of protonated nitriles under the given conditions is indicated by the existence of spin–spin coupling of the proton attached to the nitrogen atom with the protons of the alkyl group in the nitrile. For example, the signal of the methyl group in the protonated acetonitrile is a doublet (δ = 3.25 ppm) with $^4J_{H-H}$ = 2.4 Hz, which is comparable in magnitude to the analogous constant for methyl-ethyne (2.9 Hz). In the ^{13}C NMR spectrum of the protonated [^{13}C]acetonitrile, the signal of the nitrile carbon atom is displaced downfield by 10 ppm relative to the signal of acetonitrile, but the chemical shift nevertheless indicates the retention of *sp* hybridisation of this carbon atom.[22]

An appreciably greater downfield shift of the H^a and H^b protons than for the H^c proton (1.5 and 0.6 ppm respectively) is observed in the ^1H NMR spectrum of the protonated acrylonitrile. This apparently indicates appreciable delocalisation of the carbonium ion centre in protonated unsaturated nitriles.

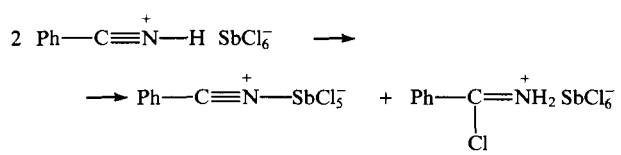
It is interesting to note that Olah and Kiovsky[22] were unable to achieve the protonation of nitriles by fluorosulfonic acid, which they attribute to the insufficient acidity of the medium in

the given instant. This fact makes it necessary to treat with caution reports about the preparation of type **4** NH-nitrilium salts by the interaction of nitriles with even weaker acids.

The formation of NH-nitrilium salts on dissolution of trifluoromethanesulfonic acid in nitriles has been reported.[11]

4a

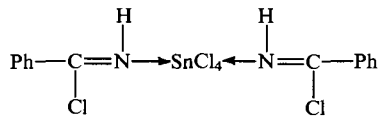
R = Me, Pr, Ph.



Nitrilium trifluoromethanesulfonates **4a** were isolated from solution in the form of a red oil. The IR spectra of these compounds show a 50 cm^{-1} hypsochromic shift of the $\nu(C\equiv N)$ vibrational frequency compared with the free nitriles, which led the authors[2] to attribute to them the structure of the nitrilium salts **4**. However, other data confirming this hypothesis are not quoted. Solutions of trifluoromethanesulfonic acid in nitriles are able to interact with phenols and their ethers via a reaction analogous to the Hoesch reaction.[11] After 20–30 days, the yields reach 70%–80% and acylation takes place in the *para*-position.

R = Alk, Ph; R′ = Me, Pr.

Halonitriles dimerise on treatment with CF_3SO_3H, which indicates the fundamentally similar nature of the interaction of nitriles with various protic acids.



It is also essential to mention the NH-nitrilium salts with complex anions. The synthesis of such compounds has been reported in a number of communications.[1,12,14] The most detailed study[12] showed that the formation of the nitrilium salt **4** ($X = SbCl_6^-$) is not observed in the interaction of HCl with the complex $PhCN-SbCl_5$, which the authors attribute to the instantaneous disproportionation of the salt.

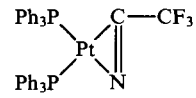
The only NH-nitrilium salt which it has been possible to isolate is apparently compound **13**. It has been shown by conductimetric measurements that it is not the donor–acceptor complex **14**.[12]

13

14

However, the salt **13** also disproportionates above 50 °C.

A recent investigation of the Houben–Hoesch reaction showed[23] that the most probable species undergoing acylation is the dication



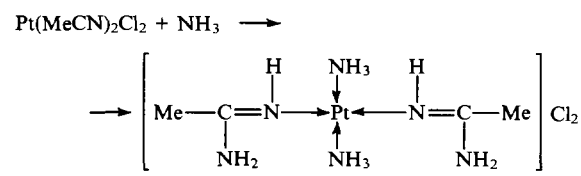
This hypothesis has been confirmed by the fact that the monocationic reagent *N*-methylbenzonitrilium triflate reacts with benzene only in the presence of an acid as strong as the $CF_3SO_3H-SbF_5$ mixture, whereas trifluoroacetic acid does not catalyse the process at all. Trifluoromethanesulfonic acid without added SbF_5 has only a slight catalytic effect.

It is also of interest to note that the complexes of nitriles with $FeCl_3$ and $AlCl_3$ do not react with HCl at all even at temperatures above 120 °C.

Thus the principal types of interaction of nitriles with protic acids are the formation of the immonium salts **6** in the case of aliphatic nitriles and the formation of the dimer salts **8** in the case of aromatic and α-halo-substituted nitriles. The formation of NH-nitrilium salts **4** can be detected only in superacid media for aliphatic nitriles.

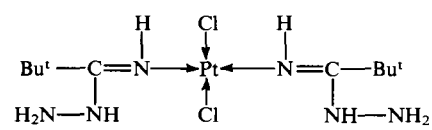
III. Coordination of nitriles to transition metals

It has been suggested that in the complexes of nitriles with transition metals there is a possibility of interaction of the acceptor (the metal ion) both with the π-electron system of the triple bond of the nitrile and with the lone pair of the nitrogen atom.[3] In the IR spectrum of compound **15**, the frequency $\nu(C\equiv N)$ is 1780 cm^{-1}, which is 350 cm^{-1} lower than in the initial nitrile.



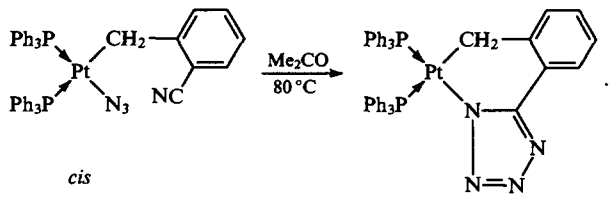
15

Such a low stretching vibrational frequency has been attributed to the formation of a π-complex with the platinum atom.



For the majority of the complexes between nitriles and transition metals, X-ray diffraction studies have shown that the MNC angle is close to 180°, whilst the length of the $C\equiv N$ bond diminishes on coordination to the metal atom,[24] i.e. its strength increases. The frequency $\nu(C\equiv N)$ increases under these conditions by 50–300 cm^{-1}.[4,25,26] However, despite this, the coordinated nitriles have enhanced electrophilic properties, which is reflected in a number of reactions.

For example, coordinated nitriles interact much more readily with amines and other nitrogen bases than the free nitriles. The nitrile complexes are converted quantitatively into amidine complexes at room temperature.[27]



Similar reactions have been observed for the complexes $Re(RCN)_2Cl_4$ (R = Me, Ph) and a series of aromatic amines.[27]

It has been shown[28] that nitriles may be converted into amidines on treatment with hydrazine. The interaction of *trans*-$Pt(Bu^tCN)_2Cl_2$ with hydrazine hydrate in solution in ethanol leads to the formation of complex **16**.

16

An interesting example of intramolecular cyclisation has also been observed:[29]

cis

Such cyclisation does not occur when the initial complex is the *trans*-isomer.

The catalytic effect of transition metal ions on the rate of hydrolysis of nitriles, noted in a number of investigations,[29-31] has been attributed to the intermediate formation of nitrile complexes with subsequent conversion of the inner-sphere nitriles into the amides of the corresponding acids.[3] It is also believed that the facilitation of the reactions with nucleophiles when the nitrile is coordinated to a transition metal atom is associated with the decrease in the electron density on the nitrile carbon atom as a consequence of its displacement towards the central atom.[3,32]

It has been noted[4,33] that the introduction of strongly electron-accepting substituents into the nitrile molecule may alter the nature of its participation in complex formation, transforming it from an electron-donating to an electron-accepting component. For example, in the formation of complexes between nitriles and electron acceptors containing a central metal atom with populated *d* orbitals (Rh, Ru, Co, Mo), the transfer of electron density from the nitrile group to the metal may be accompanied by the additional formation of a donor–acceptor bond as a result of the interaction of the electrons of the metal *d* orbitals and the unoccupied π^* orbitals of the nitrile.[4] The participation of the π MO of the nitrile in the η^5-cyclopentadienylmanganese dicarbonyl and phosphine-molybdenum dicarbonyl complexes of nitriles has been demonstrated by electronic spectroscopic methods.[34,35] The intense charge-transfer band at $\lambda \approx 500$ nm, observed in the electronic spectra of these compounds, constitutes, according to Michurin et al.,[4] definite confirmation of the manifestation of π-electron-accepting properties by the nitrile in these complexes.

The π-electron-accepting properties of nitriles are exhibited also in complexes of the type Et_3N-SO_2-RCN, where $R = CCl_3$ or p-$NO_2C_6H_4$. The appreciable bathochromic shift of $\nu(C\equiv N)$ (by 20–30 cm^{-1}) in the IR spectra of these compounds indicates the transfer of electron density to the antibonding π MO of the nitrile.[36]

IV. Interaction of nitriles with Lewis acids

Nitriles are extremely effective electron donors in complex formation with Lewis acids.[4] The formation of complexes can be detected even for weak Lewis acids such as the halogens and interhalogen compounds.[37-39] It was shown in the above studies by UV spectroscopy that the equilibrium constants for the complex formation reactions between nitriles and the halogens increase in the sequence $Br_2 < I_2 <$ IBr < ICl. An increase in the equilibrium constant is favoured also by an increase in the electron-donating capacity of the hydrocarbon group in the nitrile.[37-39]

The complexes of nitriles with metal halides have been thoroughly investigated. They are formed on simple mixing of the reactants and can be readily isolated in a pure form and characterised. Table 1 shows that the hypsochromic shift of the $\nu(C\equiv N)$ vibrational frequency is observed in all the complexes of nitriles with metal halides, which is a common phenomenon for all the complexes of nitriles whose formation involves the lone pair of the nitrogen atom.[4]

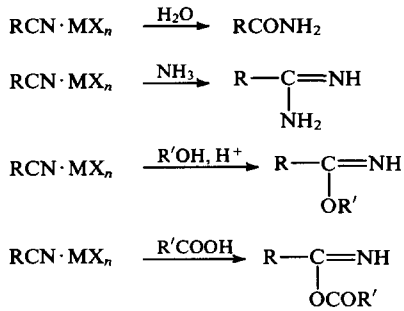


Table 1. The quantities $\nu(C\equiv N)$ and $\Delta\nu$ for the complexes of nitriles with Lewis acids.

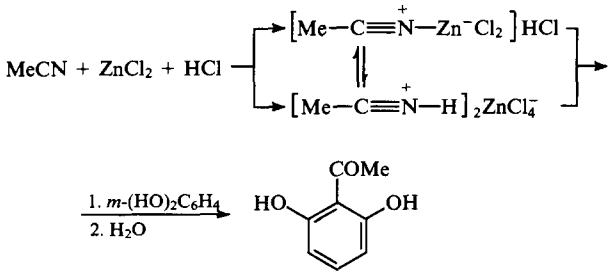
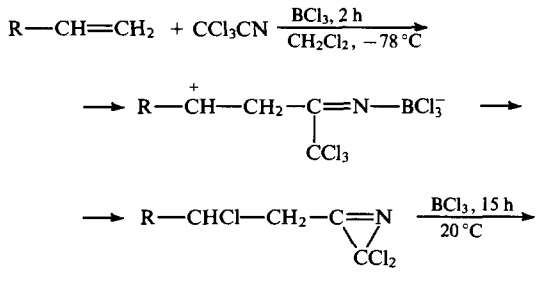
Composition of complex	$\nu(C\equiv N)/cm^{-1}$	$\Delta\nu/cm^{-1}$	Ref.
$MeCN\cdot BF_3$	2359	111	40
$MeCN\cdot BCl_3$	2328	81	41
$PhCN\cdot BCl_3$	2304	75	41
$MeCN\cdot AlCl_3$	2330	77	42
$MeCN\cdot AlBr_3$	2335	82	42
$2\,MeCN\cdot ZnCl_2$	2306	44	43
$2\,MeCN\cdot SnCl_4$	2300	38	44
$PhCN\cdot SnCl_4$	2258	27	45
$2\,MeCN\cdot NiCl_2$	2286	41	46
$2\,PhCN\cdot TiCl_4$	2269	38	47
$4\,EtCN\cdot NiBr_2$	2290	42	48
$4\,MeCN\cdot RuCl_2$	2270	29	49
$H_2C{=}CHCN\cdot NbCl_5$	2264	36	50
$H_2C{=}CHCN\cdot FeCl_2$	2257	29	51
$H_2C{=}CHCN\cdot CoCl_2$	2260	32	51
$2\,MeCN\cdot ReCl_4$	2310	59	52
$2\,MeCN\cdot TiCl_4$	2280	26	53



The causes of such increase in the vibrational frequency of the C≡N bond have not been fully elucidated. Initially, this phenomenon was attributed to the increasing charge separation and hence to a larger dipole moment of the C≡N bond in the complexes.[54] In a later study,[55] it was shown that one of the causes may be the kinematic interaction between the stretching vibration of the N–B and C–B bonds with the normal C≡N mode in the complexes $MeCN\cdot BX_3$ (X = Cl, F, Br). However, according to the results of Bittie and Gilson,[56] the observed increase in $\nu(C\equiv N)$ cannot be accounted for solely by the kinematic effect, since calculation yields a shift of 25 cm^{-1}, whilst the observed experimental values are 70–100 cm^{-1}. Nevertheless the shift of the $\nu(C\equiv N)$ vibrational frequency is regarded as a reliable criterion of the formation of complexes of nitriles via the lone pair of the nitrogen atom.[1,2,4]

This conclusion has been confirmed by X-ray diffraction for a series of complexes of acetonitrile with Lewis acids.[11,44,57] A linear $Me-C\equiv N-MX_n$ coordination and a shortening of the C≡N bond (1.10–1.15 Å) were observed in all these investigations.

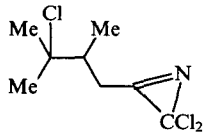
The chemical properties of the nitrile–Lewis acid complexes are characterised by a greater ease of nucleophilic attack on the nitrile carbon atom compared with the free nitrile. This is manifested in their interactions with water, organic acids, alcohols, and nitrogen bases. In fact, all these reactions proceed smoothly only in the presence of Lewis acids.[1-3]



The Hoesch reaction, which was already known at the beginning of the century, also proceeds in the presence of a Lewis acid — $ZnCl_2$.[11]

The recently discovered reaction of complexes of nitriles containing electrophilic substituents with BCl_3 and BBr_3 is of the greatest synthetic interest.[57-59] Japanese investigators[57,58] observed that, in the presence of BCl_3, trichloroacetonitrile interacts with a wide range of alkenes, affording the products of the electrophilic attack by the nitrile on the double bond of the unsaturated compound. The mode of the reaction then depends significantly on the structure of the unsaturated compound.

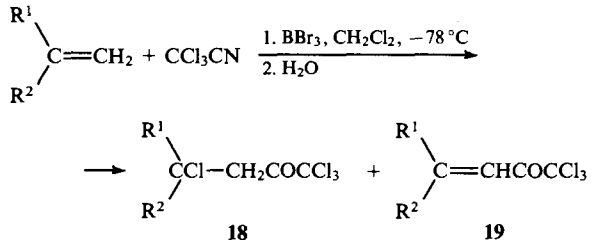
Thus, it has been shown that the interaction of α-alkenes with trichloroacetonitrile in the presence of BCl_3 in methylene chloride at −78 °C leads to satisfactory yields of dichloroaziridines **16**, which may be converted into the corresponding dichloronitriles.[57]



16

17

R	Yield (%)	
	16	**17**
n-C_6H_{13}	90	60
Bu^n	90	66
Bu^{iso}	90	77
$EtMe_2C$	92	59
Bu^t	68	65
$PhCH_2$	44	19



In the case of compound **16** (R = Bu^t, $PhCH_2$), the reaction lasted 15 h and in the case where R = Bu^t the compound

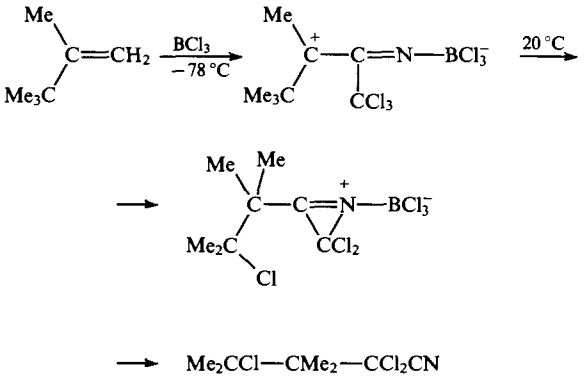
was isolated as a side product in 28% yield.

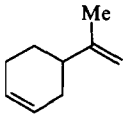
The use of BBr_3 as the catalyst in this reaction leads to the formation of the same product, which shows that the carbonium ion is stabilised by a chlorine atom in trichloroacetonitrile.[57]

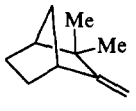
A different mode of reaction has been observed for 1,1-disubstituted alkenes — aziridines are not formed and the stabilisation of the carbonium ion is achieved either by the 'abstraction' of a halide ion from the catalyst or as a result of the elimination of an α-proton. A different origin of the halogen from that in the preceding reaction is indicated by the formation of a bromoketone when BBr_3 is employed as the catalyst.[57]

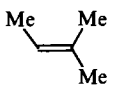
18 **19**

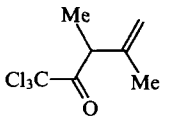
In the case of *tert*-butyl(methyl)ethene, an increase of the reaction temperature to room temperature leads to the formation of rearrangement products (Table 2).

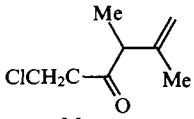


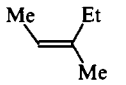


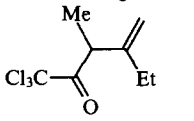


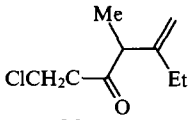


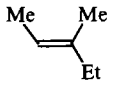


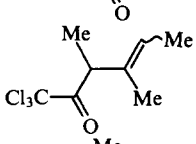


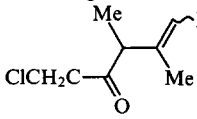


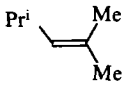


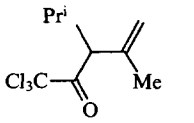


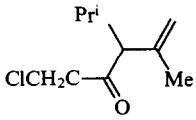


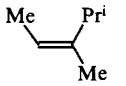


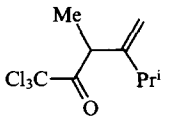


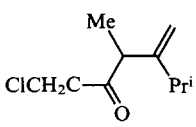


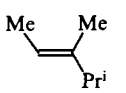


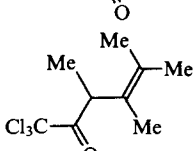


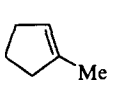


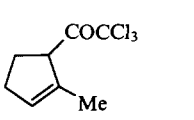


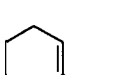












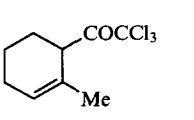


Table 2. The yields and ratios of the products **18** and **19**.

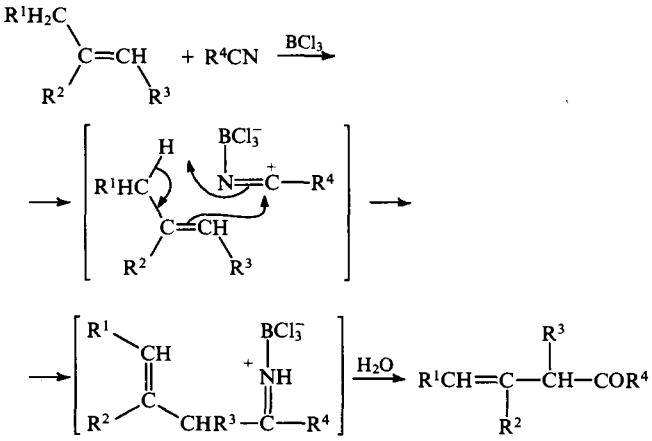
Alkene	Overall yield (%)	Compound **18**: compound **19**
	92	80:20
	90	80:20
	91	86:14
	95	0:100
	89	0:100
	75	0:100



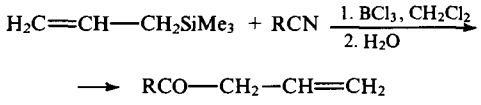
The causes of the different modes of reaction for different alkenes are not discussed in the communication of Hamana and Sugasawa.[57] It is noted that only BCl_3 and BBr_3 are suitable as catalysts. When $AlCl_3$, $TiCl_4$, or $BF_3.OEt_2$ and nitriles with less strongly electron-accepting substituents than CCl_3 are employed, the reaction does not occur.

A different mode of reaction occurs for trisubstituted alkenes. β,γ-Unsaturated ketones are formed exclusively in this instance. It is believed[58] that the reaction proceeds via the 'ene' mechanism.

Table 3. Conditions in the preparation and yields of the β, γ-unsaturated ketones **20**.

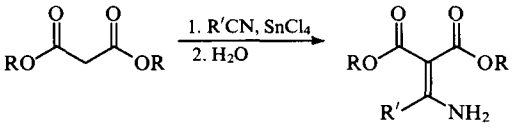
Alkene	Nitrile	Product	Yield (%)
	Cl_3CCN		70
	H_2CClCN		74
	Cl_3CCN		76
	H_2CClCN		70
	Cl_3CCN		74
	H_2CClCN		70
	Cl_3CCN		74
	H_2CClCN		71
	Cl_3CCN		74
	H_2CClCN		71
	Cl_3CCN		45
	Cl_3CCN[a]		90
	Cl_3CCN[a]		90

Note. When CCl_3CN was used, the reaction was carried out at −78 °C for 2 h, whereas in the case of $ClCH_2CN$ it was carried out at 20 °C for 20 h.
[a] The reaction time 5 h.



20

Table 3 shows clearly the difference between the reactivities of trichloroacetonitrile and chloroacetonitrile. In the latter case, the reaction requires room temperature and a time longer by a factor of 10.

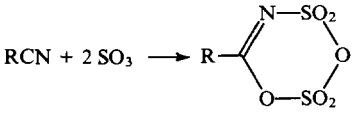


The concerted reaction mechanism of the 'ene' type is confirmed by the rigorous regiospecificity of the reaction. When two possible modes of reaction are possible, the proton is abstracted from the alkyl group located in the *cis*-position relative to the vinyl proton.

In the interaction of trichloroacetonitrile and chloroacetonitrile with allyltrimethylsilane in the presence of BCl_3, allylketones are formed.[59]

R = CCl_3, CH_2Cl.

It has been also observed recently that the complexes of nitriles with tin tetrachloride may be alkylated by malonic acid esters, which leads to the formation of derivatives of α,β-dehydroaminoacids in 20%–60% yields.[60]



R′ = Me, Et, Ph, CH=CHPh, CH=CHMe.

Thus, although numerous studies were devoted to the investigation of the structures and physicochemical properties of complexes of nitriles with Lewis acids already in the 1960–1970s, the study of their synthetic possibilities as acylating agents is only just beginning.

V. Interaction of nitriles with sulfur trioxide

The interaction of nitriles with sulfur trioxide has been described in detail in the communications of Bodrikov, Michurin, and coworkers.[61,62] Thus it has been shown that the reaction with SO_3, leading to the formation of 1,3,2,4,5-dioxadithiazine 2,2,4,4-tetroxides **21**, is a general reaction of nitriles (Table 4).

21

Table 4. Some characteristics of 1,3,2,4,5-dioxadithiazine 2,2,4,4-tetroxides **21**.

R	Yield (%)	T_m/°C	ν(C≡N)/cm^{-1}
Me	96	40–42	1665
Et	97	46–48	1662
Bu^t	92	57–59	1660
H_2C=C(Me)	95	45–48	1636
CCl_3	98	46–48	1670
CBr_3	92	76–78	1668
$CHCl_2$	97	54–56	1672
Ph	98	81–83	1645
p-MeC_6H_4	97	165–167	1642
p-ClC_6H_4	99	132–134	1650
m-$O_2NC_6H_4$	95	193	1658
p-$O_2NC_6H_4$	96	177–180	1657
3,5-$(O_2N)_2C_6H_3$	98	140–142	1665

For alkylnitriles and nitriles with unsaturated substituents, the reaction temperature varies from −75 to −60 °C, whilst for halonitriles and aromatic nitriles it varies from −40 to −25 °C. The structure of compound **21** has been confirmed by X-ray diffraction.[63]

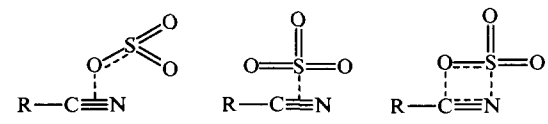
However, it has been found[64] that 1,3,2,4,5-dioxadithiazine 2,2,4,4-tetroxides are not the primary products of the interaction of SO_3 with nitriles. This is indicated by the hypsochromic shift of ν(C≡N) when nitriles are mixed with SO_3 in CCl_4. The absorption frequencies of the cyano-group of the nitriles (ν) and their mixtures with SO_3 in CCl_4 (ν') are given below.

R	ν(C≡N)/cm^{-1}	ν'(C≡N)/cm^{-1}
Me	2255	2285
Et	2251	2282
Bu^t	2239	2283
H_2C=C(Me)	2232	2262
Ph	2231	2261
p-MeC_6H_4	2231	2260
p-ClC_6H_4	2234	2267
m-$O_2NC_6H_4$	2238	2270
p-$O_2NC_6H_4$	2238	2270
m-MeC_6H_4	2232	2259
p-$MeOC_6H_4$	2229	2258

For nitriles with strongly electron-accepting substituents [R = CCl_3, CBr_3, 3,5-$(NO_2)_2C_6H_3$], the presence of SO_3 does not induce a hypsochromic shift of ν(C≡N) in the IR spectrum but gives rise to a decrease in the intensity of this band.

It has been suggested[64] that the observed changes in the IR spectra of nitriles in the presence of SO_3 should be regarded as the result of the formation of the donor–acceptor complexes **22**.

The initial formation of the donor–acceptor complexes on mixing nitriles with SO_3 has also been confirmed by the observed kinetic features in the formation of the tetroxide **21**. These features are consistent with a two-stage mechanism.[65]

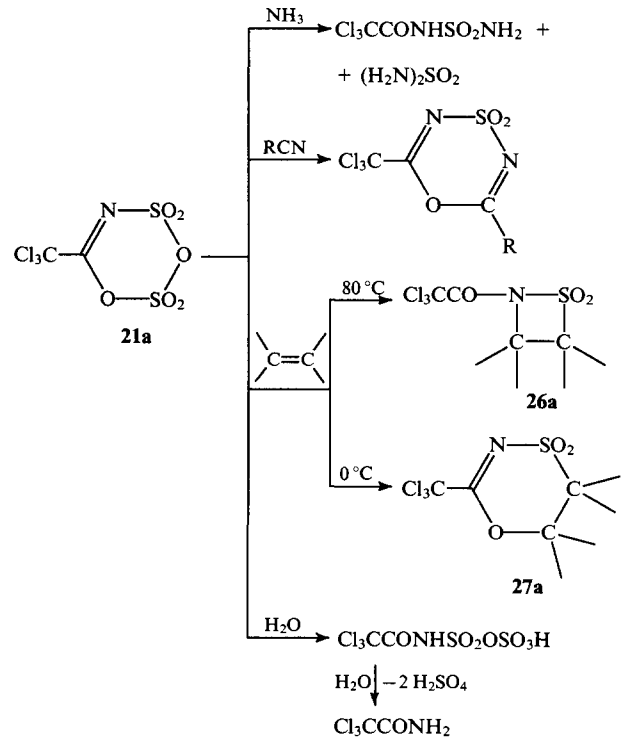


$$RCN + SO_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} RCN\cdot SO_3$$

22

$$RCN\cdot SO_3 + SO_3 \xrightarrow{k_2} \mathbf{21}$$

$k_2 > k_1$.



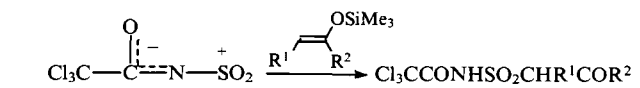
Quantum-chemical analysis of the possible forms of the donor–acceptor complexes of nitriles with SO_3 has shown that the most probable form of the complexes of nitriles having strongly electron-accepting substituents with SO_3 is form **23**, whilst for the remaining nitriles forms **24** and **25** are equally probable.

23 **24** **25**

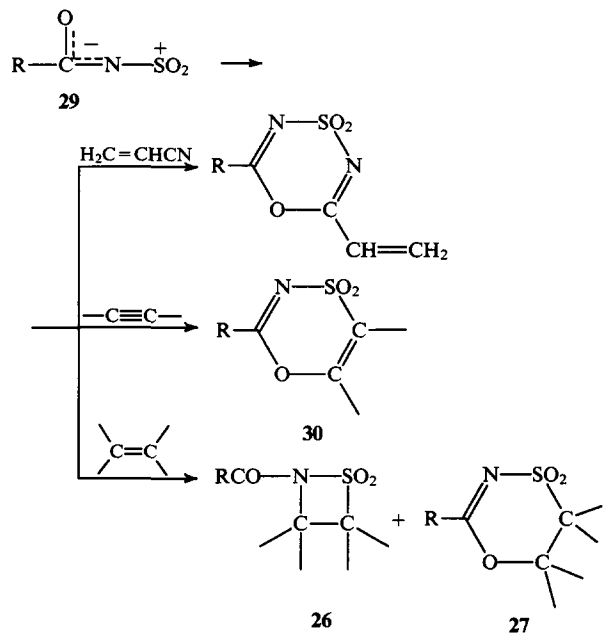
The chemical properties of 1,3,2,4,5-dioxadithiazine 2,2,4,4-tetroxides depend on the structure of the group R in the nitrile entering into the composition of the tetroxide. Tetroxides having strongly electron-accepting substituents interact with nucleophiles with retention of the C–O bond in the tetroxide (Scheme 1).[6]

Scheme 1

In the interaction of nitriles having strongly electron-accepting substituents with tertiary amines, the dipolar compounds **29** are formed. Their structure has been demonstrated by X-ray diffraction.[67]

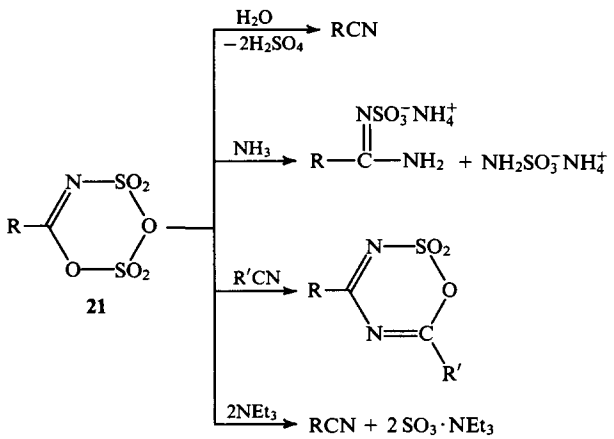


$$\mathbf{21} + NEt_3 \xrightarrow[-SO_3\cdot NEt_3]{} R{-}C(=O){-}N^{+}{-}SO_2^{-}$$



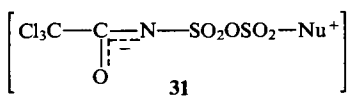
29

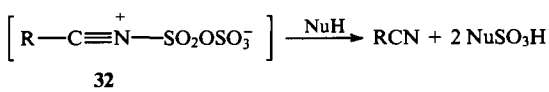
R = CCl_3, CBr_3, 3,5-$(O_2N)_2C_6H_3$.



Like the tetroxides **21**, compound **29** reacts with unsaturated compounds.[68]

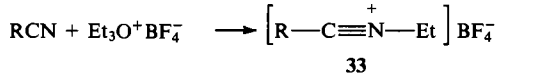
The formation of compounds **26** may be detected only when trimethylethene or styrene is used as the substrate. In all the remaining cases (in the reactions with allyl chloride, allylbenzene, *p*-methylallylbenzene, *p*,β-dimethylstyrene, isoprene, phenylethyne, diphenylethyne, and *tert*-butylethyne), the [4+2]-cycloaddition reaction takes place with formation of compound **27** or **30** respectively.[69] The interaction of compounds **29** with the trimethylsilyl ethers of enols proceeds with formation of 2-oxosulfonamides.





On the other hand, tetroxides containing electron-donating and weakly electron-accepting substituents react with nucleophiles with dissociation of the C–O bond.[63–65]

It has been suggested[65] that the observed differences in the behaviour of tetroxides **21** with strongly electron-accepting substituents and with electron-donating or weakly electron-accepting substituents are due to the fact that in the former case the reaction proceeds via the relatively stabilised intermediate **31**.



On the other hand, in the case of electron-donating substituents, the formation of the azacarbenium type intermediate **32**, the decomposition of which affords the initial nitrile, proves to be favourable.[65]

VI. Alkylation of nitriles. Alkylnitrilium salts

Meerwein et al.[69] reported in 1956 the synthesis of a large number of alkylnitrilium salts for nitriles and various alkylating agents. This study still remains the main source of information about alkylnitrilium salts.

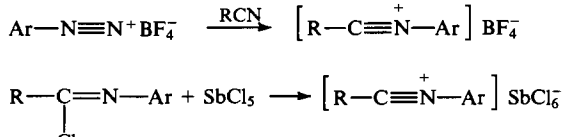
Alkylnitrilium salts may be obtained by the reaction of nitriles with triethyloxonium tetrafluoroborate followed by the removal of ether (Table 5).[70]

Nitrilium tetrafluoroborates and tetrachloroaluminates are extremely hygroscopic, deliquesceing in air almost instantaneously. The composition of the compounds obtained has been confirmed by elemental analysis for the halogen.

Table 5. The alkylnitrilium salts obtained by alkylating nitriles with triethyloxonium salts.

Alkylnitrilium salt	T_{decomp}/°C	Yield (%)
$[MeC{\equiv}N^+Et]BF_4^-$	—	89
$[EtC{\equiv}N^+Et]BF_4^-$	68–75	70
$[PhC{\equiv}N^+Et]BF_4^-$	92–98	64
$[PhC{\equiv}N^+Et]SbCl_6^-$	170–172	64
$[PhC{\equiv}N^+Et]AlCl_4^-$	—	36

Nitrilium salts can also be obtained from complexes of nitriles with Lewis acids and alkyl halides.[69]



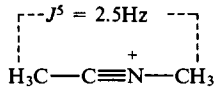
The alkylation time then depends on the ease of the formation of the carbonium ion from the alkyl halide (Table 6).

Table 6. Conditions in the alkylation of the complex $PhCN^+ - SbCl_5^-$.

Alkyl chloride	Nitrilium salt	PhCN : RCl	Time	Yield (%)
EtCl	$PhCN^+ - Et\,SbCl_6^-$	1 : 12	1 month	75
Pr^iCl	$PhCN^+ - Pr^i\,SbCl_6^-$	1 : 10	1 month	83
Bu^tCl	$PhCN^+ - Bu^t\,SbCl_6^-$	1 : 2.2	1 min	90

This method of synthesis of alkylnitrilium salts is extremely convenient and is widely used on the preparative scale.

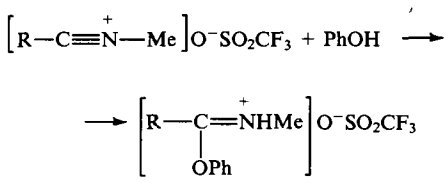
The methods described above are not suitable for the synthesis of *N*-arylnitrilium salts, and the latter are therefore synthesised by the interaction of nitriles with arenediazonium salts or by treating iminohalo-derivatives with Lewis acids.[70]



The synthesis of alkylnitrilium triflates by the interaction of nitriles with methyl triflate has been reported:[70]

The structure of alkylnitrilium salts has been investigated by IR and NMR spectroscopy. The IR spectra of alkylnitrilium

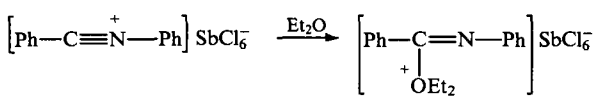
salts, like those of the protonated nitriles and their complexes with Lewis acids,[21,70,71] exhibit an 80–100 cm^{-1} hypsochromic shift of $\nu(C\equiv N)$. It has been suggested that this finding indicates unambiguously that the main contribution to the structure of the nitrilium salts comes from the form with the charge localised on the nitrogen atom.[71] The ^1H NMR spectra of the nitrilium salts indicate the existence of spin–spin coupling between the alkyl group at the nitrogen atom and the α-protons of the nitrile.[21]



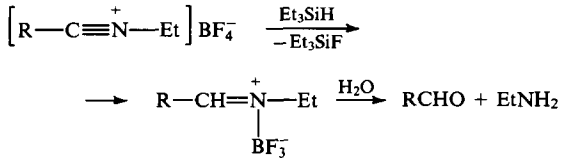
δ = 2.67 ppm δ = 3.66 ppm

The linear structure of the alkylnitrilium ions has been confirmed by an X-ray diffraction study of *N*-(2,6-dimethylphenyl)acetonitrilium tetrafluoroborate.[72]

N-Alkyl- and *N*-aryl-nitrilium salts interact with nucleophiles at the nitrile carbon atom. For example, their hydrolysis leads to *N*-alkylamides.[69]

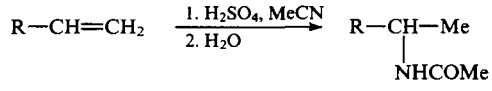


Nitrilium salts react similarly with phenol.[70]

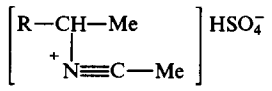


R = Me, Ph.

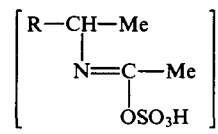
An unstable compound of an *N*-arylnitrilium salt with ether has been obtained.[69]



The interaction of *N*-alkylnitrilium salts with triethylsilane leads to the formation of aldehydes and amines.[73]

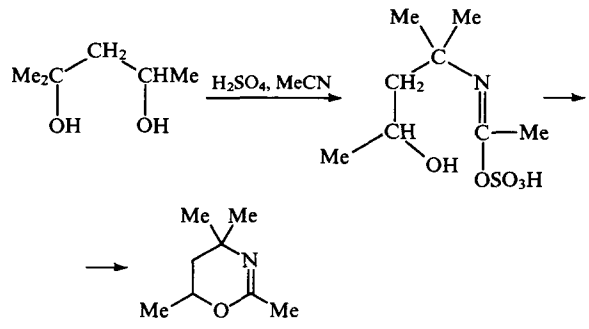


VII. The Ritter reaction

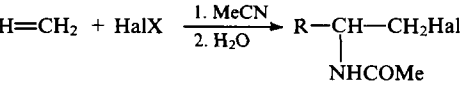


The classical version of the Ritter reaction involves the alkylation of nitriles by the carbonium ions generated in an acid medium from alkenes and alcohols with subsequent hydrolysis, which leads to *N*-alkylamides.[74,75]

The reaction mechanism presupposes the intermediate formation of the alkylnitrilium salt **34**.



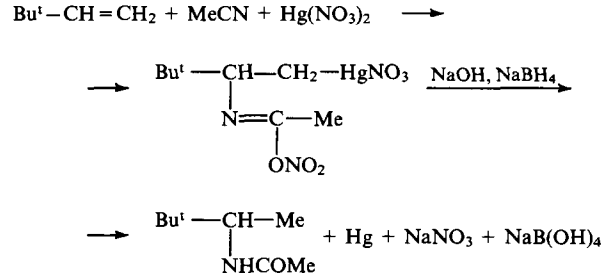
34



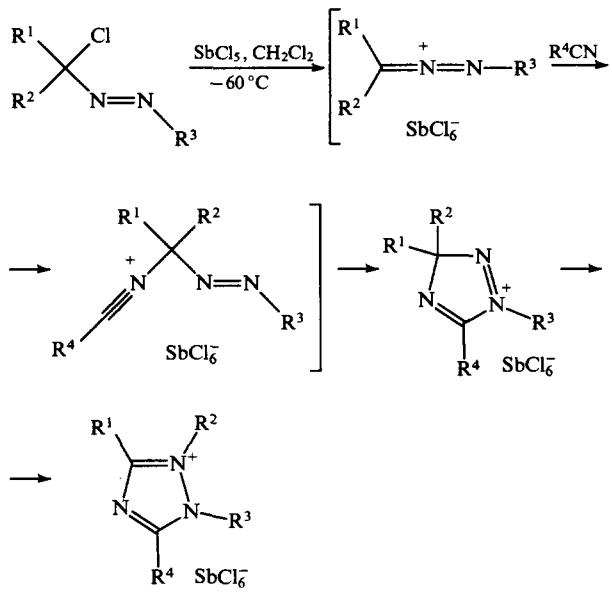
35

However, the direct detection of such intermediates in the Ritter reaction has not so far been reported in the literature. Bearing in mind the complexity of the chemical behaviour of nitriles in acid media (see Section I), it is fairly difficult to imagine the true reaction mechanism. The majority of investigators, including Ritter himself, prefer to represent the intermediate by formula **35** with a covalently bound anion.

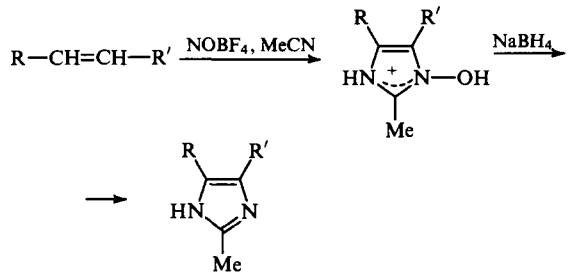
The development of the synthetic possibilities of the Ritter reaction arose primarily from its use in the reaction of the nitrile with molecules having a variety of functional groups. Thus heterocyclic compounds may be synthesised by the Ritter reaction.[76,77]



Another direction in the synthetic development of the Ritter reaction involved the employment of electrophiles other than the proton. For example, the halogens have been used as the electrophiles.[78–80]

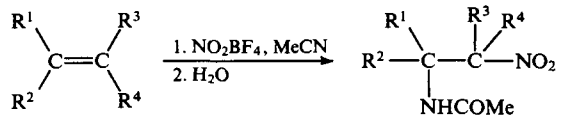


Hal = Cl, Br; X = Cl, Br, OH, N_3, HCONH, ClNCOOEt.

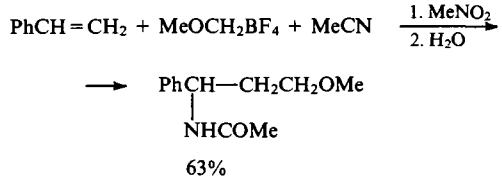


The use of mercury(II) nitrate and acetonitrile leads ultimately to the same products as the Ritter reaction, but makes it possible to avoid acid conditions. The value of this approach has been demonstrated in the reaction of acetonitrile with *tert*-butylethene, which occurs without a skeletal rearrangement.[81]

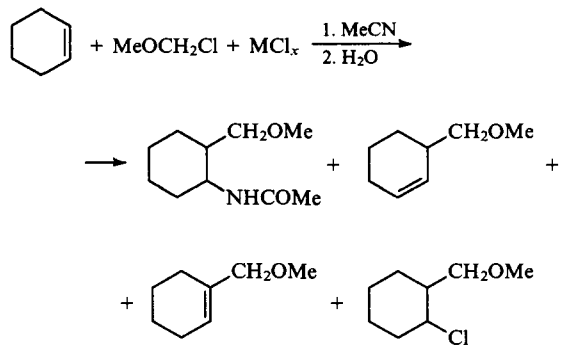
The diversity of the carbonium ions capable of allylating nitriles is well illustrated by their reactions with 1-aza-2-azonioallene salts.[82]



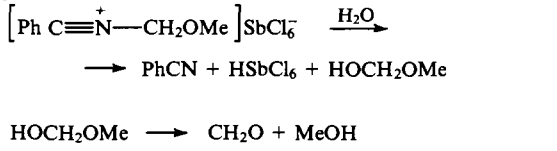
An interesting example of a modified Ritter reaction is the interaction of nitrosonium[83] and nitronium[84,85] tetrafluoroborates with alkenes. The yield of the imidazole derivatives depends on the structure of the alkene.



R = Me, R′ = H (80%); R = R′ = Me (80%);
R = Ph, R′ = H (50%); R + R′ = $(CH_2)_4$ (50%).



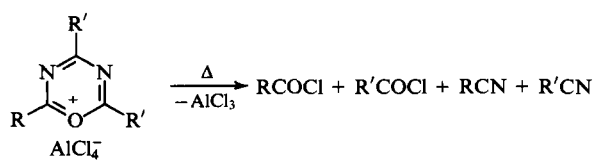
Nitronium tetrafluoroborate interacts with alkenes in acetonitrile, giving rise to β-*N*-acylaminonitro-derivatives after hydrolysis.[84,85] The best yields in this reaction (80%–90%) have been obtained for substituted styrenes.[85]



The reaction involving the coupled formation of C–C and C–N bonds is of special interest. It was first described[86] in relation to styrene.

The possibility of the employment of the chloromethoxymethane–Lewis acid–acetonitrile system for this reaction was investigated in a later study,[87] but the yields of the target products do not exceed 40% in this instance and the formation of side products is observed.

It is interesting to note that, according to Meerwein's data, alkylnitrilium salts of the type $[Me-C\equiv N-CH_2.OMe]^+X^-$ should be formed under the conditions of the last two reactions. However, in contrast to the remaining known nitrilium salts, their interaction with a nucleophile (in the given instance with an alkene) involves an alkyl and not the nitrile carbon atom. This finding agrees well with Meerwein's data for the interaction of a similar alkylnitrilium salt with water. This was the only instance in which he observed that hydrolysis entailed the formation of the initial nitrile and not an *N*-alkylamide.[69]

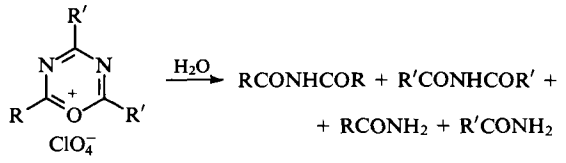


VIII. Acylation of nitriles. Acylnitrilium salts

The syntheses of a series of acylnitrilium salts via the acylation of a series of complexes of nitriles with Lewis acids by acyl halides have been described in Meerwein's classical paper.[69] The compositions of the reaction products were confirmed by elemental analysis for the halogen.

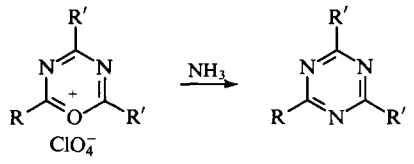
PhCN·$PhCOZnCl_3$ (**36**),
2 PhCN·$PhCOAlCl_4$ (**37**),
2 PhCN·$PhCOSbCl_6$ (**38**),
2 MeCN·$MeCOSbCl_6$ (**39**),
2 PhCN·$PhSO_2SbCl_6$ (**40**),
3 PhCN·$MeCOSbCl_6$ (**41**),
3 PhCN·$(PhCO)_2SnCl_4$ (**42**),
3 PhCN·$MeCOAlCl_4$ (**43**).

Meerwein et al.[69] believe that the acylnitrilium salt PhCN.$PhCOZnCl_3$ **36** constitutes benzonitrile acylated at the nitrogen atom. They attribute the structure of the diazapyrylium salts **44** to the salts **37**–**40**, which has been confirmed by their thermal decomposition, in which exchange of substituent groups is observed.



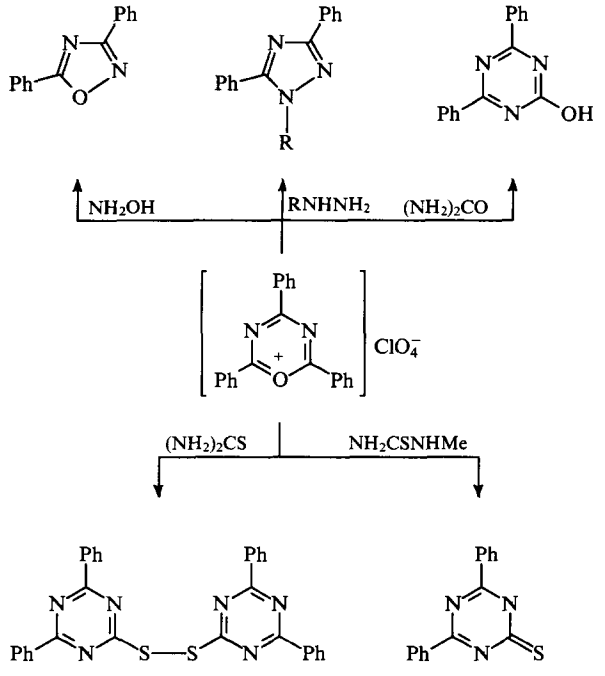
44

For complexes **41**–**43**, the authors consider the structure of acylated triazines, but they present no data whatever to confirm this hypothesis.



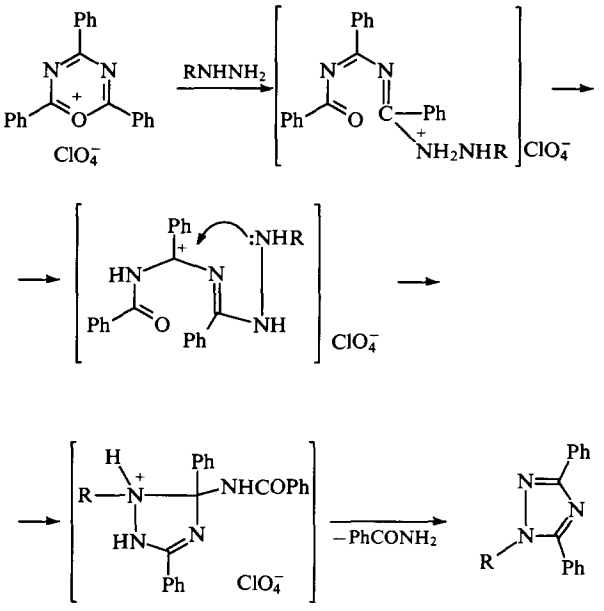
In Schmidt's study,[88] the structure of aryldiazapyrylium salts obtained by Meerwein's method, involving the heating of the

benzonitrile–Lewis acid complex with an acyl halide, was confirmed by a series of chemical reactions. Thus their hydrolysis leads to a mixture of two amides and two acylamides.

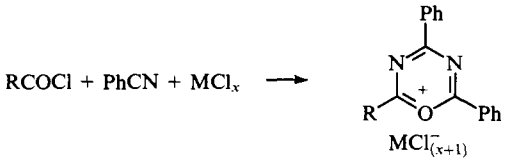


R, R′ = Ar.

Reaction with ammonia converts the diazapyrylium salts into triazines.



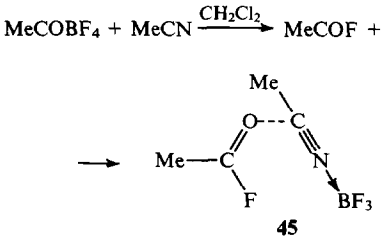
R, R′ = Ar.



Schmidt also observed a series of reactions of triphenyldiazapyrylium perchlorate, which take place with elimination of benzamide.

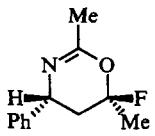
Apparently the primary attack by the nucleophile is directed to the nitrile carbon atom linked to oxygen.

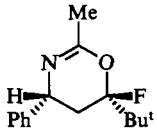
The IR spectra of a series of diazapyrylium salts synthesised by the interaction of acyl halides with Lewis acids and benzonitrile in nitrobenzene, dichloroethane, or without a solvent have been investigated.[89]

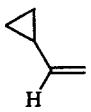


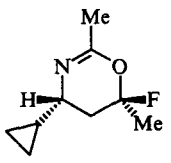
R = Me, Ph, CH_2Cl; MCl_x = $SbCl_5$, $SbCl_3$, $SnCl_4$.

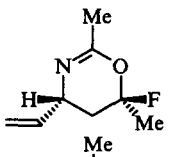
It is of interest to note the differences between the conditions in the synthesis of the diazapyrylium salts mentioned by Sumarokova et al.[89] Thus the reaction of the complex $PhCN.SbCl_5$ with acyl halides takes place rapidly at room temperature, whereas the synthesis of the diazapyrylium salts involving the use of $SnCl_4$ or $SbCl_3$ as the Lewis acid requires prolonged maintenance at 80 °C and the yields of the target products are in this case lower.

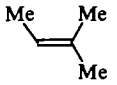


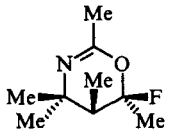


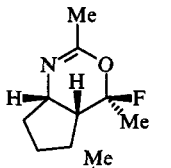


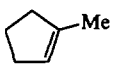


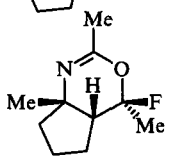


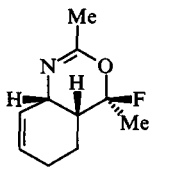






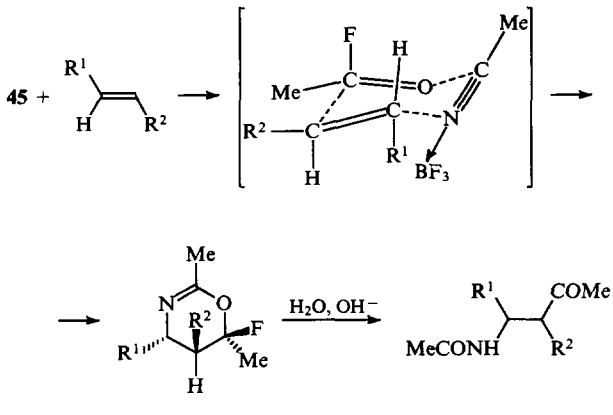






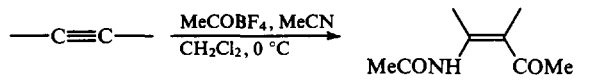
The diazapyrylium salts have been obtained in the form of yellow or orange crystals; their structure has been confirmed by measurements of the molecular mass (by the cryoscopic method), by elemental analysis, and by IR spectroscopy. The IR spectra of the diazapyrylium salts contain no absorption bands above 1650 cm^{-1}, but they do contain a group of bands in the region 1540–1640 cm^{-1}, which Sumarkova et al.[89] assigned to the diazapyrylium ring vibrations.

The interaction of acetyl tetrafluoroborate with acetonitrile in methylene chloride has been studied in detail.[90] It was shown by NMR spectroscopy that this interaction involves the transfer of boron trifluoride from acetyl fluoride to acetonitrile, which leads to the reformation of complex **45**, in which the oxygen atom of the acetyl fluoride is coordinated to the electrophilic carbon atom of the complex $MeCN.BF_3$.



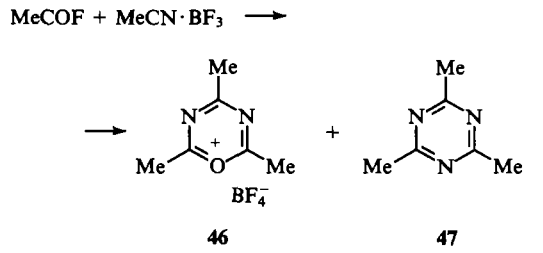
45

Table 7. The structure of the fluorooxazines obtained by the acylamidation reaction.



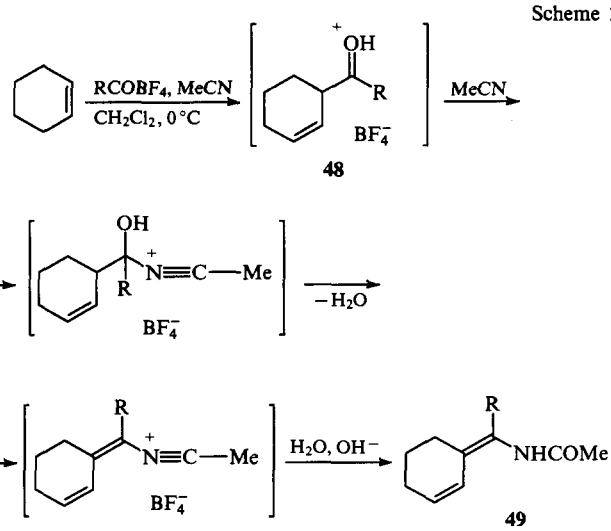
Reagent	T/°C	Product	Yield (%)
	0		62
	0		52
	−10		35
	−10		33
	0		57
	0		48[a]
	0		66[a]
	−20		25[b]

[a] Approximately 20% of the corresponding 3-acetylcyclopentene was isolated. [b] The low yield is due to the polymerisation of the product.

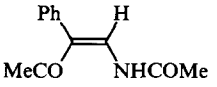


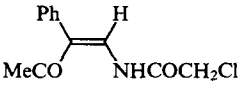
The formation of complex **45** is confirmed by the fact that, when an unsaturated hydrocarbon is added to the MeCOF–MeCN–BF_3 system, the acylamidation reaction, leading to the *syn*-stereospecific formation of the corresponding 6-fluoro-5,6-dihydro-1,3-oxazines, takes place (Table 7).[90–94]

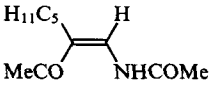
The reactions with ethynes, which give stereospecifically products of the *syn*-acylamidation of the triple bond, take place similarly (Table 8).[95]

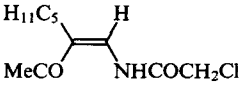


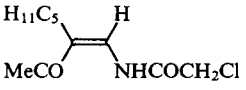
When the MeCOF–MeCN–BF_3 system is kept for a long time in a sealed tube, the formation of a dark-red solution, containing the diazapyrylium salt **46** and the triazine **47**, is observed. This solution does not interact with unsaturated hydrocarbons.[90]

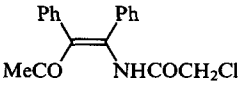






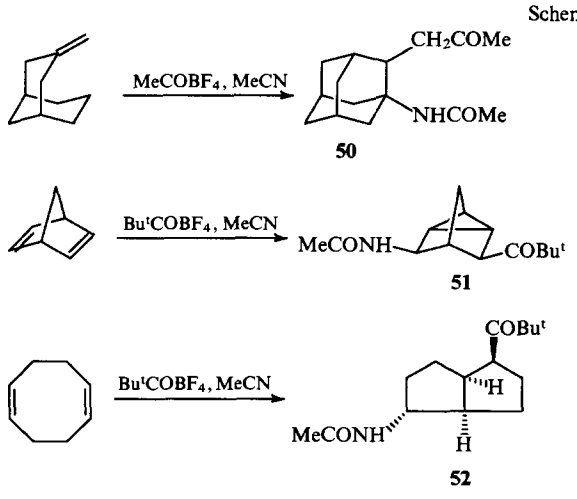






The complexity of the processes occurring in the acyl fluoride–nitrile–boron trifluoride system is indicated by the results of a study of the influence of the structure of the unsaturated substrate on the nature of the acylamidation reaction.[96–98] For example, in contrast to cyclopentene, cyclohexene does not afford 1,2-adducts on interaction with the MeCOF–MeCN–BF_3 system. The diene amide **49**, isolated in this reaction (Scheme 2), is formed via the interaction of the protonated unsaturated ketone **48** with the nitrile.[96] Thus in certain cases complex **45** can function also as an acylating agent.

Scheme 2



Nonconjugated cyclic dienes interact with the acyl fluoride–nitrile–boron trifluoride system to form the polycyclic amides **50–52**, which are the products of transannular cyclisation (Scheme 3).[97,98] The acylating properties of complex **45** are apparently also manifested in these reactions, but the unusually high stereospecificity observed in these reactions[98,99] may be evidence that in this case too the nitrile does not behave simply as an external nucleophile, participating in some way in the transition state of the reaction.[98]

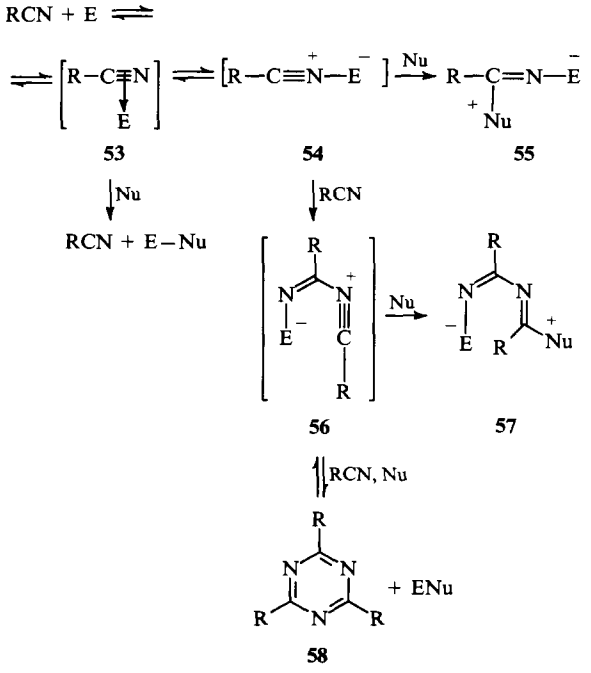


Table 8. The acylamidation of ethynes.

Ethyne	Nitrile	Conditions		Product	Yield (%)
		T/°C	time/h		
Ph–C≡CH	MeCN	20	1		35
Ph–C≡CH	$ClCH_2CN$	0	1		41
n-C_5H_{11}–C≡CH	MeCN	20	1		45
n-C_5H_{11}–C≡CH	$ClCH_2CN$	0	1		39
Ph–C≡C–Ph	MeCN	42[a]	—		0
		42[a]	—		44

[a] The reaction was carried out by refluxing in CH_2Cl_2.

Scheme 3

IX. Conclusion

In conclusion of the consideration of the reactions of nitriles with electrophiles, mention should be made of the fact that they are common to different electrophiles.

The majority of investigators believe that the primary products of the interaction of nitriles with electrophiles are donor–acceptor complexes **53**. A sufficiently strong interaction between the nitrile and the electrophile has not yet been manifested in these π-complexes, so that their treatment with nucleophiles leads to the regeneration of the nitrile. Under appropriate conditions (usually at higher temperatures), the π-complexes **53** are converted into the n-complexes **54**. The n-complexes **54** have a linear structure, their C≡N bond is shortened, and attack by the nucleophile is directed to the nitrile carbon atom with formation of type **55** compounds.

Under favourable conditions (usually in those cases where R is a fairly strong electron-accepting substituent), the second nitrile molecule behaves as the nucleophile and the dimeric salts **56** are formed. These may be stabilised by interaction with the former electrophile, affording compounds having the general formula **57**. Attack by the nucleophile in its interaction with compound **57** is usually directed to the nitrile carbon atom of the second nitrile molecule. Finally, the triazine **58** may be formed; this reaction path is also favoured by electron-accepting substituents R.

The understanding of the by no means simple pattern in the interaction of nitriles with electrophiles, achieved only recently, makes it possible to seek new reactions of nitriles, which will undoubtedly enrich synthetic organic chemistry.

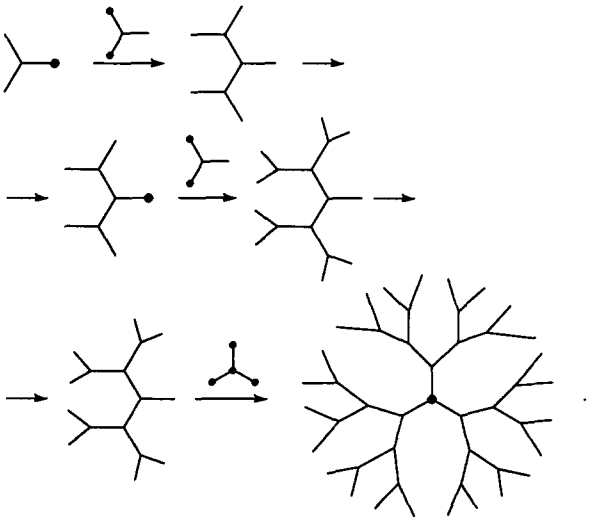
Abstract. The methods of synthesis, the structure, and properties of the dendritic polymers formed under the conditions of uncontrolled single-stage synthesis are surveyed. The bibliography includes 69 references.



I. Introduction

Studies on polymeric compounds of a fundamentally new type have become one of the most promising and rapidly developing aspects of modern chemistry during the last decade. Their macromolecules have a specific (largely spherical) close-packed shape and the three-dimensional close-packed framework of each molecule consists of concentric layers of branching elementary units. The objects which are studied in this chemical field are so unusual and so difficult to describe within the framework of the IUPAC nomenclature that a new terminology for their designation had to be developed. At the present time, this process is not yet complete and many of the terms, designations, and symbols employed still cannot be regarded as generally accepted. The only firmly established name for the compounds of this class themselves is 'dendrimers' or 'starburst dendrimers' proposed by Tomalia et al.[1] The terms 'arborols' (proposed by Newkome et al.[2]) and 'cascade compounds' are used to a lesser extent. More general designations such as nanomolecules and nanoscopic objects are also employed. The choice of terminology is dictated by the structure of the macrochains, which resembles that of the crown of a tree [dendron (Greek), arbor (Latin) = tree] or a cascade of repeating structural elements, and by the average dimensions of the molecules of these substances (1 – 100 nm). The terms hyperbranched and highly branched polymers have begun to be used recently for the group of dendrimers distinguished by a smaller degree of order in the molecular framework. These objects are in fact the subject of the present review.

One of the fundamental differences between the classical dendrimers and the highly branched polymers is the method of their synthesis. The former are obtained by many repetitions of the chosen sequence of reactions, which makes it possible to grow gradually new generations of layers of elementary fragments around the central atom (or molecule) called the initiator core of the dendritic molecule (divergent scheme), i.e.

or the reverse procedure is employed: the formation of the molecule begins from its periphery and proceeds with increase at each stage in the size of the intermediate dendrons, having a conventional conical shape, the dendrons becoming attached to the core only in the last stage to form the final dendritic macromolecule (convergent scheme), i.e.

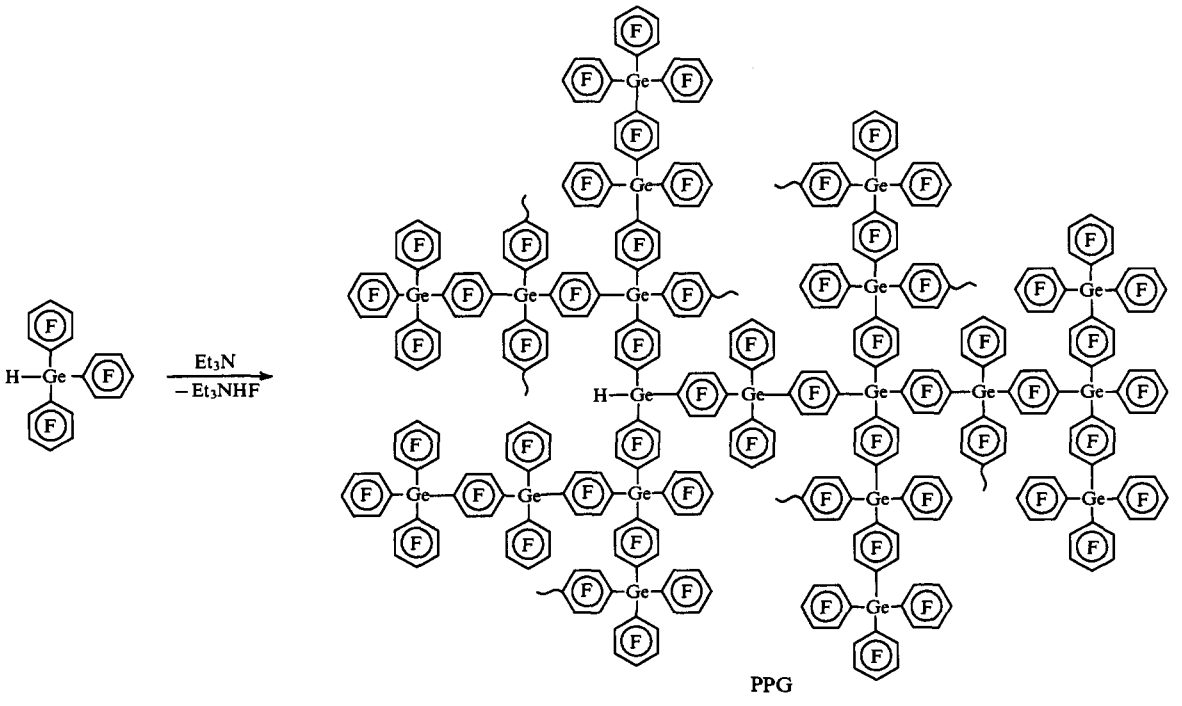
In both cases, the formation of each generation normally includes at least two reactions (for example, the addition of the initial monomer with protected functional groups to the growing molecule and the removal of the protection from the functional groups). Thus both approaches are not only multistep but also multistage. The combination of these methods, i.e. the formation of giant molecules by the addition of monomer molecules or dendrons to the dendrimer molecule previosly synthesised by the divergent or convergent methods, should also be noted. This procedure makes it possible to synthesise heterolayered dendrimers with a high molecular mass.[3]

In contrast to this, highly branched polymers are obtained under the conditions of uncontrolled single-stage synthesis in which the initial monomers employed are compounds of the type $A-R-B_x$ ($x \geqslant 2$), where A and B are functional groups of two types, which under certain conditions enter into a polycondensation or polyaddition reaction with formation of A–B bonds. Such continuous processes and their possible products have in fact been used as models in the theoretical studies of Flory[4] and Stockmayer,[5] whose communications were the first on the subject of hyperbranched formations with a hierarchical architecture of the molecular framework. However, the first specific synthesis of such compounds, achieved 30 years later by Vögtle and coworkers,[6] were carried out according to a multistep divergent scheme. This strategy of the synthesis, i.e. numerous repetitions of the selected reaction sequence, was adhered to by the vast majority of investigators in the field of dendrimers and cascade compounds.[7–10]

The monodispersity of the polymers obtained under these conditions and the predictability of the architecture of the framework, of the number of functional groups on the surface of macromolecules, and of their shape, size, and molecular mass give incontrovertible advantages to the stepwise method. This procedure has been used for the synthesis of diverse dendrimers, such as polyamidoamine dendrimers,[11] compounds with a carbochain skeleton,[12] including optically active,[15] carbosilane,[13] and carbosiloxane[15] compounds, dendrimers with ferrocenyl end-groups,[16] dendrimers with fullerene as the core,[17] dendrimers with coordinated cobalt[18] and ruthenium[19] atoms, carbaboranyl,[20] phenoxy-,[21] phenylethynyl,[22] phosphino-,[23] phosphonio,[24] phenylene,[25] and high-spin polyradical[26] dendrimers, cascade crown-ethers,[27] tetrathiofulvalene dendrimers,[28] etc.

At the same time, together with the above advantages, the stepwise strategy suffers from a series of disadvantages, the most serious of which is the considerable amount of labour involved due to the need for numerous repetition of the operations. Furthermore, the use of large excesses of the reactants creates problems in the isolation and purification of the dendrimers (intermediate generations and target products). Owing to these difficulties, the dendrimers obtained by the multistep synthesis belong to the category of fairly expensive substances which are difficult to obtain.



The single-stage method of synthesis of analogous derivatives is free from this disadvantage.

II. Single-stage methods of synthesis and types of dendrimers

As is frequently the case, the invention of compounds with a branched but not cross-linked molecular framework is due to nature, which employs this principle for the formation of glycogen, amylopectin, certain other polysaccharides, and proteins.[29–31]

The first mention of the artificial compounds formed on polycondensation of monomers of the type $A-R-B_x$ and having a cascade structure of the macrochain dates back to the 1920s[32] when the reaction between 2,4,6-trihalophenols and alkali metals with subsequent polycondensation of the resulting phenoxide 2,4,6-$X_3C_6H_2OM$ was carried out. One may assume that weakly ordered dendritic polymers had been obtained even earlier by the Friedel–Crafts polycondensation of benzyl halide derivatives under mild conditions.[33,34] However, in none of these instances were the products considered from the standpoint of the possible organisation of the macromolecules and their belonging to a new class of substances. The same approach to the products, treated as the usual branched polymers without consideration of the specific features of their structure, was also employed in a later study by Kricheldorf et al.,[35] who achieved the cocondensation of 3-(trimethylsiloxy)benzoyl chloride with a small amount of 3,5-bis(trimethylsiloxy)benzoyl chloride. As will be shown below, 3,5-bis(trimethylsiloxy)benzoyl chloride was used subsequently also by other investigators to obtain dendritic polyesters.

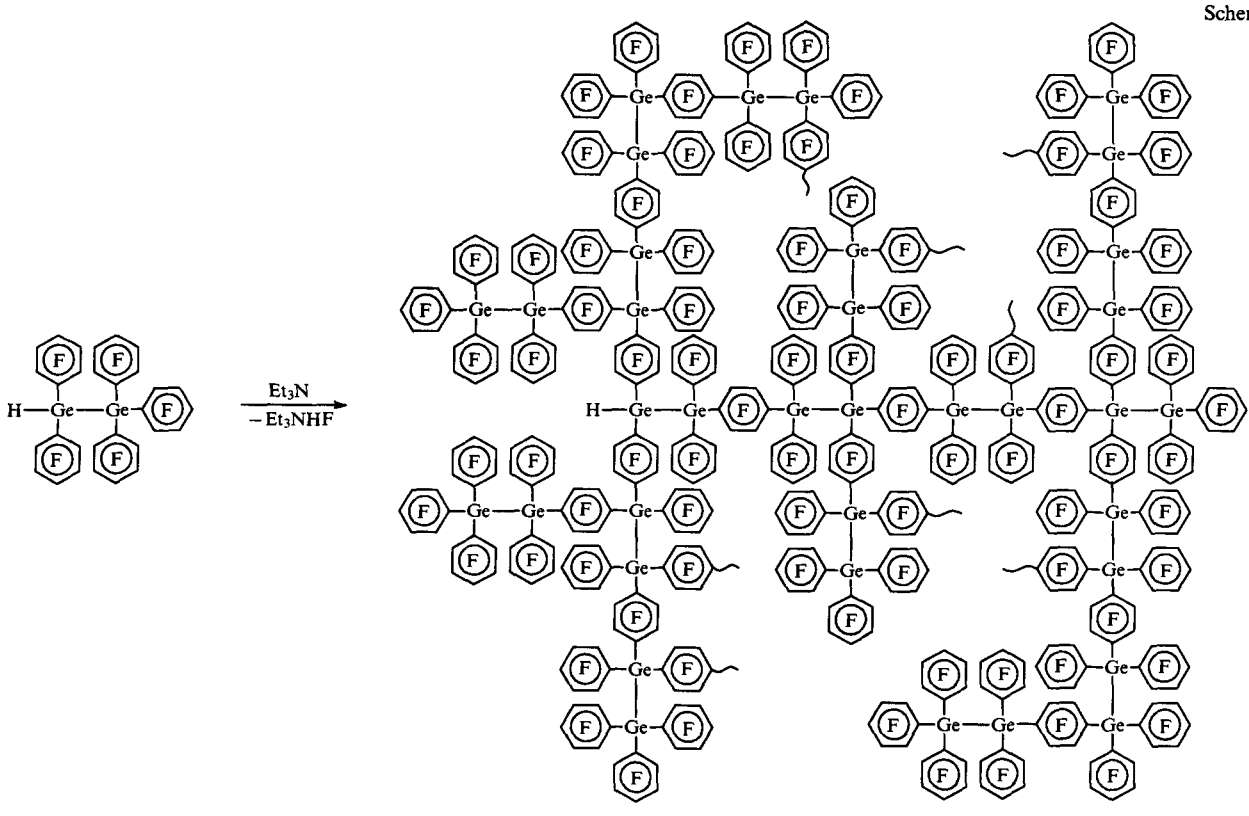
Scheme 1

The first specific synthesis of a dendrimeric compound by a single-stage method was achieved by the present authors on the basis of tris(pentafluorophenyl) derivatives of germanium $(C_6F_5)_3GeX$ (X = H, Br, GeR_3).[36-38] The synthesis was based on the earlier observations of the formation of disubstituted tetrafluorophenyl derivatives *p*-MC_6F_4M in the reactions of the organogermanes $(C_6F_5)_3GeX$ with electropositive metals and their organic derivatives.[39-41] A reinvestigation of these reactions and of the substances formed established that in all cases the main organogermanium product is a dendritic polymer — perfluorinated polyphenylgermane (PPG) with the formula $[(C_6F_5)_2.Ge(C_6F_4)]_n$. The best results were obtained when the reaction of the hydride $(C_6F_5)_3GeH$ with triethylamine in tetrahydrofuran (THF) was employed. Synthesis of PPG includes two stages occurring simultaneously: the formation of the anions $(C_6F_5)_3Ge^-$ and their polycondensation as a result of the nucleophilic substitution of the fluorine atoms in the *para*-positions (Scheme 1).

This mechanism of the synthesis of PPG has been confirmed indirectly by the formation of the mercurate complex $\{[(C_6F_5)_3Ge]_3Hg\}^-[(Me_3Si)_2NH_2]^+$ on interaction of $(C_6F_5)_3.GeH$ with $(Me_3Si)_2NH$ in the presence of $[(C_6F_5)_3Ge]_2Hg$ [40] and by the formation of the cross-linked insoluble perfluoropolyphenylenegermanes $[(C_6F_5)_2Ge]_n$ and $[(C_6F_5)_2GeGe(C_6F_5)_3]_n$ from the dihydride $(C_6F_5)_2GeH_2$ and the dihydrodigermane $(C_6F_5)_2Ge(H)-Ge(H)(C_6F_5)_2$.[42] It is interesting to note that the closest analogues of tris(perfluorophenyl)germane $(C_6F_5)_3EH$ (E = C, Si, Sn) as well as the germanol $(C_6F_5)_3GeOH$ do not undergo self-condensation in the presence of amines even on heating.[43] The tin-containing dendritic polymer $[(C_6F_5)_2Sn(C_6F_4)]_n$ was obtained in a low yield by heating $(C_6F_5)_3SnBr$ with alkali metals in THF. The condensation of tris(pentafluorophenyl)silane under the same conditions is accompanied by the elimination of pentafluorophenyl groups.

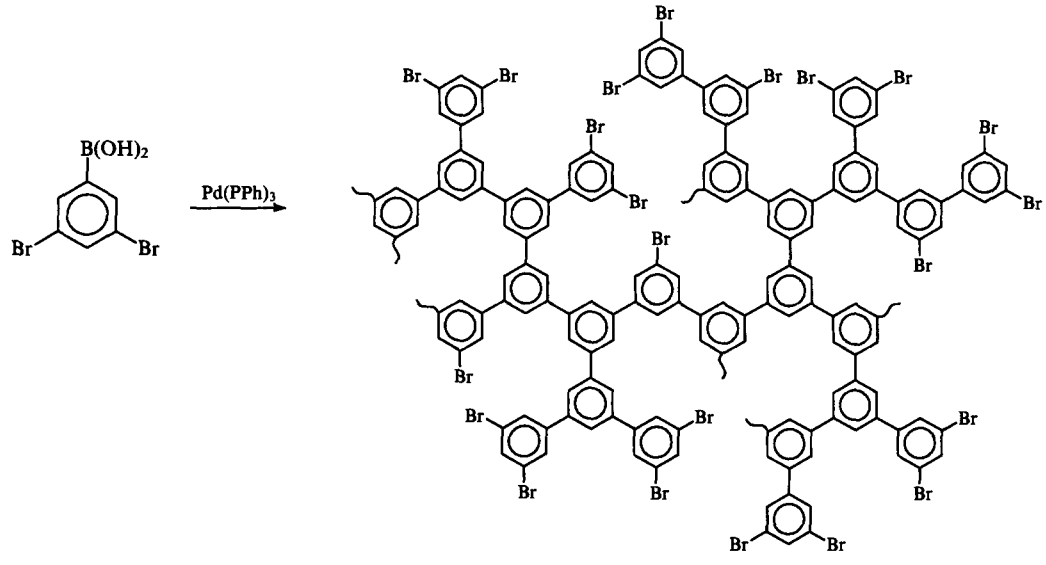
Side reactions, which lower the yield of the polymer and lead to significant disturbances of the cascade structure of the macromolecules, have been noted also in the polycondensation of the asymmetric digermane $(C_6F_5)_3GeGe(C_6F_5)_2H$ (Scheme 2).[44]

In this case not only the C–F bond but also the Ge–Ge group is subject to attack.



An attempt has been made to synthesise perfluoropolyphenylenegermane from the trihydride $C_6F_5GeH_3$.[45] It might have been expected that the condensation of this monomer in accordance with Scheme 1 would lead to the formation of a dendrimer resembling PPG but having on the surface of the macromolecules the hydride functional groups GeH_3 instead of $(C_6F_5)_3Ge$. The synthesis of such a polyhydrogermane appeared especially attractive, since the high reactivity of the Ge–H group promised to impart to the new polymer properties which would expand its synthetic possibilities. However, in contrast to other pentafluorophenylhydrogermanes, $C_6F_5GeH_3$ does not interact with amines and its reactions with derivatives of reactive metals (RMgX, $C_{10}H_8Na$) lead to linear insoluble polymers $[(C_6F_4)GeH_2]_n$ which are complicated by the elimination of the C_6F_5 groups.

Two brief communications concerning the synthesis of highly branched polyphenylenes by the polycondensation of $3,5\text{-}Br_2C_6H_3MgBr$ (on heating) and $3,5\text{-}Br_2C_6H_3B(OH)_2$ (under catalytic conditions) appeared simultaneously with the first publication on the synthesis of PPG.[46,47] The latter reaction was subsequently investigated in greater detail.[25] The condensation was carried out in an organic solvent–water mixture in the presence of sodium carbonate and $Pd(PPh_3)_4$ (Scheme 3). The mobility of the terminal Br atoms made it possible to employ the dendrimer **1** for the synthesis from it of a series of modified polymeric substances (see Section IV).



The polycondensation of 3,5-bis(trimethylsiloxy)benzoyl chloride, mentioned above, on heating to 250 °C leads to the formation of a low-molecular-mass and weakly branched polyester in a low yield.[35] By carrying out this reaction with the monomer purified beforehand by distillation, Frechet and coworkers[48] obtained the dendritic polyester **2** in up to 96% yield and a degree of branching of 55%–60%† (Scheme 4).

† The degree of branching is understood as the percentage ratio of the sum of the number of terminal units and the number of units with branching points to the total number of units of the polymer [(see C J Hawker, R Lee, J M J Frechet *J. Am. Chem. Soc.* **113** 4583 (1991)].

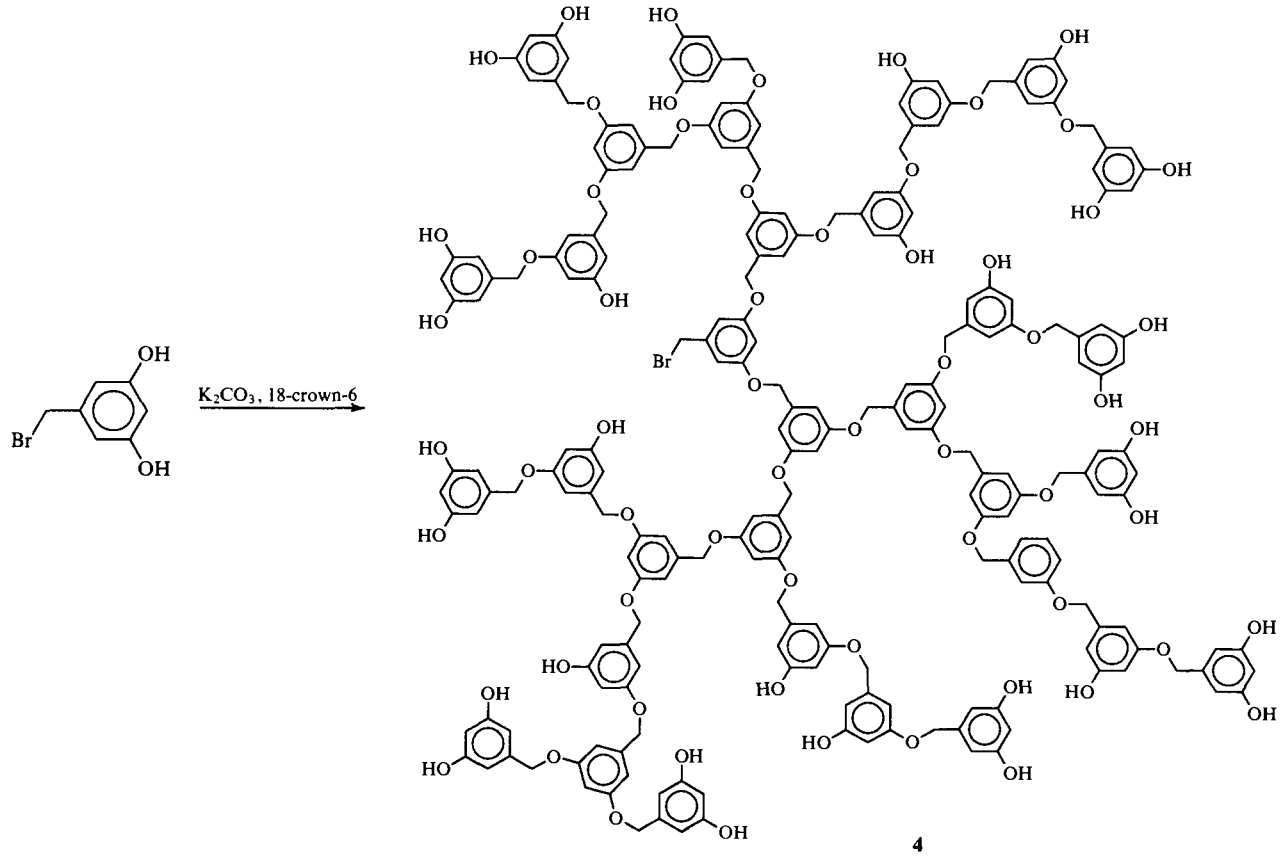
Apart from $3,5\text{-}(Me_3SiO)_2C_6H_3COCl$, 3,5-diacetoxybenzoic,[49] 5-(2-hydroxyethoxy)isophthalic, and 5-acetoxyisophthalic acids[50,51] have been used to obtain similar polyesters. The reactions were carried out in the monomer melt without a catalyst or in the presence of ammonium salts. The polycondensation of the hydroxyethoxy-derivative takes place at 180 °C in the presence of catalytic amounts of $Bu_2Sn(OCOMe)_2$ (Scheme 5).

The condensation of 5-acetoxyisophthalic acid requires heating to 250 °C, which promotes dehydration of the carboxy-groups and the formation of the cross-linked insoluble polymer **3a**, which is readily converted into the soluble dendrimer **3b** with acid end-groups on refluxing in a THF–water mixture. The COOH end-groups in the polymers **3a, b** were protected by converting them into ester of amide groups. The cocondensation of 5-acetoxyisophthalic acid with 3-(4-acetoxyphenyl)propionic acid, which occurs under similar conditions, leads to dendritic copolymers with different contents of linear fragments.[51]



The polyester **4**, based on 3,5-dihydroxybenzyl bromide and having a cascade structure, is synthesised by treatment with K_2CO_3 (Scheme 6).[52,53] Polymer specimens in which the phenolic

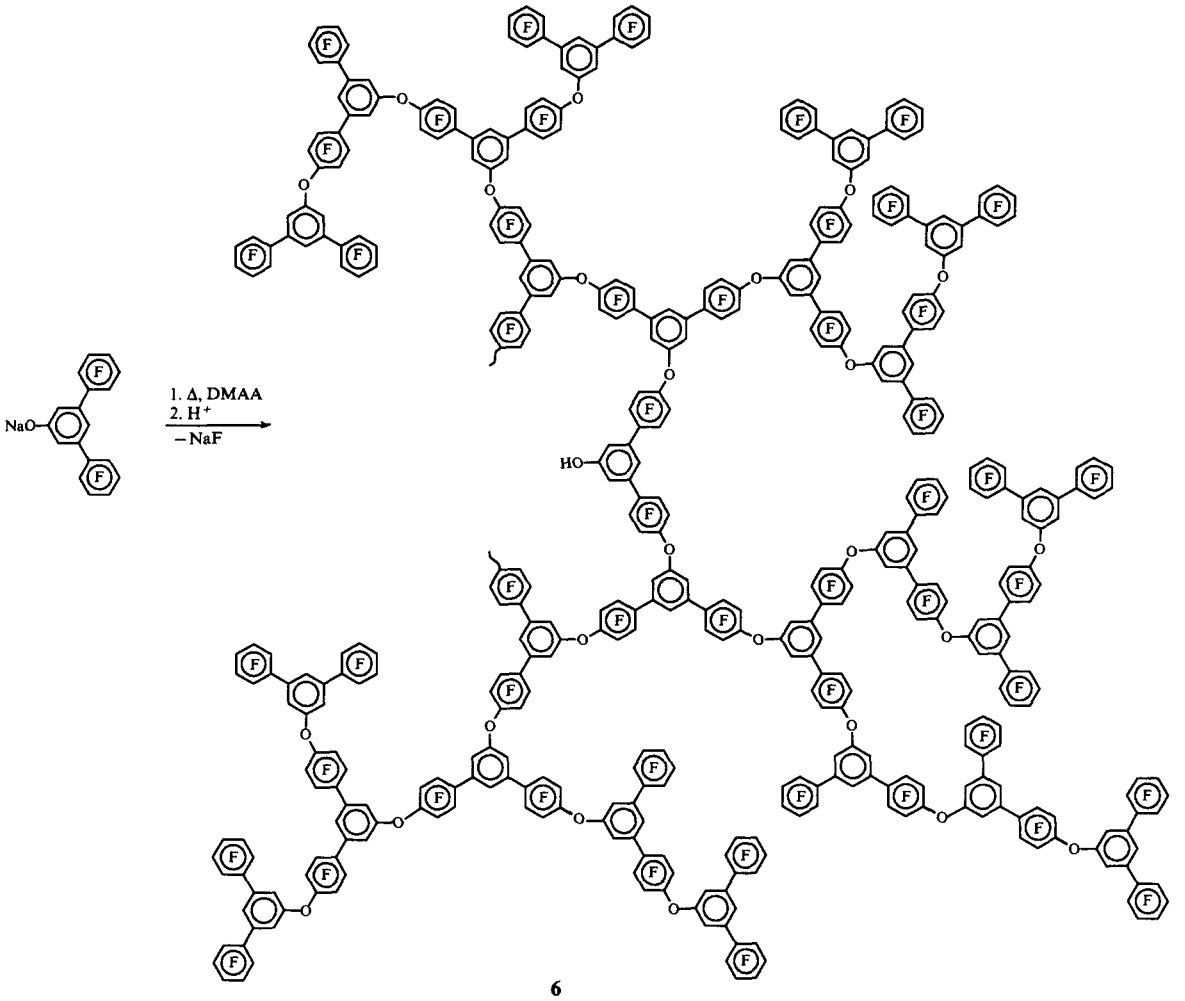
end-groups had been replaced by the inert benzyl groups as a result of the reaction with benzyl bromide were used for subsequent investigations and measurements. The solvent exerts a significant influence on the yield and the molecular mass of the product in this instance: in dichloroethane, the yield does not exceed 38% and $\overline{M}_n$ = 2800, whereas in acetone the yield reaches 73% with $\overline{M}_n$ = 14700. According to ^{1}H NMR data, the polymers formed contain 20%–30% of *C*-alkylated fragments, which are a result of C–C condensation in a side reaction.



The dendritic aromatic polyamides **5a, b** were obtained from 1,3,5-trisubstituted benzenes in two ways: by the neutralisation of the hydrochloride with subsequent condensation of the resulting free amine (Scheme 7) and by the hydrolysis of the chloride of the sulfinylaminoacid 3,5-$(OSN)_2C_6H_3COCl$ [or 3,5-$(ClCO)_2C_6H_3NSO$].[54]

The dendritic analogues of the well known and widely used linear poly(phenylene oxides) are formed on polycondensation of phenoxides containing pentafluorophenyl or *p*-fluorophenyl substituents in the 3- and 5-positions (Scheme 8).[55]

Other dendrimers of this group were obtained under the same conditions from their monomers

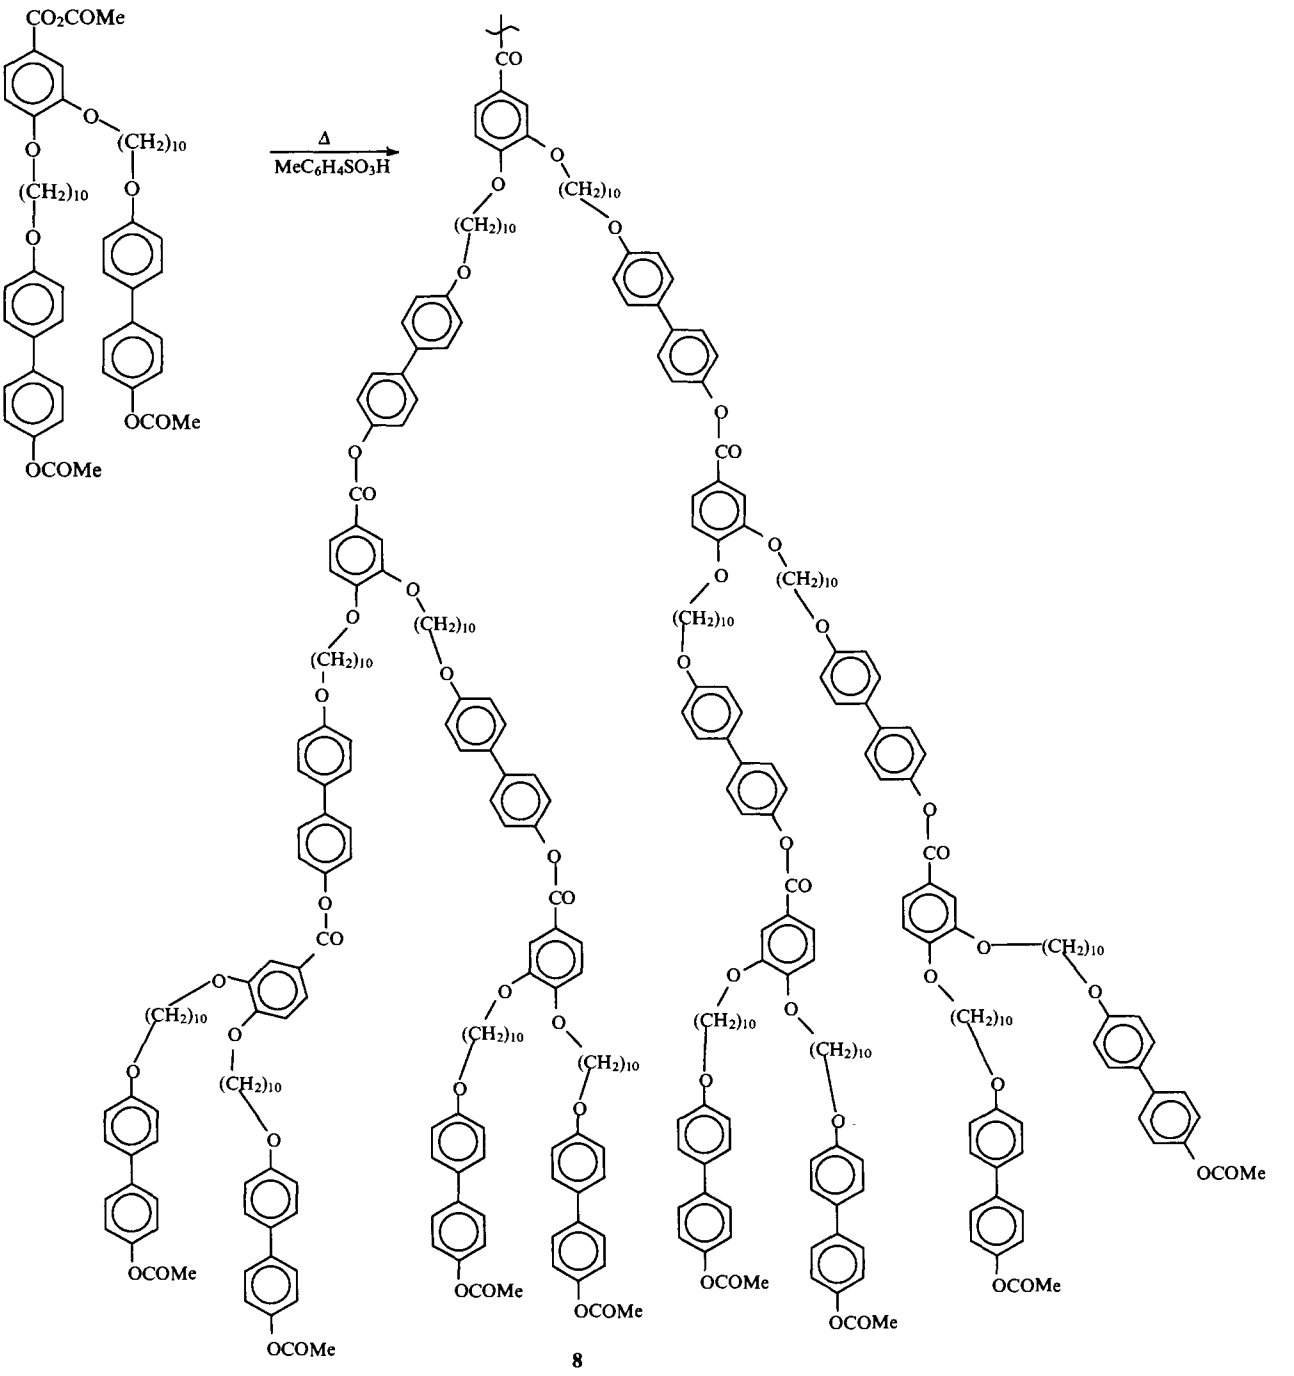
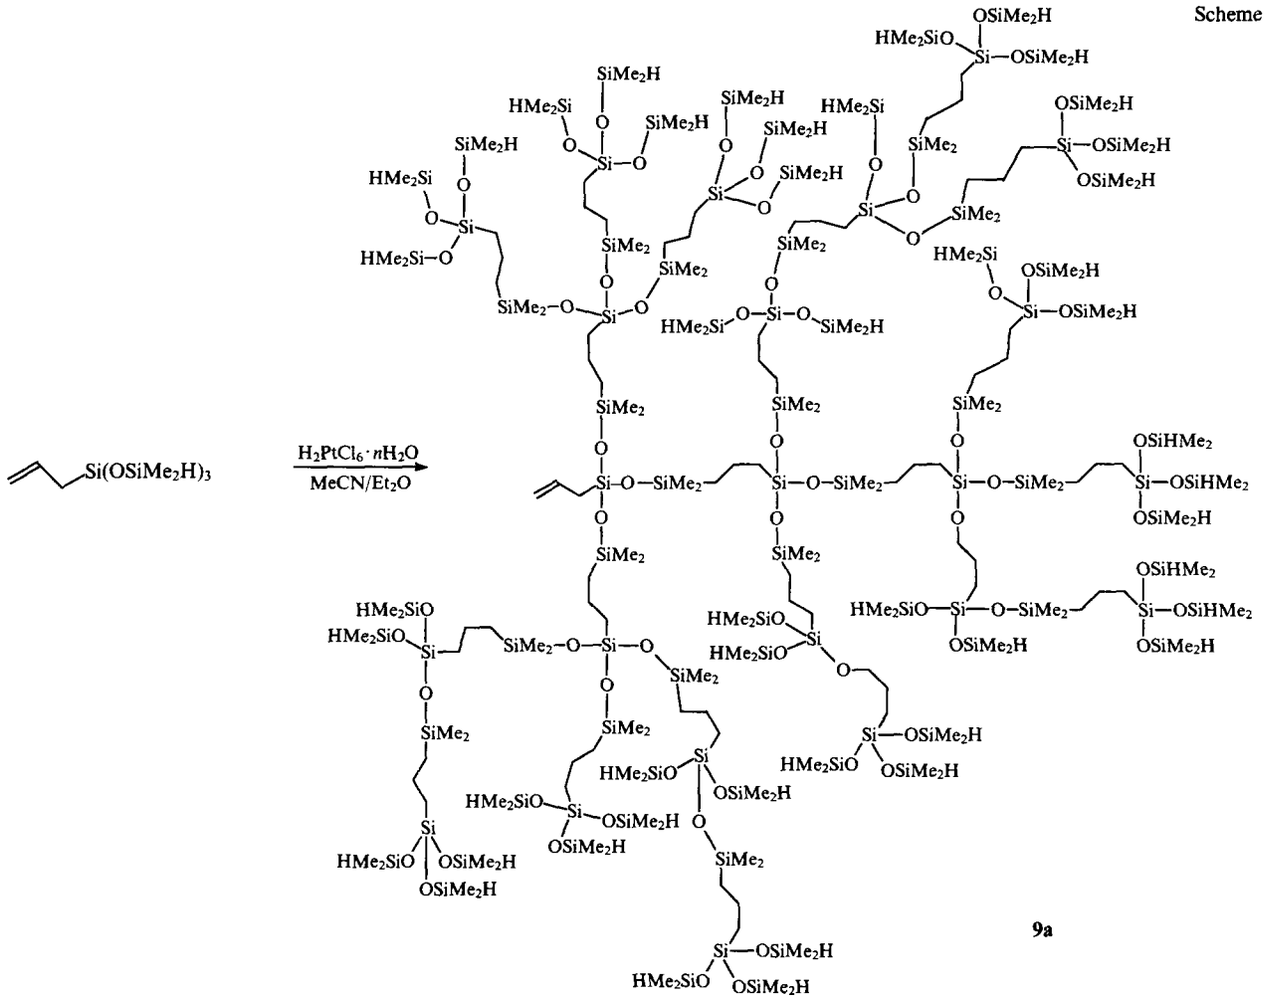
R = $(CH_2)_3CH_3$, $(CH_2)_5CH_3$, $(CH_2)_7CH_3$, CH_2Ph.

The dendritic polymers **7** of the unusual 'willow-like' type have been synthesised recently from 6-bromo-1-(4-hydroxy-4'-biphenyl)-2-(4-hydroxyphenyl)hexane **7a** and the corresponding decane **7b**.[56,57] The polyesterification was carried out under the conditions of phase transfer catalysis in the presence of tetrabutylammonium hydrogen sulfate with subsequent alkylation of the terminal hydroxy-groups (Scheme 9). Similar polymers have been obtained[57] from the diols



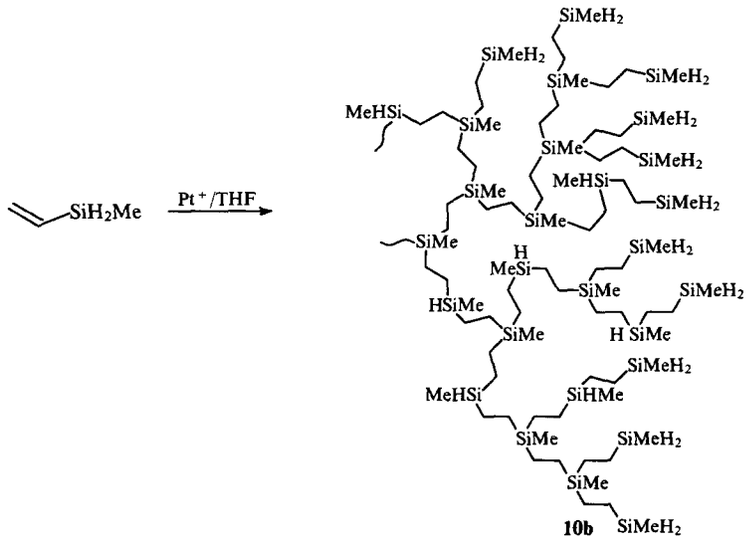
The choice of the monomers for these syntheses was dictated by their mesogenic nature, which permitted the hope that liquid crystal properties might appear in the products.

This was also the aim in the synthesis of the polyester **8** by heating a melt of the monomer at 240 °C in the presence of toluene-*p*-sulfonic acid (Scheme 10).[58] After the polycondensation had been completed, the end-groups were functionalised by adding to the mixture the chloride of a substituted benzoic acid with asymmetric substituents.



In order to obtain the dendritic polycarbosiloxanes **9a, b**, the allyl(siloxy)silanes $CH_2=CHCH_2Si(OSiMe_2H)_3$ and $CH_2=CHCH_2SiMe(OSiMe_2H)_2$ were synthesised by the cohydrolysis of chlorodimethylsilane with allyldichlorosilane and allyldichloro(methyl)silane respectively.[59,60] The subsequent polymerisation of these monomers in the presence of a platinum catalyst at 52 °C led to dendrimers containing 3–4 layers of monomer units (Scheme 11). In order to prevent intermolecular

Scheme 10



8

Scheme 11

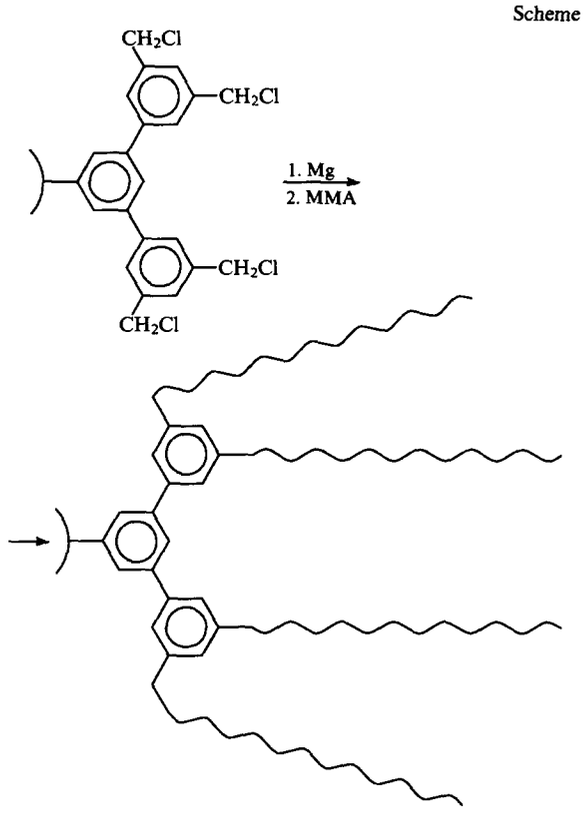
Scheme 12

cross-linking as a consequence of the oxidation of the Si–H end groups and the formation of Si–O–Si bridges, leading to a decrease in the solubility of the polymers, the freshly prepared polysiloxanes **9a**, **b** were treated with allyl phenyl ether. As a result of the addition of the latter, the reactive Si–H groups were replaced by the inert ether end-groups Si–$CH_2CH_2CH_2OPh$.

The same reaction, i.e. catalytic hydrosilylation, was used to obtain the group of dendritic polycarbosilanes **10a–d** from the allyl- and vinyl-silanes $(CH_2{=}CHCH_2)_2MeSiH$, $(CH_2{=}CHCH_2)_3SiH$, $CH_2{=}CH(Me)SiH_2$, and $(CH_2{=}CH)_2{=}MeSiH$ (Scheme 12).[61] All the reactions come to an end after several hours (at 85 °C) and afford high yields of dendritic polymers in the form of viscous transparent liquids. Derivatives with allyl end-groups were then used to obtain modified carbosilanes.

III. The molecular mass, shape, and structure of the macromolecules

In considering the theoretically ideal polycondensation reaction of type $A-R-B_x$ monomers, de Gennes and Hervet [62] concluded that such a reaction should lead to the maximum possible molecular mass, i.e. to a polymer the molecular mass of which is determined solely by the amount of the monomer introduced into the reaction. However, studies have shown that all real processes give rise to dendrimers with a limited molecular mass and size of the macromolecules. The addition in this instance of the initial monomer to the reaction mixture after the completion of the process leads neither to an increase in the molecular mass nor to the appearance of a new fraction of the polymer with a new value of $\overline{M}$.[25,36,61] This finding cannot be rigorously explained, because the molecules of all the dendrimers described above contain on their surface active functional groups capable of combining with additional monomer molecules and hence of giving rise to new generations of layers.



The limitation of the molecular mass of the polymers in real processes has been attributed [25,59,60,63] to steric hindrance, which increases with increase in the size of the macromolecule, or to the formation of an intramolecular ring incorporating group A in the growing dendron $A-[R]_n-B_y$. Apparently this explanation is valid for the convergent mechanism of the formation of the dendritic molecule. However, there are grounds for the hypothesis that, under the conditions of the uncontrolled single-stage synthesis, all versions of the growth occur—convergent, divergent, and their combinations. All three mechanisms are then equally probable in the initial stages. The contributions of the convergent and combined mechanisms ensure a rapid growth of the molecule up to a definite critical size, after the attainment of which the divergent mechanism becomes dominant (as a result of the decreased shielding of the active centres), which leads to a sharp retardation of the increase in $\overline{M}$. (In this respect, there is no doubt about the influence of steric factors.) Hence it follows that the observed limiting values of $\overline{M}$ for all types of dendritic polymers obtained via a single-stage synthesis are only apparent. The introduction of an additional amount of the monomer into the reaction mixture should lead not only to the formation of a new portion of molecules with the 'standard' size but also to some increase in the molecular mass ($\Delta\overline{M}$) of the molecules already present. However, this increase is readily masked against the background of the increase in the overall mass of the polymer.

An indirect confirmation of this hypothesis is provided by the procedure discovered for the rapid increase in the molecular mass of PPG,[36] in which the least soluble fraction and hence the fraction with the highest molecular mass, isolated beforehand from the standard polymer, is introduced into the reaction with a fresh portion of the monomer, where it plays the role of a giant initiator core. The sixfold repetition of this operation made it possible to obtain PPG with a molecular size in excess of 2200 Å for an initial diameter of 50–55 Å. On the other hand, in the synthesis of PPG in the presence of $(C_6F_5)_4Ge$, which plays the role of a kind of inhibitor of the convergent path, a polymer with a lower molecular mass was obtained.[43]

The same principle, i.e. the use of dendritic molecules as the starting compounds, was used in the synthesis of star polymers based on the polyphenylene dendrimer **1** (Scheme 13)[63] and the carbosilane dendrimer **10a**.[61]

The degree of polymerisation n in real cascade compounds obtained in a single stage synthesis varies from 9–15 (for dendrimer **7a**)[56] to 200–300 (for PPG and the polymers **6a–d**).[55] Evidently the type of the monomer and not the rate of reaction exerts a decisive influence under these conditions. Thus, the dendrimer **1** with $n = 25-30$ and PPG with $n = 300$ are formed equally rapidly at room temperature, whereas the triphenylene polymer **6a** ($n \approx 330$) is formed on heating for 0.5–2.0 h.

Scheme 13

The conditions under which the synthesis is carried out affects the degree of polymerisation to a lesser extent. However, in a number of instances a change of the solvent, of the monomer concentration, of the temperature, and of the reaction time entails a change in the degree of polymerisation by a factor of 2–3.[48,55]

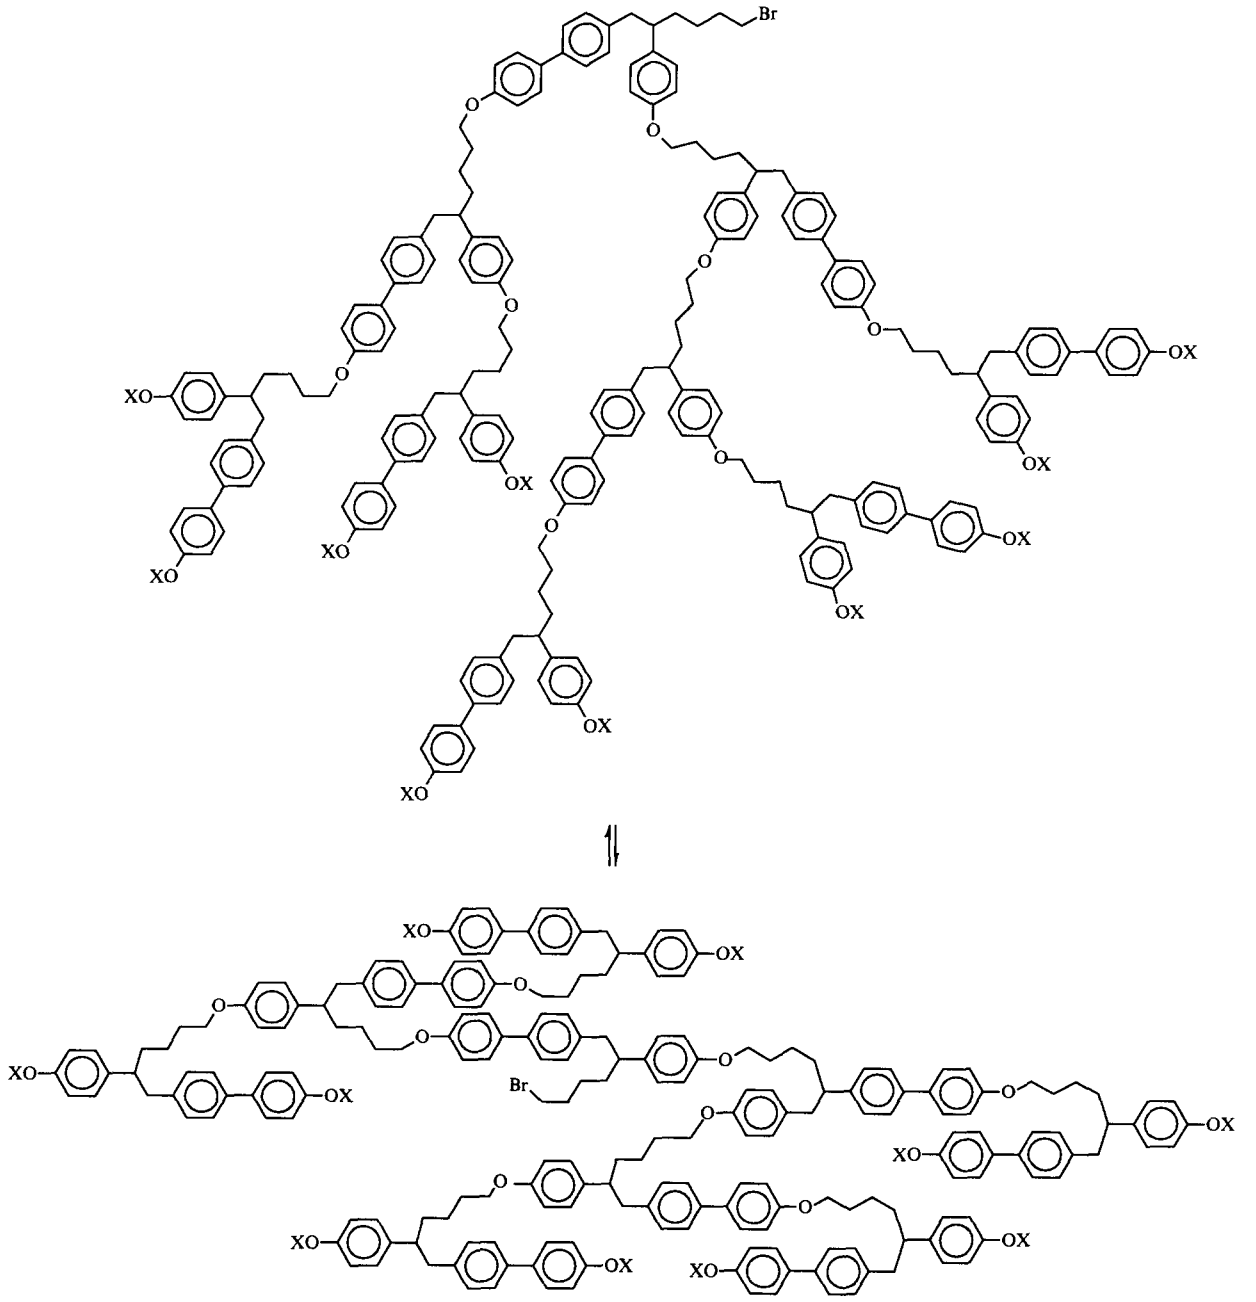
The polydispersity of the dendritic polymers obtained by a single stage synthesis does not exceed three in most cases. M_w/M_n exceeds 4 only for certain specimens of the polymers **6a–d** and is up to 10 for the dendrimer **3b**. In the case of the polymer **3b**, the molecular mass distribution of the product is polymodal.[51]

One of the most important characteristics of dendrimers is the shape and linear dimensions of the macromolecules. The construction of three-dimensional models of dendrimers showed that after only 3 generations the molecules approach a spherical shape and become regularly spherical following a further increase in the number of generations. The spherical form of the cascade compounds is apparently in fact responsible for their antifriction properties.[64]

Another characteristic feature of the dendrimer molecules is the presence of cavities, the size of which depends on the geometrical characteristics of the elementary unit.[25,43] In the dendrimers **1** and in PPG, the size of the cavities is 5–6 Å. The presence of unoccupied cavities in the molecules of the dendrimers makes it possible to employ them in compositions of the 'guest–host' type. Such complexes have been obtained for the polyphenylene–*p*-toluidine system.[25]

In the case of PPG,[36–38,43] the molecular diameter was determined by small angle laser scattering (SLS), small angle X-ray scattering, electron microscopy, and the calibrated filter method. The first two methods give rise to a significant scatter. For a PPG specimen with a molecular mass of $(1-1.5) \times 10^5$, which corresponds to $n = 180-270$ and a number of generations $G = 4-5$, it was found that the diameter of the macromolecules is 130–140 Å. Spherical particles with a similar diameter (~200 Å) have been observed by electron microscopy for the same specimen. PPG with a molecular mass of 400 000 has particles of the same size. However, repeated measurements on a standard PPG specimen demonstrated a significantly smaller

average diameter, namely 50–55 Å.[43] The unduly large molecular dimensions obtained from measurements by small angle laser and X-ray scattering are evidently associated with the low accuracy of these methods.



Computer modelling showed that PPG molecules have a diameter of 52.9 Å for $G = 4$ and 63.2 Å for $G = 5$. The calculated molecular masses of the polymer (for a 100% degree of branching) with $G = 4$ and 5 are respectively 90 000 and 270 000. Taking into account the smaller degree of branching in the real polymer, the agreement of the values of $\overline{M}$ obtained with the experimental value of 100 000–150 000 may be regarded as satisfactory.

It has been found for the dendritic polyphenylene **1**[25] and the polyester **2**,[48] in which the multiplicity of the monomer unit is 2, that the degree of branching of these polymers (according to NMR spectroscopic data) does not exceed 60%–70%. In addition, one should take into account the fact that, when the molecule is formed under the conditions of uncontrolled synthesis, the role of initiator core may be assumed not only by the $A-R-B_x$ monomer with a blocked functional group A but also by the ring $[-A-R-B_x-]_n$ formed in the initial stage via intramolecular condensation. As a result of this, the deviation from the ideal dendritic structure is inevitably reflected in the molecular mass and linear dimensions of the macromolecules obtained. It has been suggested that a decrease in the monomer concentration in the initial reaction mixture promotes the formation of intramolecular rings.[55]

IV. Properties

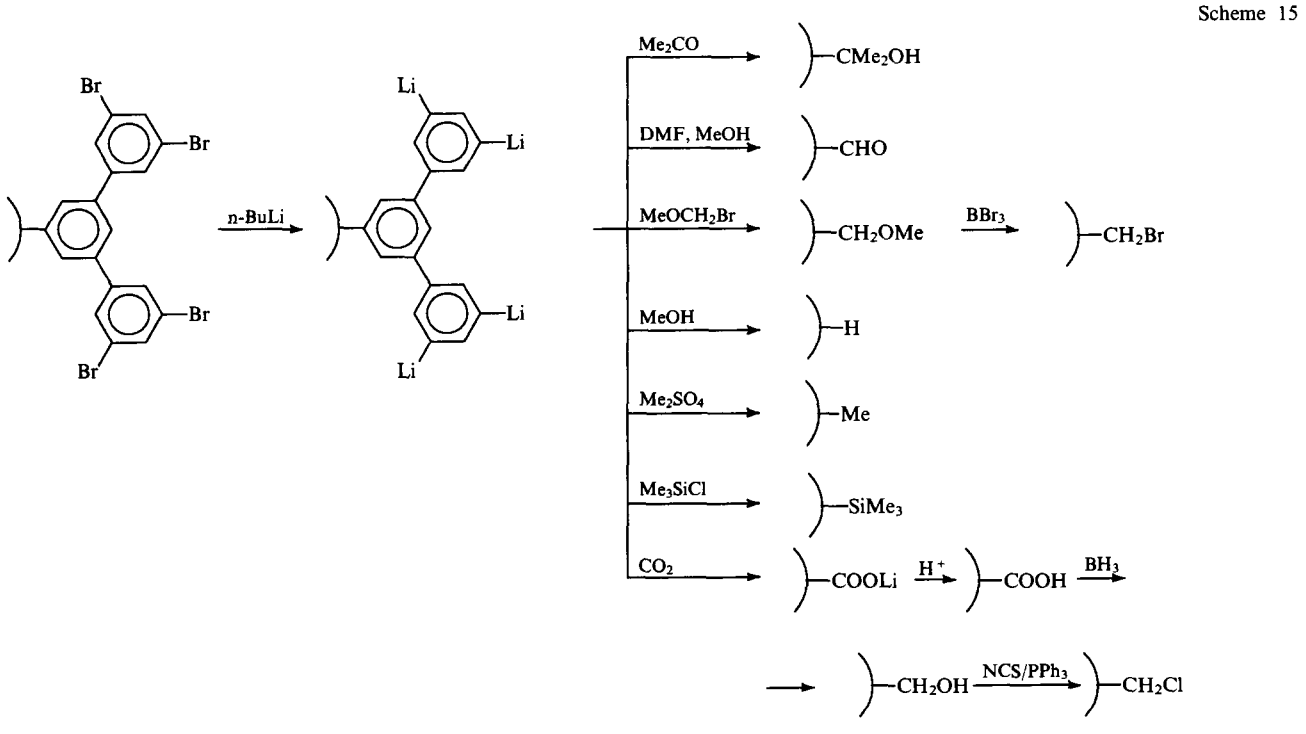
Like the usual flexible-chain polymers, the dendrimers obtained by a single-stage synthesis are viscous liquids, amorphous white powders, or vitreous colourless or pale-yellow substances. Many of them are capable of forming film coatings, but their mechanical properties (for example, their tensile strength) are significantly inferior to those of the usual polymers. However, their employment as modifying additives to rubber compositions based on siloxane raw rubbers leads to a significant increase in the tensile strength of the latter.[61]

Scheme 14

All dendritic polymers are readily soluble in organic solvents such as toluene, chloroform, acetone, and THF. Compared with the linear polymers formed from isotypical elementary units, the solubility of dendrimers is higher. It has been suggested that this is associated with the spherical shape of the molecules, which prevents the close packing of the polymer segments.[48] The peripheral functional groups also exert a considerable influence on the solubility: thus the introduction of alkyl terminal substituents tends to increase the solubility of the polymers in hydrocarbons, whilst the use of carboxylate, hydroxy-, or hydrochloroammonio-end-groups solubilises previously insoluble dendrimers.[25,54,63]

One of the characteristic properties of all dendrimers, including cascade polymers, is a low viscosity of their solutions [the viscosity of PPG solutions is four orders of magnitude lower than that of the solutions of poly(butyl methacrylate) with a similar molecular mass].[65] The molecular mass and concentration of the solutions exert little influence on their viscosity.[36,51,65] In terms of their rheological properties, these substances are closer to suspensions than to solutions of flexible-chain polymers. It is of interest to note that, when a small amount of the dendrimer is added to the normal polymer, the viscosity of the melt of the mixture is significantly reduced.[63]

The spatially fractal nature of the macromolecular framework of dendrimers indicates their possible crystallinity. However, the deviations in the spatial disposition of the elementary units from the ideal sites as well as the reduced degree of branching in the real specimens make it possible to obtain crystals only for first and second generation dendritic compounds.[66] All the remaining polymers of this class are amorphous, which is indicated by the absence of melting points and crystallisation temperatures in these compounds.[55,67] The glass points of isotypical polymers depend little on the molecular mass, but change markedly when the end-groups are altered.



The 'willow-like' dendrimers **7**, obtained by Percec and Kawasumi[56,57] from monomers having mesogenic properties by virtue of their conformational isomerism, are thermotropic liquid crystal substances. It has been suggested that, both in the isotropic phase and in solution, these substances contain mesogenic elementary units in the *gauche*-conformation (or in a *gauche*–*anti* dynamic equilibrium). Such conformation of the units gives rise to the hierarchical architecture of the molecular framework characteristic of dendrimers. On decrease in temperature, the elementary units pass to the *anti*-conformation, which entails a change in the tree-like macromolecular skeleton. They acquire a compact form, corresponding to the nematic mesophase of the polymer (Scheme 14). The transition has been noted in the temperature range from 20 to 40 °C depending on the length and nature of the end-groups of the macrochains.

The existence of a liquid-crystal phase at room temperature has also been noted in a study of solutions of the polymers **5a, b** in amides.[54] For the dendritic polyester **8**, the formation of the cholesteric mesophase has been noted in the temperature range 60–148 °C.[58] By virtue of the presence of chiral end-groups, the same polymer is optically active.

The study of the temperature dependence of the heat capacity of PPG over a wide temperature range (0–550 K) showed that the specific features of the molecular structure of the dendrimer and the molecular shape are hardly reflected in the thermodynamic characteristics of the polymer.[67]

The thermal stability of dendritic polymers is as a rule higher than that of their linear analogues and the corresponding monomeric compounds.[46,48,55,63,68] The polyphenylene dendrimers **1** and **6** belong to the class of the most thermally stable polymeric substances. They begin to decompose in air on heating above 500–550 °C.[55,63] PPG is almost as stable.[68] When PPG is heated at 420 °C for 1.5 h, it loses 4.5% of its mass, the elimination of C_6F_5H and C_6F_6 molecules and partial cross-linking of the macromolecules being noted under these conditions. Among other thermal decomposition products, fluorine and the digermane $[(C_6F_5)_3Ge]_2C_6F_4$ were noted. Decomposition at 580 °C leads to the formation of carbon and germanium. It has been found that the addition of small amounts of dendrimers to the usual polymeric substances frequently increases the thermal stability of the latter.[63,68,69] It has been observed for PPG that the temperature range in which the dendritic polymer exhibits a stabilising activity coincides with the temperature range of its decomposition. This suggests that the substances responsible for the stabilising effect are not the dendrimers themselves but the low-molecular-mass products of their decomposition.[69]

Scheme 15

The possibility of modifying polymers **1** and **4** by replacing the peripheral functional groups has been investigated.[47,52,63] It has been found that the bromine atoms and the phenolic groups in the dendrimer **1** can be replaced by alkyl, aryl, carboxy-, carboxylate, haloalkyl, ethynyl, etc. groups (Scheme 15).

During the modification, 70% – 80% of the functional groups of the initial polymer are as a rule exchanged. It has been noted that a polymer with partially substituted functional groups enters more readily into the subsequent substitution reaction. This property, which has been observed also in relation to other examples,[3] is apparently common to all the dendritic formations. It has been suggested that this may be caused by the local polarisation of the functional groups. Thus the replacement of the functional end-groups, accompanied by significant changes in the solubility and glass point, permits the deliberate alteration of the characteristics of dendritic materials and leads to prospects for the synthesis of micellar and lyotropic systems.

The high reactivity of the peripheral functional groups in the dendrimer **1a** and its derivatives has been used to synthesise polymers of a new type, the so-called star polymers. The macromolecule of such a compound, obtained from compound **1**, closely resembles the shape of the sea urchin.[63] Its 'body' comprises the molecule of the initial dendrimer and the outgoing 'rays (needles)' consist of the linear oligomer and polymer chains. These molecules were synthesised by the successive Br/Li/$SiMe_2R$ (R = CH_3, C_8H_{17}, $C_{18}H_{17}$, $C_{30}H_{61}$) substitution of functional groups or by growing linear polymer chains [of polypropiolactone and poly(methyl methacrylate)] on the surfaces of the spherical molecules, where the dendrimer molecule plays the role of the initiator core.

Thus, one may conclude that, despite the low organisation of the molecular architecture of the dendritic polymers obtained by a single-stage synthesis, their physicochemical properties differ little from those of the dendrimers obtained by the multistep method. Taking into account the advantages of a single-stage synthesis of the dendrimers and the highly promising practically useful properties of such substances, one may confidently predict a vigorous development of this aspect of modern chemistry in the immediate future.

Abstract. The review is devoted to the synthesis and biological properties of the amides and peptides containing the stereoisomers of 4-[bis(2-chloroethyl)amino]phenylalanine. The approaches to the selection of the structures of the compounds indicated, ensuring an increase in the selectivity of their antitumour activity, are examined. The bibliography includes 131 references.

I. Introduction

Sarcolysine (Sarc) or 4-[bis(2-chloroethyl)amino]-DL-phenylalanine hydrochloride **1** and melphalan (Mel) or 4-[bis(2-chloroethyl)amino]-L-phenylalanine hydrochloride **2**, which are antitumour preparations widely used at the present time, have been synthesised and investigated independently and simultaneously by two groups of investigators in the USSR and England.

1–3

Continuing the idea of L F Larionov concerning the use of essential metabolites, in particular aminoacids, as carriers for the alkylating group, sarcolysine[1] and its enantiomers based on L- and D-phenylalanines have been synthesised in the Soviet Union. The D-enantiomer **3** [medphalan (Med)] was synthesised in England under Bergel's supervision.[2,3]

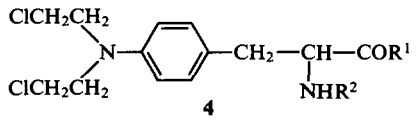
On the basis of experimental data, the authors[2,4] established that the L-form **2** is more active than the D-form **3**. This is probably associated with the difference in the transport of the stereoisomers, their chemical transformation in the organism (medphalan is deaminated by D-aminooxidase much faster than melphalan), and the nature of the tumours.[5]

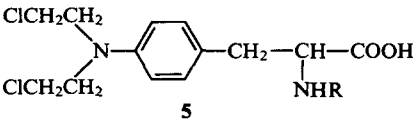


It was established that the transport of melphalan to the tumour cell takes place with the aid of two transferring systems: the L system, which transports leucine, phenylalanine, tryptophan, and valine, and a system similar to ASC, which transports alanine, serine, and cysteine.[6–8] The pharmacokinetics of ^{14}C-labelled sarcolysine and melphalan have been considered in a review[9] and in another communication.[10] Melphalan has been used clinically for the treatment of the same tumours as sarcolysine.[11]

The high activities of sarcolysine and melphalan and their successful clinical application stimulated the development of a new aspect of the chemotherapy of cancer — the synthesis and study of the derivatives of these compounds, as well as the synthesis of the cytotoxic derivatives of other aminoacids. Aminoacids and peptides are known to pass through the membranes of tumour cells 4–5 times more readily than through those of normal cells[12] and there is therefore a possibility of their accumulation in the cancer cell. On this basis, aminoacids and peptides have been frequently used as 'transporters' of alkylating agents.

II. *N*-Acyl derivatives of 4-[bis(2-chloroethyl)-amino]phenylalanine and their esters, amides, and salts

Some information about the chemistry of alkylating preparations, including the chemistry of sarcolysine peptides, has been surveyed in earlier reviews[13,14] and in the review of Giller et al.[12] Since sarcolysine has a toxic side effect in relation to hematopoiesis, attempts were made to increase the selectivity of its transport into tumour cells by synthesising a wide variety of *N*-acyl derivatives; esters, amides, and hydrazides. A large series of derivatives **4**, synthesised after sarcolysine had been obtained, have been described in a review.[5]

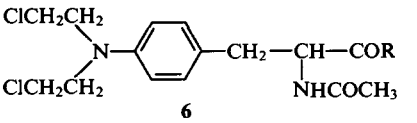


A series of compounds with other aliphatic and aromatic acyl groups as well as urethane and sulfonamide analogues of sarcolysine **5** were obtained later.[15]

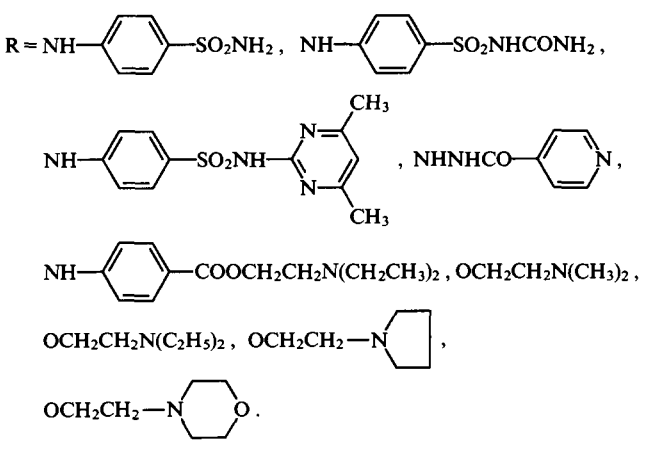
4

R^1 = OH, OCH_3, OC_2H_5, $OCH_2C_6H_5$, OC_3H_7-iso, NH_2, NHC_2H_5, NHC_6H_{11}-cyclo, $NHNH_2$ etc.;

R^2 = H, CHO, CH_3CO, CH_3CH_2CO, $CH_3(CH_2)_2CO$, $CH_3(CH_2)_3CO$, $CH_3(CH_2)_{14}CO$, $CH_3(CH_2)_{16}CO$, $HOOC(CH_2)_2CO$, $ClCH_2CO$, ICH_2CO, p-$(ClCH_2CH_2)_2NC_6H_4CH_2CO$, nicotinoyl, tetracyclinylmethylene, hydroxytetracyclinylmethylene, etc.

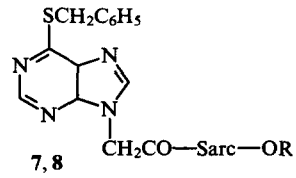


5



R = CH_3CO, $C_5H_{11}CO$, $C_8H_{17}CO$, $C_{11}H_{23}CO$, $C_6H_5CH_2CO$, C_6H_5CO, sec-C_4H_9OCO, C_6H_5OCO, p-$CH_3C_6H_4SO_2$.

The compounds were used in biological tests in the form of salts with ethanolamine. They are all characterised by a lower toxicity than sarcolysine. *N*-Acetylsarcolysine **5** (R = CH_3CO) possesses the highest antitumour activity. There is no clear-cut correlation between the physicochemical and biological properties of the compounds. The capacity for metabolic transformations is apparently very important. It may be that the antitumour activity is shown to a greater extent the easier the deacylation of the preparation in vivo.



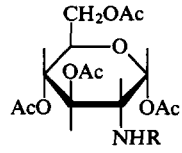
In order to investigate the antitumour properties, a large number of sarcolysine amides were synthesised, for example the *N*-acetylsarcolysine derivative **6** containing streptocide, urosulfan, sulfadimesine, tubazid, and novocaine residues, as well as the dialkylaminoalkyl esters of *N*-acetylsarcolysine.[16]

6

The 6-benzylthio-9*H*-purin-9-ylacetic acid residue was used as the agent for the transfer of sarcolysine into the tumour cell. The derivative **7** was obtained by alkylating 6-benzylthiopurine with the ethyl ester of *N*-(bromoacetyl)sarcolysine. The alkaline hydrolysis of the derivative **7** leads to compound **8**.[17]

7, 8

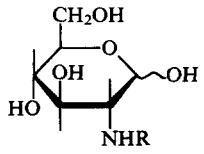
R = C_2H_5 (**7**), H (**8**).



In order to diminish the hematotoxic activity of sarcolysine caused by the introduction of the ferrocene fragment, the methyl ester of N^{α}-ferrocenoylsarcolysine **9** and the ferrocenylamide of *N*-acetylsarcolysine **10** were synthesised.[18]

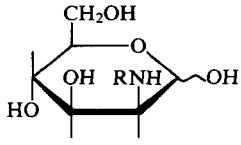
9 **10**

Fc = ferrocenyl.



The combination of the biologically active carrier of the cytotoxic group and of the active principle of the latent activity was used in the synthesis of the 1,3,4,6-tetraacetyl-2-amino-2-deoxy-D-glucopyranose derivatives **11** and **12** of *N*-acetylsarcolysine.[19]

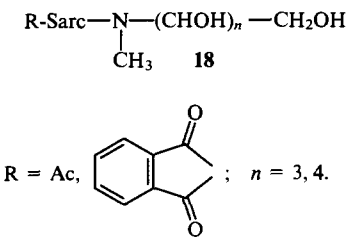
11, 12



R = Ac-Sarc (**11**), Ac-Sarc – DL-Val (**12**).

Compounds **11** and **12** are readily soluble in water, are less toxic, and exhibit a somewhat higher antitumour activity than sarcolysine. A series of 2-amino-2-deoxy-D-glucopyranose derivatives **13**–**16** and the 2-amino-2-deoxy-D-mannose derivative **17**, in which the amino-group is acetylated by *N*-acetylsarcolysine or a peptide containing it, have been synthesised.[20] Compounds **13**–**17** possess a weak antitumour activity.

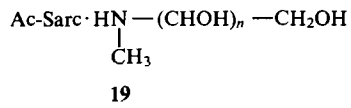
13–16



R = Ac-Sarc (**13**),
Ac-Sarc – Val (**14**),
Ac-Sarc – Leu (**15**),
Ac-Sarc – Gly – Gly (**16**).

17

R = Ac-Sarc (**17**).

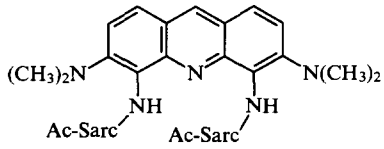


The sarcolysine derivatives of polyhydric 1-methylamino-1-deoxy-alcohols **18** (the 1-methylamino-1-deoxy-derivatives of D-glucitol, D-galactitol, D-mannitol, and L-arabitol) were obtained by the anhydride method or the mixed anhydride method.[20,21] A relation between the structures of the compounds and their biological activities was established. The highest activity was shown by the D-galactitol and D-mannitol derivatives. The spectrum of the antitumour activity of compound **18** resembles that of sarcolysine. In contrast to sarcolysine, all the substances exhibited a minimal effectiveness in the treatment of leukaemia and the highest in the treatment of the MORS-406 plasmacytoma.

18

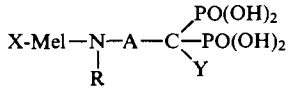
R = Ac, ; $n = 3, 4$.

In order to make the compounds soluble in water, the salts of *N*-acetylsarcolysine with the amino-derivatives **19** of the polyhydric alcohols listed above were obtained.[22]



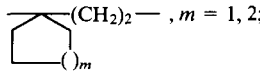
19

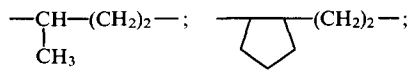
$n = 3, 4$.



The acetyl derivatives showed a low toxicity and exhibited the highest antitumour activity towards MORS-406 plasmacytoma.

The varied biological activities of the disubstituted 3,6-acridines served as a basis for the synthesis of compound **20**.[23]

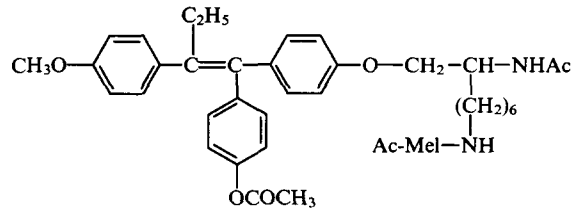




20

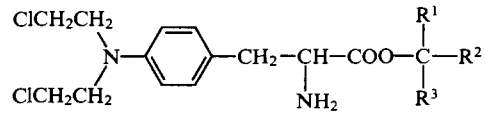
In view of the tropism of the 1,1-diphosphonic acid derivatives in relation to bone tissue, a series of melphalan amides **21**, containing two phosphonic acid residues, were synthesised. They exhibit an antitumour activity towards certain tumours.[24]

21



A = $-(CH_2)_n-$, $n = 2-5$;  , $m = 1, 2$;

R = CH_3, H; X = HCO, $(CH_3)_3COCO$, H; Y = OH, H.



The above acids as well as their tetraethyl esters and sodium salts can be used in the treatment of dense tumours such as multiple myeloma, osteosarcoma, the mammary gland carcinoma, the carcinoma of the ovaries, leukaemia, and lymphomas. The substances are characterised by a high therapeutic index, a low toxicity, and a ready solubility in water, which permits their parenteral and oral administration.

Acetylmelphalan was used, among other cytostatic agents, for the synthesis of antitumour compounds (for example compound **22**) with an affinity for steroid hormone receptors.[25]

22

The antitumour activities and toxicities of the lower esters **23** differ little from those of sarcolysine.[5] The *tert*-butyl esters of sarcolysine **23** ($R^1 = R^2 = R^3 = CH_3$) have been used as therapeutic agents to prevent the occurrence of metastases in the brain.[26]

23

R^1-R^3 = H, Cl, Br, F, I, Alk(C_1-C_3).

One of the groups $R^1 = R^3$ may be a haloalkyl group.

III. The di- and tripeptides derived from the stereoisomers of 4-[bis(2-chloroethyl)amino]-phenylalanine

The procedure used in the synthesis of the 4-[bis(2-chloroethyl)-amino]phenylalanine peptides proved extremely fruitful in increasing the selectivity of the antitumour activity of this compound†. By virtue of the ready availability of sarcolysine, numerous studies have been carried out on the synthesis of peptides based on it with both optically active and racemic aminoacids (mixtures of stereoisomers were then obtained). In the early studies, the content of the stereoisomers in the mixtures was not determined, although interesting results were in fact obtained in the study of their biological activity. The development of methods of synthesis of sarcolysine-containing peptides has been justified objectively, because in the synthesis of potential biologically active compounds a mixture of stereoisomers was frequently isolated initially and then, when a high physiological activity had been discovered, the mixture was separated into the individual stereoisomers. The methods for the formation of the peptide bond, the selective removal of the protecting group, etc. developed for racemic mixtures, have not lost their importance to this day.

A large number of peptides derived from sarcolysine, in which the latter is the N- or C-terminal aminoacid or is present in the middle of the chain, have been synthesised and investigated.[5] Peptides with melphalan have also been described in the review of Rasteikene et al.[5]

A large series of studies on the synthesis of dipeptides, the preparation of individual diastereoisomers, the analysis of their diastereoisomeric purity, and the study of the relation between the biological activity of the compounds and their structure have been carried out under the supervision of E N Shkodinskaya. Dipeptides with *N*-acetylsarcolysine at the N-end occupy a special place among the sarcolysine peptides. It was found that the *N*-acetylsarcolysine dipeptides exhibit a high antitumour activity and at the same time act more selectively than sarcolysine or its dipeptides with a free, formylated, or benzoylated amino-group. The first peptide synthesised and investigated — the ethyl ester of *N*-acetylsarcolysyl-DL-valine **24** (asalin),[27] which has

† With the exception of specially stipulated instances and compounds **1** and **3**, all the aminoacids belong to the L-series.

found an application in practical oncology, was obtained by the dicyclohexylcarbodiimide (DCHC) method.

Ac-Sarc–DL-Val-OC_2H_5 (**24**),
Ac-Sarc–Phe-OC_2H_5 (**25**),
Ac-Sarc–DL-Met-OC_2H_5 (**26**),

Ac-Sarc–DL-Asp$(OC_2H_5)_2$ (**30**),
Ac-Sarc–Asp-$(OC_2H_5)_2$ (**31**),
Ac-Sarc–DL-Asp$(OCH_2C_6H_5)_2$ (**32**),
Ac-Sarc–DL-Asp$(OH)_2$ (**33**).

The ethyl esters of *N*-acetylsarcolysine peptides with both racemic aminoacids (methionine, cysteine, phenylalanine, and alanine)[27] and with optically active aminoacids [L-phenylalanine (asaphan **25**), L-methionine (asamet **27**)] were synthesised similarly. The syntheses of a series of *N*-acetylsarcolysine peptides by the mixed anhydride method using the chloride of isovaleric acid have been described.[28] The dipeptides **24–33** with DL-valine, L-phenylalanine, DL- and L-methionine, DL-serine, and L- and DL-aspartic acids have been obtained by this method. Subsequently asalin, asaphan, asamet, asaley (the ethyl ester of *N*-acetylsarcolysyl-L-leucine) and astyron (the ethyl ester of *N*-acetylsarcolysyl-L-tyrosine) became the subject of a more far reaching study in order to introduce the best of them into oncological practice.

A comparative study was made of the toxicity of asalin, asaley, and astyron administered in different ways.[29] Their toxic effects on the organism proved to be similar. Asalin and asaley exhibit a weaker inhibiting effect on the haematopoietic system compared with sarcolysine.[30] The mechanism of the antitumour activities of asalin and asaley[31,32] and their influence on the immune system[33,34] have been investigated comprehensively. The effect of asalin on haematopoiesis,[35–38] the molecular mechanism of antitumour activity,[39–41] the molecular mechanism of its effect on the functional state of mitochondrial membranes in vivo,[42] and its mutagenic activity[42] have been investigated. A method of synthesis of ^{14}C-labelled asaley, containing a label either in the sarcolysine or in the leucine residue, has been developed for the study of its pharmacokinetics.[44]

Asalin has undergone clinical tests and has been recommended for the treatment of myeloma, lymphosarcoma, reticulosarcoma, and ovarian seminoma. Asalin may find the most effective practical application in the treatment of tumours in patients with symptoms of a moderate inhibition of haematopoiesis after radiation therapy and the use of alkylating agents.[11]

In order to obtain water-soluble *N*-acetylsarcolysine dipeptides, a method has been proposed for the deblocking of the carboxy-group by means of the alkaline hydrolysis under mild conditions of their methyl and ethyl esters.[45] The bis(2-chloroethyl)amino-group is unaffected under these conditions. The dipeptides with DL-valine, DL-tryptophan, L-phenylalanine, L-methionine, and L-leucine were synthesised by this method.

The mixed anhydride method employing methyl chlorocarbonate has been used to obtain the sarcolysine-modified carnosine, homocarnosine, and anserine (compounds **34–38**).[46]

Ac-Sarc–β-Ala-OH (**34**),
Ac-Sarc–γ-Abu-OH (**35**),
Ac-Sarc–β-Ala–His-OH (**36**),
Ac-Sarc–β-Ala–N^{im}-Me-His-OH (**37**),
Ac-Sarc–γ-Abu–His-OH (**38**).

The solid-phase synthesis of the peptides **39–41**, analogues of compound **36**, employing *N,N'*-carbonyldiimidazole as the condensing agent, has been described.[47]

HCO-Sarc–β-Ala–His-OCH_3 (**39**),
HCO-Sarc–β-Ala–His-$OCH_2C_6H_5$ (**40**),
HCO-Sarc–β-Ala–His-OH (**41**).

As mentioned above, *N*-acetylsarcolysine dipeptides with optically active aminoacids are mixtures of two diastereoisomers differing in their biological activities. The maximum antitumour activity of each dipeptide is associated with a definite combination of optically active aminoacids. Thus the L,L-isomer is the most active for asaphan, while the L,D- and D,D-forms are the most active for asalin.[13] The preparation of optically active dipeptides of *N*-acetyl-4-[bis(2-chloroethyl)amino]phenylalanine was hindered by the low availability of compounds **2** and **3** and the appreciable racemisation of their acetyl derivatives during the peptide synthesis. It was found that the optically active dipeptides can be obtained most simply by the interaction of *N*-acetylsarcolysine (the racemic form) with the esters of L- and D-aminoacids with subsequent fractional crystallisation of the optical isomers.[13]

For example, the methods for the isolation and the properties of the enantiomers and of the diastereoisomeric mixtures of asalin **24** have been described.[48] The diastereoisomeric racemates were separated chromatographically into the racemate I (compounds **42** and **43**) and the racemate II (compounds **44** and **45**).

Ac-L-Sarc–L-Val-OC_2H_5 (**42**),
Ac-D-Sarc–D-Val-OC_2H_5 (**43**),
Ac-D-Sarc–L-Val-OC_2H_5 (**44**),
Ac-L-Sarc–D-Val-OC_2H_5 (**45**).

The optically active dipeptides **42–45** were isolated by chromatographic separation of the diastereoisomeric peptides synthesised by the reaction of *N*-acetylsarcolysine and the ethyl esters of L- and D-valine. The asalin specified in the pharmacopoeia consists mainly of the racemate II with an admixture of 0.8% of the racemate I. The racemate II proved to have the highest antitumour activity and the highest toxicity of the two racemic diastereoisomeric mixtures.

In order to investigate the influence of the stereoconfiguration of the aminoacids and of the protection of the amino-group on the antitumour properties of the diastereoisomers, the sarcolysylleucine diastereoisomers **46–57** were synthesised (from the aminoacid enantiomers).[49] These peptides contain sarcolysine with a free or formylated amino-group, the C-end being protected by an ester or remaining free. The starting materials employed were the enantiomers of *N*-formylsarcolysine and the *p*-nitrobenzyl ester of leucine. These were condensed with the aid of *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline, which prevents racemisation.

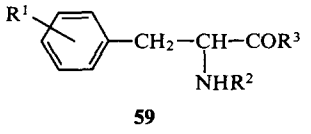
53: R^1 = CHO, R^2 = H.
54: R^1 = H, R^2 = H.

R^1-D-Sarc—L-Leu—OR^2

55–57



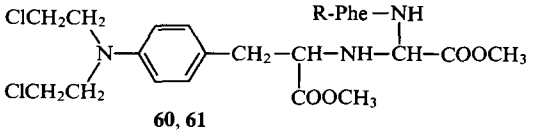
55: R^1 = CHO, R^2 = $CH_2C_6H_4NO_2$.
56: R^1 = CHO, R^2 = H.
57: R^1 = H, R^2 = H.

Dependent on the method of synthesis, isolation, and purification of the *N*-acetylsarcolysine dipeptides with optically active aminoacids, the products are dipeptides with different contents of the diastereoisomers, which is not always reflected in properties such as the melting point and the specific rotation but exerts an appreciable influence on the biological activity. A method has been developed for the quantitative determination of the diastereoisomers of *N*-acetylsarcolysine dipeptides,[50] which involves the chromatographic separation of the diastereoisomers on Silufol UV-254 plate or their preparative separation on silica gel plates with subsequent extraction of the diastereoisomer bands with alcohol and spectrophotometric measurements on the resulting solutions.

The study of the biological activity of the melphalan dipeptide with L-glutamic acid Ac-Mel-Glu(ONa)$_2$ (compound **58**) established that this compound possesses radiation protective properties.[51]

In the further consideration of the studies devoted to the synthesis of peptides modified by 4-[bis(2-chloroethyl)amino]-phenylalanine stereoisomers, special attention will not be given to the methods of formation of the peptide bond because all the peptides were obtained by methods widely known in peptide chemistry with protecting groups constantly employed in amino-acid chemistry and in accordance with schemes which the authors regarded as optimal. In most cases, sarcolysine or its enantiomers were attached to the peptide chain in the last step, because of the presence in the molecule of the labile nitrogen-containing nitrogen mustard group.

The studies of Italian workers headed by Barbieri,[52-54] who synthesised cytotoxic peptides with a postulated dual mechanism of action — alkylation and metabolic inhibition — merit attention. Peptides of melphalan and of its *meta*- and *ortho*-[bis-(2-chloroethyl)amino]-analogues with natural aminoacids (glycine, glutamic acid, lysine, histidine, arginine, phenylalanine, methionine, etc.) or their antagonists (norvaline, norleuceine, ethionine, methylmethionine, methylphenylalanine, *p*-fluorophenylalanine, β-2-thienylalanine, etc.) having the general formula **59** were obtained.



59

R^1 = $N(CH_2CH_2Cl)_2$; R^2 = H, $COOCH_2C_6H_5$, aminoacid residue; R^3 = OH, OAlk, aminoacid residue.

The chemotherapeutic activities of compounds **59** as well as the dipeptides listed above depend significantly on their stereo-configuration and may vary within wide limits. The effect of certain cytotoxic dipeptides on oxidative phosphorylation, etc. processes was studied in the same investigations using experimental strains. Data were obtained confirming the different effects of certain peptides on the enzyme systems of tumours and on the analogous systems in normal tissues.

In order to achieve the selective inhibition of pyruvate kinase in tumour cells, compounds **60** and **61** were synthesised. In these substances, the melphalan residue is attached via an amino-group to the α-carbon atom of the glycine in the phenylalanylglycine molecule.[55]

60, 61

R = $C_6H_5CH_2OCO$ (**60**), H·3HCl (**61**).

The antitumour activity of the conjugate **61** proved to be higher in experiments on animals and its acute toxicity was found to be lower than the corresponding properties of melphalan.

Melphalan-containing peptides **62-81**, which are 1,1-diphosphonic acid derivatives, were obtained.[56] These are analogues of the corresponding amides **21** incorporating two phosphonic acid residues.

Mel-Ala-$NH(CH_2)_3C(OH)[PO(OH)_2]_2$ (**62**),
Mel-D-Ala-$NH(CH_2)_3C(OH)[PO(OH)_2]_2$ (**63**),

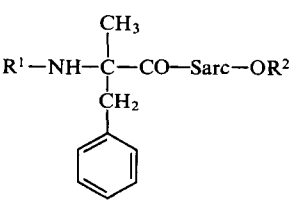
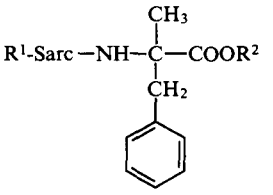
A =  .

It was established that compounds **62-81** have antitumour and antimetastatic properties and also exhibit a high inhibiting activity on the growth of nucleic acids in experiments in vitro and an appreciable antitumour activity in vivo. It is believed that these compounds can be used in the treatment of dense tumours: multiple myeloma, osteosarcoma, the metastases of the bone and mammary gland carcinomas, ovarian and testicular carcinomas, as well as various types of lymphomas and leukaemias.

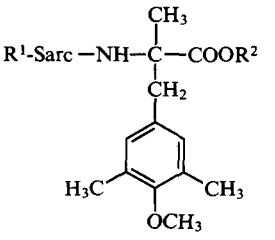


IV. 4-[Bis(2-chloroethyl)amino]phenylalanine peptides with nonprotein aminoacids

The synthetic sarcolysine peptides with protein aminoacids possess a high antitumour activity, but the latter is attained when they are administered in maximum tolerable or toxic doses. The inadequately selective activity of these preparations leads to serious damage to mucous membranes and to the breakdown of haematopoietic and metabolic processes. The hypothesis was put forward that the use of nonprotein aminoacids and the presence of anomalous peptide bonds would make it possible to alter the physiological properties of such peptides.



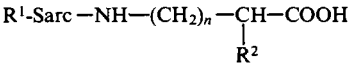
For this purpose, sarcolysine dipeptides with structural analogues of natural aminoacids — 4-methoxy-3,5-dimethylphenylalanine and α-methylphenylalanine (compounds **82-89**) — were synthesised.[57] Dicyclohexylcarbodiimide was used in the condensation stage and the protecting groups were removed by hydrogenolysis.



82, 83

84, 85

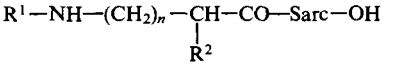
86, 87



88, 89

R^1 = HCO, R^2 = $CH_2C_6H_5$ (**82, 84, 86, 88**);
R^1 = R^2 = H (**83, 85, 87, 89**).

The antitumour activities and toxicities of compounds **82–89** were investigated. As in the case of dipeptides with protein aminoacids, the antitumour activities of the diastereoisomers proved to be various.



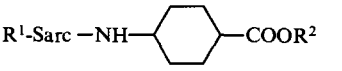
A series of experiments were carried out on the synthesis of peptides containing DL-α-aminobutyric acid (compounds **90, 93, 96,** and **99**), DL-β-aminobutyric acid (compounds **91, 94, 97,** and **100**), and DL-γ-aminobutyric acid (compounds **92, 95, 98,** and **101**).[58–60]

In relation to these compounds, an attempt was made to establish the rules governing the variation of toxicity and antitumour activity, depending on the position of the sarcolysine residue in the peptide, the structure of the second aminoacid, and the presence of the formyl protecting group at the N-terminal aminoacid group.[61–64]

90–95

90: R^1 = H, R^2 = C_2H_5, n = 0; **91**: R^1 = H, R^2 = CH_3, n = 1;
92: R^1 = H, R^2 = H, n = 2; **93**: R^1 = HCO, R^2 = C_2H_5, n = 0;
94: R^1 = HCO, R^2 = CH_3, n = 1; **95**: R^1 = HCO, R^2 = H, n = 2.

96–101

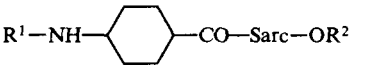


96: R^1 = H, R^2 = C_2H_5, n = 0; **97**: R^1 = H, R^2 = CH_3, n = 1;
98: R^1 = H, R^2 = H, n = 2; **99**: R^1 = HCO, R^2 = C_2H_5, n = 0;
100: R^1 = HCO, R^2 = CH_3, n = 1; **101**: R^1 = HCO, R^2 = H, n = 2.

It was found that the toxicity of the peptides with N-terminal sarcolysine is independent of the position of the amino-group in the C-terminal aminoacid. The toxicity of the peptides with C-terminal sarcolysine is reduced as the methylene bridge becomes longer. In the *N*-formylpeptides, the toxicity diminishes already in the presence of one additional CH_2 group. The peptides containing α-aminobutyric acid have the strongest antitumour activity. In terms of the spectrum of antitumour activity, compounds **90–101** differ little.

The mutagenic and inactivating activities of the peptides **90, 92–95, 96,** and **98–101** in the form of their sodium salts on bacteriophage systems in experiments in vitro have been investigated.[65] The compounds containing sarcolysine at the C-end proved to be more toxic, while those with sarcolysine at the N-end were less toxic. The presence of the formyl group in the peptide does not alter the toxicity of the compound in relation to the bacteriophage.

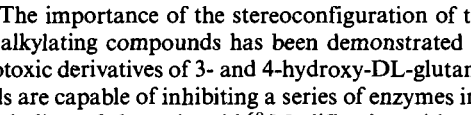
The study of the mutagenic activities of compounds **90, 92–95, 96,** and **98–101** showed that a change in the structure of the second aminoacid in the sarcolysine peptide molecule alters only slightly the effectiveness of the mutagenic activity. A correlation between the structural changes in the second aminoacid and the mutagenic and inactivating activities of the peptide was not found in the given series of compounds.



In the course of the continuation of studies designed to establish the possible relations between the toxicological and antitumour characteristics, on the one hand, and the characteristic features of the structure of the sarcolysine peptides, on the other, a series of compounds **102–113**, containing *cis*- and *trans*-4-aminocyclohexanecarboxylic acids (4-ACHCA), were obtained.[66]

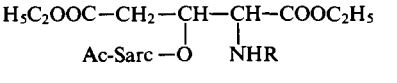
102–109

cis	*trans*
102: R^1 = CHO, R^2 = C_2H_5;	**103**: R^1 = CHO, R^2 = C_2H_5;
104: R^1 = H·HCl, R^2 = C_2H_5;	**105**: R^1 = H·HCl, R^2 = C_2H_5;
106: R^1 = $C_6H_5CH_2OCO$, R^2 = $C_6H_5CH_2$;	**107**: R^1 = $C_6H_5CH_2OCO$, R^2 = $C_6H_5CH_2$;
108: R^1 = H, R^2 = H;	**109**: R^1 = H, R^2 = H.



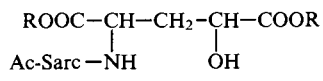
The 4-ACHCA derivatives containing N- and C-terminal sarcolysine residues with both formylated and unsubstituted amino-groups are less toxic compared with the initial sarcolysine. The compounds with a free carboxy-group in 4-ACHCA are less toxic compared with the corresponding esters. All the compounds exhibit a high antitumour activity. The derivatives containing amino- and carboxy-groups in the *trans*-positions are less toxic and have a more pronounced antitumour activity compared with the analogous *cis*-4-ACHCA derivatives.[67]

110–113



cis	*trans*
110: R^1 = $C_6H_5CH_2OCO$, R^2 = $C_6H_5CH_2$;	**112**: R^1 = $C_6H_5CH_2OCO$, R^2 = $C_6H_5CH_2$;
111: R^1 = H, R^2 = H;	**113**: R^1 = H, R^2 = H.

The importance of the stereoconfiguration of the 'carrier' of the alkylating compounds has been demonstrated in relation to cytotoxic derivatives of 3- and 4-hydroxy-DL-glutamic acids. The acids are capable of inhibiting a series of enzymes involved in the metabolism of glutamic acid.[68] Modification with sarcolysine can make the inhibition irreversible. By varying the method by which *N*-acetylsarcolysine is attached to the above compounds, i.e. by the formation of ester or peptide bonds with the *threo*- or *erythro*-diastereoisomers of 3- and 4-hydroxyglutamic acids, the derivatives **114–122** were obtained.[69–71]



114–116

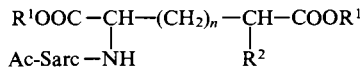
cis: R = $COOCH_2C_6H_5$ (**114**); H·HCl (**115**)
trans: R = H·HCl (**116**).

threo-**117**, *erythro*-**118**.

119–122

threo: R = $CH_2C_6H_5$ (**119**); H (**120**).

erythro: R = $CH_2C_6H_5$ (**121**); H (**122**).



The stereoisomers of the esters **114–118** and the peptides **120–122** exhibited low antitumour activities and an appreciable toxicity, but differed both as regards the magnitude of the antitumour activity and the spectrum of the latter.[69, 71] This shows that, as in the case of the sarcolysine peptides with protein aminoacids, the configuration of the nonprotein aminoacids entering into the composition of the cytotoxic esters and peptides exerts an appreciable influence on the antitumour activity.

An attempt has been made[72] to investigate the influence of the stereoconfigurations of the individual aminoacids forming part of the peptide on the antitumour activity of the latter. The stereoisomers of the tripeptides **123–126** were synthesised.

Lys–Med–Glu (**123**), Lys–Mel–Glu (**124**),
Lys–Sarc–*threo*-4-OH-Glu (**125**),
Lys–Sarc–*erythro*-4-OH-Glu (**126**).

Compounds **123–126** are modified fragments of the ribonuclease S-peptides. Furthermore, the tripeptides **124** incorporate, as it were, two dipeptides: Lys–Mel and Mel–Glu, which exhibit a very high antitumour activity on various strains of tumours. However, the results of tests of compounds **123–126** on animals revealed their low antitumour activities, which precluded a conclusion about the influence of aminoacids on the latter.

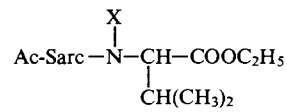
In order to increase the proteolytic stability and biological activity of the sarcolysine dipeptides, peptides based on homoglutamic and diaminoadipic acids and the diastereoisomers of diaminoglutaric acid (compounds **127–133**) were synthesised.[73]

127–133

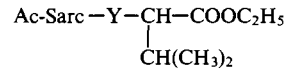
127: R^1 = C_2H_5, R^2 = H, n = 2;
128: R^1 = C_2H_5, R^2 = Ac-Sarc–NH, n = 2;
129: R^1 = C_2H_5, R^2 = Ac-Sarc–NH, *meso*-, n = 1;
130: R^1 = C_2H_5, R^2 = Ac-Sarc–NH, *threo*-, n = 1;
131: R^1 = Na, R^2 = H, n = 2;
132: R^1 = Na, R^2 = Ac-Sarc–NH, n = 2;
133: R^1 = Na, R^2 = Ac-Sarc–NH, *meso*-, n = 1.

Despite the increase in the susceptibility to alkylation in experiments in vitro, the introduction of a second sarcolysine residue into the molecules of compounds **128–130**, **132**, and **133** did not lead to an increase in the antitumour activity. This can probably be accounted for by the difficulty of transporting the disarcolysine compound through the membranes of the tumour cell.

The tripeptides of the β-, γ-, and ε-aminoacids **134** containing N- and C-terminal *N*-acetylsarcolysine residues with different numbers of CH_2 groups between them as well as their analogues — *N*-acetylsarcolysine alkylenediamides **135** — were synthesised and investigated.[74]

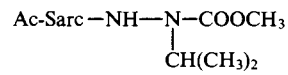


134, n = 2, 3, 5.



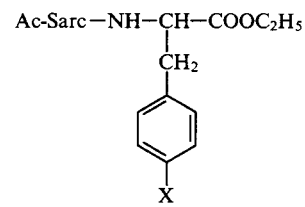
135, n = 2, 3.

Compounds **134** proved to be inactive, while compounds **135** exhibited a moderate activity.

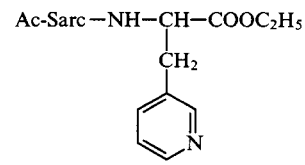


The antitumour preparations asalin[75] and asaphan[76] have been modified. The peptide bond was altered in asalin **24**. The hydrogen in the peptide amide group was replaced by various residues (compounds **136**): the amide group was replaced by ester, hydrazide, or amidoxy-groups (compounds **137**) and DL-valine was replaced by 2-azavaline (compound **138**).

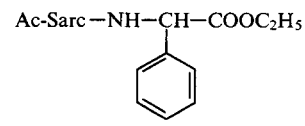
136: X = C_2H_5, OC_2H_5, OH, $NH_2 \cdot HBr$.



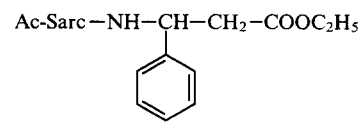
137: Y = O, NHNH, NHO.



138



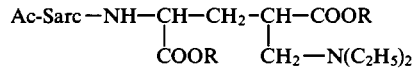
In asaphan, the benzene ring of phenylalanine was modified and its position in the aminoacid was also altered (compounds **139–142**).



139: X = Cl, NO_2, n-C_3H_7, iso-C_3H_7, n-$C_7H_{15}O$.

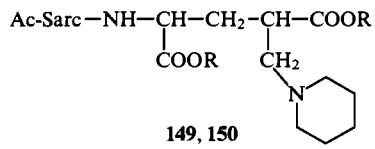
140

141



142

The asalin and asaphan analogues **136–142** obtained exhibited towards a series of tumours antiblastic activities similar to and in some cases lower than those of asalin and the ethyl ester of *N*-acetylsarcolysyl-DL-phenylalanine used as controls.



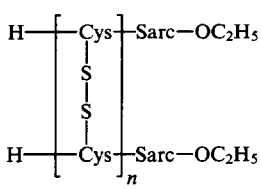
The *N*-acetylsarcolysine dipeptides with the ethyl esters of *N*-methyl-*N*-phenylglycine (compounds **143** and **144**) and of aminohydroxyacids (compounds **145** and **146**)[16] and also with glutamic acid derivatives (compounds **147–150**)[71] have been synthesised.

Ac-Sarc-N(CH_3)$CH_2COOC_2H_5$ (**143**),
Ac-Sarc-N(C_6H_5)$CH_2COOC_2H_5$ (**144**),
Ac-Sarc-NHOCH(C_2H_5)$COOCH_3$ (**145**),
Ac-Sarc-NHOC$H_2COOC_2H_5$ (**146**)

147, 148

R = $CH_2C_6H_5$ (**147**), H (**148**).

149, 150



R = $CH_2C_6H_5$ (**149**), H (**150**).

Thus compounds of interest for practical oncology have not so far been discovered among the sarcolysine peptides with nonprotein aminoacids.

V. Polypeptides containing 4-[bis(2-chloroethyl)-amino]phenylalanine

One of the ways of increasing the selectivity of the action of cytostatic substances involves the use of biopolymers, and in the first place polypeptides, for their transport into the tumour cell. Polypeptides have a series of advantages: rapid passage of some of them through the membranes of cancer cells (compared with normal cells) and extensive possibilities for the variation of their composition. The antitumour activities of polypeptide derivatives have been investigated as a function of the nature and configuration of the aminoacid and the length of the peptide chain. A series of homopolypeptidyl derivatives of sarcolysine (compounds **151**–**154**,[77] **155**,[77,78] **156**, and **157**[79]) have been obtained by the polycondensation of the *N*-carboxyanhydrides of various α-aminoacids in the presence of the ethyl ester of sarcolysine. In the case of L-cystine, the derivative **158**, containing disulfide bonds, was synthesised.[80]

$(Val)_n$–Sarc-OC_2H_5 (**151**),
$(D\text{-}Val)_n$–Sarc-OC_2H_5 (**152**),
$(DL\text{-}Nle)_n$–Sarc-OC_2H_5 (**153**),
$(Sar)_n$–Sarc-OC_2H_5 (**154**),
$(Phe)_n$–Sarc-OC_2H_5 (**155**),
$(Lys)_n$–Sarc-OC_2H_5 (**156**),
$(Asp)_n$–Sarc-OC_2H_5 (**157**)

158

The toxicity of compounds **151**–**158** depends on the length of the peptide chain and on the nature of the α-aminoacid constituting the chain. An increase in chain length lowers the toxicity. The polysarcosyl derivatives **154** showed the highest antitumour activity.

The inclusion of an additional aminoacid between the polypeptide chain and sarcolysine alters the activity of the compound (compounds **159**–**165**).[81]

$(DL\text{-}Ala)_n$–Gly–Sarc-OC_2H_5 (**159**),
$(DL\text{-}Ala)_n$–DL-Val–Sarc-OC_2H_5 (**160**),

$(DL\text{-}Val)_n$–DL-Ala–Sarc-OC_2H_5 (**162**),
$(DL\text{-}Ala)_n$–DL-Nle–Sarc-OC_2H_5 (**163**),
$(Gly)_n$–DL-Ala–Sarc-OC_2H_5 (**164**),
$(DL\text{-}Nle)_n$–Gly–Sarc-OC_2H_5 (**165**).

After the inclusion of an additional aminoacid, the polypeptidyl derivative of which is active, the antitumour activities of the initial homopolypeptides are retained.

Copolypeptides of two types but with the same composition, where one of the two aminoacids entering into the composition of the copolypeptide was introduced between the sarcolysine ethyl ester residue and the polypeptide chain, have been synthesised (compounds **166**–**169**).[81]

$[(DL\text{-}Ala)_{n-1}$–$(DL\text{-}Val)_n]$–DL-Ala–Sarc-OC_2H_5 (**166**),
$[(DL\text{-}Ala)_n$–$(DL\text{-}Val)_{n-1}]$–DL-Val–Sarc-OC_2H_5 (**167**),
$[(Gly)_{n-1}$–$(DL\text{-}Nle)_n]$–Gly–Sarc-OC_2H_5 (**168**),
$[(Gly)_n$–$(DL\text{-}Nle)_{n-1}]$–DL-Nle–Sarc-OC_2H_5 (**169**).

It was established that the antitumour activity of the polypeptide depends on which aminoacid is linked directly to sarcolysine.

A series of copolypeptidyl derivatives of sarcolysine with an irregular structure have been obtained (compounds **170**–**177**[78] and **178**–**184**[79]).

Poly(DL-Ala, DL-Val)–Sarc-OC_2H_5 (**170**),
Poly(Sar, DL-Val)–Sarc-OC_2H_5 (**171**),
Poly(Sar, DL-Nle)–Sarc-OC_2H_5 (**172**),
Poly(Gly, DL-Nle)–Sarc-OC_2H_5 (**173**),
Poly(Gly, DL-Leu)–Sarc-OC_2H_5 (**174**),
Poly(DL-Leu, DL-Nle)–Sarc-OC_2H_5 (**175**),
Poly(DL-Nle, Phe)–Sarc-OC_2H_5 (**176**),
Poly(DL-Nle, DL-Val)–Sarc-OC_2H_5 (**177**),
Poly(Lys, Gly)–Sarc-OC_2H_5 (**178**),
Poly(Lys, DL-Ala)–Sarc-OC_2H_5 (**179**),
Poly(Lys, DL-Val)–Sarc-OC_2H_5 (**180**),
Poly(Lys, DL-Nle)–Sarc-OC_2H_5 (**181**),
Poly(Lys, Phe)–Sarc-OC_2H_5 (**182**),
Poly(Asp, DL-Ala)–Sarc-OC_2H_5 (**183**),
Poly(Asp, DL-Nle)–Sarc-OC_2H_5 (**184**).

Among the copolypeptidyl derivatives, compounds containing glycine or DL-alanine are the most active. It has been shown that both the homopolypeptides and the copolypeptides exhibit a distinct antiblastic activity in relation to tumour strains, but they are largely inferior in their activity to sarcolysine. A number of substances have antitumour activities in relation to certain experimental tumour strains which are superior to that of sarcolysine and at the same time do not exert a general toxic effect on the organism such as that of sarcolysine.[82,83]

The use of conjugates of melphalan with poly-L-aminoacids, in particular with poly-L-lysine (compounds **185** and **186**) and poly-L-glutamic acid (compounds **187** and **188**) as agents transferring the alkylating substances into tumours has been described (Table 1).[84] Poly-L-lysine or poly-L-glutamic acid was condensed with melphalan or its derivative by the DCHC method, after which the protecting groups were removed if necessary.

The conjugates **185**–**188** exhibited in experiments in vitro an alkylating activity amounting to 42%–70% of that of melphalan. Studies of compounds **187** and **188** in experiments on animals established that they are transferred into tumours with the aid of the lymphatic system; this can be used to prevent the occurrence of metastases in lymph nodes.

Table 1. The composition of the conjugates of polyaminoacids with melphalan.

Positions of conjugates	Mel–poly(L-Lys)		Mel–poly(L-Glu)	
	185	**186**	**187**	**188**
Number of aminoacid residues per melphalan molecule	6.7	6.9	23.0	23.1
Number of melphalan molecules per polyaminoacid molecule	83.0	2.3	20.2	4.7

VI. Analogues of natural proteins containing 4-[bis(2-chloroethyl)amino]phenylalanine

In most of the studies quoted above, the combination of aminoacids in the cytotoxic peptides was empirical in character and did not correspond to a definite aminoacid sequence in natural peptides. Studies on the synthesis of analogues of natural proteins containing sarcolysine or its enantiomers are presented below.

Thus, in the search for compounds with a high selectivity in their antitumour activities, the short peptides **189**[85,86] and **190–193**[86] have been synthesised. These are fragments of biologically important proteins such as ribonuclease and histones, because it is known that certain fractions of histones have the ability to inhibit the DNA-dependent synthesis of RNA in experiments in vitro.[87–89] Sarcolysine was introduced into the peptide instead of phenylalanine or alanine or as an additional aminoacid.

Lys–Val–Sarc-OH (**189**),
Lys–Arg–Nle–Sarc-OCH_3 (**190**),
Lys–Sarc-OCH_3 (**191**),
Ala–Lys–Sarc-OCH_3 (**192**),
Ala–Ala–Lys–Sarc-OCH_3 (**193**).

Despite the presence of the labile bis(2-chloroethyl)amino-group, the peptides containing a sarcolysine residue can be obtained by solid-phase synthesis. Thus the sarcolysine-modified glutathione fragment **194** has been obtained on a partially chloromethylated styrene–divinylbenzene copolymer.[90] DCHC was used as the condensing agent. The sarcolysine residue was attached in the last stage.

HCO-Sarc–Cys–Gly-OH · $NH(C_6H_{11})_2$ (**194**)

In the mechanism of the antitumour activity of sarcolysine, two main components have been differentiated: the nuclear component, associated with the breakdown of the structure and functions of DNA and nuclear proteins, and the membrane component, associated with the damage to the internal membranes of mitochondria and the membranes of the endoplasmic reticulum. The second component actually became the basis of the search for substances interacting irreversibly with various membrane receptors. The peptide hormones, acting at extremely low concentrations and exhibiting a high biological activity and selectivity in their action, have become particularly attractive for the creation of new medicinal preparations from this standpoint. Compounds containing sarcolysine or its enantiomers have been synthesised from fragments of hypophyseal hormones such as the luteinising hormone (LH), the adrenocorticotropic hormone (ACTH), and the somatotropic and α-melanocyte-stimulating hormone (α-MSH). Investigations[91] showed that α-MSH is able to bind to plasma membranes of specific types of tumour cells, particularly to the membrane receptors of human melanoma.

A series of studies[92–102] have been devoted to the synthesis of α-MSH fragments (compounds **195–232**) containing sarcolysine or its enantiomers (Table 2, see over) in order to obtain substances with a high selectivity in their antitumour activity.

The stereoisomers of the tetrapeptides **195**, **196**, **198**, and **199** were synthesised from sarcolysine and separated by column chromatography. The protected pentapeptides **216–219** were obtained from them.[92]

Compounds **220–227** were synthesised from the corresponding peptides with N-terminal formylsarcolysine and were then separated chromatographically on silica gel columns and *N*-formylmelphalan and *N*-formylmedphalan were isolated. After the removal of the formyl group, the compounds were condensed with the N-terminal fragment.

In the study of the antitumour activity, it was established that some of the compounds exhibit an antiblastic activity towards a series of transplantable tumours. However, appreciable advantages compared with sarcolysine were not discovered.[101] The compounds with melphalan are more active. The conjugate **232** of α-MSH with melphalan exhibited a greater affinity for receptors than a simple mixture of these compounds.[102] It was established that the replacement of methionine, arginine, or phenylalanine in the initial sequence of α-MSH by melphalan leads to the irreversible binding of the conjugate to the receptor and the prolongation of activity and that on replacement of glycine no inhibition was observed.[96]

It was found that the peptides **214**, **215**, **228**, and **230** exhibit a lower mutagenic activity than melphalan. Presumably, when these compounds are used as antitumour agents, the probability of the appearance of secondary tumours is lower than in the case where melphalan is employed.[99] The peptides **214**, **215**, **228**, and **230** differ also in their toxicity to particular types of cells. They are all less cytotoxic than melphalan.[101]

Attempts have been made recently to increase the selectivity of the action of sarcolysine by attaching it to hypothalamic hormones, the so called releasing factors of releasing-inhibiting factors (according to another nomenclature—liberins and statins), which respectively stimulate or inhibit the liberation of hypohyseal hormones. By regulating the activity of the hypophyseal-adrenal system and steroid genesis, hypothalamic hormones act on hormone-dependent tumours. For example, analogues of the LH-releasing factor and the gonadotropin-releasing factor exhibit an antitumour activity towards experimental tumours.[103] One of the gonadotropin-releasing factor analogues has been used successfully in medical practice in the treatment of hormone-dependent tumours.[104] Melanostatin exhibits an inhibiting activity towards melanoma.[105–107] Hypothalamic hormones are peptides with a relatively small number of aminoacids, which makes their synthesis comparatively simple and easy to carry out.

This stimulated the synthesis and study of analogues of the α-MSH releasing-inhibiting factor (melanostatin)—compounds **233**,[108], **234**,[108–110] **235**,[108, 109] **236–238**,[108] **239**,[108, 110, 111] and **240**.[109, 111]

Pro–Leu–Gly-NH_2 (melanostatin),
Pro–Sarc–Gly-NH_2 (**233**),
Pro–Mel–Gly-NH_2 (**234**),
Pro–Med–Gly-NH_2 (**235**),
HCO-Sarc–Pro–Leu–Gly-NH_2 (**236**),
HCO-Mel–Pro–Leu–Gly-NH_2 (**237**),
HCO-Med–Pro–Leu–Gly-NH_2 (**238**),
Mel–Pro–Leu–Gly-NH_2 (**239**),
Med–Pro–Leu–Gly-NH_2 (**240**).

Note. Aminoacid residues identical to those in the initial natural peptide are designated by a continuous line.

[a] Form = HCO. [b] Z = $C_6H_5CH_2OCO$. [c] Here and henceforth the aminoacid designation starting with a lower case letter indicates the D-configuration.

Higher antitumour activity of the melphalan-containing melanostatin derivatives compared with the medphalan analogues was discovered.[109] It was noted that the melanostatin fragment in compound **237** protects the organism against the toxic effect of melphalan.[110]

Hypothalamic hormones and their analogues inhibit the secretion of the protein hormones from the hypophysis and the latter inhibit in their turn the secretion of the steroid hormones from the adrenal glands, the levels of which in the hormone-dependent tumours are unduly high. The analogues of hypothalamic hormones can therefore be used to synthesise agents with a high selectivity in their antitumour activity. The synthesis of derivatives of the LH-releasing factor (luliberin) led to the discovery of substances with agonistic and antagonistic properties. These compounds have been used as powerful contraceptives. Luliberin controls the liberation of LH and the follicle-stimulating hormone (FSH), which stimulate in their turn the synthesis of sex hormones. A series of medphalan-containing peptides (compounds **241–259**) have been synthesised from luliberin analogues with agonistic and antagonistic properties (Table 3).[112–116]

The introduction of hydrophobic D-aminoacids in the 1-, 2-, 3-, and 6- positions and partly in the 5-, and 10-positions in the initial luliberin sequence led to the creation of powerful antagonists. On the other hand, the introduction into the hormone molecules of fragments comprising antitumour preparations known in oncology, such as melphalan or its D-enantiomer, may help to solve the problem of the attainment of a higher selectivity in the antitumour activity. The peptide component of the luliberin analogue makes it possible to increase the selectivity of the action of the alkylating agent as a result of the increased affinity of the peptide fragment for particular receptors on the cell membranes of the hormone-dependent tumours. It has been established that the binding is reversible and no alkylation of the receptors takes place. It is then possible to observe under these conditions a chain of biochemical reactions occurring in the cell.[112]

The peptides have been synthesised mainly by the solid-phase method and only the side chains were attached by the 'classical' method. The compounds obtained were purified with the aid of HPLC. Medphalan was used as an extremely suitable hydrophobic D-aminoacid residue, which can ensure an increase in the biological activity of luliberin analogues.[113]

The medphalan residue was either introduced directly into the peptide chain in the 6-position instead of the glycine residue or it was attached to the ω-amino-groups of lysine and ornithine located in the 6-positions in the luliberin fragments. In a number of cases, a diaminopropionic acid residue was used as the connecting unit for the attachment of two medphalan molecules to lysine or ornithine. The increase in enzyme stability and the formation of active compounds were achieved by the additional incorporation of D-aminoacid residues in the peptide molecules. By estimating the results of the modification of the initial aminoacid sequence in luliberin (the 3- and 6-positions) in compounds **254–259**, one can demonstrate that there is a fine balance between the agonistic and antagonistic activities determined by the substituents in these positions. The replacement of D-lysine by D-ornithine in compounds **254** and **255** increased the affinity for the receptors of the mammary gland tumour. Among the luliberin analogues, compounds **241** and **244** exhibited the highest agonistic and antagonistic activities respectively. They exhibited a high affinity for the membrane receptors of the cells of a series of tumours.

Compounds **245–253** inhibit the incorporation of [^{3}H]thymidine in DNA in cultures of the mammary gland and prostatic gland tumours and also inhibit the growth of the prostatic gland tumour (in experiments on animals). The peptides **254–259** are characterised by a broad spectrum of their affinity for the receptors of the hypophysis and the cell membranes of the mammary gland and prostatic gland tumours.

Table 3. Alkylating analogues of luliberin.

[d] A_2pr = diaminopropionic acid residue $[-NH-CH_2-CH(NH-)]CO-$. [e] IA = indole-3-acetic acid residue.

A series of analogues of the gonadotropin-releasing hormone (compound **260**), in which melphalan is attached to the transferring molecule via the additional functional group of the aminoacid in the 6-position, have been synthesised.[117] These compounds can be used in veterinary practice to sterilise animals and in medicine in the chemotherapy of hormone-dependent tumours.

The analogues of the hypothalamic hormone somatostatin are of special interest for oncology. The concept of the effect of somatostatin derivatives on tumours is analogous to that for luliberin. Somatostatin **262** — a tetradecapeptide — inhibits the liberation of the growth hormone and exhibits a broad spectrum of inhibiting properties.

Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys
(1–14 disulfide bridge)

262

Some of its derivatives have been introduced into medical practice.[119] Conformational analysis and studies of the relation between the structure and function of somatostatin analogues have shown that the sequence necessary for the manifestation of biological activity consists of the β-twisting fragment Phe-Trp-Lys-Thr corresponding to the 7–10 residues of somatostatin.

A group of compounds related to somatostatin (compounds **263–273**) have been synthesised.[120] They differ from one another in the aminoacid residues in the 1-, 3-, 6-, and 8-positions in the peptide chain (Table 4).

Somatostatin retards the growth of tumours in patients with endocrine pancreatic tumours such as insulinoma, glucanoma, and others. However, the hormone is relatively unsuitable for tumour therapy owing to its multiple activity and its brief antisecretary effect. Somatostatin analogues are effective in the treatment of certain types of tumours, including treatment in combination with luliberin analogues.[120] Somatostatin analogues with alkylating fragments can exert both direct and mediated effects on the hormone-dependent tumours, functioning as substances transferring chemotherapeutic agents.

Compounds **263–273** have been synthesised by the solid-phase method and purified by gel filtration on Sephadex or by inverse phase HPLC (all the operations were performed at 4 °C and in the shortest possible time in view of the decomposition of the peptide). They exhibit an inhibiting effect on the liberation of the hypophyseal growth hormone, bind to the membranes of tumour cells, inhibit the incorporation of [^{3}H]thymidine in DNA in cell cultures, and inhibit the growth of particular tumour cells. For use in medical practice, the compounds are obtained in the form of salts: chlorides, phosphates, acetates, etc. or in the form of salts of alkali and alkaline earth metals.[120]

A series of modified derivatives of bombesin have been synthesised as substances interacting irreversibly with the bombesin membrane receptors. Bombesin **274** has been isolated from frog skin and is a tetradecapeptide (Table 5).

The gastrin-releasing peptide, consisting of 27 aminoacid residues and constituting one of the growth factors of the small cell lung carcinoma, is a twin of bombesin in the human organism. By competing with the natural ligand for the receptors, the bombesin antagonists inhibit a series of events leading to abnormal cell proliferation. A large number of melphalan-containing peptides — the bombesin antagonists **275–314** have now been synthesised and patented (Table 5).[121–123] All the compounds have been obtained by the classical methods of peptide chemistry in solutions.

Melphalan has been introduced into both bombesin antagonists and into bombesin analogues with a high affinity for receptors and with agonistic properties. The modified analogues are peptides of the C-terminal component of bombesin obtained by the removal, inversion, or substitution of aminoacids. The analogues in which melphalan is in the 6-position in the bombesin chain exhibit a higher affinity for receptors than the compounds containing melphalan in the 3-position.

Compounds **282**, **285–288**, **293**, **307**, **308**, and **311–314** are less cytotoxic and do not bind to other receptors, for example the epidermal growth factor receptors, which is due to the aminoacid sequence of these compounds.

Gastrin **315** — the gastrointestinal tract hormone — stimulates almost all the functions of the tract: secretion, motor response, and absorption. The amide **316** of the C-terminal tetrapeptide exhibits the full spectrum of physiological activity albeit more weakly than that of the complete molecule.

Table 5. Alkylating analogues of bombesin **274**.

In order to create gastrin analogues based on the modification of the C-terminal tetrapeptide **316**, which might act selectively on the tumours of the gastrointestinal tract, a series of derivatives **317**,[124] **318**,[125] and **319–324**[126] have been synthesised. Sarcolysine was used as the starting compound. The mixture of stereoisomers was separated by preparative chromatography. Compounds **319–324** proved to be active in relation to L-1210 lympholeukaemia, the mammary gland adenocarcinoma, the large intestine adenocarcinoma, and sarcoma 37. The peptide **318** has been used in the study of gastrin analogues as inhibitors in a radioimmunoassay system employing antisera, but it exhibited a weak affinity for antibodies and proved physiologically inactive under experimental conditions.

The introduction of various alkylating agents into the peptide chain makes it possible to investigate the characteristics of the interaction of hormones with the receptors and to obtain antagonists to peptide hormones. Melphalan has been used as a label in the study of the affinity of hormones for polypeptide receptors. Derivatives of bradykinin (compound **325**[127]), angiotensin II (compounds **326–328**[128]), and leucine-enkephalin (compounds **329**,[129,130] **330–332**,[130] and **333–336**[131]) have been obtained for this purpose.

Each of the compounds **325–336** synthesised was tested towards the type of receptors to which the corresponding hormone is bound. In particular, enkephalin analogues were studied as irreversible antagonists of the δ-opiate receptor.

333–336

333: R^1 = H, R^2 = $CH_2CH{=}CH_2$.
334: R^1 = H, R^2 = $CH_2C_6H_5$.
335: R^1 = CH_3, R^2 = $CH_2CH{=}CH_2$.
336: R^1 = CH_3, R^2 = $CH_2C_6H_5$.

Studies on the synthesis and mechanisms of action of polypeptide hormones containing sarcolysine stereoisomers yielded extremely interesting results, the final interpretation of which requires further research.

Thus a large number of peptides, incorporating 4-[bis-(2-chloroethyl)amino]-DL-, L-, and D-phenylalanine and their derivatives have now been synthesised. Sarcolysine dipeptides with protein aminoacids were obtained initially. In many cases, these compounds were of considerable interest for practical oncology. Further search for effective antitumour compounds led to the incorporation of nonprotein aminoacids and aminoacids which are antimetabolites of natural aminoacids in the peptides. Particular attention was then paid to the dependence of the antitumour activity on the stereoconfiguration of the 'carrier' of the alkylating compound.

A series of studies have been devoted to the synthesis of biologically active polymers which are homo- and co-polypeptides modified by sarcolysine and melphalan. The dependence of the antitumour activity on the nature and configuration of the aminoacid and the length of the polypeptide chain in these compounds has been investigated.

Fragments of biologically important proteins, such as histones, enzymes, and hormones, modified by sarcolysine and its enantiomers, were obtained later. The introduction of melphalan or medphalan into fragments of peptide hormones makes it possible to study the mechanism of the interaction of these compounds with the corresponding receptors, which is exceptionally important for the creation of substances with prespecified properties. The presence of an alkylating fragment in the molecule has a mediating effect on the chain of reactions occurring in the cell and makes it possible to obtain compounds with a highly specific activity. These may be not only substances with antitumour activities but also compounds with other types of biological activity.

* * *

The data presented in the review demonstrate the usefulness of the development of methods for the synthesis and study of the peptides of 4-bis(2-chloroethyl)amino]-DL-, -L-, and -D-phenylalanine with natural aminoacids, their synthetic analogues, and fragments of biologically important proteins, because compounds with both high antitumour activity and other types of physiological activity may be discovered among these substances.

Abstract. The present state and prospects for the development of the X-ray crystallography of globular proteins are analysed. The mechanisms of the functioning of membrane receptors, the immune proteins of T-lymphocytes, the histone octameric core of nucleosomes, DNA topoisomerase, the aspartate proteases of retroviruses, and the proteins of the actomyosin complex of skeletal muscles are examined on the basis of the three-dimensional structures of the protein molecules which have become known in recent years. It is shown that the results of the X-ray diffraction analysis of proteins has played a decisive role in the creation of an experimental basis and the development of the approaches necessary for the establishment of theoretical biology. A large proportion of the review is devoted to the advances in X-ray crystallography as regards the sources of radiation, the phase problem, and the experimental conditions. The use of synchrotron radiation and the abandonment of multiplet isomorphous substitution in the determination of phases not only significantly simplify the study of the molecular structures of proteins but permit an approach to securing information about the structures of protein intermediates which had previously been inaccessible. The bibliography includes 324 references.

I. Introduction

One of the most outstanding scientific investigations not only in biology but throughout natural sciences in the course of the passing century was completed at the end of the 1950s and the beginning of the 1960s. Perutz and Kendrew determined the three-dimensional structures of haemoglobin and myoglobin, having first solved the problem, posed more than a quarter of a century earlier by Bernal, of the determination of the three-dimensional structures of protein molecules with the aid of X-ray diffraction. This event implied the establishment of a new direction in the development of biology — the morphology of elementary biosystems, revealing previously invisible possibilities for discovering the structure of living matter. Without knowing the atomic-molecular structures of proteins, it is impossible to understand the nature and specific features of their interactions, and the mechanisms of the functioning of enzymes, the immune system, the genetic apparatus, the membrane proteins, and many others. The advances achieved in the first investigations were of universal importance, which was reflected in the state of virtually all aspects of the research into the organic world. After more than three decades have elapsed since the publications by Perutz and Kendrew, X-ray diffraction still remains the only direct method for the determination of the three-dimensional structures of protein molecules and their complexes at the atomic level. The data obtained with its aid still remain the irreplaceable experimental basis of any search for solutions to fundamental problems such as those of the structural and structural-functional organisation of protein molecules. Taking into account the active role of proteins in vital processes and their universal biochemical and biophysical properties, one may claim that the creation of theories of the structural and structural-functional organisation of proteins will entail the establishment of quantitative theoretical biology.

After the classical studies by Perutz and Kendrew and also Phillips, who established in 1965 the three-dimensional structure of the first enzyme (lysozyme), X-ray diffraction analysis began to develop rapidly in many scientific centres. After only two years, the structures of ribonuclease A,[1,2] α-chymotrypsin,[3] and carboxypeptidase A,[4] were elucidated. By 1975 some 70 proteins had had their crystal structure determined with a resolution of better than 3.5 Å (Blundell and Johnson[5]) and at the present time the number approaches 3000.[6] The rate of advance was determined mainly by the difficulties in obtaining single crystal specimens of sufficient size and with a high degree of order. Proteins do not form regular macroscopic structures in the cells and organisms and the growing of protein crystals under laboratory conditions requires much skill and patience. The difficulties in obtaining high quality specimens are mentioned in almost all investigations. The following is, for example, a typical remark made by investigators[7] who studied the three-dimensional structure of lipoxygenase-1, an enzyme made up of 839 aminoacid residues: 'the protein crystals were obtained after trying more than 1000 different crystallisation conditions'.

This review is devoted to the analysis of the current state of the X-ray crystallography of proteins and the prospects for the development of the method in the immediate future. For this purpose, the studies which in some way constitute the most major advances at the present time were selected from the multiplicity of publications.

Sections II – VI present the results of X-ray diffraction studies on proteins, the scientific importance of which is determined by the importance of the objects analysed themselves. The three-dimensional structures of the molecules of membrane receptors, the immune proteins of T-lymphocytes, the histone octameric core of nucleosomes, DNA topoisomerase, the aspartate proteases of retroviruses, and the proteins of the actomyosin complex of skeletal muscles, all of which have become known only in recent years, are discussed in these sections. Studies of this kind have given rise to an extensive development of the study of the morphology of biosystems at the atomic-molecular level and will continue with increasing intensity.

In Sections VII and VIII, the use of the first methodological improvements in the X-ray diffraction analysis of proteins, concerning the sources of radiation, the exposure time, the phase problem, and the experimental conditions, is emphasised. Novelties of this kind are of special interest because they yield previously inaccessible information and hence lead to a vigorous development of the study of the morphology of proteins.

II. Membrane proteins

One of the greatest advances in the X-ray diffraction analysis of proteins in recent years is the start made on the elucidation of the three-dimensional structures of the first membrane proteins. It is useful to report briefly what had been known about these proteins before their investigation by X-ray diffraction. In the usual plasma membrane, the protein content is about 50% of its mass. However, in certain membranes, for example in the internal membranes of mitochrondria and chloroplasts, the protein content increases to 75%, whilst in others, for example in the myelin membrane, it falls to 25%. The lipid bilayer is threaded by many membrane proteins right through and the proteins are in contact with the aqueous medium on either side of the membrane. The molecules of these proteins, referred to as the transmembrane proteins, as well as the lipid molecules surrounding them possess amphipathic properties because they contain hydrophobic sections, interacting within the bilayer with the hydrophobic tails of lipids, and hydrophilic sections turned towards water on either side of the membrane. Another group of membrane proteins is in contact with water only on one side of the bilayer. Some of them are immersed in the outer or inner layer of the membrane, others are associated via nonvalence interactions with transmembrane proteins, whereas a third set of proteins of this kind are attached to the membrane via the chains of aliphatic acids bound covalently to them and inserted in the lipid layer.

By virtue of the dynamic properties of the membranes, the proteins associated with them can be separated from the lipids. Sometimes this operation is fairly simple and can be performed under mild conditions, for example by extraction with a salt solution. The liberated membrane proteins are referred to as peripheral. In other cases, usually involving transmembrane proteins, the isolation is more complex and is not always successful. Many proteins, called 'integral' on the basis of the method for their purification, can be isolated only after the complete disruption of the bilayer with the aid of detergents and organic solvents. On mixing with the membrane, the nonpolar, hydrophobic ends of the detergent molecules interact with the lipids and, by disrupting their association with the proteins, bind to the hydrophobic sections of the latter. As a result of this, the polar, hydrophilic ends of the proteins become oriented in the direction of the aqueous medium. The solubilised membrane proteins, which acquire the ability to dissolve in water, pass into solution in the form of complexes with the detergent. After the removal of the latter, the proteins lose their solubility and precipitate, forming a mixture of different proteins. As a rule, the membranes are heated to 100 °C in a 1% solution of a strong detergent as a preliminary step, which leads to the disruption of all the noncovalent protein–protein and protein–lipid interactions. Helenius and Simons[8] developed a method for the separation of proteins by electrophoresis in a polyacrylamide gel in the presence of a detergent (sodium dodecyl sulfate).

Further studies on membrane proteins — the investigation of their functions, the mechanisms of their action, and their three-dimensional structures — encountered major difficulties. It was found that the liberation of the protein molecules from the membrane is frequently accompanied by the irreversible denaturation of their native structures and hence by the loss of activity. In the rare favourable cases when the proteins are solubilised under mild conditions and when their concentrations are low, their functional properties are not lost, which indicates at least partial retention of the native conformations. The most detailed information about the proteins in the lipid bilayer has been obtained in the study of the plasma membrane of human erythrocytes, which contain haemoglobin — a nonmembrane protein which is the most abundant constituent of these cells. The convenience of this object is due to the fact that the erythrocyte membranes, called 'shadows', are the only ones in the cell and they can be easily isolated in a pure form with and without rupture and can even be obtained turned inside out. In the study of erythrocyte shadows, it was possible to establish for the first time that the membrane bilayer is threaded right through by certain membrane proteins and that the outer and inner sides of the membrane are asymmetric. Studies on the proteins of the human erythrocyte plasma membrane by one-dimensional electrophoresis in a polyacrylamide gel in the presence of sodium dodecyl sulfate led to the identification of about 15 principal proteins with molecular masses ranging from 15 to 250 kDa. Three of them — spectrin, glycophorin, and the so called band III protein — constitute altogether 60% of the mass of all the membrane proteins in the cell. They are bound in different ways to the membrane and can serve as examples of three typical ways in which proteins are associated with membranes.

Spectrin (240 kDa) can be equally regarded as a membrane protein and as a component of the cytoskeleton of erythrocytes. Two of its polypeptide chains, which are twisted relative to each other, form mobile dimers, which are combined into tetramers, as a result of interactions with the short actin filaments and other proteins, covering the cytoplasmic surface of the membrane in a dense network. The structural organisation enables spectrin to regulate the mobility of proteins and their distribution in the plasma membrane.

Glycophorin is the first membrane protein for which the aminoacid sequence has been determined. This transmembrane glycoprotein contains 131 aminoacid residues and about 100 sugar residues; its molecular mass is 30 kDa. Fig. 1 shows that a large proportion of the polypeptide chain of glycophorin is on the outer surface of the membrane, where the hydrophilic N-terminal fragment is located. The C-terminal section of the chain, also made up predominantly of hydrophilic residues, is immersed in cytoplasm, while the hydrophobic fragment, in the form of a single α-helix comprising 20 aminoacid residues, passes through the nonpolar lipid bilayer.

The band III protein from the human erythrocyte membrane is a transmembrane protein with a molecular mass of about 100 kDa (approximately 800 aminoacid residues). This is a transport protein, two molecules of which form an anionic channel for Cl^- and HCO_3^- ions moving passively through the membrane in accordance with their concentration gradients. The bilayer is threaded several times by the polypeptide chain of the protein in the α-helical conformation; approximately one third of the chain from the N-terminus is immersed in cytoplasm, whilst the short C-terminal section is located in the extracellular space (Fig. 1).

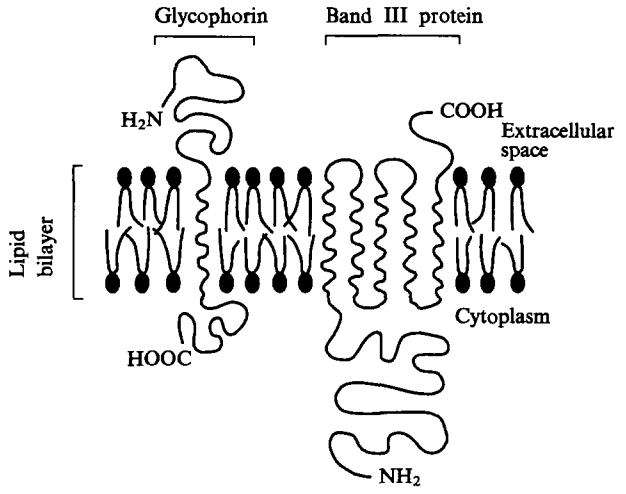

Figure 1. Schematic illustration of the disposition of glycophorin and the band III protein in the human erythrocyte membrane.

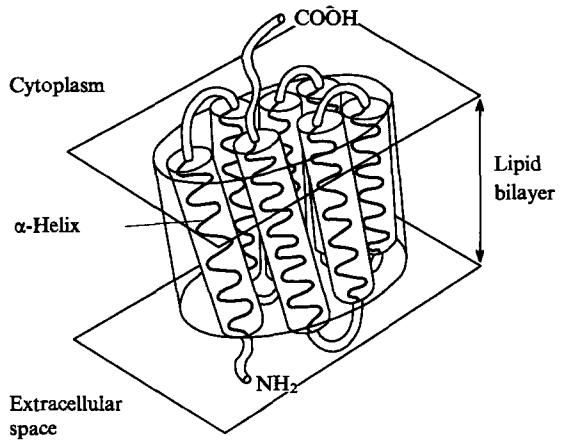

Figure 2. The structure of the bacteriorhodopsin molecule in the lipid bilayer.

In order to understand the mechanism of the functioning of the band III transport protein as well as the mechanisms of the action of other membrane proteins, it is necessary to know at least the three-dimensional structure of the molecule under the conditions of the lipid bilayer. Here it is necessary, first, to separate the transmembrane protein from the lipids and other membrane proteins without simultaneously damaging its three-dimensional molecular structure, which is very difficult; second, a highly ordered single crystal of the required size must be obtained from the isolated protein molecules. An alternative approach to the preparation of protein objects for X-ray diffraction analysis, which also concerned crystallographic studies on membrane proteins, arose in the 1980s. The approach involves genetic engineering based on the site-specific recombination of DNA. As a result, it became possible to devise specific, including artificial, genetic programs and to obtain the required proteins and their fragments in amounts sufficient not only for theoretical but also for applied purposes. However, genetic engineering methods have not radically facilitated the preparation of crystalline specimens made up of the native conformations of protein molecules and giving rise to distinct diffraction patterns. Nevertheless, the prospect of obtaining chemically pure membrane proteins, their mutants, and components of any length and with any variation of the aminoacid sequences greatly expanded the field where solutions to this problem may be sought.

Until recently, the only membrane transport protein for which certain details of its three-dimensional structure, obtained with a resolution of ~7.0 Å, were known was baceteriorhodopsin discovered in the plasma membrane of the purple bacterium *Halobacterium halobium*. Its polypeptide chain consists of 248 residues. Bacteriorhodopsin functions as a photoactive proton pump. After activation by a single light quantum, the excited chromophore induces conformational changes in the protein, as a result of which two protons are transferred from the inner surface of the cell to the outer surface. A proton concentration gradient and an electric potential gradient are created in the membrane and give rise to the synthesis of ATP. The bacteriorhodopsin molecules in the membrane form a planar crystal lattice resembling a two-dimensional crystal. Henderson and Unwin[9] used a combination of low intensity electron microscopy and small angle X-ray scattering to determine the three-dimensional structure of the protein and its orientation in the membrane. As a result of attaining record accuracy for both methods in the above investigation, it was shown that the polypeptide chain of bacteriorhodopsin forms seven α-helices in the membrane, each of which contains about 30 aminoacid residues (Fig. 2). All the helices intersect the lipid bilayer approximately at right angles to the plane of the membrane. They are close-packed and do not form a water-filled channel. The protons therefore apparently pass through the membrane via a series of protein chains of the α-helical residues, interacting with one another, the functioning of which is initiated by the excited chromophore.

A considerable proportion of the membrane proteins are receptors, i.e. are allosteric proteins capable of rearranging in a definite manner the three-dimensional structure of the molecule on interaction with hormones — specific signal mediators. The allosteric change in conformation is transmitted via the transmembrane chain of coupled proteins or domains of a single large protein within the cell and stimulates the corresponding physiological process in the latter. The available information about the three-dimensional structures of receptors and other components of transmembrane proteins is extremely scanty. Until recently, it has been possible to obtain the crystals and to determine the structures of only two specific membrane receptors — the photoreceptor centre[10,11] and porin.[12] In the 1990s, the studies on receptor proteins began to acquire a more systematic character. The information obtained hitherto about their three-dimensional structure refers, as will be shown below, not to the structures of whole membrane receptors but so far only to the outer portions of the molecules — extracellular domains.

1. The structure of the complex between the human growth hormone (hGH) and the outer part of the receptor (hGHbp)

De Vas et al.[13] established by X-ray diffraction with a resolution of 2.8 Å the three-dimensional structure of the protein complex between the hGH ligand and the extracellular domain of the hGHbp receptor, the interaction of which activates the growth and metabolism of the cells in the muscle, cartillage, and bone tissues. The molecule of the hGHbp membrane receptor consists of components separated in space: the extracellular fragment binding the hormone and located on the outer side of the membrane, the transmembrane fragment threaded through the lipid bilayer, and the intracellular component the function of which is as yet not entirely clear. There is also no clear idea about the mechanism of the interaction of all the components with one another and about the transfer into the interior of the cell of the signal which follows the association of the hormone with the outer part of the receptor.

The X-ray diffraction analysis of the hormone-receptor complex showed that the extracellular protein chain of the hGHbp molecule forms two easily distinguishable domains consisting of fragments incorporating the 1-123 and 128-238 aminoacid residues and linked by the 124-127 labile section. Each domain contains seven tiers of β-sheets, which give rise to a sandwich structure. De Vas et al.,[13] attribute a major importance

to the C-terminal octapeptide 239–246 section in the performance of the hormonal function. On sorption of the substrate, it ensures the conformational mobility of two domains of the receptor, which is necessary for the achievement of effective nonvalence contacts. In addition, it assists in the approach of the extracellular component of one receptor to the corresponding component of another and hence involves the two analogous outer domains of the latter in the binding of the hormone. This results in the formation of the complex hGH(hGHbp)$_2$, in which both receptors interact with the hormone virtually to the same extent despite the fact that there is no full structural similarity between the two centres for the binding of the hGH molecule to the pairs of domains of the two receptors. The three-dimensional structure of the complex hGH(hGHbp)$_2$ outwardly resembles the complex of an antigen with two pairs of domains (Fab) of immunoglobulin.

2. The structure of the extracellular domain of the aspartate receptor of the bacterium *Salmonella typhimurium* and its complex with the ligand

The three-dimensional structure of the domain in the free state of the receptor and in the receptor associated with aspartate has been determined by Milburn et al.[14] with resolutions of 2.4 and 2.0 Å. Being a typical transmembrane protein, the whole molecule of the aspartate receptor consists of three components: the outer ligand-binding domain, the cytoplasmic signal domain, and an intermediate domain located in the lipid bilayer. The periplasmic section of the 31–188 protein sequence, containing the Asp binding centre, is linked by two peptide fragments (7–30 and 189–212), threaded through the membrane, to the inner, largest domain, which is made up of the 1–6 and 213–552 residues.[15,16]

The aminoacid sequence of the extracellular 31–188 domain has been synthesised by a genetic engineering method.[17] The purified polypeptide crystallised exclusively in the form of a dimer having the same affinity for the aspartate ligand as the entire protein of the natural type. The diffraction pattern, which was initially diffuse, acquired a sharper outline on cross-linking of the two chains of the dimer by the disulfide bond formed by the Cys residues in positions 36. The preparation thus obtained did not differ from the domain of the native receptor as regards its functional properties.

The three-dimensional structures of the subunits of the dimer not associated with the ligand are identical and have the form illustrated schematically in Fig. 3. Each of them consists of four α-helices forming a cylinder ~20 Å in diameter and > 70 Å long.

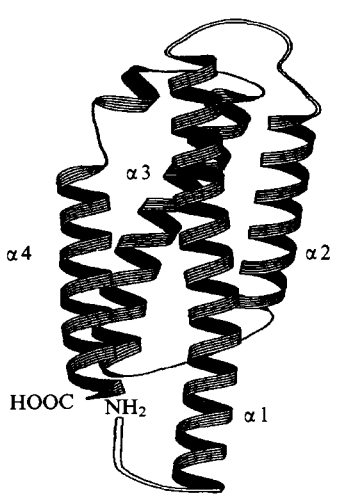

Figure 3. Schematic ribbon representation of the three-dimensional structure of the extracellular domain of the aspartate-binding receptor.[14]

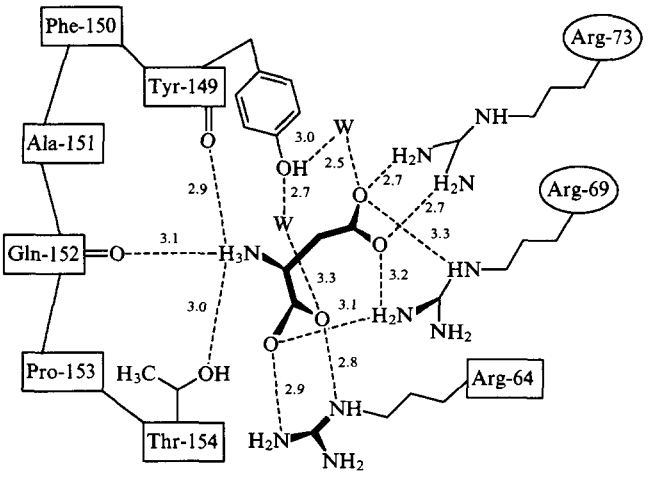

Figure 4. Schematic illustration of the hydrogen bonds between aspartate and the ligand-binding centre formed by the extracellular domains of two aspartate receptors. The aminoacid residues of one of the receptors are indicated in rectangles and those of the other in ovals; [14] W is a molecule of the water of crystallisation.

The dimer cross-linked by the disulfide bridge exhibits C_{2v} symmetry. On interaction with the ligand and formation of a complex, the symmetry breaks down. The centre for the binding of aspartate to the receptor is located near the apex of the dimer between the contact surfaces of the subunits at a height exceeding 60 Å above the postulated surface of the outer phospholipid layer of the membrane. In conformity with its symmetry, the dimer made up of the extracellular domains of two receptors has two hydrophilic ligand-binding pockets. One of them, most clearly manifested on electron density charts, is illustrated in Fig. 4. It incorporates the Arg-64 residue and the 149–154 fragment of one subunit and the Arg-69 and Arg-73 residues of another subunit, together with molecules of water of crystallisation, which form with aspartate a complex network of hydrogen bonds in the ligand–receptor complex. The sorption of two aspartate molecules induces the mutual approach of the residues forming the hydrophilic pockets and an overall compaction of the dimeric complex. The mean square deviation of the C^{α} atoms of one subunit (without taking into account the 77–85 fragment) is 0.47 Å and that of the C^{α} atoms of the other subunit (without taking into account the 25–36 fragment) is 0.34 Å. The deviations of the C^{α} atoms in the 77–85 and 25–36 sections exceed appreciably the above values. The conformational changes in the dimer on binding of aspartate lead to the rotation of the subunit by 4° relative to the short axis perpendicular to the twofold axis and the contact surfaces of the ligand-binding domains. The extent to which the above conformational deviations reflect the specific allosteric effect of the receptor still remains unelucidated.

3. The structure of prostaglandin H_2 synthase (PGHS)

Prostaglandins — aliphatic acid derivatives with 20 carbon atoms in the chain — constitute an important family of local chemical mediators, the source of which is cells of many types. They bind to a large number of receptors on the cell surface and induce the contraction of smooth muscle, diminish the capacity of thrombocytes for aggregation, activate the central nervous system, act on inflammatory processes, and liberate renin.[18] It has been established recently that prostaglandins also play an important role in the pathophysiology of cancer and of cardiovascular diseases.[19–21]

The crystal structure of the first membrane enzyme, prostaglandin H_2 synthase (PGHS), was first established in 1994.[22] The protein catalyses two processes in the first stage of the

biosynthesis of prostaglandins. It initiates and activates, firstly, the cyclooxidase reaction, during which arachidonic acid is converted into prostaglandin PGG_2 and, secondly, the subsequent peroxidase reaction, in which PGG_2 is converted into PGH_2, the latter being rapidly transformed into one of the prostanoids. The integral membrane protein PGHS is located predominantly in the endoplasmic reticulum. Its liberation from the membrane is achieved by extraction with a salt solution and by solubilisation with a nonionic detergent, in the presence of which crystallisation is also carried out. In the resulting specimen, the protein molecules are associated with flurbiprofen, a nonsteroid antiinflammatory preparation, and form dimeric complexes with a twofold symmetry axis. Two isomers of prostaglandin H_2 synthase have been detected in the cells: PGHS-1 and PGHS-2. These are distinguished by their activity and their distribution in the tissues. The three-dimensional structure of the sheep PGHS-1 has been determined[22] with a resolution of 3.5 Å. It is a glycosylated protein with a molecular mass of 70 kDa and 587 aminoacid residues, which participates in the maintenance of tissue homeostasis. As regards the function of PGHS-2, it has been suggested that the enzyme is responsible for the biosynthesis of prostaglandins during cell division and in inflammatory processes.

The three-dimensional structure of the PGHS-1 molecule consists of three largely autonomic and apparently independently coiling subunits: a small N-terminal domain, a membrane-bound section of the chain, and an enzyme domain. The first N-terminal domain comprises the 33–72 section of the polypeptide chain (the 1–24 residues constitute a signal sequence, which can be split off, and do not enter into the mature enzyme; the 25–32 residues could not be interpreted on the basis of the electron density maps obtained). Its conformation, stabilised by three intradomain disulfide bonds, is very similar to the structure of the epidermal growth factor (EGF). Polypeptide modules, similar to EGF, have been found in many extracellular proteins — factors stimulating the growth of neurons and the clotting of blood, and also in the proteins of surface cells necessary for their survival and proliferation. The function of the EGF-like domain of the PGHS-1 molecule is unknown. The second domain, incorporating the 73–116 residues, consists of four α-helices, oriented along one side of the monomer. Its conformation, highly amphipathic properties, and the hydrophobic surface profile quite definitely indicate the possible integration of the enzyme in only one lipid layer, so that the given membrane protein is monotopic according to Blobel's classification.[23] The third, largest catalytic domain of the PGHS-1 molecule (the 117–587 residues) has a globular structure consisting of two lobes twisted relative to one another but nevertheless fairly distinguishable. One of them, the larger, has a V-shape made up of two α-helices held together by an intermediate third helix acting in a manner resembling a pair of forceps. This construction serves as a framework around which a further four α-helices and the loops connecting them are packed. The small 'lobe' of the catalytic domain consists of a packet of six parallel helices.

As a bifunctional enzyme, the PGHS-1 protein has two active centres: the peroxidase and cyclooxidase centres. The former is on the surface of a narrow groove between the large and small 'lobes' of the catalytic domain and contains the prosthetic group — the high-spin Fe(III)-protoporphyrin IX — the proximal surface of which is turned towards the small 'lobe'. The peroxidase activity involves only the reduction of the PGG_2 synthesised in the cyclooxidase centre and the activation of the cyclooxidase reaction. This mechanism is typical for the haem-dependent peroxidases, which reduce hydroperoxidase substrates via a two-electron transfer reaction, leading to the formation of the oxoferrylporphin radical-cation. The oxidised haem returns to the initial stage after two successive one-electron transfers to the substrates being reduced or as a result of the transfer of oxygen to aryl sulfide compounds. The PGHS-1 molecules reduce preferentially PGG_2 and other long-chain aliphatic acids as well as aliphatic hydroperoxidases. The cyclooxidase active centre consists of a long narrow channel (8 × 25 Å) extending from the outer surface of the domain, linked to the membrane via its helix, to the centre of the monomeric PGHS-1 molecule. The diffuse diffraction pattern arising from the crystals, which have so far been grown for onlyone enzyme–inhibitor complex, did not allow the authors[22] to put forward on the basis of the data obtained a mechanism of the catalytic reaction occurring in the cyclooxidase centre.

In conclusion of the brief consideration of the results of the X-ray diffraction analysis of prostaglandin H_2 synthase, one should mention that the importance of this study, as the first investigation of the three-dimensional structure of a membrane enzyme, does not lie solely in the experimental facts themselves, the value of which is quite evident. A no less important feature of the study is associated with the influence of the data obtained on the very formulation of the relevant questions on a qualitatively different, higher level. The search for solutions to important problems such as the incorporation of enzymes in membranes, the function of the EGF-like module, the conformational and chemical aspects of the catalytic steps performed in the cyclooxidase and peroxidase active centres, and a number of others, which are of general interest, can now be based on concrete structural data.

III. Proteins of the immune system

Although the proteins of the immune system are membrane proteins, nevertheless, bearing in mind their functional characteristics, it is useful to consider the latest advances in X-ray diffraction analysis in the study of their three-dimensional structure in a separate section.

It was established in the 1960s that the two main types of immune responses are affected by different types of lymphocytes — T and B. The T-lymphocytes, which are responsible for cellular immunity, multiply in the thymus — the central lymphoid tissue. The antibodies produced and the B-lymphocytes responsible for the humoral response are formed from the stem cells of the haemopoietic tissue in mammals and in the Fabricius sac in birds. They subsequently migrate with the bloodstream to peripheral lymphoid tissues. The immune response of the cellular type implies the proliferation of specialised cells responding to foreign antigens, which are disrupted either directly on the surfaces of the cells produced or with the aid of other cells, such as macrophages. The humoral response consists in the activation of the synthesis of antibodies, circulating in the liquid media of the organism and interacting specifically with the foreign molecules. The binding of the antibody to the antigen facilitates the absorption of the latter by phagocytes and frequently activates the special system of the blood proteins — the complement system, which assists in the destruction of the antigen.[24,25] One of the functional problems in immunology is associated with the study at the atomic-molecular level of the mechanisms of the recognition and of the response reactions of the immune system to the appearance in the organism of infective antigens — foreign proteins, viruses, bacteria, and pathogenic substances.

According to Burnet's theory of clonal selection,[26,27] the specificity of the antigen response of lymphocytes is due to the presence on the surfaces of the T- and B-cells of receptor proteins, which interact selectively with particular antigens.

It is known that, on stimulation by the antigen, the T-lymphocytes begin to divide vigorously and are converted into active effector cells. Depending on the antibodies produced by them on the cell surface, they can be divided into at least three groups.[28] The first group comprises cytotoxic cells, which, by reacting with the foreign viral antigens, kill the infected cells before the onset of the replication of the virus. The molecular mechanism responsible for the destruction of the target cell has

so far not been elucidated. Nevertheless, it is known that this requires direct contact between the cytotoxic T-lymphocyte (the killer cell) and the infected cell (the target cell).[29] The second group of the activated T-lymphocytes includes the so called T-helpers, the helper cells required both by B- and T-cells to generate the humoral and cellular immune responses and also for the activation of macrophages. Finally, the third group is made up of T-suppressors, which suppress the response of the B-cells or other T-cells to antigens. It has been noted that, like the majority of T- and B-lymphocytes, the T-suppressors function only when they are continuously stimulated in this respect by the T-helpers, which, by activating the T-tissues of the suppressor, are themselves inhibited. Such feedback in the complex network of the interactions of lymphocytes ensures the self-regulation of the activities of cells of both types.

A large proportion of the T-lymphocytes recognise foreign agents, provided that they are not associated on the cell surfaces with membrane glycoproteins, which are coded by the genes of the major histocompatibility complex (MHC).[30] There are two classes of MHC molecules, I and II, each of which consists of a set of glycoproteins of the cell surface.[31-33]

The recognition by the T-lymphocytes of an antigen associated with the MHC glycoproteins on the surface of the target cell is effected by the T-cell antigen receptor (TCR) and one of the transmembrane proteins, CD4 or CD8, which are TCR coreceptors.[34-36] It has been suggested that a nonvalence complex is formed as a result of the stabilising contact between variable sections of the TCR molecule, the antigen, and the polymorphic sections of the MHC and also between the CD4 (or CD8) membrane proteins and the nonpolymorphic sections of the class II (or class I) MHC respectively. The coordinated interactions of TCR and CD4 (or CD8) with the MHC proteins of the target cells require a definite set of properties of the T-cells, which appear during the development of lymphocytes in the thymus, their differentiation, and maturation.[37-43]

The interaction of CD8 with MHC-I molecules triggers the intracellular signal system via the $p56^{lck}$ protein, an src-bound tyrosine kinase, associated directly in the lipoid cells with both CD4 and CD8.[44] In this case, the CD8–$p56^{lck}$ complex can function virtually like growth factor receptors, in which the linkage with the intracellular domain activates the intracellular tyrosine kinase.

The X-ray diffraction data on the three-dimensional structures of membrane proteins and their individual domains involved in the functioning of the T-cell immune system began to appear only in the 1990s. Since this concerns mainly the structures of the membrane proteins, the use of the X-ray diffraction method in cellular immunology has encountered major preparative difficulties which have not yet been fully overcome. Incidentally, the situation is also similar in all other aspects of molecular biology concerned with the study of phenomena occurring on the surfaces of cells. Therefore, in assessing the results of the X-ray diffraction analysis discussed below, one must bear in mind that they represent only the beginning of an extensive penetration of the method into the problems of T-cell immunology.

1. The structure of the extracellular fragment of the CD8 coreceptor of T-lymphocytes

The CD8 protein has been detected on the surfaces of T-cells in two forms: the disulfide-linked homodimer α_2 and the heterodimer $\alpha\beta$.[27] Both forms have N-terminal extracellular domains, the aminoacid sequences and structural features of which are similar to those of the variable domains of the immunoglobulin Ig-V.[45,46] The CD8 homodimer α_2 is illustrated schematically in Fig. 5. The extracellular region of CD8 includes 162 residues, 114 of which constitute the N-terminal immunoglobulin domain linked to the transmembrane section by a chain of 48 residues. The intracellular region consists of a highly polar aminoacid sequence interacting directly with tyrosine kinase $p56^{lck}$.

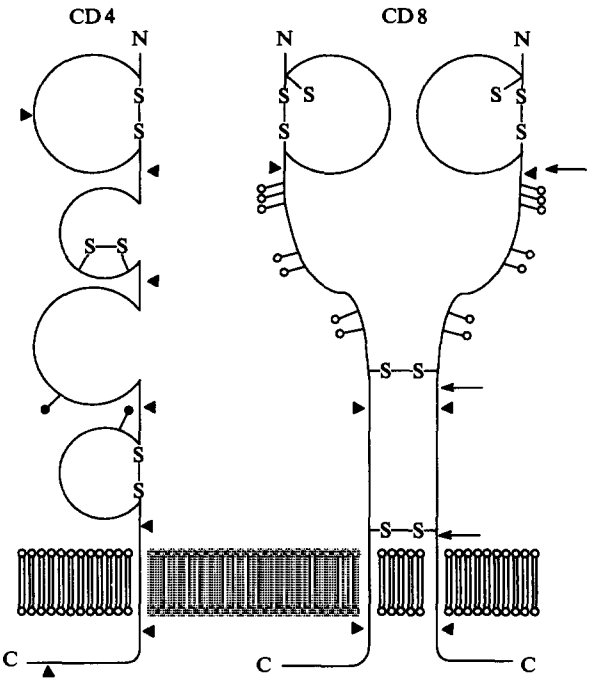

Figure 5. Schematic illustration of the CD4 receptor and the homodimer of the CD8 receptor. Each large circle corresponds to an immunoglobulin domain; the open circles denote the potential *O*-glycosylation sites, whilst the filled circles denote the corresponding *N*-glycosylation sites; the arrows indicate the ends of expression, whilst the dark triangles represent the limits of the intron sequences.[47]

The three-dimensional structure of a large part of the extracellular polypeptide chain of the human CD8 coreceptor, the length of which corresponds to 146 residues (CD8-146), has been established[47] with a resolution to within 2.6 Å. The crystals employed for the determination of the structure had the necessary size and gave rise to a satisfactory diffraction pattern only after the treatment of the protein preparation with neuraminidase, *O*-glycosidase, and V8-protease. In the CD8-146 structure thus determined, the overall character of the coiling of the polypeptide chain of the N-terminal domain proved to be identical to that of the variable domains of the immunoglobulin Ig-V. Its three-dimensional structure also contains, as can be seen from Fig. 6,

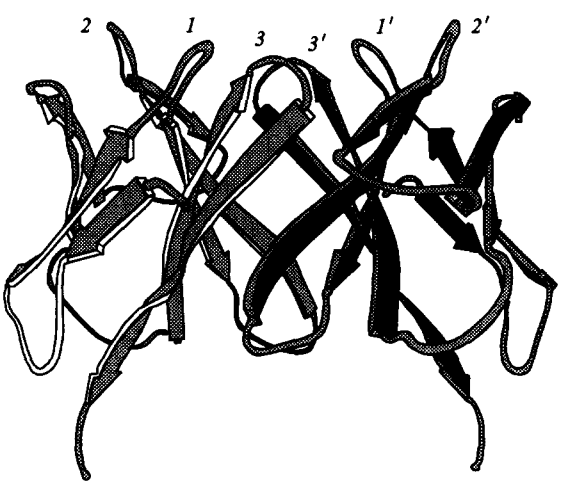

Figure 6. Schematic ribbon illustration of the three-dimensional structure of the CD8-146 homodimer. The numerals *1*, *2*, *3* and *1'*, *2'*, *3'* denote the CDR-1-, CDR-2-, and CDR-3-like loops of the two subunits.[47]

two antiparallel β-pleated sheets made up of five and four β-tiers linked by loops having the same topology. Two domains of the CD8-146 fragment make up a homodimer, similar to the immunoglobulin F_v, with a twofold symmetry axis. However, the electron density maps do not permit the identification of the geometry of the 115–141 fragment, which follows the N-terminal domain. The absence of the corresponding clear reflections from the diffraction pattern indicates a disordered state of this fragment in the crystal.

The joint consideration of the steric structure of the CD8 domain discovered and the crystal structure of the MHC-I (HLA-A2) protein established previously by Bjorkman et al.[48] revealed the existence of steric and electrostatic complementarity of the potential energy surface profiles of the two polypeptides and made it possible to reproduce their nonvalence complex and to construct the corresponding atomic model. The binary complex was supplemented by yet another participant — the T-cell receptor (TCR), the surface of which is apparently complementary to the residual unoccupied peptide-binding groove of the HLA-A2 molecule of the target cell. Thus Leahy et al.[47] concluded that the CD8 domain and TCR are linked simultaneously to the same MHC-I molecule in the antibody-antigen complex, while the second domain of the CD8 dimer is linked to a second MHC-I molecule. This scheme of the interactions of the receptors of the killer cell with the MHC-I molecules of the target cell agrees with experimental data.[49]

2. The structure of the extracellular fragment of the CD4 receptor containing domains 3 and 4

It was supposed previously that the three-dimensional structures of the molecules of the CD4 and CD8 receptors are very similar and that their interactions with the molecules of the class II and class I MHC should therefore have the same effect on the activation and development of the T-lymphocytes.[50] However, crystallographic studies on CD4 [51,52-54] and CD8 [47] showed that the three-dimensional structures of these proteins, at any rate in the extracellular region, differ significantly from one another. The principal differences concern two features. Firstly, the N-terminal Ig-V-like domain of CD4 functions in the monomeric state, while the N-terminal domain of CD8 forms the F_v-like homodimer. Secondly, the structure of CD4 in the extracellular region consists of four largely autonomous domains, while CD8 consists of only one domain, linked to the transmembrane component of the receptor by an apparently labile section comprising 48 aminoacid residues, which is virtually undetectable in the diffraction pattern. The only structural feature characteristic of both CD4 and CD8 and absent from the immunoglobulin variable domains is that the length of the CDR2 loop is greater by six aminoacid residues. The functional significance of such local alteration of the sequence remains obscure.

We shall deal in greater detail with the three-dimensional structure of the CD4 receptor. The CD4 molecule is that of a transmembrane glycosylated protein. It is present on the surfaces of T-lymphocytes belonging to the subpopulation which recognises the target cells containing antigens associated with the MHC-II proteins,[27] similarly to the way in which another subpopulation of the T-lymphocytes with CD8 molecules on the surface recognises foreign cells containing antigens linked to the MHC-I proteins.[55-57] The cytoplasmic region of CD4 is in close contact with the tyrosine kinase p56, which plays an important role in triggering the production of T-cells. The CD4 molecule is the principal receptor interacting with the human immunodeficiency virus (HIV-1),[58-61] which is discussed in detail in Section VI.

On the basis of results of the analysis of aminoacid sequences of CD4 and immunoglobulins, it was predicted that the extracellular part of the receptor would consist of four domains, which have been assigned to the IgSF superfamily.[58,62] This hypothesis was soon confirmed by the results of direct structural studies. Admittedly, all attempts to carry out the X-ray diffraction analysis of the entire extracellular component of the molecule comprising 371 residues were unsuccessful owing to its poor crystallisation. However, it was possible to obtain crystals giving an entirely satisfactory X-ray diffraction pattern, which were individually made up of the two halves [of one of the two halves? (Ed. of translation)] of this part of the CD4 sequence. Each crystalline specimen incorporated two domains — D1D2 [52,53] and D3D4.[51,54] The cryotechnique, which made it possible to determine the three-dimensional structure with a resolution to within 2.6 Å, was used in the crystallographic study of D3D4; at room temperature, the resolution was to within 2.8 Å. Cooling of the crystals to −150 °C was accompanied by a 1%–2% decrease in the size of the unit cell without disturbance of the symmetry group. The mean square deviation of the C^{α} atoms of the aminoacid residues following the change in temperature from room to −150 °C was 0.86 Å (0.93 Å for the D3 domain and 0.57 Å for the D4 domain). Comparison of the three-dimensional structures of the four domains showed that the three-dimensional structures of the sequences have a series of common features, the D1 and D2 domains resembling more closely the D3 and D4 domains respectively. The differences between the D3D4 and D1D2 geometries consist primarily of the greater distance in D3 between the β-pleated sheets, which is evidently associated with the absence of the disulfide bond in this domain and, secondly, of the change by ~25° in the mutual orientation of the D3 and D4 domains relative to the orientation of D1 and D2.

In the model of the entire extracellular part of the CD4 receptor, proposed by Lange et al.[51] on the basis of the known three-dimensional structures of D1D2 and D3D4 and consistent with a series of indirect data,[63,64] the four domains have a rod-shaped form with a length of ~120 Å, which is approximately equal to the sum of the lengths of the two D1D2 (65 Å) and D3D4 (60 Å) fragments. The conformation of the intervening section consisting of three residues (179–181) remained unestablished. In the D1D2 fragment, these residues are C-terminal and, since they are apparently appreciably mobile in the crystal, they are not manifested on the electron density maps. In the proposed CD4 model (D1D2D3D4), the N-terminal sections of the D1 and D2 domains are accessible to the establishment of contacts with the MHC-II proteins and some sections of the surfaces of the D3 and D4 domains are able to interact with the proteins of the T-cell receptor complex of their own lymphocyte; incidentally, the structures of the two components are so far unknown.

3. The structure of the class II HLA-DR1 antigen

The human MHC antigens HLA (human leukocyte antigens) were first discovered on leukocytes. Like MHC, the antigens of the HLA group can be divided into two classes, I and II, consisting of sets of cell surface glycoproteins. As already mentioned, in transplantation responses, the cytotoxic T-cells mainly respond to foreign class I glycoproteins, whereas the T-helpers respond to foreign class II glycoproteins. The HLA-II molecules are transmembrane αβ heterodimeric proteins with a molecular mass of 60 kDa. They are initially expressed by special antigen-producing cells such as macrophages, stem cells, and B-lymphocytes. The class II of the HLA antigens embraces proteins which are transformed from extracellular antigens into T-cell helpers in the course of the identification of foreign antigens and immune responses.[65,66] In man, the molecules of this class are polymorphous and can therefore interact specifically with sets of different proteins. The polymorphism of HLA is probably responsible for the different immune responses of different individuals exposed to the action of the same foreign agents; different susceptibilities to diseases, the breakdown of tolerance to own antigens, and the appearance of autoimmune responses are associated with such polymorphism.[67,68]

The crystals were grown in an aqueous solution of class II HLA-DR1 belonging to several variants of alleles. The protein

was first purified with the aid of immunoaffinity chromatography and detergents and then freed from the transmembrane region and the cytoplasmic domain by treatment with papain.[69,70] The three-dimensional structure of the extracellular part of HLA-DR1 was determined with a resolution to within 3.3 Å by means of a combination of X-ray diffraction data obtained from three different specimens.[70] In all cases, the protein crystallised as the dimer of the DR1 αβ heterodimer. The structure discovered was similar to the molecular structure of HLA-I [71] and was found to correspond to the hypothetical model of the peptide-binding centre of this protein constructed on the basis of crystallographic data for the three-dimensional structure of class I HLA-A2.[72] The three-dimensional structure of the monomeric unit of class II HLA-DR1 in the αβ heterodimer consists of two α-helical domains and two β-structural domains (β_1 and β_2). The molecule is intersected by a long peptide-binding groove, the bottom of which is lined with eight tiers of an antiparallel β-sheet and the walls are lined with two antiparallel helical sections. There are four contact regions between the DR1 molecules in the dimer (Fig. 7). Two of them are located near the two fold axis of rotation and include the interactions of the 49–55 (β_1) and 88–111 (α_2) residues. The other two contact regions, most remote from the membrane, are made up of five pairs of aminoacid residues of two close β_1 domains. The crystal structure of DR1 [70] permits the formation of a complex with CD4, postulated previously on the basis of the study of mutagenic derivatives.[73] If in the T-cell recognition of DR1, the latter is in a dimeric form, then, it follows from the X-ray diffraction analysis of the protein that the α_2 domain of the second molecule of the dimer can also be in contact with CD4, giving rise to an additional interaction of DR1 with CD4.

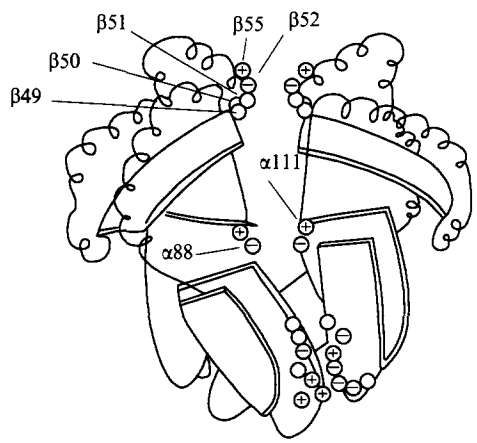

Figure 7. The contact regions of the subunits of the class II HLA-DR1 αβ heterodimer.[70]

Brown et al.[70] proposed a hypothetical mechanism of the assembly of the antigen-specific intercellular complex of HLA-II, TCR, and the CD4 coreceptor. It is suggested that in the first stage the αβ T-cell receptor and its associated CD3 and subunits form weak dimers, similar to the DR1 dimers, which are unstable before the appearance of the DR1–TCR complex. The complex becomes irreversible as soon as the DR1 molecules bind to specific peptides via TCR. The final stabilisation of the complex creates conditions for the appearance of effective interactions of the four-domain CD4 coreceptor simultaneously with both TCR monomers and the MHC-II proteins. The association of CD4 implies the inclusion of the signal system for the triggering of the immune response of the cellular type.

4. The structure of the HLA-DR1 – peptide complex

The antigens of the major histocompatibility complex (MHC or HLA in man) are transmembrane glycoproteins. They bind the peptides within the cell in the cytoplasmic space and supply them to the extracellular space, where they become accessible to the T-cells participating in the mechanism of the functioning of the immune system, in the identification of the foreign antigen, and in the response to its appearance.[74,75] The interaction of the T-cell antigen receptor with the peptide associated with the MHC(HLA) stimulates the expression of the proteins of the major histocompatibility centre in the T-cell. An individual organism has a small set of varieties of such proteins. Furthermore, there are facts indicating that each of them is able to bind an enormous number of pathogenic peptides and of signalling the need for response activities. The apparent contradiction is resolved by virtue of the broad polymorphism of the molecules of the MHC proteins, i.e. the lability of their three-dimensional structures or, in other words, the possibility that individual, predominantly surface sections of the protein globule can assume a large number of different conformational states. The polymorphism of the aminoacid residues of the class I and II HMC proteins forming the binding centres is responsible for their ready adaptability to peptides with different sequences. However, this does not rule out the specificity of the interactions. The MHC-I proteins are as a rule associated with short peptides, usually comprising ten residues, and are distinguished by a high selectivity in relation to aminoacids in fully defined sites of the oligopeptides sequence combined with tolerance in the nature of all other sections of the chain.[76–78] The MHC-I proteins function in the endoplasmic reticulum, where a vigorous peptide-generating proteolytic process takes place simultaneously. The MHC-II proteins act in the endosomal and liposomal compartments, where proteolysis also proceeds simultaneously. Representatives of this class usually bind longer peptides and also exhibit a high sensitivity to the locations of various aminoacids in the sequence.[79–82]

The results of the X-ray diffraction analysis of the extracellular parts of several human HLA-I [83–86] and mouse MHC-I [87,88] proteins indicate the operation of a common mechanism of the binding of peptides by class I proteins. In the structures of all the peptide–protein complexes investigated, the peptides had similar conformations stabilised at the binding centres by what is in principle the same system of hydrogen bonds and by the specific dispersion interactions of the side chains of several residues of the associated peptide with the hydrophobic pockets of the protein globule complementary to them.[86–92]

The binding of peptides to class II MHC (HLA) proteins can be inferred from the results of the X-ray diffraction study by Stern et al.[93] of the three-dimensional structure of the complex between the extracellular part of the HLA-DR1 protein and the peptide of the HA influenza virus — the tridecapeptide fragment (306–318) of haemagglutinin (the membrane glycoprotein of this virus). The diffraction pattern was obtained from a single crystal at −170 °C with the aid of synchronous radiation with λ = 0.910 Å. The three-dimensional structure of the HLA-DR1 – HA complex was determined with a resolution to within 2.75 Å.

The HA tridecapeptide was sorbed at the HLA-DR1 binding centre in the extended (twisted with a large pitch) form. It represents the best possibilities for interactions, on the one hand, with the aminoacid residues surrounding the peptide and, on the other, with the surface residues of the T-cell receptor. Thus the peptide is open to intercellular interactions. A schematic illustration of the twelve hydrogen bonds formed in the HLA-DR1–HA complex is presented in Fig. 8. The bonds are formed only between the atoms of the main chain of the HA peptide and the atoms of the conservative aminoacid residues of the α-helical and β-structural regions of HLA-DR1. Consequently the system of hydrogen bonds is independent of the particular sequence of the peptide, i.e. is universal for class II HLA-DR1 peptide complexes. This finding also indicates the similar orientations of the peptides in the complexes simultaneously in relation to the binding centres of the HLA-DR1 and TCR proteins belonging to other cells.

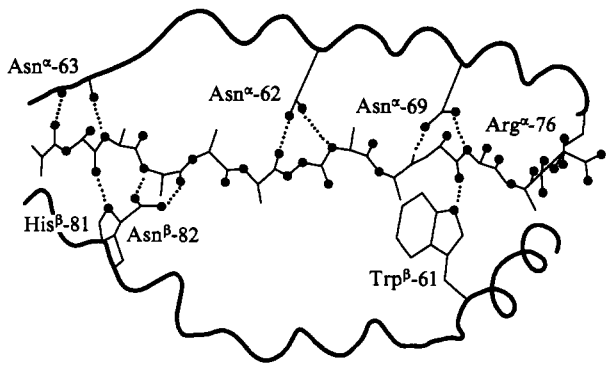

Figure 8. Schematic illustration of the hydrogen bonds between the peptide and the peptide-binding centre of the HLA-DR1 – HA complex.

IV. Aspartate proteases

The first attempt to solve with the aid of X-ray diffraction the problem of the structural organisation of membrane proteins, examined in Sections II and III, ended with relative success. The three-dimensional structures of the periplasmic domains, containing ligand-binding centres, were established for a series of transmembrane receptors and antigen-specific complexes of T-lymphocytes. Further development of studies on this aspect of the field should lead to the determination of the three-dimensional structures of whole receptor molecules, incorporating also transmembrane and cytoplasmic domains. The atomic-molecular foundations for the theoretical and experimental study of the structural-functional organisation of membrane proteins and the mechanisms of their functioning will be ultimately created. The difficulties on this path, which are mainly methodological in character, are still very large.

The latest advances in the X-ray diffraction analysis of proteins, the knowledge of the three-dimensional structures of which is of vital importance for man, are examined below. These are aspartate proteases, primarily the protease of the human immunodeficiency virus (HIV-1) and renin, one of the principal participants in the system for the regulation of the tonus of the blood vessel walls, skeletal muscles, and other tissues. It is becoming increasingly more evident that the search for radical therapeutic means of combating the acquired immunodeficiency syndrome (AIDS), other types of viral diseases, as well as hypertonicity, i.e. the solution of strictly applied medical-biological problems of extraordinary importance, requires a high level of development of theoretical molecular biology. A necessary, although not entirely sufficient, precondition for its attainment is information about the three-dimensional structures of the corresponding protein molecules. In contrast to structural studies on membrane receptors, the retarding factor in this instance is not the difficulties in the isolation, purification, and crystallisation of the proteins but difficulties of a more fundamental character.

Table 1. X-Ray diffraction analysis of native aspartate proteases and their inhibitors.

Enzyme	Inhibitor	Resolution/Å	Ref.
Pepsin	–	2.7, 2.3, 2.0, 1.8	94–98
	AcPhe–TyrOMe	3.0	99
Pepsinogen	–	1.8	100, 101
Chymosin	–	2.3	102–104
Renin	–	2.5, 2.8	105, 106
	His–Pro–Phe–His–Leu–Leu–Tyr–Tyr–Ser	2.5, 2.4, 2.6, 2.0	106–109
Penicillopepsin	–	2.8, 1.8	110–112
	Iva–Val–Val–Lysta–OEt	2.6, 1.8	113, 114
Endothiapepsin	–	3.0, 2.4, 2.1	115–117
	Pro–Thr–Clu–Phe(CH_2NH)Phe–Arg–Glu	2.0	118
	Boc–Thr–His[NHCH(CH_2Ph)CH(OH)N(CH_2CHMe_2)CO]Lys–Phe	1.8	119
	Boc–His–Pro–Phe–His–Sta–Leu–PheNH_2	2.2	120
Rhizopuspepsin	–	2.5, 1.8	115, 121
	AcVal–Sta–Ala–StaOH	2.5	122, 123
	D–His–Pro–Pro–Phe–His–Phe(CH_2NH)Phe–Val–Tyr	1.8	124
Proteinase of the bird myeloblastosis virus (BMV)	–	2.4	125
Proteinase of the Rous sarcoma virus (RSV)	–	2.0	126
Proteinase of the human immunodeficiency virus (HIV-1)	–	2.0, 2.8	127, 128
	Val–Ser–Gln–Asn–Leu ψ[CH(OH)CH_2]Val–Ile–Val (U-85548e)	2.5	129
	AcSer–Leu–Asn–Phe ψ[CH(OH)CH_2]Pro–Ile–Val–OMe (JG-365)	2.4	130
	AcThr–Ile–Nle–CH_2–Nle–Gln–Arg–NHMe (MVT-101)	2.3	131
	PR[a]–Gly–Gly–Ser–Ser–Gly–PR	1.8	132

[a] PR = HIV-1 proteinase.

Before considering the results of the X-ray diffraction analysis of the molecules of the HIV-1 protease, which belongs to the family of the RNA-containing viruses (*Retroviridae*) and of renin (a mammalian proteolytic enzyme), which have attracted exceptional attention in recent years as promising therapeutic targets, we shall deal briefly with the overall state of structural research into aspartate proteases.

The first crystalline structures of aspartate proteases became known in 1977, when the results of X-ray diffraction analysis of the molecular structures of four enzymes were published simultaneously: pepsin, penicillopepsin, endothiapepsin, and rhizopuspepsin (Table 1). The structures were determined with a resolution of 2.5–3.0 Å. About ten years elapsed before the resolution could be improved to 1.8–2.1 Å, which made it possible to infer with adequate reliability the details of the structures both of the enzymes themselves and of the inhibitor and water molecules interacting with them. The structures of a further two aspartate proteases were elucidated during this period — chymosin and renin, as well as the structures of a series of inhibitor complexes of the four enzymes mentioned above.

X-Ray diffraction analysis showed that, despite the significant differences between the aminoacid sequences, the three-dimensional molecular structures of the aspartate proteases of animals and microorganisms are similar. They are all made up of two symmetrically arranged domains which consist almost wholly of β-structures. Both domains reproduce the same structural motif and contain the Asp–Thr–Gly sections, which form part of the active centre of the enzyme. In the contact region, the domains form a groove intersecting a major part of the protein globule. The two catalytically important residues Asp-32 and Asp-215 (the numbering is that for pepsin), the carboxy-groups of which are close to one another and to several other residues as well as the molecules of water of crystallisation, are located at the centre of the groove. The system is stabilised by a network of hydrogen bonds and electrostatic and dispersion interactions (Fig. 9).

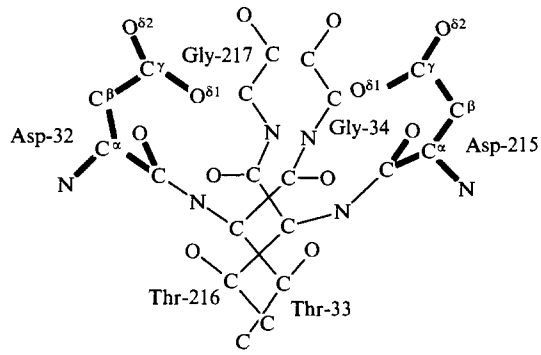

Figure 9. Catalytically important residues of the active centre in aspartate proteinases.

The studies on the three-dimensional structures of the complexes between aspartate proteases and substrate-like inhibitors (Table 1) made it possible to identify the sites of the active centre for each enzyme and to relate them to the sections of the substrate responsible for the primary and secondary specificity of the enzymic reaction. Comparison of the structures of native proteases with their inhibitor complexes showed that the binding of the oligopeptide ligands, differing only slightly from the substrates, is accompanied by the rotation of one domain relative to another by ~4° and its displacement by ~0.3 Å along the axis passing through the C^{α} atoms of the Asp-32 and Asp-215 residues. The change in the mutual orientation of the domains leads to the squeezing of the groove and an appreciable deformation of the active centre, an increase in the distance between certain residues by ~2.0 Å, and a displacement of the side chains by up to 3.5 Å. It was postulated that such changes are necessary for the occurrence of enzymic reactions and hence take place also on formation of enzyme–substrate complexes.[133]

The concept of the purely chemical aspects of the enzymic reactions of aspartate proteases was formulated even before the establishment of protein crystallography. Detailed studies on the nonenzymic hydrolysis of a wide variety of esters, amides, and model peptides, carried out mainly in the 1960s, showed that the catalysis is effective only in a medium incorporating the following three components: a nucleophile attacking the carbonyl carbon atom of the peptide bond to be cleaved, a basic catalyst promoting the elimination of a proton from the nucleophile, and an acid catalyst ensuring the protonation of the leaving group.[134] These investigations as well as the study of the kinetics and thermodynamics of the enzymic reactions of proteases permitted yet another important conclusion of a general character: the chemical mechanisms proper of the activity of all the proteolytic enzymes can be reduced to two types — covalent catalysis and general base catalysis. In the former case, the nucleophile of the protein molecule, interacting directly with the substrate and forming intermediate covalent compounds with the latter, is the component initiating the enzymic reaction. In the proteolytic hydrolytic reactions of the second type, the enzyme does not form covalent compounds with the substrate throughout the entire catalytic step. Its nucleophilic atom group behaves in this case as a basic catalyst, which, by interacting with a water molecule, deprotonates it and thereby converts it into an effective nucleophile, which attacks directly the carbonyl carbon atom of the peptide bond to be cleaved.

The employment by Antonov, Ginodman, and co-workers[134–137] of the method based on the incorporation of the heavy oxygen atom of the $H_2{}^{18}O$ molecule into the products of enzymic reactions has apparently played a decisive role in the determination of the type of catalytic reaction of aspartate proteases. The first comparative studies on the hydrolysis catalysed by various amide hydrolases[134] showed that the serine and cystein proteases function in accordance with the covalent mechanism, while the aspartate and metal-containing proteases function in accordance with the mechanism of the general base catalysis. This conclusion agrees with the most unambiguously interpreted results of chemical, kinetic, and thermodynamic studies on the catalytic reactions of endoproteases. It was subsequently confirmed by the results of the X-ray diffraction analysis of enzymes and is at present generally accepted.

1. The structure of the HIV-1 aspartate protease

Interest in the mechanism of the action of aspartate proteases has grown particularly in recent times in connection with the detection of enzymes of this group in the retroviruses inducing in human and animal organisms diseases such as AIDS, certain types of leukemia, sarcomas, and malignant mammary gland tumours. It is very significant that the aspartate proteases of these viruses play a key role in their life cycles.[138–141] In the host cell, they hydrolyse the proteins of the nuclear capsules surrounding the viral RNA and split the polyprotein chains into mature structural proteins and enzymes participating in the replication of the retroviruses. The viral proteases are also able to hydrolyse the proteins of the infiltrated cells, disturbing thereby the integrity of their structural-functional organisation. On the other hand, the cellular proteolytic enzymes are unable to cleave the viral proteases and to perform their functions. Thus, in the absence of proteases or when the latter are inhibited, the immunodeficiency viruses in man (HIV-1, HIV-2) and in monkeys (SIV), as well as the tumour-generating viruses would be unable to assume infective forms. This is why the proteases of retroviruses have become the object of such constant attention by enzymologists and medical scientists. The aspartate proteases of retroviruses have become some of the most thoroughly

Table 2. Distances (Å) between the atoms of the Asp-32 and Asp-215 side chains (numbering for pepsin) in the crystal structures of aspartate proteases.

experimentally investigated enzymes after only 2–3 years since their discovery. Attention has been concentrated on the HIV-1 aspartate protease, about the structure and function of which more is perhaps known nowadays than about a classical object such as pepsin, which was discovered as early as 1836.

The aminoacid sequence of the HIV-1 protease consists of 99 aminoacid residues, whereas the aspartate proteases of vertebrates and microorganisms contain more than 300 aminoacids. The Asp–Thr–Gly fragment, present in each domain in all pepsin-like enzymes, is encountered in this sequence. According to Pearl and Taylor,[142] the physiologically active form of the HIV-1 protease includes two molecules associated via nonvalence interactions. This hypothesis has been confirmed experimentally.[143] A polypeptide chain of 203 aminoacid residues, constituting two molecules of the HIV-1 protease, the C- and N-ends of which are linked by the Gly–Gly–Ser–Ser–Gly pentapeptide section, has been synthesised by genetic engineering methods. This dimer, linked by valence bonds, assumed spontaneously the conformation of the native dimer under physiological conditions and exhibited an activity identical with that of the latter. This conclusion has been recently confirmed in a study[132] where the three-dimensional structure of a similarly linked dimer of the HIV-1 protease was determined with a resolution of 1.8 Å. When one of the two catalytically important Asp-25 residues is replaced by Gly, the activity is lost. Another investigation[144] of the valence-linked HIV-1 protease dimer with a Gly–Gly dipeptide bridge and with the replacement of Asp-25 by Asn and Glu led to the same results.

Tomasselli et al.[139] determined the dissociation constant of the native dimer of the HIV-1 protease, which proved to be 2 pM. According to the data of Cheng et al.,[143] its value is 50 pM. Despite the considerable discrepancy between the dissociation constants obtained, one can nevertheless postulate that the HIV-1 protease dimerises in the nanomolar region, i.e. at a concentration much lower than that in the viral particle. The study of Seelmeier et al.[145] showed that the catalytic activity of the HIV-1 protease is suppressed by pepstatin inhibitors, which is characteristic of all aspartate proteases. It was noted in the same study that the replacement of the Asp-25 residue in the aminoacid sequence of the viral protease by Thr leads to the complete loss of activity. The same effect has been observed following the replacement of the Asp-25 residue in the aminoacid sequence of the HIV-1 protease by Asn,[140,145] Ala,[146,147] Tyr, and His.[146] The activity also falls to zero in pepsin following a similar mutagenesis of one of its Asp catalytic residues.[148]

Thus one may claim that the dimeric form of the HIV-1 protease, in which both aspartic acid residues (Asp-25 and Asp-125) play a catalytically important role, is physiologically active. Only this form possesses all the distinctive features of aspartate proteases. Consequently, like pepsin, renin, rhizopus-pepsin, and other enzymes of the given group, the dimeric form of the HIV-1 protease should function in accordance with a general base catalysis mechanism. To some extent, the conclusion that there is a unique chemical mechanism of the catalytic reactions involving aspartate proteases has been confirmed by the results of the X-ray diffraction analysis of the retroviral proteolytic enzymes.

The three-dimensional structures of three retroviral aspartate proteases (HIV-1, RSV, and BMV) and of three complexes of the HIV-1 protease with substrate-like inhibitors (U-85548e, JG-365, and MVT-101) are known at the present time (Table 1). They are all dimers and are structurally related to one another and to the aspartate proteases from other sources. Furthermore, one can assume that all the known proteases have geometrically identical active centres (these are understood as the direct sites of the sorption of the peptide group to be cleaved). This is indicated by the similarity of the distances between the corresponding atoms of the two functional residues of aspartic acid in the enzyme molecules (Table 2). Thus one may conclude that the enzymic reactions involving aspartate proteases of the vertebrates, microorganisms, and retroviruses have the same initial conditions and hence should proceed by the same mechanism, namely the general base catalysis mechanism.

The crystal structures of the native HIV-1 protease and of its inhibitor complexes are compared in Fig. 10, and Fig. 11 presents a map of the distances between the C^{α} atoms (up to 10 Å) in two associated protease molecules. The numerous and varied, as regards their nature, nonvalence contacts (dispersion and electrostatic contacts and contacts via hydrogen bonds) between two pairs of N-terminal (1–8, 101–108) and C-terminal (87–99, 187–199) fragments make the greatest contribution to the stabilisation of the dimer. The arrangement achieved during

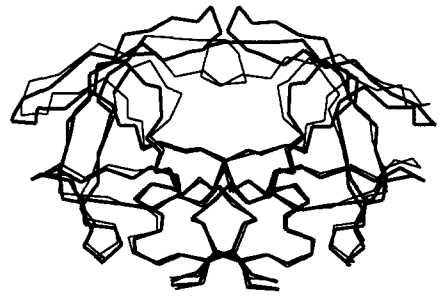

Figure 10. The principal chains of the native HIV-1 protease (thick line) and of its complex with the JG-365 inhibitor (thin line).

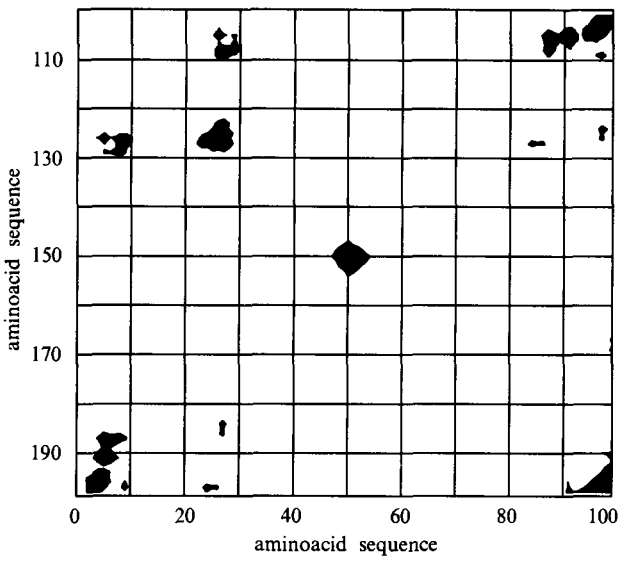

Figure 11. Map of the distances between the C^{α} atoms of the HLA-1 molecules of the protease in the homodimer (the shaded regions correspond to distances < 10 Å).

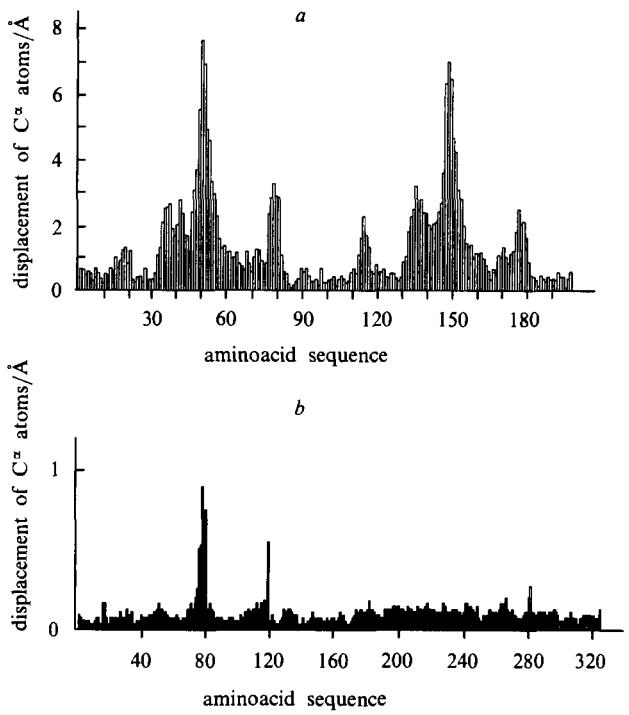

Figure 12. The displacements of the C^{α} atoms in the molecules of the dimeric HIV-1 protease on formation of a nonvalence complex with the JG-365 inhibitors (*a*) and in the rhizopuspepsin molecule on formation of a nonvalence complex with an inhibitor (*b*).

the dimerisation process in this close-packed and apparently most stable part of the HIV-1 protease exerts an appreciable and direct influence on the formation of the active centre in close proximity. The interactions of more than 40 aminoacid residues of the four terminal fragments are extremely selective. This is indicated, for example, by the absence of catalytic activity from the dimeric complex made up of mixed chains of the HIV-1 and HIV-2 viruses, which are closely homologous.[149] Three changes, in the 6, 92, and 95 positions, were found to be sufficient for activity to be lost, the sequences of the enzymes in the two viruses being identical in all other sections which are in contact within the dimer.

The 23–28 and 123–128 fragments also come close to one another in the dimeric complex of the HIV-1 protease. They include the effectively interacting tripeptide fragments Asp-25–Thr-26–Gly-27 and Asp-125–Thr-126–Gly-127—the permanent components of the active centres of all the aspartate proteases. This contact region of the two molecules is stabilised additionally by nonvalence interactions with the 7–9 and 107–109 residues of the N-terminal fragments and the 84–85 and 184–185 residues of the C-terminal fragments.

Finally, there is yet another region of intermolecular interactions in the dimeric HIV-1 protease. It is made up of two β-pleated sheets (45–57 and 145–157) overhanging, like open wings, the active centre (the term 'flaps' has been applied to them). In the native state of the enzymes, they do not participate in the stabilisation of the dimeric form and their position is maintained by the interactions of the 48–52 and 148–152 pentapeptide sections, which are in close proximity (Figs 10 and 11), and also apparently by the contacts with the neighbouring dimer in the crystal lattice.

The flaps play an important role in the stage involving the formation of the nonvalence complex. The enzyme–substrate (inhibitor) interactions entail an enormous, without precedent in the catalytic reactions of other enzymes (at any rate proteolytic enzymes), conformational rearrangement of a considerable proportion of the native structure. It involves not only the side chains of the residues in the active centre, which usually occurs, but also the main chains of both molecules of the HIV-1 protease. The sections 45–57 and 145–157 undergo the greatest changes on complex formation. Judging from the shifts of the C^{α} atoms, they reach ~8.0 Å in the central 50 and 51 and 150 and 151 residues, gradually diminishing to 1.0 Å in the terminal 45 and 57 and 145 and 157 β-structure residues (Fig. 12*a*). The ends of the flaps projecting towards one another, as in cantilevers, are displaced towards the substrate (inhibitor) molecule sorbed in the active centre. The 77–81 and 177–181 fragments undergo synchronously appreciable displacements (2.0–3.0 Å), which also diminish the size of the cavity in the active centre. The displacements of the C^{α} atoms in the two HIV-1 protease molecules in the dimeric complex are similar but not identical.

The changes in the positions of the flaps on formation of complexes were observed also in other aspartate proteases. However, as can be seen from Fig. 12*b*, which illustrates the displacements of the C^{α} atoms in the enzyme–inhibitor complex of rhizopuspepsin, here the differences are much less appreciable. As regards other sections of the main chain of the protein, the latter hardly respond to the association with the inhibitor.

The knowledge of the HIV-1 protease dimerisation process is of considerable interest, primarily in the search for antiviral medicinal preparations. The question whether the association of the molecules occurs without change in their three-dimensional structure or whether the process is accompanied by the conformational adaptation of the partners merits special attention in this instance. If the changes occur, then it becomes possible to prevent the formation of the active complex by a specific action on the enzyme molecules, which would preclude the conformational rearrangements necessary for their combination. It may be that this aspect of the development of an antiviral therapy will prove to be the most promising by virtue of the exceptional nature of the mechanism of the formation of the active forms of the retroviral proteases compared with the aspartate proteases from other sources.

However, it is not possible to observe directly the three-dimensional structure of an individual HIV-1 protease molecule in order to compare it with the structure of a subunit in the dimeric complex, because the enzyme crystallises only in the form of the dimer. Only a theoretical procedure remains for the solution of the problem: a priori calculation of the conformation of a free HIV-1 protease molecule from the known aminoacid sequence.

Fig. 13 presents projections of the three-dimensional structure of one of the subunits in the native dimeric associated species, from which it is seen that the first nine N-terminal and subsequent six C-terminal residues of the sequence do not interact either with one another or with the remainder of the molecule because of their remoteness. The uncoiled conformational states of these fragments are more favourable for the intermolecular interactions which they undergo in the structure of the catalytically active HIV-1 protease dimer (Figs 10 and 11). It was noted above that the intermolecular contacts of the four terminal groups of the two sequences actually make the main contribution to the stabilisation of the dimer. On the other hand, the uncoiled forms of the 1–9 and 94–99 sections are energetically unfavourable for the free enzyme molecules and their occurrence in a dilute solution is unlikely. Consequently, the dimerisation process should involve a conformational transition from the coiled forms, favourable for the free molecules, to the uncoiled forms preferred by the associated molecules. It is seen from Fig. 13 that the conformational state of the 45–57 flap should change simultaneously. In the complex, this state is determined by the interaction of a second molecule with the flap and possibly by the interactions with the dimer of an adjoining unit cell.

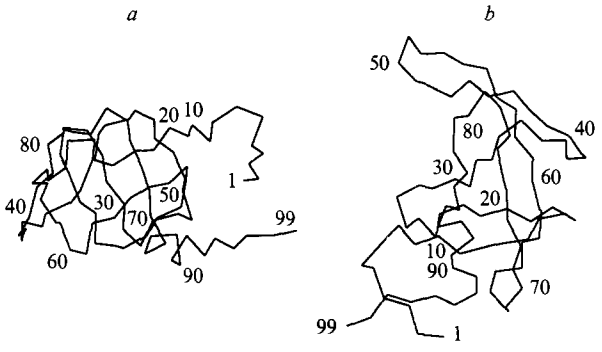

Figure 13. Projections (*a*, *b*) of the HIV-1 protease molecule in the dimer.

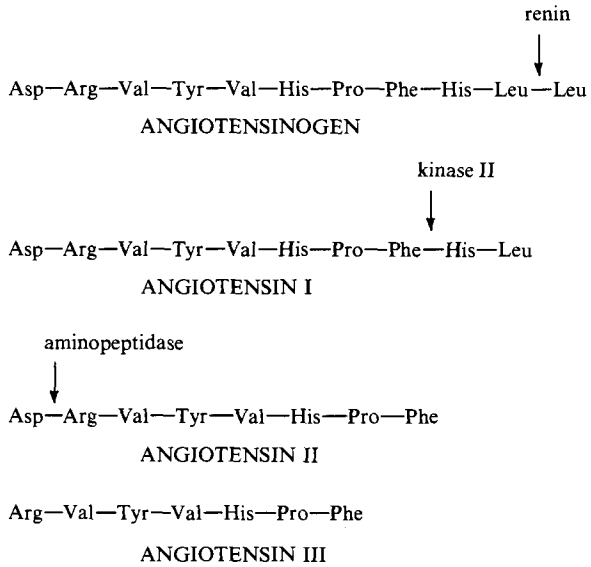

From the foregoing, one may conclude that there is the possibility of a search for therapeutic agents for protection against retroviruses, in particular the human immunodeficiency virus — of devising preparations which would prevent the dimerisation of the molecules of aspartate proteases. Without this, the functioning of the enzyme and hence the operation of the life cycle of the virus are impossible.

Another approach to the preparation of the necessary medicines involves the creation of special inhibitors of the retroviral aspartate proteases. This is an extremely complex task and at the present time has not yet been achieved. Among the requirements which must be met by the properties of the inhibitors, the main and most difficult one concerns the selectivity of their action. Inhibitors exhibiting a therapeutic effect should be primarily highly specific to such an extent that, while deactivating the retroviral protease, they do not disturb the normal functioning of both aspartate and other proteolytic enzymes of the host cell. The specific search for inhibitors satisfying this requirement requires the availability of quantitative data on all the stages of the catalytic step performed by the viral protease, similar to the data concerning the mechanisms of the functioning of the proteases of the infiltrated cell and the methods for the solution of the reverse structural problem, i.e. the development of the chemical structure of the inhibitor on the basis of the specified three-dimensional form. In connection with the problem of the specificity of the enzyme–substrate interactions, X-ray diffraction data on renin — the aspartate protease of blood plasma — are especially important.

In contrast to not only the other aspartase proteases but in general amidohydrolases, this enzyme exhibits a virtually absolute specificity. Renin is known to hydrolyse only its own natural substrate angiotensinogen, abstracting from its N-terminal part of a decapeptide, as well as a small number of synthetic analogues which are highly homologous with respect to the N-terminal aminoacid sequence of angiotensin.[134,150] Almost any aminoacid replacement in the pentapeptide fragment of the substrate before the bond to be cleaved ($P_5 - P_1$) and in the tetrapeptide section beyond it ($P_1' - P_4'$) leads to a nonproductive Michaelis complex and the absence of hydrolysis. The reason for such phenomenal specificity of renin still remains unelucidated.

2. The structure of renin and of its inhibitor complexes

Renin, a glycosylated protein, forms part of the enzyme system which effects the biogenesis and decomposition of the octapeptide tissue hormone angiotensin II, the most powerful of the known pressor agents in the blood circulation system. Angiotensin II stimulates the narrowing of the peripheral arterioles throughout the organism and hence increases the arteriole pressure. Apart from this, it activates the secretion of a series of hormones (mainly aldosterone) and influences the work of the heart, the liver, the central and peripheral components of the nervous system, etc. Its direct precursor, angiotensin I, is formed from the globular blood protein angiotensinogen, already mentioned, as a result of the abstraction from it of the N-terminal decapeptide by renin. According to the scheme presented below, the hydrolysis of the peptide bond between the Leu-10 and Leu-11 residues is the first and rate-determining stage in the cascade of enzymic reactions leading to the conversion of angiotensinogen into angiotensin II with its subsequent decomposition.

The three-dimensional structure of renin has been investigated in a number of studies.[105–109] The three-dimensional structure of the partially deglycosylated native human recombinant renin has been identified with a resolution of 2.5 Å. Some of the peptide sections on the periphery of the globule were disregarded on the electron density maps and for this reason they were assigned to the group of conformationally labile loops lacking defined structures. The X-ray diffraction analysis of the glycosylated native human renin and of its inhibitor complexes was subsequently carried out[106] with resolutions of 2.8 and 2.4 Å respectively. The structure of the enzyme–inhibitor complex of this protein was also determined in another study[109] with a resolution of 2.6 Å. The stabilising interactions of specific pockets of the active centre of the enzyme with the side chains of the $P_4 - P_4'$ residues on the octapeptide sections of the inhibitors were described in the above communications.

Table 3. Dihedral angles of rotation φ, ψ, and ω (deg) of the main chain of the CH-66 inhibitor in the active centre of renin and of the U-85548t, JG-365, and MVT-101 inhibitors in the active centre of the HIV-1 protease.[108,129-131]

[a] The angles correspond to the nonstandard P_1-P_1' sections of the inhibitor chain.

The crystal structure of the submaxillary mouse renin, inhibited by the substrate-like CH-66 decapeptide, has been studied in greatest detail and with the best resolution (2.0 Å).[151]

Piv-His-Pro-Phe-His-[Leu(ψ)-CH(OH)CH_2]-Leu-Tyr-Tyr-Ser-NH_2

($P_6-P_5-P_4-P_3-P_2-P_1$——————$P_1'-P_2'-P_3'-P_4'$),

Here Piv is a pivaloyl blocking group and CH(OH)CH_2 is a hydroxyethylene group with the (*S*)-configuration of the second asymmetric carbon atom of Leu(ψ). The positions of 10038 and 325 aminoacid residues of the glycosylated enzyme, 364 atoms of the inhibitor, and 613 oxygen atoms of the water of crystallisation were determined. The mean square error in the coordination of the atoms was 0.21 Å and the standard deviations from the standard bond lengths and angular distances were 0.026 Å and 0.54 Å respectively.

The three-dimensional structures of the renins investigated have the same characteristic features as other aspartate proteases. They are also structural proteins consisting of two domains. Between them, there is a substrate-binding groove, in the centre of which the catalytically important Asp-32 and Asp-215 residues are accommodated and, as in other enzymes of this group, these residues are followed by Thr and Gly. The three-dimensional structures of the renin molecules from different sources are very similar. For example, the difference in the orientations of the domains in the structures of mouse and human renins does not exceed 1.7°. The positions of the domains in pepsin and endothiapepsin differ from that in mouse renin by 6.9° and 18.8° respectively.

The decapeptide ligand in the enzyme–inhibitor complex has the β-pleated sheet conformation extended along the substrate-binding groove (Table 3).[128-131,151] Its carboxyethylene group between two Leu residues occupies in the active centre of the enzyme a sensitive site of the substrate and forms hydrogen bonds with the carboxy-groups of the Asp-32 and Asp-215 catalytic sections. The conformational states of the main and side chains of all the inhibitor residues in the complex with renin correspond to the lowest-energy forms of the free aminoacids and, being uncoiled structures, provide at the same time the best conditions for effective interactions with the residues of the active centre of the enzyme. Table 3 lists the dihedral angles φ, ψ, and ω, which determine the geometry of the main chain of the renin inhibitor (CH-66)[151] and three inhibitors of the HIV-1 aspartate protease (U-85548e, JG-365, MVT-101).[129-131] It follows from the comparison of the data in Table 3 that, on association with the active centres of the mammalian and retroviral aspartase proteases, the completely different inhibitors assume similar conformational states. At any rate, the differences between the dihedral angles of the inhibitors of renin and the HIV-1 protease are not greater than the differences between the angles of the inhibitors of a single enzyme. This finding as well as the data in Table 2 indicate that the structural states of the substrate-binding centres of the aspartate proteases are similar regardless of their source.

X-Ray diffraction analysis of the inhibitor complex between mouse renin and the decapeptide[151] made it possible to identify the aminoacid residues of the enzyme which form specific pockets and to make certain quantitative assessments of their interactions with the side chains of the inhibitor residues. Bearing in mind the similarity of the latter to the N-terminal aminoacid sequence of angiotensinogen, the data presented in this instance are of undoubted interest for the subsequent theoretical study of the nonvalence interactions of renin with a true substrate and for the solution of the problem of the nature of its exceptional specificity.

Table 4 presents the 34 renin residues which form ten substrate-binding pockets (S_6-S_4'), the interatomic contact distances between which and the inhibitor in the complex do not exceed 4.2 Å. The residues presented in Table 4 are located on the surface of the globule of the water-soluble protein and yet they are all hydrophobic (with the natural exception of the catalytically important Asp-32 and Asp-215), like the substrate

Table 4. The aminoacid residues of renin, the atoms of which form close contacts with the P_6-P_4' residues of the CH-66 inhibitor (< 4.2 Å).[151]

residues interacting with them, so that the complexes are stabilised mainly via dispersion forces.

The highly complementary nature of the potential energy surfaces of the active centre of renin and of the decapeptide inhibitor (substrate) and hence their predisposition to undergo effective nonvalence interactions can be inferred from the numerous interatomic contacts between the enzyme and the ligand. This is confirmed quantitatively by the data presented in Table 5. They demonstrate a sharp contraction, on sorption of the inhibitor, of the surface (accessible to the solvent) of the aminoacid residues forming the $S_6 - S_4'$ loci. Approximately half of the residues, including Asp-32, and Asp-215, and certain residues of the flap, behave as ligands fully shielded from contact with the external medium. The overall area of the active centre accessible to the solvent, which is ~460 Å², diminishes to ~220 Å² in the complex.

The accessible surface areas of the side chains of the $P_5 - P_4'$ residues of the CH-66 inhibitor in two complexes — with renin and with endothiapepsin — are compared in Table 6. According to a calculation,[151] this area is ~64 Å² in the former case and ~130 Å² in the latter. The data in this table indicate an appreciably greater packing density of the same inhibitor in the active centre of renin compared with that of endothiapepsin. Exceptionally pronounced complementary conditions in the renin complex occur in the middle part of the decapeptide ligand, i.e. in the region of the peptide bond being cleaved.

Table 6. Comparison of the accessible surface areas of the side chains of the $P_5 - P_4'$ residues of the CH-66 inhibitor in complexes with renin and endothiapepsin.

Designation of residue	Residue	Surface area of complex accessible to solvent/Å²	
		renin	endothiapepsin
P_5	His	20.6	35.7

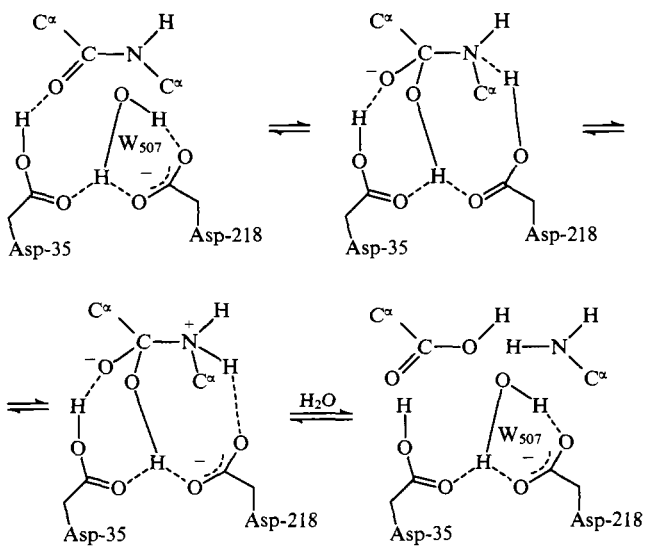
We shall attempt to answer the question of the advances contributed by X-ray diffraction analysis in the study of aspartate proteases and to what extent the knowledge of the three-dimensional structures of these enzymes and of their inhibitor complexes can deepen our understanding of the mechanisms of the catalytic reaction of aspartate proteases. The answer to this question is of general importance for enzymology, because, as already mentioned, proteases are objects in biocatalysis which have been most thoroughly investigated in all respects. We shall consider the hypothetical models of the mechanisms of the action of aspartate proteases, which have been developed on the basis of data on the three-dimensional structures of the enzymes and their complexes with substrate-like inhibitors.

3. The mechanism of the catalytic reaction of aspartate proteases

The first stereochemical model was proposed in 1985 by James and Sielecki,[112] who used for this purpose the crystal structure of penicillopepsin, solved with a resolution of 1.8 Å.[111,112] A series of considerations, based on the knowledge of the three-dimensional structures of the enzymes, had been put forward earlier concerning the mechanism of the action of aspartate proteases.[111,123,152-158] However, they were all to some extent incomplete and did not claim to provide a consistent description of the entire process involving the hydrolysis of the peptide bond catalysed by aspartate proteases. The W_{284} molecule of the water of crystallisation plays an important role in the stereochemical model of the productive covalent Michaelis complex devised by James and Sielecki. In the active centre of penicillopepsin, it occupies a site which is extremely convenient also for the formation of an effective hydrogen bond with the side chain of Asp-33, which increases its nucleophilicity, and for attack on the carbonyl carbon atom of the bond being hydrolysed, which weakens the latter. The protonated carboxy-group of the Asp-213 residue, polarising the carboxy-group of the substrate via a hydrogen bond and hence acting as an electrophilic component of the system, acts in the same direction (Scheme 1).

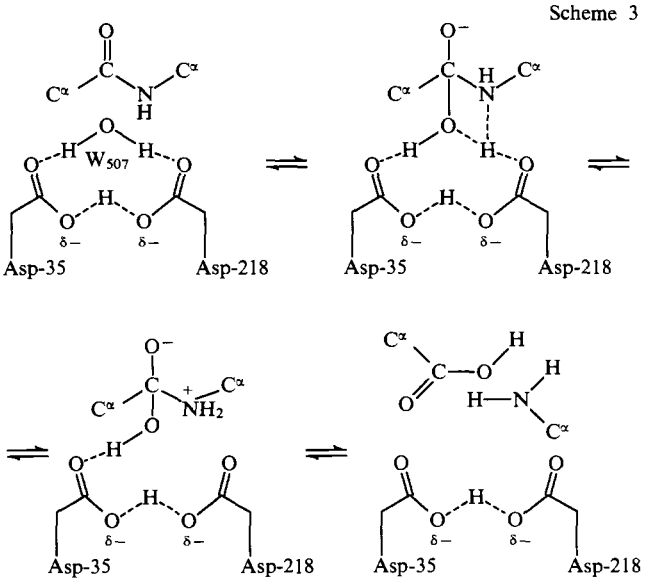
The three interactions noted above initiate the disruption of the delocalised $\pi - n$ electron system of the peptide bond being cleaved, the pyramidalisation of the nitrogen and carbonyl carbon atoms, and the appearance at the latter of *gem*-hydroxy-groups, which are involved in hydrogen bonding with the protonated carboxy-group of Asp-33. The return of the lone electron pair to the nitrogen atom enhances its tendency to be protonated and, according to James and Sielecki,[112] can be



Scheme 1

achieved in two equally probable ways. In one of them, the inversion of the configuration of the bonds involving the nitrogen atom, occurring via the rotation of the amino-group of the substrate by ~60° around the C–N bond, is postulated. As a result, the lone pair is oriented towards the solvent and the nitrogen is readily protonated, particularly in aspartate proteases with a highly acid pH. The alternative procedure involves the transfer of a proton to the nitrogen atom from one of the hydroxy-groups of the tetrahedral adduct, which is in the *syn*-configuration relative to the lone pair of the nitrogen atom. The compound formed is unstable and decomposes into two parts, one of which includes the amino-group and the other the carboxy-group.

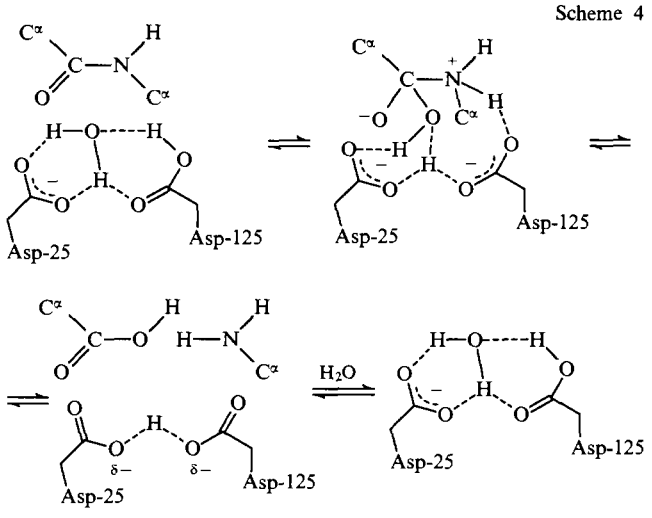
The initial hypothesis of James and Sielecki[112] that the nucleophile in the catalytic reaction of aspartate proteases is the W_{284} group has been rejected by Suguna et al.,[124] who hold a different view on the mechanism of the action of the enzymes. The stereochemical model which they constructed is based on crystallographic data for the three-dimensional structures of native rhizopuspepsin[122] and its complex with an octapeptide inhibitor having a reduced peptide bond, which is cleaved on interaction with substrates. Suguna et al.[124] chose as the nucleophile the W_{507} water molecule (W_{39} in terms of the numbering for penicillopepsin), which is located between the two carboxy-groups of the Asp-35 and Asp-218 residues and forms three hydrogen bonds with the latter (Scheme 2). It is suggested



Scheme 2

that the W_{507} molecule is not displaced by the substrate because, following its sorption, the peptide bond to be hydrolysed is subjected to steric hindrance and assumes a nonplanar energetically unfavourable configuration. In this position of the substrate, the carbonyl carbon atom of the bond being cleaved is located opposite the attacking oxygen atom of the W_{507} molecule and the oxygen of the carbonyl group is placed at a distance from the hydroxyl of the Asp-35 side chain which is optimal for the formation of a hydrogen bond. As a result of the formation of the tetrahedral adduct, the OH group of the water molecule passes to the substrate, while the hydrogen atoms initially pass to the carboxy-group of the Asp-218 residue and then to the nitrogen atom. The reorganisation of the intermediate leads to the rupture of the peptide bond of the substrate, the desorption of the reaction products, and the regeneration of the active centre.

In the mechanism of the catalytic reaction of aspartate proteases proposed by Pearl,[159] the nucleophile is the W_{507} water molecule, as in Scheme 2 examined above (Scheme 3). The new feature in this model consists in the hypothesis of the equality of the acidity constants and hence of the electronic equivalence of the carboxy-groups of the Asp-35 and Asp-218 residues having a delocalised proton and, furthermore, in the introduction as an electrophilic component, giving rise to an additional polarisation of the carbonyl oxygen atom of the bond being cleaved, of the two NH groups of the Gly-78 and Asp-79 residues (according to the numbering for rhizopuspepsin), which enter into the aminoacid sequence of the flap overhanging the substrate. According to the previous models of the mechanism of the functioning of aspartate proteases, the effects of the nucleophile and the electrophile lead to the formation of an unstable intermediate compound, which decomposes from the N- and C-ends. In both this case and in those discussed above, the author follows the concept of stress and enforced deformation, i.e. he postulates the possibility of the transformation of the energy of enzyme–substrate nonvalence interactions into an energy of distortion of the peptide bond, which brings it closer to the transition state and hence facilitates the hydrolysis.



Scheme 3

The model of the mechanism of action of aspartate proteases proposed by Jaskolski et al.[129] is based on the three-dimensional structure of the HIV-1 retroviral protease. The W_{507} molecule (the numbering is that for penicillopepsin), located in an equidistant position between the side chains of the Asp-25 and Asp-125 residues (Scheme 4), was chosen as a nucleophile in this case also. Bearing in mind the symmetry of the enzyme, the authors placed one of the hydroxy-groups of H_2O along the twofold axis in such a way that it is able to form a

forked hydrogen bond with the inner carboxyl oxygen atoms of the aspartic acid residues. The second hydroxy-group of H_2O is directed towards the outer oxygen atom of the Asp-25 carboxylate. The acid proton of the unionised Asp-125 side chain forms a hydrogen bond with the oxygen atom of the W_{507} molecule of the water of crystallisation. Thus, according to the dynamic model,[129] the native HIV-1 protease in the equilibrium state contains a symmetrical system of five oxygen atoms, in the field of which the hydrogen atoms migrate in an appropriate manner. The symmetry of the active centre breaks down on interaction of the enzyme with the substrate. As a result of nucleophilic attack, there is a simultaneous disruption of the carbonyl group of the bond being cleaved, the hybridisation of the carbon and nitrogen atoms changes ($sp^2 \rightarrow sp^3$), a C–OH valence bond is formed, and the nitrogen is protonated. In other words, the enzyme–substrate complex passes in one stage through an unstable intermediate state, which is completed by the formation of the reaction products and the return of the enzyme to its initial state.

Scheme 4

Despite the significant differences between the models proposed, they are unified as regards their initial postulates.

Firstly, it is suggested that the aspartate proteases function through general catalysis and therefore do not form covalent intermediate complexes with the substrate during the reaction.

Secondly, it is claimed that the manifestation of the catalytic activity of proteases required the presence in the system of a nucleophile — basic and acid catalysts (the differences concern their selection).

Thirdly, it is postulated in all the hypotheses that the enzymic reaction involving the hydrolysis of the peptide bond proceeds via a stage of an unstable intermediate (a tetrahedral adduct).

Fourthly, a common feature of all the proposed stereochemical models is the treatment of the stimuli to the functioning of aspartate proteases based on the concept of deformation and stress.[160]

These postulates were formulated and confirmed experimentally in the study of enzymic and model nonenzymic reactions even before the X-ray diffraction analysis had been carried out on even one aspartate protease. The determination of the three-dimensional structures of the enzymes and their complexes with substrate-like inhibitors provided additional confirmation of some of the earlier conclusions and made it possible to visualise the ideas already established.

Thus the mechanism developed for enzyme catalysis are interesting in the sense that they arose, in essence, from the same experimental data, including X-ray diffraction data obtained in recent years, and are based on the same theoretical ideas concerning the nature of biocatalysis which arose before the establishment of protein crystallography and have long become traditional. The imperfection of the generalisations made is indicated by the fact that, whilst the initial experimental data and theoretical foundations were the same and also a single approach was followed, not one but four different models of the functioning of aspartate proteases have been proposed and their number may, incidentally, be even greater. They do not form a series indicating a quantitative development of knowledge about the mechanism of the action of enzymes, but are more likely to represent different points of view. The hypotheses examined correspond to a single level of understanding of the phenomenon investigated and are equivalent as regards the arguments adduced and their predictive power. The question arises what new advances have been contributed by the X-ray crystallography of proteins to the study of the catalytic reactions of aspartate proteases and other enzymes.

In the first place, one should note that X-ray diffraction data have made it possible to determine not only the region of the active centre of the enzyme but also its geometry at the level of atomic coordinates. It would at present be impossible to achieve this quite so fully and reliably by any other procedure. Furthermore, the use of this method to solve the three-dimensional structures of the native enzyme and its complexes with various inhibitors made it possible to discover the conformational rearrangements of the active centres which may occur at different stages of the catalytic step. These data are also unique and informative.

X-Ray diffraction played a major role in the study of the specificity of enzyme–substrate interactions and of the locations of the regions of the active centres which bind to the sensitive sites of the substrate and the residues adjoining it on either side. As regards the mutual orientations of the bond being cleaved and of the catalytically active residues of the enzyme corresponding to the productive binding of the true substrate, the problem remains unsolved. As can be seen in relation to the four different stereochemical models of the functioning of aspartate proteases which have been proposed, the views expressed can be divided into more or less probable, but, despite the knowledge of the conformations of the enzyme in the native state and in the complex with the inhibitor, both are hypothetical in character.

The data concerning aspartate proteases examined here as well as the similar data on chymotrypsin, trypsin, carboxypeptidase, and lysozyme described previously[161] provide grounds for the conclusion that the appearance of unique quantitative information about the three-dimensional structures of enzymes and their complexes did not entail a conceptual development of enzymology and revision of the existing ideas about the nature of biocatalysis.

With the advent of X-ray diffraction analysis of enzymes, there was no transition from speculative ideas about enzyme catalysis to a rigorous quantitative description of this phenomenon. Nor has there been any change in the direction of biocatalytic investigations, which, as before, follow from function to structure, which is not fortuitous because X-ray diffraction studies can only lead to the knowledge of the morphology of biosystems at the atomic-molecular level, which by itself is not the final aim of the study of enzymes. The morphology of the object is always a preliminary feature which is completely necessary for the subsequent investigation of the structural and structural-functional organisation of biosystems. For this reason, the three-dimensional structures of many hundreds of enzyme molecules discovered with the aid of X-ray diffraction did not solve the problem of biocatalysis, but led to a real development of an approach to the study of enzyme catalysis in the direction from structure to function and to an a priori quantitative description of the mechanism of the catalytic reaction. By virtue of the development of the crystallography of proteins, the problem of creating a general theory of biocatalysis and the corresponding computational methods acquired for the first time the form of a truly scientific problem soluble at the present level of scientific knowledge.

V. DNA-binding proteins

This section describes certain crystallographic studies on proteins carried out in recent years. The studies examined below demonstrate the latest advances in crystallography which have made it possible to solve at the atomic level the three-dimensional structures of proteins and complexes consisting of thousands and more of aminoacid residues. The technical development of the method was manifested in the transition noted at the beginning of the 1990s, from X-ray diffraction studies on individual protein molecules to the no less detailed investigation of the three-dimensional structures of macromolecular protein oligomers and their aggregates with other compounds and subcellular systems. In other words, structures of more complex biological systems began to be understood at the atomic level.

Objects which were of interest as regards their structural-functional organisation and at the same time illustrated clearly the current advances in protein crystallography were chosen for consideration. These undoubtedly include the DNA-binding proteins, which participate directly both in the establishment of the genetic apparatus and in all the stages of its functioning. In eukaryotic cells, such proteins are traditionally subdivided into two groups: the histone proteins participating in the establishment of a definite structure of DNA within the cell nucleus and the nonhistone proteins ensuring the biosynthesis of RNA. The results of X-ray diffraction analysis of histones and β-galactosidase, which are representatives of both groups of the DNA-binding proteins, are considered below.

1. The structure of the histone core of the nuclesome

Histones constitute five varieties (H1, H2A, H2B, H3, and H4) of small structural proteins, the aminoacid sequences of which contain respectively 220, 128, 124, 134, and 102 residues. They ensure the close packing of the DNA double helix, which is very long in the extended state. For example, in each human chromosome it is on average 5 cm long. Histones are necessary primarily for the ordered disposition of the long double-stranded polynucleic acid within the small volume of the cell nucleus. However, this is not their only purpose: the nature of the packing of DNA influences the activity of the corresponding sections of the genome. Consequently its histone structural organisation is one of the ways of regulating and controlling the transcription of RNA from DNA. The aminoacid sequences of histones contain about 40 positively charged Lys and Arg residues, which enables them to bind effectively to the DNA double helix regardless of its nucleotide composition.

Histones, especially H2A, H2B, H3, and H4, are some of the most conservative of the known proteins. The rates of change in the aminoacid sequences for a series of proteins and the histone H4 throughout the period of evolution are compared in Table 7. The figures presented suggest that approximately four out of each five random aminoacid replacements are harmful in haemoglobin and 17 out of each 18 replacements are harmful in cytochrome *c*, while in histone H4 there are virtually no harmless replacements.

Table 7. Changes in the aminoacid sequences of proteins throughout evolutionary time.[162]

Protein	Unit of evolutionary time/million years[a]
Fibrinopeptide	1.2
Haemoglobin	6.1
Cytochrome-*c*	21.0
Histone H4	600.0

[a] The unit of evolutionary time is the average time necessary for the appearance of one acceptable replacement in the given protein for each 100 aminoacid residues.

Since all the DNA base pairs are equally subject to random mutations, the evolutionary stability of histones suggests that they play an extremely responsible role in the organisation and functioning of the genetic apparatus.

Histones constitute about half of the mass of the chromosome, where they participate in the organisation of several levels of packing of the DNA double helix. Together with other proteins, histones form complexes with DNA, which are called chromatin. In 1974, Kornberg isolated the repeating structure of the chromatin unit for the first time[163] and later established[164] that it consists of an octameric protein core comprising two molecules of each of the histones H2A, H2B, H3, and H4 and a fragment of the DNA double helix. It was postulated[165] that the double-stranded DNA is twisted around the histone core and forms two turns of a superhelix made up of 165 base pairs. This figure was later corrected to 146.[166] The observed chromatin structural unit was called a nucleosome.[167] Studies on the histone core with the aid of different physicochemical methods showed that the octamer consists of a heterogeneous protein ensemble $(H2A-H2B-H3-H4)_2$ comprising three structural subunits: a tetramer $(H3-H4)_2$ and two dimers (H2A–H2B). The DNA double helix in chromatin extends as a continuous filament from one nucleosome to another. The linear DNA linker sections located between the nucleosomes have different lengths, which are usually small, amounting on average to 60 nucleotides. The nucleosomal filament is responsible for the higher levels of compaction of chromatin. Ultimately it appears under the electron microscope in the form of the so called 30-nanometer chromatin fibril.

The histone H1 is responsible for the packing of the nucleosomal filament within the chromatin fibril. The central part of its molecule consists of a globule, which interacts with a specific section of the nucleosome. The N- and C-terminal fragments of the protein have extended forms. The N-terminal fragment is associated with the preceding linker DNA in the region of its contact with the nucleosomal particle, while the C-terminal fragment is in contact with the histone core of the next nucleosome. Furthermore, it has been noted[168] that a free H1 molecule interacts more readily with DNA in the vicinity of another histone molecule, which has already been added, than in the region separate from it. This is the reason for the tendency of the H1 proteins to bind to DNA in groups of eight and more molecules. It has been suggested that the interaction of this type, called cooperative binding, constitutes the basis of the activation of genes. The condensation of the H1 molecules induced by such interaction converts certain chromatin sections into a kind of microcrystals, the 'fusion' of which under the influence of an external regulator signal leads to the disruption of the histone cluster and a local rearrangement of chromatin.[162,169]

The elucidation of the internal structural organisation of the histone core and of its interactions with the DNA double helix, began, as already mentioned, in 1974.[163] Soon the structure of the octamer was investigated in solution by a small angle neutron and X-ray scattering methods with a resolution of ~20 Å[170-172] and in the crystalline state by X-ray diffraction[166,173,174] (with resolutions of 22 Å,[175] 7.0 Å,[176,177] and 3.5 Å). According to crystallographic data,[177] the pure histone core of the chick erythrocyte is an octamer having the form of an ellipsoid with axes 110 and 65–70 Å long. The model proposed by the authors of the above study consisted of three parts: the central tetramer $(H3-H4)_2$ and two dimers (H2A–H2B) disposed on its opposite sides. However, both the form and the size of the octamer differed significantly from the parameters obtained in a series of other investigations.[166,173-175] Repeated diffraction analysis[178,179] established the external dimensions of the histone core, which agreed with the data obtained from other studies (height ~ 55 Å, diameter ~ 70 Å).

According to some workers, the three-dimensional structure of the histone core resembles a flat disc, others see it as a pin or a spool, while according to a third group it is a wedge. Therefore,

only one thing is clear: the structure of the octamer is fairly complex and has no direct analogies. A more detailed discussion of the geometry of the complex $(H2A-H2B-H3-H4)_2$ may be based only on the results of the later studies,[178,179] since they were obtained with a resolution of 3.1 Å, which already permits the identification of the conformational state of the aminoacid residues and even of individual side chains.

In an earlier X-ray diffraction analysis of a whole nucleosome,[166,170,173] it was shown that the right-handed DNA double helix is twisted around the histone core in the form of a left-handed superhelix ~55 Å long and with an internal diameter of ~70 Å. This was confirmed in a study of the structure of an isolated octamer,[178,179] on the surface of which the groove of a protein superhelix was observed. It had an external diameter of ~65 Å, a pitch of ~28 Å, and a left-handed twist, which is fully consistent with the parameters of the DNA superhelix in the nucleosome. Thus, the surfaces of the histone core and of the DNA double helix twisted round it bear the same relation to one another as the surfaces of a screw and a nut. Nevertheless, the formation of a nucleosome can hardly be regarded as the screwing of the protein octamer into a strictly defined nucleotide structure. This is prevented firstly, by the presence on the helical groove of the nucleosome core of alternating hillocks and hollows, and secondly, by the fact that the superhelix of the DNA molecule in a free state is not a stable form, although it is apparently a low-energy conformation. It is more likely that the nucleosome is formed by the screwing of the labile DNA double helix onto the histone core, in a manner resembling the winding of a thread on a spool. The mechanism of the opposite process involving the liberation of the double-stranded DNA from the protein complex is the same. This model is supported by the finding that the hillocks and hollows on the inner central part of the nucleosome are complementary in relation to the profile of the contact surface of the DNA superhelix formed by the B-form of its double helix.

In connection with the determination of the three-dimensional structure of the histone octamer $(H2A-H2B-H3-H4)_2$ and of its steric interrelations with DNA, a whole series of fundamental problems have arisen. For example, the question arises: what is the mechanism and the causes of the spontaneous appearance of the protein complex and the self-assembly of the nucleosome as a whole. No less interesting is the question how the nucleotide chain is liberated from the histone core. The point is that the accessibility of the DNA forming part of the composition of nucleosomes is significantly restricted on those sections where the double helix is in contact with the surface of the octamer. The attachment of specific regulator proteins to the functionally active nucleotide sequence becomes possible only when the corresponding DNA binding sections are liberated from the nucleosomes. The elucidation of the cause of the decomposition of the nucleoprotein complexes is therefore just as important as the study of the cause of their appearance. One may assume that, after the mechanisms of the creation and decomposition of nucleosomes has been subjected to a quantitative treatment, one of the most intriguing questions concerning histone proteins will also be solved, namely why the histones H2A, H2B, H3, and H4 are some of the most conservative proteins in nature as regards their aminoacid sequences (Table 7). One cannot rule out the possibility that the nucleosome is a unique cell subunit in terms of its structural organisation. On the grounds of general considerations, one may postulate that it should combine an ideal consistency between the intramolecular and intermolecular interactions of the proteins constituting the histone octamer, complementary surfaces of the nucleosomal core, and the contact surface of the DNA superhelix, together with a fine balance between forces acting from opposite directions, the disturbance of which, combined with the corresponding changes in external forces, leads to the rapid shift of the equilibrium towards the appearance or decomposition of the nucleoprotein complex. The conservative nature of the histones H2A, H2B, H3, and H4 shows that the normal functioning of such a system virtually rules out changes in aminoacids.

2. The structure of the N-terminal fragment of DNA topoisomerase I

In the replication of DNA, the rate of polymerisation in bacteria and mammals varies from 500 to 50 nucleotides per second. For each ten base pairs of the newly synthesised chain, the parent DNA double helix must execute one complete turn around its axis in order to avoid being tangled up (Fig. 14). Hence, in order to achieve an obstacle-free movement of the replication fork at the experimentally observed rate, the entire chromosome, ahead of the fork, must execute 50 ± 5 turns per second. Exactly the same 'twisting problem' evidently arises in the transcription and recombination of DNA. In all cases, it is solved with the aid of special enzymes, DNA topoisomerases, which form a kind of 'hinge' within the helices.

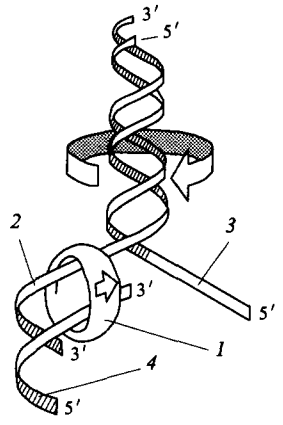


Figure 14. Rotation of the DNA double helix during its replication; (*1*) DNA polymerase on the leading chain; (*2*) matrix for the synthesis of the leading chain; (*3*) matrix for the synthesis of the lagging chain; (*4*) newly synthesised DNA chain.

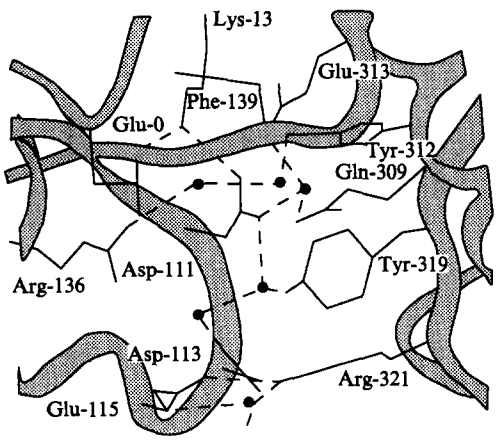
DNA topoisomerase I cleaves the phosphodiester bond in one of the DNA chains and becomes covalently attached, as a rule via a tyrosine side chain, to the free 5'-end formed. Chain termination enables the two halves of the double helix to rotate freely around the phosphodiester bond located opposite the break and hence to release the accumulated stress. The protein–DNA covalent bond is of the high-energy type and the enzymic hydrolysis of the phosphorus diester bond is therefore a reversible reaction and does not require the involvement of ATP. After the removal of stress, the broken ends of the DNA chain are rejoined. Thus, in terms of its function, the DNA topoisomerase constitutes something in the nature of a 'reversible nuclease' or a 'reversible DNA polymerase'. DNA topoisomerase was first isolated from the cells of *E. coli* in 1971.[180] It still remains the most widely investigated enzyme of the subfamily of type I DNA topoisomerases, which includes the topoisomerases III of the bacteria *E. coli*[181] and *Saccharomyces cerevisiae*[182,183] as well as the reversible gyrase of the archebacterium *Sulfolobus acidocaldarius*,[184,185] which were discovered many years later. Apart from the reaction described, enzymes of this type catalyse the relaxation of an incorrectly twisted linear DNA superhelix, the disentanglement and ring closure of a single-stranded DNA chain, the pairing of complementary rings, and a series of other related operations. A common feature of the type I DNA topoisomerases is the mechanism of the catalytic step, which proceeds without the employment of the energy of ATP and invariably includes the stage in which only one chain of the DNA double helix is temporarily broken. Enzymes with similar

functions, which, however, cleave not one but two phosphodiester bonds and are bound covalently to both chains of the double helix, constitute the subfamily of the type II DNA topoisomerases.[186]

The results of the X-ray diffraction analysis of the three-dimensional structure of the N-terminal fragment of the DNA topoisomerase I of *E. coli* were published in 1994.[187] The three-dimensional structure of the fragment of the polypeptide chain comprising 553 aminoacid residues and having a molecular mass of 67 kDa (that of the whole protein is 97 kDa) was determined with a resolution of 2.2 Å following the interpretation of the diffraction patterns obtained at a temperature of −168 °C using synchroton radiation. This was the first crystallographic study of a topoisomerase.

DNA topoisomerase I is a metalloenzyme, the C-terminal fragment of which contains three zinc(II) atoms and three sections with two disulfide bonds.[188] The catalytic reaction involving the cleavage of the DNA nucleotide chain includes transesterification between the phosphodiester bond of the substrate and the Tyr-319 side chain of the enzyme.[189] The C-terminal fragment of the protein with disulfide bonds does not participate in this reaction. The zinc atoms also do not affect the phosphodiester bond cleavage stage, but are necessary for the reconnection of the broken chain after the relaxation of DNA.[190] The fragment of DNA topoisomerase I with a molecular mass of 67 kDa, investigated by Lima et al.,[187] can therefore catalyse the cleavage of a single nucleotide chain, but is unable to restore the integrity of the DNA superhelix. Its substrate specificity and kinetic characteristics are the same as those of the native protein or the zinc-free protein.[190,191]

The three-dimensional structure of the N-terminal fragment consists of an irregular extended torus with external dimensions of ~67 × 43 × 86 Å. It is made up of domains I–IV, which are separated from one another and are easily observable. Domain III includes the catalytically important Tyr-319 residue (Fig. 15, Scheme 5).



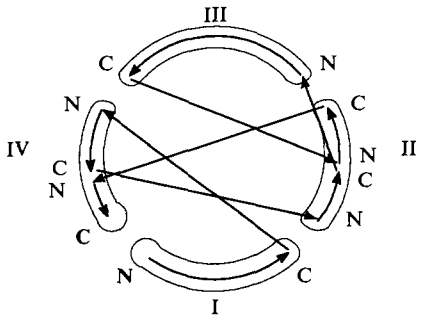


Figure 15. The active centre of DNA topoisomerase formed by domains I and II. The hydrogen bonds are designated by dashed lines.[187]

Scheme 5

The aperture in the torus, free from the side chains of the residues, has a diameter of ~28 Å, so that the insertion of the DNA double helix in the B-form into it should not be accompanied by steric hindrance. The arrangement of the effectively interacting domains I, III, and IV led to the formation of a large substrate-binding groove and of yet another aperture in the immediate vicinity of the principal aperture in the torus and the active centre with the Tyr-319 aminoacid residue. The second aperture has a small diameter but it is quite sufficient for the passage of a single DNA chain.

The view that the appearance of new complex proteins in the course of evolution takes place as a result of the merging of preexisting proteins has come to be generally accepted.[192,193] The three-dimensional structure of the multidomain protein is thus represented as an ensemble of largely independent globular domains which had previously existed as individual proteins, and the aminoacid sequence is represented by a set of polypeptide chains of the domains in which the C-terminus of the preceding domain is linked to the N-terminus of the next domain. The structural organisation of DNA topoisomerase is in no way consistent with this method of the formation of complex proteins, and its polypeptide chain cannot be represented by the sequential and independent formation of domains.

Assembly of the aminoacid sequence of the 67 kDa fragment apparently begins from the N-terminal domain I, which consists of a continuous polypeptide section (Scheme 5). Then, instead of proceeding immediately to domain II, the chain extends to domain IV and only then proceeds to domain II, having, however, completed the formation of domain IV only to the extent of one third. Next, having participated in this instance in the construction of only half of domain II, the chain passes to domain III. After completing its organisation, it returns again initially to domain II and then to IV, completing their construction. In the aminoacid sequence described, all the interactions of domain III with domains I and IV are restricted to nonvalence contacts. The covalently linked domains II and III, the polypeptide chain of which is not intertwined with the chains of other domains, can migrate as a solid body relative to the remainder of the protein. Such structural organisation of the enzyme molecule with two forms of the torus (open and closed) is, according to the authors,[187] of decisive importance for the functioning of the DNA topoisomerase I, since the migration of domains II and III makes the active centre accessible to both single-stranded and double-stranded DNA.

The hypothesis that appreciable conformational changes in the molecule of the DNA topoisomerase in the course of the formation of the nonvalence Michaelis complex are necessary is confirmed also by a number of other no less convincing structural features of the enzyme. One of them concerns the catalytically most important Tyr-319 residue. It belongs to domain III and is located next to the substrate-binding chain. In the native enzyme, Tyr-319 is accommodated in the narrow gap between domains I and III and is shielded from contact with the external medium by the Arg-321 protein chain, forming salt bridges simultaneously with the Asp-113 and Glu-115 side chains. The transition from the closed form of the molecule to the open form not only permits the penetration by DNA into the inner part of the torus but also moves the Tyr-319 residue onto the surface, providing conditions for the approach of the latter to the nucleotide chain of the substrate and attack on the phosphodiester bond. The migration of domains II and III as a single whole is stimulated by the nonvalence protein–DNA interactions, because a cofactor such as ATP is absent in the given instance. This feature distinguishes DNA topoisomerase I from DNA topoisomerase II, the catalytic action of which also involves conformational changes, but these require the participation of ATP.

In a study of the three-dimensional structure of the N-terminal fragment of DNA topoisomerase I,[187] the authors devoted much attention to the description of many details of the

mechanism of the catalytic step. However, these data, like the results of other similar investigations, are phenomenological in character.[194] The importance of X-ray diffraction data for enzymes clearly does not lie merely in making possible the adjustment of the existing theoretical mechanisms of catalytic action for consistency with them or in inventing new ones. These data are valuable by virtue of the potential possibility of their being used as a unique experimental basis for an a priori approach to a quantitative description of the catalytic step as a spontaneous process.[195]

3. The structure of β-galactosidase

The following two factors led me to include, in the section devoted to DNA-binding proteins, an enzyme which strictly speaking does not belong to this group: first, the structural organisation of the β-galactosidase molecule, which it had proved interesting to compare with the organisation of DNA topoisomerase just examined above; and second, the involvement of the enzyme in the regulation of the transcription activity of DNA, manifested by its influence on the effectiveness of the reading process in the course of the transcription of a whole cluster of genes (including its own gene) responsible for the metabolism of lactose. β-Galactosidase has played an historical role in the development of molecular biology, specifically in the concept of the general molecular principles of the regulation of the action of genes. It is in fact the study of the biosynthesis of this enzyme at the transcription level in bacteria which enabled L'vov, Jacobi, and Monod at the beginning of the 1960s to develop a theory of the transfer of genetic information and of the regulation of the protein synthesis (the operon concept). According to this concept, each operon incorporates a regulator gene, a promoter, an operator, and the structural genes of specific proteins (cystrones), in which the corresponding iRNA (polycystrone RNA) is transcribed and for the operation of which the three preceding regulator sections of the DNA double helix are responsible.

The first studies on the mechanism of genetic control were devoted to the synthesis of β-galactosidase, which hydrolyses lactose (a disaccharide) to glucose and galactose (monosaccharides) in the *E. coli* cell. The experiments led to the discovery of the repressor protein for the lactose operon initiating the transcription of structural genes (in the given instance the gene of β-galactosidase, as well as permease and galactoside transacetylase). This is achieved by binding the repressor to the operator section of DNA with a length equivalent to 21 nucleotides, which overlaps the aminoacid sequence of the promoter. This blocks the access by RNA polymerase to its binding section and the transcription of cystrones becomes impossible. The induction and repression of the synthesis of the protein, i.e. the changes in the rate of the process in opposite directions, require the presence in the model of the regulator mechanism of yet another inductor element, which should, on the one hand, control the action of the lactose operon repressor protein and, on the other, should be directly or indirectly related to the function of the enzyme being synthesised. Such as inductor has indeed been discovered and it proved to be the substrate of β-galactosidase, namely lactose or, more precisely, allolactose.

β-Galactosidase is an inducible enzyme, the rate of synthesis of which depends on the composition of the medium and the conditions in the latter, in particular on the lactose concentration. The amount of enzyme increases rapidly with increase in the substrate concentration, so that the relation between the inductor and β-galactosidase is evident. The effect of lactose, via allolactose, on the repressor is allosteric in character. When the intracellular lactose content begins to exceed the norm, the concentration of allolactose increases, which induces conformational changes in the repressor molecule. Its linkage with DNA is weakened and it liberates the promoter and hence enables RNA polymerase to transcribe the β-galactosidase genes. Depression of the gene takes place, iRNA is formed, and the enzyme, which is necessary only when the cell contains lactose, begins to be synthesised.

The three-dimensional structure of the *E. coli* β-galactosidase has been recently investigated with a resolution of 2.5 Å.[196] X-Ray diffraction analysis demonstrated that the aminoacid sequence of the protein comprising 1023 residues has an extended N-terminal 1–51 α-peptide section and five structurally autonomous domains: 51–217 (I), 220–334 (II), 334–627 (III), 627–736 (IV), and 736–1023 (V). In contrast to the type I DNA topoisomerase, where the polypeptide chain passes from one incomplete domain to another and, without completing its construction, is directed to the third, etc. (see Scheme 5), in galactosidase the chain passes from the N-terminus of the molecule to its C-terminus in strict succession through all the domains. The assembly of the long polypeptide chain of the protein is thereby facilitated, because in the modular structural organisation of the native enzyme each domain may act as an independent subunit capable of coiling up.

The quaternary structure of β-galactosidase in the form of a homotetrameric nonvalence complex with a molecular mass of 465 kDa exhibits an enzyme activity. Structural analysis showed that the complex belongs to the 222 symmetry point group. The four tetramers constitute an asymmetric unit cell belonging to the space group $P2_1$ with the parameters a = 107.9 Å, b = 207.5 Å, c = 509.9 Å, and β = 94.7°. At the present time, among all the three-dimensional structures of proteins identified at the atomic level, the molecular structure of β-galactosidase has the longest polypeptide chain. The study by Jacobson et al.[196] demonstrated for the first time the possibility of investigating protein crystals with a unit cell size exceeding 500 Å and a relative molecular mass of ~2000 kDa per asymmetric unit.

It had been shown earlier that the Glu-461, Met-502, Tyr-503, and Glu-537 residues should play an important role either directly in the catalytic reaction itself or in the construction of the active centre.[197,198] Indeed, in the observed three-dimensional structure of the enzyme they proved to be close to one another, being located around a deep well, which apparently represents a substrate binding pocket. The residues constituting it, like the four residues noted above, are highly conservative.

VI. Proteins of skeletal muscles

One of the most surprising properties of proteins, which are not manifested by other compounds, is undoubtedly their capacity for a macroscopic displacement i.e. greatly exceeding the dimensions of their molecules. This is due to the presence in a series of proteins, which have been called allosteric of several energetically preferable and comparatively readily interconvertible conformations which are sensitive to changes in the external medium and interact selectively with other molecules. When energy is consumed, the conformational transitions lose their reversibility and become ordered; the displacement becomes directional and the protein performs useful work.[199] For example, it can 'pass' through a thin filament, a microtube, or a DNA double helix. Such allosteric 'striding' proteins, employing the energy of the hydrolysis of ATP, are DNA helicase participating in the replication of DNA, kinesin, and dynein, which ensure intracellular mobility, and the muscle protein myosin, to the structure and functions of which this section is mainly devoted.

Myosin is a multifunctional protein. In the contraction of skeletal, hard, and smooth muscles, and in intracellular movement, it performs simultaneously at least three key functions: structural, allosteric, and enzymic. The most useful information about the functions of myosin may be obtained by investigating the tranversely striped skeletal muscle, which contracts spontaneously, as well as the analogous tissues of the invertebrates, primarily the flying muscles of insects. Electron microscope study of the longitudinal and transverse thin sections through skeletal muscles, carried out for the first time in 1953 by Huxley,[200]

revealed a high level of their structural organisation. By the following year, Huxley[201] had already proposed the so called sliding filament model, which was of fundamental importance for an understanding of the nature and the molecular mechanism of muscular contractions.

Skeletal muscles are bundles of muscle fibres, the largest repeating structural element of which is the myofibril, a cylindrical filament 1–2 μm (1000–2000 Å) in diameter, which extends from one end of the cell to the other. The myofibril contains in its turn protein filaments of two types—thick and thin. The principal proteins of the thick and thin filaments are myosin and actin filaments in the myofibril are strictly ordered. The functional contractile unit of the myofibril is the sarcomer, which is about 2.5 μm long and is subdivided into discs I and A (Fig. 16). The thick filaments (~1.6 μm long and 0.015 μm thick) extend from one edge of disc A to the other, while the thin filaments (~1.0 μm long and 0.008 μm thick) extend from the *Z* line and enter the gaps between the thick filaments of disc A. In muscle contraction, each sarcomer is shortened in proportion to the entire muscle, only disc I being compressed, while the dense disc A does not change its dimensions. The essential feature of the filament sliding model[201] is that the contraction of the myofibril and hence of the muscle fibre takes place as a result of the sliding of the thick filaments relative to the thin ones, whilst the lengths of both remain the same.

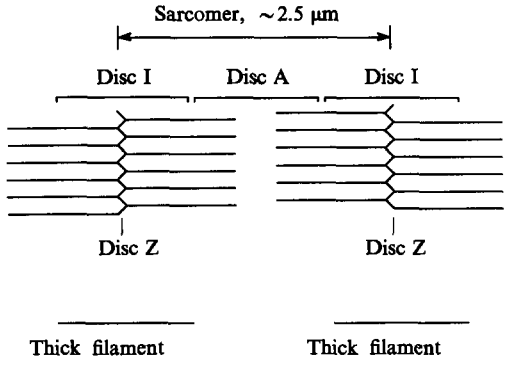

Figure 16. Schematic illustration of the structure of the sarcomer.

The filament sliding model has undergone prolonged experimental tests and has been confirmed most convincingly by data obtained by the direct electron microscope and X-ray diffraction methods. They demonstrated that the shortening of the muscle is indeed unaccompanied by changes in the intrinsic length of the filaments and in the nature of their packing in the sarcomer. The force developed by the muscle proved to be proportional to the degree of mutual overlap of the myosin and actin filaments and is therefore due to their interactions over the entire overlapping section. Following the introduction of high-resolution electron microscopy (second half of the 1960s; resolution 20–40 Å), it became possible to observe a multiplicity of lateral projections, forming ~0.013 μm (~130 Å) transverse bridges between the thick and thin filaments. It became evident that the relative displacement of the filaments is effected with the aid of these bridges. They belong to myosin and operate by employing the energy of the hydrolysis of ATP, like miniature oars. The presence of ATP in muscle fibres has been known since 1929, because it was in fact isolated for the first time from muscles. The fact that myosin catalyses the hydrolysis of ATP, i.e. is an ATPase, was established by Engelhardt and Ljubimova in 1939.[202] This discovery was the first indication of the source of energy for the contraction of muscles and of the role of myosin in the utilisation of the energy.

Towards the beginning of the 1970s, the phenomenological stage in the study of the functioning of muscles was largely complete; the overall mechanism of the process, its principal participants, and the source of energy were discovered.[203–206] Further study consisted in the search for answers to the following questions: what is the molecular mechanism of the contraction of muscles, how is the chemical energy of the hydrolysis of ATP transformed into mechanical work at the molecular level, and how does a nerve pulse trigger the movement of the muscle fibres?

The study of this problem began with experimental structural investigations by electron microscope methods, especially by cryoelectron microscopy, which can lead to a resolution at the atomic level under favourable conditions,[207,208] X-ray diffraction of oriented fibres, and X-ray crystallography. The combined approach, employing the results of both electron microscopy and X-ray diffraction analysis for the construction of models of the three-dimensional structures of the protein molecules consistent with the data obtained by these methods, has been recently (the 1990s) gradually introduced into practical use.[209] This approach has already found an application in studies on muscle proteins and spherical viruses.[210–212]

1. The structure of actin filaments

The thin filaments include as part of their composition actin, which, as already stated, constitutes the basic component of the filaments, tropomyosin, and troponin. The standard procedure for the isolation of actin involves the extraction of the dried and ground muscle tissue with a dilute salt solution. Such treatment cleaves the actin filaments into globular subunits, each of which is made up of a single polypeptide chain with a molecular mass of 41.8 kDa; this is globular actin or G-actin. One Ca^{2+} ion is bound to each molecule of G-actin, stabilising its globular conformation. In addition, one ATP molecule is associated with G-actin via a nonvalence interaction. In the nonvalence polymerisation of globular actin, the terminal phosphate of ATP is split off and fibrillar actin or F-actin is formed. The polymerisation may be induced by increasing the salt concentration to nearly the physiological level. The process does not require the consumption of energy, although it is in fact accompanied by the hydrolysis of ATP, which appreciably increases the rate of polymerisation and influences its dynamics. According to data obtained by electron microscopy, the actin filaments consist of two chains of globular molecules, the length of which is ~65 Å and the thickness in the widest part is ~40 Å. The F-actin chains form a double helix consisting of 13 molecules in six turns repeated at 360 Å intervals.[213]

After attempts in the course of many years, the G-actin molecules were crystallised but only together with the molecules of deoxyribonuclease I in proportions of 1:1. The three-dimensional structure of monomeric actin at the atomic level was therefore discovered from X-ray crystallographic data for the G-actin–deoxyribonuclease I complex.[214] The X-ray scattering pattern for the F-actin fibre was obtained simultaneously with a resolution of 6 Å and the orientation of the G-actin monomer and of the double helix of the polymer was found by comparing the calculated and observed X-ray diffraction patterns.[213] The remaining uneliminated differences reflect the fact that the polymerisation of actin is accompanied by slight conformational changes, but only to some extent, because the use of a refined structural model of G-actin in the construction of a model of the F-actin filament led recently to a better agreement between the calculated and experimental results.[215] Further refinement of the model is difficult owing to the lack of the X-ray diffraction pattern for F-actin with a resolution better than to within 6 Å. A solution may be found by resorting to a theoretical approach and to the employment of conformational analysis[216] and molecular dynamics[217] methods. The atomic model of F-actin, constructed by adjusting for consistency the results of X-ray

diffraction of G-actin crystals and thin F-actin filaments, agreed with the model reconstructed from cryoelectron photomicrographs of the actin filament.[218,219]

Two auxiliary proteins, tropomyosin and troponin, are closely associated with each actin filament. Their principal function is the regulation of muscle contractions as a function of the concentration of Ca^{2+} ions and hence nerve impulses. The rigid rod-shaped α-helical tropomyosin molecules ~400 Å long are located in longitudinal grooves extending along the actin filament, imparting thereby the necessary rigidity to the F-actin double helix (Fig. 17). The globular form of troponin is made up of three different subunits (troponins T, I, and C). Troponin T has a section for the binding of tropomyosin and is responsible for the attachment of the entire complex to the actin filament. When troponin I is added to troponin T and tropomyosin, a complex preventing the interaction of actin with myosin even in the presence of Ca^{2+} ions is formed. In the presence of troponin C, this complex continues to block the interaction of myosin with actin, but only in the absence of Ca^{2+}. When free calcium appears in the medium, troponin C binds four Ca^{2+} ions and removes the blockade in this state. Precisely this effect actually constitutes the basis of the excitation of the muscle contraction by calcium ions. We shall return to the problem of the way in which tropomyosin and troponin control the interaction of myosin with actin after considering the structural organisation of the thick filaments.

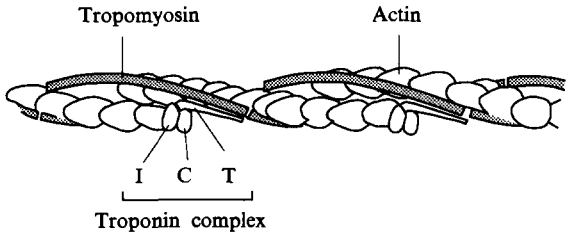

Figure 17. Schematic illustration of the thin filament.

2. The structure of myosin filaments

The contents of myosin, actin, tropomyosin, and troponin in the myofibrils are approximately 55%, 25%, 15%, and 5% respectively. A distinctive feature of the myosin in the skeletal muscles is its ability to form spontaneously, under in vitro conditions, giant polymeric complexes greatly exceeding in size the myosin aggregates from nonmuscle tissues. Myosin can be extracted from skeletal muscles with concentrated salt solutions, in which it is readily soluble. Muscle treated in this way loses only the thick filaments, which decompose into the component myosin molecules having a molecular mass of ~520 kDa. On treatment with a concentrated solution of urea or another detergent, the myosin molecule decomposes into six polypeptide chains: two identical heavy chains with a molecular mass of ~220 kDa and two pairs of light chains with molecular masses of ~22 and

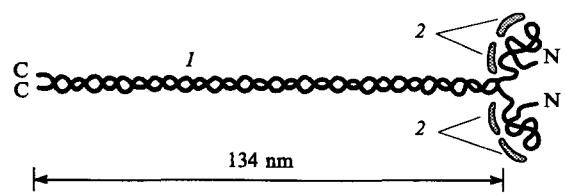

Figure 18. Schematic illustration of the structure of the myosin molecule: (*1*) twisted α-helices; (*2*) light chains.

~15 kDa.[220-224] It was established for the first time in 1963 with the aid of electron microscopy[223] that myosin consists of two globular 'heads', each of which is attached to a heavy chain, containing a long α-helical section. In the native myosin molecule, the α-helices of two heavy chains are twisted round one another into a super helix, forming a rod-shaped tail, from which two heads project. Each head is made up of the globular part of the heavy chain (~95 kDa) and includes one molecule of each of the two types of the light chain (Fig. 18).

The thick filaments are formed as a result of the association of the myosin molecules via their rod-shaped tails: several hundreds of molecules, arranged in parallel with lengthwise displacements, form a bundle from which laterally disposed heads project (Fig. 19). The entire structure is dipolar. The projecting heads are absent only along the small middle section of the filament, where two oppositely directed bundles of myosin tails are joined together. The globular heads of the myosin molecules interact with actin and form transverse bridges between the thick and thin filaments.

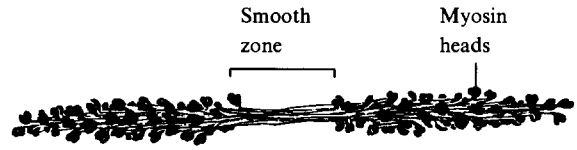

Figure 19. Schematic illustration of the thick filament of the skeletal muscle.

The proteolysis of the heavy filaments showed that the myosin head can be readily separated from the remainder of the protein, forming the so called subfragment-1 (S1) and a superhelical rod, responsible for the self-assembly of myosin and for the creation of the structural base of the thick filaments.[220,225] The subfragment-1 contains the nucleotide-binding active centre for ATP, an actin-binding surface, and two regions corresponding to contacts with the light chains. Thus the globular head retains all its function even outside the filament. The light chains incorporated in it differ from one another in structure and properties. In some forms of myosin, they do not exert an appreciable influence on the ATPase activity of the enzyme.[226] However, in certain types of myosin the light chains of its head may participate in the regulation of the hydrolysis of ATP, but only in the presence of actin.[227,228]

As early as the end of the past century, it was noted that myosin exhibits double refraction. However, until recently, the entire knowledge about the three-dimensional structure was limited to information about the external outline of the molecule and its size obtained with the aid of electron microscopy. In particular, it was known that the myosin head has a pear-shaped form approximately ~190 Å long and 50 Å wide, while the double helix of the tail section is ~1500 Å long and ~20 Å wide.[228-231] Rayment et al.[232] were able to obtain the crystals needed for analysis by employing the procedure, altogether unusual in protein crystallography, involving *N*-methylation under mild conditions, of the side chains of all the Lys residues of the myosin fragment-1. In order to make sure that the methylation did not lead to a drastic alteration of the conformational and enzyme properties of the protein, the authors subjected lysozyme to a similar chemical modification and did not observe after this procedure significant changes in the three-dimensional structure of the enzyme. In addition, the kinetic properties of the methylated myosin S1 were tested.[233] It retained its catalytic activity, although deviations of the kinetic parameters of the hydrolysis of ATP from the values for the native specimen were in fact observed.

The three-dimensional structure of the myosin subfragment-1 was determined[232,234,235] by X-ray diffraction with a resolution of 2.8 Å. This resulted in the refinement of not only the external dimensions of the myosin head, which confirmed that it lacks any kind of symmetry, is 165 Å long, and has a cross-section of 65 × 40 Å in the thickest part, but also led to the construction of an atomic model comprising 1072 aminoacid residues (out of the total number of 1157). The structure contains many α-helices (~48%), the longest of which extends over a distance of 85 Å from the thickest part in the direction of the C-end of the S1 heavy chain. Most of this helix is surrounded by light chains, ELC (essential light chain) and RLC (regulatory light chain), one of the principal purposes of which is conformational stabilisation of the heavy chain of the myosin head (for example, when RLC is removed, the S1 structure breaks down).[236] In addition, the light chains promote the conformational rearrangements which occur when the nucleotide is bound to and liberated from the thickened part of the head. In order to facilitate the description of the three-dimensional structure of subfragment-1, its heavy chain can be usefully divided into three parts: the N-terminal part incorporating the Asp-4–Glu-204 residues, the central part with Gly-216–Tyr-626, and the C-terminal part with Gln-647–Lys-843. Loops lacking secondary structures are located between them. These are subjected to tryptic cleavage, which gives rise to heavy chain fragments with molecular masses of 25, 50, and 20 kDa.

The thickened part of the myosin head contains nucleotide and active binding centres and thus has all the components necessary for the generation of motion. The essential moving, motor part of myosin is a complex of secondary structures disposed around the β-layer consisting of seven largely parallel β-tiers. It includes the components of all three trypsin-cleaved fragments of the heavy chain. The nucleotide-binding packet is located at the end of the central β-pleated sheet and adjoins the 25 kDa fragment on one side and the 50 kDa fragment on the other. The location of the aminoacid residues forming the nucleotide active centre of myosin has been determined by the tracer atom method[237] and by analogy with the sequences of the phosphate loops in the adenylate kinase and ribonuclease structures.[238,239] The binding pocket is ~13 Å deep and approximately just as wide. Since the crystals were grown in the absence of ATP, the active centre corresponds to an open conformation in the observed structure of the myosin subfragment-1.

The interrelation between the hydrolysis of ATP and muscle contraction, discovered, as already mentioned, as early as 1939, was considered in a large series of kinetic studies. The results, obtained for the first time in 1971[240] and in subsequent years,[234,241–243] have not undergone fundamental changes and lead to the same idea about the actin-myosin mechanism of muscle contraction. It is illustrated in Fig. 20 and corresponds to a four-stage process involving the conversion of the energy of the hydrolysis of ATP into mechanical work. In the first stage (*a*) of the proposed mechanism, the myosin head, carrying the ATP-hydrolysis products (ADP and phosphate), is attached to the actin filament. The second stage (*b*) (the 'working step') begins with a change in the conformation of the head induced by its interaction with actin, which liberates the hydrolysis products and results in the appearance of stress in the actomyosin complex, which is released during the longitudinal displacement of the thin filament. After the completion of the motion, conditions arise for the addition of a new ATP molecule to the myosin head, which is accompanied by the breakdown of the actin–myosin contacts (stage *c*). The cycle terminates with the hydrolysis of ATP and a change in the conformation of the head, which assumes the initial position (stage *d*). It has been suggested that each head of the myosin molecule executes its own cycle independently.

Thus the most significant features of the mechanism of the action of the actomyosin complex are that, firstly, the hydrolysis of ATP is completed at the time when myosin does not interact with actin, and, secondly, the driving force of the process arises on liberation of the ADP and γ-phosphate produced.

Not only the results of kinetic studies but also a multiplicity of experimental data obtained by other methods agree with the idea described above that the myosin heads 'stride' along the actin filaments. In particular, the generally accepted idea is confirmed by the three-dimensional structures of monomeric actin[213,214] and the myosin head,[232,234] which were discovered recently, as well as the structural model of the actomyosin complex constructed, with a resolution of 5–8 Å on the basis of these structures using cryoelectron microscope data.[235] One of the key features of this complex, which became evident after the construction of the model, is the existence of nonvalence contacts between actin and the C-terminal domain of the 50 kDa tryptic fragment. Interactions of this type may stimulate conformational changes in myosin at the instant of its mutual approach with actin in the second stage of the muscle contraction process (Fig. 20). In a study of skeletal muscles by the small angle X-ray scattering method, data were obtained recently, indicating convincingly a significant change in the form of the myosin head during the binding of nucleotides.[244]

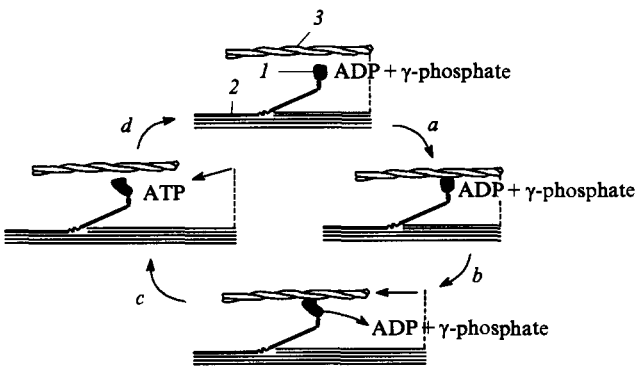

Figure 20. Schematic illustration of the mechanism of the utilisation of the energy of the hydrolysis of ATP for the movement of the actin filament relative to the myosin filament: (*1*) myosin head; (*2*) thick filament; (*3*) thin filament.

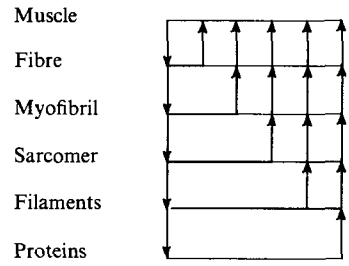
The conformational rearrangement of myosin is accompanied by an allosteric effect — the closure of the long narrow groove at the boundary between the thick and thin halves of the pear-shaped head. This results in the mutual approach of actin and the nucleotide centre of myosin and in the liberation of ADP and inorganic phosphate. This is the reason why myosin is an actin-dependent ADPase. It was noted long ago that the rate-limiting stage of the catalytic reaction is not the binding of the ATP molecule to the active centre and not the hydrolysis proper, but the liberation of the products of the enzymic reaction, remaining firmly bound to myosin, which in fact prevents the onset of the next catalytic step.[203,204] The ATPase activity of the purified myosin is low: the enzyme requires approximately 30 s for the hydrolysis of one ATP molecule. In the presence of actin, each myosin molecule is capable of hydrolysing from 5 to 10 ATP molecules per second.

The thick filament contains ~500 myosin heads and they all operate simultaneously but not synchronously, drawing in the actin filament. In the new cycle of the interaction with actin, the head is attached to another monomer of the thin filament located closer to the *Z*-plate. The limiting contraction of the muscle develops in hundredths of a second (~0.02 s). The muscle at rest is elastic and can be easily stretched. The contracted muscle, on the other hand, is inelastic and rigid; its extension is prevented by the bonds between the actin and myosin filaments, which persist when the ATP concentration is inadequate.

Skeletal muscle contracts when the action potential of the nerve fibre is switched on and when a signal is obtained from the corresponding motoneuron. The electrical excitation spreads rapidly over the so called T-tubes, which surround each myofibril in the region of the *Z*-plates. Here the electric signal is transmitted to the sarcoplasmic reticulum—a system of branched intercommunicating vesicles. At the instant of activation by the electric pulse which has passed through the T-tubes, the sarcoplasmic reticulum injects into the cytosol large amounts of Ca^{2+} ions stored in the vesicles, which initiates the contraction of the myofibrils. The signal from the muscle cell membrane reaches the sarcomers in several milliseconds via the T-tubes and the sarcoplasmic reticulum, so that all the myofibrils of the muscle cell contact almost simultaneously. The relation between the muscle contraction and the changes in the Ca^{2+} concentration is due to the functions of the auxiliary proteins tropomyosin and troponin, which are associated with the actin filaments (Fig. 17). They participate in the regulation of the muscle contraction of the Ca^{2+} ions and thereby render the ATPase activity of myosin sensitive to the concentration of these ions.



It has been suggested that tropomyosin and troponin effect the Ca^{2+}-dependent regulation of the muscle contraction via steric hindrance to the mutual contacts between actin and myosin. With increase in the concentration of Ca^{2+} ion, the positions of the tropomyosin molecules change, possibly as a result of the change in the shape of the troponin molecules bound to them, in the first place troponin C molecules. In the absence of Ca^{2+}, tropomyosin, troponin T, and troponin I form a complex, which prevents the interaction of actin with myosin. After the appearance of calcium ions, troponin C binds four Ca^{2+} ions and in this state removes the blockade and enables the myosin heads to interact with actin.[245]

The determination of the three-dimensional atomic structures of the proteins G-actin and the myosin subfragment-1, and the reproduction on this basis, resorting to electron microscopy and small angle X-ray scattering, of the three-dimensional structures of the thin and thick filaments, implies the virtually complete visualisation of the elementary constituent sarcomer, capable of demonstrating the principles of the contraction of skeletal muscles and a concrete conformational-electronic mechanism of the transformation of chemical energy into mechanical work. The development of the atomic-molecular model of the actomyosin complex has been one of the outstanding achievements in molecular biology during recent years both in methodological and in purely scientific respects. Without dwelling in detail on the possibilities for the experimental study of the muscle contraction process which have greatly expanded in recent years,[246] we shall only observe that the most notable event in this instance has been the application of the molecular genetics[247] and 'laser trap'[248] methods, which effectively supplement X-ray diffraction and electron microscopy. The 'laser trap' method makes it possible to follow the 100–200 Å displacements of single proteins and to measure the strength of their interactions up to 7 pN (7×10^{-7} dyn). We shall consider below the further improvement of the model itself—the problem of the transition from the phenomenological description of the mechanism of action of the molecular muscle motor to the creation of a rigorous theory of the contraction of muscles and of a quantitative method for the analysis of this process.

The model of Rayment and Holden does not merely constitute a general description of the authors' and coworkers' own work,[232,234,235] but constitutes a logical completion of a series of numerous investigations during the last four decades and in the first place the studies during the 1990s on G- and F-actins by X-ray diffraction and cryoelectron microscopy.[213,214,218,246]

The relation between the knowledge of the structure of the muscle system and the understanding of the mechanism of its action, i.e. between the morphology of the various levels of the structural organisation and the physiology of the muscle, is illustrated in Scheme 6. The thick arrows indicate the direction of the successive steps in the discovery of the structure and the oppositely oriented thin arrows denote the steps in learning about the function of the biosystem. It is seen from the scheme presented that the more complete and detailed the information about the form and composition of the simplest subsystems, the deeper the understanding of the mechanism of the functioning of the entire system. This nature of the dependence of the depth of understanding of the essential features of the physiological phenomenon and the knowledge of the morphology of its participants is a common feature of the processes involved in learning about biological systems. The treatment of the properties of a biological system is always relative and is based on information about the structures of the underlying subsystems.

Scheme 6

The existence of common characteristics and of a single fundamental plan in the development of research into biosystems leads, despite their perhaps self-evident nature, to nontrivial conclusions which are of special interest at the present time. The development of biology throughout history has been determined by two countercurrent streams of investigations: morphological, directed from objects and phenomena with a complex organisation to simpler ones, and physiological, with the opposite direction. The first and second streams were the driving and driven components respectively. However, at the beginning of the second half of the 20th century, in its progress from complex to simple constructions based on the advances in morphology, biology reached the most universal and simplest level in biosystems—a kind of molecular 'bottom'. Further development on the same lines (from morphology to physiology) and in the same direction (from complex to simple constructions) has become impossible. The usual source of qualitatively new information has fizzled out, because the morphological data about the possible underlying subsystems (individual aminoacids, atomic groups, and atoms) contain no specific biological features and hence are not directly linked to the function of any of the biosystems considered.

Thus the approach employed in biology is completed by the determination with the aid of X-ray diffraction, electron microscopy, or another experimental method of the three-dimensional structures of proteins. The preexisting or newly formulated more detailed and better founded ideas about the mechanism of the functioning of the biosystem are confirmed, an atomic-molecular model of the process is developed, and the corresponding hypothesis is formulated on the basis of experimental data on the structure of the biosystem at the molecular level. All that was done previously as regards biosystems with a complex organisation is in essence done in securing new information about the morphology of the underlying subsystems.

The importance of the role of X-ray diffraction analysis of proteins consists in the fact that the study of biosystems at the molecular level was initiated with its aid, and without which it is difficult to imagine the establishment of molecular biology.

The question arises: what is required for further progress in biology and for its transition to the next improved qualitative state. Since the paths leading to the development of studies on all biosystems are in principle the same, the answer to the question posed above does not lose its significance and generality if it is obtained by considering some kind of concrete object, for example, the actomyosin complex. Another question is what additional information (apart from morphological) about the structures of myosin, actin, and certain other proteins is needed in order to not only compare the hypothetical idea about the operation of the actomyosin complex, about the interactions with the ATP molecules supplying it with energy, and about the Ca^{2+} ions regulating its functioning but also to proceed further and attempt to understand why this occurs. This requires data (quantitative data) on the conformational and chemical changes which have taken place, on their sequence, and on the stimuli and their interdependence. With the three-dimensional structure of the actomyosin complex already known, the quantitative description of the mechanism of its action as a spontaneous periodic process may serve as a criterion of the reliability of our knowledge. Here the main problem is not so much the amount and even the quality of the experimental data as its physicochemical interpretation, i.e. the availability of the corresponding theories which provide a logical and quantitative link between the aminoacid sequence, the three-dimensional structure, and the function of the protein molecule.

VII. Synchrotron radiation

The application of synchrotron radiation, which is much more powerful than the radiation from the traditional X-ray tubes, in protein crystallography may be regarded as one of the most significant methodological advances in X-ray diffraction structural analysis during the last decade. In the 1960s–1970s, the majority of the three-dimensional structures of proteins were solved with the aid of sealed sharp-focus tubes with a copper anode giving rise to a characteristic wavelength $\lambda(K_\alpha)$ of approximately 1.54 Å. Their intensity, estimated from the stream of photons in a collimated X-ray beam (10^9–10^{10} photons s^{-1}), is several times higher than for the usual tubes and the focussing of the beam onto a much smaller area makes it possible to obtain diffraction patterns with a higher resolution and a shorter exposure.

In 1959, Parratt proposed that a synchrotron be used as a source of X-rays in crystallography.[249] Moving in a circle within the synchrotron at relativistic velocities in a homogeneous magnetic field, charged particles begin to emit, following retardation and curvature of their trajectories, a continuous spectrum of electromagnetic waves in the form of a very sharp conical beam with a divergence angle of $\sim 1'$ and an axis which coincides with the instantaneous (tangential) direction of motion. The short-wavelength part of the synchrotron (magnetic retardation) radiation spectrum has a broad maximum in the region of interest for X-ray diffraction analysis. In contrast to traditional sources, the polychromatic radiation of the synchrotron may be rendered monochromatic over a much wider range of wavelengths and hence can give rise to a powerful X-ray flux. Thus, in the synchrotron in Daresbury (Great Britain), the useful flux $N(\lambda)$ is at least 10^2–10^3 times more intense than in the best current X-ray tubes with a rotating anode. Parratt's idea became the subject of serious discussions, but remained unrealised for a long time. Both the possibility of the actual increase in the intensity of the diffraction beams and the ability of protein crystals to withstand an intense radiation gave rise to doubts.[250] It was not until 1971 that synchrotron radiation was applied in diffraction studies on biological objects. Studies on muscle fibres by the small angle scattering method showed that, after being rendered monochromatic and after focussing, the intensity of the synchrotron radiation employed is two orders of magnitude higher than the maximum intensity of the collimated filtered CuK_α radiation from an X-ray tube and does not cause the disruption of the irradiated object.[251–253]

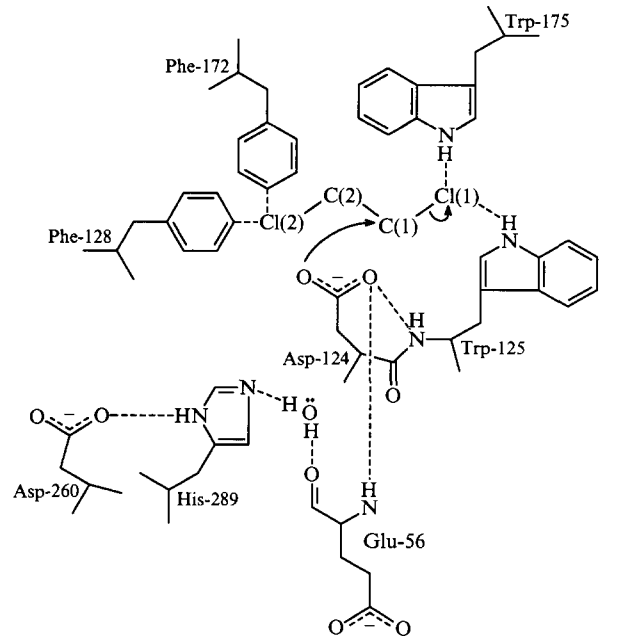
The question of the possible application of synchrotron radiation in the X-ray diffraction analysis of protein single crystals was first examined theoretically by Wykoff[254] and Harrison[255] and experimentally by Phillips et al.[256] The last group of workers obtained X-ray diffraction patterns for protein single crystals comprising those of rubredoxin, azurin, the nerve cell growth factor, and L-glutamine-aspariginase, using an electron–positron synchrotron (Stanford, USA).

The authors showed that, when the radiation from an X-ray tube is replaced by synchrotron radiation (keeping all other experimental conditions the same), the intensity of the scattering by the same protein crystals increases by a factor greater than 60 and hence the exposure time diminishes by the same factor, but the risk of the rapid decomposition of the crystals was not eliminated. On the other hand, owing to the decrease in exposure time, the rate of decomposition of the test object proved to be significantly lower than in the case where the radiation from an X-ray tube is used. Together with the above advantages, the authors also noted the small angular divergence of the synchrotron beam and the ease of tuning the synchrotron to a chosen wavelength, which facilitates the selective optimisation of the anomalous contributions to the scattering factor. More than one third of the studies on X-ray crystallography of proteins are nowadays carried out with the aid of synchrotron radiation and multichannel recording systems.

A no less important factor in the X-ray diffraction of proteins (as is incidentally the case in the entire modern X-ray diffraction analysis) was the appearance of the so called coordinate (multichannel) X-ray detectors (or 'area' detectors), which make it possible to record simultaneously all the diffraction maxima arising from the crystal in the given orientation. Such detectors, which are as a rule complex electronic systems with simultaneous recording of a multiplicity of reflections, are the modern analogues of photographic films used previously at the dawn of X-ray diffraction analysis. The recording of a single diffraction pattern (with a large number of diffraction spots) for a specified orientation of the crystal may last several seconds or less, which, together with a powerful radiation source (synchrotron), diminishes the duration of the X-ray diffraction experiment by several orders of magnitude.

Table 8 presents certain results of the X-ray diffraction analysis of proteins, the diffraction patterns of which were obtained both with the aid of synchrotron radiation (Nos. 1–8 and 17–20) and the radiation from X-ray tubes with rotating copper anodes (Nos. 9–16). The table reflects only a small proportion of the publications from the end of 1993 until the first half of 1994 devoted to the solution of the three-dimensional structures of protein molecules and their complexes. If the advantages of the two methods are judged on the basis of the resolutions and the divergence factors (R), then one must conclude that the nature of the radiation source hardly affects the final result. With the aid of synchrotron radiation and an X-ray tube, it has been possible to elucidate the three-dimensional structures of protein molecules with a record resolution, having overcome in both cases the one angstrom barrier [Table 8, bacterial trypsin (No. 2) and crambin (No. 13)] and having attained at the same time a divergence factor R of about 10%—a value close to that of the factor R for the refined structures of small organic molecules.

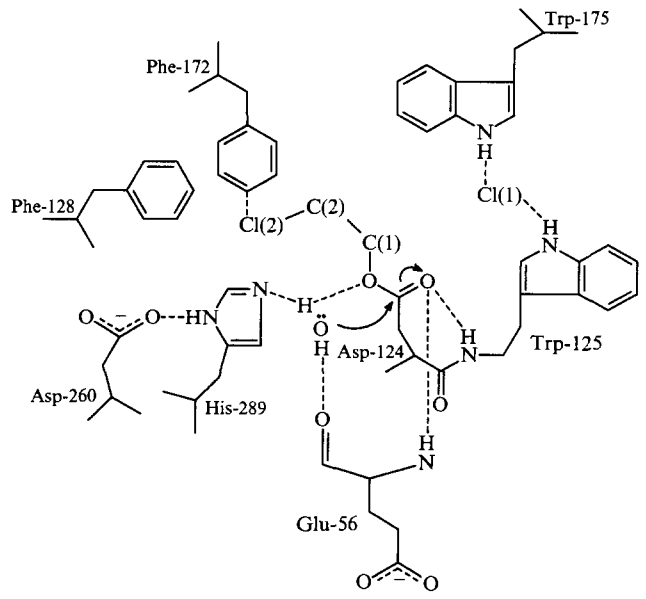
The methods also do not differ appreciably as regards the size of the irradiated crystal and the diameter of the focussed spot. Thus, in the determination of the three-dimensional structure of the antibody Fab 17/9 (Table 8, No. 16) by means of an X-ray tube with a rotating anode, the size of the specimen was 0.30 × 0.04 × 0.02 mm and the size of the focussed spot was only 0.1 mm. These parameters are not inferior to the experimental conditions when a synchrotron is employed.



However, one can assume that the powerful synchrotron radiation and its sharp focus are somewhat preferable, since it is then possible to use smaller crystals. Nowadays the problem of the crystallisation of proteins is in both cases just as acute as decades ago. As already mentioned, the situation is particularly complex in the crystallisation of membrane proteins (for a description of the efforts made in this connection and of the relative successes, see Refs 233 and 236–238).

Comparison of the data presented in Table 8 leads to the conclusion that the X-ray diffraction methods employing synchrotron radiation and the radiation from an X-ray tube have no appreciable advantage relative to one another in the study of the native conformations of protein molecules and their stable complexes, i.e. in all those cases where the static problem of the determination of atomic three-dimensional structures is being solved. Until recently, it has been assumed that, in principle, X-ray diffraction analysis cannot be applied to the consideration of problems involving the dynamics of proteins. The use of synchrotron radiation and of modern systems for the simultaneous rapid measurement of the intensities of multiple reflections made it necessary to question the incontrovertible nature of this view if not demand its complete reversal. As can be seen from Table 8, it is possible to shorten the exposure time from many tens of hours (No. 9), days (No. 16), and even weeks (No. 11) to fractions of a second (Nos 3 and 5). According to Thomas,[277] the diffraction reflections from protein crystals exposed to synchrotron radiation may be measured over a period of 100 ps (i.e. 10^{-10} s). The appreciable shortening of the exposure not only makes it possible to shorten significantly the duration of the analysis of the three-dimensional protein structure but also leads to a fundamentally new prospect for the study of the mechanisms of the processes occurring in protein crystals by investigating the structures of the intermediates, when their lifetimes are fairly long or can be prolonged by altering the external conditions. The possibilities which have arisen render the X-ray diffraction method still more unique. One may postulate that the employment of synchrotron radiation promotes the direct monitoring of the kinetics of the conformational and chemical changes in the structures of proteins at the atomic level in the course of, for example, enzymic reactions. A study has been carried out (discussed below) in which an attempt has been made to solve this kind of problem.

1. The mechanism of the functioning of haloalkane dehalogenase



Verschueren and coworkers[175,265] applied X-ray crystallography to the study of the mechanism of the catalytic step involving haloalkane dehalogenase (Table 8, No. 10). The structures of the enzyme, a single crystal of which was kept permanently in the mother liquor, were solved both in the absence and in the presence of the substrate (1,2-dichloroethane) in the solution. At pH 5 and $T = 4$ °C, i.e. far from the optimum conditions (pH 8.2 and 22 °C, the substrate was bound to the active centre, but the catalytic reaction did not develop. The nonvalence enzyme–substrate Michaelis complex remained stable indefinitely and its structure could therefore be determined with the aid of the radiation from an X-ray tube, for an exposure time of 48 h, and with retention of all other conditions in the analysis of the native enzyme. The observed disposition of the substrate in the active centre is illustrated schematically in Scheme 7. One of the chlorine atoms [Cl(1)] in the complex is located at distances of 3.6 and 3.2 Å from the nitrogen atoms of the Trp-125 and Trp-175 side chains and interacts with the hydrogen atoms of two N–H bonds. The other chlorine atom [Cl(2)] is stabilised by dispersion interactions with the Phe-128 and Phe-172 benzene rings. In the observed conformation of the substrate in the active centre, the C(1) carbon atom has been brought closer to the $O^{\delta 1}$ oxygen atom of the Asp-124 side chain (3.8 Å), which is in fact the main reason for the productivity of the nonvalence complex.

Scheme 7

When a crystalline specimen is heated to room temperature, the C(1)–C(1) bond dissociates, which is accompanied by the formation of the $Cl(1)^-$ ion and the alkylation of the $O^{\delta 1}$ oxygen atom of the Asp-124 residue. Such a change in the complex is in fact indicated by the solved three-dimensional structure, which arises and remains stable at pH 5 and 22 °C (Scheme 8). Finally, at pH 6.2 and 22 °C, the alkylated fragment is hydrolysed by a water molecule activated by the side chains of the His-289 and Asp-260 residues interacting with one another. The reaction products are removed and the enzyme returns to the initial state, which is in fact revealed by the X-ray diffraction analysis.

Scheme 8

Thus the two-step mechanism of the reaction involving haloalkane dehalogenase, proposed previously,[278] has been confirmed experimentally.[265] In the catalytic reaction involving this enzyme and occurring under in vivo conditions, the lifetime of the intermediates is too short for crystallographic study. By varying the pH and the temperature, the authors were able to slow down the process, separate it into two stages, and investigate

Table 8. Certain X-ray diffraction data for proteins obtained with the aid of synchrotron radiation and radiation from X-ray tubes with a rotating anode.

No.	Protein	Source	Molecular mass/kDa	Structural data	Resolution/Å	*R* factor (%)	Remarks	Ref.
1	Haemaglutinin	*Influenza virus*	60	Homotrimeric complexes of glycoprotein with receptor analogues	2.15	21.6	Crystal dimensions $0.70 \times 0.70 \times 0.70$ mm; synchrotron radiation with $\lambda = 0.905$ Å; temperature 108 K	257

the atomic three-dimensional structures of the corresponding enzyme–substrate complexes with a resolution of 2.0–2.4 Å. It was shown that the central role is assumed by the carboxy-group of the Asp-124 residue as the nucleophile in the first (alkylation) stage and by a water molecule, attacking the central carbon atom of the ester group of the covalent intermediate, in the second (dealkylation) stage.

2. Deacylation of trypsin

A similar study has been carried out with a classical object in enzymology — trypsin.[261] The Laue method for the recording of synchrotron radiation with time resolution was used in the above study.

The chemical mechanism of the catalytic step in the reactions involving serine proteases, including trypsin, presented below has been known for a fairly long time.[279–281]

$$\underset{\text{I}}{E+S} \rightleftharpoons \underset{\text{II}}{ES} \rightleftharpoons \underset{\text{III}}{ES^*} \rightleftharpoons \underset{\text{IV}}{EA + P_1} \rightleftharpoons \underset{\text{V}}{EA^*} \rightleftharpoons \underset{\text{VI}}{EA} \rightleftharpoons \underset{\text{VII}}{E+P_2}$$

E = enzyme, S = substrate, A = acylenzyme, P_1 and P_2 = hydrolysis products.

According to the proposed scheme, the mechanism of the tryptic hydrolysis includes a consecutive chain of chemical interrelations between the enzyme and the substrate via covalent intermediates. The catalytic process begins with the formation of a nonvalence Michaelis complex (II) in which the hydroxyl of Ser-195 and the imidazole ring of His-57 in the enzyme are respectively close to the carbonyl and amide groups of the peptide or ester bond of the substrate to be cleaved. As a result of their concerted interactions, the nonvalence enzyme–substrate bonding is converted into covalent bonding with the initial formation of a relatively unstable intermediate — the so called tetrahedral adduct (III). The latter decomposes into the acylenzyme and the amine (IV), while on hydrolysis of the ester it decomposes into the acylenzyme and the alcohol. Next follows deacylation, which proceeds similarly in principle, but in the opposite sequence and with participation of a water molecule as the nucleophile and not the O^γ atom of the Ser-195 side chain. A metastable tetrahedral adduct (V) is again formed and then decomposes, via the nonvalence complex (VI) stage, into the initial enzyme and the second reaction product (VII). The chemical mechanism for the proteolytic serine enzymes was developed before the results of the X-ray diffraction analysis of the three-dimensional structure of the molecules became available.

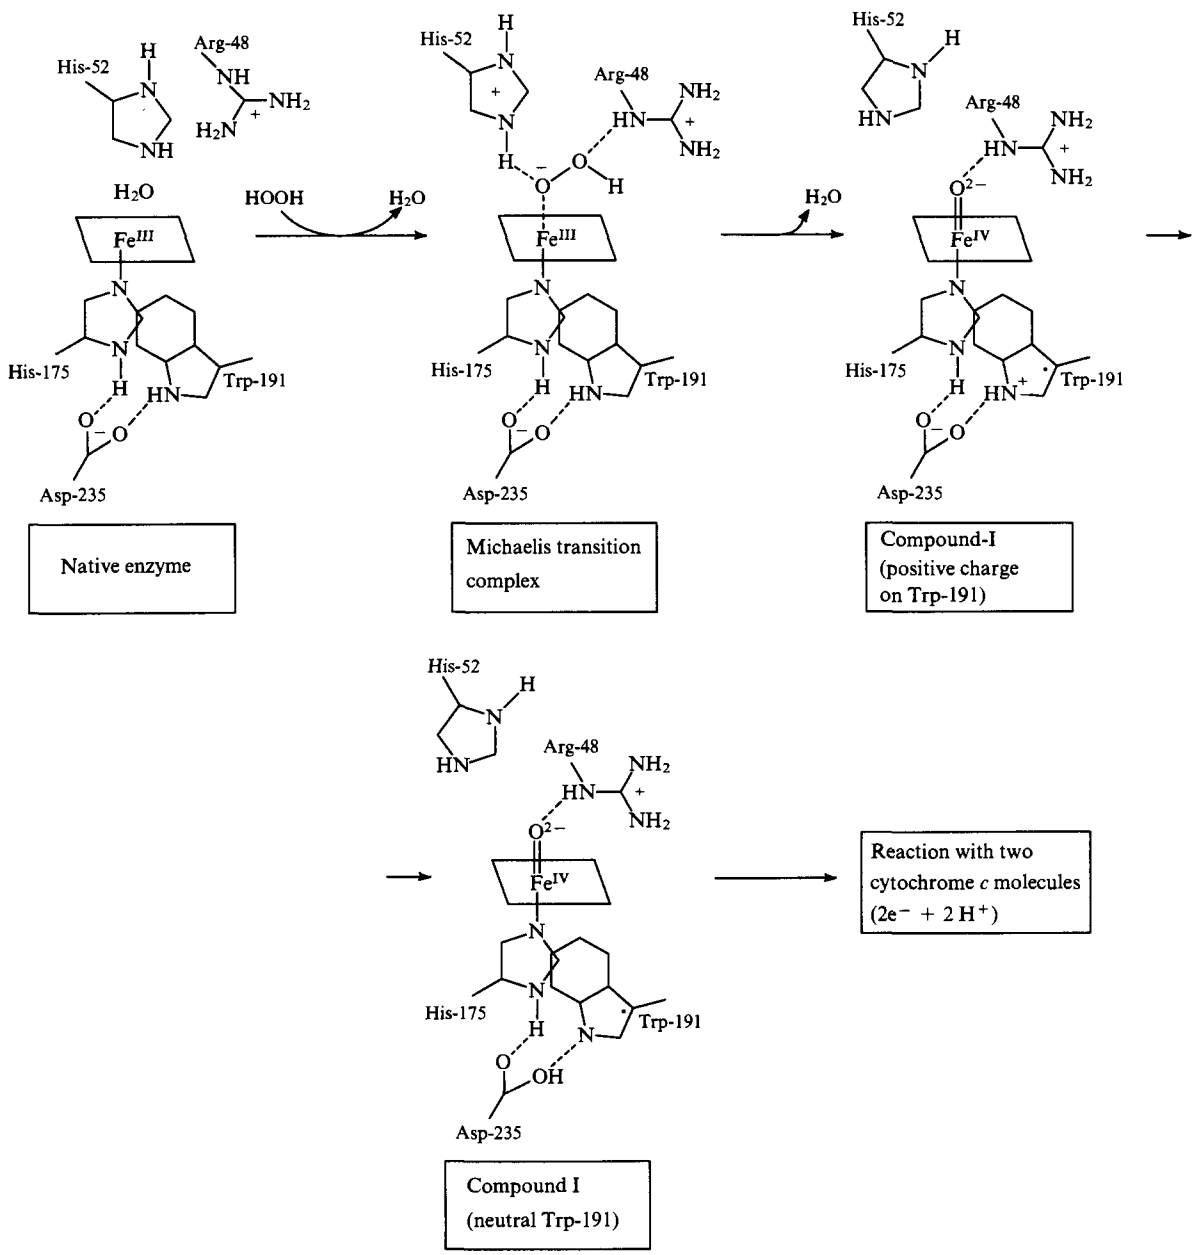
The crystal structure of native trypsin has been established[282–287] with a resolution of 1.8 Å and refined to within 1.5 Å. The geometry of the active centre was identified on the basis of the results of X-ray diffraction analysis of complexes of trypsin with protein inhibitors of animal and plant origin[288–290] and with irreversible synthetic inhibitors.[291] It was shown that the hydroxy-group of the Ser-195 residue and the imidazole ring of His-57, located on the surface of the protein globule and forming the $N^{\varepsilon 2}\ldots H-O^\gamma$ hydrogen bond, participate directly in the interaction with the substrate and in the formation of intermediate products of the catalytic reaction. The His-57 residue is also close to Asp-102, the $N^{\delta 1}-H\ldots O^{\delta 2}$ interaction occurring between them.

We shall now return to the study[261] in which the mechanism of action of trypsin in the second stage of the catalytic step (IV–VII) was investigated by X-ray diffraction with synchrotron radiation. The study began with the preparation of a stable intermediate of the enzymic reaction — the acylenzyme

(VI) — by the addition of *p*-guanidinobenzoate (GB) to the Ser-195 residue of trypsin present in the crystalline state in the mother liquor at pH 5.5. On rapid increase in the pH to 8.5, the process, monitored by three-dimensional Laue diffraction, was initiated. The diffraction of X-rays was detected in three series of irradiations of various sections of the crystalline specimen with a five-second exposure for one photograph in each series. The first series of exposures (t_0) was carried out before injecting a buffer solution at pH 8.5 into the flow cell, while the second and third series were carried out after 3 and 90 min respectively (t_3, t_{90}). The three-dimensional structures of three enzyme–substrate complexes were solved with a resolution of 1.8 Å and *R* factors of ~20%. Comparison of their structures before and after increasing the pH showed that one of the water molecules in the active centre of the enzyme is predisposed to attack the acyl group in the stage involving the initiation of hydrolysis of the acylenzyme and exhibits a tendency to approach the carbonyl carbon atom during the reaction. Thus the claim that water is involved in the deacylation of the trypsin intermediate is transformed from an extremely probable hypothesis into an experimental fact.

3. The structure of the intermediate compound in the first stage of the reaction of cytochrome *c* peroxidase with hydrogen peroxide

According to existing idea, cytochrome *c* peroxidase (CCP) catalyses the reduction of peroxides via a mechanism consisting of the following three stages:[292–295]



$$CCP(Fe^{III}) + H_2O_2 \rightarrow \text{compound-I } (Fe^{IV}O^{2-}, \text{Trp-191}^{*}) + H_2O \quad (1)$$

$$\text{Compound-I } (Fe^{IV}O^{2-}, \text{Trp-191}^{*}) + \text{Cyt-}c(Fe^{II}) + H^{+} \rightarrow \text{compound-II } (Fe^{IV}O^{2-}) + \text{Cyt-}c(Fe^{II}) \quad (2)$$

$$\text{Compound-II } (Fe^{IV}O^{2-}) + \text{Cyt-}c(Fe^{II}) + H^{+} \rightarrow CCP(Fe^{III}) + \text{Cyt-}c(Fe^{III}) + H_2O \quad (3)$$

In the first stage of the reaction of cytochrome *c* peroxidase with hydrogen peroxide, a doubly oxidised intermediate, which has been called 'compound-I', is formed. The three-dimensional structures of the native enzymes and of compound-I as well as

Scheme 9

the conformational changes in CCP, occurring on formation of the intermediate in the first stage of the catalytic reaction, have been described.[259]

Compound-I was obtained in a crystalline form from yeast cytochrome *c* peroxidase on reaction of the crystalline enzyme, placed together with the mother liquor in a flow cell, with hydrogen peroxide, also in the mother liquor. The reaction between the enzyme and H_2O_2, the occurrence of which was detected with the aid of absorption spectra in the visible region (550–750 nm), was almost completed after several minutes at 6 °C. The concentration of compound-I formed then remained virtually constant (90%–95%) for at least 30 min. The three-dimensional structures of the native enzyme and of its first intermediate were solved by three-dimensional Laue diffraction with a resolution of 2.2 Å and a divergence factor $R \sim 15.8\%$ (Table 8, No. 3). The size of the crystalline specimens was 0.4 × 4.0 × 1.0 mm. Polychromatic synchrotron radiation was employed; the duration of one exposure was ~0.3 s. Altogether, four series of independent experiments were performed on four crystals for four different orientations of the specimens (four for the native enzyme and four for compound-I).

On comparing the geometries of the observed structures, the authors[259] noted changes induced by the conversion of CCP into compound-I. They concerned only the region of the active centre and principally its distal part (Scheme 9). In the native state of the enzyme, the ligand-binding pocket over the iron atom is filled with three water molecules. On formation of the enzyme–substrate complex, two of them are eliminated, while the third is slightly displaced but still remains bound to the Trp-51 residue and the Fe-containing haem group. After the formation of compound-I and the heterolytic cleavage of the peroxide bond, the substrate oxygen atom is bound to the iron, altering its oxidation state from the high-spin ferri-state to the low-spin ferro-state ($Fe^{III} \rightarrow Fe^{IV}$). Having formed a Fe–O bond ~1.7 Å long, the iron atom is displaced by 0.3 Å from the plane of haem in the direction of the distal His-52. The Arg-47 side chain, located somewhat to one side, is displaced by 1.3 Å towards the ferro-oxygen atom and forms a hydrogen bond with the latter. The distances between the ferro-oxygen atom, on the one hand, and the N^{ε} atom of the Arg-48 residue, the $N^{\varepsilon 1}$ atom of the Trp-51 residue, and the $N^{\varepsilon 2}$ atom of the His-52 residue are 2.8, 2.7, and 3.6 Å respectively, and are too large for the formation of a hydrogen bond.

On formation of compound-I, the indole ring of the proximal Trp-191 residue is oxidised by giving up an electron to ferro-oxygen. The resulting radical-cation, bearing a charge on the indole nitrogen atom, interacts via the $N^+-H\ldots O^{\delta 1}$ hydrogen bond with the oxygen of the charged carboxy-group of the Asp-235 side chain; the second oxygen atom of this residue ($O^{\delta 2}$) is bound to the N–H group of the His-175 residue. Since there is no appreciable change in the geometry of the active centre in this region, the above considerations concerning the distribution of electron density in the proximal residues constitute merely one of the possible versions.

4. Photolysis of the myoglobin – carbon monoxide (Mb – CO) complex

Two structural studies on this complex, which in experimental terms can be regarded as the greatest advances in modern protein crystallography, have been published recently.[296,297] Both investigations were devoted to the mechanism of the photodissociation of the carbon monoxide-inhibited myoglobin.

$$Mb-C + h\nu \rightarrow Mb^*OC \rightarrow Mb + CO$$

The aim of both studies was to determine the position of the CO molecule in the transition state and to elucidate the response of the protein active centre to the dissociation of the Fe–O bond. The experimental solution of both problems required the determination of the three-dimensional structure of the short-lived intermediate Mb* and its comparison with the structures of the native myoglobin and its inhibitor complex.

Schlichting et al.[296] chose as the object of study a mutant myoglobin forming a hexagonal lattice. The specimen was cooled to ~20 K and irradiated with visible light from the usual source to initiate and maintain the photolysis; the X-ray diffraction pattern was obtained with the aid of synchrotron radiation (Fig. 21). The second experiment mentioned was formulated in accordance with a similar scheme.[297] The differences consisted in the employment in the latter case of native myoglobin (from whale sperm), the crystals of which have a monoclinic and not a hexagonal lattice; the specimen was cooled to ~40 K and was irradiated with light from a powerful laser source.

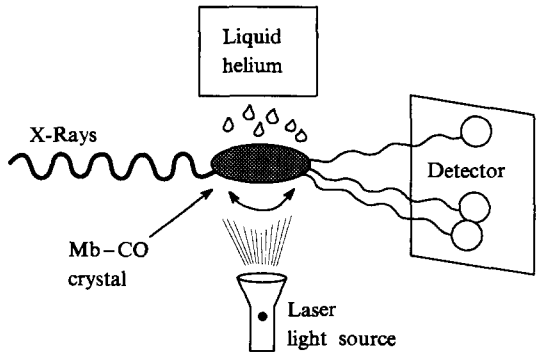


Figure 21. Schematic illustration of the experimental apparatus for X-ray diffraction by Mb–CO crystals during photolysis.[296–298]

Apart from certain quantitative discrepancies in the estimation of the conformational changes in the myoglobin active centre, the results of both investigations agreed. It was found in both cases that, on photodissociation of the complex, the CO molecule is removed from the Fe atom but remains in the active centre and is located parallel to the plane of the haem group at a distance of ~3.6 Å. The Fe atom shifts simultaneously in the same direction over a distance of 0.2 Å (data of Schlichting et al.[296]). In addition, on photolysis, changes were noted in the positions of the side chains of the distal His and Arg residues and of the proximal His residue and also of the α-helix F. Teng et al.[297] did not observe such changes, which apparently cannot be accounted for by the different packing of the crystals in the native and mutant myoglobin. It had been shown earlier that the mutation of the specimen employed by Schlichting et al.[296] does not entail conformational changes in the three-dimensional structure of the protein and does not affect it physiological properties.[299] The structural changes noted on photolysis agree with spectroscopic data[300,301] and the results of a molecular dynamics calculation.[302,303]

The results of the X-ray diffraction studies on the mechanisms of the functioning of proteins, carried out using synchrotron radiation and published towards the end of 1994, have been examined in this section. So far there have been few such investigations, but there is no doubt that they reflect the fundamental trend in the development of the method. Whereas only a few years ago, its purpose might have been formulated as concerning only the study of the three-dimensional structures of protein molecules and their stable complexes, nowadays the three-dimensional structures of the intermediates at the same atomic level have become accessible to investigation. Thus X-ray diffraction analysis has passed from the study of the molecular morphologies of the starting materials and final products of physiological reactions to the molecular morphologies of the intermediates. This finding denotes a jump in the development of the method — a qualitative change in its possibilities for the solution of an enormous number of new problems in molecular biology.

VIII. Multiwave anomalous diffraction

The most complex problem in X-ray crystallography is undoubtedly the phase problem. It has in fact held back the elucidation of diffraction patterns and the determination of three-dimensional molecular structures.

In the case of proteins, a solution to the phase problem was found by introducing into the X-ray diffraction analysis isomorphous derivatives — nonvalence complexes of the protein with heavy atoms (Au, Pb, Hg, Ag, Tl, etc.), the addition of which should not distort the three-dimensional structure of the protein molecule and the crystal lattice. The differences between the intensities of the beams diffracted by the crystals of the native protein and its derivatives can be used to determine the phases, provided that one establishes beforehand the positions of the heavy atoms. There are several different ways of solving this problem.[5,304]

The method for the determination of phases with the aid of heavy atoms, which has been called multiplet isomorphous substitution (MIS), was first tested in 1954 in a study of the crystal structure of haemoglobin.[305] Since then and almost until the very latest time, it remained virtually the only approach to the calculation of the required phase angles. However, throughout all these years the search for an alternative approach did not cease, because the MIS method is far from perfect.

Another solution to the phase problem became possible by employing the anomalous X-ray scattering effect. The classical theory of this phenomenon was developed by Honl as early as 1933.[306]

According to diffraction theory, the atomic scattering amplitude f is a complex quantity and can be formulated as follows:

$$f = f^0 + f^\Delta e^{ik} = f^0 + f' + f'' ,$$

where f^0 is the amplitude of the elastic 'normal' scattering, whilst $f^\Delta e^{ik}$ is the 'anomalous' correction formulated as the sum of the real dispersion (f') and imaginary absorption (f'') components. The correction f^Δ depends greatly on the radiation wavelength λ, whereas the usual scattering amplitude (f) is largely a function of the Bragg scattering angle θ.

The absolute value of f'' is proportional to the absorption coefficient. It therefore acquires great importance when the frequency of the X-ray quantum is close to the absorption edge of the atom.

The crystals of compounds containing no anomalous centres scatter X-rays in the normal manner. There is no anomalous scattering in this case, since the frequencies of the intrinsic vibrations of the H, C, N, O, and S atoms are far too remote from the frequency of the K emission for resonance to occur. The overall diffraction by a crystal (including a protein crystal) having anomalously scattering centres is described for each measured reflection by the structure factor ${}^\lambda F_T$. It includes the normal component ${}^0F_T$, consisting of the scattering components due to all the atoms in the protein structure, and the anomalous component. The latter is equal to the product of the normal components for the anomalously scattering centres ${}^0F_A$ and the ratio of the anomalous and normal scattering factors $f^\Delta(\lambda)/f^0(\theta)$. Consequently

$${}^\lambda F_T = {}^0F_T + {}^0F_A \cdot f^\Delta(\lambda)/f^0(\theta) .$$

Karle in 1980 [307] and later Hendrickson[308] showed that precise measurements of the intensities of all the diffraction reflections from a single crystalline protein specimen with anomalous scattering, obtained for several (3–5) X-ray wavelengths, make it possible to calculate from the set of experimental ${}^\lambda I$ data the real components of the factors $|{}^0F_T|$, $|{}^0F_A|$, and $\Delta\Phi^0 = \Phi_T^0 - \Phi_A^0$. The values of $|{}^0F_A|$ are then used to determine the positions in space of the anomalous scattering centres. Initially the values of Φ_A^0 and then, knowing $\Delta\Phi^0$, those of Φ_T^0 are calculated on this basis.

Thus the phase problem may also be solved without resorting to the multiplet isomorphous substitution method. However, the cost of such a solution remained for a long time too high and at least two conditions, fairly difficult to fulfill, had to be observed. Firstly, the test specimen must contain anomalously scattering atoms, which may not be present in the native protein. Secondly, in order to optimise the anomalous scattering effect, it is necessary to have a source of X-rays, such as the radiation from a synchrotron, continuously tuned to different wavelengths with a high accuracy and over a wide spectral range. Currently, the above difficulties of the multiwave anomalous diffraction (MAD) method have been largely overcome and its evident advantages over the traditional approach to the solution of the phase problem (MIS) have begun to play a decisive role.

The monopoly of the isomorphous substitution method in the X-ray crystallography of proteins was first broken in 1981[309] when it became possible to establish the three-dimensional atomic structure of crambin from the diffraction pattern of a single crystalline specimen. The phase problem was solved by the MAD method employing three wavelengths of the synchrotron radiation and the anomalous scattering by the sulfur atoms in the methionine residues forming part of the aminoacid sequence of the protein. It became evident that synchrotron radiation may render MAD a powerful instrument in the study of protein structures. However, the use of sulfur as the anomalously scattering centre was not entirely satisfactory. The dispersion (f') and absorption (f'') components of the anomalous scattering factor for this atom are much smaller than the normal component of the structure factor and are many times smaller than the corresponding values of the components of the anomalous scattering by heavier atoms. In the subsequent X-ray diffraction analysis of proteins with the aid of MAD, the use of sulfur as the anomalously scattering atom had to be abandoned. Proteins containing metal atoms (Fe, Zn, Cu, etc.) in the native state and isomorphous heavy atom derivatives of proteins became the objects of study, as in the MIS method. After crambin, the structures of parvalbumin,[310] cytochrome c',[311] azurin,[312] haemoglobin,[313,314] ferroxin,[314] selenolanthionine,[315] and selenobiotinyl-streptavidin[314] were solved by using anomalous scattering.

The experience gained in studies involving MAD made it possible to improve many experimental and mathematical procedures of the resonance method,[316] as a result of which the calculations of the phases with the aid of MAD are just as accurate as in the multiplet isormorphous substitution procedure. The solution to the phase problem based on the anomalous scattering effect has become universal and is applicable to any crystalline protein specimens containing anomalously scattering centres. The method for the introduction of diffraction labels, necessary in connection with the use of MAD, has also become general.[317]

The accuracy of the X-ray diffraction data obtained with the aid of MAD and MIS evidently improves the closer the isomorphism of the protein derivatives with resonance centres (for MAD), and with heavy atoms (for MIS). In this respect, the situation is preferable in the case of anomalous scattering, because here all the necessary data for the determination of the three-dimensional structure of the protein molecule can be obtained by irradiating a single crystal at several wavelengths. In order to make use of this advantage, it is necessary to have a method which would guarantee the reduction to a minimum of the probability of the breakdown of iso-morphism when resonance labels are employed in situ, which would be sufficiently simple, and which could be used in the X-ray diffraction analysis of any protein. The method used to obtain selenomethionine protein preparations, giving rise to anomalous scattering, is extremely close to satisfying these requirements.[317]

As early as 1957, it was established that auxotrophic [auxoheterotrophic? (Ed. of Translation)] *E. coli* cells, which have lost the ability to synthesise methionine, can develop successfully and can give rise to at least 100 generations after the addition of selenomethionine to the nutrient medium.[318]

It was shown thereby that the proteins required for the maintenance of the life of *E. coli*, in which all the Met residues have been replaced by Se-Met, continue to function normally. Later these results were confirmed by the deliberate creation of a clone auxotrophic in relation to methionine by damaging the MetA gene.[319] It became possible to synthesise the aminoacid sequences of *E. coli* in which all the sites designated for the Met residues contain the Se-Met residues. Developing further this aspect of the research, Hendrickson et al.[317] devised a method for the incorporation of Se-Met residues into recombinant proteins produced by the *E. coli* plasmids. The authors' preceding studies on the three-dimensional structures of the selenolanthionine[315] and selenobiotinylstreptavidin[314] molecules with the determination of the phases by the MAD method showed that the Se atom is an extremely effective anomalous scattering centre. One can therefore assume that the proposed method for the incorporation of selenomethionine residues in the methionine positions will become a universal approach for proteins, especially those which do not contain natural resonators in the native state.

The authors of the method used it to obtain two thioredoxins of the T4 cells of *E. coli* with 100% replacement of methionine by selenomethionine. The crystals of [Se-Met]-substituted thioredoxins proved to be fully isomorphous with the crystals of the natural recombinant proteins. The diffraction measurements were performed at three selected synchrotron radiation wavelengths. One wavelength corresponded to minimum anomalous scattering (f'_{min}), the second corresponded to the maximum absorption energy (f''_{max}), and the third wavelength was remote from the band due to the electronic transitions in the Se atom and hence corresponded to the normal scattering factor (f^0). Fig. 22 presents the dependence of the anomalous scattering factors f' and f'' on the irradiation wavelength obtained for a single orientation of the *E. coli* [Se-Met]-thioredoxin crystal. The high sensitivity of f' and f'' to changes in the wavelength in the region of 0.98 Å and the distinct edge effect indicate the considerable possibilities of the MAD method in the solution of the phase problem: the phases are initially found for several anomalously scattering centres and then, on this basis, for all the nonhydrogen atoms of the protein (for further details, see Hendrickson[320]).

Thus, towards the beginning of the 1990s the internal problems of the multiwave anomalous diffraction method were largely solved. Hendrickson's method for the preparation of selenomethionine derivatives of proteins rapidly gained recognition. In the studies of recent years, the crystals of such proteins have frequently served for the measurement of the diffraction patterns arising from both anomalous (using the resonance wavelengths) and normal scattering (considering selenium as a heavy atom). The study of Ramakrishnan et al.,[273] in which the three-dimensional structure of the globular domain of the linker histone H5 was determined with a resolution of 2.5 Å, is precisely of this kind.[273] The [Se-Met]-derivative of the domain was synthesised by genetic engineering methods. The crystals grown from it were fully isomorphous with the crystals of the native protein. The phases were determined by means of the MAD and MIS methods. The authors noted that treatment of the results by the traditional method combined with the recently proposed procedure for the refinement of the heavy atom parameters, called the maximum entropy or maximum similarity method,[321,322] led to somewhat preferable electron density maps compared with the procedure called the algebraic method.[316]

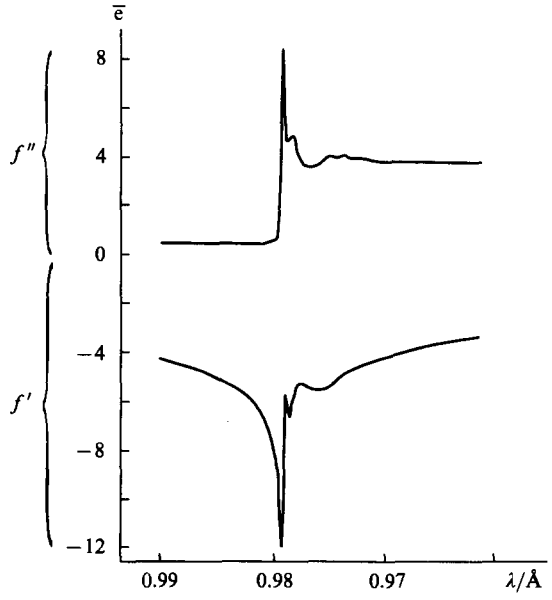

Figure 22. Anomalous scattering factors f' and f'' for crystals of *E. coli* selenomethionine thioredoxin measured in the vicinity of the absorption edge of selenium.

Newman et al.[323] established with a resolution of 1.95 Å the crystal structure of restriction endonuclease Bam HI, consisting of 213 aminoacid residues. The authors resorted to the use of the selenomethionine version after the failure of attempts to interpret the Patterson map constructed from measurements for several heavy atom protein derivatives. The [Se-Met]-endonuclease was expressed in the auxotrophic *E. coli* cells grown in a medium incorporating selenomethionine instead of methionine together with 19 standard aminoacids.[317] The object of study thus obtained had the same activity as the native enzyme and its crystals were fully isomorphous with those of the latter. The novel feature of the above investigation is the fact that the three-dimensional structure of the endonuclease was determined by the combination of the phase information, contained in the anomalous diffraction data, obtained by the maximum entropy and algebraic methods.[316,321,322] Both methods lead to approximately the same phase errors in relation to the phases of the refined model. The authors suggest that the averaged phases are appreciably closer to reality than those obtained by one of the methods. The [Se-Met]-BamHI crystals were irradiated at 5 °C at three wavelengths corresponding to the Se absorption edge (0.979 Å) and peak (0.978 Å) and the remote region of the spectrum (0.900 Å).

A human embryo gonadotropin, the structure of which has been described,[324] is a glycoprotein of the placenta hormone (237 aminoacid residues) stimulating the secretion of the steroid progesterone, which maintains the pregnancy. Like the recombinant [Se-Met]-protein, it was synthesised in the cells of the hamster ovary. This somewhat unexpected finding shows that the eukaryotic mammalian cells can be just as highly tolerant as the prokaryotic *E. coli* cells as regards the complete substitution of methionine by selenomethionine. The level of substitution in the above study was 92%. The structure of gonadotropin after partial deglycosylation was identified with a resolution of 2.6 Å. Diffraction data obtained by the MAD method were employed. The crystalline specimen was irradiated at four synchrotron radiation wavelengths. Two of them (~0.98 Å) were at the Se absorption edge and peak, whilst the other two were to one side of the absorption band. The approximate values of the anomalous scattering components f' and f'' were found for each wavelength.

The MAD method has been used[276] to determine the three-dimensional structure of the allosteric regulator enzyme glutamine–5-phosphoribosyl-1-pyrophosphate (PRPP) amidotransferase.[276] The protein consists of 465 aminoacid residues and an Fe atom, which is an anomalously scattering centre on irradiation at three wavelengths from a synchrotron (1.7425, 1.7390, and 1.5000 Å). The crystalline form of PRPP amidotransferase was obtained in the form of a homotetramer with a molecular mass of ~200 kDa. In the preceding X-ray diffraction analyses by the anomalous diffraction method, the objects of

study were proteins whose molecular masses did not exceed 30 kDa. The above study indicates the major possibilities of MAD in the determination of the three-dimensional structures of cumbersome protein complexes.

IX. Conclusion

The studies examined clearly leave no doubt that during the 1990s the X-ray diffraction analysis of proteins was applied to the solution of new problems of primary interest for molecular biology whilst retaining the previous high rate of extensive development. The main cause of the qualitative change which has arisen in the possibilities of the crystallography of macromolecules is associated with the employment of synchrotron radiation and new methods for the measurement of the diffraction pattern. Firstly, the transition to a new source of X-rays weakens the requirements which must be met by the size of the crystals, which is especially important in the structural analysis of high-molecular-mass proteins and their complexes with large unit cells. Secondly, the continuous synchrotron radiation spectrum and the ease of selecting any wavelength of the monochromatic radiation permitted a new approach to the solution of the phase problem and the development of the multiwave anomalous diffraction method, in which only one crystalline specimen is required for the determination of the phases. The procedure for the recombinant formation in auxotropic cells of proteins in the aminoacid sequences of which all the methionine residues have been replaced by selenomethionine supplemented significantly the MAD method. The use of [Se-Met]-proteins not only frees the X-ray diffraction analysis from the prolonged routine procedure involving the preparation of several isomorphous heavy atom protein derivatives but virtually eliminates the very problem of isomorphism.

Finally, the most important feature—the application in protein crystallography of synchrotron radiation and of new coordinate detectors—reduces the exposure time by at least 2–3 orders of magnitude. It is difficult to overestimate the importance of this fact, since the determination of the three-dimensional structures at the atomic level of intermediates in the processes involved in vital activity becomes possible. Whereas until recently, X-ray diffraction analysis was in fact the only direct method for the investigation of the native conformations of protein molecules with atomic resolution, nowadays, literally in front of our very eyes, it is becoming a source (also the only one available) of just as detailed information about the three-dimensional structures of intermediates.

Abstract. Experimental data on the homogeneous catalysis by iron compounds of the activation of O_2 and H_2O_2 and of their oxidation of organic substances, and the current ideas on this subject are described. Data concerning the formation of various intermediate species and of their role in these processes are analysed. A series of catalytic systems simulating the functional activity of certain enzymes are considered at a model level. The bibliography includes 338 references.

I. Introduction

The activation of O_2 and H_2O_2 by aquoiron ions and iron complexes in biological, environmental, and industrial oxidation–reduction processes has been the subject of numerous publications. The experimental results available on this question have been partly surveyed in monographs and reviews.[1–5] The mechanisms of model and real processes have been investigated mainly at a qualitative level and only rarely at a semi-quantitative level. This situation is due to the complexity of the systems investigated, the multivariability of the possible routes followed by the processes, and the dependence of the latter on many parameters. Molecular oxygen and hydrogen peroxide, which are ecologically ideal oxidants, are reduced in the presence of iron compounds, generating highly reactive superoxide and hydroxyl radicals as well as species of the ferryl type $LFe^{IV}=O^{2+}$. The rapid reaction of these species in biological or nonbiological processes, the difficulty of their identification, their specific and nonspecific activity, and the influence of various parameters (temperature, the nature of the solvent and the ligand L, pH, the ratio of the ligand and iron ions, the characteristics of the oxidant, the concentrations of the components, etc.) create significant difficulties in the study of the mechanisms of the catalytic processes in which they participate. Nevertheless, during the last 10–15 years vigorous studies have been performed on the mechanisms of catalytic reactions involving the oxidation of various substrates by environmentally pure oxygen and hydrogen peroxide, on the mode of these reactions, and in particular on the elucidation of the role of iron compounds as catalysts in these reactions. Conditions have been developed for the optimisation of the processes and foundations have been laid for the prediction of the paths in the reactions of the substrates. The role played by iron compounds in the manifestation of toxicity by the products of the conversion of O_2 in vivo has been explained at a model level.

In order to establish the mechanisms of the catalytic oxidation of the various organic substances, it is important to have information about the radical and nonradical intermediates formed under these conditions, for example the ferryl complexes. The experimental data concerning the latter refer mainly to the 1980s.

II. Iron compounds and the mechanisms of catalytic decomposition of H_2O_2

1. Catalysis by Fe^{2+} and Fe^{3+} aquo-ions

After the demonstration of the catalytic activity of aquoiron ions in the H_2O_2 decomposition reactions (see the relevant reviews[1,3]), a detailed study was made of the $Fe^{2+}-H_2O_2$ system (the Fenton reagent)[2] and the mechanism of this process was analysed and discussed.[1–3,6–14] Numerous studies have been devoted to the kinetics of the decomposition of H_2O_2 by the Fe^{3+} aquo-ions.[1,3,6,7,9,15–19, etc.]

The study of the $Fe^{2+}-H_2O_2$ system (and also the $Fe^{2+}-H_2O_2$–substrate systems) made it possible to develop mechanisms for the decomposition of H_2O_2 catalysed by aquoiron(II) ions. All the reactions considered in this respect are compiled in Table 1. The question of the generation of the $^{\bullet}OH$ radicals in the $Fe^{2+}-H_2O_2$ system is of fundamental importance. It has now been demonstrated unambiguously that such radicals are formed in this process. The experimental data obtained (surveyed in a monograph[3] and partly presented in Scheme 1 and in Table 1) made it possible to determine the elementary stages in the decomposition of H_2O_2 by Fe^{2+} aquo-ions and their sequence depending on the experimental conditions.

Scheme 1 (p. 1107) presents the reactions involved solely in the H_2O_2 decomposition process in the $Fe^{2+}-H_2O_2$ system.[3]

[a] The rate constants are expressed in litre $mol^{-1}\ s^{-1}$, the decomposition constants in s^{-1}, and the equilibrium constants in mol $litre^{-1}$.

The following set of consecutive reactions in the $Fe^{2+}-H_2O_2$ system is nowadays regarded as generally accepted.

Scheme 2

1. $Fe^{2+}+H_2O_2 \longrightarrow Fe^{3+}+HO^{\bullet}+OH^-$
13. $Fe^{2+}+{}^{\bullet}OH \longrightarrow Fe^{3+}+OH^-$
20. ${}^{\bullet}OH+H_2O_2 \longrightarrow HO_2^{\bullet}+H_2O$
18. $Fe^{3+}+HO_2^{\bullet} \longrightarrow Fe^{2+}+H^++O_2$
19. $Fe^{3+}+O_2^{\bullet-} \longrightarrow Fe^{2+}+O_2$
14. $Fe^{2+}+HO_2^{\bullet} \longrightarrow Fe^{3+}+HO_2^-$

This series of stages occurs under the following conditions: $0.5 < [H_2O_2]/[Fe^{2+}] < 200$, pH > 2. The catalytic decomposition of H_2O_2 by Fe^{2+} aquo-ions proceeds in accordance with a radical-ion cyclic mechanism (a characteristic feature of this mechanism is the equality of the rates of the chain initiation and propagation stages) when $0.5 < [H_2O_2]/[Fe^{2+}] < 3\times10^6$ and in accordance with a radical-chain mechanism {only in this case it is possible to differentiate clearly the chain initiation [reaction (1)], propagation [reactions (20) and (21)], and termination [reaction (18) and/or (19)] steps} when $[H_2O_2]/[Fe^{2+}] > 3\times10^6$.

Scheme 1

A. Processes with participation of Fe^{2+}

1. $Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + {}^{\bullet}OH + OH^-$
2. $Fe^{2+} + H_2O_2 \longrightarrow FeO^{2+} + H_2O$
3. $Fe^{2+} + H_2O_2 \longrightarrow Fe^{4+} + 2OH^-$
4. $FeOH^+ + H_2O_2 \longrightarrow Fe^{3+} + {}^{\bullet}OH + 2OH^-$
5. $FeOH^+ + H_2O_2 \longrightarrow FeO^{2+} + H_2O + OH^-$
6. $(H_2O)_5Fe(H_2O)^{2+} + H_2O_2 \rightleftharpoons (H_2O)_5Fe(H_2O_2)^{2+} + H_2O$
7. $(H_2O)_5Fe(H_2O_2)^{2+} \xrightarrow[-H^+]{} (H_2O)_4(OH^-)FeO^{2+} + H_2O$
8. $(H_2O)_5Fe(H_2O_2)^{2+} \xrightarrow[-H^+]{} (H_2O)_5(OH^-)Fe^{3+} + {}^{\bullet}OH$
9. $(H_2O)_5Fe(H_2O_2)^{2+} + Fe^{2+}(H_2O)_6 \longrightarrow 2\,(H_2O)_5Fe^{3+}(OH^-) + H_2O$
10. $Fe^{2+} + HO_2^- + H_2SO_4 \longrightarrow Fe(SO_4H)(OOH) + H^+$
11. $Fe^{2+}SO_4 + H_2O_2 \longrightarrow FeSO_4(H_2O_2)$
12. $Fe(SO_4H)(OOH) + H_2O_2 \longrightarrow Fe(SO_4H)(OH) + H_2O + O_2$
13. $Fe^{2+} + {}^{\bullet}OH \longrightarrow Fe^{3+} + OH^-$
14. $Fe^{2+} + HO_2^{\bullet} \longrightarrow Fe^{3+} + HO_2^-$
15. $Fe^{2+}(H_2O_2)(HO_2) \rightleftharpoons Fe^{2+}(HO_2^{\bullet})(HO^+) + OH^-$
16. $Fe^{2+}(HO_2^{\bullet})(HO^+) \rightleftharpoons Fe^{3+}(HO_2^{\bullet})(HO^{\bullet})$
17. $[Fe_2(OH)_2]^{2+} + H_2O_2 \longrightarrow [Fe_2(OH)_2]^{4+} + 2OH^-$

B. Processes with participation of Fe^{3+}

18. $Fe^{3+} + HO_2^{\bullet} \longrightarrow Fe^{2+} + H^+ + O_2$
19. $Fe^{3+} + O_2^{\bullet-} \longrightarrow Fe^{2+} + O_2$

C. Processes with participation of ${}^{\bullet}OH$, $HO_2^{\bullet}$ ($O_2^{\bullet-}$)

(in addition to those listed above)

20. ${}^{\bullet}OH + H_2O_2 \longrightarrow HO_2^{\bullet} + H_2O$
21. $HO_2^{\bullet} + H_2O_2 \longrightarrow O_2 + H_2O + {}^{\bullet}OH$

D. Processes with participation of Fe^{4+}

22. $FeO^{2+} + H_2O_2 \longrightarrow Fe^{2+} + O_2 + H_2O$
23. $Fe^{4+} + OOH^- \longrightarrow Fe^{2+} + O_2 + H^+$
24. $Fe^{4+} + HO_2^- \rightleftharpoons FeOOH^{3+} \longrightarrow Fe^{3+} + HO_2^{\bullet}$
25. $(H_2O)_4(OH^-)Fe^{2+}O + H_2O \longrightarrow (H_2O)_4(OH^-)_2Fe^{3+} + {}^{\bullet}OH$
26. $(H_2O)_4(OH^-)Fe^{2+}O + Fe^{2+} \longrightarrow 2\,Fe^{3+}(OH^-)(H_2O)_5$
27. $Fe^{4+} + Fe^{2+} \longrightarrow 2\,Fe^{3+}$
28. $FeO^{2+} + H_2O_2 \longrightarrow HO_2^{\bullet} + OH^- + Fe^{3+}$

E. Acid–base equilibria

29. $Fe^{2+} + H_2O \rightleftharpoons FeOH^+ + H^+$
30. $2\,Fe^{2+} + 2\,H_2O \rightleftharpoons Fe_2(OH)_2^{2+} + 2\,H^+$
31. $H_2O_2 \rightleftharpoons HO_2^- + H^+$
32. $HO_2^{\bullet} \rightleftharpoons H^+ + O_2^{\bullet-}$
33. $(H_2O)_5Fe(H_2O_2)^{2+} \rightleftharpoons (H_2O)_4(OH^-)Fe(H_2O_2)^{2+} + H^+$

According to a series of data,[16,20,46,50,65–73] the decomposition of H_2O_2 by Fe^{3+} aquo-ions (Ruff's system)[74,75] in an acid medium (at pH $\leqslant$ 2) proceeds via a radical-chain mechanism. A different mechanism of this process has sometimes been suggested.[45,49,51–53,57,76–81] All the possible steps of the process occurring in the $Fe^{3+}-H_2O_2$ system, proposed by various investigators, are presented in a monograph.[3]

Of the principal experimental evidence in support of the operation of a radical-chain mechanism of the decomposition of H_2O_2 in the $Fe^{3+}-H_2O_2$ system, we shall mention the following: (a) evidence based on the inhibiting effects of various organic substances;[16,17,20,50,66–73,82] (b) evidence indicating (directly or indirectly) the generation of the ${}^{\bullet}OH$ radicals[72,73,83–89] and/or $O_2^{\bullet-}$ radical-ions[16,50,66–68,82,90] in the system; (c) evidence confirming the existence of one-electron transfer steps which include the oxidation-reduction cycle

$$Fe^{3+} \underset{-\bar{e}}{\overset{\bar{e}}{\rightleftharpoons}} Fe^{2+},$$

(the assumption[91,92] of the formation of Fe^{2+} has been confirmed[16,20,85,92]).

The question arises of the evidence used by the supporters of the ion-molecule mechanism. The principal evidence is believed to be[49,76–79,81,93–95] the formation in the reaction medium of active intermediate compounds and primarily peroxo-complexes. Indeed the peroxo-complex $FeHO_2^{2+}$ is formed in the system.[49,51,76–79,81,94–98] However, it has been shown[3] that this does not conflict with the occurrence of the process by a radical-chain mechanism.

Purmal'[16] demonstrated qualitatively and quantitatively that, among all the possible reactions considered in the literature as steps in the H_2O_2 decomposition by Fe^{3+} aquo-ions,[3] only the series of consecutive steps presented in Scheme 3 actually occur. This scheme is nowadays generally accepted to be the description of the mechanism of the decomposition of H_2O_2 by Fe^{3+} aquo-ions.

Scheme 3

Initiation

$FeHO_2^{2+} \longrightarrow Fe^{2+} + HO_2^{\bullet}$

$FeHO_2^{2+} + FeOH^{2+} \longrightarrow 2\,Fe^{2+} + O_2 + H_2O$

Chain propagation

$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + {}^{\bullet}OH + OH^-$

${}^{\bullet}OH + H_2O_2 \longrightarrow HO_2^{\bullet} + H_2O$

$O_2^{\bullet-} + Fe^{3+} \longrightarrow Fe^{2+} + O_2$

Chain termination

$Fe^{2+} + HO_2^{\bullet} \longrightarrow Fe^{3+} + HO_2^-$

$Fe^{2+} + {}^{\bullet}OH \longrightarrow Fe^{3+} + OH^-$

$HO_2^{\bullet} + HO_2^{\bullet} \longrightarrow H_2O_2 + O_2$

Acid–base equilibria

$H_2O_2 \rightleftharpoons H^+ + HO_2^-$

$HO_2^{\bullet} \rightleftharpoons H^+ + O_2^{\bullet-}$

$Fe^{3+} + H_2O \rightleftharpoons FeOH^{2+} + H^+$

$Fe^{3+} + H_2O_2 \rightleftharpoons FeHO_2^{2+} + H^+$

Analysis of the literature devoted to studies of the kinetics and mechanisms of catalytic decomposition of H_2O_2 by Fe^{2+} and Fe^{3+} aquo-ions demonstrated, firstly, the complexity of the reactions occurring in the $Fe^{2+}-H_2O_2$ and $Fe^{3+}-H_2O_2$ systems; secondly, it demonstrated the possibility of kinetic studies on such systems and the limitations of this possibility; thirdly, it made it possible to devise procedures for the determination, discrimination, and justification of the reaction mechanisms in complex systems including a set of a large number of consecutive elementary stages.

When iron ions are replaced as catalysts by their coordination compounds, the decomposition of H_2O_2 is in many cases accelerated.[1,3,16,99,106] The catalytic activity of the Fe^{3+} complexes is in many cases higher than that of aquoiron ions. Among the iron complexes with a catalase-like activity, the coordination compounds of Fe^{3+} with triethylenetetramine ('inorganic catalase') exhibit the highest activity in the hydrogen peroxide decomposition reaction.[3]

Complex formation promotes the occurrence of the process by different mechanisms depending on the nature of the ligand. This can be seen from the data presented in Table 2.

The oxidation-reduction decomposition of H_2O_2 by iron(III) complexes can also proceed via different mechanisms: radical-chain (I), ion-molecule (II), and chain-nonradical (III). A general scheme for the reactions occurring in the Fe^{3+} – ligand – H_2O_2 systems is presented in Scheme 4.

Cycle I. The free radical species $O_2^{\cdot-}(HO_2^{\cdot-})$ and $^{\cdot}OH$ are generated during the process and the one-electron transfer stages

$$L''Fe^{3+} \underset{-\bar{e}}{\overset{\bar{e}}{\rightleftharpoons}} L'''Fe^{2+}$$

occur. The rate of gas evolution (w_{O_2}) appreciably exceeds the rate of initiation (w_i). This mechanism operates in the Fe^{3+}–2,2′-Bipy – H_2O_2,[3,15,107] Fe^{3+} – EDTA – H_2O_2,[117–119] Fe^{3+} – H_2LM – H_2O_2[3,113,120] Fe^{3+} – Acid Chrome Dark-Blue – H_2O_2,[2] Fe^{3+} – ethylenediamine – H_2O_2,[119,121] Fe^{3+} – glutamic acid – H_2O_2,[122,123] and certain other systems.

Cycle II. The main process does not include the reactions of the $^{\cdot}OH$ and $O_2^{\cdot-}$ radical species. The two-electron transfer stage

$$L'Fe^{2+} \underset{-2\bar{e}}{\overset{2\bar{e}}{\rightleftharpoons}} L'Fe^{4+}$$

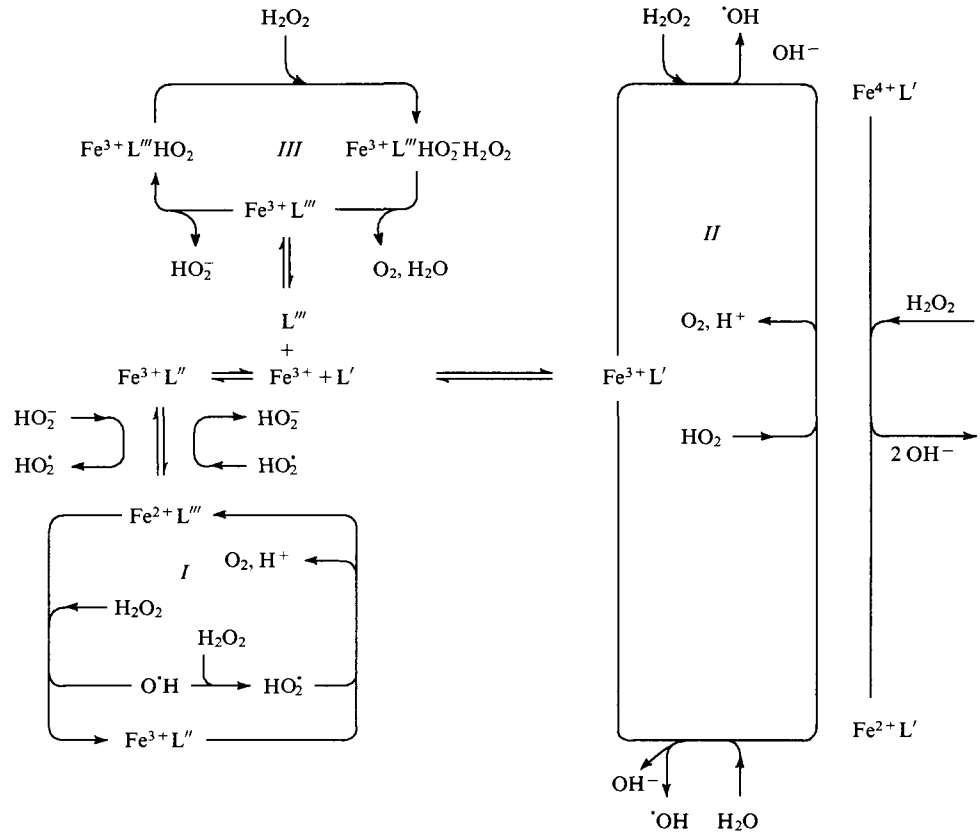
takes place. As in cycle I, $w_{O_2} \gg w_i$.

This mechanism operates, in particular, in the decomposition of H_2O_2 by the coordination compounds of Fe^{3+} with triethylenetetramine[3,104–106] and histidine.[3,111,124–126]

Cycle III. The catalytic process proceeds via the formation of mono- and di-peroxo-complexes. In the course of the reaction, the oxidation state of the central ion in the complex catalyst remains unchanged and the $^{\cdot}OH$ and $HO_2^{\cdot}$ ($O_2^{\cdot-}$) radical species are not generated in the reaction medium. It has been shown that the decomposition of H_2O_2 by the coordination compounds of Fe^{3+} with 4′,4″,4‴-tetrasulfophthalocyanine (PTS),[116] *N,N′*-bis-(2-methylpyridyl)ethylenediamine,[127] and quaterpyridyl[127] proceeds in accordance with this mechanism.

Analysis of published data[3] made it possible to arrange systematically the factors determining the catalytic activity of the Fe^{2+} and Fe^{3+} ions on complex formation and the characteristic features of the catalytic processes in the presence of coordination compounds of iron. The hydrolytic stability of iron ions, their electrochemical properties, and the lability of the coordination sphere change on complex formation. All this leads ultimately to a change in the catalytic activity of the aquoiron ions.

2. Oxidation of organic substrates by the $Fe^{2+}(LFe^{2+})$–H_2O_2 system



The results of the numerous studies devoted to the elucidation of the mechanisms of the oxidation of organic substrates by the Fe^{2+} – H_2O_2 system have been arranged systematically to the fullest extent by Walling.[29] However, the scheme which he presented does not embrace the entire wide variety of such mechanisms. The question of the nature of the substrate (S) is considered to only a limited extent in his communication,[29] the influence of the formation of a complex between the substrate

Table 2. The mechanisms of the interaction of the iron(II) complexes with H_2O_2.

System[a]	Elementary mechanism of the interaction with H_2O_2	Process mechanism	pH of medium	Ref.
$Fe^{2+}-Bipy-H_2O_2$	$FeBipy_n^{2+} + H_2O_2 \longrightarrow FeBipy_n^{3+} + {}^{\cdot}OH + OH^-$	radical-chain	4–6	107
$Fe^{2+}-Phen-H_2O_2$	$FePhen^{2+} + H_2O_2 \rightleftharpoons FePhenH_2O_2^{2+} \longrightarrow$ $\longrightarrow FePhen^{3+} + O^{\cdot}H + OH^-$	radical-ion	4–5	108
	$FePhen_n^{2+} + H_2O_2 \longrightarrow FePhen_n^{3+} + {}^{\cdot}OH + OH^-$	"	2–5	109
$Fe^{2+}-His-H_2O_2$	$Fe(His)_2 + H_2O_2 \longrightarrow Fe(His)_2^+ + {}^{\cdot}OH + OH^-$	"	2–5	110
	$Fe^{2+}(His)_2 + H_2O_2 \longrightarrow Fe^{4+}(His)_2 + 2\,OH^-$	ion-molecule	7–8	111
$Fe^{2+}-H_4T-H_2O_2$	$H_2TFe^{2+} + H_2O_2 \longrightarrow H_2TFe^{3+} + {}^{\cdot}OH + OH^-$	radical-ion	2–4	112
$Fe^{2+}-DFH_4-H_2O_2$	$FeDFH_3^+ + H_2O_2 \longrightarrow FeDFH_3^{2+} + {}^{\cdot}OH + OH^-$	cyclic radical-ion	2–4	112
	$FeDFH_2 + H_2O_2 \longrightarrow FeDFH_2 + {}^{\cdot}OH + OH^-$	"	2–4	112
$Fe^{2+}-H_3Cit-H_2O_2$	$FeHCit + H_2O_2 \longrightarrow FeHCit^+ + {}^{\cdot}OH + OH^-$	radical-ion	2–4	112
$Fe^{2+}-H_2LM-H_2O_2$	$Fe^{2+}HLM + H_2O_2 \longrightarrow Fe^{4+}HLM + 2\,OH^-$	radical-chain	2–5	113
$Fe^{2+}-EDTA-H_2O_2$	$EDTAFe^{2+} + H_2O_2 \longrightarrow EDTAFeO^{2+}$	ion-molecule	4–6	2, 114
$Fe^{2+}-TETA-H_2O_2$	$TETAFe^{2+} + H_2O_2 \longrightarrow TETAFe^{4+} + 2\,OH^-$	"	7–8	106
$Fe^{2+}-CN^--H_2O_2$	$[Fe(CN)_5H_2O]^{3-} + H_2O_2 \longrightarrow [Fe(CN)_5(H_2O)]^{2-} + {}^{\cdot}OH + OH^-$	radical-ion	3–5	115, 116

[a] The following notation has been adopted: Bipy = α,α′-bipyridyl, Phen = 1,10-phenanthroline, His = histidine, H_4T = tartaric acid, DFH_4 = dihydroxyfumaric acid, H_3Cit = citric acid, H_2LM = lumomagneson, EDTA = ethylenediaminetetraacetic acid, and TETA = triethylenetetramine.

Scheme 4

L', L'', and L''' are ligands of different kinds.

and Fe^{2+} on the oxidation mechanism is not considered, and no account is taken of the fact that the oxidation proceeds under aerobic conditions (under the influence of oxygen), as usually happens in real systems involving the use of the Fenton reagent and in other similar systems. The problem of the change in the mechanism of the oxidation of organic substrates following the introduction of an additional ligand into the system also requires special consideration. In order to take into account the above factors, it is essential to analyse the results obtained in typical ferroperoxide systems, which are listed below.

1.	$Fe^{2+} - H_2O_2 - S(S_1)$	$S(S_1)$ = noncomplex-forming or weakly complex-forming substrate. In contrast to S, the substrate S_1 has pronounced reducing properties
2.	$Fe^{2+} - H_2O_2 - S - O_2$	Aerobic system
3.	$Fe^{2+} - L - H_2O_2 - S$	The additional ligand L has been introduced into the system
4.	$Fe^{2+} - L - H_2O_2 - S - O_2$	Aerobic system with additional ligand
5.	$Fe^{2+} - H_2O_2 - S_L$	S_L = substrate which functions simultaneously as a ligand
6.	$Fe^{2+} - H_2O_2 - S_L - O_2$	Aerobic system with S_L
7.	$Fe^{2+} - L - H_2O_2 - S_L$	System incorporating L and S_L
8.	$Fe^{2+} - S_L - H_2O_2 - S$	System incorporating S_L and S
9.	$Fe^{2+} - S_L - H_2O_2 - S - O_2$	Aerobic system incorporating S_L and S

These systems can be divided into two groups. In the first group (systems 1–4), the substrate being oxidised does not form a complex with Fe^{2+} or forms it very ineffectively. Here there is little overlap of the electron orbitals of Fe^{2+} and S. The oxidation reaction in systems of this group should proceed via an outer-sphere route (outside the first coordination sphere of Fe^{2+}, i.e. in the reaction volume). In the second group (systems 5–9), the substrate is also a ligand. Here one should expect the formation of intermediate compounds with the substrate and inner-sphere electron transfer. Such subdivision into two groups reflects only the extreme manifestations of complex-forming properties and there is a possibility of a series of intermediate versions.

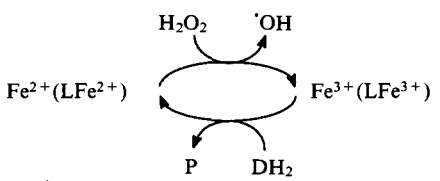
We shall analyse briefly the data obtained in the study of some typcial systems.

a. The $Fe^{2+} - H_2O_2 - S(S_1)$ system

Organic substances (S and S_1) without a chelating capacity towards iron ions or forming relatively unstable complexes with the latter are oxidised by the Fenton reagent.[3,128–134] Analysis of the results shows that, when the chosen substrate (S) or the substrate radical formed (R$^{\cdot}$) has no reducing properties (and the latter also has oxidising properties), the process mechanism includes the following stages:

Scheme 5

1. $Fe^{2+} + H_2O_2 \xrightarrow{k_1} Fe^{3+} + {}^{\cdot}OH + OH^-$
2. ${}^{\cdot}OH + S \xrightarrow{k_2} R^{\cdot}$
3. ${}^{\cdot}OH + H_2O_2 \xrightarrow{k_3} HO_2^{\cdot} + H_2O$
4. $Fe^{3+} + HO_2^{\cdot} \xrightarrow{k_4} Fe^{2+} + H^+ + O_2$
5. $Fe^{2+} + HO_2^{\cdot} \xrightarrow{k_5} Fe^{3+} + HO_2^-$
6. $Fe^{2+} + {}^{\cdot}OH \xrightarrow{k_6} Fe^{3+} + OH^-$



It is not difficult to demonstrate that, when $[S]/[H_2O_2] \geqslant 0.01$ (recalling that k_2 is 2–3 orders of magnitude higher than k_3), only the first two stages will occur in the system — in this case, because $k_6 = 3 \times 10^8$ litre mol^{-1} s^{-1}, $[S]/[Fe^{2+}]$ should be greater than

unity.[29] Consequently the rate of oxidation of the substrate under such conditions is defined by the following expression:

$$w_S = k_1[Fe^{2+}][H_2O_2][S]^{1\to 0}.$$

In this case, Fe^{2+} and S are actually oxidised in the system by hydrogen peroxide via a radical and not a chain mechanism. After the conversion of the initial Fe^{2+} into Fe^{3+}, the oxidation of the substrate also ceases. Since the rate constants for all the elementary stages in Scheme 4 are known, it is possible to calculate theoretically the necessary Fe^{2+}, H_2O_2, and S concentrations in each specific case for the catalytic process to occur via the radical-ion cyclic mechanism. Only when this mechanism operates can one expect the effective oxidation by the Fenton reagent of substrates of the type considered. The effectiveness of the oxidation may be increased also by the additional introduction into the reaction medium of a substance capable of reducing Fe^{3+} to Fe^{2+}, i.e. of regenerating the initial form of the catalyst. The addition of the appropriate reductant (DH_2) leads to the appearance of an oxidation-reduction (OR) cycle in which the $^{\cdot}OH$ radicals, oxidising the substrate, are generated.

Scheme 6

P = product.

Similar OR cycles arise also in the $Fe^{3+}(LFe^{3+}) - H_2O_2 - S$ systems. Such systems, containing $Fe^{2+}(LFe^{2+})$ ions (or other transition metal ions, for example Cu^{2+}),[47] hydrogen peroxide, and the reductant, have been called 'reversible' and have been described, in particular, in the monographs of Dolgoplosk and Tinyakova.[11,13] Various sugars, dienols, rongalite, hydrazine, cysteine, and a series of other organic and inorganic compounds are used as reductants. For example, ascorbic acid (AH_2) increases appreciably the effectiveness of the oxidation of ethyl alcohol by the Fenton reagent[135] ($Fe^{2+} - S_L - H_2O_2 - S - O_2$ is a typical system).[3]

The oxidation reactions of substrates with reducing properties are of greatest interest in the analysis of systems of the type considered because they play a decisive role in the formation of a reversible OR cycle incorporating the following reactions:

Scheme 7

1. $Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + {}^{\cdot}OH + OH^-$
2. $^{\cdot}OH + S_1 \longrightarrow R_1^{\cdot}$
3. $Fe^{3+} + S_1 \longrightarrow R_1^{\cdot\prime} + Fe^{2+}$

$R_1^{\cdot\prime}$ = substrate radical.

As a consequence of this, the substrate undergoes effective catalytic oxidation.

When the reactivity of the substrate radicals (including the reactivity with respect to O_2) is low, the oxidation mechanism (Scheme 7) does not include additional stages. It does not change under aerobic conditions either—conditions are considered where $[S_1]/[H_2O_2] \geqslant 0.1$, since otherwise it is also necessary to take into account the possible occurrence of stages 3–6 (Scheme 5). A similar mechanism has been adopted also in the anaerobic and aerobic oxidation of indigocarmine (IC), indigotetrasulfonate (ITS) and Methylene Blue (MB) by the Fenton reagent.[136] Since the ability of these substrates to form complexes with Fe^{2+} (the OR potential of the Fe^{3+}/Fe^{2+} couple hardly changes when the dye is added), one may assume that the catalyst in the $Fe^{2+} - H_2O_2 - IC(MB, ITS)$ systems is the Fe^{2+} aquo-ion.

A more complex picture is observed (and a greater variety of products are accordingly formed) when the substrate radical in the $Fe^{2+} - H_2O_2 - S(S_1)$ systems is reactive (it possesses mainly reducing properties).

The mechanism of the oxidation of type $S(S_1)$ substrates under anaerobic conditions in the typical $Fe^{2+} - H_2O_2 - S(S_1)$ systems has been investigated in numerous studies, which have been surveyed in the monograph of Sychev and Isak.[3] It has been most fully elucidated, justified qualitatively, and generalised in the publications of Walling and coworkers.[137–140] It has been suggested that the $^{\cdot}OH$ radical formed in the system as a consequence of the interaction of Fe^{2+} with H_2O_2.

Analysis of the possible steps occurring in the $Fe^{2+} - H_2O_2 - S(S_1)$ systems under anaerobic conditions, where the reactive substrate radical is formed, combined with allowance for other data[29,139,140] leads to the following series of consecutive steps:[3]

Scheme 8

Step	Reaction	k_i/litre mol^{-1} s^{-1}
1	$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\cdot}OH + OH^-$	53
3	$^{\cdot}OH + H_2O_2 \rightarrow HO_2^{\cdot} + H_2$	3×10^7
4	$Fe^{3+} + HO_2^{\cdot} \rightarrow Fe^{2+} + H^+ + O_2$	2.1×10^6
5	$Fe^{3+} + HO_2^{\cdot} \rightarrow Fe^{3+} + HO_2^-$	1.5×10^6
6	$Fe^{2+} + {}^{\cdot}OH \rightarrow Fe^{3+} + OH^-$	4×10^8
7	$Fe^{3+} + S_1 \rightarrow Fe^{2+} + R_1^{\cdot}$	–
8	$^{\cdot}OH + R_\alpha H^* \rightarrow R_\alpha^{\cdot} + H_2$	$\sim 10^9$
9	$^{\cdot}OH + R_\beta H^* \rightarrow R_\beta^{\cdot} + H_2$	$\sim 10^9$
10	$^{\cdot}OH + R_\gamma H^* \rightarrow R_\gamma^{\cdot} + H_2$	$\sim 10^9$
11	$R_\alpha^{\cdot} + Fe^{3+} \rightarrow Fe^{2+} + P$	$\sim 10^8$
12	$R_\alpha^{\cdot} + H_2O_2 \rightarrow ROH + {}^{\cdot}OH$	1.6×10^5
13	$R_\alpha^{\cdot} + {}^{\cdot}OH \rightarrow ROH$	$\sim 10^{10}$
14	$R_\gamma^{\cdot} + Fe^2 \rightarrow RH + Fe^{3+}$	–
15	$2R_\beta^{\cdot} \rightarrow$ products (dimers)	–
16	$RH + HO_2^{\cdot} \rightarrow R^{\cdot} + H_2O_2$	–
17	$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}$	$\sim 10^9$

Organic compounds (hydrocarbons, alcohols, aldehydes, acids, etc.), the interaction of which with $^{\cdot}OH$ in the positions indicated (α-, β-, or γ-) results in the abstraction of a hydrogen atom, are designated by an asterisk (RH*).

If the rate constants for the elementary stages presented and the concentrations of the corresponding species are known, it is possible to estimate which reactions make the main contribution to the process under consideration. It is easy to demonstrate that, in a specific instance involving certain concentrations, Scheme 8 reduces to Walling's scheme, which is well known in the literature and has been proposed for the oxidation of organic compounds of different classes under anaerobic conditions.[29] If account is taken of data[29,130,137,138,141–145] indicating the addition of $^{\cdot}OH$ to the substrate and the formation of 'adhesion' radicals, the following additional steps must be included in the mechanism:

Scheme 9

8. $R_iH + {}^{\cdot}OH \longrightarrow R_i^{\cdot}HOH$
10. $R_kH + {}^{\cdot}OH \longrightarrow R_k^{\cdot}HOH$
11. $R_i^{\cdot}HOH + Fe^{3+} \longrightarrow R_i^{\prime}HO + Fe^{2+} + H^+$
14. $R_k^{\cdot}HOH + Fe^{2+} \xrightarrow{H^+} R_k^{\prime}H_2OH + Fe^{3+}$
17. $R_j^{\cdot}HOH + R_jH \longrightarrow R_j{-}R_j + H_2O$

R_i = substrate radical with reducing properties, R_k = oxidant radical, and R_j = radical tending to dimerise.

The mechanism in each specific case must be determined by specified concentration conditions with allowance for the established reaction kinetics, the data concerning the types of

substrate radicals formed in the systems and their reactivities, as well as information about the intermediates obtained and the rate constants for elementary reactions. The problem of obtaining complete information for a particular system is difficult to solve: it is rare to achieve an unambiguous experimental determination of all the types of substrate radicals formed and it is as a rule impossible to detect the intermediates; the rate constants for any elementary stages of the oxidation process are frequently unknown. For this reason, the mechanisms of oxidation of organic substrates by the Fenton reagent under anaerobic conditions have been at the present time justified only at a qualitative level. Nevertheless the overall mechanism (Schemes 8 and 9) makes it possible to describe more fully and adequately the mechanism of the oxidation of organic substrates than Walling's scheme.

b. The $Fe^{2+}-H_2O_2-S-O_2$ system

The process mechanism under aerobic conditions becomes even more complicated when molecular oxygen is involved in the oxidation. In this case, the amount of H_2O_2 consumed in the presence of O_2 on the oxidation of a specific amount of S diminishes, while the amount of the accumulated product of the oxidation of S in the presence of O_2 exceeds the theoretical maximum value established from the amount of H_2O_2 consumed.

The question arises how molecular oxygen influences the oxidation process. It has been established experimentally that the aerobic oxidation of substrates in the absence of Fe^{2+} and H_2O_2 hardly occurs (although iron ions are a universal contaminant and it is virtually impossible to get rid of them).

The available data on the activation of O_2 by Fe^{2+} aquo-ions indicate that the process includes the reactions[2]

$$18.\ Fe^{2+} + O_2 \underset{k_{-18}}{\overset{k_{18}}{\rightleftharpoons}} (FeO_2)^{2+},$$

$$\left(K = \frac{k_{18}}{k_{-18}} = 10^{-10}\ \text{litre mol}^{-1}\right),$$

$$19.\ (FeO_2)^{2+} + Fe^{2+} \overset{k_{19},\,2H^+}{\rightleftharpoons} 2Fe^{3+} + H_2O_2,$$

$$(k_{19} = 10^6\ \text{litre mol}^{-1}\ \text{s}^{-1}).$$

However, the influence of O_2 is exerted via the intermediates formed in the $Fe^{2+} - H_2O_2 - S$ system and not via the initial components (the last two stages may be neglected[3]). The primary product of the oxidation of organic substances by the Fenton reagent is the substrate radical R$^{\bullet}$, which possesses mainly reducing properties. Consequently, it can react effectively with O_2. Thus, in the typical systems considered, the radicals R$^{\bullet}$ formed may be consumed via the reactions with H_2O_2, Fe^{3+}, and O_2. If the interaction of $^{\bullet}OH$ with ethanol results in the formation of the alkoxy-radical $CH_3C^{\bullet}HOH$ ($R^{\bullet}_{\alpha}$), i.e.

$$20.\ C_2H_5OH + {}^{\bullet}OH \xrightarrow{k_{20}} CH_3C^{\bullet}HOH + H_2O,$$

$$(k_{20} = 1.6 \times 10^9\ \text{litre mol}^{-1}\ \text{s}^{-1}),$$

then the following reactions involving its consumption may be considered:

Step	Reaction	k_i/litre mol^{-1} s^{-1}	Ref.
12	$R^{\bullet}_{\alpha} + H_2O_2 \xrightarrow{k_{12}} ROH + {}^{\bullet}OH$	$k_{12} = 1.6 \times 10^5$	146
21	$R^{\bullet}_{\alpha} + Fe^{3+} \xrightarrow{k_{21}} P + Fe^{2+} + H^+$	$k_{21} = 2.7 \times 10^8$	147
22	$R^{\bullet}_{\alpha} + O_2 \xrightarrow{k_{22}} RO^{\bullet}_2$	$k_{22} = 4.6 \times 10^9$	148

Comparative analysis of stages 12, 21, and 22 permits the conclusion that under aerobic conditions the radicals $R^{\bullet}_{\alpha}$ are almost fully consumed on the interaction with O_2. Consequently, in contrast to the mechanism operating under anaerobic conditions (Scheme 7) and also Walling's general mechanism,[29] the above scheme should include new elementary stages involving the formation and further reactions of the peroxyl radical $CH_3C^{\bullet}H(OO)OH$ ($RO^{\bullet}_2$) derived from the alcohol. The complete mechanism of the oxidation of ethanol under aerobic conditions (an example of a typical $Fe^{2+} - H_2O_2 - S - O_2$ system), put forward by Sychev et al.,[149] is given in Scheme 10.

Scheme 10

$$1.\ Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + {}^{\bullet}OH + OH^-$$

$$20.\ {}^{\bullet}OH + C_2H_5OH \longrightarrow R^{\bullet}_{\alpha} + H_2O$$

$$22.\ R^{\bullet}_{\alpha} + O_2 \longrightarrow RO^{\bullet}_2$$

$$23.\ RO^{\bullet}_2 \longrightarrow CH_3CHO + HO^{\bullet}_2$$

$$24.\ RO^{\bullet}_2 + ROH \longrightarrow CH_3CH(OOH)OH + R^{\bullet}_{\alpha}$$

$$25.\ RO^{\bullet}_2 + Fe^{2+} \xrightarrow{H^+} Fe^{3+} + CH_3CH(OOH)OH$$

$$26.\ HO^{\bullet}_2 + C_2H_5OH \longrightarrow R^{\bullet}_{\alpha} + H_2O_2$$

$$5.\ HO^{\bullet}_2 + Fe^{2+} \xrightarrow{H^+} Fe^{3+} + H_2O_2$$

$$4.\ HO^{\bullet}_2 + Fe^{3+} \longrightarrow Fe^{2+} + O_2 + H^+$$

$$27.\ CH_3CH(OOH)OH \longrightarrow CH_3CHO + H_2O_2$$

On the basis of this scheme, it is possible to derive an expression for the initial rate of formation of acetaldehyde on the assumption that $k_{25}[Fe^{2+}] \leqslant k_{23} + k_{24}[ROH]$ and $k_{26}[ROH] \ll k_5[Fe^{2+}] + k_4[Fe^{3+}]$:

$$w_{o,A} = \frac{k_1[Fe^{2+}][H_2O_2]}{(1 + k_{27}[H_2O_2])(1 + k_{24}[ROH]/k_{23})}.$$

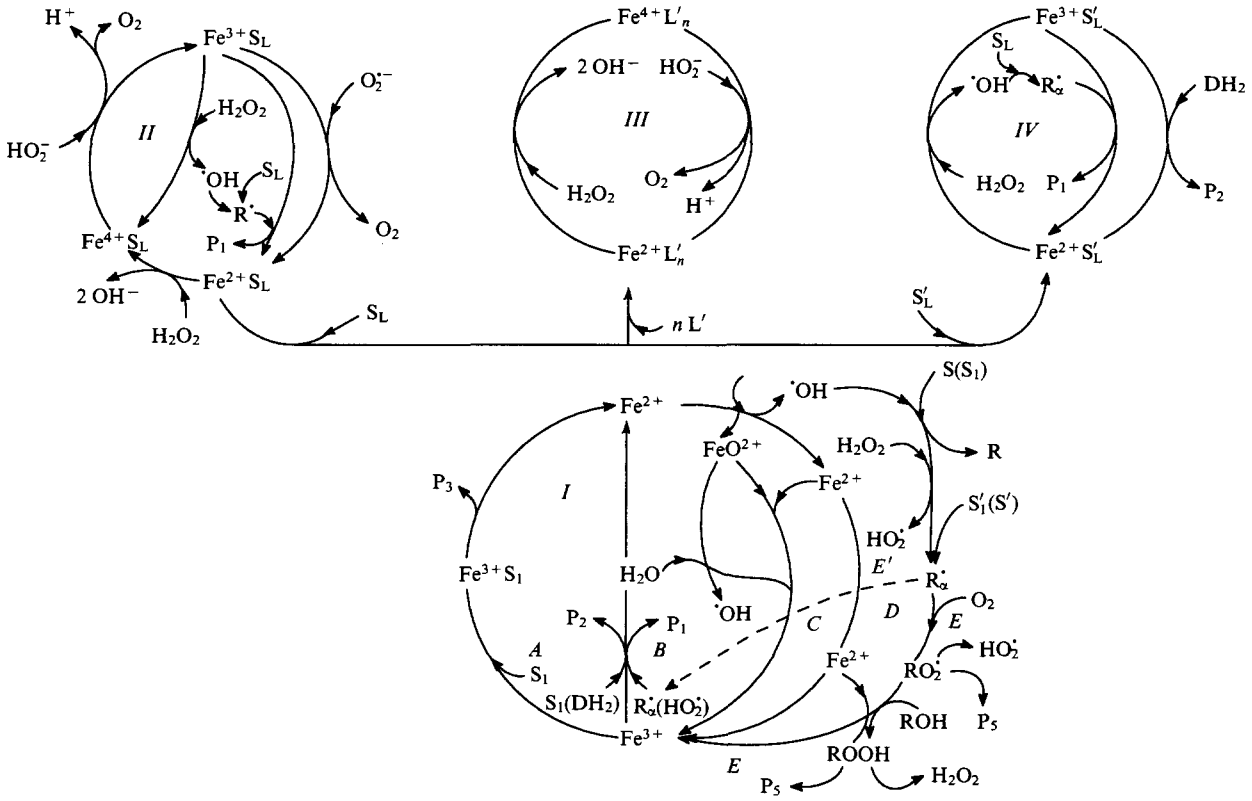
It is consistent with the experimentally observed features.[149]

The participation of oxygen in the aerobic oxidation of organic substrates by the Fenton reagent and the complication of the reaction mechanism under these conditions has also been noted in other studies.[2, 3, 144, 150–153]

A similar mechanism operates in the oxidation of substrates also in the typical $Fe^{2+}-S_L-H_2O_2-O_2$ and $L-Fe^{2+}-H_2O_2-S-O_2$ systems with the sole difference that the coordination compounds of Fe^{2+} with S_L and L respectively function as catalysts in this case.[3]

The following features should be included in the experimental evidence for the occurrence of the process under aerobic conditions according to Scheme 10:

(1) the difference between the rates of oxidation of the substrate in the aerobic and anaerobic systems;



(2) the greater amount of the substrate oxidation product compared with the amount of disproportionated H_2O_2;

(3) the generation of $^{\bullet}OH$ radicals, the decrease in the Fe^{2+} concentration during the reaction, and the accumulation of Fe^{3+}.

Thus one may postulate that the mechanism of the oxidation of organic substrates under aerobic conditions by the $^{\bullet}OH$ radicals generated by ferroperoxide systems in cases where an active radical (of the type $R^{\bullet}_{\alpha}$) is formed can be described by Scheme 10. Consequently the role of H_2O_2 in the aerobic oxidation of organic substrates (especially alcohols) reduces to the preparation of the latter for their subsequent oxidation by oxygen (in the case of alcohols, for the conversion of ROH into $R^{\bullet}_{\alpha}$).

On the basis of the analysis of literature data, the mechanisms of the decomposition of H_2O_2 and of the oxidation of substrates can be represented by the generalised Scheme 11.[3]

Scheme 11

If iron(II) coordination compounds serve as the catalyst, the general mechanism assumes as a rule a form (mainly in acid and weakly acid media) analogous to fragment *I* of Scheme 11 ($Fe^{2+}L_n$ participates in the reaction instead of Fe^{2+}).

For simplicity, not all possible reactions of the $^{\bullet}OH$ radicals generated have been included in fragments *II*, *IV*, and also *I* (sequence *C*) (they are all analogous to the reactions presented in sequence *E* of fragment *I*).

The ferroperoxide systems may be classified in terms of different features: in terms of the effectiveness of their action, in terms of the complex-forming capacity of the substrate relative to Fe^{2+}, and in terms of the mechanisms of the disproportionation of H_2O_2 and the oxidation of the substrate.

If the substrate S introduced and the substrate radical $R^{\bullet}$ formed have no reducing properties, then the oxidation process decays as a function of time and reaches completion after the conversion of all the Fe^{2+} into Fe^{3+} (sequence *D* or *C* occurs — see Scheme 11). If the substrate S_1 and/or the substrate radical $R^{\bullet}_{\alpha}$ formed are effective reductants, then quantitative oxidation of the substrate takes place under anaerobic conditions, the process being more effective the higher the reducing 'strength' of the latter (or of the corresponding substrate radical). Such processes include the reaction sequences *D* (or *C*), *E*, and *B* (Scheme 11). The formation of an active substrate radical increases the effectiveness of the oxidation of the substrate also under aerobic conditions as a consequence of the realisation of sequences *D* (or *C*), *E*, and *B*. In such cases, the role of hydrogen peroxide consists merely in preparing the substrate (via the formation of $R^{\bullet}_{\alpha}$) for the subsequent interaction with O_2. It is possible to infer which of the mechanisms operates in the oxidation of a particular substrate by ferroperoxide systems, provided that the rate constants for the elementary stages of the interaction of the substrate and substrate radicals with $^{\bullet}OH$ and O_2 are known.

The role of the added inert ligand consists in enhancing the oxidising capacity of the ferroperoxide systems and of ensuring their operation in weakly acid and neutral media. This occurs as a consequence of the change in the OR potential of the Fe^{3+}/Fe^{2+} couple and the stabilisation of a particular oxidation state of iron at higher pH. If one-electron transfers from the complex catalyst to the substrate are preferred in the system, then the fundamental process mechanism is as a rule similar to that operating in the $Fe^{2+} - H_2O_2 - S$ system (Scheme 11, fragment *I*) with the sole difference that the catalyst is a Fe^{2+} ion bound in a complex. If two-electron transfers are preferred, then the mechanism as a rule changes (fragments *II* and *III* in Scheme 11). Consequently, in order to increase the effectiveness of the ferroperoxide systems, it is necessary to choose a suitable ligand and to establish conditions under which cyclic or radical-chain H_2O_2 disproportionation and substrate oxidation processes take place. If the reducing 'strength' of the substrate (or the substrate radical) is low, effective reductants (of the type of ascorbic and dihydroxyfumaric acids, etc.), capable of regenerating the active form of the catalyst (Fe^{2+}), must be introduced into the system.

The substrates S which do not form complexes are oxidised in the reaction volume by the $^{\bullet}OH$ radicals (sequences *D* or *C* in Scheme 11), while those which possess a reducing capacity (S_1) are oxidised in sequences *D* (or *C*), *E*, and *B* (Scheme 11) and also by Fe^{3+} ions (or complexes).

The substrates S_1 which form complexes with Fe^{2+} alter the OR potential of the catalyst, which may increase the catalytic activity of the latter and the fundamental mechanisms of the disproportionation of H_2O_2 and the oxidation of substrate may remain virtually unaltered under these conditions (fragment *IV* in Scheme 11) or may undergo some changes (fragment *II*). Depending on the mechanism operating, such substrates may be oxidised via an inner-sphere route (via the transfer of one or two electrons) and also in the reaction volume by the $^{\bullet}OH$ or $O_2^{\bullet-}$ radical species generated. If S_L forms complexes only with Fe^{3+}, the process mechanism includes sequence *A* instead of sequence *B* (Scheme 11).

All the ferroperoxide systems can be divided into two groups in terms of the H_2O_2 and substrate oxidation mechanisms: a radical-ion mechanism (cyclic or radical-chain) mechanism operates in the first group and is described by fragments *I*, *II*, and *IV*, while an ion-molecule mechanism operates in the second group (fragment *III* in Scheme 11).

3. Oxidation of organic substrates by the $Fe^{3+}(LFe^{3+})-H_2O_2$ system

As observed already in an early investigation,[74,75] the Fe^{3+} aquo-ions also catalyse the decomposition of H_2O_2. The disproportionation of the Fe^{3+} ions proceeds via a radical-chain mechanism,[1,3,16,85,154,155] which includes stages involving the generation of $^{\cdot}OH$ free radicals. Since the formation of radicals actually ensures the high reactivity of the Fenton reagent in the oxidation reactions of organic substrates, one may expect that the substrates will be oxidised effectively also in the Ruff system, i.e. this system may be used for hydroxylation. Indeed, it has been shown[154] that acetone, *tert*-butyl alcohol, methanol, acetic acid, and other substrates are oxidised by the Ruff system.

The data concerning the influence of the type of substrate radical on the mechanism of the decomposition of H_2O_2 and on the oxidation of the substrate in the $Fe^{3+} - H_2O_2 - S_x$ system (and hence also on the composition of the oxidation products) [3] agree almost fully with those which have been obtained in the study of the oxidising activity of the Fenton reagent. The principal postulates and conclusions concerning the oxidation of S in the $Fe^{2+} - H_2O_2$ system are therefore applicable also to the oxidation of organic substrates by the Ruff system.

The mechanism of the oxidation of S by Fe^{3+} ions, as well as certain coordination compounds of trivalent iron, in the course of the catalytic disproportionation of H_2O_2, has been considered from similar standpoints.[70,85,89,142,156–162]

The reactions involving the oxidation of organic dyes by the Ruff system (and also by the Fenton reagent) are used widely in the kinetic methods for the determination of microamounts of iron ions in weakly acid aqueous media.[3,163–168]

The set of consecutive stages occurring in each specific case in the oxidation of substrates in the $Fe^{3+} - H_2O_2$ systems depends on the type of substrate, the properties of the substrate radical formed, and the experimental conditions (primarily on the concentrations of the reactants and on the occurrence of the process under aerobic or anaerobic conditions). All the factors noted above affect the process mechanism in the given system, as in the $Fe^{2+} - H_2O_2$ system. In planning the experiment and in considering the mechanism of the oxidation of substrates by the Ruff system, one may be guided by the generalised Scheme 11, which has been developed for the Fenton reagent and ferroperoxide systems.

III. Intermediates of the type of ferryl ions and complexes in the catalysis of oxidation processes

The fundamental mechanisms of the activation of oxygen, the catalytic decomposition of hydrogen peroxide, and the oxidation by the latter of organic substrates in the presence of iron ions or coordination compounds of iron were examined above. The role of the intermediate reactive species formed on reduction of O_2 or decomposition of H_2O_2 — the superoxide ($HO_2^{\cdot}$) and especially hydroxyl ($^{\cdot}OH$) radicals — was fairly widely dealt with in this connection.

Since the beginning of the 1930s, the nature and role of the reactive species formed in the interaction of iron ions or complexes with hydrogen peroxide has been the subject of numerous publications and discussions. Since the investigations of Haber and Weiss,[169,170] the view that the initial activation of H_2O_2 by Fe^{2+} ions is accompanied by the formation of the $^{\cdot}OH$ radical has been quite firmly established.

$$Fe^{2+}(aq) + H_2O_2 \longrightarrow Fe^{3+}(aq) + OH^- + {}^{\cdot}OH \qquad (1)$$

This was confirmed by the experimental observation of the acceleration of the polymerisation of various monomers when H_2O_2 and Fe^{2+} ions are introduced into the reaction medium, by the analysis of the products of the hydroxylation of numerous organic compounds by the Fenton system, and by comparing the rate constants for the elementary stages in the interaction of various substrates with hydroxyl radicals (generated in the radiolysis of water), and also by the results of the study of the catalytic decomposition of H_2O_2 by the Fe^{2+} aquo-ions.[3]

However, the question arises whether reaction (1) is elementary. If it is not, then what are the reactive species which precede the appearance of the $^{\cdot}OH$ radical and what are their properties? Many investigators postulate that the generation of Fe^{3+} ions and the hydroxyl radicals $^{\cdot}OH$ by the $Fe^{2+}(aq.) - H_2O_2$ system does not constitute unambiguous proof that reaction (1) is elementary and that these species are merely the detectable products of a complex process.

Since the study of Bray and Gorin[171] up to the present time, there has existed also another point of view, according to which the hydrogen peroxide decomposition process in the $Fe^{2+}(aq.) - H_2O_2$ system proceeds with formation of the ferryl

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{IV}{=}O^{2+} + H_2O \qquad (2)$$

ion $(Fe^{IV} = O)^{2+}$:

$$L_nFe^{2+} + H_2O_2 \longrightarrow (L_nFe^{IV}{=}O)^{2+} + H_2O\,. \qquad (3)$$

At a higher pH, a complex is formed:

The occurrence of stage (2) requires the simultaneous transfer of two electrons from the catalyst to H_2O_2. Although direct experimental evidence for the formation of the ferryl ion FeO^{2+} in the given system has not been obtained, nevertheless this idea has been supported by many investigators,[2,116,172–177] who used it to account for the mechanism of the activity of the Fenton reagent. Subsequently the possibility of the formation of the ferryl species as a constituent of complexes at pH 7 and not in an acid medium, where only the $Fe^{2+}(aq.) - H_2O_2$ system may exist, was also considered.[178] Be it as it may, one cannot rule out the possibility of the formation of the ferryl ion in ferroperoxide systems. It may be that the interaction of Fe^{2+} with H_2O_2 results in the initial formation of an intermediate complex, where electron transfers lead to the generation of the ferryl ion, giving

$$Fe^{2+} + H_2O_2 \underset{-H^+}{\rightleftharpoons} Fe^{2+}(HO_2^-) \xrightarrow{H^+} \qquad (4)$$

$$\longrightarrow FeO^{2+} + H_2O \longrightarrow Fe^{3+} + HO^- + {}^{\cdot}OH$$

rise to the $^{\cdot}OH$ radicals as a result of the reaction with water.

If the contribution of the inner-sphere electron transfer in the intermediate complex, leading to the formation of FeO^{2+}, is large and the ferryl ion interacts rapidly with a water molecule, then only the $^{\cdot}OH$ radicals and Fe^{3+} ions are detected in the system. This explains the impossibility of the experimental detection of the FeO^{2+} species in the Fenton system. This problem has been analysed in detail in the monograph of Sychev and Isak.[3]

In more complex systems (metal complexes, enzymes and their models which incorporate iron at the active centre of the enzyme, as well as hydrogen peroxide and dioxygen), there is an increase in the likelihood of the generation of the ferryl species bound in a complex as a consequence of the greater probability of the transition of iron to the Fe(IV) oxidation state and the stabilisation of the latter by the surrounding ligands (L). The number of examples of this kind has been increasing recently.

There is experimental proof that at a low pH the $^{\cdot}OH$ radicals are generated by reaction (1) in the Fenton system, whereas at a high pH, where the iron ion is bound in a complex, there is an increase in the probability of the appearance, instead of the $^{\cdot}OH$ radical, of the less reactive ferryl complex species $L_nFe^{IV}{=}O^{2+}$ via reaction (3). This species acts more specifically as an oxidant.

The mechanisms of reactions (1) and (3) apparently include the formation of the intermediate Fe^{II} and Fe^{III} peroxo-complexes.[178] However, it is not entirely clear which oxidising species are formed in the course of these reactions. The proof of the formation at different pH of oxidising species differing from one another is provided by the characteristic features of the product distribution in the reactions of a series of substrates. In acid media, the distribution is close to that attained when the $^{\bullet}OH$ radicals, generated by radiolysis, are employed whereas in neutral and alkaline media it is more stereospecific. In other words, in the latter case the oxidant is not the $^{\bullet}OH$ radical but another species, tentatively ferryl iron.[29,179-183] Different experimental methods have been used in experiments of this kind:[184,185] pulse radiolysis, the stopped flow method, the generation of iron(IV) compounds as a result of the oxidation of iron(III) salts or complexes by $^{\bullet}OH$ free radicals, and the reduction of the ferrate ion (FeO_4^{2-}) to the perferryl ion (FeO_4^{3-}) by the hydrated electron or the $CO_2^{\bullet-}$ radical. Ferryl (Fe^{IV}) and perferryl (Fe^{V}) forms of iron have different spectroscopic characteristics. On the other hand, in terms of their chemical behaviour they are very similar and this is why perferryl can sometimes be used as a model for the investigation of the interaction of ferryl with organic substrates. Thus iron in the +4 oxidation state has been detected in the presence of inorganic ligands (OH^-, $P_2O_7^{4-}$, and HCO_3^-/CO_3^{2-}) or their mixtures.[185]

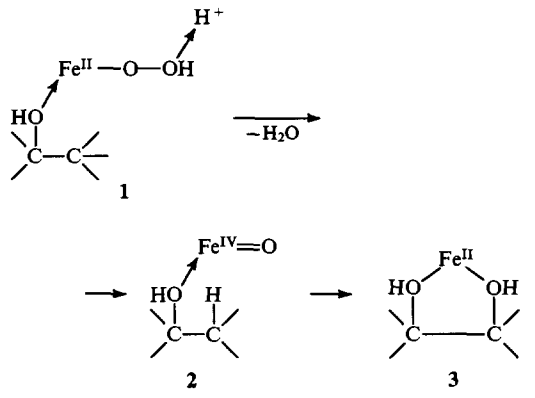
$$^{\bullet}OH + Fe(OH)_4^- \longrightarrow Fe^{IV} + H_2O \quad (k = 10^8 \text{ litre mol}^{-1} \text{ s}^{-1})$$

$$^{\bullet}OH + HCO_3^-/CO_3^{2-} \longrightarrow H_2O/OH^- + CO_3^{\bullet-} \quad (k = 4 \times 10^8 \text{ litre mol}^{-1} \text{ s}^{-1})$$

$$CO_3^{\bullet-} + L_nFe^{III} \longrightarrow L_nFe^{IV} + CO_3^{2-} \quad (k = 2.4 \times 10^8 \text{ litre mol}^{-1} \text{ s}^{-1})$$

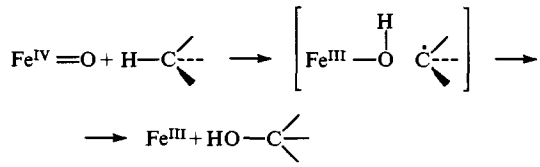
$$^{\bullet}OH + [Fe^{III}OH(P_2O_7)_2]^{6-} \longrightarrow [Fe^{IV}(OH)(P_2O_7)_2]^{5-} + OH^- \quad (k = 5 \times 10^7 \text{ litre mol}^{-1} \text{ s}^{-1})$$

Although the different iron(IV) complexes have very similar spectroscopic characteristics ($\lambda_{max} \approx 430$ nm, $\varepsilon = 900 \pm 100$ litre $mol^{-1} s^{-1}$), the kinetics of their reactions depend on the pH and the nature of the ligand (the half-reaction time $\tau_{1/2}$ varies from 0.1 to 1.0 s).[184-186] The iron(V) compounds are relatively stable in alkaline solutions ($\tau_{1/2} \approx 170$ ms) and their UV spectra have a shoulder between 260 and 300 nm [$\varepsilon = (4 - 5) \times 10^3$ litre $mol^{-1} s^{-1}$].[185] The iron(V) complexes are much more reactive than the iron(VI) complexes: the ratio of the rate constants for the oxidation of formate is



$$\frac{k_{Fe^V + HCOO^-}}{k_{Fe^{VI} + HCOO^-}} = 10^5 .$$

Such or an even greater increase in reactivity is observed on passing from iron(V) to iron(IV) complexes.



In systems of the Fenton type under the conditions involving the formation of superoxidised iron states, the latter may exhibit a greater specificity (stereospecificity) in oxidation and hydroxylation reactions.[186] Such specificity is especially important when the reactions proceed in biological systems.

One of the first fairly convincing experimental pieces of evidence for the generation of the ferryl ion in oxidation-reduction catalytic reactions has been obtained by Groves.[187] In the oxidation of cyclohexanol by hydrogen peroxide in the presence of iron(II) salts and perchloric acid in acetonitrile, in addition to cyclohexanone, the products included cyclohexane-diols, 72% of which comprised *cis*-cyclohexane-1,3-diol. Such regioselectivity was explained by the appearance of an iron(IV) intermediate capable of subsequently transferring an oxygen atom. This view has been confirmed by the existence of a whole series of salts and other compounds in which the oxidation state of iron is +4.

The above regioselectivity might have been the result of the formation of an iron(II) complex **1** with the OH group of cyclohexanol and the peroxide ion. The reaction is accompanied by the heterolysis of the peroxide, which leads to the formation of complex **2**, and the insertion of oxygen in the substrate (complex **3**).

The transfer of oxygen from the ferryl intermediate to the carbon atom of cyclohexanol, accompanied by the formation of the corresponding diol, most probably proceeds in accordance with the mechanism

Somewhat later, the iron in the 'ultrahigh' oxidation state was detected in the reaction of hydrogen peroxide with the water-soluble iron(III)-porphyrin.[188] The compound formed, in which the iron atom is in the same oxidation state, is characterised by an appreciable lifetime in aqueous solution.[184] The reduction potential of the ferryl/ferriporphyrin couple is ~ 0.9 V, which is lower by 1.3 V than for the $^{\bullet}OH/H_2O$ couple at pH 7.[178] The maximum (FeO^{2+} – chelate)/(Fe^{3+} – chelate) potential is approximately 2 V, i.e. the ferryl complex is a weaker and more selective oxidant than the $^{\bullet}OH$ radical.

Yet another piece of experimental evidence for the possibility of the formation of a ferryl complex is provided by the results obtained in the study of the interaction of the coordination compound Fe^{II}EDTA with H_2O_2 and the way the system is acted upon by various alcohols, aminoacids, and acids. The reaction of Fe^{II}EDTA with H_2O_2 may involve the formation of either the $^{\bullet}OH$ radical or the ferryl complex of EDTA, the latter being more probable. Indeed, it has been shown that this process can be described by the following equations:[189]

$$Fe^{II}EDTA + H_2O_2 \xrightarrow{k_1} I_1 \xrightarrow{Fe^{II}EDTA} Fe^{III}EDTA$$

$$I_1 + H_2O_2 \xrightarrow{k_2} I_2 \xrightarrow{Fe^{II}EDTA} Fe^{III}EDTA$$

I_1 and I_2 = intermediates

where $k_1 = 1.75 \times 10^4$ and $k_2 = 3.2 \times 10^3$ litre $mol^{-1} s^{-1}$. It has been suggested that the intermediate I_1 is most probably the ferryl-EDTA complex and not the hydroxyl radical, while the intermediate I_2, capable of reacting with ferricytochrome *c*, is the $^{\bullet}OH$ radical. The difference between I_1 and I_2 is manifested by their different reactivities towards *tert*-butyl alcohol and ethanol ($^{\bullet}OH$ radical-fixing agents). The intermediate I_1 is not fixed by *tert*-butyl alcohol, whereas the intermediate I_2 is fixed. I_1 is much less reactive towards the benzoate ion, *tert*-butyl alcohol, the acetate ion, arginine, and serine than the $^{\bullet}OH$ radical, but it is fixed by compounds with easily oxidisable functional groups such

as ethanol and isopropyl alcohol. All this indicates that the intermediate I_1 does not effect reactions characteristic of the hydroxyl radical and as an oxidant has a reactivity closer to that of the metal ion, i.e. it resembles the complex (FeO^{2+})EDTA.[189]

Although the formation of the 'OH radical in the Fe^{2+}–EDTA – H_2O_2 systems has been confirmed by various methods (the spin trapping method,[190] the hydroxylation of aromatic compounds,[191] and comparison of the rate constants for the interaction of certain substances with the above radicals and the 'OH radicals obtained by radiolysis),[192] nevertheless there exists the view, based on the dehydration of cytochrome *c* in the given system, according to which the reactive species is more likely to be the ferryl complex and not the 'OH radical. The formation of the ferryl complex may precede the formation of 'OH radicals. Indeed, two oxidising species are generated in the reactions of haemoglobin with H_2O_2, one of which hydroxylates aromatic compounds (the 'OH radical), while the other cannot effect this reaction.[193] It has been suggested that this second species is the ferryl complex. Thus there are two possibilities for the formation of reactive species in vivo.[194–201] The predominance of one or other possibility depends on the biological target to which the iron ions bind.[193]

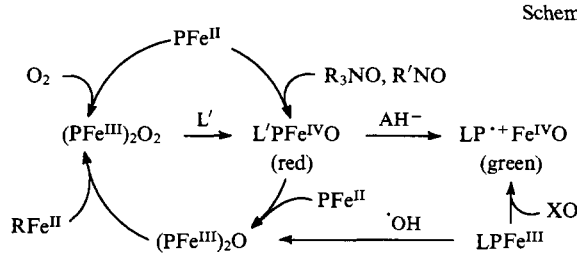
The generation of the ferryl group on protonation of plant peroxidases has been confirmed with the aid of resonance Raman spectroscopy. A hydrogen bond, in which the oxygen atom bound to the ferryl ion of the peroxidase participates, arises in this process.[202–204] The formation of the ferryl group has been confirmed also by the study of the interaction of peroxidases and catalases with peroxides.[205] Two intermediates are formed (green and red compounds), the first of which is formally $Fe^{V}O^{3+}$, or more precisely a $[P^{\cdot+}Fe^{IV}O]^{3+}$ haem (one electron is transferred to iron by the porphyrin ligand), while the other is an Fe^{IV} haem. Indeed, bands characteristic of the vibrations of the $Fe^{IV}=O$ groups have been noted in the resonance Raman spectra of the second haem intermediate. The frequencies of these vibrations are extremely sensitive to the effect of the environment. Peroxidase exhibits an enzyme activity only when the $Fe^{IV}=O$ group binds the hydrogen of a remote aminoacid group.

The interaction of ferrimyoglobin with H_2O_2 has also been examined as a possible model of the activity of catalase. It was postulated that the structure of the intermediate includes the ferryl ion (FeO^{3+}).[206]

The presence of the ferryl group in model systems simulating the peroxide oxidation of lipids has been demonstrated experimentally.[207] Whereas it had been suggested previously that the 'OH radical is the initiator of the peroxide oxidation (peroxidation) of lipids, later this role began to be attributed to an ionic complex of adenosine diphosphate ($ADP.Fe^{2+}.O_2$). Initiation by the 'OH radical is more likely in the absence of appreciable amounts of iron chelates. Otherwise (for example, in biological systems) the peroxidation of lipids apparently proceeds without the involvement of the hydroxyl radical. Two additional electrons convert the initial complex into the ferryl complex. This reaction resembles reaction (2).[187] It has been postulated that the ferryl ions are formed preferentially in the reaction of the

$$ADP\cdot Fe^{2+}\cdot O_2 \xrightarrow{2H^+,\,2\bar{e}} ADP\cdot(FeO_2)^{2+} + H_2O$$

adenosine diphosphate complex of iron(II) with hydrogen peroxide. The principal evidence for the absence of the hydroxyl radicals from the $ADP\cdot Fe^{2+}\cdot O_2$ system is the fact that, after the addition of a strong acceptor (mannitol), the rate of peroxidation of lipids remains almost unchanged. Thus the oxidation is promoted by the ferryl ions forming part of the ADP complex and not by the 'OH radicals.



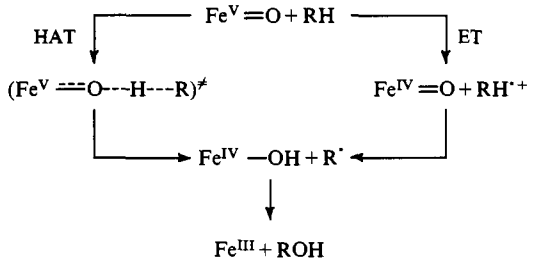
The involvement in the process of 'OH radicals or ferryl complexes depends to some extent on the hydrogen peroxide concentration in the system, which has been observed in the reaction involving the membrane peroxidation of lipids.[208] At low H_2O_2 concentrations and in the presence of haemoproteins (myoglobin, haemoglobin), lipids are oxidised mainly by ferryl species, whereas at high concentrations they are oxidised by hydroxyl radicals.

The epoxidation of alkenes and the hydroxylation of alkanes by various oxidants in the presence of iron-porphyrin complexes can proceed via different mechanisms.[5,209] The mechanism of the epoxidation of alkenes by iodosobenzene, hydrogen peroxide, and hydroperoxides (the catalysts are various porphyrin complexes of iron) includes the formation of the $P^{\cdot+}Fe^{IV}=O$ oxoporphyrin π-radical-cation as the oxidant. This species has not been isolated, but its existence has been confirmed by the presence in the resonance Raman spectrum of an intense band at 852 cm^{-1} (~ 15 K), which appears during the irradiation by a laser of the oxygenated iron complex of *meso*-tetraphenylporphyrin $Fe(TPP)O_2$.[210] This species may be formed in the presence

$$Fe(TPP)Cl + XO \longrightarrow Fe^{IV}O(TPP^{\cdot})Cl + X\,.$$

of an oxidant (XO) in accordance with the mechanism
The length of the Fe=O bond is ~ 1.60 – 1.66 Å.[211] Examination of the molecular orbitals in the $FeO(P)H_2O$ complex (P = porphyrin) shows that the ferryl group has the electronic configuration $\sigma^2\pi^4\pi^{*2}$, i.e. it contains the Fe=O double bond.[212] The paths leading to the formation of such species at temperatures below −50 °C have been examined in fair detail. Depending on the source of oxygen, the nature of the axial ligand (L′ or L), the way in which these species are obtained, the solvent, and the temperature, the oxo-transfers occur with formation of different intermediates.[213]

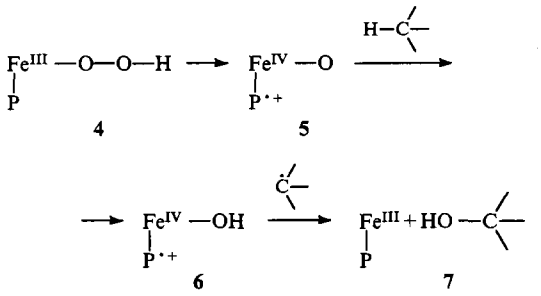
Scheme 12



Here PFe^{II} is the porphyrin complex of iron(II), $L'PFe^{IV}O$ is the complex with the additional ligand L′ = methylimidazole or pyridine), $LP^{\cdot+}Fe^{IV}O$ is a similar complex with $L = ClO_4^-$, $LPFe^{III}$ is the iron(III) complex, $(PFe^{III})_2O$ is the dinuclear oxoiron(III) complex, $(PFe^{III})_2O_2$ is the μ-peroxo-dimer, AH^- is the electron acceptor, and XO is the oxidant (R_3NO or R′NO). The $Fe^{IV}O$ species cannot be detected in aqueous solutions or isolated in the form of the corresponding porphyrin complex. It can be more easily detected in a nonaqueous medium. The different routes to its formation are presented in Scheme 12.

When alkanes are hydroxylated by dioxygen in the presence of the same catalyst, the oxoiron(IV)-porphyrin participates in the process. The mechanism of the hydroxylation by iodosobenzene is radical in character. When this reaction proceeds with participation of hydrogen peroxide, the oxidising species is the 'OH radical, whereas in the case where hydroperoxides participate in the reaction, two oxidation mechanisms are possible: with formation of RO' (free-radical reactions) and with generation of high-valence oxoferryl species.

The hydroxylation of the substrate RH by an oxygen donor (iodosobenzene, peroxy-acids, etc.) in the presence of iron(III)-porphyrin has been discussed.[214] Two possible mechanisms were postulated: with hydrogen atom transfer (HAT) and with electron transfer (ET) from RH to the perferryloxygen atom ($Fe^{IV}=O$) formed in the system.

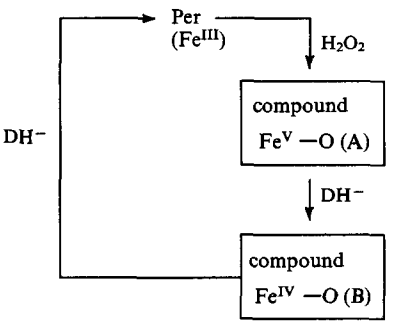


Scheme 13

The electron transfer path predominates when the hydroxylation substrates are electron-rich substances. An oxoferryl compound and a substrate radical-cation are formed in this case. The latter is deprotonated and affords the same pair of substances as in the transfer of a hydrogen atom. The interaction of this pair leads to the formation of a hydroxylated substrate. If the process is carried out in solvents with a low polarity and with the participation of substrates with an oxidation potential below 1.2–1.4 V, the HAT mechanism is preferred. In more polar solvents and with the participation of a substrate with an oxidation potential of 1.2–1.8 V, the ET mechanism predominates.

The formation of the oxoiron(IV)-porphyrin radical-cation is postulated in the hypothetical model of the generation of the active catalyst in hydroxylation reactions effected by cytochrome P-450.[215,216] The mechanism of this process provides for the heterolytic dissociation of the O–O bond in the hydroperoxoiron complex **4** with formation of the iron-porphyrin **5**, which has undergone one-electron oxidation and is an active oxidant. On reaction with the substrate, this complex accepts a hydrogen atom and gives rise to the hydroxoiron(IV) complex **6**. The radical centre of the substrate then recombines with the OH group of the hydroxoiron(IV) complex, which leads to the formation of the hydroxylated substrate and the initial ferri-form **7** of cytochrome P-450. The mechanism of this process can be represented in the following form:[217]

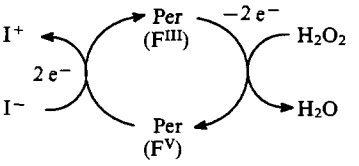
Scheme 14



The interaction of various peroxidases (Per) with hydrogen peroxide results in the formation of outer- and inner-sphere intermediates and then of the compound PerO of the ferryl type ($Fe^{V}-O$ or more precisely $P^{\cdot+}Fe^{IV}O$):[218]

$$Per + H_2O_2 \rightleftharpoons (PerH_2O_2) \rightleftharpoons PerH_2O_2 \longrightarrow PerO + H_2O.$$

The formation of the Fe–O bond and other rearrangements do not require that a high energy barrier be overcome (the activation energy for this process is approximately 14.7 kJ mol^{-1}). The rates of formation of compounds of the type $Fe^{V}O$ are similar for different haemoproteins. The addition of an oxygen atom to the Fe^{III} atom of the native enzyme converts the latter formally into the Fe^{V} state but, in the presence of a suitable reductant (DH^-) or of an additional electron, the source of which may be some kind of haemoprotein, the final product becomes a compound of the type $Fe^{IV}O$, which can be in its turn reduced to the Fe^{III} state of the initial peroxidase.



Scheme 15

This reaction cycle is characteristic, in particular, of horse peroxidase (the data on the magnetic susceptibilities of compounds A and B have been interpreted as referring to the Fe^{V} and Fe^{IV}states respectively). In the case of other peroxidases (chloroperoxidase, cytochrome *c* peroxidase), approximately the same reactions with some deviations have been observed.

The reactions of a type $Fe^{V}O$ compound can be demonstrated in relation to the interaction of the native horse peroxidase with the iodide ion.

Scheme 16

The same two-electron mechanisms of the interaction of the enzyme with hydrogen peroxide and of compound A with the iodide ion is characteristic also of chloroperoxidase. When nitrous acid (or the nitrite anion) participates in the usual enzymic cycle, compound A undergoes one-electron reduction to compound B and the latter is reduced to the initial peroxidase.

The reactions of a type $Fe^{IV}O$ compound have been investigated in particular detail in relation to horse peroxidase. Compounds A and B may compete with one another for the reductant. At a low pH, this competition is won by compound B, whilst at pH 9 it is won by compound A. Under such conditions, the yield of compound B may be made quantitative and the conversion of $Fe^{IV}O$ into PFe^{III} may be observed spectrophotometrically at the wavelength $\lambda = 425$ nm. In the general case, the interaction of various peroxidases with hydrogen peroxide affords compounds A and B in a similar way, although these processes also differ somewhat from one another.

The details of the oxidation of iron(III) porphyrinate by hydrogen peroxide or by organic peroxides in the catalytic cycle involving peroxidases and catalases were refined in subsequent studies. Thus it has been demonstrated by electronic and Mössbauer spectroscopy and also by EPR spectroscopy that compound A is the oxoiron(IV)-porphyrin π-radical-cation,[219] i.e.

$$P^{\cdot+}F^{III} + H_2O_2 \longrightarrow P^{\cdot+}Fe^{IV}{=}O,$$

whereas compound B is formed as a result of the one-electron reduction of compound A:

$$P^{\cdot+}Fe^{IV}{=}O + DH^- \longrightarrow PFe^{IV}{=}O + {}^{\cdot}DH.$$

The formation of compound A in the cytochrome P-450 cycle has also been postulated.

The better understanding of the mechanisms of the interaction of H_2O_2 or of the hydroperoxides ROOH with peroxidases, catalases, and cytochrome P-450 considered here is assisted by the study of model systems of the type $PFe^{III} - X - H_2O_2(ROOH)$. Evidence has been obtained[220]

that the peroxide (hydroperoxide) O–O bond is dissociated homolytically in the $(Ph_4P)Fe^{III}Cl - H_2O_2(ROOH)$ systems (Ph_4P = 5,10,15,20-tetraphenylporphyrinate) in methanol. This results in the formation of highly oxidised forms of iron porphyrinate of the oxoferryl type.

$$(Ph_4P)Fe^{III}(Cl) + ROOH \longrightarrow [(Ph_4P)Fe^{IV}O(Cl)RO^{\cdot}] \longrightarrow \begin{cases} [(Ph_4P^{\cdot+})Fe^{IV}O(Cl)] + RO^- \\ [(Ph_4P)Fe^{IV}O(Cl)] + RO^{\cdot} \end{cases}$$

It is much more difficult to investigate the catalytic decomposition of H_2O_2 in model systems of the type $PFe^{III}X - H_2O_2$ and to demonstrate the formation in this process of oxoferryl complexes in aqueous solutions, because in this instance it is necessary to create conditions preventing the appearance of the inactive dinuclear iron(III) porphyrinates and the stabilisation of oxoferryl species. The use of the $(TDSP)Fe^{III}(H_2O) - H_2O_2 - ABTS - H_2O$ model systems (30 °C), where $(TDSP)Fe^{III}(H_2O)$ = 5,10,15,20-tetra(2,6-dimethyl-3-sulfophenyl)porphyrinatoiron(III) hydrate and ABTS = 2,2′-azinodi(3-ethylbenzothiazoline-6-sulfonate), a trapping agent for the highly oxidised form of iron, made it possible to avoid the formation of dinuclear complexes and to stabilise the oxoiron(IV) porphyrinate species.[188] Depending on the pH (in the range 1–12), iron(III) complexes of different composition are formed initially: $(TDSP)Fe^{III}(H_2O)(H_2O_2)$ at a low pH, $(TDSP)Fe^{III}(OH^-)(H_2O_2)$ at an intermediate pH, and $(TDSP)Fe^{III}(OH^-)(HO_2^-)$ at a high pH. The homolytic or heterolytic dissociation of the peroxide O–O bond in the intermediate leads to the formation of $(TDSP)Fe^{IV}O$ and $^{\cdot}OH$ and of $(TDSP^{\cdot+})Fe^{IV}O$ and H_2O respectively.

Thus very numerous pieces of experimental evidence have been obtained in recent years for the generation of ferryl ions, their complexes, and enzyme compounds of types A and B, which are strong and at the same time specific oxidants for organic substrates (in hydroxylation, epoxidation, etc. reactions), competing with $^{\cdot}OH$ radicals. The $(Fe^{IV}=O)^{2+}$ species and $^{\cdot}OH$ radicals are highly reactive: the former can be converted into the latter under the conditions of the catalytic oxidation of any kind of substrate, for example in the $Fe^{2+}(aq.) - H_2O_2 - S$, $L_nFe^{2+} - H_2O_2 - S$, and enzyme $-Fe^{2+} - O_2(H_2O_2) - S$ systems. Hence it follows that the experimental identification of the ferryl species is in general fairly difficult and the question of the generation of such 'ultra-oxidised' iron states in the specific systems investigated is not yet clear. Even in the case where the formation of such species has been demonstrated by some kind of experimental method (with varying degrees of reliability), the information obtained is factual in character and does not account for the differences between the catalytic activities (for example in the decomposition of hydrogen peroxide) of different transition metal ions and of the different effects on the latter by the ligands and also for the appearance of different intermediate species (peroxo-complexes, free radicals) in the initiation steps.

Hence arises the need for the theoretical estimation of the possibility of the generation of ferryl species in the step involving the initiation of the decomposition of H_2O_2, starting with the simplest Fenton system $Fe^{2+}(aq.)-H_2O_2$ (working in weakly acid media) and ending with more complex $L_nFe^{2+} - H_2O_2$ systems.

It has been suggested that the initiation stage in the decomposition of hydrogen peroxide in the Fenton system is elementary.[1] According to an alternative view, the generation of the $^{\cdot}OH$ radical and the Fe^{3+} ion is not unambiguous evidence that this stage is elementary. It may be that the two-electron transfer from the catalyst to the substrate results in the initial formation of the ferryl ion.[171]

$$[(H_2O)_5Fe^{II}(H_2O)]^{2+} + H_2O_2 \xrightarrow[-H_2O,\ -H^+]{} [(H_2O)_5Fe^{IV}O]^{2+} \xrightarrow{H_2O} [(H_2O)_5Fe^{III}(OH^-)]^{2+} + {}^{\cdot}OH$$

It was later suggested[177] that a peroxo-complex is generated intially and a complex with a ferryl ion is formed from it as a consequence of intramolecular electronic transitions. The latter complex is then converted into an iron(III) complex and $^{\cdot}OH$.

$$[(H_2O)_5Fe^{II}(H_2O)]^{2+} + H_2O_2 \xrightarrow{-H_2O} [(H_2O)_5Fe^{II}(H_2O_2)]^{2+} \xrightarrow{-H^+} [(H_2O)_4(OH^-)Fe^{IV}O]^{+} \xrightarrow{H_2O} [(H_2O)_4(OH^-)_2Fe^{III}]^{+} + {}^{\cdot}OH$$

However, as already stated above, there is no convincing experimental evidence in the literature for the proposed mechanisms of the initiation of the decomposition of H_2O_2. On the contrary, according to the data of Koppenol and Liebman,[178] $^{\cdot}OH$ radicals are formed in this system in acid media and the possibility of the appearance of ferryl complexes increases only in neutral and alkaline media (where the iron ions are bound in complexes). Nevertheless, the idea that a ferryl species is formed in ferroperoxide systems has been discussed in numerous investigations.[3]

For a theoretical consideration of the possibility of the initial formation of ferryl species in the Fenton system, quantum-chemical calculations of the electronic structure of $Fe(H_2O)_6^{n-}$ and of a series of hypothetical complex compounds, postulated[171,177] as intermediates, have been performed. Calculations have also been carried out for all the peroxide species (H_2O_2, HO_2^-, $HO_2^{\cdot}$, and $^{\cdot}OH$) by the LCAO-MO SCF method in terms of the Mulliken–Wolfsberg–Helmholtz (MWH) approximation.[221] Self-consistent atomic charges and orbital populations as well as the electronic energy levels and the coefficients of the LCAO of the corresponding MO were found from these calculations (Fig. 1). Furthermore, the electron transfer from the MO of the complex to the MO of the peroxide species has been assessed quantitatively and the amounts of charge transferred (δq) have been found.

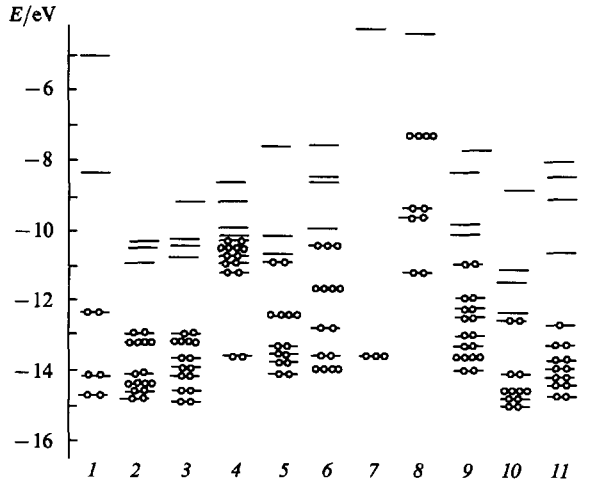


Figure 1. Energy level diagram for the molecular orbitals of the active regions of the molecules: (*1*) H_2O_2; (*2*) $[Fe^{II}(H_2O)_6]^{2+}$; (*3*) $[Fe^{II}(H_2O)_5.(H_2O_2)]^{2+}$; (*4*) $[Fe^{II}(OH^-)(H_2O)_4(H_2O_2)]^{+}$; (*5*) $[Fe^{IV}O(H_2O)_4(OH^-)]^{+}$; (*6*) $[Fe^{III}(OH)_2(H_2O)_4]^{+}$; (*7*) $^{\cdot}OH$; (*8*) HO_2^-; (*9*) $[Fe^{II}(H_2O)_5(HO_2^-)]^{+}$; (*10*) $[Fe^{IV}O(H_2O)_5]^{2+}$; (*11*) $[Fe^{III}(OH^-)(H_2O)_5]^{2+}$.

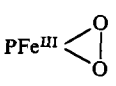
Analysis of the energy levels of the complexes indicates a low probability of the formation of the peroxo-complex $[Fe^{II}(H_2O)_5(H_2O_2)]^{2+}$ (energy level set *3*) and the impossibility of the occurrence of intramolecular transformations in which $[Fe^{II}(OH^-)(H_2O)_4(H_2O_2)]^+$ (*4*) and $[Fe^{IV}O(H_2O)_4(OH^-)]^+$ (*5*) are generated, because the levels of the highest occupied molecular orbitals (HOMO) and the lowest unoccupied orbitals (LUMO) of these species are much higher than the corresponding levels of both $[Fe(H_2O)_6]^{2+}$ (*2*) and $[Fe^{II}(H_2O)_5(H_2O_2)]^{2+}$ (*3*). Thus the formation of the ferryl ion in a very acid medium is impossible, in agreement with the experimental data.

However, as the pH increases, the intermediate peroxo-complex $[Fe^{II}(H_2O)_5(HO_2^-)]^+$ may be formed, which is indicated by analysis of the nature of the HOMO and LUMO levels of the species $[Fe(H_2O)_6]^{2+}$ (*2*) and HO_2^- (*8*) and of the hypothetical complex $[Fe^{II}(H_2O)_5(HO_2^-)]^+$ (*9*) and also by calculation of the charge transfer from the aquoiron(II) complex to H_2O_2 and from HO_2^- to the aquo-complex ($\delta q = -0.05$ e and 0.76 e respectively). Comparison of the energy levels of the MO of the peroxo-complex $[Fe^{II}(H_2O)_5(HO_2^-)]^+$ (*9*), on the one hand, and the MO of the complexes $[Fe^{IV}O(H_2O)_5]^{2+}$ (*10*) and $[Fe^{III}(OH^-)(H_2O)_5]^{2+}$ (*11*), on the other, indicates the possibility of a multistage course for the process.



$$[Fe^{II}(H_2O)_6]^{2+} + H_2O_2 \xrightarrow[-H^+]{} [Fe^{II}(H_2O)_5(HO_2^-)]^+ \xrightarrow{H^+}$$

$$\longrightarrow [Fe^{IV}O(H_2O)_5]^{2+} \xrightarrow{H_2O} [Fe^{III}(H_2O)_5(HO^-)]^{2+} + {}^{\cdot}OH$$

Thus, quantum-chemical calculations have confirmed the possibility of the formation of the peroxo-complex $[Fe^{II}(H_2O)_5(HO_2^-)]^+$ and the ferryl ion $[Fe^{IV}O(H_2O)_5]^{2+}$ as intermediates. If the reactions considered are rapid, then it is in fact impossible to detect these species at the present level of experimental technique and only $[Fe^{III}(H_2O)_5(OH^-)]^{2+}$ and the radical ·OH can be detected in the system. This indicates the limits of the existing experimental possibilities and confirms the importance of the quantum-chemical calculations.

IV. Porphyrin and other iron complexes in the catalysis of epoxidation and hydroxylation reactions

Numerous studies (see, for example, Refs 222–229, etc.) have been devoted to the mechanisms of the oxidation of alkenes, alkanes, and other organic substrates by dioxygen under the influence of various monooxygenases (cytochrome P-450 and others) and these problems will not be specially considered here. It is sufficient to note that the prosthetic group in monooxygenases is the iron(III) complex of the porphyrin (P), which in the course of the interaction with O_2 is converted into the highly reactive ferryl species $P^{\cdot+}Fe^{IV}=O$ or $PFe^{IV}=O$ (compounds A and B), which selectively epoxidise or hydroxylate alkenes or alkanes. When these reactions take place only with participation of iron complexes of porphyrin, which may be regarded as the closest structural model of monooxygenases, similar oxoferryl species are also formed. The mechanisms of the epoxidation and hydroxylation by these model compounds have their characteristic features, determined by the nature of the oxidant transferring oxygen to the iron atom of the porphyrin complex, the characteristics of the catalyst and the solvent, and the temperatures.[230–232] Thus the introduction of individual substituents into the porphyrin can prevent the transition of the monomeric peroxoiron(II) complex of the porphyrin[233–236]

into the μ-oxodimer $(PFe^{III})_2O$.[237] Under conditions where the peroxoiron(III) complex of tetramesitylporphyrin (TMP) was acylated by acetic anhydride (Ac_2O) at low temperatures (−45 °C), the product was $TMP^{\cdot+}Fe^{IV}=O$.[238,239] The same reactive species was generated in a series of other model systems[239,240] and in the interaction of peroxidase with H_2O_2.[241] The formation of a similar species from the acylated iron complex (TMPFeOOAc) is the rate-determining stage of the entire process.[242] On this basis, the catalytic model system[242]

$$T_{piv}PPFeBr - Zn(Hg) - MV^{2+} - Ac_2O - O_2 ,$$

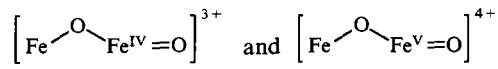
was developed. Here $T_{piv}PP$ = tetra(α,α,α,α-*o*-pivaloylaminophenyl)porphyrin, whose complex with iron is not converted into the μ-oxodimer,[243] while the dioxygen complex $T_{piv}PPFe(O_2)$ is stable at room temperature,[244,245] Zn(Hg) is zinc amalgam, which plays the role of the reductant, and MV^{2+} is methylviologen, which facilitates electron transfer from the reductant to $T_{piv}PPFe(O_2)$. The oxidation by this system of substrates (RH) such as cyclohexene, cyclohexane, and 1,2-dimethylcyclohexane was investigated.[242] The reactions occurring in this process are presented in Scheme 17.

Scheme 17

1. $Zn(Hg) + MV^{2+} \longrightarrow MV^{\cdot+}$
2. $Zn(Hg) + PFe^{III} \longrightarrow PFe^{II}$
3. $MV^{\cdot+} + PFe^{III} \longrightarrow PFe^{II} + MV^{2+}$
4. $PFe^{II} + O_2 \longrightarrow PFeO_2$
5. $PFeO_2 + MV^{\cdot+} \longrightarrow PFeO_2^-$
6. $PFeO_2^- + Ac_2O \longrightarrow P^{\cdot+}Fe^{IV}=O + 2\,AcO^-$
7. $P^{\cdot+}Fe^{IV}=O + RH \longrightarrow PFe^{III} + ROH$
8. $P^{\cdot+}Fe^{IV}=O + MV^{2+} \longrightarrow PFe^{III} + \text{products}$
9. $MV^{\cdot+} + O_2 \longrightarrow MV^{2+} + O_2^{\cdot-}$
10. $O_2^{\cdot-} + Ac_2O \longrightarrow AcO_2^{\cdot} + AcO^-$
11. $AcO_2^{\cdot} + RH \xrightarrow[-AcOOH]{} R^{\cdot} \xrightarrow{O_2} ROH + R'O$
12. $P^{\cdot+}Fe^{IV}=O + PFe^{III} \longrightarrow \text{products}$

The following equation can be written for the rate of formation of cyclohexanol (ROH):[246]

$$\frac{d[ROH]}{dt} = \frac{k_7[RH](k_1[MV^{2+}] + k_2[PFe^{III}])}{2\,(k_7[RH] + k_8[MV^{2+}] + k_{12}[PFe^{III}])} + \frac{k_9[O_2](k_1[MV^{2+}] - k_2[PFe^{III}])}{2\,k_3[PFe^{III}]} .$$



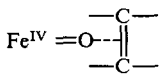
This equation agrees well with experimental data. The activity of the system may be greatly increased by immobilising the above catalyst on a solid polymeric support. The activation of O_2 in the hydrocarbon oxidation processes in the presence of metalloporphyrins can be achieved also by means of other systems.[247,248]

A wider range of iron-porphyrins in acetonitrile solutions was used in subsequent studies and the kinetics of the oxidation of cyclohexane by atmospheric oxygen (at 20 °C) in the presence of carboxylic acids (acetic and benzoic) and a reductant (zinc dust) were investigated both with and without the introduction of methylviologen.[249] The addition of methylviologen was accompanied by the accelerated absorption of O_2 and the generation of H_2O_2. On interaction with H_2O_2, the iron-porphyrins gave rise to a species of the type $P^{\cdot+}Fe^{V}=O$ or $P^{\cdot+}Fe^{IV}=O$ [250] and the oxidation mechanism resembles the 'shunted' mechanism involving the oxidation of hydrocarbons by cytochrome P-450. In the absence of methylviologen, the activation of O_2 in these systems is

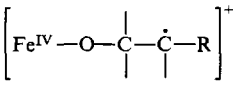
apparently achieved almost in the same way as in the cytochrome P-450 system.[249]

In order to form an oxene (an oxygen atom) from O_2 and transfer it to iron, it is necessary to bind the water residue (O^{2-}) to acceptors of some kind (the most suitable acceptor is acetic anhydride). The latter interacts with O_2 and iron-porphyrin and gives rise to the complex PFe–O–O–Ac at −70 °C, which is converted into $P^{\cdot+}Fe{=}O$ at −50 °C.[251] Numerous pieces of evidence have been obtained for the involvement of precisely the $P^{\cdot+}Fe{=}O$ species (detected spectroscopically) in the interaction with alkenes and alkanes.[251–256,279] The ferryl complex with the radical-cation of a nonhaem ligand, which interacts with alkanes,[257] has recently been characterised for the first time, i.e. the study of the analogues of nonhaem monooxygenases has been initiated.

The possibility of the formation of a ferryl species, but this time as part of the composition of a dinuclear complex, has been postulated also in reactions involving the use of methane monooxygenase.[253,258,259] A general method of synthesis of complexes of this kind has been developed[260,261] and alkanes have been oxidised by hydrogen peroxide in acetonitrile with their participation. The postulated mechanism of the oxidation of alkanes includes the formation of a hydroxoperoxoiron complex, which decomposes heterolytically with formation of the ferryl species[253]

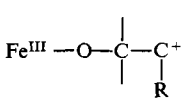


Apart from the haem and nonhaem[262–265] iron complexes, generating ferryl intermediates on treatment with oxenoids (O_2, H_2O_2, ROOH, PhIO, ClO^-, etc.), other active species may also be formed. Brief information about these has been published.[253,266]

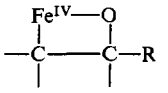


The possibility of the replacement of O_2 by other oxidants capable of transferring an oxygen atom to the metalloporphyrin and of generating the same oxoferryl species as those produced by dioxygen has been discussed in detail in a number of reviews.[5,242,267,268]

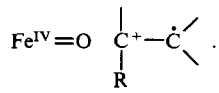
Oxidants such as iodosobenzene (PhIO), NaClO, H_2O_2, and hydroperoxides (ROOH) are usually employed in alkene epoxidation reactions catalysed by iron-porphyrin complexes. The epoxidation of alkenes in the FeTPP–PhIO catalytic system (H_2TPP = tetraphenylporphyrin) is stereospecific: only *cis*-epoxides are obtained from *cis*-alkenes. *cis*-Alkenes are much more reactive than their *trans*-isomers. The oxidant for the substrate is the oxoiron(IV)-porphyrin π-radical-cation $P^{\cdot+}Fe^{IV}{=}O$, which can react in different ways with the alkene, affording intermediates:



via the direct transfer of an oxygen atom,

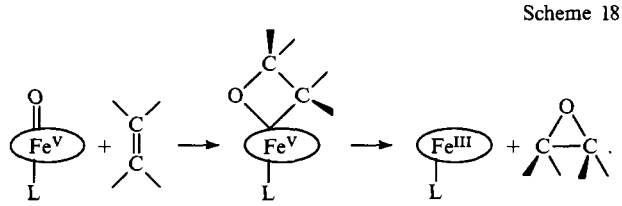


via the free-radical addition of the alkene,



or its electrophilic addition,

via the formation of ferra(IV)oxetane,



or via electron transfer with formation of an alkene radical-cation[5,269]

The decomposition of the ferra(IV)oxetane to the epoxide, electron transfer or partial charge transfer from the alkene to the oxoiron(IV)-porphyrin π-radical-cation, and other processes have been considered on the basis of kinetic data as the rate-determining stages of the reaction.[5,270]

It was postulated that the intermediate metallooxenes[271] are formed when oxygen is transferred from the highly oxidised oxoiron-porphyrins to the alkenes in the epoxidation reactions.[268,272–275] The following mechanism has been proposed for this process:[272,273]

Scheme 18

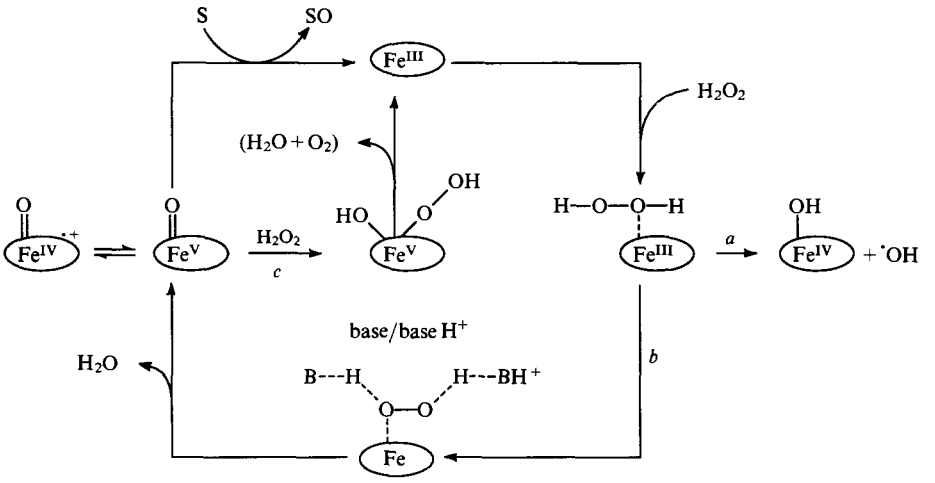
It has proved impossible to characterise the intermediate ion complex with the aid of EPR and NMR spectra.[274] The principal piece of evidence for its formation is the proportions of the reaction products. The involvement of the ferra(IV)oxetane in the epoxidation of *cis*-cyclooctene (as well as norbornene) in the presence of *meso*-[tetra(pentafluorophenyl)porphyrinato]-iron(III) chloride [$(F_{20}TPP)Fe^{III}(Cl)$] and C_6F_5IO has been reflected in the mechanism of this process developed on the basis of kinetic data.[276,277]

Scheme 19

$(F_{20}TPP)Fe^{III} + C_6F_5IO \rightleftharpoons (F_{20}TPP)Fe^{III}-OIC_6F_5$

$(F_{20}TPP)Fe^{III}-OIC_6F_5 \longrightarrow (F_{20}^{\cdot+}TPP)Fe^{IV}O + C_6F_5I$

$(F_{20}^{\cdot+}TPP)Fe^{IV}O + \text{alkene} \rightleftharpoons \text{Fe(IV)oxetane}$

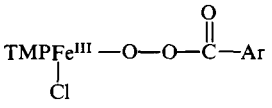


$\text{ferra(IV)oxetane} \longrightarrow (F_{20}TPP)Fe^{III} + \text{epoxide}$

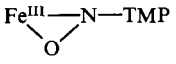
The rate constants indicate that the rate of the process is determined by the stage involving the decomposition of ferra(IV)oxetane to the epoxide and the initial catalyst $(F_{20}TPP)Fe^{III}$.[277]

However, in the study of, for example, the oxidation of *trans*-cyclooctene and other alkenes in the presence of iron porphyrinates as catalysts, the idea of the formation of the ferraoxetane as an intermediate was rejected and the epoxidation was regarded as a result of electron transfer from the alkene to the highly oxidised iron intermediate.[278–281] In the case where the epoxidation substrate was ethene, a biradical intermediate was more likely to participate in the reaction than the ferraoxetane.[282] In the oxoiron-porphyrin systems, radical intermediates are formed preferentially in the reactions with alkenes. Thus one must take into account the possibility that the epoxidation reactions proceed not only via metallaoxetanes but also via other routes, especially since the evidence for the existence of metallaoxetanes is incomplete. This situation resembles somewhat that which has arisen in the study of the possibility of the existence of the oxoferryl ion. Indeed, if the ferraoxetane is highly reactive (this means that it is short lived), then it is difficult or impossible to detect it experimentally. Hence it follows that the question of the formation of metallaoxetanes in the epoxidation reaction remains controversial.[283]

The epoxidation of alkenes (S) by hydrogen peroxide in the presence of iron-porphyrin complexes may proceed via different reaction paths:[5] via a homolytic path with the generation of $^{\cdot}OH$

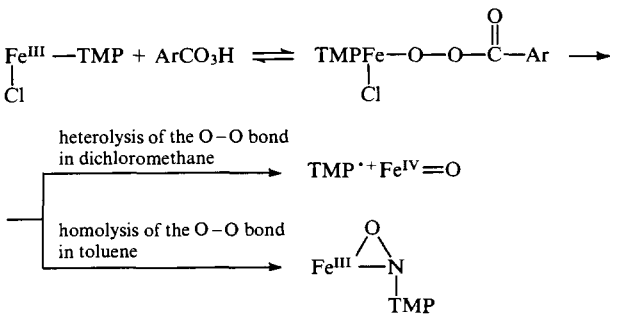


Scheme 20



(path *a*, Scheme 20), via a heterolytic path with formation of oxoferryl species (path *b*), and via a catalase path, in which the addition of a second H_2O_2 molecule with formation of O_2 and H_2O is postulated (path *c*). Path *b* is the main one,[5,209] while path *c* is the second in importance.

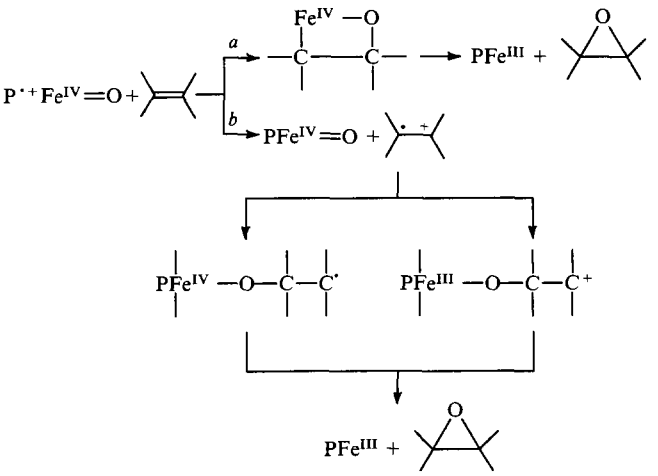
The epoxidation by hydroperoxides involves their decomposition by iron(III)-porphyrins as a result of a homolytic process with formation of a complex between oxoiron(IV) and the alkoxyl radical RO·,[5,284] i.e. via a free-radical mechanism, although other paths are not ruled out.



The nature of the solvent also exerts a significant effect on the nature of the intermediates formed and on the process selectivity. Thus, in the epoxidation of a 1 : 1 mixture of norbornylene and α-methylstyrene by chloroperbenzoic acid in the presence of the complex Fe^{III}TMP(Cl) [tetramesitylporphyrinatoiron(III) chloride] as the catalyst at −78 °C in dichloromethane, norbornylene is oxidised to a greater extent than α-methylstyrene (100 : 9).[285] In these reactions, the colour of the solution changed from brown to green after the addition to the system of $ArCO_3H$ as the source of oxygen, which indicates the formation of the oxoiron(IV)-porphyrin π-radical-cation ($TMP^{\cdot+}Fe^{IV}=O$) from the intermediate peracid complex of iron.

When the epoxidation is carried out in an aromatic solvent (toluene), the selectivity with respect to the alkenes changes significantly: comparable amounts of norbornylene and α-methylstyrene are oxidised. In this case, the active species in the epoxidation process is the *N*-oxide[286]

while the formation of the $TMP^{\cdot+}Fe^{IV}=O$ species is less probable.[285]

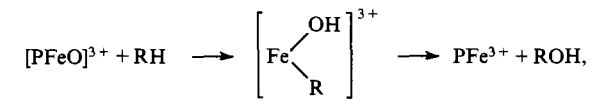


Hence the nature of the active intermediate species produced and the selectivity determined by this factor depend to a large extent on the choice of solvent.

The nature of the substituents in the porphyrin ring and of the axial ligand also influences the activity of the catalyst in the epoxidation reactions. It has been established that an increase in the number of electron-accepting substituents in the porphyrin ring and an increase in the electron-accepting capacity of the axial ligand increase the electrophilicity (oxidising power) of the intermediate oxoiron(IV)-porphyrin π-radical-cation, as a consequence of which the activity of this species increases.

The details of the formation of the type $P^{\cdot+}Fe^{IV}=O$ intermediates in living systems are not as yet entirely clear. One of the possible routes is the formation of a peroxide bridge. For example, in the interaction of the complex $[Fe^{III}(OH^-)(TMP)]^+$ with *p*-$NO_2C_6H_4CO_3H$, the intermediate Fe^{III}(TMP) peroxybenzoate is formed initially and its decomposition then affords $(TMP^{\cdot+})Fe^{IV}=O$, i.e. the same species as in the processes occurring under the influence of cytochrome P-450. It has been suggested that the mechanisms of the epoxidation of different alkenes (for example, norbornene) in the presence of iron(III)-tetraarylporphyrin and pentafluoroiodosobenzene by systems modelling cytochrome P-450 involve the formation of the $P^{\cdot+}Fe^{IV}=O$ intermediate, which interacts with alkenes at a rate close to that of a diffusion process, as a result of which it is impossible to isolate it at normal temperatures. It has been suggested in this connection[287] that electrocyclic addition (*a*) and electron transfer (*b*) mechanisms operate.

Scheme 21

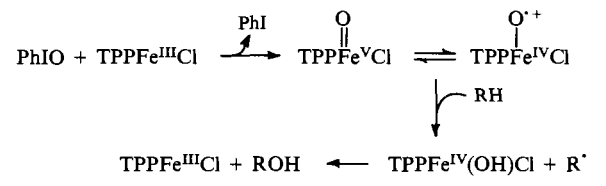


The first mechanism includes the electrolytic addition of the alkene to $Fe^{IV}=O$ with formation of a ferracyclooxetane and the second involves initial electron transfer with formation of a

radical-cation and the subsequent decomposition of the latter into either radical or cationic species. The idea of electron transfer (path *b*) agrees with all the available kinetic data and with the proportions of the reaction products. This is the most probable mechanism of the oxidation of alkenes in both model and enzyme systems.[287]

The characteristic features of processes involving the hydroxylation of alkanes as well as the epoxidation of alkenes depend on the source of oxygen, the nature of the catalyst, and other factors. Thus the oxidation of cyclohexane with the aid of PhIO and FeTTPCl [*meso*-(tetra-*o*-tolylporphyrinato)iron chloride] leads to the formation of cyclohexanol and cyclohexanone, hydroxylation proceeding via a radical mechanism.[5] It has been shown[288] that alkanes may be oxidised also in accordance with a cryptoradical mechanism via the formation of the $P^{\cdot+}Fe^{IV}=O$ active species.

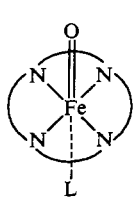
The introduction of substituents into the porphyrin alters the regioselectivity of the oxidation of alkanes.[239,289–291] The regioselectivity of these reactions should depend on steric and electronic factors, which has in fact been demonstrated in a study of the oxidation of hexane by iodosobenzene, where a tetraphenylporphyrin complex of iron (TPPFeCl) was used as the catalyst.[242] The ratio of the oxidation products (2-hexanol and 3-hexanol) was then determined mainly by steric factors, while the ratio of 1-hexanol and 3-hexanol depended on both steric and electronic characteristics of the substituents. An increase in steric hindrance in the porphyrin molecule increased the proportions of both 1-hexanol and 2-hexanol relative to 3-hexanol because of the greater accessibility of the atoms of the first two alcohols. The introduction of electron-accepting substituents into the porphyrin molecule promotes the generation of a more electrophilic oxoferryl species, which also facilitates the formation of the primary alcohol. Thus the study of the steric and electronic effects in model systems made it possible to understand better the nature of similar effects generated by proteins in the monooxygenase enzyme systems.[242,292,293]



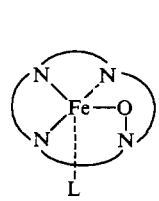
Insertion of an oxygen atom into a C–H bond of the alkane in model systems is apparently a two-electron process, which proceeds with the intermediate formation of an alkylhydroxocomplex,[242] i.e.

$$[PFeO]^{3+} + RH \longrightarrow \left[\begin{array}{c} OH \\ Fe \\ R \end{array}\right]^{3+} \longrightarrow PFe^{3+} + ROH,$$

although the preliminary formation of the $[PFeOH + R^{\cdot}]^{3+}$ couple cannot be ruled out in individual instances.



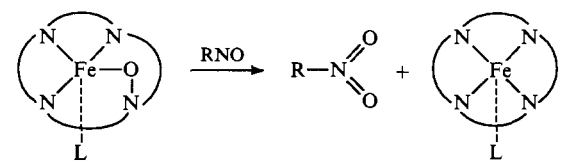
A similar mechanism of the hydroxylation of cyclohexane (RH) by iodosobenzene has been proposed on the basis of the analysis of spectroscopic and EPR data.[294]



$$PhIO + TPPFe^{III}Cl \xrightarrow{PhI} TPPFe^{V}(O)Cl \rightleftharpoons TPPFe^{IV}(O^{\cdot+})Cl$$

$$TPPFe^{IV}(OH)Cl + R^{\cdot} \xrightarrow{RH} TPPFe^{III}Cl + ROH$$

As in many other investigations (see, for example, Refs 268 and 295–297), in this case the structure of the active catalyst (the oxoferryl species) was represented by formula **8**.



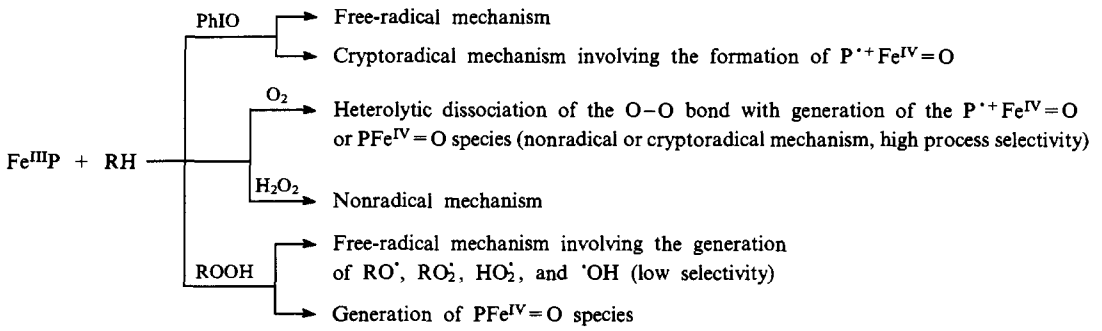
8

9

However, both experimental[298–300] and theoretical[212,301–303] points of view give rise to doubts about structure **8**. As a result, another structure (formula **9**) was proposed in which the oxygen atom was inserted in one of the iron–nitrogen bonds. This model of the oxoiron-porphyrin was used [304] to describe the oxidation of the nitroso-compounds RNO (R = Ar or Bu^t) to the nitro-compounds RNO_2. In the presence of PhIO and the very effective catalyst TPPFe(III)Cl at 0 °C and even at −78 °C (in dichloromethane), this reaction proceeds very rapidly, so that the yield of the nitro-compound reaches more than 90% after several minutes. The tentative mechanism of the formation of RNO_2 from the oxoferryl species **9** can be represented in the following way:[304]

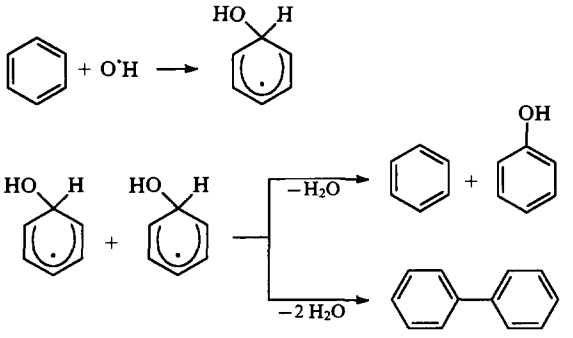
In the presence of *meso*-[tetra(pentafluorophenyl)porphyrinato]iron (F_{20}TPP)Fe, isobutane is hydroxylated at a low temperature in Bu^{t}OH with a selectivity up to 95%. The hydroxylation can occur even at room temperature, but this requires *meso*-[tetra(pentafluorophenyl)-β-octabromoporphyrinato]iron as the catalyst. The proposed mechanism involves the reduction of the iron(III)-porphyrin complex to the iron(II) complex, the formation of an oxoiron μ-complex, and its subsequent conversion into the $Fe^{IV}=O$ form. The latter reacts with isobutane, abstracting a hydrogen atom.[5]

In the presence of hydrogen peroxide as the source of the oxygen, polyhalogenated iron-porphyrins, containing bromine, chlorine, or fluorine in the β-pyrrole positions, catalyse the hydroxylation of aromatic compounds (for example, benzene to phenol) at room temperature.[5]



On the other hand, if the oxidants are alkyl hydroperoxides ROOH, then two paths leading to the activation of a C–H bond of the substrate are followed in the presence of iron-porphyrins: via the homolytic cleavage of the O–O peroxide bond with formation of a RO$^{\cdot}$ free radical or via the heterolytic dissociation of this bond with generation of oxoferryl species.[305] Thus the mechanisms of the hydroxylation of alkanes when different oxygen sources are employed can be represented in a general form as shown in Scheme 22.

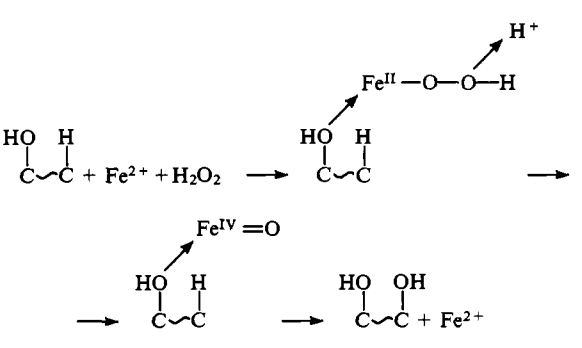
These hydroxylation mechanisms predominate, although it has been suggested that, depending on the nature of the iron porphyrinates, the choice of the solvent, and temperatures, other mechanisms, differing in certain details, may also operate.[5]



Despite the entire wide variety of the systems modelling monooxygenases and of the iron-porphyrin complexes employed in them, and also despite the dependence of the mechanisms of the oxidation of alkenes and alkanes on the surroundings of the catalyst active centre, one may say that, overall, the processes involving the epoxidation and hydroxylation of organic substrates proceed via the formation of highly reactive oxoferryl iron complexes, although one cannot fully exclude other paths.

Numerous studies have been devoted to the catalytic hydroxylation of the aromatic ring by the Fenton reagent ($Fe^{2+} + H_2O_2$).[130,306–311] Under these conditions, benzene, phenol, and their derivatives are hydroxylated in an aqueous medium via the generation of $^{\cdot}OH$ radicals, which interact with the corresponding substrates via the formation of various intermediate substrate radicals. For example, the hydroxylation of benzene involves the formation of the hydroxycyclohexadienyl radical, which, on subsequent disproportionation or dimerisation, is converted into phenol or biphenyl respectively.

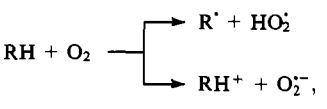
Scheme 22



Scheme 23

The effectiveness of the hydroxylation of benzene by the Fenton reagent depends in many respects on the reactant ratios, the pH of the medium, and other factors. The selectivity of the hydroxylation of benzene and phenol derivatives is low and the reaction proceeds via a radical mechanism. It has been shown that, in the hydroxylation of the aromatic ring (especially in benzene) by the Fenton, Udenfriend [$Fe^{3+}-O_2(H_2O_2)$–EDTA–AH_2, where AH_2 = ascorbic acid], and Hamilton (Fe^{3+} – L – H_2O_2, where L = different ligands) systems, the highest yield of the product is observed in the last case.[130] However the selectivity and yields are nevertheless low in all the systems, although it is sometimes possible to increase them.[312]

In aqueous-aprotic or aprotic solvents, both the selectivity and the yield of the hydroxylation products increase in a number of instances and a series of physicochemical characteristics also change. It therefore becomes impossible to describe the hydroxylation reaction as a radical process involving the interaction of ·OH with substrates, and the formation of an oxoferryl species, which promotes the insertion of an oxygen atom in the C–H and C=C bonds and in the aromatic ring, is postulated in this instance. For example, in the oxidation of an alcohol by the Fenton reagent in acetonitrile, proportions of the isomers in the reaction products uncharacteristic of a radical process are observed, which can be accounted for by the fact that the active hydroxylating species is not the ·OH radical but an oxoferryl compound.[313]



The formation of an oxoferryl intermediate in a process involving the Fenton reagent is also indicated by the extremely high NIH shifts (the migration of hydrogen isotopes on hydroxylation of labelled compounds), which are observed when an oxygen atom is inserted into the 4-deuteriochlorobenzene, 4-deuterioanisole, and 1,4-dideuterionaphthalene in nitromethane and acetonitrile (the NIH shifts are 38%, 30%, and 68% respectively). Small NIH shifts correspond to radical processes. Thus, in the hydroxylation of the first two compounds in water, the NIH shifts were 2% and 3% respectively.[314,315] The appreciable increase in the NIH shift on passing from aqueous to aprotic media shows that in the latter case the hydroxylation of aromatic compounds proceeds via the formation of oxoferryl intermediate.[315]

V. The role of iron compounds in the manifestation of toxicity by the products of the reduction of O_2 in vivo

Iron compounds as catalysts activate O_2 and H_2O_2, generating reactive species $O_2^{\cdot-}$, ·OH, and $LFeO^{2+}$) via the reduction of dioxygen and hydrogen peroxide. These species are responsible for the toxicity of the products of the reduction of O_2, participating both in the peroxide oxidation of lipids and in the decomposition (damage) of deoxyribonucleic acids (DNA) and other biological targets in vivo.[316]

Iron complexes play an important role in the peroxide oxidation of lipids, i.e. in a process where the substrates are aliphatic acids, especially polyunsaturated acids. This process exerts a significant effect on biological membranes, influences the toxicity of medicinal preparations, and contributes to carcinogenesis and other manifestations of the oxidative stress. A detailed survey of the lipid peroxidation processes may be found in many of the articles in a collected volume.[317] In the present section, attention is concentrated on the role of iron compounds in this process and on their interaction with oxygen species, especially with the superoxide radical-ion $O_2^{\cdot-}$.

The direct interaction of O_2 with organic compounds in vivo, i.e.

with formation of $O_2^{\cdot-}$ is extremely slow as a consequence of the endothermic nature of this reaction. However, in biological systems a number of reductants, for example the flavines (FH_2), may interact nonenzymically with O_2 via a radical mechanism to form the hydroperoxyl radical $HO_2^{\cdot}$.[318]

The hydroperoxyl radical is also generated in the autoxidation of cytochrome P-450[319] in the xanthine–xanthine oxidase system and in many other cases.[318]

The interaction of $O^{\cdot}_2^-$ with H_2O_2 affords the radical $^{\cdot}OH$:

$$O^{\cdot}_2^- + H_2O_2 \longrightarrow O_2 + OH^- + {}^{\cdot}OH.$$

However, in aqueous solution the rate constant for this reaction is close to zero and at low concentrations of the starting materials the interaction does not take place noncatalytically.

The presence in vivo of iron ions or compounds (under physiological conditions, at micromolar concentrations) makes this reaction catalytic (the Haber–Weiss reaction).

$$Fe^{3+} + O^{\cdot}_2^- \longrightarrow Fe^{2+} + O_2$$
$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^- + {}^{\cdot}OH$$
$$O^{\cdot}_2^- + H_2O_2 \xrightarrow{Fe^{III}} O_2 + OH^- + {}^{\cdot}OH$$

In aqueous solutions, $O^{\cdot}_2^-$ has reducing rather than oxidising properties. However, in vivo there are many other reductants (NADPH, NADH, cysteine, etc.), which may compete with $O^{\cdot}_2^-$. Hydrogen peroxide readily permeates through cell membranes, whereas $O^{\cdot}_2^-$ can pass only through special channels.[320] Furthermore, a ferryl species together with a suitable iron complex, similar to the active compounds A and B of peroxidase and cytochrome P-450 as regards the oxidation state of oxoiron, may be formed via the reaction

$$LFe^{3+} + {}^{\cdot}OH \longrightarrow (LFe^{IV}{=}O)^{2+} + OH^-,$$

and also via another route.

The human organism contains on average approximately 4 g of iron, 66% of which is present in haemoglobin, ~ 10% in myoglobin, a small amount in various iron-containing enzymes and in the transport protein transferrin, while the rest is present in storage tissues (ferritin and haemosiderin) and in certain other tissues, organs, and intercellular fluids.[320]

The presence of iron in the living organism makes possible the formation of ferryl species or $^{\cdot}OH$ radicals. The latter are capable of abstracting a hydrogen atom from the lipid (LipH) and of forming a hydrocarbon radical derived from polyunsaturated aliphatic acids (Lip$^{\cdot}$), which reacts rapidly with O_2 and generates a peroxyl radical ($LipO^{\cdot}_2$). This radical interacts with the lipid molecule, forming the lipid hydroperoxide (LipOOH), which is fairly stable under physiological conditions. One of the functions of compounds of iron (and certain other transition metals) consists in catalysing the decomposition of LipOOH. In vivo, such iron complexes may be formed by phosphates, phosphate esters (ADP), and porphyrins (haemoglobin, methaemoglobin, peroxidase, cytochrome P-450, other cytochromes, and nonhaem iron-proteins) and can participate in the propagation of the membrane lipid peroxidation chain with formation of alkoxyl and alkylperoxyl radicals (LipO$^{\cdot}$ and $LipO^{\cdot}_2$ respectively), which stimulate the given chain reaction. All these reactions can be represented as follows:[320]

$$LipH + {}^{\cdot}OH \longrightarrow Lip^{\cdot} + H_2O,$$
$$Lip^{\cdot} + O_2 \longrightarrow LipO^{\cdot}_2,$$
$$LipO^{\cdot}_2 + LipH \longrightarrow LipOOH + Lip^{\cdot},$$
$$LipOOH + LFe^{2+} \longrightarrow LFe^{3+} + OH^- + LipO^{\cdot},$$
$$LipOOH + LFe^{3+} \longrightarrow LFe^{2+} + H^+ + LipO^{\cdot}_2.$$

It is frequently assumed that the iron complexes initiate the peroxide oxidation of lipids. In reality, however, in most cases they also induce the decomposition of the lipid hydroperoxides formed previously and the generation of oxygen radicals ($O^{\cdot}_2^-$ and $^{\cdot}OH$).

$$LFe^{2+} + O_2 \rightleftharpoons LFe^{2+}O_2 \longleftrightarrow LFe^{3+}O^{\cdot}_2^- \rightleftharpoons LFe^{3+} + O^{\cdot}_2^-$$
$$2O^{\cdot}_2^- + 2H^+ \longrightarrow H_2O_2 + O_2$$
$$LFe^{2+} + H_2O_2 \longrightarrow LFe^{3+} + OH^- + {}^{\cdot}OH$$

Indeed the hydroperoxides formed on peroxidation are unstable and their subsequent decomposition to iron(II, III) compounds leads to the formation of numerous products, containing aldehyde, keto-, hydroxy-, epoxy-, and carboxy-groups. The aldehyde products formed are frequently responsible for the poor taste of many food products, in particular for the incipient bitter taste of fats and oils. It has been shown that highly reactive aldehydes, such as hydroxyalkenals (for example, 4-hydroxynonenal) are formed in vivo on peroxidation of liver microsomal lipids and that, by accumulating in the NADPH–Fe systems, they inhibit the syntheses of many substances important for cells.[321]

The available kinetic data also fail to confirm the hypothesis[322] that the peroxidation of lipids is initiated by species of the type $Fe^{2+}O_2 \leftrightarrow Fe^{3+}O^{\cdot}_2^-$ or $O^{\cdot}_2^-$. The $O^{\cdot}_2^-$ species cannot be an initiator in the absence of iron ions.[323] Indeed, it has been shown[324] that the cell toxicity of the product of the adriamycin (an antibiotic used in tumour therapy) redox cycle in vivo is associated with the enhanced formation of oxygen radicals, which initiate the peroxide oxidation of lipids only in the presence of Fe^{3+} ions.

Redox cycle:

$$\text{Adriamycin} + \tfrac{1}{2}\text{NADP} + H^+ \xrightarrow{\text{NADPH–cytochrome P-450}} \text{adriamycin semiquinone} + \tfrac{1}{2}NADP^+$$
$$\text{Adriamycin semiquinone} + O_2 \longrightarrow \text{adriamycin} + O^{\cdot}_2^-$$

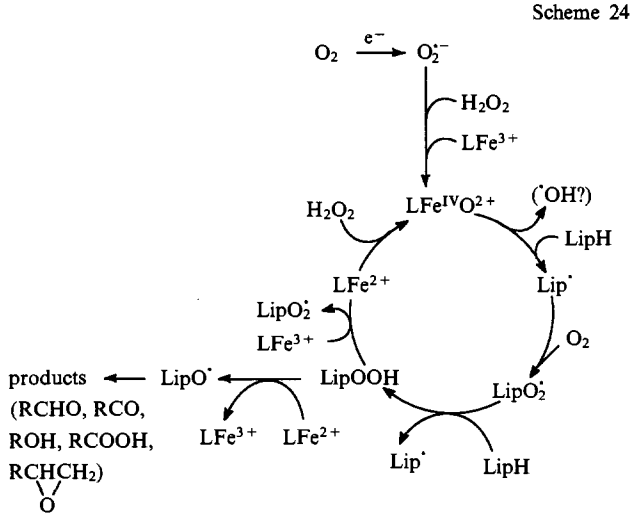
Stimulation:

$$Fe^{3+} + O^{\cdot}_2^- \longrightarrow Fe^{2+} + O_2$$

Peroxidation of lipids:

$$LipH + O_2 + Fe^{2+} + H^+ \longrightarrow Lip^{\cdot} + H_2O_2 + Fe^{3+}$$
$$Lip^{\cdot} + O_2 \longrightarrow LipO^{\cdot}_2$$
$$LipO^{\cdot}_2 + LipH \longrightarrow LipOOH + Lip^{\cdot}$$
$$Fe^{3+} + \tfrac{1}{2}NADPH + H^+ \xrightarrow{\text{NADPH–cytochrome P-450}} Fe^{2+} + NADP^+$$

Seemingly the $^{\cdot}OH$ radical should be the initiator of the peroxidation of lipids.[325] However, another point of view has been put forward nowadays, according to which the initiator of this process is tentatively identified as the ferryl species and not the $^{\cdot}OH$ radical, since the latter cannot be detected with the aid of usual trapping agents. It may be that the $^{\cdot}OH$ radical reacts with the hydrophilic lipid 'heads' and does not therefore reach the aliphatic acid side chains.[320] The formation of the ferryl species has also been postulated in the model microsomal and xanthine oxidase oxidation processes.[322]



$$ADP{-}Fe^{2+}O_2 \xrightarrow[-2e^-]{2H^+} ADP{-}[FeO]^{2+} + H_2O$$

It has been assumed that this species may be the main product of the reaction of the adenosine diphosphate (ADP) complex of iron(II) with H_2O_2. This assumption was based on the fact that the addition of mannitol (which removes the $^{\cdot}OH$ radicals) to the $ADP{-}Fe^{2+} - H_2O_2 - LipH$ system did not alter the rate of peroxidation of lipids.

Similar claims concerning the formation of the ferryl species have been made in a communication[323] which dealt with the study of the model nonhaem system Fe^{2+} – diethylenetriaminepentaacetic acid – H_2O_2 – LipH. However, the idea that the oxoferryl species plays an initiating role requires further confirmation and elucidation.

Nevertheless, the peroxidation of lipids catalysed by the ferryl species $LFeO^{2+}$ (or 'OH?) may be illustrated by Scheme 24.

Scheme 24

Reductants such as ascorbate, NADH, NADPH, and others, which on interaction with H_2O_2 can also generate 'OH and can play an even more important role than $O_2^{\bullet-}$, are present in the cells in fairly large amounts.[326] Furthermore, H_2O_2 may oxidise ADP – Fe^{2+} to ADP – F^{3+} (L = ADP), generating 'OH, although the latter does not initiate the peroxidation of the lipid under these conditions, which is indicated by the finding that mannitol (an 'OH trapping agent) does not inhibit the reaction.[327] Thus the problem of the initiation of the peroxide oxidation of lipids is to a large extent controversial.

Together with the peroxide oxidation of lipids, there are a multiplicity of other processes, whose substrates are biological targets capable of being damaged by the products of the catalytic reduction of O_2 in the presence of iron compounds (degradation of deoxyribonucleic acid, phagocytosis, autoxidation of monosaccharides, and other reactions). In order to carry out in vivo reactions of the Haber – Weiss type, it is necessary to have not only sources of $O_2^{\bullet-}$ (discussed above), but also sufficient amounts of H_2O_2 and iron compounds.

Hydrogen peroxide is produced by bacteria of various types, it is generated in phagocytes, in spermatozoa, in mitochondria, and in many other formations. Thus H_2O_2 is produced by a series of enzymes (for example, by glycolate and urate oxidases).[320] the crystalline lens of the human eye also contains micromolar concentrations of hydrogen peroxide.[328] Its vapour is evolved even during human respiration [329] (although such vapour may be partly or fully the product of activity of dental bacteria [320]).

Iron compounds, not bound to a protein, at concentrations of several micromoles per litre, migrating between transferrin, cell cytoplasm, mitochondria, and ferritin and interacting with H_2O_2, can effect Fenton type reactions in which 'OH radicals are generated.[330] In aqueous solution, the $O_2^{\bullet-}$ species reduce iron(III) to iron(II), creating thereby conditions for the occurrence of the catalytic Haber – Weiss reaction accompanied by the formation of the 'OH radical. Under these conditions, different ligands affect differently the ability of $O_2^{\bullet-}$ to reduce iron(III). For example, the specific ligands desferrioxamine and bathophenanthroline inhibit this reaction [iron(III) is not reduced to iron(II)], while ethylenediaminetetraacetic acid, adenosine triphosphate, and picolinic acid promote it by the rapid reduction of the corresponding iron(III) complexes to iron(II) complexes.[320]

The use of specific complex forming agents, which bind iron(III) and thereby prevent its reduction, can promote the inhibition of the oxidative damage in the therapy of afflictions of the heart, the kidneys, the skin, and other tissues and can also weaken the post-traumatic degeneration of tissues in the brain and the spinal column.[193]

The 'OH radical formed in vivo by the Haber – Weiss reaction acts more disruptively and specifically than the same radical generated by radiolysis. In the former case, following its formation the radical interacts (by virtue of its high reactivity) with the nearest biological target separated from it by not more than 5 – 10 Å, while in the latter case the interaction takes place over a larger volume of the solution. On the other hand, if the $O_2^{\bullet-}$ radical-ion, with a low reactivity towards many biological molecules, is generated, then it is capable of diffusing over fairly long distances until it encounters an iron(III) complex of a biological target (for example, DNA).[193,196–198] The iron(III) in these complexes is reduced by the $O_2^{\bullet-}$ species to iron(II). By interacting with H_2O_2, the iron(II) compounds may generate 'OH in the vicinity of a biological target, which serves as the ligand for iron(III) and a substrate for 'OH. These 'OH radicals, generated by a locally specific mechanism, act more effectively and selectively than the same radicals obtained directly in the cell.[331]

The phagocytotic mechanism of the action of 'OH in the cell is described similarly.[332] The biological target may be protected by introducing into the system substances such as thiourea and mannitol, which are capable of binding iron and of extracting it from the biological targets.[196,197,333]

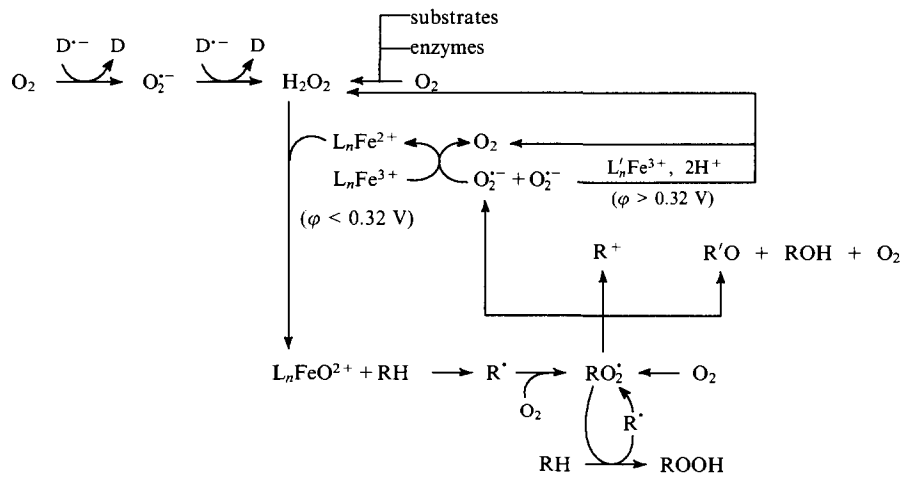
An alternative to the formation of 'OH radicals is the generation of iron(IV) or ferryl species, which, being less reactive than 'OH, exhibit also a different toxicity in relation to biological objects. Such compounds have been identified in the reactions of hydrogen peroxide with the water-soluble iron(III)-porphyrin.[188]

Protection against the toxicity of $O_2^{\bullet-}$ is known to be achievable with the aid of many iron(III) compounds, which catalyse the dismutation of $O_2^{\bullet-}$ via the action of superoxide dismutases in accordance with the 'ping-pong' mechanism.

$$Fe^{3+} + O_2^{\bullet-} \longrightarrow Fe^{2+} + O_2$$

$$\underline{Fe^{2+} + O_2^{\bullet-} + 2H^+ \longrightarrow Fe^{3+} + H_2O_2}$$

$$2O_2^{\bullet-} + 2H^+ \longrightarrow H_2O_2 + O_2$$



If the rate of the third stage exceeds significantly the rate of the second stage of the Haber – Weiss mechanism, then the iron compound will protect the biological system against the toxicity of $O_2^{\bullet-}$.[331]

A number of enzymes (catalase, glutathione peroxidase, cytochrome *c* peroxidase) protect the organism against oxidative damage.[334]

A thermodynamic condition for the occurrence of the Haber – Weiss reaction is a fairly low reduction potential of the iron complex ($\varphi = 0.32$ V under standard conditions).[335] For a higher potential ($\varphi = 0.32 - 0.94$ V), the iron complexes catalyse the dismutation reaction, but not the Haber – Weiss reaction. Thus, by employing different ligands, it is possible to vary the superoxide toxicity (this includes also a reduction of the toxicity). The inhibition or, conversely, the enhancement of the superoxide toxicity depend not so much on the stability of the iron(III) complexes formed with specific or nonspecific ligands as on the oxidation – reduction potential of iron, which varies under their influence. Depending on this factor, the process proceeds either via the dismutation path, whereupon the toxicity is suppressed, or via the path involving the Haber – Weiss reaction whereupon it is enhanced.

The overall mechanism of the manifestation of the oxygen toxicity has been described.[335,336] It can be supplemented slightly by taking into account the influence of specific (L') and nonspecific (L) ligands (Scheme 25).

Scheme 25

The electron donor $D^{\cdot -}$ reduces O_2 to $O_2^{\cdot -}$ and H_2O_2. By acting on L_nFe^{II}, the latter forms the ferryl species L_nFeO^{2+}, which, being an oxidant, interacts with the biological target, generating $R^{\cdot}$. On combining with O_2, the radical $R^{\cdot}$ gives rise to $RO_2^{\cdot}$, which is converted jointly with RH into the hydroperoxide ROOH and $R^{\cdot}$. Depending on the nature of the ligand (L or L') and the oxidation-reduction potentials φ, either the Haber–Weiss reaction or the dismutation reaction can take place. Lipids can also serve as the biological targets RH. Since the cell contains numerous reductants (for example, ascorbic acid), which may reduce iron(III) directly to iron(II) at a higher rate than that achieved by the superoxide radical-ion $O_2^{\cdot -}$, the decisive role of the latter in the manifestation of oxygen toxicity becomes doubtful, although it is not excluded.[187,337]

Oxygen toxicity is manifested in the autoxidation of monosaccharides (for example, glyceraldehyde). The monosaccharide enediols formed are oxidised catalytically by iron compounds, generating ketoaldehydes, $O_2^{\cdot -}$, H_2O_2, and $^{\cdot}OH$.[338] The oxidation of monosaccharides may be accompanied by the glycolysis of the proteins and a colour change (to brown). It promotes the appearance of hyperglycaemia (diabetes), i.e. the joint oxidation of tissues, which is frequently accompanied by secondary processes — atherosclerosis, kidney failure, cataracts, and pathological conditions in the eye retina. The autoxidation of monosaccharides may promote the appearance of diabetic complications. The concentration of monosaccharides increases greatly in hyperglycaemia, i.e. the content of hydrogen peroxide and other reactive species ($O_2^{\cdot -}$, $^{\cdot}OH$), participating in the autoxidation of monosaccharides, also rises. For example, the above species, toxic to cells, may be generated in erythrocytes and in the crystalline lens of the eye. The catalytic oxidation of the monosaccharide enediols by iron compounds may be accompanied by oxidative stress in hyperglycaemia and the atherosclerosis associated with it.[338]

VI. Conclusion

Comparative analysis of the experimental and theoretical data on the catalytic activation of dioxygen and hydrogen peroxide and the oxidation of organic substrates by these compounds made it possible to devise general mechanisms for these processes. In considering the mechanisms of catalytic reactions, the possible role of intermediates of the type of ferryl ions and complexes was emphasised, since their identification and vigorous investigation have begun comparatively recently. We attempted to consider from a single standpoint three main mechanisms of catalytic oxidation-reduction processes: radical, radical-chain, and ion-molecule. Since porphyrin and certain other iron complexes as well as ferryl species play an extremely important role in living organisms, the epoxidation and hydroxylation reactions with participation of these species have been examined in greatest detail. Using the general mechanisms of the catalytic oxidation-reduction reactions, we discussed in detail also the role of iron compounds in the manifestation of toxicity by the products of the reduction of dioxygen in vivo.

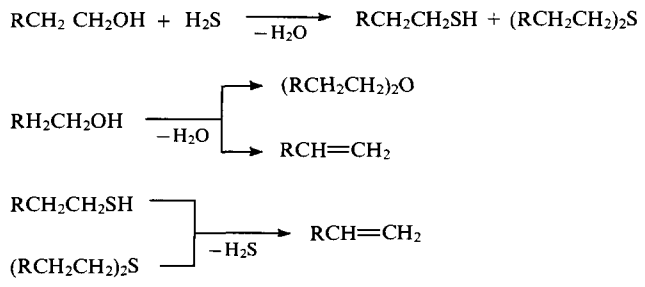
Heterogeneous catalytic synthesis of alkanethiols and dialkyl sulfides from alcohols and hydrogen sulfide

A V Mashkina

Contents



I.	Introduction	1131
II.	Catalysts for the conversion of alcohols into thiols by hydrogen sulfide	1132
III.	The mechanism of conversion of alcohols into thiols by hydrogen sulfide	1138
IV.	Selection of catalysts and conditions for the conversion of alcohols into thiols	1143
V.	Conclusion	1145

Abstract. The results of studies of the heterogeneous acid-base catalysis of reactions of alcohols with hydrogen sulfides, which yield alkanethiols and dialkyl sulfides, are surveyed. Data concerning the activity and selectivity of the catalysts under the reaction conditions are considered. A relation is established between the catalytic and acid–base properties of the catalysts. The mechanism of the thiolation reaction is discussed and the criteria for the selection of the effective catalysts are formulated. The bibliography includes 97 references.

I. Introduction

Catalysis has played an important role in the development of the chemistry of organic compounds of sulfur.[1] This applies also to the synthesis of compounds with thiyl and sulfide groups, in particular of alkanethiols and dialkyl sulfides, which have valuable properties and have therefore found extensive applications.

Alkanethiols and dialkyl sulfides may be obtained also by noncatalytic methods, but these require the employment of expensive starting materials, which are in many cases difficult to obtain. It is more convenient to synthesise these substances from the industrially produced alcohols and hydrogen sulfides.

The thermodynamic feasibility of reactions involving the formation of alkanethiols and dialkyl sulfides from alcohols and hydrogen sulfide, the dehydration of alcohols with formation of a dialkyl ether and an alkene, and the decomposition of alkanethiols and dialkyl sulfides with formation of hydrogen sulfides and alkenes is very high.[1–5]

The conversion of alcohols into thiols occurs only in the presence of catalysts. By regulating their composition and the reaction conditions, it is possible to direct the process towards the formation of the desired product. The heterogeneous-catalytic method of synthesis of alkanethiols and dialkyl sulfides is the most promising because it is highly productive and is susceptible to technological application, which makes it possible to simplify the isolation of the reaction products and the catalyst from the reaction medium and to reduce the amount of ecologically harmful waste.

The practical application of effective processes leading to the synthesis of alkanethiols and dialkyl sulfides requires active and selective solid catalysts. In 1910, Sabatier[6] was the first to use a solid catalyst (thorium dioxide) in the gas-phase reactions of alcohols with hydrogen sulfide, which lead to the formation of alkanethiols and dialkyl sulfides. In 1921, this reaction was achieved[7] in the presence of ThO_2 deposited in an amount of 25 mass% on pumice, at 260 – 380 °C, atmospheric pressure, and for the molar ratio H_2S : alcohol = 0.75 – 2.0. The main products of the reactions of hydrogen sulfide with methanol, ethanol, 1- and 2-butanols, and 2-pentanol were the corresponding thiols, with yields of 35% – 52%; aldehydes were also formed in yields up to 20% together with small amounts of alkenes and traces of dialkyl sulfides. During the first world war, this catalyst was used to produce butane-1-thiol from 1-butanol and hydrogen sulfide.[2,8,9] Further studies were directed to the search for more active and selective catalysts, which led to the creation abroad in the 1950s – 1970s of industrial processes in which unpromoted alumina was employed initially and then also other catalysts. However, neither the technology of the manufacturing process nor the catalysts employed are known.[8]

The available information about the catalysts and the conditions in the synthesis of alkanethiols and dialkyl sulfides from alcohols and hydrogen sulfide referring to the period up to 1970 – 1975 is contained mainly in patents and the reviews based on them.[2,8–10] It is claimed that catalysts active in the syntheses of methanethiol and dimethyl sulfide may be used in the synthesis of alkanethiols and dialkyl sulfides from hydrogen sulfide and various alcohols, but specific examples almost always refer to the reaction of methanol with hydrogen sulfide. Certain theoretical publications also appeared during this period, but the relevant

studies were not systematic and no attempts were made at a quantitative comparison of the properties of the catalysts in the thiol formation processes. Since the publication of the reviews mentioned above,[2,8-10] data have accumulated, but have not yet been arranged systematically, on the catalysts used in the gas-phase heterogeneous synthesis of alkanethiols and dialkyl sulfides from alcohols and hydrogen sulfide and on the mechanism of the thiolation reactions, which is important for the prediction of the catalytic action and the creation of new effective catalysts. These data are surveyed in the present review.

II. Catalysts for the conversion of alcohols into thiols by hydrogen sulfide

Alcohols are converted into thiols by treatment with hydrogen sulfide in the presence of both massive and supported catalysts. The rate of reaction (w) and the selectivity (S) in the formation of the thiol and the sulfide, which is equal to the ratio of the yield of the corresponding product to the degree of conversion of the alcohol (x), depend on the reaction conditions: temperature, molar ratio of hydrogen sulfide to the alcohol (M), the pressure (P)†, and the contact time (τ)‡.

1. Metal oxides and sulfides

The reaction of alcohols with hydrogen sulfides is accelerated, albeit to different extents, by massive metal oxides and sulfides. Silicon dioxide is relatively ineffective in the conversion of alcohols into thiols.[11-13] Thus, in the interaction of methanol with hydrogen sulfide in the presence of SiO_2, the yields of methanethiol and dimethyl sulfide were 5 mol% and 1.2 mol% respectively (360 °C, M = 0.6–1.6, τ = 42 s, $x \leqslant 20\%$).[11,12] The activity of magnesium oxide is also low in this reaction: the yield of methanethiol was 2 mol%–3 mol% (350 °C, M = 0.5–2.0, $\tau \approx 2$ s).[14] The reaction of 1-butanol with hydrogen sulfide on MgO leads to the formation of butane-1-thiol and butene in 32 mol% and 50 mol% yields respectively (300 °C, M = 10, τ = 21 s, x = 62%).[15] High yields of sulfur-containing products have been attained in the conversion of alcohols into thiols on a series of massive oxides. It has been found[14] that, in the interaction of methanol with hydrogen sulfide on TiO_2 (anatase), the selectivity with respect to methanethiol is 31% and 57% and that with respect to dimethyl sulfide is 52% and 41% respectively for M = 0.5 and 2.0 (350 °C, $\tau \approx 5$ s, and x = 32%–91%). On TiO_2 (rutile), the degree of conversion under these conditions is lower (15%–45%), but a high selectivity with respect to methanethiol and a reduced selectivity with respect to dimethyl sulfide are observed (85%–95% and 3% respectively). Methanol decomposes with formation of methane on both modifications of TiO_2. The conversion of ethanol into the thiol takes place less selectively on TiO_2: dimethyl ether (15%) and ethene (19%) are formed in addition to ethanethiol and diethyl sulfide [yields 56 mol% and 9 mol% respectively (320 °C, M = 2.5, x = 97%)].[2] Tungsten and vanadium oxides exhibit a high activity in the conversion of alcohols into thiols. Thus, on WO_3 at 360 °C and for M = 1.6, the yield of methanethiol corresponding to the complete conversion of methanol was 81 mol% (τ = 0.5 s), whilst the yield of dimethyl sulfide was 31 mol% (τ = 4.2 s).[11]

The activities of the Mg, Ti, Zr, Ce, and Al oxides in the reaction of methanol with hydrogen sulfide for M = 0.5–2.0, 350 °C, and τ = 2–6 s have been compared.[14] It was found that the degree of conversion of the alcohol diminishes on all the catalysts with decrease in the H_2S:CH_3OH molar ratio and the selectivity with respect to methanethiol falls, but the selectivity with respect to dimethyl sulfide increases. The oxides investigated differ in their catalytic properties. Thus the activities of the oxides in the conversion of methanol into the thiol (for M = 1) vary in the following sequence:

$$Al_2O_3\,(99) > CeO_2\,(59) \geqslant TiO_2\ \text{(anatase)}\,(52) > > ZrO_2\,(34) > MgO\,(3)\ .$$

The degree of conversion of methanol [x(%)] is indicated in brackets. The catalysts can be arranged in approximately the same sequence in terms of the selectivity in the formation of dimethyl sulfide (the selectivity expressed in % is given in brackets):

$$Al_2O_3\,(84) > TiO_2\ \text{(anatase)}\,(57) > ZrO_2\,(9) \geqslant \geqslant CeO_2\,(7) > MgO\,(0)\ .$$

On the other hand, the virtually opposite sequence is observed for the variation of the selectivity of the catalysts with respect to methanethiol:

$$MgO\,(100) > ZrO_2\,(90) > CeO_2\,(50) > > TiO_2\ \text{(anatase)}\,(36) > Al_2O_3\,(15)\ .$$

The authors[14] attribute the observed variations to the different acid–base characteristics of the above oxides. The strong basic centres in magnesium oxide and the higher electronegative charge on the oxygen atom promote a low degree of conversion of methanol and a high selectivity with respect to methanethiol.

The low rate of the reaction of methanol with hydrogen sulfide on certain oxides can be explained also by their low specific surfaces (for example, the specific surface of ZrO_2 is 18 $m^2\ g^{-1}$ and that of ZrO is 5.4 $m^2\ g^{-1}$). Mashkina et al.[11] inferred the relative activities of the oxides from the rate of reaction per unit surface for a constant degree of conversion achieved by varying the contact time. The highest rate of conversion of methanol and a high selectivity with respect to methanethiol are observed on tungsten and vanadium oxides; aluminium and titanium oxides are approximately an order of magnitude less active, while Zr, Be, Mg, Zn, and Si oxides are less active by 2–3 orders of magnitude (Table 1). The specific activities of the majority of the oxides investigated increase with increase in the ionisation potentials of the cations (Table 1), which may indicate a dependence of the activity on the electron-accepting capacity of the cation.

Table 1. The specific activities and selectivities of metal oxides in the reaction of methanol with hydrogen sulfide (360 °C, M = 1.6, x = 50%–60%).[11]

Catalyst (ionisation potential/eV)	w/ mmol $m^{-2}\ h^{-1}$	S (%)	
		CH_3SH	$(CH_3)_2S$
SiO_2 (45.13)[a]	0.006	22	7

MgO (15.03)[a]	0.05	65	0
ZrO_2 (33.97)	0.06	85	4
ZnO (17.96)	0.10	0	12
TiO_2 (43.24)	1.2	56	27
γ-Al_2O_3 (28.44)	1.9	37	35
η-Al_2O_3 (28.44)	3.2	35	38
WO_3 (56)	32	73	13
V_2O_5 (65.2)	44	85	0.4

[a] $x \leqslant 40\%$.

† In most cases, the experiments are carried out at P = 0.1 MPa, so that henceforth the pressure will be indicated only when it is higher than atmospheric.

‡ The contact time τ is equal to the ratio of the volume of the catalyst (in ml) to the gas flow rate (in ml s^{-1}) at 20 °C and P = 0.1 MPa. In certain cases the values of τ calculated from the volume flow rates quoted in the relevant communications have been used in the review; such quantities are designated by the symbol $\approx$.

Although the activity of aluminium oxide calculated per m^2 of the surface area is low, it has an advantage over other massive oxides, since it can have a large surface area thus ensuring a high activity per unit weight of catalyst. Furthermore, Al_2O_3 is fairly thermostable, is relatively readily available, and is cheap. For this reason, it was initially preferred to use Al_2O_3 as the catalyst for the conversion of alcohols into thiols.[2,8] In the interaction of methanol with hydrogen sulfide in the presence of γ-Al_2O_3, a high rate of reaction per unit weight of the catalyst is attained. The principal reaction products are methanethiol, dimethyl ether, and dimethyl sulfide, whilst under severe conditions carbon oxides and methane are also formed. In the presence of a deficit of hydrogen sulfide relative to methanol and at a high temperature, dimethyl sulfide is formed preferentially. In order to obtain methanethiol with a high selectivity, it is necessary that the hydrogen sulfide : methanol ratio should be greater than 5.[3] The phase composition of the catalyst is also improtant — γ- and η-Al_2O_3 are the most active.[11,12,16] The inadequate stability of Al_2O_3 during a prolonged thiolation reaction, caused by the saturation of the surface by coke, has been noted.[13] The high activity of aluminium oxide in the reaction involving the conversion of methanol into the thiol has been explained[11] by the presence in the oxide of paired acid–base centres promoting the activation of the reactants.

The reactions of higher alcohols with hydrogen sulfide on Al_2O_3 take place at a lower temperature than the reaction of methanol. The conversion of the alcohol into the thiol is accompanied by its dehydration with formation of an ether and an alkene, which entails a decrease in selectivity in the formation of sulfur-containing products. Table 2 presents some examples of the conversion of alcohols into thiols in the presence of Al_2O_3.

The massive Cd, Sb, Ni, W, Mo, Re, K, and Na sulfides also accelerate the interaction of alcohols with hydrogen sulfide,[2,3,11,13,20,21] although it has been noted[2] that they sometimes exhibit a reduced activity in the thiolation reaction compared with the corresponding metal oxides. Thus Sb_2S_3 has a low activity in the reaction of methanol with hydrogen sulfide: $x = 14\%$ and methanethiol is not formed, the yield of dimethyl sulfide amounting to 5 mol% (360 °C, $M = 1.6$, $\tau = 50$ s).[11] In the reaction of ethanol with hydrogen sulfide[2] on the NiW sulfide catalyst, ethanethiol is formed in 6 mol% yield (220–280 °C, $M = 3.5$, $\tau = 3.5$–4.0 s, $x = 21\%$), while on WS_2 the yield of ethanethiol is 27% (280 °C, $M = 3.3$, $\tau = 3.3$–4.0 s, $x = 99\%$). On Re_2O_7, the yield of dodecane-1-thiol, obtained from 1-dodecanol and hydrogen sulfide, is 55 mol%. The reaction is accompanied by the formation of a large amount of dodecene (240 °C, 10 MPa, duration of the experiment in an autoclave 3 h, $M = 0.7$; the reaction takes place in the presence of hydrogen).[22]

2. Aluminosilicates and zeolites

Silicon dioxide, which hardly exhibits any activity in the conversion of alcohols into thiols, acquires such an activity when some of the $(SiO_4)^{4-}$ ions are replaced by $(AlO_4)^{3-}$ ions with formation of aluminosilicates — amorphous (AlSi) and crystalline (zeolites). Thus, in the reaction of methanol with hydrogen sulfide on AlSi, the rate of conversion of methanol is 14 mmol g^{-1} h^{-1}, which is seven times higher than on SiO_2: under these conditions, the selectivity is 6% with respect to methanethiol and 62% with respect to dimethyl sulfide; dimethyl ether is formed (360 °C, $M = 1.6$, $\tau = 6.3$ s, $x = 87\%$).[11] In the presence of a reduced content of hydrogen sulfide in the reaction mixture, the selectivities with respect to methanethiol and dimethyl sulfide are 5% and 68% respectively (450 °C, $M = 0.6$, $\tau \approx 9$ s, $x = 76\%$).[23] The higher activity of AlSi compared with SiO_2 is due to the difference between their acid–base properties: SiO_2 contains only very weak proton and basic centres, while AlSi contains strong proton and Lewis acid centres as well as moderately strong basic centres, which participate in the activation of the reactants.[11] On the amorphous AlSi, 2-propanol reacts with hydrogen sulfide to form propane-2-thiol in 29%–47% yield (275–300 °C, $P = 0.9$ MPa, $M = 5$–6, $\tau \approx 0.14$–0.50 s).[19]

The conversion of alcohols into thiols is also accelerated by decationated zeolites. On HNaX, the selectivities in the formation of methanethiol and dimethyl sulfide from methanol and hydrogen sulfide are 2%–5% and 8%–19% respectively (350 °C, $M = 1$–2, $\tau \approx 6$ s, $x = 90\%$–95%),[24] whilst on HNaY (under the same conditions, for the total conversion of methanol) the selectivities are $\leqslant 10\%$ and $\leqslant 20\%$.[25,26] Best results have been obtained by employing the decationated high-silica HZSM-5 zeolite, on which the selectivity reached 5%–40% with respect to methanethiol and 50%–93% with respect to dimethyl sulfide for $\tau \approx 4.5$ s. The authors[25,26] attribute the activity of the decationated zeolites to the presence in the latter of the acid OH groups, which play the role of catalytically active centres. In the conversion of ethanol and 1-propanol into the thiols on HNaY and HZSM-5 (350 °C, $M = 1$–4, $\tau \approx 6.7$ s, $x = 70\%$–85%), the yields of the thiols did not reach 1 mol%; ethanethiol and diethyl sulfide were detected qualitatively in the ethanol conversion products, while propane-1-thiol, dipropyl sulfide, and traces of propane-2-thiol, ethanethiol, and dimethyl sulfide were detected in the 1-propanol conversion products.[27] The low selectivity is due to the dehydration of the alcohols with formation of alkenes at a high rate. In the presence of HZSM-5, 1-butanol is also only dehydrated with formation of but-1-ene and but-2-ene in the presence of a large excess ($M = 10$) of hydrogen sulfide (300 °C, $M = 10$, $\tau = 0.003$–0.025 s, $x = 26\%$–90%).[1,5]

In order to compare the catalytic properties of zeolites, a kinetic study of the reaction of methanol with hydrogen sulfide was carried out.[28,29] It was found that the rate and selectivity of

Table 2. The interaction of alcohols with hydrogen sulfide on Al_2O_3.

the process depend on the degree of conversion of methanol ($x = 20\%-90\%$) and the concentrations of the reactants in the range 38 vol%–62 vol%. The activity and selectivity series for the zeolites investigated were established. For example, at 360 °C, $x = 50\%$, and $M = 0.6$ and 1.6, the rate of conversion of methanol (w/mmol g^{-1} h^{-1}; the first figure in brackets corresponds to $M = 0.6$ and the second corresponds to $M = 1.6$) varies in the sequence:

$$\text{HZSM-5}\,(175;\ 280) > \text{HNaY}\,(61;\ 92) > \\ > \text{NaX}\,(27;\ 52) > \text{NaY}\,(3;\ 7)\ .$$

The selectivities of these catalysts are presented below.

Catalyst	NaX	NaY	HNaY	HZSM-5
S_{MeSH} (%)	60–88	69–76	8–16	5–20
S_{Me_2S} (%)	36–24	38–12	32–36	86–80

The authors[28,29] explained the characteristic features of the variation of the catalytic properties as a function of the composition of the zeolites by the difference between the acid–base characteristics of the catalyst surfaces. The strength and concentration of the active centres of zeolites and other catalysts (Table 3) have been determined[11,12,29–32] by analysing the IR spectra of adsorbed probe molecules. Ammonia and pyridine were used in testing the proton centres, carbon monoxide was used in testing the Lewis acid centres, and deuteriochloroform was used in testing the basic centres.[33] On the basis of the data presented in Table 3, the authors[28,29] explained the high activity of the decationated zeolites and their selectivity with respect to dimethyl sulfide by the high content of strong acid centres on the surface. The reduced activity of NaX compared with the decationated forms of the zeolites (by a factor of 2–10 under the given conditions) is attributed to the difficulty of activating methanol on a surface lacking strong acid centres. The high selectivity with respect to methanethiol is due to the occurrence on paired centres (sodium cations–lattice oxygen atoms adjoining the cation) of the dissociative chemisorption of hydrogen sulfide with formation of reactive thiyl groups. The reduced activity of NaY compared with NaX is explained by the lower content in NaY of the nonlocalised Na^+ cations, which play an important role in the activation of hydrogen sulfide. However, the reaction mechanisms on NaX and NaY are the same, so that the selectivities in the formation of methanethiol and dimethyl sulfide are similar on both catalysts.

The activity of alkaline forms of zeolites has also been investigated.[25,26] An increased selectivity with respect to methanethiol (70%–90%) and a low selectivity with respect to dimethyl sulfide (5%–15%) have been observed not only on NaX (350 °C, $M = 1-4$, $\tau \approx 6$ s, $x = 30\%-80\%$) but also when a proportion of the sodium in the zeolite has been replaced by Li, K, or Cs. Under the conditions indicated, the same zeolites accelerate the reaction of hydrogen sulfide with ethanol: for $x = 47\%-82\%$, the selectivity is 17%–70% with respect to ethanethiol and 0%–6% with respect to diethyl sulfide; ethene is also formed, the selectivity with respect to this substance amounting to 24%–83%.[24,27,34] It has been found[35] that the interaction of ethanol with hydrogen sulfide on the NaX, NaY, CaX, HY, and Ln/Y (a type Y zeolite containing lanthanide elements), zeolites leads to the formation of only ethanethiol (350 °C, $P = 0.6-3.0$ MPa, $x \leqslant 5\%$). The rate of reaction (w/mmol g^{-1} s^{-1}) varies in the following sequence:

$$\text{HY}\,(1.12) > \text{Ln/Y}\,(0.89) > \text{CaX}\,(0.31) > \\ > \text{NaY}\,(0.24) > \text{NaX}\,(0.15)\ .$$

Since the activity increases on passing from cation-containing to decationated forms of zeolites, it was concluded[35] that the reaction proceeds via an ionic mechanism and is facilitated in the presence of proton centres on the surface.

In terms of the activity in the reaction involving the formation of ethanethiol from methanol and hydrogen sulfide, the zeolites can be arranged in the sequence

$$\text{LiNaX} < \text{NaX} < \text{CsNaX} < \text{KNaX}\ ,$$

[a] The content of promoting agents is indicated in mass%.
[b] A dash indicates the absence of centres.
[c] The presence of the Lewis acid centre is due to the presence of sodium, magnesium, chromium, and potassium cations (Al^{3+} in the remaining cases).

which reflects the increase in the electronegativity of the cations on passing from lithium to potassium. It has been suggested that the cations play the role of active centres activating hydrogen sulfide and participating in the formation of acid hydroxy-groups, which are necessary for the activation of the alcohols.[24]

The reaction of ethanol with hydrogen sulfide is accelerated by the $M^{2+}NaX$ (M = Cd, Zn, Ni, Co, Mn) zeolites.[36,37] The yield of the sulfur-containing product depends on temperature and the ratio $H_2S : C_2H_5OH$. Thus on ZnNaX at 300 °C, $M = 2$, $\tau \approx 6$ s, and $x = 100\%$, the selectivity is 20% in the formation of ethanethiol and 80% in the formation of diethyl sulfide, whilst at 350 °C and $M = 1$ the selectivities are 7% and 40% respectively. The reaction is complicated by the dehydration of ethanol with formation of ethene. It is believed[36,37] that the active centres in the $M^{2+}NaX$ system in the conversion of ethanol into the thiol are the acid OH groups arising from dissociative chemisorption of hydrogen sulfide on the cations and the basic centres coupled with them. The selectivity in the formation of diethyl sulfide increases with increase in the strength of the proton centres:

$$CdNaX > ZnNaX > CoNaX \gg NiNaX \gg MnNaX .$$

The ethanol dehydration side reaction occurs with participation of the acid–base centres of the $M^{2+}NaX$ zeolite.

The interaction of 1-propanol with hydrogen sulfide on NaX leads to the formation of propane-1-thiol in 10%–20% yield with a small amount of ethanethiol and dimethyl sulfide (350 °C, $\tau \approx 6$ s, $M = 1-4$). On NaY, the yield of propane-1-thiol under these conditions is less than 2 mol%. The thiolation reaction is accompanied by the decomposition of 1-propanol with formation of propene.[27] In the interaction of 1- and 2-propanols with hydrogen sulfide on the $M^{2+}NaX$ (M = Cd, Zn, Ni, Co, Mn) zeolites, the dehydration of the alcohol with formation of propene predominates. The overall selectivity with respect to the thiol and the sulfide (with the former predominating) is 2%–36% (350 °C, $M = 1-4$, $x = 10\%-90\%$).[27,38] It is suggested that the acid OH groups and the cationic centres of the zeolites participate in the thiolation process. At a high concentration of strong proton centres on the zeolite surface, the contribution of the alcohol dehydration side reaction increases.

The interaction of 1-butanol with hydrogen sulfide has been investigated[15] in the presence of the NaX zeolite. The reaction products are butane-1-thiol and butenes, which are formed with selectivities of 40% and 60% respectively (300 °C, $M = 10$, $\tau = 0.4-2.1$ s, $x = 27\%-83\%$).

Table 4. Synthesis of alkanethiols from alcohols and hydrogen sulfide in the presence of cationic forms of zeolites.

Alcohol	Zeolite	T/°C	M	τ/s	x (%)	Yield of alkanethiol (mol%)	Ref.
Methanol	NaX	350	4	~6	85	65	24, 25
	NaX	360	1.6	4.2	80	66	29
	KNaX	350	2	~6	80	71	25
	NaY	350	4	~6	50	30	25, 26
	NaY	360	1.6	8.4	64	40	29
Ethanol	NaX	350	4	~6	95	74	34
	KNaX	350	2	~6	82	52	24
	CdNaX	250	2	~6	85	21	36
	NiNaX	300	2	~6	76	28	36
1-Propanol	NaX	350	4	~6	70	20	27
	CdNaX	250	4	~6	80	23	38
2-Propanol	CdNaX	250	4	~6	80	10	38
1-Butanol	NaX	300	10	21	83	35	15

Thus dialkyl sulfides are formed under the influence of various forms of zeolites, their cationic forms being more suitable for the synthesis of alkanethiols. The highest attained experimental yields of alkanethiols are indicated in Table 4.

3. Supported catalysts

From the practical point of view, it is preferable to use catalysts obtained by depositing the active components on a carrier, since this involves a smaller consumption of the active substance, a high degree of its dispersion is attained, and thermal stability of the catalyst is ensured. This was already noted in an early study,[7] the authors of which established that ThO_2 deposited on pumice is preferable to the massive oxide. Catalysts consisting of the oxides, sulfides, and salts of Group 1–6 and 8 elements deposited on aluminium oxide, silicon dioxide, aluminosilicate, pumice, and carbon have been mentioned in patents (see the relevant reviews[2–8]). In the later studies considered in the present review, the supported catalysts for the conversion of alcohols into thiols were compared quantitatively, in many instances on the basis of kinetic investigations, and the relations between the catalytic and acid–base properties of the catalysts were deduced.

a. Acid catalysts

The catalysts obtained by modifying SiO_2 with phosphoric and sulfuric acids as well as the carrier itself exhibit a low activity in the reaction of methanol with hydrogen sulfide. Thus, on the H_3PO_4/SiO_2 specimens, the degree of conversion of methanol was less than 1% and sulfur-containing products were not formed (350 °C, $M = 0.5-2.0$, $\tau \approx 10$ s).[14] On the 30% H_3PO_4/SiO_2 catalyst at 360 °C, $M = 1$, and $\tau \approx 25$ s, the selectivities with respect to methanethiol and dimethyl sulfide were 1% and 10% respectively for a rate of consumption of methanol of 5 mmol g^{-1} h^{-1}, whilst after the increase in τ to 42 s and for $M = 0.6$, the degree of conversion x reached 100% and the selectivity with respect to dimethyl sulfide was 25%.[11,12] According to the authors[11,12] the activity of catalysts of this type is determined by the presence on the surface of proton centres, but the low acidity of H_3PO_4/SiO_2 as well as the low acidity of SiO_2 (Table 3) made the thiolation reaction ineffective.

It has been established[19] that hydrogen sulfide reacts with an alcohol at an elevated pressure on the H_3PO_4 (50 mass%–85 mass%)/kieselguhr catalyst, but the isomeric thiol is then formed preferentially. For example, instead of propane-1-thiol, propane-2-thiol is formed from 1-propanol is 41% yield (276 °C, $P = 0.9-1.0$ MPa, $M = 6$, $\tau = 0.14$ s); in the interaction of hydrogen sulfide with 1-dodecanol, only dodecane-2-thiol was obtained (350 °C, $P = 1.2$ MPa, $M = 4$); on interaction with hydrogen sulfide, 2-propanol, 2-butanol, and 2-pentanol are converted into the corresponding alkane-2-thiols in 37%–63% yields (175–300 °C, $P = 0.9-1.0$ MPa, $M = 4-5$, $\tau \approx 0.14$ s).[19]

Heteropolyacids with a Keggin type anion, such as silicotungstic acid $H_4SiW_{12}O_{40}$ (HSiW) and phosphotungstic acid $H_3PW_{12}O_{40}$ (HPW), deposited on silicon dioxide and containing very strong proton centres on the surface, were found to be more effective in the reaction of methanol with hydrogen sulfide[11,13] (Table 3). Thus the selectivities with respect to methanethiol and dimethyl sulfide on the 7.5% $HSiW/SiO_2$ catalyst at 360 °C, $M = 1.6$, and $x = 80\%$ were 49% and 51% respectively. The increase in the HSiW concentration to 25 mass% leads to an increase in the selectivity with respect to dimethyl sulfide to 80%. On the 30% HPW/SiO_2 catalyst, the selectivities under the conditions indicated were 70% with respect to methanethiol and 24% with respect to dimethyl sulfide, which differs from the results obtained on massive HPW, where the selectivities with respect to methanethiol and dimethyl sulfide were 16% and 64% respectively. The increase almost by an order of magnitude in the activity of the deposited heteropolyacid compared with SiO_2 and H_3PO_4/SiO_2 can be explained by the increased proton acidity. The different selectivities in the formation of thiolation products on the deposited and massive

Table 5. The activities and selectivities of supported acid catalysts in the reaction of methanol with hydrogen sulfide at 360 °C, $x = 80\%$, and a methanol concentration of 38–62 vol%.[11,12,30]

HPW are due to the decrease in the strength of the proton centres of the heteropolyacid on the carrier. However, in the reactions of hydrogen sulfide with higher alcohols, the heteropolyacids are relatively ineffective catalysts. Thus the HPW/SiO_2 catalyst as well as massive HPW are almost inactive in the reaction of 2-propanol with hydrogen sulfide:[38] at 250 °C, $M = 4$, $\tau \approx 6$ s, the degree of conversion of the alcohol being less than 1%. Only the dehydration of the alcohol with formation of but-1-ene and but-2-ene takes place in the reaction of hydrogen sulfide with 1-butanol on the 25% $HSiW/SiO_2$ specimen (300 °C, $M = 10$, $\tau = 0.04-5.40$ s, $x = 38\%-100\%$).[15]

The reaction of methanol with hydrogen sulfide is accelerated by transition metal oxides deposited on SiO_2 or AlSi and having on their surfaces strong proton centres, weak Lewis acid centres, and moderately strong basic centres (Table 3). The catalytic properties of these specimens differ little from that of the proton-donor $HSiW/SiO_2$ catalyst (Table 5).

By varying the reaction conditions (360 °C, $M = 0.6-1.6$, $\tau = 4-7$ s, $x = 80\%-95\%$) in the presence of chromium, molybdenum, and tungsten oxides deposited on SiO_2, it was not possible to obtain methanethiol and dimethyl sulfide in yields exceeding 40 mol% and 60 mol% respectively.[11,12] Higher alcohols react with hydrogen sulfide with difficulty. Thus, even in the presence of an excess of hydrogen sulfide, 1-butanol is converted on Cr_2O_3/SiO_2 into butane-1-thiol and butenes, the selectivities in the formation of which amount to 20% and 80% respectively (300 °C, $M = 10$, $\tau = 0.36-7.90$ s, $s = 20\%-92\%$).[15]

The reaction of methanol with hydrogen sulfide has been investigated[11,12] on catalysts obtained by introducing acid additives (boric, sulfuric, and hydrofluoric acids and the Cr, V, Mo, and W acid oxides) into Al_2O_3. The selectivities of the above catalysts were close to that of the $HSiW/SiO_2$ acid catalyst, but their activities were 25–50 times higher than that of the latter. In terms of their catalytic properties, the acid aluminium oxide catalysts do not differ greatly from pure aluminium oxide. Certain data on this point are presented in Table 5. According to the authors,[11,12] this is due to the similarity of the acid–base characteristics of their surfaces. It follows from Table 3 that the Al_2O_3 surface contains strong Lewis acid centres and moderately strong basic centres, weak proton centres also being present. The modification of Al_2O_3 by acid additives leads to an increase in the strength of the Lewis acid centres, arising due to the presence of Al^{3+}, a decrease in the basicity of the specimen, and also the appearance of strong proton centres; it may be that weak Lewis acid centres (cations) may also function as active centres on the surfaces of specimens containing chromium, molybdenum, and tungsten oxides on Al_2O_3.

An increase in the acidity of aluminium oxide catalysts leads to an increase in the rate of conversion of methanol per gram of the catalyst.[11,12] The rate of reaction, referred to a single Lewis acid centre, increases with increasing strength of these centres. A decrease in the basicity of the catalyst, for example as a result of the introduction of hydrofluoric acid into Al_2O_3, reduces the selectivity for the formation of the products of the reaction involving the conversion of methanol into the thiol and promotes the formation of dimethyl ether (360 °C, $M = 0.6$, $x = 80\%$).

With increase in the content of transition metal oxides on Al_2O_3, the activity of the catalyst also increases, whilst the selectivity changes little. It follows from the results of the above studies[11,12] that acid aluminium oxide catalysts are insufficiently selective with respect to methanethiol: in the presence of chromium, molybdenum, and tungsten oxides as well as sulfuric, hydrofluoric, and boric acids deposited on Al_2O_3, the yield of methanethiol obtained from methanol and hydrogen sulfide does not exceed 50 mol% (360 °C, $M = 1.6$, $\tau = 0.12-1.10$ s, $x = 80\%-100\%$). On the other hand, dimethyl sulfide is formed selectively on these catalysts, the yield amounting to 80 mol% – 95 mol% (360 °C, $M = 0.6$, $\tau = 0.5-3.0$ s, $x = 80\%-100\%$).

It has been found[39] that, among the catalysts containing Cu, Cr, Co, Ni, Th, and Mg oxides on Al_2O_3, the specimens modified with 0.11 mass% of chromium or 0.22 mass% of copper are the most effective as regards the formation of dimethyl sulfide from methanol and hydrogen sulfide; in their presence, the yield of dimethyl sulfide is 90 mol%–97 mol% and that of methanethiol is 2 mol%–3 mol% (400 °C, $M = 0.6$, $\tau = 6.2$ s).

The reactions of hydrogen sulfide with methanol homologues on acid aluminium oxide catalysts have been investigated to a lesser extent. The reaction involving the conversion of 1-propanol into the thiol on the 3.7% WO_3/Al_2O_3 catalyst results in the formation of propane-1-thiol, propene, and dipropyl ether with selectivities of 24%–29%, 13%–17.5%, and 26.7%–31.5% respectively (250–270 °C, $M = 4.7$, $\tau = 0.1-2.0$ s, $x \leqslant 10\%$).[40] In the presence of Al_2O_3 modified by titanium and zirconium oxides, the yield of dodecane-1-thiol, obtained from 1-dodecanol and hydrogen sulfide at 200–400 °C, did not exceed 12 mol%.[22] Massive HPW, which is inactive in the conversion of 1-propanol into the thiol, became active after its deposition in an amount of 16 mass%–44 mass% on δ-Al_2O_3: the yields of propane-1-thiol and propane-2-thiol from 1- and 2-propanols reached 20 mol% (250 °C, $M = 4$, $\tau \approx 6$ s, $x = 35\%-75\%$).[38] However, it may be that the activity of this catalyst is only partly associated with the presence of the heteropolyacid, since the latter decomposes on contact with the carrier.[30]

b. Basic catalysts

The modification of the carrier by alkali metal compounds leads to the formation of catalysts with a reduced activity, a low selectivity with respect to the dialkyl sulfide, but with a high selectivity in the formation of the alkanethiol. This was already noted in early studies devoted to the conversion of methanol into the thiol.[2-4,8] Under identical conditions (400 °C, $M = 2$, $\tau = 5.5$ s, $x = 70\%-80\%$), the selectivity in the formation of methanethiol on the alkali-modified aluminium oxide is 1.2 times higher than on the unpromoted Al_2O_3, while the selectivity with respect to dimethyl sulfide is lower by a factor of 2.4. Similar changes occur in the reactions of hydrogen sulfide with ethanol (400 °C, $M = 2$, $\tau = 5.6$ s, $x = 70\%-90\%$) and with 1-octanol (317 °C, $M = 2.9$, $\tau = 5.6$ s, $x = 83\%-91\%$): the selectivity with respect to the alkanethiol on the alumina–potassium tungstate specimen is higher by a factor of 1.4–2.3 than on pure Al_2O_3, while the selectivity with respect to the dialkyl sulfide is significantly lower.[4] In the reaction of 1-propanol with hydrogen sulfide, aluminium oxide with added potassium or sodium oxide is an order of magnitude less active than pure Al_2O_3; the selectivities for the formation of propane-1-thiol are 15% and 34%–80% respectively on pure Al_2O_3 and on the oxide modified by various amounts of alkalies (290 °C, $M = 2$, $x \leqslant 10\%$).[40]

The interaction of methanol with hydrogen sulfide on carriers modified by potassium or sodium hydroxide, carbonate, and tungstate has been studied in detail.[31,41-45] The rate of conversion of methanol and the selectivity with respect to dimethyl sulfide on these catalysts are low, while the selectivity with respect to methanethiol is high. The activity of the catalysts may be due to the presence on their surfaces of definite numbers of acid–base centres. In contrast to SiO_2, which contains mainly weak proton centres, in the SiO_2 with added potassium compounds there are no proton centres—weak Lewis acid centres (apparently alkali metal cations) and strong basic centres are present (Table 3). Compared with pure silicon dioxide, the activity of the alkaline specimen at 360 °C is higher by a factor of 1.5–4.0, the selectivity with respect to methanethiol has increased from 25% to 70%–98%, while the selectivity with respect to dimethyl sulfide remains low (2%–15%). The promoting effect of the alkaline additive to SiO_2 is higher, the higher the potassium or sodium content of the silicon dioxide. For the same atomic content of potassium, the activity of, for example, K_2CO_3/SiO_2 is twice as high as that of K_2WO_4/SiO_2, but methanethiol is formed somewhat more selectively on the tungstate specimen.

The acid–base characteristics of aluminium oxide also change after the introduction of an alkaline additive (Table 3): the number of the weak proton centres present in the Al_2O_3 diminishes or they vanish altogether, the concentration and strength of the Lewis acid centres (Al^{3+}) decrease, and weak Lewis acid centres (alkali metal cations) probably also appear. Furthermore, together with the moderately strong basic centres present in the Al_2O_3, a large number of strongly basic centres are generated.

The introduction of alkaline additives into Al_2O_3 increases the activity of the catalyst in the conversion of methanol into the thiol to a greater extent than their introduction into the SiO_2. This is due to the presence on the surfaces of the aluminium oxide specimens of Al^{3+} ions, which are stronger Lewis acid centres than alkali metal cations.

The change in the acid–base properties of Al_2O_3 when the latter is modified by alkali leads, in its turn, to a change in the catalytic properties. Thus the introduction of an alkaline additive into Al_2O_3 lowers the activity with respect to methanethiol by 1–1.5 orders of magnitude and that with respect to dimethyl sulfide by 2–4 orders of magnitude compared with pure Al_2O_3. The selectivity with respect to methanethiol increases accordingly from 35%–50% on Al_2O_3 to 98% on the modified catalyst, whilst that with respect to dimethyl sulfide falls sharply. The content of the alkaline additive also affects the catalytic properties: with increase in the concentration of the promoting agent, the activity and selectivity of Al_2O_3 with respect to dimethyl sulfide diminish, whilst the activity with respect to methanethiol increases.

The similarity of the acid–base properties of specimens with identical atomic contents of the alkali metal on Al_2O_3 also ensures their virtual identical activity at 360–500 °C.[31,42,45] The nature of the anion exerts a stronger influence: among the specimens containing potassium on Al_2O_3, the carbonate and tungstate specimens exhibit the highest and lowest activities respectively, but the latter are more selective with respect to methanethiol. The carbonate and hydroxide specimens exhibit an increased activity for the formation of decomposition products—methane and carbon oxides. These differences are associated with the acid–base properties of the surface. It follows from Table 3 that the KOH/Al_2O_3, $NaOH/Al_2O_3$, and K_2CO_3/Al_2O_3 specimens differ little as regards the concentration and strength of the Lewis acid centres. Very strong basic centres are also present in the carbonate and hydroxide specimens. On the other hand, the tungstate catalyst, which is most selective with respect to methanethiol,[44] contains stronger basic centres than in the above specimens. The catalytic properties are independent of the nature of the tungstate promoting agent. Thus the catalysts obtained by introducing sodium heptatungstate, dodecatungstate, metatungstate, and the normal tungstate into Al_2O_3 exhibit approximately the same activities in the reaction of methanol with hydrogen sulfide.[43] The specimen in which the alkali metal : tungsten atomic ratio is 2 : 1 exhibits the greatest selectivity with respect to methanethiol. The similarity of the catalytic properties of the specimens obtained by impregnating Al_2O_3 with solutions of the monomeric normal tungstate and by different polynuclear oxo-complexes of tungsten is a consequence of the formation of similar surface compounds.

The conversion of methanol homologues into thiols in the presence of Al_2O_3 modified by alkaline additives takes place at a lower temperature. The selectivity in the formation of alkanethiols from primary alcohols is fairly high (80%–90%) even for a high degree of conversion of the alcohol, but diminishes when secondary alcohols are converted into thiols, since this is accompanied by side reactions involving the formation of alkenes, ethers, etc. Thus in the interaction of ethanol with hydrogen sulfide on 10% K_2WO_4/Al_2O_3, the selectivities with respect to ethanethiol and diethyl sulfide are 93%–78% and 2.5%–3.6% respectively (290–382 °C, $M = 2$, $x = 60\%-83\%$).[4] In the interaction of 1-octanol with hydrogen sulfide on the same catalyst, the selectivity for the formation of octane-1-thiol is 99%–74% (235–318 °C, $M = 7.7$, $x = 48\%-100\%$); the reaction is accompanied by the formation of an alkene.[4] In the reaction of 1-butanol with hydrogen sulfide on potassium-modified Al_2O_3, the selectivity with respect to butane-1-thiol was 92%–98%, but-1-ene being formed as a side product (300 °C, $M = 10$, $\tau = 1.2-12.1$ s, $x = 30\%-95\%$).[15] The reaction of 1-dodecanol with hydrogen sulfide on the K/Al_2O_3 catalyst afforded dodecane-1-thiol with a selectivity of 47%–82%, a selectivity of 7%–42% with respect to dodecene, and a selectivity of 2%–33% with respect to the sum of dodecyl ether and dodecyl sulfide [(300–350) °C, $M = 2.6-24.0$, $\tau = 0.04-2.50$ s, $x = 15\%-100\%$].[46] 2-Butanol, a secondary alcohol, is largely dehydrated in hydrogen sulfide on the catalysts indicated above with formation of butene; among the sulfur-containing substances, only butane-2-thiol is formed with a selectivity of 11%–26% (275–300 °C, $P = 0.1-0.3$ MPa, $M = 4$, $\tau = 0.3-0.9$ s, $x = 59\%-71\%$).[47]

Thus the composition of the catalysts exerts a considerable influence on the rate of the interaction of alcohols with hydrogen sulfide and on the mode of the reaction. By varying the type of the acid–base centres and their numbers on the surface, it is possible to obtain an active and selective catalyst for the formation of the thiol. Deliberate search for such catalysts is facilitated when the reaction mechanism is known.

III. The mechanism of conversion of alcohols into thiols by hydrogen sulfide

1. Routes to the formation of the reaction products

Knowledge of reaction paths is important for the regulation of the process selectivity. This problem has been elucidated in greatest detail for the interaction of methanol with hydrogen sulfide.

It has been postulated[25,26,28,29] that the products of the thiolation of methanol and dimethyl ether are formed from methanol by independent paths on the NaX, NaY, HNaY, and HZSM-5 zeolites. In a number of instances, for example on AlSi and γ-Al_2O_3 (both pure and modified by HF and B_2O_3), the selectivity in the formation of dimethyl ether for low degrees of conversion of methanol was much higher than the overall selectivity with respect to methanethiol and dimethyl sulfide.[11,12,17] This justified the conclusion that the latter are formed as a result of the interaction of hydrogen sulfide with dimethyl ether produced on dehydration of methanol.

The routes to the formation of methanethiol and dimethyl sulfide may differ. It has been suggested[25,26,29] that they are obtained via independent paths on zeolites. However, the view that dimethyl sulfide is a secondary product arising from methanethiol predominates.

The most reliable conclusions concerning the routes to the formation of the products from methanol and hydrogen sulfide on different catalysts have been reached on the basis of kinetic studies.[11,12,30,31,45,48,49] The primary oxygen-containing product arising from methanol is its dehydration product—dimethyl ether:

$$2\,CH_3OH \rightleftharpoons (CH_3)_2O + H_2O\,.$$

Dimethyl ether as well as the initial methanol can decompose with formation of carbon oxides and methane.[50] The increase in selectivity with respect to methanethiol with decrease in the degree of conversion of methanol permitted the conclusion that methanethiol is the primary sulfur-containing product of the interaction of methanol with hydrogen sulfide:

$$CH_3OH + H_2S = CH_3SH + H_2O\,.$$

However, the reaction of hydrogen sulfide with dimethyl ether is also possible:

$$(CH_3)_2O + H_2S = CH_3SH + CH_3OH\,.$$

For example, it may occur on Al, K, W, and Mo oxides and sulfides.[2,4,45,48,49,51,52] The rates of reaction of methanethiol and dimethyl ether and also the selectivities in the formation of methanethiol with hydrogen sulfide under similar conditions are comparable.[45,48,49] Hydrogen sulfide is consumed in the reaction with methanol on different catalysts only in the formation of methanethiol and dimethyl sulfide and the degree of its conversion is therefore equal to the overall yield of these products.

Methanethiol, formed from hydrogen sulfide and methanol, can undergo various reactions, in particular reactions involving the formation of dimethyl sulfide. The formation of the latter from methanethiol is indicated by a series of experimental facts.[45,49,53] Thus the selectivity with respect to methanethiol decreases and that with respect to dimethyl sulfide increases with increase in the degree of conversion of the reactants (methanol, dimethyl ether, hydrogen sulfide). When methanethiol is added to the initial reaction mixture, the rate of formation of dimethyl sulfide increases. Indirect evidence is provided also by the occurrence on the catalysts accelerating the interaction of methanol with hydrogen sulfide of the selective reaction involving the synthesis of dimethyl sulfide by the decomposition of methanethiol in helium or of the reactions of methanethiol with methanol or dimethyl ether. However, although the selectivity with respect to dimethyl sulfide in the above reactions increases with increasing degree of conversion of the reactants, it does not reach 100% even for the total conversion of the latter, which is associated with the occurrence of a reversible reaction of dimethyl sulfide with hydrogen sulfide. The catalysts active in the reaction of methanol with hydrogen sulfide or methanethiol accelerate the above interaction as well.[54,55] The experimental data presented demonstrate that the following reactions take place involving methanethiol:

$$CH_3SH + CH_3OH = (CH_3)_2S + H_2O\,,$$

$$CH_3SH + (CH_3)_2O = (CH_3)_2S + CH_3OH\,,$$

$$2\,CH_3SH \rightleftharpoons (CH_3)_2S + H_2S\,.$$

For a long contact time and at an elevated temperature, methanethiol and dimethyl sulfide are partly decomposed with formation of methane and the deposition of coke on the surface.[54]

Thus the products of the interaction of methanol with hydrogen sulfide may be formed as a result of the occurrence of the reactions listed below on various catalysts, the composition of which influences only the rates of individual stages. The dehydration of methanol leads to the formation of dimethyl ether. The reaction of methanol with hydrogen sulfide or possibly with dimethyl ether affords methanethiol, which is converted into dimethyl sulfide either by reacting with a second molecule of methanol or dimethyl ether or by disproportionating. The partial decomposition of dimethyl ether and methanol leads to the formation of carbon monoxide and methane. The latter is also a product of the degradation of methanethiol and dimethyl sulfide.

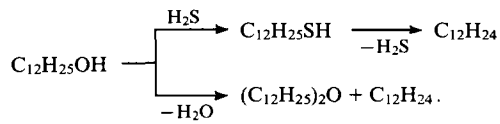
In the conversion of higher alcohols into thiols, additional reaction paths appear—the decomposition of the initial alcohol and of the sulfur-containing products formed from it. In the interaction of hydrogen sulfide with ethanol and 1- and 2-propanols on zeolites, both decationated and in the sodium-form, the principal reaction products are the corresponding thiols and an alkene. The occurrence of the consecutive reactions,

$$RCH_2CH_2OH \xrightarrow[-H_2O]{} RCH{=}CH_2 \xrightarrow{H_2S} RCH_2CH_2SH\,,$$

has been suggested.[27,36] The alcohol is dehydrated with formation of an alkene, which then reacts with hydrogen sulfide to produce the thiol. However, the authors do not rule out also the possibility of the parallel formation of the thiol and the alkene.

$$RCH_2CH_2OH \begin{cases} \xrightarrow{H_2S} RCH_2CH_2SH \\ \xrightarrow[-H_2O]{} RCH{=}CH_2 \end{cases}$$

According to the authors,[27,36] a small amount of ethanethiol and dimethyl sulfide is formed in this reaction when hydrogen sulfide interacts with the propanol decomposition products.



Kinetic study[5] led to the conclusion that, in the presence of Al_2O_3, 1-propanol reacts via three independent paths in hydrogen sulfide:

$$C_3H_7OH \begin{cases} \xrightarrow{-H_2O} C_3H_8\,, \\ \xrightarrow{-H_2O} (C_3H_7)_2O\,, \\ \xrightarrow{H_2S} C_3H_7SH\,. \end{cases}$$

The reaction of hydrogen sulfide with 1-butanol on the NaX, MgO, Al_2O_3, and Cr_2O_3/SiO_2 catalysts does not lead to the formation of dibutyl ether and dibutyl sulfide, only butane-1-thiol and butenes (mainly but-1-ene) being produced. The selectivity with respect to the latter compounds is independent of the degree

of conversion of butanol.[15] On the grounds of these findings, it is suggested that the 1-butanol conversion products, like those obtained from 1-propanol,[5] are obtained via independent routes from the initial alcohol. However, bearing in mind the high rate of the decomposition of alkanethiols and dialkyl sulfides compared with alcohols[27,46,56] and its increase with increasing molecular mass,[57-59] one cannot rule out the possibility that butenes appear on decomposition not only of the alcohol but also of the products of its thiolation.

The routes to the formation of the products of the reaction of 1-dodecanol with hydrogen sulfide on the alkali-modified aluminium oxide have been investigated.[56] The main products are dodecane-1-thiol and dodecene, the overall yield of dodecyl ether and dodecyl sulfide not exceeding 5 mol%. The selectivity with respect to dodecane-1-thiol remains approximately constant at $x \leqslant 60\%$, decreasing at higher degrees of conversion. This is owing to the fact that mainly the dodecanethiol and not the initial alcohol decomposes, which is indicated by the form of the variation of the selectivity in the formation of the 1-dodecanol conversion product, by the increased yield of dodecene when dodecane-1-thiol is added to the initial mixture, and also by data on the decomposition of 1-dodecanol under a helium atmosphere and of dodecane-1-thiol in hydrogen sulfide. Mainly the consecutive process involving the formation and decomposition of dodecane-1-thiol takes place, the contribution of the parallel alcohol dehydration reaction being small:

2. Relation between the catalytic and acid–base properties

The acid–base properties of the surfaces of the catalysts influence not only their activity in the reaction of an alcohol with hydrogen sulfide to form an alkanethiol and a dialkyl sulfide (see above), but also the rates of the individual stages of the process. This has been established as a result of detailed studies of the synthesis of methanethiol or dimethyl sulfide from methanol and hydrogen sulfide and of the reactions involving the formation of dimethyl sulfide by the disproportionation of methanethiol and its interaction with methanol.[11,12,28-31,53,54,60] The results permitted the conclusion that all these reactions are accelerated by catalysts having both proton and Lewis acid centres. The activity of the catalyst per centre increases with increase in the strength of the acid centre.[11,12,60] Identical features of the variation of the activity as a function of the nature and strength of the centres are characteristic of different reactions. This is illustrated by the results, presented in Table 6, of the determinations of the activities of the catalysts in various reactions involving the synthesis of methanethiol and dimethyl sulfide. Taking into account the available data concerning the acid–base properties of the catalyst (Table 3), one may conclude that the reactions proceed under the influence of both proton and Lewis acid centres. A catalyst with weak proton centres (H_3PO_4/SiO_2) exhibits a low activity in the formation of methanethiol and dimethyl sulfide. Catalysts with strong proton centres ($HSiW/SiO_2$) have the best parameters. The activity of catalysts having weak Lewis acid centres (NaX, MgO, Cr_2O_3/SiO_2) is approximately at the same level as that of the catalysts with strong proton centres. The activity of aluminium oxide catalysts containing strong Lewis acid centres is appreciably higher than that of the catalysts with strong proton centres. For this reason, the activity of the proton-donating specimens containing even a small number of strong Lewis acid centres (decationated zeolites) is higher than the activity of a 'purely' proton-donating specimen.

The effectiveness of catalysts with strong Lewis acid surface centres is due to the presence of the basic centres associated with them, which participate in the activation of both the alcohol and hydrogen sulfide. The suppression of the basic centres, even when it is accompanied by some increase in the strength of the acid centres (for example, as a result of the introduction of hydrofluoric acid into Al_2O_3), lowers the overall activity and selectivity of the catalyst as regards the formation of the products of the thiolation reaction.[12] It has been established[11,12,28-31,53,54,60] that both the overall activity of the catalysts in all the reactions indicated and their activity in relation to the formation of dimethyl sulfide decrease with increase in the strength of the basic centres and with decrease in the strength of the acid centres (for example, when the carrier is modified by alkali). The selectivity with respect to methanethiol increases under these conditions in the reaction of hydrogen sulfide with methanol. A catalyst containing strong Lewis acid centres and moderately strong basic centres (for example Al_2O_3 modified by acid additives or a decationated high-silica zeolite) is an active and selective catalyst in the synthesis of dimethyl sulfide from methanol and hydrogen sulfide or methanethiol.

Since the type, concentration, and strength of the active centres influence the activity of the catalyst equally in all the reactions indicated above, the conclusions concerning the routes to the formation of the products of the thiolation of methanol, reached on the basis of kinetic studies, must be regarded as valid (see Section III).

The acid–base properties of the catalyst surfaces influence the rate of the reaction of hydrogen sulfide with methanol homologues and the mode of the reaction. Thus it has been established[15] that the rate of conversion of 1-butanol in an excess of hydrogen sulfide is very high on catalysts with very strong proton centres (decationated zeolite, heteropolyacid), whilst on catalysts with weakened Lewis acid centres (NaX, MgO, Cr_2O_3/SiO_2) it is much lower. Butanol is converted fastest on Al_2O_3, having strong Lewis acid centres and moderately strong basic centres. The rate of reaction increases with increase in the concentration and strength of the acid centres on the surface. Thus the rate of conversion of 1-butanol, referred to one acid centre, is higher the greater the strength of these centres. However, 1-butanol decomposes rapidly with formation of butenes on highly active acid catalysts, the rate of the process increasing with increase in the acidity of the surface. An additional amount

Table 6. The rates of formation of methanethiol and dimethyl sulfide on catalysts with different acid–base properties.

Catalyst	Rate of formation/μmol m^{-2} h^{-1}			
	of methanethiol[a]	of dimethyl sulfide		
		b	c	d
H_3PO_4/SiO_2	0.22	18	–	3
$HSiW/SiO_2$	28	30	17	34
NaX	46	10	5	10
MgO	33	–	–	20
Cr_2O_3/SiO_2	37	8	12	12
γ-Al_2O_3	715	4066	800	3200
η-Al_2O_3	1137	869	–	2000
Cr_2O_3/Al_2O_3	1126	1269	1000	2720
H_2SO_4/Al_2O_3	863	–	270	1900
$NaOH/Al_2O_3$	44	3	6	10
HNaY	8.4	24	91	8
HZSM-5	112	300	200	600

[a] Methanethiol is formed by the $CH_3OH + H_2S$ reaction: $T = 360$ °C, $[CH_3OH] = 17$ mM, $[H_2S] = 28$ mM, $x = 80\%$, $M = 1.6$.[11,29]
[b] $CH_3OH + H_2S$: $T = 360$ °C, $M = 0.6$, $[CH_3OH] = 28$ mM, $[H_2S = 17$ mM, $x = 80\%$.[11,12,29]
[c] $CH_3OH + CH_3SH$: $T = 350$ °C, $[CH_3SH] = 3.2$ mM, $[CH_3OH] = 1.7$ mM, $x = 50\%$.[53]
[d] $2CH_3SH \rightleftharpoons (CH_3)_2S + H_2S$: $T = 350$ °C, $[CH_3SH] = 2$ mM, $x = 20\%$.[60]

of butenes probably appears as a consequence of the decomposition of the sulfur-containing substances produced. The formation of the products of the thiolation reaction between 1-butanol and hydrogen sulfide is therefore hindered on acid catalysts: dibutyl sulfide was not detected at all and the selectivity with respect to butane-1-thiol was low. In the presence of catalysts with strong basic centres and weakened Lewis acid centres (for example, K/Al_2O_3), butane-1-thiol is mainly formed. The decrease in the selectivity in the formation of the products of the thiolation reaction in the presence of acid catalysts and the increase in the selectivity in the formation of an alkanethiol on basic catalysts have been observed also in the reactions of hydrogen sulfide with ethanol, 1- and 2-propanols, and 1-dodecanol.[2,3,5,24,27,36–38,46]

3. Adsorption

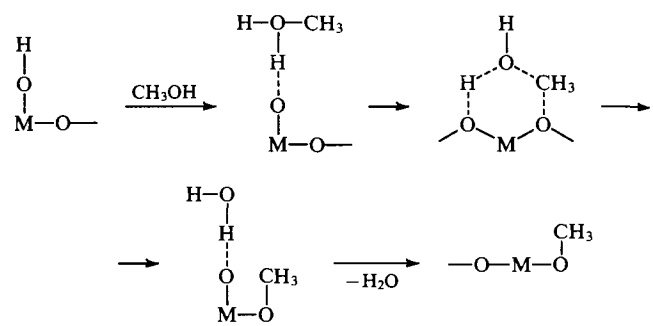
In considering the mechanism of the conversion of alcohols into thiols by hydrogen sulfide, it is necessary to take into account the available information about the structure and reactivity of the intermediate surface compounds arising when the reactants and their reaction products are adsorbed on the catalyst. These data have been obtained mainly by IR spectroscopic, NMR, and thermoprogrammed desorption (TPD) methods.

Alcohols may be adsorbed on the surfaces of acid–base catalysts[61,62] in the molecular form as a result of the interaction of the oxygen atom of the alcohol with a proton or Lewis acid centre of the catalyst and of the hydrogen atom of the alcoholic hydroxy-group with a basic surface centre. The decomposition of the alcohol in the molecularly adsorbed form leads to the formation of hydroxide and alkoxide groups on the surface. The latter may in addition form a hydrogen bond with the basic centres of the catalyst.

The adsorption of a dialkyl ether[63,64] on proton-donating catalysts at a low temperature leads to the appearance of a hydrogen-bonded form involving a proton catalyst centre and the oxygen atom of the ether. On catalysts with paired acid–base centres, a coordinate bond is formed between the oxygen atom of the ether and the Lewis acid centre together with an additional bond between a hydrogen atom of the alkyl group and a basic centre. At an elevated temperature, these forms decompose with formation of alkoxide groups on the surface.

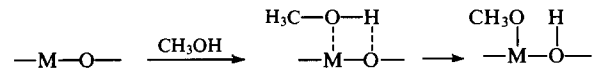
In the adsorption of an alkanethiol on the surface of an acid–base catalyst, there is a possibility of the formation of an associatively bound form as a result of the interaction of the sulfur atom of the alkanethiol with an acid catalyst centre and of the hydrogen atom of the thiyl or alkyl group with a basic centre. The decomposition of the molecular form of the adsorbed thiol leads to the appearance of OH and RS groups on the surface and also to the formation of hydrogen sulfide and the alkoxylation of the surface.[1,58,65–69]

The dialkyl sulfide is adsorbed on the surface[1,65,67] with participation of different centres. At a low temperature, the sulfide is protonated at the sulfur atom by the acid OH groups on the surface; a donor–acceptor complex with participation of the sulfur atom in the sulfide is formed on Lewis acid centres; there is also a possibility of an additional bond between a hydrogen atom of the alkyl group and a basic centre. At an elevated temperature, and also at a low surface coverage, the surface complex decomposes at the C–S bond to form RS and RO groups.



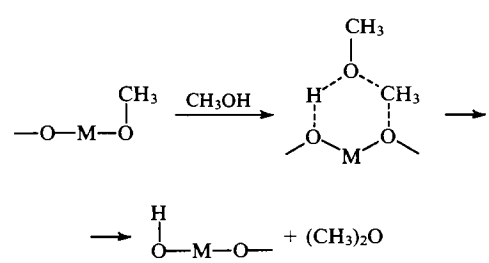
Hydrogen sulfide is adsorbed on proton-donor catalysts only via an associative mechanism:[70–74] a hydrogen-bonded form arises as a consequence of the interaction of the sulfur atom with a proton centre. On catalysts with paired Lewis acidic–basic centres, hydrogen sulfide is chemisorbed. At a reduced temperature and a high surface coverage, a donor–acceptor bond is formed between the sulfur atom and a Lewis acid centre and between a hydrogen atom of hydrogen sulfide and a basic surface centre. With increase in temperature and with decrease in surface coverage, the initial structure decomposes and acid OH groups and HS fragments are formed on the surface. There is a possibility of the dissociation of both H–S bonds in hydrogen sulfide with formation of S^{2-} groups, whereupon the concentration of the acid OH groups on the surface increases.

4. Elementary stages of the thiolation reaction



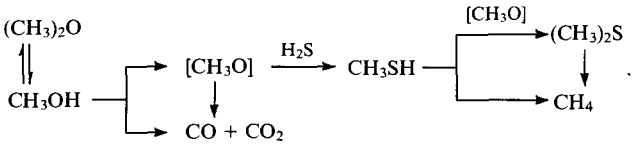
In view of the ease of the dissociative chemisorption of alcohols, the majority of investigators assumed that the thiolation reaction begins with the formation of alkoxide groups on the catalyst surface. This applies to the reactions of hydrogen sulfide with methanol on massive metal oxides and sulfides, deposited acid and alkaline catalysts, heteropolyacids, and zeolites,[11,12,25,26,28–31,75] with ethanol on the M^{2+} NaX zeolites,[36] with 1- and 2-propanols on NaX, NaY, HNaY, HZSM-5,[27] and Al_2O_3,[5] with 1-butanol on MgO, NaX, Cr_2O_3/SiO_2, K/Al_2O_3, and γ-Al_2O_3,[15] and with 1-dodecanol on K/Al_2O_3.[56]

It has been suggested[25,26,28,29] that the acid OH groups, present in the initial decationated zeolite or produced as a consequence of the dissociative chemisorption of hydrogen sulfide on the cationic forms of the zeolites, participate in the interaction of methanol with hydrogen sulfide on zeolites. However, it has been established[69,76] that methanol may be adsorbed on the sodium-forms of the NaX and NaY zeolites with participation of the sodium cation. On other catalysts, without strong proton centres on the surface (for example, the massive Al, Ti, Mg, Zr, and Ce oxides and deposited catalysts of the basic type), the coordination of methanol to the paired centres is most probable:[14,45,61] the oxygen atom of the alcohol is coordinated to a Lewis acid centre, while the hydrogen atom of the alcoholic OH group is coordinated to a basic centre. The subsequent decomposition of the associatively bound methanol leads to the methoxylation of the surface. The surface methoxide groups may react. Thus their interaction with a second alcohol molecule leads to the formation of dimethyl ether. The processes occurring on the proton and paired acid–base surface centres may be described by the following schemes (Schemes 1–3):



Scheme 1

Scheme 2



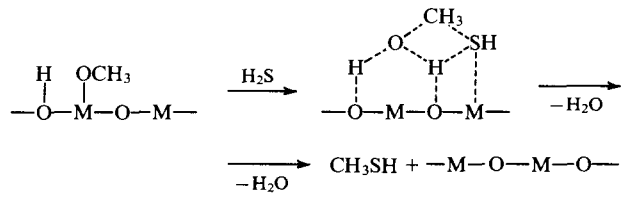
Scheme 3

As already mentioned above, dimethyl ether may react with hydrogen sulfide, affording methanethiol and dimethyl sulfide. Since the ether is readily dissociatively chemisorbed on different catalysts with formation of surface RO groups, there are no grounds for the hypothesis that methanethiol and dimethyl sulfide are formed directly from dimethyl ether. Its involvement in the formation of the thiolation products is usually accounted for by the decrease in the selectivity with respect to the ether as the degree of conversion of the alcohol increases. However, this may be a consequence not of the consumption of the ether in the formation of sulfur-containing compounds, but of the decrease in the surface concentration of the CH_3O groups interacting with hydrogen sulfide and methanethiol, which leads to a decrease in the rate of interaction of the RO groups with the alcohol.[29] The increase in the rate of conversion of methanol into the thiol, sometimes observed[77-79] in the presence of dimethyl ether, may be due to the additional methoxylation of the surface.

The following sequence of catalytic reactions with participation of methanol and hydrogen sulfide has been postulated:[45]

Both associatively[25,26,29] and dissociatively adsorbed hydrogen sulfide[45,49,80,81] may participate in the formation of methanethiol and dimethyl sulfide.

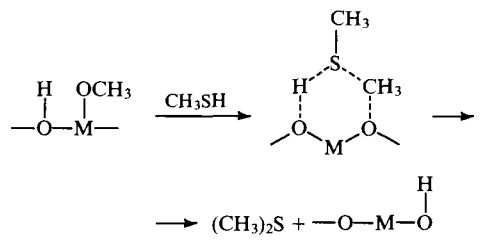
The conclusion that the thiolation reaction takes place with participation of surface methoxide groups and activated hydrogen sulfide has been confirmed by studies on the process by NMR and IR spectroscopic methods. Thus it has been found[14] that the addition of hydrogen sulfide to a SiO_2 specimen on which methanol has been adsorbed previously with subsequent heating to 350 °C leads to the disappearance of the absorption bands due to the methoxy-groups (1152 and 1044 cm^{-1}) from the IR spectrum, and to the appearance of the absorption bands of methanethiol (960 and 2845 cm^{-1}) and dimethyl sulfide (980, 1032, 1435, and 2980 cm^{-1}). The absorption bands due to methane (3017 and 1306 cm^{-1}) and the bands due to the formate structures produced on decomposition of methanol (1372, 1386, and 1583 cm^{-1}) appear under certain conditions. Similar results have been obtained on the decationated HNaY zeolite,[25,26] TiO_2, and Al_2O_3.[14] The exposure of the weakly active PO_4^{3-}/SiO_2 catalyst to hydrogen sulfide leads to some decrease in the intensity of the absorption bands due to the methoxide groups, but the high strength of the bond with the surface virtually precludes their reaction and the IR spectrum contains no absorption bands due to sulfur-containing compounds.[14]



After the exposure to hydrogen sulfide of Al_2O_3 modified by potassium or sodium compounds and containing preadsorbed methanol and after heating to 200 °C, there is a decrease in the intensity of the IR absorption bands not only of the CH_3O group but also of the thiyl groups bound to Al^{3+} (in the range 2560–2580 cm^{-1}); the absorption bands due to adsorbed methanethiol and dimethyl sulfide appear simultaneously.[45]

Similar conclusions have been reached on the basis of studies of the reaction of methanol with hydrogen sulfide by the high-resolution ^1H and ^{13}C NMR methods in the solid state.[49,82] For example, when an Al_2O_3 specimen containing adsorbed methanol was exposed to hydrogen sulfide, the anisotropic line due to CH_3O ($\delta = 50$ ppm) disappeared from the ^{13}C NMR spectrum after heating above 150 °C and new lines due to dimethyl ether ($\delta = 61.9$ ppm), methanethiol ($\delta = 6.7$ ppm), and dimethyl sulfide ($\delta = 19.8$ ppm) appeared. After heating the specimen to 400 °C, the line due to methane ($\delta = -8.4$ ppm) appeared in the spectrum. On the NaX specimen, a decrease in the intensity of the signal due to the adsorbed hydrogen sulfide—molecular hydrogen sulfide ($\delta = 1.0$ ppm) and the dissociatively chemisorbed hydrogen sulfide ($\delta = -3.6$ ppm) in equilibrium with the molecular form ($H_2S \rightleftharpoons HS^- + H^+$)—was also observed.

On interaction of hydrogen sulfide with NaX on which dimethyl ether had previously been adsorbed, signals due to the methanol, methanethiol, and dimethyl sulfide formed were observed in the ^{13}C NMR spectrum and there was a simultaneous decrease in the intensity of the signal due to dimethyl ether.

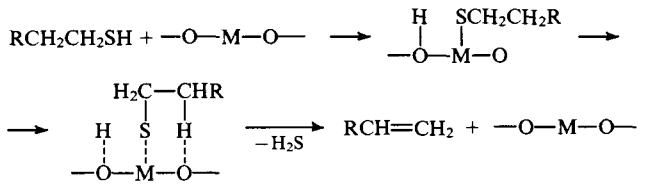


The results of the study of the conversion of methanol into the thiol on aluminium oxide catalysts made it possible to postulate the following mechanism.[45,49,80,81] When methanol interacts with a catalyst, it undergoes dissociative chemisorption, as a result of which the surface is methoxylated (Schemes 1 and 2). The interaction of the chemisorbed hydrogen sulfide with the methoxide groups leads to the formation of methanethiol (Scheme 4).

Scheme 4

The methoxide groups interact with methanethiol, activated with participation of the basic surface centres, affording dimethyl sulfide (Scheme 5).

Scheme 5



The differences between the activities and selectivites of the catalysts with respect to the formation of methanethiol depend mainly on the form in which hydrogen sulfide reacts. On proton-donor catalysts, molecular hydrogen sulfide (from the gas phase or associatively adsorbed on the surface) participates in the reaction with the CH_3O groups.[25,26,29] On catalysts with paired acid–base centres, the HS groups produced by the dissociative chemisorption of hydrogen sulfide interact with the methoxide groups, which increases the rate of formation of methanethiol. Dimethyl sulfide is formed as a result of the interaction of the CH_3O groups with the methanethiol associatively adsorbed on a basic centre, the attainment of a high rate of reaction requiring that the strength of the bond between methanethiol and the surface is optimal.[80]

The detailed mechanism of the conversion of higher alcohols into thiols has been investigated. It is believed[27,36] that in the initial stage of the reaction of hydrogen sulfide with ethanol and 1-propanol on a fresh zeolite specimen, the alcohol is dehydrated with formation of an alkene, which then reacts with the surface HS groups and is converted into the thiol; propane-2-thiol is then formed from 1-propanol. On the catalyst modified by the influence of the reaction medium, the reaction proceeds via the stage involving the interaction of hydrogen sulfide with the surface alkoxide groups, in which ethanethiol and propane-1-thiol are formed, i.e. it is postulated that the thiolation mechanism is analogous to the mechanism of the formation of methanethiol from methanol (see Scheme 4). Mashkina and coworkers[15,56] took into account the high probability of the occurrence of side reactions in the conversion of higher alcohols into thiols. In particular, the alkanethiols and dialkyl sulfides appearing on interaction of the alkoxide groups with hydrogen sulfide may be

adsorbed preferentially on the active centres, being stronger bases than the initial reactants, decomposing under these conditions with formation of alkylthio-groups (RS). An additional bond between the β-hydrogen atom of the RS group and a basic surface oxygen atom is formed on catalysts containing basic centres on the surface. As a result of the decomposition of this two-point surface complex, the alkene is eliminated. For example, the elimination of the alkene from alkanethiol is described by Scheme 6.

Scheme 6

On proton-donor catalysts without sufficiently strong basic centres, the alkene may be formed on decomposition of the hydrogen-bonded associative complex. As a result of the occurrence of similar processes, the alkene is also eliminated from the surface alkoxide groups.[77]

5. Kinetics

The validity of the postulated mechanism of the conversion of alcohols into thiols has been confirmed by the study of the kinetics of the reactions of methanol with hydrogen sulfide, of methanethiol with methanol, and of hydrogen sulfide with 1-dodecanol. A simplified mechanism, in which the formation of small amounts of CO and CH_4 is neglected and the rapid occurrence of the stages involving the chemisorption of hydrogen sulfide, the methoxylation of the surface, and the desorption of methanethiol is assumed, has been postulated for the reaction of methanol with hydrogen sulfide on acid aluminium oxide catalysts.[45,48,49,79,81] Account is also taken of the possibility that water blocks the surface (Scheme 7).

Scheme 7

$$CH_3OH + [X_1] \overset{(1)}{\rightleftharpoons} [X_2] + H_2O$$

$$H_2S + [X_2] \overset{(2)}{\rightleftharpoons} [X_1] + CH_3SH$$

$$CH_3SH + [X_2] \overset{(3)}{\rightleftharpoons} [X_1] + (CH_3)_2S$$

$$CH_3OH + [X_2] \overset{(4)}{\rightleftharpoons} [X_1] + (CH_3)_2O$$

$$H_2O + [X_1] \overset{(5)}{\rightleftharpoons} [X_3]$$

$[X_1]$, $[X_2]$, and $[X_3]$ are the initial active surface centre, the methoxylated centre, and the centre covered by water respectively.

Because of the wide distribution of the acid and basic centres on the catalyst surfaces with respect to their strength, the theoretical procedure developed by Temkin[83] for the description of the kinetics of heterogeneous-catalytic reactions occurring on a uniformly inhomogeneous surface, where the heat of adsorption varies linearly with the surface coverage by the reactants, was employed in devising the kinetic model. By assuming a high coverage of the active surface sites by water and that the rate of the process is limited by stages *2–4*, the following simplified kinetic equations were obtained:

$$w_{H_2S} = k_2^0 k P_{H_2S} P_{MeOH}^{1/2} P_{H_2O}^{-1} ,$$

$$w_{Me_2S} = k_3^0 k P_{MeSH} P_{MeOH}^{1/2} P_{H_2O}^{-1} ,$$

$$w_{Me_2O} = k_4^0 k P_{MeOH}^{3/2} P_{H_2O}^{-1} ,$$

$$w_{MeSH} = w_{H_2S} - w_{Me_2S} ,$$

where

$$k = \left(\frac{k_1^0 k_{-5}}{k_{-1}^0 k_5}\right)^{1/2} .$$

When alkali metal ions are introduced into the acid aluminium oxide catalyst, the Lewis acid centres are weakened. This hinders the activation of methanol and methanethiol involved in the formation of dimethyl ether and dimethyl sulfide. As a result, the third and fourth stages (Scheme 7) are suppressed and may be neglected, whereupon the kinetic equation assumes the form

$$w_{MeSH} = \frac{k' P_{H_2S} P_{MeOH}^{1/2}}{[P_{H_2O}(P_{H_2S} + \lambda P_{H_2O})]^{1/2}} ,$$

where

$$k' = \left(\frac{k_1^0 k_2^0 k_{-5}}{k_5}\right)^{1/2} ; \qquad \lambda = k_{-1}^0 k_2^0 .$$

Subject to certain assumptions, this equation is identical with the equation for the kinetics of the conversion of methanol into the thiol on an acid aluminium oxide catalyst. A kinetic equation of the same form has been obtained for the reaction of methanethiol with methanol.[53,81,84,85]

Formally the mechanism of the reversible reaction in which methanethiol decomposes to dimethyl sulfide and hydrogen sulfide is represented by a two-stage scheme:[30,81,85–88] The dissociative chemisorption of methanethiol leads to the formation of hydrogen sulfide and the methoxylation of the surface, after which the methoxide groups interact with a second methanethiol molecule with formation of dimethyl sulfide:

$$CH_3SH + [X_1] \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [X_2] + H_2S ,$$

$$CH_3SH + [X_2] \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [X_1] + (CH_3)_2S .$$

The simplified kinetic equation for the reaction on an inhomogeneous surface assumes the form

$$w = \frac{k P_{MeSH}^{3/2} (1 - P_{H_2S} P_{Me_2S} / P_{MeSH}^2 K)}{P_{Me_2S}^{1/2}} ,$$

where

$$k = k_1 \left(\frac{k_2}{k_{-2}}\right)^{1/2} .$$

The kinetic equations for the reaction of 1-dodecanol with hydrogen sulfide were derived[56] on the basis of the mechanism:

$$C_{12}H_{25}SH + [X_1] \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [X_2] + H_2O ,$$

$$H_2S + [X_2] \xrightarrow{k_2} [X_1] + C_{12}H_{25}SH ,$$

$$C_{12}H_{25}SH + [Y_1] \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} [Y_2] ,$$

$$[Y_2] \xrightarrow{k_4} [Y_1] + C_{12}H_{24} + H_2S ,$$

$$H_2O + [X_1] \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} [X_3] ,$$

where $[X_1]$ and $[Y_1]$ are the active centres on the initial catalyst surface and $[X_2]$, $[Y_2]$, and $[X_3]$ are the active centres on the surface covered by alkoxide groups, the chemisorbed dodecanethiol, and water respectively. The simplified equation

describing the dependence of the rate of formation of dodecane-1-thiol (w_1) and dodecene (w_2) on the partial pressures of 1-dodecanol (P_1), hydrogen sulfide (P_2), dodecane-1-thiol (P_3), and water (P_4) are

$$w_1 = k_1' P_1^{1/2} P_2 P_4^{-1} ,$$

$$w_2 = k_2' P_3 ,$$

where

$$k_1' = k_2 \left(\frac{k_1 k_{-5}}{k_{-1} k_5}\right)^{1/2} ; \quad k_2' = \frac{k_4 k_5}{k_{-5}} .$$

The reaction rates calculated by these equations agree satisfactorily with the experimental values, which confirms the validity of the postulated reaction mechanism.

It follows from the results of a study of the mechanism of the conversion of alcohols into thiols that an active catalyst should ensure in the first place the dissociative chemisorption of the alcohol with formation of reactive alkoxide groups on the surface. This is possible on both acid and basic catalysts. Furthermore, dissociative chemisorption of hydrogen sulfide with formation of thiyl groups reacting with the alkoxide groups should take place on an effective catalyst for the synthesis of an alkanethiol. Such conditions are satisfied by catalysts with paired acid – base centres. In order to reduce the probability of the further reaction of the alkanethiol — its interaction with alkoxy-groups involving the formation of a dialkyl sulfide or decomposition accompanied by the elimination of an alkene, the acid centres must be weakened and the basic centres must be strong. In contrast to the above, an active catalyst for the synthesis of a dialkyl sulfide must contain strong acid centres and moderately strong basic centres. The presence of weakened basic centres promotes the activation of the alkanethiol, which is necessary for its interaction with alkoxide groups and the formation of a dialkyl sulfide, but does not induce the decomposition of the alkanethiol to the alkylthio-groups which readily react further with formation of an alkene.

IV. Selection of catalysts and conditions for the conversion of alcohols into thiols

1. Synthesis of alkanethiols

The results of studies on the synthesis of alkanethiols under various conditions have been published.[3,4,11,14,23,25,29,30,42,48,56] A survey of these data permits the conclusion that, overall, the degree of conversion of the alcohol increases with increase in temperature, contact time, and the hydrogen sulfide : alcohol ratio. Bearing in mind the difficulty of separating an alcohol and an alkanethiol, it is recommended[47] that industrial processes be carried out under the conditions of extensive, best of all total, conversion of the alcohol. With increase in contact time, the yield of the alkanethiol increases only up to a certain value, after which it falls. With increase in temperature, the yield of the alkanethiol also rises, but the selectivity then diminishes. The temperature for conversion of higher alcohols into thiols is lower than for methanol. An increase in selectivity with respect to the alkanethiol is promoted by an increase in the hydrogen sulfide : alcohol ratio, especially in the conversion of higher alcohols into thiols. However, even in the presence of a large excess of hydrogen sulfide in the system, the selectivity with respect to the formation of alkane-2-thiols is low. It rises when carbonyl compounds are added to the reaction mixture. Thus the addition of 5 mass% of acetone to 2-propanol on a 4% K_2O/Al_2O_3 catalyst increases the overall rate of reaction by a factor of 4, while the selectivity with respect to propane-2-thiol increases from 50% to 80%. A much smaller effect is observed in the case of primary alcohols.[40]

The rate of formation of the alkanethiol increases in proportion to the partial pressure of hydrogen sulfide and the partial pressure of the alcohol (in the conversion of 1-propanol into the thiol)[5] or its square root (in the conversion of methanol and 1-dodecanol into the thiols).[56] In practice, the thiols are synthesised in the following ranges of parameters: synthesis temperatures of 350–420 °C for methanethiol and 300–350 °C for its homologues; contact time 5–35 s depending on the temperature; molar ratio hydrogen sulfide: alcohol = 1.5–7.5; overall pressure in the system as a rule not above 1 MPa.[47]

Table 7. Optimum conditions in the synthesis of alkanethiols on basic catalysts at $P = 0.1$ MPa.

Alcohol	Catalyst	Reaction conditions			Degree of conversion of alcohol (%)	Yield of alkanethiol (%)	Ref.
		T/°C	M	τ/s			
Methanol	10% K_2WO_4/Al_2O_3	400	2	5.6	92.7	90.9	4
	10% K_2WO_4/Al_2O_3	320	1.8	39[a]	98.5	90	89, 90
	K_2WO_4/Al_2O_3	400	1.5	10.5[b]	100	80	47
	25% K_2WO_4/SiO_2	360	1.6	25	84	77	31
	20% K_2CO_3/SiO_2	360	1.6	25	84	75	31
	2.9% Na_2O/Al_2O_3	360	1.6	4.2	80	75	31
	6.4% K_2CO_3/AlO	360	1.6	8.4	74	72	31
	10% K_2WO_4/Al_2O_3	360	1.6	4.2	95	62	31
Ethanol	10% K_2WO_4/Al_2O_3	318	2.86	5.6	83.4	68.7	2, 4
1-Propanol	K_2WO_4/Al_2O_3	330	3	10	95	80	47
1-Butanol	4.3% K_2O/Al_2O_3	300	10	10.4	93	91	15
2-Butanol	K_2WO_4/Al_2O_3	275	4	0.9[b]	59	15	47
	K_2WO_4/Al_2O_3	300	4	0.3	71	8	47
1-Hexanol	K_2WO_4/Al_2O_3	310	7.5	10.7[c]	100	80	47
1-Octanol	10% K_2WO_4/Al_2O_3	287	7.73	7.4	100	91	2, 4
1-Dodecanol	K/Al_2O_3	300	15	2.5	100	70	46, 92

[a] $P = 0.8$ MPa; [b] $P = 0.3$ MPa; [c] $P = 0.2$ MPa.

High yields of alkanethiols may be obtained under certain conditions on a series of supported acid catalysts and on zeolites in the cationic form. However, the process is insufficiently selective, particularly in the syntheses of methanethiol homologues and the selectivity of the above catalysts cannot be increased by varying the reaction conditions. Supported basic catalysts, in particular alkali-modified Al_2O_3, exhibit a high selectivity with respect to alkanethiols: in their presence, the selectivity is close to 100%. Table 7 presents the optimum conditions for the syntheses of alkanethiols on such catalysts.

The quality of the alkaline aluminium oxide catalyst for the synthesis of alkanethiols is influenced not only by the nature of the active component but also by its content on the surface, as well as by the characteristics of the carrier—specific surface, porous structure, phase composition, and purity. Although the use of various alkaline additives is usually mentioned, in practice potassium tungstate deposited on Al_2O_3 is apparently employed, its content being $\geqslant$10 mass%.[3,4,89–91] The active component must be present on the surface in a highly disperse state, so that the Al_2O_3 used as the carrier must have a specific surface not less than 200 $m^2\ g^{-1}$.[89–91] The presence of an considerable number of transport pores in the catalyst is necessary in order to rule out diffusional complications. γ-Al_2O_3 is usually employed, but the use of other phases is also permissible.[93] The method used to prepare the catalyst is also important, but the relevant data have scarcely been published or it has been stated[2–4] that the catalyst was prepared by impregnation or mixing methods.

The active and selective IKT-31-1 catalyst for the synthesis of methanethiol from methanol and hydrogen sulfide has been developed by the Institute of Catalysis of the Siberian Division of the Russian Academy of Sciences jointly with the Special Technical Design Bureau for Catalysts. It is prepared in two ways.[93] In the first procedure, an aqueous solution of the alkali metal compound is deposited in the form of an aerosol on an aluminium oxide carrier incorporating γ-Al_2O_3 and 20%–30% of χ-Al_2O_3 with a large macropore volume (radius exceeding 100 nm). The second procedure consists in mixing an aqueous solution of the active substance with aluminium hydroxide and subsequent granulation. The specimens obtained are heat-treated. The IKT-31-1 catalyst is employed in the industrial manufacture of methionine (the stage involving the synthesis of methanethiol) by the 'Orgsintez' Volga Industrial Conglomerate.

Alkaline aluminium oxide catalysts are more stable in the reaction involving the conversion of alcohols into thiols than the unpromoted Al_2O_3.[3,4] The activity of the catalyst does not change when the starting material contains carbon disulfide or dimethylamine[4] and also carbon monoxide[47] as impurities. Although water in fact inhibits the process, its presence in an amount of 0.5 mass%–1 mass% has a positive effect on the stability of the catalyst.[3,4] Preliminary sulfiding of the catalyst by treatment with hydrogen sulfide before use has a stabilising effect on it.[5,91] The stability of the catalyst is reduced if the process is carried out at a temperature exceeding 420 °C, since the surface becomes saturated with coke.[3] For the stable operation of the alumino–potassium tungstate catalyst, it is important to provide for the effective removal of heat from the system. The simultaneous passage of methanol and hydrogen sulfide through the K_2WO_4/Al_2O_3 catalyst at an initial temperature of 320 °C leads to the heating of the catalyst, which decreases its surface area and the yield of methanethiol. This deficiency is eliminated by dividing the catalyst into consecutively arranged layers, all the hydrogen sulfide being introduced into the first layer, whilst methanol is added in portions to each catalyst layer. This ensures the stable operation of the catalyst for three years.[89–91]

2. Synthesis of dialkyl sulfides

It has been stated in patent specifications (see the relevant reviews[2,8]) that various dialkyl sulfides R_2S ($R = C_1–C_{12}$) may be obtained under certain conditions by the reactions of alcohols with hydrogen sulfide, but real results have been published only for the synthesis of dimethyl sulfide.

The parameters of the synthesis of dimethyl sulfide are influenced by the reaction conditions. Thus an increase in the yield of dimethyl sulfide is promoted by an increase in temperature and contact time and by a decrease in the hydrogen sulfide : alcohol ratio.[2,11,12,14,17,23,25,28,30,94] The rate of formation of dimethyl sulfide increases with increase in the partial pressure of methanol and of the methanethiol formed from it. On acid aluminium oxide catalysts, the rate of reaction increases with the square root of the partial pressure of methanol and with the partial pressure of methanethiol; water inhibits the process.[49,79,81]

It follows from the analysis of the kinetic equations obtained that, in order to increase the selectivity with respect to dimethyl sulfide, it is necessary to carry out the process at a reduced partial pressure of methanol, while the hydrogen sulfide concentration should be below that required for the establishment of the stoichiometric component ratio (0.5 : 1).

In the presence of alkaline catalysts, high yields of dimethyl sulfide cannot be attained by varying the conditions in the reactions of methanol with hydrogen sulfide. This can be achieved only by employing acid catalysts and also cationic forms of zeolites on the surfaces of which strong Brønsted acid centres arise under the reaction conditions. Table 8 indicates the optimum conditions for the synthesis of dialkyl sulfides on acid catalysts. Evidently dimethyl sulfide may be obtained in an almost quantitative yield (up to 97 mol%). However, the synthesis of its homologues is difficult. Thus a relatively high yield of diethyl sulfide (up to 67 mol%) is reached in the reaction of ethanol with hydrogen sulfide only on cationic forms of zeolites. On other catalysts, active in the synthesis of dimethyl sulfide, dialkyl sulfides are not formed in the interaction of higher alcohols with hydrogen sulfide even when the reaction conditions are varied.

The achievement of the second stage in the reaction of an alcohol with hydrogen sulfide, namely its interaction with the alkanethiol, gives rise to considerable possibilities for the synthesis of dialkyl sulfides from higher alcohols in a preparative yield.

The interaction of methanol with methanethiol has been investigated[9,10,53,75,95] in the presence of various acid catalysts (see, for example, Table 6). The reaction conditions influence the rate and mode of this process.[53,81,84,85] With increase in temperature, the degree of conversion of the reactants and the yield of dimethyl sulfide also increase. At a constant temperature, the degree of conversion of the reactants and the yield of dimethyl sulfide increase with contact time; dimethyl ether is formed as a side product, its yield diminishing with increasing degree of conversion of the alcohol. Dimethyl ether and dimethyl sulfide are formed via independent paths. The rate of formation of dimethyl sulfide increases in proportion to the square root of the partial pressure of methanol and to the partial pressure of methanethiol, water inhibiting the process. An equation taking into account the degree of utilisation of the catalyst surface when the reaction takes place under conditions of internal diffusion has been obtained.[96] It follows from the analysis of the kinetic data that the influence of the side reaction involving the formation of dimethyl ether diminishes, while the selectivity with respect to dimethyl sulfide increases with decrease in the methanol : methanethiol ratio and with increase in the degree of conversion of methanol.

Unfortunately, only isolated examples of the synthesis of higher dialkyl sulfides by this procedure have been described. Thus the interaction of ethanethiol with aliphatic $C_1–C_4$ alcohols on Al_2O_3 and AlSi results in the formation of alkyl ethyl sulfides.[95]

Table 8. Optimum conditions for the synthesis of dialkyl sulfides by the reactions of alcohols with hydrogen sulfide on catalysts having different compositions.

V. Conclusion

Thus the studies initiated previously on the gas-phase heterogeneous-catalytic synthesis of alkanethiols and dialkyl sulfides from alcohols and hydrogen sulfide have developed further in our time. During the last 20–25 years, the main efforts in this field have been directed to the determination of the relation between the catalytic and acid–base properties of catalysts of various composition and to the elucidation of the mechanism of the thiolation reactions by means of a set of physicochemical methods (kinetic, adsorption, IR spectroscopic, and NMR methods). This made it possible to create active and selective catalysts for the synthesis of methanethiol and dimethyl sulfide, which are widely used in the manufacture of methionine (a food additive) and dimethyl sulfoxide (extractant, solvent, medicinal preparation). Higher alkanethiols (C_2–C_{12}) can be obtained in fairly satisfactory yields by the interaction of hydrogen sulfide with 1- and 2-alkanols on the catalysts proposed. The alkanethiols are employed as odorants for fuel gases, as starting materials for the synthesis of agrochemicals, as domestic chemicals, as surfactants, and as regulators of the polymerisation processes in the manufacture of raw rubbers and plastics.[97] The parameters of the processes involving the synthesis of higher alkanethiols which have been achieved may be improved by a more precise regulation of the acid–base characteristics of the catalyst surfaces.

The problem of the creation of effective catalysts for the synthesis of dimethyl sulfide homologues is still by no means fully solved. Active catalytic systems have been found only for the synthesis of diethyl sulfide. It has so far been impossible to obtain dialkyl sulfides in preparative yield by the interaction of higher alcohols with hydrogen sulfide, because the thiolation process is complicated by the occurrence of competing reactions. There are good prospects for the practical utilisation of dialkyl sulfides, since they can serve as extractants for noble metals, as flotation agents, and as additives to oils. They can also be used as the starting compounds for the synthesis of biologically active substances.[97] Bearing in mind the practical importance of dialkyl sulfides and the availability of the starting material, it may be expected that studies in the field of their catalytic synthesis will be continued, primarily with the aim of elucidating the detailed reaction mechanism, since this will help in the deliberate regulation of the properties of the catalyst and in controlling the thiolation process.
